Abstract

In an election campaign, political parties pledge to implement various projects–should they be elected. But do they follow through? To track election pledges from parties' election manifestos, we need to distinguish between pledges and general statements. In this paper, we use election manifestos of Swedish and Indian political parties to learn neural models that distinguish actual pledges from generic political positions. Since pledges might vary by election year and party, we implement a Multi-Task Learning (MTL) setup, predicting election year and manifesto's party as auxiliary tasks. Pledges can also span several sentences, so we use hierarchical models that incorporate contextual information. Lastly, we evaluate the models in a Zero-Shot Learning (ZSL) framework across countries and languages. Our results indicate that year and party have predictive power even in ZSL, while context introduces some noise. We finally discuss the linguistic features of pledges.

1 Introduction

Before any election, political parties publish manifestos that summarize their pledges to the voters. The exact nature of those pledges varies. A single-issue party might campaign on the same promise year after year, but most parties will adapt to the shifting trends and needs of the electorate. However, there is a difference between pledging and fulfilling. Political scientists are highly interested in whether pledges were fulfilled, a question that is gaining a growing interest in the broader scientific community (Naurin et al., 2019). Several approaches exist, but they are primarily confined to manual analysis of individual countries or elections. They indicate that governmental parties mostly fulfill their election pledges (Naurin et al., 2019; Thomson et al., 2017). However, there are too many elections worldwide to analyze all campaign pledges manually. We need automated ways to identify pledges and hold governments accountable systematically.

Checking whether a pledge was fulfilled still requires manual work by trained political scientists, but the first step–*identifying* pledges–is a problem very much made for NLP, for at least two reasons. First, NLP can automate pledge identification to distinguish pledges from irrelevant content. This allows the study of pledge fulfillment at scale. An average election manifesto in our corpus has 418 sentences, but only 118 of them (27.5%) will contain a pledge. The rest is filler material. It takes several days to train an annotator, who then spends around 6-8 hours on a single manifesto, to identify those 27.5% of pledges. Cutting down on this laborious first part frees up time to focus on the more complex issue of determining whether those pledges were fulfilled. Second, NLP methods can help us understand the linguistic style and communication strategies associated with election pledges. This interpretation is necessary for social sciences to understand how political messages are structured and conveyed.

This paper presents neural pledge identification models to address these two points. Our work is part of a larger interdisciplinary project, "Mixed methods for analyzing political parties' promises to voters during election campaigns." We use a data set of almost 13k sentences from election manifestos concerning the last 25 years and 11 parties from Sweden and India. Each sentence is annotated as including a pledge ("pledge") or not ("non-pledge"). We implement several deep neural models based on BERT (Devlin et al., 2018). We use its Swedish, English (for the Indian data), and multi-lingual (mBERT) versions. We feed BERT's output into customized attention mechanisms to detect specific pledge-related patterns. We com-

pare our neural models with a Logistic Regression baseline that the deep models easily outperform.

However, pledges can not just depend on some signal words or expressions. References to the environment might be core pledges for one party, but just commentary for another. Specific issues will be pledge-worthy one year (think pandemic responses), but not in others. To measure the effects of all of these confounds (i.e., *election year* and *party*), we adopt a Multi-Task Learning (MTL) framework. The main task is to classify sentences as pledge or non-pledge, with auxiliary tasks predicting the year, party, or both. We identify the conditions where MTL models with year and party improve the models' performance, indicating when these two factors are useful confounds. There seem to be stark differences between countries, though: even using a multi-lingual approach (which has access to more training data) does not improve on language-specific approaches.

We are also interested in zero-shot learning, i.e., training models on data from a country and testing it on a different country. This would allow us to work on pledges from new countries directly, without any previous manual annotation. It turns out that the models perform reasonably well despite the challenging conditions. However, the differences between test countries indicate that pledges are not as universal as we might think.

Surprisingly, we also find that incorporating a context of any sort (that is, one or more sentences preceding the target text) does not help but hurts performance. Presumably, this happens because pledges are rare, and context introduces more noise than signal.

We are also interested in learning more about pledges' nature. I.e., what their linguistic features and patterns are. To gain those insights, we extract the Information Gain value (Forman, 2003) of 1–4-grams and visualize the model's decisions via the Sampling and Occlusion (SOC) algorithm (Jin et al., 2019). SOC provides a hierarchical view of BERT's most informative linguistic patterns in the classification.

Our data and our models are available at `https://github.com/MilaNLProc/mimac`.

Contributions The contributions of this paper are: 1) We provide a new, multi-lingual corpus of election manifestos from Swedish and Indian parties, annotated at sentence level as pledges or non-pledges; 2) We are the first to apply neural models to the task of election pledge classification, accounting for confounds; 3) We provide insights about the linguistic features of election pledges and the models' interpretation.

2 Data

We collect and annotate a corpus of election manifestos from two countries: Sweden and India. The texts are in Swedish and English, respectively. We provide some examples in Table 1.

The Swedish data contain 5098 instances from 9 parties and six elections, ranging from 1994 to 2014. The amount of pledges per manifesto is 32.09%. These texts are also part of the corpus of the Manifesto Project (MP) (Volkens et al., 2012; Merz et al., 2016, Section 7).

For all manifestos, we adopted the annotation scheme of the Comparative Party Pledges Project (CPPP) of Naurin et al. (2019) and Thomson et al. (2017). This is a large international political science project whose annotation scheme is the most appropriate for identifying campaign promises, which is the focus of our experimental designs. In particular, following the CPPP scheme, we further distinguish between broad and narrow pledges, i.e., between generic and detailed commitments to undertake determined actions. Based on this distinction, we ran additional experiments included in the Appendix. We have 23.32% narrow and 8.77%

Country	Sweden	India	Both
Nr. manifestos	16	11	27
Nr. Parties.	9	2	11
Nr. elections' year.	6 (1994-2014)	5 (1999-2019)	10 (1994-2019)
Mean sentences	318.62	702.64	475.07
Mean pledges	102.25 (32.09%)	172.27 (24.52%)	130.78 (27.53%)
Mean sentences' length	15.00	20.70	18.43

Table 2: Corpora statistics.

broad pledges in the Swedish data.

The Indian texts contain 7729 sentences from two parties and five election cycles from 1999 to 2019.[1] Here, the annotators only distinguished sentences including a narrow pledge from non-pledge sentences, with a pledge rate of 24.52%.

In total, we have 12827 sentences and 3531 pledges (27.53%). Since we only have binary labels for the Indian data, we combine broad and narrow pledges in the Swedish corpus.[2] Table 2 shows some corpora statistics.

2.1 Annotation process

In the CPPP scheme, an election pledge is a statement that can be tested for fulfillment. Annotators must therefore assess whether a statement refers to an action or outcome that is verifiable, in the sense that we can objectively determine whether it was achieved. This definition also requires annotators to have to contextual knowledge of the country and specific information about the political situation in each election campaign.

We therefore trained Swedish and Indian annotators to label the Swedish and Indian manifestos for our study, respectively. Four people were involved in the annotation of the manifestos. Two domain experts, one for each data set, conducted the training. The two annotators interacted with the two respective domain experts throughout the annotation process to handle complicated cases.

To test agreement in the Indian data, three trained annotators labeled 100 sentences. Their Krippendorff's α and Fleiss's κ are 0.65. On the Swedish data, two trained annotators labeled 100 sentences again, with Krippendorff's α and Cohen's κ at 0.61. In both cases, the agreement can be considered as 'substantial' (Landis and Koch, 1977). Our results are coherent with those reported by Naurin et al. (2019).

3 Methods

We have three experimental conditions: 1) Swedish texts alone, 2) Indian texts alone, and 3) Swedish and Indian texts together (multilingual condition).

In conditions 1) and 2) we evaluate the models on test sets from the same county (standard test split), or from the respective other country, i.e., a Zero-Shot Learning (ZSL) condition. This is not possible in the third condition, where the models are trained on data from both countries. We use this last condition to see whether performance improves with access to more training data and whether pledges are comparable across countries.

As baselines, we train two Logistic Regression (LR) models, optimized with the parameter $C = 1$, based on TF-IDF-weighted Bag-Of-Words (BOW) from $1-$ to $3-$grams, with document frequency range from 0.001 and 0.75. We feed the first models with simple $n-$gram tokens.

However, we also hypothesized that pledges could be expressed by formal grammatical patterns, such as specific Parts-of-Speech (PoS) sequences or verb tenses (future tense, modal verbs). Therefore, we trained a second LR model, fed with tokens incorporating the PoS information. Tables 3 and 4 show the performance. We evaluate our models with standard metrics: precision, recall, and F1-measure averaged over the two classes.

3.1 Neural models

For the first two experimental conditions, we consider separate, mono-lingual Swedish and English BERT models and the multi-lingual (mBERT) version. In the third experimental condition, where we merge the two data sets, we can only use the multi-lingual BERT.

---

[1] If referring to the data set, we will use *Indian*, but if referring to the language, we use *English*.

[2] We trained binary classifiers for narrow pledges in a pilot study, treating broad pledges as non-pledges. The performance was slightly worse than in the case reported here due to a more noisy "non-pledge" class and a more skewed class balance. We include those results in the Appendix.

Single-Task Learning. Our base models are binary classifiers, i.e., single-tasks (STL) models. Standard BERT classifiers perform the task with a fully connected layer on top of BERT's output. In contrast, we reframe BERT's `[CLS]` token representation as a single-row matrix, and feed it into a single-layer, single-head Transformer (Vaswani et al., 2017). Our pilot studies found that this specialized structure allows us to detect specific pledge patterns from the BERT representation more effectively than a standard dense output layer alone. Finally, the Transformer is connected to a dense output layer for the prediction.

Multi-Task Learning. We implement three different MTL versions, differing by the auxiliary task combinations. We have two potential auxiliary tasks: predicting the *election year* and the *party* that produced the manifesto. We add a further dense output layer to the base model to perform the MTL tasks: 1) predicting the election year, 2) the party, or 3) both. We use the mean of the task losses for error-backpropagation in the MTL networks. Since their magnitude is bounded by the fact that all predictions are probability distributions, no normalization is needed. Figure 1 (left) shows the scheme of the MTL models.

Contextual models. We also build models considering the sentence preceding the target text as context, allowing us to test its impact on classification performance. We incorporate the context sentence in two state-of-the-art ways: through pair-BERT, which accepts two texts as input, and through a hierarchical model. In the first case, the model is structurally equivalent to the base model: only the input representation for BERT changes to include two sentences, separated by the separator token `[SEP]`. In the second case, we stack the representations of the BERT classification tokens (`[CLS]`) of both context and target sentences and feed them into a Transformer connected to a dense layer that gives the output. Figure 1 (right) depicts its structure.

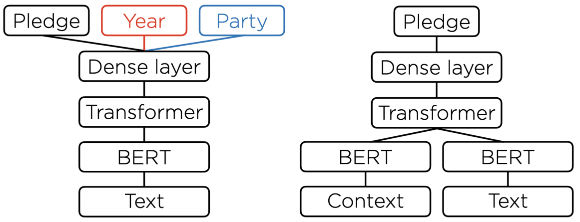

Figure 1: Left: STL and MTL model scheme. STL: black boxes. MTL with one auxiliary task: black + red or black + blue boxes. MTL with two auxiliary tasks: all boxes. Right: Hierarchical models' scheme

Settings and significance tests. To reduce the variability of the models' random initialization and make our results more robust, we run ten repeats for each experimental condition and compute the overall performance. To test the significance of the improvements over the base model, we use a bootstrap sampling test on all runs (Søgaard et al., 2014), with 1000 loops and a sample size of 30%.

For each experiment, we run 10-fold cross-validation. In each fold, we use 80% of texts as the training set, 10% for the development, and 10% for the test. In the ZSL experiments, we use 90% and 10% of a data set for training and development, respectively, and the whole other data set as the test set.

For the main task, the loss function is the binary (sigmoid) cross-entropy; it is the (soft-max) cross-entropy for the auxiliary tasks. We use the Adam optimizer (Kingma and Ba, 2014). We select the models through early-stopping that requires the development set's loss to drop by less than 8% for five consecutive epochs. Our learning rate is 0.002, drop-out probability 0.3, and batch size 512, manually tuned. The attention mechanisms that analyze BERT's outputs are single-layer, single-head Transformers.

4 Experiments

We report results on all models for each of the three experimental conditions: 1) Swedish corpus encoded with Swedish and multi-lingual BERT (Table 5); 2) Indian corpus encoded with English and

Table 7: Data set: Sweden & India. Language: Swedish and English.

multi-lingual BERT (Table 6); and 3) the joint Swedish and Indian data together, encoded with multi-lingual BERT (Table 7).

For each of these conditions, we train a baseline Logistic Regression model (Section 3)—an STL base model as described in Section 3.1—and compare them with MTL and contextual models. Since all the models outperform the Logistic Regression baselines, we report significance levels concerning the improvement over the STL models.

5 Results

We see a substantial performance difference between the two BERT encodings (Swedish and mBERT) regarding the Swedish data. The Swedish version outperforms the multi-lingual one and reaches the best performance of the experiments (Table 5).

We do not see the same performance difference in the Indian data, where English and multi-lingual BERT produce similar outcomes, with the multi-lingual even slightly better. Results are generally lower than those for the Swedish data (Table 6).

To interpret this performance gap, we need to consider the differences between the two corpora. As shown in Table 2, the Swedish and Indian data sets differ remarkably in terms of the number of parties and manifestos. Within each manifesto, the two data sets also contain a remarkably different number of sentences, pledges, and words in each sentence. In particular, the Indian data set contains a lower pledge rate than the Swedish data. This reduced amount of training examples prevents a direct comparison between the models trained on the two corpora.

As expected, the results of the multi-lingual model trained on the joint data set lie between the respective multi-lingual models on the two data sets separately. So while the Swedish BERT is more effective than the multi-lingual one on Swedish texts, the amount of data in the multi-lingual language model presumably counteracts the lack of annotated data in the Indian data set.

MTL vs STL. The MTL models are effective in several cases.First, they help in the ZSL conditions. This suggests that training the models to contextualize the notion of a pledge for party and year reduces overfitting. Also, when effective, MTL models improve precision. This is an expected effect, as the models learn to detect pledges as well as historical periods and political areas. This is an interesting feature for ZSL, where confidence in identified positive cases is more valuable than a good recall. In fact, even though models maximizing recall would make the human activity of pledge *identification* easier, in terms of downstream pledge fulfillment *verification*, it is preferable to start from a smaller set of texts that are likely to be true pledges.

Furthermore, in ZSL, by definition, the years and parties of the target country differ from those of the training country. Therefore, the auxiliary predictions for the training country are not relevant to the target country. This is the reason why we frame the problem as multi-task rather than multi-input: we could not have fed the models with test data from unseen countries/election campaigns in multi-input. Nevertheless, models trained to distinguish between different contexts for years and parties can effectively transfer this knowledge to entirely different test data, improving the predictions' precision. This suggests that some generalization is possible, even in front of different dependent variables.

We also tested the MTL models in the case of a reduced amount of data. In particular, we trained models considering the election manifestos from 2000 only. We found that the MTL contributes more strongly under those conditions. The results of these experiments are included in the Appendix.

Does Context Help? In a word, no. While a disappointing outcome, we find it important to include this finding here, as it goes very much against both intuition and prior research. Bilbao-Jayo and Almeida (2018), for example, found that contextual information is helpful when classifying political topics (see Section 7). Election pledges seem to be more self-contained statements, relying on linguistic formulas that make them recognizable (and probably memorizable) regardless of their linguistic context (Section 6).

We explored two different models to incorporate the sentence preceding the target texts. In both cases, though, we consistently find that the previous sentence's contextual information adds more noise than a helpful signal for prediction. The decrease ranges from moderate to drastic (up to 10 points in F1), particularly for the pair-BERT models where, by design, target and context representations are not trainable. The hierarchical models' performance is more stable, but the context does not improve the performance.

6 The language of pledges

To better understand the pledges' linguistic features, we follow two strategies: 1) computing the Information Gain (IG) of word n-grams, and 2) using the Sampling and Occlusion (SOC) algorithm (Jin et al., 2019).

Information Gain measures the entropy of (sequences of) terms between the different classes. The more skewed a set of terms is towards one label class at the other's expense, the higher the IG value. Tables 8 and 9 show the trigrams with the highest IG values (and relative frequencies), divided according to the class of which they are indicative, i.e., where they are more frequently found. While

Table 9: Indian tri-grams indicative of pledge (left) and non-pledge (right)

we computed the IG score from $1 - -5$-grams, we show only tri-grams here for illustration. They represent the best trade-off between meaningful and frequent chunks of text. For the complete translation of the Swedish texts, see the Appendix.

These n-grams suggest that a formulaic language characterizes election pledges: stereotypical expressions characterize specific sentences as pledges. For example, in the Swedish data set, the bullet is a clear marker that introduces statements containing some form of commitment. We also find expressions indicating volition ("Vi **vill** också" – "We also **want**..."), consequences ("**så** att det" – "**So** that..."), future ("**will** be set", "**will** be launched") and determined temporal horizons ("in five years", "over the next"). In contrast, both in the Indian and the Swedish data, references to political entities such as parties ("Alliansen"), congresses ("National Congress") and even countries ("Sverige", "India") are associated with non-pledge texts: they refer, more probably, to broad political positions or to claims about the past ("has always been", "ska vara ett" – "should be one").

Interestingly, the phrase "skarpa förslag" does *not* signal pledges, even though it means "specific policy proposals" (which are essentially the same as pledges). This distinction indicates that this phrase merely introduces pledges or provides a strong language for un-testable policy statements (such as "we promise safety to all children" or "we will put forward strict legislation to make our country safe again").

Given the relatively limited frequency of the selected n-grams, we did not measure the IG stratification by party and/or election year. However, given the relative MTL models' success, we hypothesize that, with more data, it will be possible to identify specific trends for political areas and historical moments.

Aware that the patterns detected by the neural models are not necessarily interpretable in terms of human common sense, we also wanted to highlight the words that the models find to be the most influential for their output. These patterns can feedback into the interpretation of pledge structures and mechanisms by social scientists.

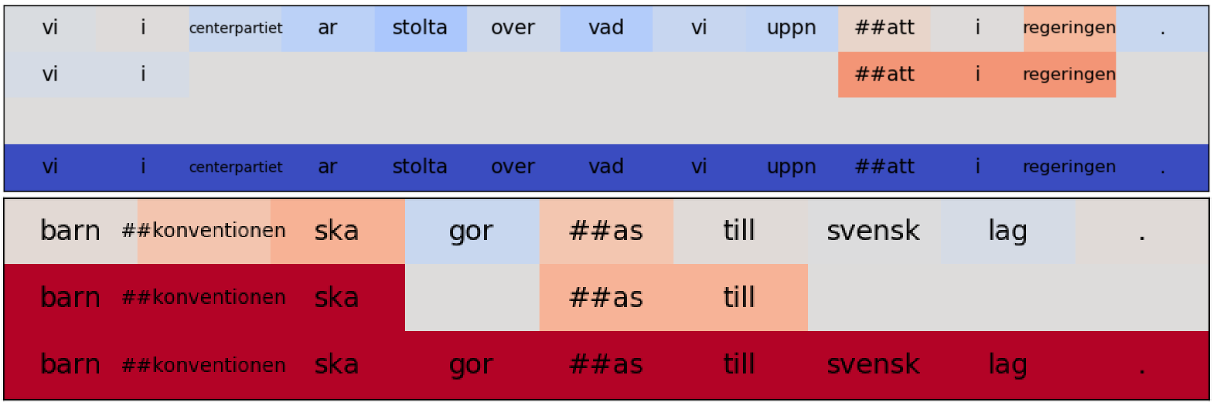

Figure 2: Output of the SOC algorithm on the Swedish corpus. The red terms predict Pledge, the blue ones predict Non-pledge.
Non-pledge translation: ‘We in the center party are proud of what we have achieved in the government.’
Pledge translation: ‘The Convention on the Children’s Rights shall be made Swedish law.’

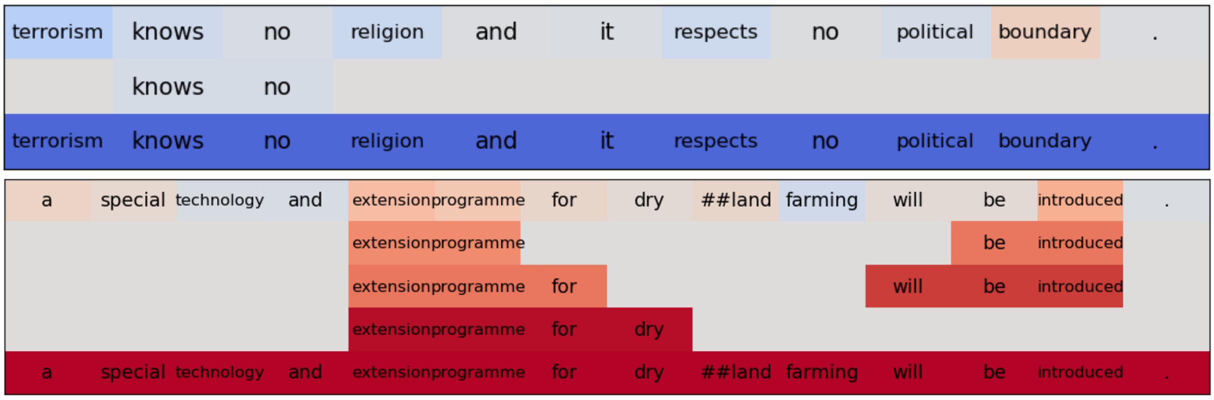

Figure 3: Output of the SOC algorithm on the English corpus. The red terms predict Pledge, the blue ones predict Non-pledge.

We also use the Sampling and Occlusion (SOC) algorithm (Jin et al., 2019), a *post-hoc* explanation algorithm that measures the importance of specific words in a sentence by considering the prediction difference after replacing each word with a MASK token (Jin et al., 2019). Since the outcomes depend on the context words, but Jin et al. (2019) are interested in the single words’ relevance, they do not use the whole context but sample words from it. In this way, they reduce the context weight, emphasizing that of the word itself.

Figure 2 and 3 show four examples of correctly classified sentences, two pledges and two non-pledges from Swedish and English language respectively (the same as shown in Table 1). The model interprets the red words as indicative of pledges, the blue ones of non-pledges. However, they cannot be interpreted as representative of the overall models’ functioning. Even so, they show how generic words such as “stolta” (“proud”) are indicative of non-pledges, while expressions indicating commitment (“ska göras till” – “to be made to”) and concrete topics (“Barnkonventionen” – “Convention on Children’s Rights”) are signals for pledges.

7 Related Work

In political sciences, the elections that we consider have been extensively studied by Håkansson and Naurin (2016), Lindvall et al. (2020) and Adhikari et al. (2020). Moreover, applying NLP methods to the analysis of political parties’ statements has recently developed into an active field of research, with various groups investing in creating dedicated corpora and annotating them for specific purposes.

The Manifesto Project (MP) (Volkens et al., 2012; Merz et al., 2016) collects electoral programs from more than 50 countries for democratic elections since 1945, making it a notable initiative within the field. It provides data on different manifesto aspects in several countries and over time. Recently, the Comparative Party Pledges Project (CPPP) of Naurin et al. (2019) has added detailed qualitative coding of what exactly pledges are made of (Naurin and Thomson, 2020).

Subramanian et al. (2018) study the MP data, addressing the identification of fine- vs. coarse-grained positions taken by political parties. Despite the different classification task, similarly to our study, they adopt hierarchical models that encode the texts' structure, finding that contextual information improves the models' performance. However, they train bi-LSTM networks from scratch, while we rely on pre-trained BERT language models.

Bilbao-Jayo and Almeida (2018) also work on the MP corpus, applying multi-input Convolutional Neural Networks (CNN) that take into account the statements' context, analogously to our study. They seek to classify the texts according to seven topics corresponding to general areas of interest.

We partially use the same data as the MP, as we study Swedish manifestos included in that data set. However, we are specifically interested in the identification of election pledges. This is similar to the task studied by Subramanian et al. (2019a). They focus on eleven Australian federal election cycles and distinguish rhetorical (broad) from detailed (narrow) pledges. The annotation of the Swedish texts considers this distinction, while the annotated Indian texts of our corpus do not (Section 2). Subramanian et al. (2019a) use a bidirectional Gated Recurrent Unit (biGRU) to carry out the prediction over ordinal classes.

From a methodological point of view, our approach is related to that of Abercrombie et al. (2019), which also uses BERT. They work on motions tabled in the UK Parliament and find that BERT effectively detects specific categories of proposals in the politicians' speeches.

Concerning the MTL methods, our study is analogous to that of Subramanian et al. (2019b). They consider texts from the 2016 Australian election and propose a new annotation scheme for different *speech acts*. They also perform the classification task using biGRU networks with ELMo embeddings (Peters et al., 2018), relying on a MTL framework in which the auxiliary task is the party prediction: this is also one of our experimental conditions.

8 Conclusion

We propose deep neural models that combine pre-trained language models and trainable attention mechanisms to identify election pledges in party manifestos. We find that these models outperform a non-neural baseline. Even in zero-shot cross-lingual conditions (with some contribution by the MTL methods), the performance of the multilingual models indicates that we could identify pledges in low-resource languages.

Finally, we gained some insight into election pledges' linguistic profile. They are self-contained statements, independent of the context in which they appear. They are likely to be characterized by formulaic expressions that express commitment, intentions, and temporal terms concerning concrete topics. These results stem from close interdisciplinary cooperation between political scientists and NLP researchers.

Pledge identification is the first step for future downstream NLP tasks within the theoretical framework of political science, which is typically interested in societal developments and explanations such as pledge fulfillment and power distribution in democracies. For example, the fine-grained study of topics, biases, and the temporal evolution of election pledges. Our results provide a blueprint for successful future research in that vein.

Acknowledgements

DH and TF are members of the Data and Marketing Insights Unit at the Bocconi Institute for Data Science and Analysis. This project is funded by Riksbankens Jubileumsfond, with ID MXM19-1137:1, "Mixed methods for analyzing political parties' promises to voters during election campaigns."

Ethical Considerations

The data we release are publicly available political manifestos. The texts are not harmful and do not contain personal information. The annotation and the relative classification task do not raise privacy concerns.

WeaQA: Weak Supervision via Captions for Visual Question Answering

Pratyay Banerjee Tejas Gokhale Yezhou Yang Chitta Baral
Arizona State University
`pbanerj6, tgokhale, yz.yang, chitta@asu.edu`

Abstract

Methodologies for training visual question answering (VQA) models assume the availability of datasets with human-annotated *Image-Question-Answer* (I-Q-A) triplets. This has led to heavy reliance on datasets and a lack of generalization to new types of questions and scenes. Linguistic priors along with biases and errors due to annotator subjectivity have been shown to percolate into VQA models trained on such samples. We study whether models can be trained without any human-annotated Q-A pairs, but only with images and their associated textual descriptions or captions. We present a method to train models with synthetic Q-A pairs generated procedurally from captions. Additionally, we demonstrate the efficacy of spatial-pyramid image patches as a simple but effective alternative to dense and costly object bounding box annotations used in existing VQA models. Our experiments on three VQA benchmarks demonstrate the efficacy of this weakly-supervised approach, especially on the VQA-CP challenge, which tests performance under changing linguistic priors.

1 Introduction

Since Visual Question Answering (VQA) was first proposed as a Turing test (Malinowski and Fritz, 2014), several human-annotated datasets (Mogadala et al., 2019) have been used to train and evaluate VQA models. Unfortunately, heavy reliance on these datasets for training has the unwanted side-effects of bias towards answer styles, question-types (Chao et al., 2018), and spurious correlations with language priors (Agrawal et al., 2018). Similar findings have been reported for natural language tasks (Gururangan et al., 2018; Niven and Kao, 2019; Kaushik et al., 2020). Evaluating VQA models on test-sets that are very similar to training sets is deceptive and inadequate and not an accurate measure of robustness.

To address this, one line of work has focused on balancing, de-biasing, and diversifying samples (Goyal et al., 2017; Zhang et al., 2016). However, crowd-sourcing "unbiased" labels is difficult and costly; it requires a well-designed annotation interface and a large-scale annotation effort with dedicated and able annotators (Sakaguchi et al., 2020). The alternative (that this paper aligns itself with) is to avoid the use of explicit human annotations and instead to train models in an unsupervised manner by synthesizing training data. These techniques, coined *unsupervised*[1], come with many advantages – human bias and subjectivity are reduced; the techniques are largely domain-agnostic and can be transferred from one language to another (low resource languages) or from one visual domain to another. For instance, template-based Q-A generation developed for synthetic blocks-world images in CLEVR (Johnson et al., 2017) can also be used to generate Q-A pairs for natural complex scenes in GQA (Hudson and Manning, 2019) or the referring-expressions task (Liu et al., 2019).

In this work, we train VQA models without using human-annotated Q-A pairs. Instead, we rely on weak supervision from image-captioning datasets, which provide multi-perspective, concise, and less subjective descriptions of visible objects in an image. We procedurally generate Q-A pairs from these captions and train models using this synthetic data, and *only evaluate* them on established human-annotated VQA benchmarks.

Why Captions? Image captioning, like VQA, has been a central area of vision-and-language research. Datasets such as MS-COCO (Lin et al., 2014; Chen et al., 2015) contain captions that describe objects and actions in images of everyday scenes. During the construction of MS-COCO, human captioners were instructed to refrain from describing past and future events or "what a person might say". On the other hand, annotators of

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3420–3435
August 1–6, 2021.

VQA (Antol et al., 2015) were instructed to ask questions that *"a smart robot cannot answer, but a human can"* and "interesting" questions that may require "commonsense". Different sets of annotators provided answers to these questions and were allowed to speculate or even guess an answer that *most people would agree on*. It has also been shown that multiple answers may exist for questions in common VQA datasets (Bhattacharya et al., 2019).

In Figure 2, the first VQA-v2 question asks how many doors the car has. Although commonsense (and linguistic priors) would suggest that "Most cars have *four* doors", only two doors can be seen in the image. What should the model predict, *two* or *four*? The second question is subjective and has multiple contradicting answers from different annotators (where one should draw the line between opaque, transparent, or reflective is not very clear). Similarly, the first GQA question is ambiguous and could refer to either the skier or the photographer.

Thus the very nature of the data-collection procedure and instructions for VQA brings in human subjectivity and linguistic bias as compared to caption annotations, which are designed to be simple, precise, and non-speculative. Motivated by this, we study the benefits of using captions to synthesize Q-A pairs, using three types of methods:

1. template-based methods similar to (Ren et al., 2015a; Gokhale et al., 2020b),
2. paraphrasing and back-translation (Sennrich et al., 2016) which provide linguistic variation,
3. synthesis of questions about image semantics using the QA-SRL (He et al., 2015) approach.

Since our Q-A pairs are created synthetically, there does exist a domain shift as well as label (answer) shift from evaluation datasets such as VQA-v2 and GQA as shown in Figure 2, thus posing challenges to this weakly-supervised method.

We evaluate two models, UpDown (Anderson et al., 2018) and a transformer-encoder (Vaswani et al., 2017) based model pre-trained on synthetic Q-A pairs and image-caption matching task. To remove the dependence on object bounding-boxes and labels needed to extract object features, we propose spatial pyramids of image patches as a simple and effective alternative.

To the best of our knowledge, this is the first work on the unsupervised[1] visual question answering, with the following contributions:

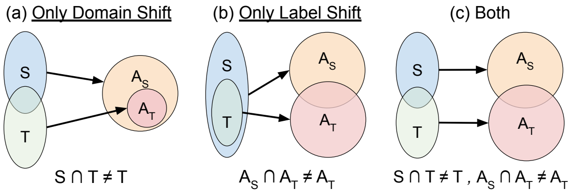

Figure 1: Aspects of generalization in VQA.

- We introduce a framework for synthesizing *(Question, Answer)* pairs from captions.
- Since synthetic samples (unlike popular benchmarks) include multi-word answer phrases, we propose a sub-phrase weighted-answer loss to mitigate bias towards such multi-word answers.
- We propose pre-training tasks that use spatial pyramids of image-patches instead of object bounding-boxes, further removing the dependence on human annotations.
- Extensive experiments and analyses under zero-shot transfer and fully-supervised settings on VQA-v2, VQA-CP, and GQA show our model's efficacy and establish a strong baseline for future work on unsupervised visual question answering.

2 Related Work

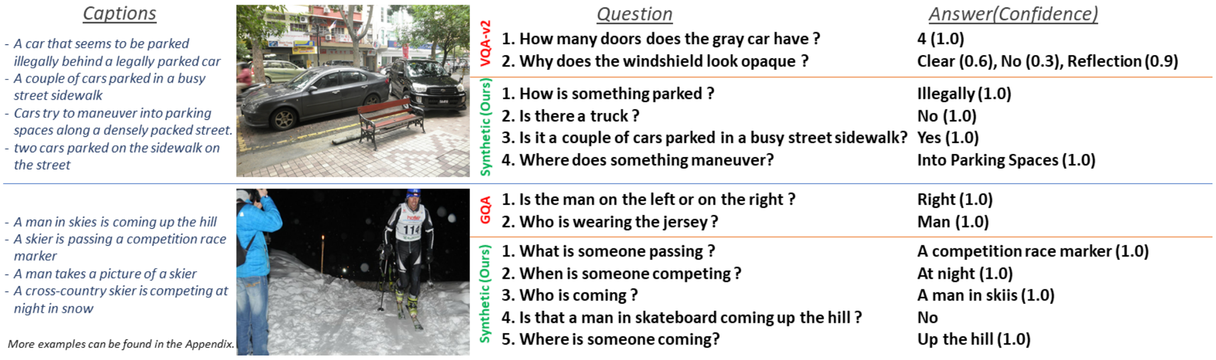
Robustness in VQA can be defined as shown in Figure 1 under two situations: domain shift and label shift. Under domain shift, generalization to a new input domain (such as different styles of questions or novel scenes) is desired, characterized by $S \cap T \neq T$ where S and T denote the train and test input domains. Under label shift, generalization to novel answers is desired (predicting answers not seen during training), characterized by $A_S \cap A_T \neq A_T$, where A_S and A_T are the set of answers seen during training and test-time.

Performance under **domain shift** has been evaluated for new domains of test questions with unseen words and objects (Teney and Hengel, 2016; Ramakrishnan et al., 2017), novel compositions (Johnson et al., 2017; Agrawal et al., 2017), logical connectives (Gokhale et al., 2020b), as well as questions that are implied (Ribeiro et al., 2019), entailed (Ray et al., 2019) or sub-questions (Selvaraju et al., 2020); or for datasets with varying linguistic styles (Chao et al., 2018; Xu et al., 2020; Shrestha et al., 2019) and different reasoning capabilities (Kafle and Kanan, 2017).

Label shift or Prior Probability Shift (Storkey,

---

[1] adhering to the usage of this term in Lewis et al. (2019a).



Captions

- *A car that seems to be parked illegally behind a legally parked car*
- *A couple of cars parked in a busy street sidewalk*
- *Cars try to maneuver into parking spaces along a densely packed street.*
- *two cars parked on the sidewalk on the street*

	Question	*Answer(Confidence)*
VQA-v2	1. How many doors does the gray car have ?	4 (1.0)
	2. Why does the windshield look opaque ?	Clear (0.6), No (0.3), Reflection (0.9)
Synthetic (Ours)	1. How is something parked ?	Illegally (1.0)
	2. Is there a truck ?	No (1.0)
	3. Is it a couple of cars parked in a busy street sidewalk?	Yes (1.0)
	4. Where does something maneuver?	Into Parking Spaces (1.0)

- *A man in skies is coming up the hill*
- *A skier is passing a competition race marker*
- *A man takes a picture of a skier*
- *A cross-country skier is competing at night in snow*

GQA	1. Is the man on the left or on the right ?	Right (1.0)
	2. Who is wearing the jersey ?	Man (1.0)
Synthetic (Ours)	1. What is someone passing ?	A competition race marker (1.0)
	2. When is someone competing ?	At night (1.0)
	3. Who is coming ?	A man in skiis (1.0)
	4. Is that a man in skateboard coming up the hill ?	No
	5. Where is someone coming?	Up the hill (1.0)

More examples can be found in the Appendix.

Figure 2: Examples of images and human-annotated Q-A pairs from VQA and GQA and our synthetic Q-A pairs.

2009) has been implicitly explored in VQA-CP (Agrawal et al., 2018), where the conditional probabilities of answers given the question type deviate at test-time. Teney et al. (2020c) have identified several pitfalls associated with the models and evaluation criteria for VQA-CP.

Unsupervised Extractive QA in which aligned *(context, question, answer)* triplets are not available, has been studied (Lewis et al., 2019b; Banerjee and Baral, 2020; Rennie et al., 2020; Fabbri et al., 2020; Li et al., 2020; Banerjee et al., 2021) by training models on procedurally generated Q-A pairs. Captions have been used to generate Q-A pairs for logical understanding (Gokhale et al., 2020b) and commonsense video understanding (Fang et al., 2020a). Li et al. (2018); Krishna et al. (2019) have explored Visual Question Generation from an input image and answer.

Weak supervision is an active area of research; for instance in action/object localization (Song et al., 2014; Zhou et al., 2016) and semantic segmentation (Khoreva et al., 2017; Zhang et al., 2017) without pixel-level annotations, but only class labels. There is also interest growing in leveraging natural language captions or textual queries as weak supervision for visual grounding tasks (Hendricks et al., 2017; Mithun et al., 2019; Fang et al., 2020b).

Visual Feature Extractors such as VGG (Simonyan and Zisserman, 2015) and ResNet (He et al., 2016) have been widely used for many computer vision tasks. Object-based features such as RCNN (Girshick et al., 2014) and Faster-RCNN (Ren et al., 2015b) have become the standard for V& L tasks (Anderson et al., 2018).

3 Framework for Synthesizing Q-A Pairs

Problem Statement: Consider a dataset containing images and associated captions as shown in Figure 2. Our work deals with learning VQA using these image-caption data, without any labeled Q-A pairs, and answer questions about unseen images.

3.1 Question Generation

Several studies (Du et al., 2017; Lewis et al., 2019a) have been dedicated to the complex domain of question generation. We approach it conservatively, using template-based methods and semantic role labeling, with paraphrasing and back-translation for improving the linguistic diversity of template-based questions. We begin by extracting object words from the caption by using simple heuristics such as extracting noun-phrases and using numerical quantifiers in the caption as soft approximations of objects' cardinality. If object-words are available explicitly, we used them as is. Questions are categorized based on answer types; *Yes-No*, *Number*, *Color*, *Location*, *Object*, and *Phrases*.

Template-based: To create *Yes-No* questions, modal verbs are removed from the caption, and a randomly chosen question prefix such as *"is there"*, *"is this"* is attached. For instance, the caption "A man is wearing a hat and sitting" is converted to "*Is there a* man wearing a hat and sitting", with the answer "Yes". To create the corresponding question with the answer "No", we use either negation or replace the object-word with an adversarial word or antonym, thus obtaining "Is there a dog wearing a hat and sitting" for which the answer is "No". An adversarial word refers to an object absent in the image but similar to objects in the image. To compute similarity, we use Glove (2014) word-vectors.

For *Object*, *Number*, *Location*, and *Color* questions, we follow a procedure similar to Ren et al.

	Template-based	Paraphrase & Back-translate	QA-SRL	VQA-v2	GQA	VQA-CP
# of Questions	600K	400K	2.5M	438K / 214K	943K / 132K	245K / 220K
# of Answers	5K	5K	90K	3.5K	1878	3.5K
Mean Question Length	7.9	8.1	4.8	6.4	10.6	6.4
Mean Answer Length	1.4	1.4	6.3	1.1	1.3	1.1
Image Source	COCO	COCO	COCO	COCO	COCO,VG,Flickr	COCO
Image Counts	120K	120K	120K	120K	113K	120K

Figure 3: Discrepancy between VQA-v2, GQA, and synthetic samples. Left: t-SNE plot of question embeddings. Right: Dataset statistics for our generated Q-A pairs with Train/Val. splits for benchmark datasets.

(2015a). To create "*what*" questions for the *Object* type, we extract objects and noun phrases from captions as potential answers and replace them with *what*. The question is rephrased by splitting long sentences into shorter ones and converting indefinite determiners to definite. A similar procedure is used for *Number* questions; numeric quantifiers of noun phrases are extracted and replaced by "how many" and "what is the count" to form the question. *Color* questions are generated by locating the color adjective and the corresponding noun phrase and replacing them in a templated question: "What is the color of the object?". *Location* questions are similar to *Object* questions, but we extract phrases with "in", "within" to extract locations, with places, scenes, and containers as answers.

Semantic Role Labeling: QA-SRL (He et al., 2015) was proposed as a paradigm to use natural language to annotate data by using Q-A pairs to specify textual arguments and their roles. Consider the caption *"A girl in a red shirt holding an apple sitting in an empty open field"*. Using QA-SRL with B-I-O span detection and sequence-to-sequence models (FitzGerald et al., 2018), for the *"when", "what", "where", and "who"* questions, we obtain Q-A pairs belonging to the *Phrases* category such as:

(what is someone holding?, an apple)
(who is sitting?, girl in a red shirt holding an apple)
(where is someone sitting?, an empty open field)

These examples illustrate that QA-SRL questions are short and use generic descriptors such as *something* and *someone* instead of elaborate references, while the expected answer phrases are longer and descriptive. Thus to answer these, better semantic image understanding is required.

Paraphrasing and Back-Translation (P&B): We apply two natural language data augmentation techniques, paraphrasing, and back-translation to increase the linguistic variation in the questions. To paraphrase questions, we train a T5 (Raffel et al., 2019) text generation model on the Quora Question Pairs Corpus (). For back-translation, we train another T5 text generation model on the Opus corpus (2012), translate the question to an intermediate language (Français, Deutsche, or Español), and translate the question back to English. For example:

Is the girl who is to the left of the sailboats wearing a backpack?
↓ Español
La chica que está a la izquierda de los veleros lleva mochila?
↓ English
Does the girl to the left of the sailboats carry a backpack?

3.2 Domain Shift w.r.t. VQA-v2 and GQA

Compared to current VQA benchmarks (which typically contain one-word answers), answers to QA-SRL questions are more descriptive and contain adjectives, adverbs, determiners, and quantifiers, as seen in Figure 2. On the other hand, synthetic questions have less descriptive subjects due to the use of pronouns. Our synthetic data contains $90k$ unique answer phrases, compared to $3.2k$ in VQA and 3k in GQA. Around 200 answers from VQA are not present in our answer phrases, such as time (11:00) and proper nouns (LA Clippers), both of which are not present in caption descriptions.

Moreover, our training data contains Q-A pair such as *("Where is the man standing?, "to the left of the table")*, generated by QA-SRL with long phrases as answers. However, the test set contains questions such as *("Which side of the car is the tree?", "left")*, which expects only *"left"* as the answer. So although the word *"left"* is seen as a sub-phrase of our training answers, it is not explicitly seen as an only correct answer.

Some of our synthetic template-based questions about counting and object presence are similar in style to those in VQA and GQA. However, QA-SRL questions require a semantic understanding of the actions depicted in the image, which are rare in VQA and GQA. We quantify this by plotting the t-SNE components of document vector embeddings of the questions from VQA, GQA, and our synthetic data, in Figure 3, and observe that our synthetic questions are a distinct cluster, while VQA and GQA overlap with each other. As such, a linguistic domain shift exists between these synthetic source questions and human-annotated target questions. In this paper, we address the challenge of learning VQA on a synthetically generated dataset and evaluating models on conventional benchmarks which have questions and answers that deviate linguistically from synthetic training samples.

4 Method

Recently, multiple deep transformer-based architectures have been proposed (Tan and Bansal, 2019; Lu et al., 2019; Chen et al., 2019), that are pre-trained on a combination of multiple VQA and image captioning datasets such as Conceptual Captions (Sharma et al., 2018), SBU Captions (Ordonez et al., 2011), Visual Genome (Krishna et al., 2017), and MSCOCO (Lin et al., 2014). These models are resource intensive as they are trained on a huge collection of data with 3 million images. We train our models only on MS-COCO captions and images ($\sim$204k), without access to any human-authored Q-A pairs or object bounding boxes.

4.1 Spatial Pyramid Patches

"Bottom-Up" object features (Anderson et al., 2018) extracted from Faster R-CNN (Ren et al., 2015b) have become the de-facto features used in state-of-the-art VQA models. These VQA models thus only use features of detected objects as input, and ignore the rest of the image. Although object features are discriminative, dense annotations are required for training and additional large deep networks for extraction. Object detection can be imperfect for small and rare objects (Wang et al., 2019); for instance if an object detection model detects only four out of six bananas in an image, features of the other two bananas will not be used by VQA models. This creates a performance bottle-neck for questions about counting or rare objects.

We take a step back and postulate that the use of features of the entire image in context could reduce this bottleneck. Image features extracted from a ResNet (He et al., 2016) trained for the ImageNet (Russakovsky et al., 2015) classification task, which is widely used for computer vision tasks, have been previously used for VQA models (Goyal et al., 2017). Unfortunately, since ImageNet contains iconic (single-object) images, using these features for non-iconic VQA images is restrictive since many questions refer to multiple objects and backgrounds in the image. Inspired by Spatial Pyramid Matching (Lazebnik et al., 2006) for image classification, we propose *spatial pyramid patch features* to represent the input VQA image into a sequence of features at different scales.

We divide each image I into a set of image patches $\{I_{k_1}, \ldots, I_{k_n}\}$, each I_{k_i} being a $k_i \times k_i$ grid of patches, and extract ResNet features for each patch. Larger patches encode global features and relations, while smaller patches encode local and low-level features.

Encoder: Our Encoder model is similar to the UNITER single-stream transformer, where the sequence of word tokens $w = \{w_1, ..., w_T\}$ and the sequence of image patch features $v = \{v_1, ..., v_K\}$ are taken as input. We tokenize the text using a WordPieces (Wu et al., 2016) tokenizer similar to BERT (Devlin et al., 2019), and embed the text tokens through a text-embedder (Sanh et al., 2019). The visual features are projected to a shared embedding space using a fully-connected layer. A projected visual position encoding, indicating the patch region (top-right, bottom-left) is added to the visual features. We concatenate both sequences of features and feed them to L cross-modality attention layers. Parameters between the cross-modality attention layers are shared to reduce parameter count and increase training stability (Lan et al., 2020), and a residual connection and layer normalization is added after cross-modal attention layer similar to Vaswani et al. (2017).

4.2 Pre-training Tasks and Loss Functions

We train the Encoder model using three pre-training tasks: Masked Language Modeling, Masked Question Answering, and Image-Text Matching.

Masked Language Modeling (MLM): We randomly mask 15% of the word tokens from the caption and ask the model to predict them. For the caption "There is a man wearing a hat", the model gets the input "There is `[MASK]` wearing a hat". Without the image, there can be multiple plausible choices for the `[MASK]` token, such as "woman", "man", "girl", but given the image the model should predict "man". This task has been shown to effectively learn cross-modal features (2019).

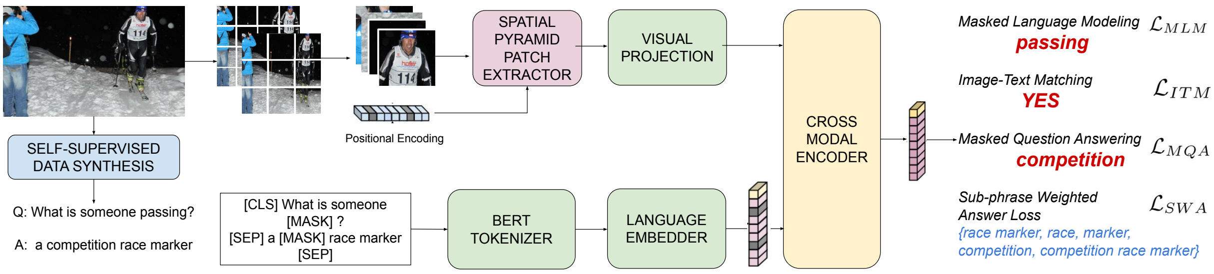


Figure 4: Our model architecture makes the use of spatial pyramids of image patches as inputs to the Encoder, which is trained for three pre-training tasks as shown.

Masked Question Answering (MQA): In this task, the answer tokens are masked, and the model is trained to predict the answer tokens. For example in Figure 2, for the input " When is someone competing? `[MASK] [MASK]`", the model should predict, "at night". To answer such questions, the model needs to interpret the image.

Image-Text Matching (ITM): We use the five captions provided by MS-COCO as positive samples for each image. To obtain negative samples, we randomly sample captions from other images that contain a different set of objects. We train the model on a binary classification task (matching / not matching) for each image-caption pair.

For VQA and ITM, we use the final layer representation $z^{[CLS]}$ of `[CLS]` token , followed by a feed-forward and softmax layer. For MLM and MQA we feed corresponding token representations to a different feed-forward layer. We train the model using cross-entropy loss for all three tasks.

Sub-phrase Weighted Answer Loss: As observed before, the questions generated in QA-SRL have long answer phrases. For instance "What is parked?" has the answer "two black cars". We extract all possible sub-phrases that can be alternate answers, but assign them a lower weight than the complete phrase, computed as $W_{sub} = \mathit{WordCount}(sub)/\mathit{WordCount}(ans)$. Thus "two black cars" has a weight 1.0, while the extracted sub-phrases and weights are: (two, 0.33), (2, 0.33), (black, 0.33), (cars, 0.33), (two cars, 0.66), (2 cars, 0.66), (black cars, 0.66), (car, 0.33). This enforces a distribution over the probable answer space instead of a strict "single true answer" training. We train the model with this additional binary cross-entropy loss, where the model predicts a weighted distribution y_{wa} over the answer vocabulary. The vocabulary is defined from the synthetic QA answer-space.

$$\mathcal{L}_{SWA} = \mathcal{L}_{BCE}(\sigma(z^{[CLS]}), y_{wa}). \tag{1}$$

The total loss, with scalar coefficients $\alpha, \beta \in (0, 1]$ is given by:

$$\mathcal{L} = \mathcal{L}_{MLM} + \mathcal{L}_{MQA} + \alpha \cdot \mathcal{L}_{ITM} + \beta \cdot \mathcal{L}_{SWA}. \tag{2}$$

5 Experimental Setup

Datasets: We evaluate our methods on the three popular visual question answering benchmarks: VQA-v2, VQA-CP-v2, and GQA. Answering questions in VQA-v2 and VQA-CP v2 requires image and question understanding, whereas GQA further requires spatial understanding such as compositionality and relations between objects. We evaluate our methods under *zero-shot* transfer (trained only on procedurally generated samples), and *fully-supervised* (where we finetune our model using the associated train annotations) settings. We use exact-match accuracies for GQA, and use VQA-metric (Agrawal et al., 2017) for VQA.

Training: Our Encoder has 8 cross-modal layers with a hidden dimension of 768. The weights are initialized using the standard definition as provided in the Huggingface repository (Wolf et al., 2019). Our models are pre-trained for 40 epochs with a learning rate of 1e−5, batch size of 256, using Adam optimizer. For finetuning, we use a learning rate of 1e−5 or 5e−5 and batch size of 32 for 10 epochs. We use a ResNet-50 pretrained on ImageNet to extract features from image patches with 50% overlap, and Faster R-CNN pretrained on Visual Genome to extract object features. We evaluate both frozen and finetuned ResNet, and observe finetuning the feature extractor to perform better. All our models are trained using 4 Nvidia V100 16 GB GPUs. All results in the fully supervised setting are reported for from-scratch trained final classification layers.

Baselines: To measure the improvements due to our proposed image patch features and SWA loss, we compare our methods to the UpDown model Anderson et al., which uses object bounding-box features. For the Zero-shot transfer setting, we compare our Encoder with UpDown when trained with spatial features as well as object features. Pretrained transformers such as UNITER use large V&L corpora, dense human annotations for objects and Q-A pairs and supervised loss functions over these. Comparisons with such models are therefore not fair in a ZSL setting; instead, we perform these comparisons in a fully-supervised (FSL) setting.

6 Results[2]

Unsupervised Question Answering: Tables 1, 2 and 3 summarize our results on the three benchmark datasets. We can observe that our method outperforms specially designed supervised methods for bias removal in VQA-CP; our model with UpDown is 1.1% better than the supervised UpDown. Under the ZSL setting for VQA-CP, our Encoder model is 6.1% better than UpDown with patches, and 6.5% better than UpDown with Object features, for VQA-v2: 6.2%, 5.4% respectively, and for GQA: 2.2%, 3.0% respectively.

For VQA-CP, our procedurally generated Q-A pairs and patch-features when used with either UpDown or Encoder are better than the baseline supervised UpDown model, showing the improvements are model-agnostic. This also shows the merits of using our Q-A generation methods when train and test-sets deviate linguistically.

Most GQA questions require understanding spatial relationships between objects. Such questions are infrequent in our synthetic training data since captions do not contain detailed spatial relationships among objects. Thus, the ZSL performance is not as competitive for GQA when compared to our performance on VQA and VQA-CP. Improving spatial and compositional question-answering with weak supervision is an interesting future pursuit.

Fully Supervised Question Answering: In the FSL setting, our methods' performance is not far from SOTA methods, even though our method uses significantly fewer annotations (no access to object bounding boxes). In GQA, the Encoder model performs on par with MAC (2018) and BAN (2018), which unlike us, use object relationship annotations. This suggests that cross-modal transformer layers can learn spatial relations from spatial pyramidal

---

Table 5: Effect of the number of spatial patches on ZSL performance {3,5} implies division of the image into a 3x3 and 5x5 grid of patches.

features.

Impact of each question-generation technique: In Table 4 we can observe the effect of different question generation techniques. All models use spatial image patch features. QA-SRL based questions and the SWA-Loss contribute the most towards gains in performance, and the paraphrased questions provide larger linguistic variation.

Effect of Spatial Pyramids: We study the effect of progressively increasing the number of spatial image patches (i.e., decreasing the patch size). Table 5 shows that an optimum exists at grid-size of 7×7 after which the addition of smaller patches is detrimental. Similarly, only using patches of large size does not allow models to focus on specific image regions. Thus a trade-off exists between global context and region-specific features. Changing the feature extractor from ResNet-50 to ResNet-101 only results in a minor improvement of 0.01% to 0.30%. Removing visual position embeddings has a significant effect on performance, with a drop of 4.60% to 8.00% in both ZSL and FSL settings.

Impact of Pre-training Tasks: Table 6 shows the effect of different pretraining tasks on the downstream zero-shot transfer VQA task. We need the

Pre-Training Task	VQA-v2	VQA-CP	GQA
SWA	39.1	38.3	25.4
MLM+SWA	42.4	41.5	27.8
MQA+SWA	42.0	41.2	26.6
MLM+MQA+SWA	45.6	44.9	29.7
MLM+ITM+SWA	44.7	43.6	28.9
All	**46.2**	**45.4**	**31.2**

Table 6: Effect of different pre-training tasks on the ZSL performance for the Encoder model.

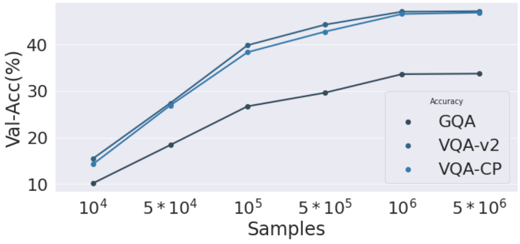

Figure 5: Learning Curve showing validation accuracy vs. number of synthetically generated training samples.

SWA task, as it is used to perform the zero-shot QA task. The combination of MLM, MQA, and ITM, all of which need image understanding, shows improved performance on the downstream task, indicating better cross-modal representations.

Effect of size of synthetic training set: Figure 1 shows our Encoder model's learning curve for the zero-shot transfer setting trained on our synthetic Q-A pairs. The performance stagnates after a critical threshold of 10^6 samples is reached. Our experiments also suggest that randomly sampling a set of questions for each image per epoch leads to a 4% gain compared to training on the entire set.

Error Analysis: Our ZSL method is pretrained on longer phrases and hence tends to generate more detailed answers, such as "red car" instead of "car". Although the SWA loss is designed to encourage a distribution over the shorter phrases, the bias is not entirely removed. On automated evaluation, we observe that for 42% of questions, the target answer is a sub-phrase of our predicted answer. Manual evaluation of 100 such samples shows that 87% of such detailed predicted answers are plausible. This shows the relevance of learning from captions and quantifies the bias towards short "true" answers in human-annotated benchmarks, calling for better evaluation metrics that do not penalize VQA systems for producing descriptive or alternative accurate answers.

In the FSL setting, we either finetune our pre-trained QA classifier with the SWA Loss or train a separate feedforward layer from scratch for the task. The pre-trained QA classifier predicts longer phrases as answers, leading to a drop in accuracy. The feedforward layer performs better (+6%), indicating our Encoder captures relevant features necessary to generalize to the benchmark answer-space. Note that we do not use object annotations during training, unlike existing methods.

Our error analysis and Figure 3 show the shift in question-space and answer-space between synthetic and human-authored Q-A pairs. These (along with inadequate evaluation metrics) act as the primary sources explaining the performance-gap between weakly-supervised methods and the fully-supervised setting. It remains to be seen whether more sophisticated question generation can be developed to reduce the performance gap further and mitigate the heavy reliance on human annotations.

7 Discussion and Conclusion

Prior work (Chen et al., 2019; Jiang et al., 2020) has demonstrated that the use of object bounding-boxes and region features leads to significant improvements on downstream tasks such as captioning and VQA. However, little effort has been dedicated to developing alternative methods that can approach similar performance without relying on dense annotations. We argue that weakly supervised learning coupled with data synthesis strategies could be the pathway for the V&L community towards a "post-dataset era".[2] In this work, we take a step towards that goal. We address the problem of weakly-supervised VQA with a framework for the procedural synthesis of Q-A pairs from captions for training VQA models, where benchmark datasets can be used only for evaluation. We use spatial pyramids of patch features to increase the annotation efficiency of our methods. Our experiments and analyses show the potential of patch-features and procedural data synthesis and reveal problems with existing evaluation metrics.

Ethical Considerations

Captions and Question-Answer pairs are both annotated by humans in existing image captioning and visual question answering datasets. However, captions arguably contain a lesser degree of subjectivity, ambiguity, and linguistic biases than VQA annotations, due to the design of annotation prompts that limit the introduction of these biases. Our work points to the potential of procedurally generated annotations in providing robustness improvements under changing linguistic priors in VQA test sets (Table 1). Hendricks et al. find that gender bias exists in image-captioning datasets and is *amplified* by models; further research in self-supervised data synthesis could potentially help alleviate such social biases.

Appendix

A Synthesized Samples

Table 7 shows illustrative examples of Q-A pairs procedurally generated from the image caption using template-based method. Table 8 shows the use of two transformations (T): negation and adversarial words (Gokhale et al., 2020b) two generate more sentences. Thus the negation of Q or substitution of a word in Q with an adversarial word results in the new question-answer pair Q_{new}, A_{new}. To increase the linguistic diversity of the questions we use paraphrasing as shown in Table 11.

B Dataset Analysis

In Table 9, we compare the distribution per answer-type of our synthetically generated samples with the distribution in the VQA-CP-v2 (Agrawal et al.,

Image	Question	Answer
	What are set on the sidewalk outside a veterinary hospital?	bags
	What is the young man holding up in front of his face ?	phone
	What is almost empty on the table	glass
	What drawn carriage with passengers in the city	horse
	What is the color of the table ?	white
	What is the color of the eyes ?	blue
	How many boats anchored by ropes close to shore?	8

Table 7: Examples of template-based data synthesis

T	Image	Q	A	Q_{new}	A_{new}
Negation		Is this bread?	yes	Is this not bread	no
		What is the color of the woman's shirt?	black	What is not the color of the woman's shirt?	white
		Is there a boy?	no	Is there no boy?	yes
Adversarial		Who is sitting in the boat ?	man	Who is sitting in the dining table ?	can't say
		How big is the plane ?	large	How big is the car ?	size
		How many puppies are on the bed ?	two	How many cats are on the bed?	none

Table 8: The effect of using transformations (T) to create new Q-A pairs

Category	VQA-CP (%)	Pretraining (%)
Yes/No	41.86	50.18
Number	11.91	8.32
Other	46.23	41.45

Table 9: Distribution of samples by answer-type in our pre-training dataset and the VQA-CP evaludation dataset.

Hyper-Parameters	Model
Batch Size	32-128
Learning Rate	$(1e^{-5}, 5e^{-5})$
Dropout	0.1
Language Layers	6
Cross-Modality Layer	4 — 12
Optimizer	BertAdam
Warmup	0.1
Max Gradient Norm	5.0
Max Text Length	30
ResNet	50 / 101 / 152
Epochs	10-40

Table 10: Hyper-Parameters for our models

2018) dataset. Since we use our synthetic samples as the pre-training data, and do not use VQA-CP samples for training in our zero-shot setup, this comparison displays the shift between the training (synthetic) and test (human annotated VQA-CP) datasets.

We further analyze this shift, by computing the t-SNE projections of questions using mean-pooled Glove (Pennington et al., 2014) embeddings for our generated questions and observe the overlap with human-authored questions in VQA and GQA (Hudson and Manning, 2019). Figure 6. We observe a marked shift between the question clusters for our procedurally generated questions and human annotated questions from VQA and GQA.

Similarly, we also show the distribution of answers in our dataset in Figure 7. It can be seen that our dataset has a slight imbalance in the proportion of questions with answer "yes" and "no". Numeric answers *0,1,2,3* are most frequent. Answers about people such as *man, woman, people, person, group of people* are also more common in the dataset. The remaining answers have a long-tailed distribution, since there are $\sim 90k$ unique answers in our dataset compared to $\sim 3.5k$ in VQA and $\sim 2k$ in GQA.

C Training Details

We use the HuggingFace (Wolf et al., 2019) and PyTorch frameworks (Paszke et al., 2019). Hyper-parameters and other training settings are given in Table 10.

Image	**Q**	**A**	$\mathbf{Q_{new}}$	$\mathbf{A_{new}}$
	How is something parked ?	illegally	How’s-what’s parked?	illegally
	what does something seem to do ?	park	What do you think something seems to be doing?	park
	Where was parked something?	behind a legally parked car	Do you know where something was parked?	behind a legally parked car
	How many cars are visible ?	2	How many cars are we looking at?	2
	Is there two cars parked on the sidewalk on the street ?	Yes	There are two cars parked on the sidewalk, right?	Yes

Table 11: Illustration of using paraphrasing to improve the linguistic variation of our questions and answers.

How well do you know your summarization datasets?

Abstract

State-of-the-art summarization systems are trained and evaluated on massive datasets scraped from the web. Despite their prevalence, we know very little about the underlying characteristics (data noise, summarization complexity, etc.) of these datasets, and how these affect system performance and the reliability of automatic metrics like ROUGE. In this study, we manually analyse 600 samples from three popular summarization datasets. Our study is driven by a six-class typology which captures different noise types (missing facts, entities) and degrees of summarization difficulty (extractive, abstractive). We follow with a thorough analysis of 27 state-of-the-art summarization models and 5 popular metrics, and report our key insights: (1) Datasets have distinct data quality and complexity distributions, which can be traced back to their collection process. (2) The performance of models and reliability of metrics is dependent on sample complexity. (3) Faithful summaries often receive low scores because of the poor diversity of references. We release the code, annotated data and model outputs.[1]

1 Introduction

The past few years have witnessed major breakthroughs and improvements in automatic summarization (See et al., 2017; Celikyilmaz et al., 2018; Jadhav and Rajan, 2018; Liu and Lapata, 2019; Liu, 2019; Dou et al., 2020; Yuan et al., 2021; Liu et al., 2021). Apart from the improvements in the summarization model architectures (Zhang et al., 2019; Zhong et al., 2020), this growth has been aided by large-scale datasets (Nallapati et al., 2016; Narayan et al., 2018a; Sharma et al., 2019) and automatic evaluation metrics (Lin, 2004; Zhao et al., 2019; Kryscinski et al., 2020) which are used for tuning hyperparameters and comparing models. While the reliability of these metrics has been explored extensively (Peyrard, 2019; Bhandari et al., 2020; Fabbri et al., 2020), few studies have focused on the underlying characteristics of different datasets, and how these impact model performance and metric reliability.

Datasets like CNN/DailyMail (Nallapati et al., 2016), Gigaword (Rush et al., 2015), XSum (Narayan et al., 2018a), and many more (Wang and Ling, 2016; Koupaee and Wang, 2018; Kim et al., 2019; Ganesan et al., 2010) were collected by scraping a large collection of web-pages. And for all the benefits this approach offers (seemingly infinite samples, diverse subjects, etc) there are some caveats:

Data Noise We have no idea about the **noise** in the dataset. In the context of text summarization, noise could be an incomplete or irrelevant reference. At the moment, its quantity and impact on the performance is unknown.

Summarization Complexity What do we really know about the nature of samples in the dataset? Gigaword is a headline generation dataset with short sources and references. Does this imply a higher volume of simpler (i.e. more *extractive*) samples? The degree of summarization complexity, and its impact on model performance is unknown.

Exploring these open questions is critical for two reasons: (1) Information about the noise could lead to more informed data collection and preprocessing methods: in a recent study, Kryscinski et al. (2019) quantified HTML artefacts in popular summarization datasets, and proposed ways to detect and remove them. (2) Awareness about the complexity could better explain model performance, metrics, and even lead to new model architectures. In the tasks of machine comprehension

and question answering, Chen et al. (2016) and Yatskar (2019) manually inspected random samples and drew insights which led to new state-of-the-art models. Such analysis could also help researchers choose datasets and metrics more carefully.

In this study, we perform intrinsic and model-centric evaluation of three popular summarization datasets (Gigaword, CNN/DM and XSum). We are interested in answering the following questions:

Q1. What are the underlying intrinsic properties of summarization datasets? We are interested in (1) Identifying and quantifying the different types of "noise" that could occur and could penalize models. (2) Whether samples have different levels of difficulty. Armed with this, we ask the following questions.

Q2 a. How do these properties impact model performance? Specifically, we'd like to know (1) If, and how, the performance varies across the different types of samples discovered from Q1. (2) If the performance is consistent across metrics.

Q2 b. If the reliability of metrics changes with these properties? This is motivated (in part) from prior metric-analysis studies, where researchers have explored inter-metric agreement and alignment with human-judgement under different conditions (Peyrard, 2019; Bhandari et al., 2020). Here we are more interested in knowing if the metrics are more correlated with human judgement for simpler samples, than complex ones.

Large-scale automatic intrinsic dataset evaluation has been explored with some promising results (Bommasani and Cardie, 2020). However, these methods rely on heuristics like content-value, density and compression (Grusky et al., 2018). We are interested in a more fine-grained, interpretable analysis that can only come from manual inspection, much like the analysis by Chen et al. (2016) and by Yatskar (2019). To that end, we first define a six-class typology: the first three classes cover types of data-noise and the last three cover varying degrees of summarization difficulty. We then proceed to answer the aforementioned research questions, and discuss our key observations which are summarized below:

Key Observations: (1) Datasets have distinct modalities – a mix of simpler samples (which we call *Extractive*) and complex ones (which we call *Paraphrase* and *Inference*. (2) Gigaword is *majorly* Extractive but suffers from data noise (45% of the targets have some key entity, or fact that is absent from the source). (3) CNN/DM is relatively cleaner, and the authors' attempts to create a more abstractive dataset seems to be successful compared with Gigaword (only 18% of samples are Extractive). (4) XSum has no Extractive samples, but also has the greatest fraction of noise: 54% of the test samples have key entities or facts missing from the source. (5) Within the datasets, the broad performance trends between the typology classes are *consistent across all metrics*: **simpler samples score higher than complex ones**. (6) Metric reliability is also complexity dependent: On CNN/DM the agreement with human judgement decreases as summarization complexity increases.

The remainder of the paper is organised as follows: in Section 2 we answer **Q1**, describe the three datasets, define the typology, and present results from the annotation. In Section 3 we explore **Q2 a.** and evaluate different models on a variety of metrics (automatic and human-judgement). In Section 4 we explore **Q2 b.** and investigate metric reliability. In Section 5 we share some learnings from our experience. We conclude with Section 7.

2 Evaluating the intrinsic properties of summarization datasets (Q1)

	Length(Doc)		**Length(Ref)**		**Sample**	
	train	test	train	test	train	test
Gigawords	31	29	8	8	3.8M	1.9K
CNNDM	691	682	51	54	287K	11K
XSum	374	376	21	21	204K	11.3K

Table 1: Statistics of the three datasets. Length refers to the average number of words per Document/Reference.

2.1 Datasets for Annotation

Among many summarization datasets, we choose the following:

Gigaword is a summarizaiton dataset extracted from news articles (Rush et al., 2015)[2].

CNN/DailyMail or "CNN/DM" question answering dataset (Hermann et al., 2015; Nallapati et al., 2016) is commonly used for summarization. The dataset consists of online news articles paired with human-generated summaries.[3]

---

[2] We use the version most commonly used by summarization systems: https://github.com/harvardnlp/sent-summary

[3] We use the non-anonymized data as See et al. (2017).

Label	Source Dataset	Source	Target	State-of-the-art Model Output
Incomplete / Irrelevant	Gigaword	Andre Blom and Mark Scharrenberg scored tries and some tactical kicks in the final 10 minutes sent the United States to the Rugby World Cup with a 21-16 victory over Uruguay on Saturday .	London testing , please ignore .	United States beats Uruguay 21-16 in Rugby World Cup .
Entity Missing	Gigaword	The United States claimed credit Tuesday for a ceasefire that ended fighting between Israel and Lebanese guerrillas , and rejected suggestions that it was forced to model the agreement after a French draft .	US takes the credit for Israel-Hezbollah ceasefire by Carole Landry .	Us claims credit for lebanon ceasefire .
Extractive	CNN-DM	Ed Miliband's US adviser pays no tax in Britain on his reported £300,000 salary, he has admitted. David Axelrod masterminded two presidential election victories for Barack Obama and was hired by the Labour leader amid great fanfare last year. He has helped refine Mr Miliband's message ...*(truncated)* ... have been aware of Labour's eye-catching crackdown on non-doms last week. But speaking in the US where he is promoting his autobiography, Mr Axelrod revealed he is not resident for tax purposes in the UK. Asked whether he pays tax in Britain, he told the Daily Telegraph: 'I don't do my accounting so I don't know but I'm not in residence there.' Labour confirmed it pays Mr Axelrod in dollars through his consultancy firm and that he 'lives in the US, works in the US and pays taxes in the US'. ... (*truncated*)	David Axelrod masterminded two Obama presidential election victories . He was hired by Labour leader Ed Miliband amid great fanfare last year . Revealed at a book launch that he is not resident for tax purposes in UK . Labour confirms it pays Mr Axelrod in dollars through consultancy firm .	David Axelrod masterminded two presidential election victories for Barack Obama . He was hired by the Labour leader amid great fanfare last year . Has helped refine Mr Miliband 's message about tackling the cost of living and making sure the wealthy pay their fair share . Mr Axelrod makes infrequent visits to the UK to meet Mr Miliband and offers advice by phone .
Paraphrase	CNN-DM	The number of women in Britain becoming nuns is at a 25-year high. Figures from the Catholic Church show the number of women taking Holy Vows has trebled from 15 in 2009 to 45 last year. From a low of only seven in 2004, the figure has been rising for the past decade. Theodora Hawksley, 29, was until recently a post-doctoral researcher in theology at the University of Edinburgh. But at the beginning of the year she decided to become a nun. *(truncated)*. Far from being trapped in traditional habits, Miss Hawksley said her order tends to dress down in T-shirts and jeans. Father Christopher Jamison, director of the National Office for Vocation of England and Wales, said: 'There is a gap in the market for meaning in our culture. One of the ways women may find that meaning is through religious life.' Sister Cathy Jones, religious life vocations promoter at the office, said: *(truncated)* .	Figures from the Catholic Church show more and more becoming nuns . The number of women taking Holy Vows stood at just seven back in 2004 . But that figure had risen to 15 in 2009 and increased further to 45 last year . One father said a ' gap in the market for meaning ' led people toward religion .	Figures from Catholic Church show number of women taking Holy Vows has trebled from 15 in 2009 to 45 last year . From a low of seven in 2004 , the figure has been rising for the past decade . Theodora Hawksley , 29 , was until recently a post - doctoral researcher in theology at the University of Edinburgh . But at the beginning of the year she decided to become a nun .
Inference	Gigaword	Three Malaysian and Indonesian seamen kidnapped by Philippine Abu Sayyaf kidnap-for-ransom group allegedly had been executed and the skeletons discovered in the southern Philippines are believed to be their remains , a local television reported Wednesday .	Abu Sayyaf hostages allegedly executed : report .	3 filipino , Indonesian seamen executed in southern Philippines .

Table 2: Examples for each of the six categories. Text spans with the same colors correspond to the same fact in the source and target. Target spans in RED are missing or unsupported in the source. The last sample is "Inference" because the writer will have to understand the concept of hostages, and then generalise from the group to an individual.

XSum or "Extreme Summarization" (Narayan et al., 2018a) was constructed from online news articles for highly abstractive summarization.

We consider these datasets because of their popularity, and the difference in the nature of samples. The latter enables a more comprehensive analysis; Table 1 captures the size of source and target documents along with the number of samples.

2.2 Typology Definition

The classes are defined below in order of priority. Some examples are in Table 2. Readers may refer to the Appendix B, C, D for more examples.

- **Incomplete/Irrelevant**: The target summary ends abruptly. Or the source and target are unrelated.
- **Entity Missing**: The target summary contains entities (names, dates, events, etc) that are absent from the source.
- **Evidence Missing**: The target summary is based on concepts which are absent from the source. However, the target is not **Incomplete** and all **Entities** are present.
- **Extractive**: The target is constructed by copying tokens from the source, mostly in-order of their appearance. Minor modifications, like stemming and abbreviating, are permitted. Word substitutions, and additions, are limited to a few. No reasoning, conclusion or co-ref resolution is performed as part of the summarization. The complete context of the target should be present in the source.
- **Paraphrase**: The majority of tokens in the target are substituted, or appear out of order, or both. There is no reasoning, conclusion or co-ref resolution. The complete context of the

target should be present in the source.
- **Inference**: A non-trivial "inference" activity has to be completed to construct the target: some reasoning, conclusion, or complex co-reference resolution. The complete context of the target should be present in the source.

We annotate 200 samples from each dataset, on par with similar studies on intrinsic evaluation (Chen et al., 2016; Cao et al., 2017). Two authors annotate samples independently. Annotations matched for 70%, 68% and 73% of Gigaword, CNN-DM and XSum samples, respectively. Disagreements were discussed between all authors before arriving at a consensus for the final label.

2.2.1 Motivation and Advantages

To the best of our knowledge, summarization datasets have not been manually analysed in this manner. A review of the most relevant summarization dataset analysis research shows that the most common form of intrinsic evaluation is to use surface-level heuristics. Most studies only cover a part of our typology, while almost all studies ignore the noise present in datasets.

Coverage , Density, Redundancy Grusky et al. (2018); Bommasani and Cardie (2020); Zhong et al. (2019b) use similar forms of token-level coverage between the source and the reference to measure the *extractiveness* of the summary. In it's simplest form, this is a ratio of the number of overlapping tokens and reference length. In our definition of **Extractive**, we first set a meaninful, well-defined criterion, and then manually check for *extractive* references, while allowing for some relaxations.

Content Compression In most papers (Grusky et al., 2018; Zhong et al., 2019b; Bommasani and Cardie, 2020), the summarization complexity is defined by a compression ratio (usually the normalized word-count ratio of the source and reference). As a standalone metric, this does indeed capture the difficulty in replication. However, token rearrangement, substitution, reformulation is ignored in this measure of "complexity". To combat this, we distinctly defined **Paraphrase** and **Inference**. By manually analysing samples, we are able to differentiate between the obviously simple Extractive samples, the relatively tougher Paraphrase samples and the most difficult Inference samples. Together these three offer a highly intuitive classification of samples. Part of the reason that the Machine Comprehension analysis by Chen et al. (2016) was so effective was the interpretability of their classes. We hope our analysis will also enable researchers to improve summarization models.

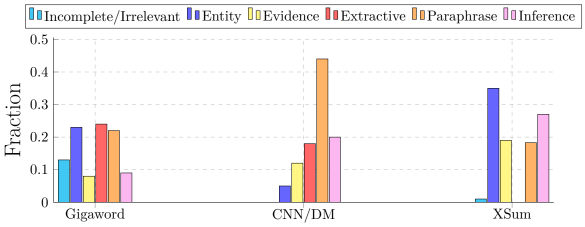

Figure 1: Distribution of the different class of samples in all datasets.

Noise Prior works have not focused on quantify the noise in popular datasets. Moreover, none of these metrics are designed to account for noise or factual inconsistencies. A high value for content compression might imply a high-degree of summarization complexity. But this ignores the possibility that the source-reference pair is unrelated (like row 1 in Table 2). In addition, the manual analysis allows us to identify factual errors and co-ref errors.

This is not to say the typology is perfect and exhaustive. Limitations and possible extensions to our typology are discussed in Section 5.

2.3 Dataset Analysis

The distribution of classes in the datasets is in Figure 1. We have made the following **key observations** in our analysis of the labels.

Gigawords is Extractive, but very noisy. 24.5% of summaries are Extractive, but 44.5% of samples belong to Entity Missing, Evidence Missing, or Incomplete. Not unexpected considering the "headline" nature of the samples.

XSum is Abstractive, but also very noisy. The authors (Narayan et al., 2018a) designed the dataset to be highly abstractive. This is reflected in the distribution: there were no Extractive samples in our analysis, suggesting a significantly higher level of difficulty. However, 55% of samples belong to Entity Missing, Evidence Missing, or Incomplete classes. The remaining 45% belongs to Paraphrase and Inference categories. Since we found only two incomplete samples, this class is ignored in all further XSum analysis.

CNN/DM is cleaner, and lives up to the design goals. The authors (Hermann et al., 2015) designed CNN/DM to be *abstractive* in nature, and this is reflected in the distribution: 64% of samples belong to Paraphrase and Inference categories. Of the three, CNN/DM has the lowest fraction of factual and data noise: there are no Incomplete/Irrelavant samples, and only 18% of samples belong to Entity Missing and Evidence Missing.

The degree with which missing facts affects automatic evaluation varies. In some samples, one or two entities are missing (like Row 2 in Table 2), but in others multiple facts are missing. Empirical analysis of model performance for each class of samples is discussed in Section 3.

3 Performance on different classes (Q2 a)

In this section, we list the different models and metrics considered for analysis, and then describe how model performance varies across class labels.

3.1 Models for evaluation

We collect outputs from 7 systems for Gigaword: (1) PEGASUS (Zhang et al., 2019), (2) PROPHET (Qi et al., 2020) (Lewis et al., 2020), (3) UNILM (Dong et al., 2019) , (4) BISET (Song et al., 2020), (5) CONCOPY (Wang et al., 2019) , (6) POINTERGENERATOR (See et al., 2017), (7) POINTERGENERATORCOPYING (See et al., 2017)

For CNN/DM, we use the outputs of 11 top-performing summarization systems collected by Bhandari et al. (2020)[4]: (1) HETERGRAPH (Wang et al., 2020), (2) MATCHSUMM (Lewis et al., 2020), (3) REFRESH (Narayan et al., 2018b) , (4) TWOSTAGERL (Song et al., 2020), (5) NEUSUMM (Wang et al., 2019) , (6) BOTTOMUP (Gehrmann et al., 2018) (7) SEMSIM (Yoon et al., 2020) (8) UNILM (Dong et al., 2019) (9) BARTABSTRACTIVE (Lewis et al., 2020) (10) BANDITSUMM (Dong et al., 2018) (11) BARTEXTRACTIVE (Lewis et al., 2020)

For XSum, we use the outputs of 9 different summarization systems: (1) CONVSEQ2SEQ (Gehring et al., 2017), (2) TCONVS2S (Narayan et al., 2018a) (3) POINTERGENERATOR (See et al., 2017), (4) BART (Lewis et al., 2020), (5) PRESUMMEXTRACTIVE (Liu and Lapata, 2019), (6) PRESUMMABSTRACCTIVE (Liu and Lapata, 2019), (7) PRESUMMTRANSFORMER (Liu and Lapata, 2019), (8) LEAD (Nenkova, 2005), (9) EXTORACLE (Nallapati et al., 2017)

3.2 Metrics for evaluation

Existing summarization systems are usually evaluated using automated metrics or manually using human judgments. We list popular automatic metrics explored in this work. Except for the last two, all outputs from every model is scored on the following metrics.

ROUGE-1/2/L measure overlap of unigrams, bigrams and longest common subsequence. respectively[5] (Lin, 2004).

BERTScore (BS) measures soft overlap between contextual BERT embeddings of tokens between the two texts[6] (Zhang et al., 2020).

MoverScore (MS) applies a distance measure to contextualized BERT and ELMo word embeddings[7] (Zhao et al., 2019).

FactCC is introduced to measure the fact consistency between the generated summaries and source documents (Kryscinski et al., 2020). Due to issues with the setup and training procedure, this metric was only used in the CNN/DM analysis.

Human Pyramid (HP) provides a robust technique for evaluating content selection by exhaustively obtaining a set of Semantic Content Units (SCUs) from a set of references, and then scoring system summaries on the number of SCUs that can be inferred (Nenkova and Passonneau, 2004). We use the scores shared by Bhandari et al. (2020) for the first 100 samples of CNN/DM subset.

3.3 Model Performance

For each dataset, we group the samples by their labels. For all samples in a subset, the model response is scored using a metric. The mean of these sample scores returns a single subset-model-metric score, which is then averaged across all models in the subset, leaving us with a single subset-metric score. This is repeated for all (subset × metric) pairs. The results are captured in Figures 2, 3 and 4 for Gigaword, CNN/DM and XSum respectively. The last column in each group is the average score across all samples.

3.3.1 Impact of Data Quality and Noise

Incomplete and Irrelevant Of the three datasets, only Gigaword contains Incomplete (or Irrelevant) samples. Across all metrics, the

[5] For ROUGE-1,2, and L, we used the Python implementation: https://github.com/sebastianGehrmann/rouge-baselines

[6] Used code at github.com/Tiiiger/bert_score

[7] We used a faster version of the code provided by the author at github.com/AIPHES/emnlp19-moverscore

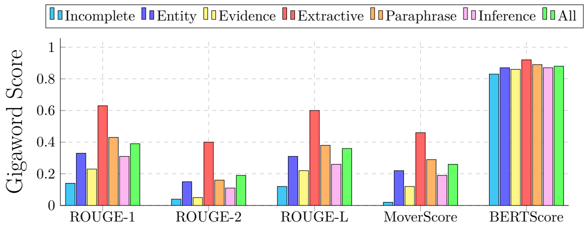

Figure 2: Gigaword class-level performance, averaged across all models.

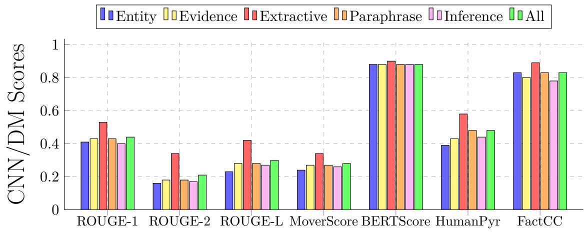

Figure 3: CNN/DM class-level performance, averaged across all models.

performance on this label is lowest, which is to be expected – high overlap will be rare if the source and target are unrelated or incomplete (like Row 1, Table 2). What's alarming is the volume of such samples in Gigaword – if the distribution is the same for the training set, then the model is being trained on extremely noisy data (almost 14%). In addition, such samples needlessly penalise the model performance during evaluation.

Entity scores more than Evidence in Gigaword! The results for these subsets are a bit surprising. In Gigaword, the Entity Missing subset receives relatively higher scores than the Evidence Missing category. We attribute this to a combination of factors. Consider Row 2 in Table 2. Entities are missing, but token overlap is high (more than 50%), which explains the high R1 scores, but low R2 scores. In our observations, the impact of missing facts and entities varies by the length of the target, as well as the number of entities.

Are Evidence Missing and Paraphrase are all the same for CNN/DM and XSum? When compared with Gigaword, samples with data quality issues (i.e. Incomplete/Irrelevant, Entity Missing and Evidence Missing samples) in CNN/DM and XSum get relatively higher scores. The reasons are similar to the Gigaword phenomenon discussed before. The average summary length of CNN/DM (54 tokens) is about 7 times that of Gigaword (8 tokens). As a result, with respect to the complete reference, one or two missing facts amounts to a much smaller fraction of the reference in CNN/DM. The high overlap with the remainder leads to higher scores.

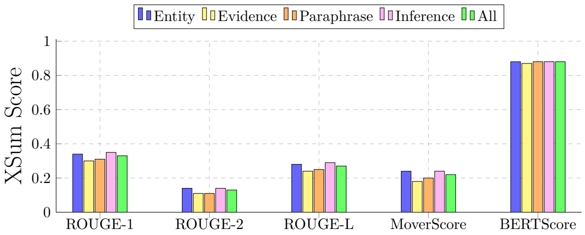

Figure 4: XSum class-level performance, averaged across all models.

Factual Correctness in CNN/DM Automatic metrics only consider the token overlap (or "semantic distance") between the target and the model output. While such metrics exhibit high correlation with human-judgement, a low score does not necessarily imply an incorrect generation, as demonstrated by Freitag et al. (2020) for machine translation. Hence we check for factual correctness of model outputs using FactCC. The competitive scores on the first three categories for FactCC in Fig .3 suggests the outputs generated by the model are factually faithful, which points to issues with the metric reliability. We discuss this in Section 4.

3.3.2 Impact of Summarization Complexity

For the last three categories (Extractive, Paraphrase and Inference) Gigaword and CNN/DM exhibit a common trend: the highest performance, across all metrics is on the Extractive subset, followed by Paraphrase samples which are more difficult to reproduce. The lowest performance is on the Inference samples. However, concluding models perform poorly would be incorrect. The last three samples in Table 2 suggest that model outputs are coherent, logical and factually faithful. FactCC scores in Figure 3 also suggest the outputs are factually consistent.

Some metrics are biased towards simpler samples? For the Extractive, Paraphrase and Inference samples, the samples we manually observed (some of which are captured in Table 2) and the FactCC scores indicates a gap in the token-based metrics. However, we cannot fault the metrics entirely. If we had diverse target references for the same sources, some outputs would have found better matches, and thus, higher scores! In fact, we see that BERTScore (a more "semantically" oriented metric) is extremely competitive across all categories in all three datasets (Figures 2, 3, 4), suggesting the generations are similar to the references. These results lead us to believe that token-based summarization metrics might also suffer from a "summarization-ese" effect: **the metrics could be biased towards simpler, more "extractive" references**. Recently, Freitag et al. (2020) also arrived at the same conclusion for machine translation and BLEU (Papineni et al., 2002).

In the next section, we continue to explore the reliability of these metrics.

4 Does the reliability of metrics change with data properties? (Q2 b)

For each document $d_i, i \in \{1 \dots n\}$ in a dataset $\mathcal{D}$, we have J system outputs, where the outputs can come from different systems. Let $s_{ij}, j \in \{1 \dots J\}$ be the j^{th} summary of the i^{th} document, m_i be a specific metric (including human judgment).

$$K^{sum}_{m_1 m_2} = \frac{1}{n} \sum_{i=1}^{n} \Big(K\big([m_1(s_{i1}) \dots m_1(s_{iJ})], [m_2(s_{i1}) \dots m_2(s_{iJ})]\big) \Big). \quad (1)$$

Correlation is calculated for each document, among the different system outputs of that document, and the mean value is reported. Like other meta-evaluation studies, we consider the Pearson correlation and Spearman correlation as measures for K. Due to space constraints we only show the Pearson plots for some critical results. More plots are available in Appendix A.1.

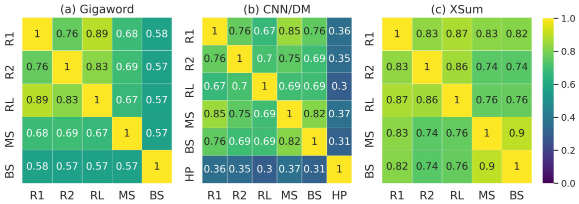

Figure 5: Pearson correlation between different metrics for all three datasets.

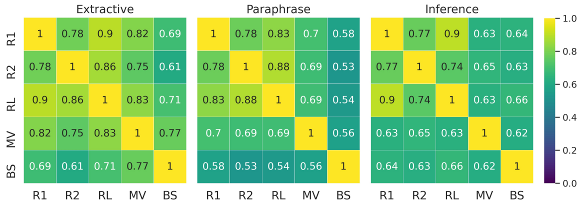
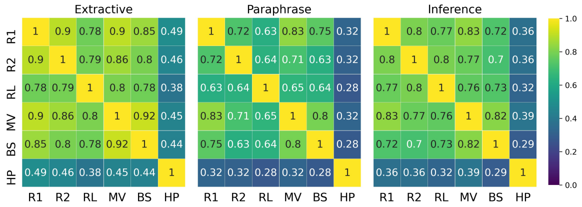


(a) Gigaword



(b) CNN/DM

Figure 6: Pearson correlations for Extractive, Paraphrase and Evidence samples in Gigaword and CNN/DM.

Inter-metric Correlation We present a pairwise correlation analysis of the automatic metrics to understand metric agreement in Figure 5. We conjecture that a strong correlation between two vastly different metrics (say ROUGE and MoverScore) might show that the metric is more reliable. Overall, we can see in Figure 5 that correlations between token-based metrics (ROUGE) and embedding-distance metrics (BERTScore, MoverScore) is lower in Gigaword, compared to CNN/DM and XSum. It is possible that the short length summaries of Gigaword is leading to this; perhaps there isn't enough context for BERTScore. Although, we could not find any results in the original papers to support this claim.

Correlation variation with complexity We observe that the correlation is heavily sample dependent. In Figure 5, averaged across all samples, R1 and MoverScore have a Pearson correlation of about 0.68 in Gigaword. This increases to 0.82 for the Extractive samples in Figure 6-(a), which are the simplest to reproduce. As the complexity increases, the correlation scores decrease (in Paraphrase, and then in Inference). The trends for R2 and MoverScore are similar. This is also observed for CNN/DM: in Figure 6-(b), correlations for R1-MoverScore and R1-BERTScore drop from 0.9, 0.85 for Extractive samples to about 0.83, 0.72 for Paraphrase and Inference samples. **This suggests that the inter-metric correlation is heavily sample dependent**. We cannot comment on XSum, because we did not encounter any Extractive samples in that dataset.

Correlation with Human Judgement For CNN/DM, we also compute the metric correlations with the human pyramid score (HP) in Figure 5 and

Figure 6-(b). We observe the highest agreement with the human-judgement for the Extractive subset, and it is significantly lower in Paraphrase and Inference. **This suggests that automatic metrics are more reliable when evaluating simpler examples, than complex ones**.

5 Discussion

Limitations of the typology. Forcing samples to have a single label did limit our analysis. In retrospect, the typology could have allowed for two labels: one for quality, one for complexity. In XSum for instance most samples which were labelled Entity Missing could also be labelled Paraphrase and Inference. We also realise that the impact of positional-bias could be important. This has been explored by Zhong et al. (2019a,b), and we plan to include similar metrics in our future work.

Collecting better datasets. Our results suggest that current metrics are not equally reliable across all categories of samples. If the quality of the references cannot be controlled, then having a diverse set of references for the source is also advised. This will allow for multi-reference evaluation and could offset the "summarization-ese" issues.

Limits of the Pyramid Scores. At the moment, the Pyramid Scores (and judgement criteria in general) only compare the output to the gold-reference, assuming the latter is *true*. As we see from our analysis, ignoring the source is not the right approach, for references from the web could have quality issues. A modified judgement procedure, that also accounts for the faithfulness of the gold-reference (perhaps by using automatic factuality metrics FactCC) might be better.

Architecture specific performance. In this study, we were interested in measuring the broader, *averaged* trends that summarization models exhibit. However, it would be interesting to see how specific architectural decisions impact individual model performance across different classes. We plan to explore this in the future.

"But what's the best metric for my data?" Specifically for metrics, our objective was to empirically demonstrate that (a) datasets have different modalities, and (b) metrics are not equally reliable across these modalities. In this process, we also observed some results suggesting possible biases in certain token-based metrics, and a need for diverse reference sets. We'll continue to explore this question.

6 Related Work

For the task of text-summarization, the data analysis heuristics presented in Zhong et al. (2019a,b); Bommasani and Cardie (2020); Grusky et al. (2018) are most relevant to our work. Their analysis is focused on surface level heuristics which ignores all noise present in the data. This has been discussed in Sections 2.2.1, 5. Researchers have also explored other dataset biases (Jung et al., 2019; Zhong et al., 2019b; Chen et al., 2020). As discussed in Section 5, we plan to include this in our future work.

For metric reliability and meta-analysis, we build on correlation analysis presented in earlier works (Peyrard, 2019; Bhandari et al., 2020; Fabbri et al., 2020). The key difference and novelty is the introduction of our typology and measuring the impact of sample complexity on model performance and metric reliability. To the best of our knowledge, metrics and models have not been evaluated on such a typology. As results in Section 3 and 4 show, sample complexity is indeed very critical for metric reliability.

7 Conclusion

In this study, we manually analysed 600 samples from three popular datasets, using a typology that captures data quality issues and varying degrees of sample-complexity. Our analysis of 27 summarization models reveals that the metric performance is heavily dependent on samples. On closer inspection, we found that the agreement of popular metrics also changes with the complexity, thus the scores might not reflect true model performance. This analysis also led to some suggestions for creating better summarization datasets and highlights some limitations of the current human-judgement procedures.

A.2 Annotation Details

Each sample is annotated by 2-3 annotators independently. Given the limited number of samples, and the laborious nature of the exercise, we chose not to select final labels based on majority vote. For all disagreements, annotators discussed their reasoning and came to an consensus for final label. For 70% of Gigaword samples, 68% of CNN-DM samples, and 73% of XSum samples, the initial annotations were in agreement.

Appendix B Gigaword

B.1 Gigaword: Paraphrase and Inference samples

Paraphrase	More than 700,000 employees face unpaid leave due to the shutdown which was triggered after the two houses of Congress did not agree on a new budget. Hyundai said affected employees who currently own its vehicles will be given a payment relief ”for as long as they are out of work”. Employees looking to buy a new car will be given a 90-day payment deferral. ”We recognize the impact on family budgets that the furlough will drive,” John Krafcik, chief executive of Hyundai Motor America, said in a statement. Hyundai had offered a similar scheme, the Hyundai Assurance programme, during the peak of the global financial crisis four years ago to help consumers who had lost their jobs. Many analysts have said that the move had helped the South Korean firm win customer loyalty and boosted its sales in recent years. The company said that its latest offer to help the federal employees was an addition to that programme and aimed at ”helping workers at a time when they most need it”. ”Like we did almost four years ago when we launched Hyundai Assurance, this is our way of saying ’We’ve got your back’ during this uncertain time,” Mr Krafcik said. Under the latest offer, Hyundai will extend all auto loan and lease payments during the shutdown for current Hyundai owners who are put on unpaid leave. The programme is available to all customers who have financed their purchase or lease through Hyundai Finance America.	US carmaker Hyundai Motor has offered financial help to federal employees who have been affected by the government shutdown .	Hyundai Motor will defer payments due from US federal employees affected by the partial government shutdown .
Paraphrase	Gary Price was suspended from all council duties for five months in November after Powys council’s Standards Committee ruled he had breached the code of conduct. His appeal has been dismissed by the Adjudication Panel for Wales following a two-day hearing in Llandrindod Wells. Mr Price has been contacted for comment. He was found to have sent information which the council said ”incorrectly and unfairly” portrayed what happened at a grievance appeal hearing, in which he was a panel member. The Adjudication Panel for Wales unanimously agreed to refer the matter back to the Standards Committee with a recommendation that Mr Price be suspended for three months. Council leader Barry Thomas said the decision ”sends out a clear message that those who enter public office have to operate within the members’ code of conduct and maintain the highest possible standards”.	A Powys council chief executive has lost his appeal against a decision to suspend him .	A decision to suspend a Powys county councillor has been upheld .
Inference	Derby City Council wanted to shut Moorways Pool from April in a bid to save about Â£350,000 a year. The Labour-led authority, which needs to save Â£79m over the next three years, said it had found the savings by making cuts in other areas. Campaigners who gathered more than 4,000 signatures on a petition said they were delighted at the news. Ranjit Banwait, leader of the authority, said the council had committed to keep it open for a year. He said the council had identified savings ”in back-office areas” and a restructuring of management jobs, which had been ”untouched” since 2010. However, he stressed if the authority failed to get a ”fair deal” from central government in the future, the pool would still have to close. Campaigners had accepted the pool, which is 33m in length, was in need of repair. There are plans for a new 50m pool to be built by 2018 to replace it. However, closing it would have left only one other public pool in the city - the Queen’s Leisure Centre, they said. Doug Whitlam, of the Derbyshire Amateur Swimming Association, said: ”One of the main things for me would have been the loss of teaching. ”Twelve hundred young people use this facility every week and that would be lost forever.”	A council has backed down over plans to close a public swimming pool in a bid to save money .	A Derby swimming pool threatened with closure is to remain open for another year , council bosses have confirmed .
Inference	It is likely to include a scrappage scheme for older diesel cars in areas with high levels of dirty air. Speed bumps could be removed in some cities to cut pollution from cars slowing down and speeding up. Environmental lawyers ClientEarth said they would ”thoroughly analyse” the proposals. According to the Royal College of Physicians, air pollution across the UK is linked to around 40,000 premature deaths every year. The UK has struggled to keep within EU limits on some pollutants, particularly nitrogen dioxide (NO2), which is produced by diesel engines and is linked to a range of respiratory diseases including asthma. Some 37 of the 43 regions of the UK are in breach of NO2 limits. Under earlier government plans, some parts of the UK would not have met EU NO2 standards until 2030. The original deadline to achieve these limits was 2010. Exasperated by what they believed was government foot-dragging on the question of cleaner air, ClientEarth mounted a legal challenge to force faster action. In April 2015, the UK Supreme Court ruled the government had to take immediate steps on the issue. Unhappy with the timescales in the plan that was then produced, ClientEarth went to the High Court last November for a judicial review. Once again the court supported the lawyers, telling the government that its scheme was ”woefully inadequate” and giving ministers until 24 April this year to produce a new draft. With a general election in the offing, the government last week asked the judge for permission to delay the draft plan. But Mr Justice Garnham disagreed and ordered publication by 9 May. ”These steps are necessary in order to safeguard public health,” he said. Earlier this week, the government said it would not appeal against the ruling and would publish. In their previous plans, ministers wanted to create ”clean air zones” in five cities outside London with high levels of NO2. Only the most polluting vehicles would have to pay a charge to enter the zone under that scheme. The new draft plan is expected to create many more such zones. Councils will be given the power to impose fines or restrictions on all polluting vehicles in these areas. In the worst cities, so called ”toxin taxes” could range up to Â£20 a day but the government is said to be keen not to punish drivers who bought diesels as a result of incentives brought in by a previous Labour administration. This is something that the lawyers at ClientEarth support. ”Successive governments have encouraged people to buy diesel. We don’t want to see diesel drivers vilified, and we think the plans should also include properly funded incentives to help people move to cleaner forms of transport,” said ClientEarth CEO James Thornton. ”We will thoroughly analyse the government’s draft plans when they are produced. If we do not think they are in line with the court order, to deal with illegal levels of pollution as soon as possible, then we will consider our next steps.” According to newspaper reports, the government has agreed to back a ”targeted” scrappage scheme for older diesel cars, but limited to vehicles in areas of high pollution. There may also be funding for a retrofitting scheme to help existing diesel car and van owners cut their emissions of NO2. The government is also said to be pushing for councils to use alternatives to charging, including the removal of speed bumps in some places and the better sequencing of traffic lights in others. Both of these measures could limit cars having to slow down and speed up repeatedly, actions that can almost double the amount of NO2 produced. However, the idea that speed bumps which slow down traffic would be sacrificed to help clean up the air we breathe is not a welcome concept according to road safety charity Brake. ”We ought not to be made to choose between having cleaner air and safer roads,” a spokesman said. ”The evidence shows that air pollution is contributing to the early deaths of thousands of people. It’s now clear that there’s more than one way a car can kill you.” The new proposals will be out for consultation for six weeks before the government produces a final plan at the end of July. Follow Matt on Twitter and on Facebook.	The government is expected to publish a new draft plan to tackle air pollution in the UK later this week .	The UK government is set to publish a draft air pollution plan after a protracted legal battle with environmental campaigners .

Abstract

Recent work demonstrates the potential of training one model for multilingual machine translation. In parallel, denoising pretraining using unlabeled monolingual data as a starting point for finetuning bitext machine translation systems has demonstrated strong performance gains. However, little has been explored on the potential to combine denoising pretraining with multilingual machine translation in a single model. In this work, we fill this gap by studying how *multilingual* translation models can be created through *multilingual finetuning*. Fintuning multilingual model from a denoising pretrained model incorporates the benefits of large quantities of unlabeled monolingual data, which is particularly important for low resource languages where bitext is rare. Further, we create the ML50 benchmark to facilitate reproducible research by standardizing training and evaluation data. On ML50, we show that multilingual finetuning significantly improves over multilingual models trained from scratch and bilingual finetuning for translation into English. We also find that multilingual finetuning can significantly improve over multilingual models trained from scratch for zero-shot translation on non-English directions. Finally, we discuss that the pretraining and finetuning paradigm alone is not enough to address the challenges of multilingual models for to-Many directions performance.

1 Introduction

A slow but increasingly growing focus on languages beyond English has contributed a large wave of models, data, and tasks for non-English languages. Much work has been dedicated to the area of translation, with increasing exploration in massively multilingual models. Despite advances in multilingual natural language processing, resources are highly unbalanced across different languages. This is an obstacle for tasks requiring large quantities of labeled data, such as translation systems, which traditionally leverage hundreds of thousands of professional human translations.

A promising avenue of research is to remove the requirement for large quantities of labeled data by leveraging unlabeled monolingual data, often in the form of large-scale pretraining (Lample and Conneau, 2019; Conneau et al., 2020; Liu et al., 2020; Tran et al., 2020; Liu et al., 2019; Brown et al., 2020). Monolingual data is far more prevalent for low resource languages, particularly in resources such as Wikipedia or Commoncrawl, a version of the web. Recent work has explored monolingual denoising pretraining (Liu et al., 2020) for bilingual models finetuning for individual translation directions (for simplicity we will refer to *monolingual denoising pretraining* as *pretraining* from now on). However, bilingual finetuning alone does not leverage the benefit of the potential of transfer learning across languages. On the other hand, recent work (Arivazhagan et al., 2019b; Fan et al., 2020) has also demonstrated much potential for performance improvement from multilingual translation models in a single model (for simplicity from now on we will use *multilingual translation model* or *multilingual model* to refer to a single model which performs machine translation for multiple languages), but these approaches do not leverage unlabeled monolingual data directly. Little has been explored regarding the combination of the two approaches. Thus, this work studies the effectiveness of combining both large scale pretraining and all-in-one multilingual translation towards universal automatic translation across human languages.

In this work, we finetune pretrained models into multilingual translation models [1]. We analyze the

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3450–3466
August 1–6, 2021.

effectiveness of *multilingual finetuning* — finetuning a single model to perform translation for multiple languages — across low, mid, and high resource translation settings to understand the benefits and limits of both pretraining and the transfer learning across languages. First, we demonstrate how to extend pretrained models to support additional languages using only monolingual data via denoising training criteria. Next, we show how to perform effective finetuning to create one-model multilingual translation. Finally, we evaluate the multilingual translation across a variety of settings to understand the strength of starting with pretraining. Ultimately, we demonstrate that finetuning to create one-model multilingual translation provides large BLEU improvements in the Many-to-English setting, but starting with pretraining is not sufficient to achieve strong English-to-Many performance.

2 Related work

2.1 Multilingual Pretraining

We build upon recent progress of pretraining techniques for NLP applications (Peters et al., 2018; Radford et al., 2018; Devlin et al., 2019; Liu et al., 2019; Song et al., 2019; Lewis et al., 2020a). In particular, recent works explored pretraining on multilingual unlabeled corpora (Lample and Conneau, 2019; Conneau et al., 2020; Liu et al., 2020; Tran et al., 2020) and significantly improved the performance of finetuning of bilingual translation models between two languages. We extend Liu et al. (2020); Cooper Stickland et al. (2021) by investigating finetuning in a multilingual setting.

2.2 Multilingual Neural Machine Translation

Training a universal translation system between multiple languages (Firat et al., 2016; Johnson et al., 2017) has shown enormous improvement for translating low-resource languages (Gu et al., 2018), even enabling zero-shot translation (Lakew et al., 2018; Gu et al., 2019; Arivazhagan et al., 2019a; Garcia et al., 2020). Previous multilingual translation work began with multitask learning (Dong et al., 2015). Subsequently, work focused on the the model capacity bottleneck, leading to exploration of various parameter sharing strategies (Blackwood et al., 2018; Platanios et al., 2018; Sachan and Neubig, 2018; Lu et al., 2018). Models for all languages (Ha et al., 2016) have also been explored and extended to incorporate language information (Tan et al., 2019). Bitext data pretraining and finetuning aiming at creating multiple machine translation models for different translation directions has also be explored (Dabre et al., 2019; Lin et al., 2020). Arivazhagan et al. (2019b); Fan et al. (2020) indicate that it is essential to train gigantic models with enough capacity to fully leverage massive multilingual corpora. A closely related concurrent work, Siddhant et al. (2020) shows it is possible to train a multilingual system jointly with monolingual datasets based on Song et al. (2019). In contrast, in this work we focus on unlabeled data denoising pretraining instead of bitext data pretraining to utilize almost unlimitedly available unlabeled texts. We aim at creating a single universal translation model across multiple languages via finetuning multilingual translation systems from a pretrained model.

2.3 Multilingual Translation Datasets

Working in a multilingual setting remains challenging, as various different datasets, evaluation settings, and preprocessing such as tokenization are used. Benchmarks for sentence embeddings (Hu et al., 2020), natural language inference (Conneau et al., 2018), and question answering (Lewis et al., 2020b) exist, but there is not yet a setting for machine translation data with different resource levels and language families at sufficiently large scale and variety. Zhang et al. (2020) propose OPUS100 with 100 languages, but the training and evaluation data are not human translated. Arivazhagan et al. (2019b) use proprietary data to train and evaluate. In contrast, we contribute the ML50 benchmark, a dataset of 50 languages with publicly available training and evaluation sets, including high, mid, and extremely low resource directions, and open source this benchmark.

3 Multilingual Translation from Monolingual Denoising Pretraining

Masked language modeling and denoising pretraining have been successful across a wide variety of tasks, including creating bilingual translation models. We describe the pretrained multilingual BART model and present multilingual finetuning, a technique to convert pretrained models into multilingual machine translation systems.

---

tuned models, and the ML50 dataset downloading scripts at `https://github.com/pytorch/fairseq/tree/master/examples/multilingual`.

mBART Multilingual BART (mBART) (Liu et al., 2020) is a sequence-to-sequence generative pretraining scheme. The model incorporates N languages by concatenating data: $\mathcal{D} = \{\mathcal{D}_1, ..., \mathcal{D}_N\}$ where each $\mathcal{D}_i$ is a collection of monolingual documents in language i. mBART is trained as a denoising autoencoder, training to predict the original text X given $g(X)$ where g is a noising function that corrupts text. We maximize $\mathcal{L}_\theta$:

$$\mathcal{L}_\theta = \sum_{\mathcal{D}_i \in \mathcal{D}} \sum_{x \in \mathcal{D}_i} \log P(x|g(x); \theta) \ , \qquad (1)$$

where x is an instance in language i and the distribution P is defined by the seq-to-seq model. This model is pretrained using two types of noise in g — random span masking and order permutation — as described in (Liu et al., 2020).

3.1 Multilingual Finetuning

To leverage pretraining to create translation systems, previous work (Liu et al., 2020) used mBART as a starting point and then performed bilingual finetuning. Concretely, the seq-to-seq model was finetuned on language i to language j translation. However, *bilingual finetuning* does not leverage the full capacity of multilingual pretraining, as the resulting translation model can only translate between two languages. Recent work on multilingual translation (Aharoni et al., 2019; Arivazhagan et al., 2019b) demonstrates that strong translation models can be created by doing multilingual training. Thus, we propose to perform *multilingual finetuning* (**ML-FT**) to retain the benefits of both multilingual translation models and unlabeled data pretraining. Multilingual translation models allow languages to transfer the learning from each other. Pretraining utilizes large amount of monolingual data to complement the lack of bitext data.

To perform multilingual finetuning, we collect bitexts of different language pairs (i, j) into a large collection $\mathcal{B}_{i,j} = \{(x_i, y_j)\}$ for each direction (i, j). We augment each bitext pair (x_i, y_j) by adding a source language token and a target language token at the beginning of x and y respectively to form a target language token augmented pair (x', y'). We then initialize a transformer based seq-to-seq model by the pretrained mBART, and provide the multilingual bitexts $\mathcal{B} = \bigcup_{i,j} \mathcal{B}_{i,j}$ to finetune the pretrained model.

Multilingual Translation Model Variants We explore 3 configurations to create different versions of multilingual translation models: *Many-to-one* (M→1), *one-to-Many* (1→M), and *Many-to-Many* (M↔M) via a pivot language. Given the presence of English language in large scale bitext data, we follow (Arivazhagan et al., 2019b) using English as the pivot language to create Many-to-Many models: the Many-to-one model encodes N languages and decodes to English, while the one-to-Many model encodes English and decodes into N languages. Finally, the Many-to-Many model encodes and decodes N languages.

Temperature Sampling When training multilingual models with many languages, the training dataset sizes are imbalanced as different languages have different quantities of bitext. Thus, we train with temperature upsampling, which upsamples lower resource pairs so that the high resource languages do not dominate the training data. We follow Arivazhagan et al. (2019b) and use the following temperature based sampling function with temperature T to sample data for each direction:

$$p_{i,j} \propto \left(\frac{|\mathcal{B}_{i,j}|}{\sum_{i,j} |\mathcal{B}_{i,j}|} \right)^{1/T}$$

4 Experimental Setting

We examine the impact of multilingual finetuning over pretrained models. First, we create the ML50 benchmark to include 50 different languages of various resource levels and language families that we can obtain from publicly available, high quality data sources. The ML50 benchmark standardizes training data, evaluation data, and evaluation procedure across different languages. Second, we detail how we obtain mBART50 pretrained models by extending mBART25. Third, we describe three strong baselines: bilingual translation models from scratch, bilingual finetuning from mBART50 pretrained models, and multilingual translation models from scratch. Finally, we describe our evaluation and generation procedure. In the next section, (Section 5), we will detail the results of the experiments.

4.1 ML50 Benchmark

To investigate the usefulness of pretraining and multilingual finetuning compared to existing alternatives, we create the ML50 Benchmark. ML50 contains training and evaluation data across 50 different languages, from extremely low resource languages like Xhosa and Gujarati to high resource languages like French and German. The full list of languages is shown in Table 1. We group the languages into five categories based on the amount of available training data: more than 10M pairs (8 languages), 1M to 10M pairs (5 languages), 100k to 1M pairs (17 languages), 10K to 100K pairs (13 languages), and finally, less than 10K pairs of training data (5 languages). While considering the resource levels, we also choose the ML50 dataset to include languages in multiple language families, from Germanic and Romance languages to Indic and African ones. Many additional languages we contribute are lower resource, compared to the languages in the original mBART25.

Training Data We gather bitext data between English and 49 other languages to form ML50, to enable the training of machine translation models. We select these 49 languages based on the amount of bitext and monolingual data to cover languages with different amount of resources and under different language families. All of the data is publicly available, such as WMT (Bojar et al., 2013, 2014, 2016, 2017, 2018; Barrault et al., 2019, 2020), IWSLT (Luong and Manning, 2015; Cettolo et al., 2017), TED58 (Qi et al., 2018), OPUS (Tiedemann, 2012), WAT (Nakazawa et al., 2019), LauraMartinus (Abbott and Martinus, 2019), ITB (Kunchukuttan et al., 2018), and FLORES (Guzmán et al., 2019). For multilingual training, each language pair can include data from multiple sources. We simply concatenate them together and remove duplicated source-target sentence pairs for each language pair. We use `fasttext` (Joulin et al., 2017) to perform language identification on both source and target sentences, and we remove sentences pairs if either source or target sentence is not predicted as expected language. We further filter out training data that match to any source or target side sentences in evaluation datasets. Compared to other datasets such as OPUS100 (Zhang et al., 2020), the ML50 benchmark contains around 4 times more training data. The full list of languages, data sources, and amount of resulting data can be found in Table 6.

Evaluation Data To ensure high quality evaluation of languages covered in ML50, we include publicly available, widely used evaluation sets. We source these evaluation datasets from translation workshops such as WMT, IWSLT, WAT, and other published research works. We follow the evaluation protocol, including tokenization, used for each of these evaluation sets, to ensure our results are comparable with existing work. We release these scripts to make it easier for others [2]. Compared to other datasets such as OPUS100, we choose to use high quality existing evaluation datasets rather than use part of the training data as evaluation. This is because training data, particularly for low resource languages, is often very noisy and unreliable.

4.2 Creating mBART50

While multilingual pretrained models have shown strong performance in a variety of tasks (Liu et al., 2020; Conneau et al., 2020), they remain limited as they are trained on a fixed number of languages. For example, mBART was trained on 25 languages, all fairly high resource. Pretraining fully from scratch is computationally intensive — mBART trained for 2.5 weeks on 256 Nvidia V100 GPUs (Liu et al., 2020). However, there are hundreds of different languages in the world, so restarting pretraining from scratch to add any of them to mBART would be difficult. Instead, we take the existing mBART model, trained on 25 languages, and extend it to more than 50 languages.

We take the public available `mBART25` checkpoint (Liu et al., 2020) in the `fairseq` library (Ott et al., 2019) to continue the pretraining process. We extend `mBART25` embedding layers with randomly initialized vectors for an extra set of 25 language tokens. To be consistent with mBART, we reuse its 250K sentencepiece (Kudo and Richardson, 2018) model which was trained using monolingual data for 100 languages from XLMR (Conneau et al., 2020), and thus already supports languages beyond the original mBART25 was trained on [3]. To create this extended mBART model, we combine the monolingual data of original 25 languages and the new 25 languages from XLMR (Conneau et al., 2020). For pretraining, we train mBART50 for an additional 500K updates with batch size of maximum 9216 tokens per GPU using 64 V100 GPUs. We also release the pretrained mBART50 model, which will be useful for a variety of text generation tasks beyond translation.

---

[2] `https://github.com/pytorch/fairseq/tree/master/examples/multilingual`.

[3] For languages that are not supported in the original $250K$ sentencepiece vocabulary, we can extend the vocabulary to include additional sub-word units for these languages and add the corresponding embedding vectors to the pretrained models to continue the pretraining.

Data size	Languages
10M+	German, Czech, French, Japanese, Spanish, Russian, Polish, Chinese
1M - 10M	Finnish, Latvian, Lithuanian, Hindi, Estonian
100k to 1M	Tamil, Romanian, Pashto, Sinhala, Malayalam, Dutch, Nepali, Italian, Arabic, Korean, Hebrew, Turkish, Khmer, Farsi, Vietnamese, Croatian, Ukrainian
10K to 100K	Thai, Indonesian, Swedish, Portuguese, Xhosa, Afrikaans, Kazakh, Urdu, Macedonian, Telugu, Slovenian, Burmese, Georgia
10K-	Marathi, Gujarati, Mongolian, Azerbaijani, Bengali

Table 1: Languages in ML50 Benchmark. We display the languages included in the ML50 Benchmark and the quantity of training data in bitext pairs. Full breakdown is provided in Table 6.

Multilingual Finetuning from mBART50 We finetune the mBART50 model into Many-to-one (M→1), one-to-Many (1→M), and Many-to-Many (M↔M) models with the ML50 training dataset using English as pivot as described in Section 3.1. We finetune the models for 300K updates and sweep through different batch sizes (4096 and 8000 maximum tokens per GPU), learning rates $(1e{-}4, 2e{-}4, 5e{-}4)$, and upsampling temperature $(1.5, 3, 5)$ for best performing multilingual models on validation, using 32 GPUs for each training instance.

4.3 Baselines

We compare our proposed multilingual finetuning to three strong baselines: bilingual training from scratch, bilingual finetuning, and multilingual models trained from scratch.

Bilingual Trained from Scratch (BL-SC) We train bilingual translation models with standard Transformer (Vaswani et al., 2017) models for translation into and from English to 49 languages. For directions with more than 1 million bitext training data (de, cs, fr, ja, es, ru, pl, zh, fi, lv, lt, and hi), we train Transformer Big models as there is more data to benefit from additional model capacity. For directions with more than 10 million bitext training data (de, cs, fr, ja, es, ru, pl, and zh), we also train Transformer Large models as there is even more data to benefit from additional model capacity. The best performing bilingual model is selected as the Bilingual Train from Scratch baseline. Please refer to Table 5 for details of these architectures.

Bilingual Finetuning (BL-FT) Bilingual finetuning adapts the mBART model into bilingual machine translation models by training for longer on translation bitext. For each language direction, we follow Liu et al. (2020) and finetune for 40K updates to obtain the Bilingual Finetuning baseline.

Multilingual Trained from Scratch (ML-SC) We train 3 different multlilingual models from scratch: Many-to-one (M→1), one-to-Many (1→M), and Many-to-Many (M↔M) with English as pivot. We train for 500K updates and sweep through different batch sizes (4096 and 8000 maximum tokens per GPU), learning rates $(1e{-}4, 2e{-}4, 5e{-}4)$, and upsampling temperature $(1.5, 3, 5)$ for best performing multilingual model on validation, using 32 GPUs for each training instance.

4.4 Evaluation and Generation

We evaluate performance with tokenized BLEU, following the tokenization in mBART (Liu et al., 2020). To generate, we decode using beam search with beam size $N = 5$ with length penalty$= 1.0$ on the validation set. We do not perform checkpoint averaging. To select the best performing model in a sweep, we compare BLEU on the validation set.

5 Multilingual Finetuning Performance

We evaluate the performance of multilingual finetuning on the ML50 Benchmark — we compare multilingual finetuning models with bilingual training from scratch, bilingual finetuning, and multilingual training from scratch. Results of multilingual finetuning comparing to all baselines are displayed in Table 2 (per direction comparison is available in Figure 1). The results demonstrate strong improvement over the baselines on many-to-English and comparable performance on English-to-many directions. We also evaluate multilingual finetuning many-to-many models zero-shot performance on non-English directions without bitext data. Our results demonstrates multilingual finetuning models' strong improvement on zero-shot directions comparing to multilingual models trained from scratch.

Data	Multilingual FT Translation to English						Multilingual FT Translation from English

Table 2: Multilingual Finetuning on 50 **languages comparing to 3 baselines: (1) bilingual from scratch, (2) bilingual finetuning, and (3) multilingual training from scratch**. Multilingual Finetuning **(a)** consistently improves over all baselines for translation into English (left), while **(b)** performs similarly over bilingual finetuning and multilingual from scratch with significant improvement over bilingual from scratch for translation from English (right). Numbers are average *BLEU difference* between multilingual finetuning models and the corresponding baselines. Per direction comparison is available in Figure 1.

5.1 Comparison to Bilingual Finetuning

To understand whether the benefit of transfer learning across languages can be stacked on top of finetuning pretrained models, we analyze the improvement of multilingual finetuning with the same model size as bilingual finetuning in Table 2.

In the Many-to-one setting, every language pair is improved by multilingual finetuning except one. Some low resource languages see substantial improvement of more than 10 BLEU points, with the largest improvement being over 15 BLEU points. On average, multilingual finetuning improves 3.5 BLEU across all directions into English. In the one-to-Many setting, performance is about the same between multilingual finetuning and bilingual finetuning with average gap of -0.5 BLEU. In many-to-many setting, on average multilinugal finetuning improves the performance of translation into English by 1.8 BLEU while with -1.0 BLEU behind for translation from English. We hypothesize that the benefit of pretraining is diminished by the challenge of decoding into many target languages in multilingual compared to bilingual finetuning.

5.2 Comparison to Multilingual from Scratch

To understand the impact of pretraining-finetuning paradigms for multilingual translation, we examine our proposed multilingual finetuning method comparing to multilingual models trained from scratch. As shown in Table 2, in Many-to-One setting, multilingual finetuning performs consistently better than multilingual model trained from scratch by 3.1 BLEU on average. For low resource directions (4k-10k bitexts), the improvement is as high as 5.8 BLEU. However, in the One-to-Many and Many-to-Many settings, multilingual finetuning does not perform better than multilingual training from scratch. For translation from English, One-to-Many multilingual finetuning performs -0.1 BLEU points worse than multilingual from scratch on average; many-to-many multilingual finetuning model performs -0.4 BLEU worse than multilingual from scratch on average. On translation into English, we also observe that many-to-many multilingual finetuning models performs -0.1 BLEU worse than multilingual from scratch on average. Again we hypothesize that the benefit of monolingual data pretraining is dominated by the challenges of a large amount of decoding tasks for individual target languages. We will discuss the challenges of to-many translation further in Section 6.1.

5.3 Comparison to Bilingual from Scratch

To understand the combined benefits of pretraining-finetuning and multilingual transfer learning, we examine the improvement of multilingual finetuning with the same model size over bilingual from scratch in Table 2. In the Many-to-one setting, every language pair is improved by multilingual finetuning — on average multilingual finetuning improves over bilingual models by 12.0 BLEU. Some low and mid resource languages see substantial improvement of more than 20 BLEU points (see Figure 1). In the one-to-Many setting, multilingual finetuning outperforms almost all bilingual models except for 5 directions with minor gaps (mostly less than 1 BLEU). In many-to-many setting, multilingual finetuning improves translation

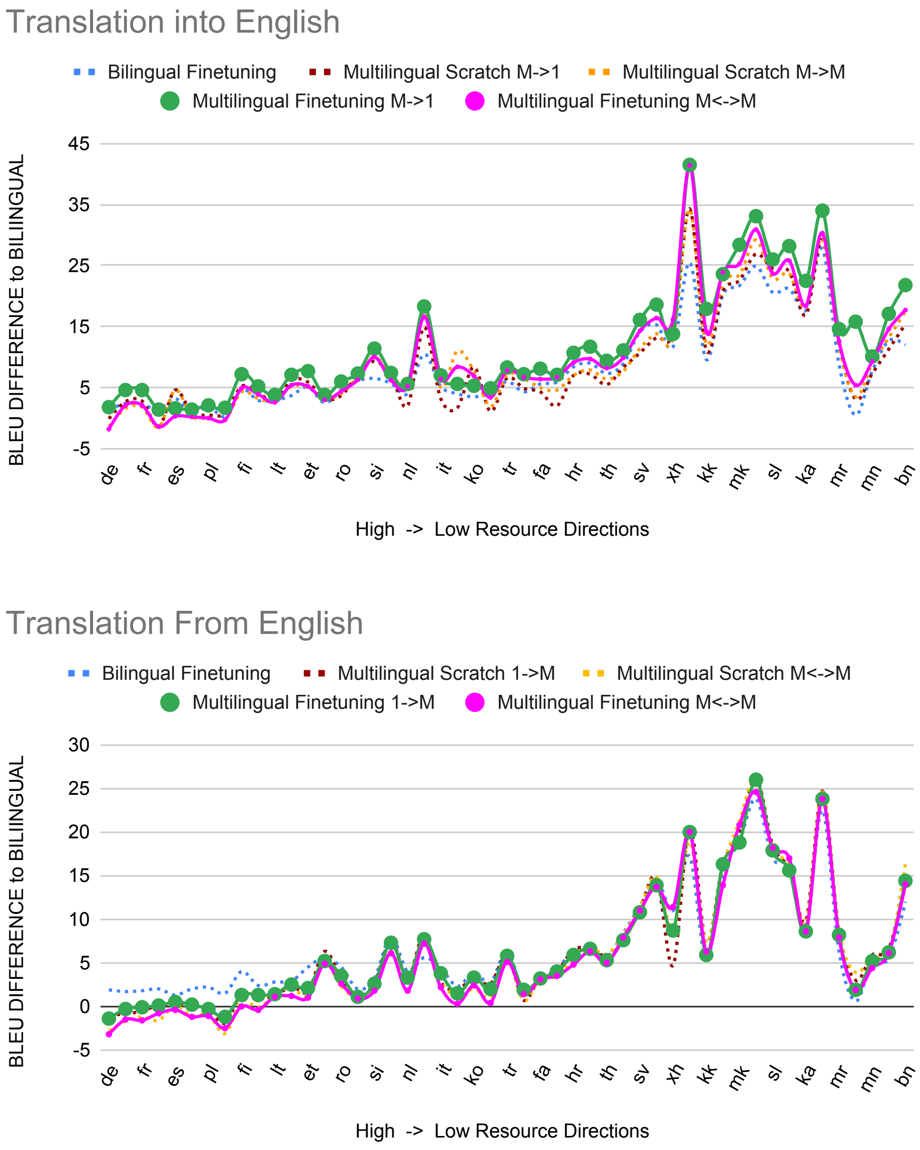

Figure 1: Multilingual Finetuning and Other Baselines Comparing to Bilingual Models for 50 Languages Translation. Y-Axis numbers are BLEU difference to bilingual models trained from scratch.

into English by 10.3 BLEU while with 5.8 BLEU improvement for translation from English. Thus concludes that multilingual finetuning can achieve the significant improvement over bilingual baselines across all directions translation into English and from English.

5.4 Zero-shot on Non-English Directions

We study the impact of multilingual finetuning on zero-shot non-English directions without any bitext training data. We evaluate multilingual many-to-many scratch and finetuning over WMT 13 and 20 test data (fr-de and de-fr test data are from WMT20 (Barrault et al., 2020) and the other test data is from WMT 13 (Bojar et al., 2013)). As shown in Table 4, many-to-many multilingual finetuning model outperforms many-to-many multilingual from scratch models by a large margin with average 11.9 BLEU improvement. We hypothesize that the zero-shot non-English translation performance gain is from two factors (1) that pretrained mBART multilingual encoders and decoders are well-trained with monolingual data; (2) that pretrained mBART decoders are not coupled with specific source languages as multilingual scratch models. Note that decoders of multilingual models from scratch are always trained with English as the source language in the encoders while multilingual finetuning models' decoders are trained with both English and the target

6 Discussion

6.1 Challenges of To-Many Directions

In the Many-to-one setting, large improvements are obtained by using pretrained models as a starting point. Multilingual modeling increases the quantity of target-side English data seen by the model. For example, compared to bilingual finetuning, our multilingual finetuning model is exposed to English target side data from 50 different language pairs.

However, in the one-to-Many setting and the Many-to-Many setting, models must decode into 50 different languages in both multilingual paradigms — being either trained from scratch or pretrained-and-finetuned. As shown in Table 2 (and Table 9, Figure 1), multilingual models — either from scratch or multilingual finetuning — perform worse than bilingual finetuning for English to Many. This indicates that the challenge of decoding into many languages is a dominating factor in the multilingual models, even with pretraining. Note that there are 49 decoding tasks in One-to-Many and 50 decoding tasks in Many-to-Many, while only 1 in Many-to-One. Additional research, for example following

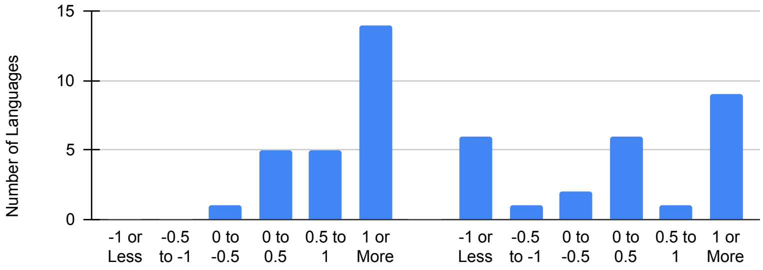

Figure 2: **mBART50 and mBART25 Bilingual Finetuning BLEU Delta**. mBART50 is better than mBART25 over new languages on average. (left) Translation into English; (right) Translation out of English.

the study framework used in (Grönroos et al., 2020), is needed to understand **(1)** the interaction between pretraining and finetuning and multiple decoding tasks, and **(2)** the difference between multiple encoding tasks and multiple decoding tasks.

6.2 Continuous Pretraining is Effective

Pretraining models at large scale is costly. By proposing multilingual finetuning, we introduce a dependency on pretrained models for multilingual translation, which can be a limitation if the pretrained model does not cover the desired languages for translation. Thus, we examine the possibility and effectiveness of incrementally extending pretrained models to support additional languages. We found that for the languages which are supported by the original pretrained models, bilingual finetuning from both previously pretrained and continuously pretrained models demonstrate the almost exactly the same performance (see Figure 3 for our analysis of the bilingual finetuning performance of both models over the original 25 languages). Thus, extending pretraining does not hurt performance on the originally supported languages, despite doubling the number of languages supported by the pretrained model. This removes a big limitation of using pretrained models — that users are often limited to choices made during the original pretraining, and thus if languages are not supported, they cannot be used.

We also examine the effectiveness of such continued pretraining. We find that mBART50 has stronger bilingual finetuning performance (see Figure 2) than mBART25 over the newly supported 25 languages on average, indicating that pretrained models are able to be extended to support additional languages if model capacity allows.

7 Conclusion

We demonstrate that multilingual translation models can be created from pretrained models such as mBART using *multilingual finetuning*. While using pretrained models could theoretically limit the number of languages, we show that mBART can be extended to double the number of original languages without loss of performance. To train and evaluate on 50 languages, we develop and release the ML50 benchmark. We show that by performing multilingual finetuning, strong improvements can be achieved in the Many-to-one setting. However, pretraining and finetuning paradigm alone is not enough to address the challenges of multilingual models for One-to-Many. Our future work will include analysis of improved strategies for One-to-Many translation, model capacity and inference latency trade-off, an in-depth study of zero-shot translation, training strategies for better data efficiency, and applications of the universal text representation and generation frameworks in other crosslingual tasks.

Annotations Matter: Leveraging Multi-task Learning to Parse UD and SUD

Abstract

Using multiple treebanks to improve parsing performance has shown positive results. However, to what extent similar, yet competing annotation decisions play in parser behavior is unclear. We investigate this within a multi-task learning (MTL) dependency parser setup on two parallel treebanks, UD and SUD, which, while possessing similar annotation schemes, differ in specific linguistic annotation preferences. We perform a set of experiments with different MTL architectural choices, comparing performance across various input embeddings. We find languages tend to pattern in loose typological associations, but generally the performance within an MTL setting is lower than single model baseline parsers for each annotation scheme. The main contributing factor seems to be the competing syntactic annotation information shared between treebanks in an MTL setting, which is shown in experiments against differently annotated treebanks. This suggests that the impact of how the signal is encoded for annotations and its influence on possible negative transfer is more important than that of the input embeddings in an MTL setting.

1 Introduction

Multi-task learning (MTL; Caruana, 1997) has shown promise in various NLP tasks such as semantic dependency parsing (Peng et al., 2017; Hershcovich et al., 2018; Kurita and Søgaard, 2019), machine translation (Dong et al., 2015) and mulitiword expression detection (Taslimipoor et al., 2019).

MTL inherently is designed to share information between tasks, which has helped various NLP components (Collobert and Weston, 2008). One active research question however is what information in specific tasks should be shared, as well was what indicators can be used to predetermine the cost-benefit trade-offs of MTL for a given application. Findings have shown that label distributions (Martínez Alonso and Plank, 2017), data sizes (Bollmann et al., 2018) and single task loss curves (Bingel and Søgaard, 2017) have all been respective indicators for MTL performance. Different tasks, data sizes, and settings can all show different relative performance gains (Adouane and Bernardy, 2020). Thus, it is still an open question under which circumstance MTL can be used to achieve max performance boosts over a single task system.

In syntactic parsing, learning a closely related task (e.g. POS tagging) in a joint paradigm benefits overall performance (Bohnet and Nivre, 2012; Zhang and Weiss, 2016), and work has also exploited MTL by leveraging two or more treebanks against each other (see section 2). We often assume simply increasing data and the sharing of syntactic information will inherently benefit all parsers, but this assumes that all syntactic sharing, specifically all annotation sharing, is positive and complementary. However, annotation decisions have been shown to favor parsing preferences (Rosa, 2015; Rehbein et al., 2017; Kohita et al., 2017). This means that is is not necessarily clear if sharing annotations benefits all parsers equally. This is especially true if two annotation schemes choose drastically different approaches when annotating specific linguistic phenomena.

We look to examine this issue further by utilizing a set of treebanks that are annotated on parallel data, Universal Dependencies (UD; Nivre et al., 2016) and Surface-Syntactic Universal Dependencies (SUD; Gerdes et al., 2018), to examine how two competing syntactic annotation schemes behave when used in an MTL setup. Using parallel treebanks also removes the lexical variation and influences of domain differences that are present in most MTL treebank setups. Whether this is a positive or negative in an MTL setup is unclear,

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3467–3481
August 1–6, 2021. ©2021 Association for Computational Linguistics

but reduction in domain differences tend to benefit single model parsers.

We utilize the graph-based Deep Biaffine Parser of Dozat and Manning (2017) in an MTL architecture, treating each UD and SUD treebank of a selected language as a task, and experiment with sharing different embeddings, layers, and loss functions. Additionally, we look at the how different embeddings interact with these annotations along with their role in encoding the signal utilized by the MTL parsers, and whether results follow any linguistic patterns. Finally, we perform additional experiments with treebanks from SPMRL shared task (Seddah et al., 2013, 2014) to support our analysis. We look to investigate the following questions:

1. How will competing syntactic annotations schemes on parallel treebanks behave in an MTL parser?
2. What impact do different input embeddings have on behavior in such a setup?
3. When a treebank is paired with a non-parallel treebank possessing noticeably different syntactic annotations, do trends hold?

2 Related Work

The use of multiple treebanks has been successfully incorporated in parsing strategies. Recent multilingual multi-treebank work by Schuster et al. (2019) extended the Biaffine parser by Dozat and Manning (2017) to incorporate deep contextualized multilingual embeddings in combination with multiple treebank sources, demonstrating gains for zero-shot parsing. Smith et al. (2018a) noted using smaller groups of closely related languages is preferable to larger datasets of dissimilar ones. Multiple synthetic treebanks derived from closely related languages were used to parse Faroese by Barry et al. (2019), though a single language source model yielded the best results.

More directly related work is Johansson (2013), who shares features between two treebanks of the same language that differ in annotation schemes by identifying overlapping features. Using a graph-based parser, he achieved noticeable relative error reduction in UAS for four language pairs, with the largest performance gains on the smaller treebanks. This was followed by Johansson and Adesam (2020) using a neural transition-based parser and leveraging a mixture of treebanks, three dependency and two constituency, against a single constituency treebank in a multi-treebank setup. They find that in all settings, performance on the target constituency treebank improves, with the highest gain coming from using all five as an auxiliary treebank. Kankanampati et al. (2020) use the Multidimensional Easy First approach introduced by Constant et al. (2016) to parse the Arabic CATiB (Habash and Roth, 2009) and its converted UD representation in a multi-task setup. They note that both treebanks showed error reduction, but that improvements were due to partial dependencies, and not primarily driven through lexical sharing.

Little direct work exists on extensive empirical investigations between UD and SUD with parsers. Recent work by Kulmizev et al. (2020) performed probing experiments across a set of languages to extract dependency graphs from BERT (Devlin et al., 2019) and ELMO (Peters et al., 2018) language models, finding that both models prefer UD, with tree shape directly correlated to preference strength.

One of the advantages of MTL is the ability to share information as well as altering objective functions between tasks. Early work examined the impact different loss functions have on downstream applications (Hall et al., 2011) and how in a hierarchy of tasks, sharing of individual layers benefits other tasks differently, with lower level task sharing most beneficial (Søgaard and Goldberg, 2016).

Both hard and soft sharing of parameters have proven successful. Duong et al. (2015) exploited soft parameter sharing between different cross-lingual treebanks possessing the same annotation schemes achieving results on the target language with only half the needed annotated data. Soft sharing of parameters allows nuances between languages of the same treebank when hard sharing all other parameters (Stymne et al., 2018).

Parameter sharing has proven effective in both monolingual (Guo et al., 2016) and multilingual parsing (Ammar et al., 2016; Kitaev et al., 2019). However, what are the optimal parameters to share, and where to do so in the architecture, particularly in cross-lingual setups, is not consistent as shown by de Lhoneux et al. (2018) in extensive experiments in sharing word and character LSTM parameters.

3 Experimental Setup

3.1 Data

UD have become a de facto standard as a source for treebanks for dependency parsing. A main annotation choice in UD is the prioritization of content words as the head. While some functional distinctions are kept, such as those between subjects and objects, many other are merged, such as complements and adjuncts. Importantly, function words are dependents of the content words.

SUD were developed as a counter-balance to UD with the belief that UD are not syntactically motivated enough, with a particular linguistically argued objection to the prioritization of content words as heads, stemming from the belief that the distributional context of words should drive headedness. While many individual labels are kept, several are collapsed into a single label (e.g. nsubj & csubj → subj). The primary result of function words becoming heads is the inherent reversal of syntactic relationships of many words.

Fig. 1 is an example of how the SUD conversion alters an English sentence from its original UD representation. One of the more noticeable differences is that the projective UD tree is now non-projective in the SUD schema. The main cause, in this example, is because the auxiliary verb *can* is now the root in SUD, rather than the content word *do* in UD. Furthermore, the only word to retain the same head word between the two sentences is *what*, while all others have new heads. We wish to emphasize however, that not all trees show such stark contrasts, but simply want to highlight how a simple choice in annotation can produce distinctly different trees, and the resultant impact on non-projectivity.

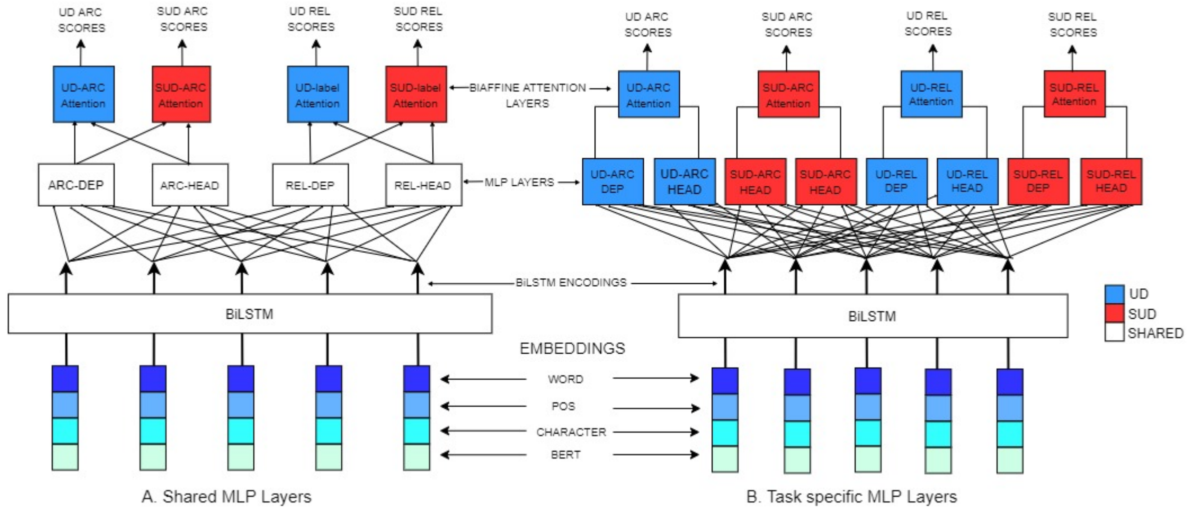
By using UD and SUD, we eliminate one of the variables in many multi-treebank setups, the different distribution of the underlying vocabulary. This effectively eliminates domain differences between the treebanks (see section 3.2), as both parsers will get more similar outputs from the BiLSTM layer, and identical ones in a joint loss setting.

We Use UD and SUD version 2.7 and select 12 different language from 10 language families. This was done in order capture sufficient linguistic variation in terms of how UD and SUD may impact various linguistic phenomena found in typologically different languages, and subsequently annotation schemes.[1] Table 1 presents statistics on the treebanks in respect to their variation in training and dev sizes. Additionally, we also note the proportion of non-projective trees found in each annotation scheme.[2] All languages show higher number of non-projective trees in SUD when compared to their UD counterparts, but for some it is much more substantial. A noticeable example is Chinese (zh) which has 40% more absolute non-projective trees in its SUD treebank compared to its UD counterpart. Noticeable increases can also be seen in Arabic and German, but most languages show only moderate differences. Hungarian (hu) is

---

[1] We restrict ourselves to treebanks that contained complete training, dev, and test splits.

[2] We note that this is not always entail explicit linguistic non-projectivity, as in many cases punctuation is the source of non-projectivity which can be viewed as non-linguistic.



A. Shared MLP Layers

B. Task specific MLP Layers

Figure 2: Multi-task model architecture.

interesting as it is the only language that shows a high proportion of non-projective trees in UD and only a moderate increase for SUD.

3.2 MTL Parsing Architecture

We use the PyTorch (Paszke et al., 2019) implementation of the Biaffine parser of Dozat and Manning (2017) provided by Zhang et al. (2020),[3] and extend it to an MTL architecture.[4]

We modify the base parser by treating parsing of each annotation scheme as a separate task. Each task shares the BiLSTM layer that is used to encode the concatenation of all input embeddings. These BiLSTM encodings are then passed through dimension reducing MLPs to strip away arc and relationship information information deemed not relevant. We implement two MLP schemes, one in which we share them across tasks (shared; Figure 2A) and the other in which each task has its own MLP layers (unshared; Figure 2B). Considering the overlap in the annotation schemes, a shared MLP setting allows us to examine the behavior of sharing information between the two annotation scheme when irrelevant information is minimized. Finally, in order for the model to learn task specific information, we apply task specific biaffine attention layers to the MLP outputs to produce scores for both arcs and labels.

The common practice in MTL is to have separate losses for different tasks and to optimize for each of them separately (*alternating loss*; Ruder, 2017). This is particularly the case when the different tasks do not share the same input. However, our dataset contains parallel sentences albeit with different annotations. It thus then becomes possible to experiment with using a *joint loss* for training both tasks as the parsers receive the same input, and a joint loss has shown improvements when joint learning POS tags and dependency parsing (Li et al., 2018). We do this by optimizing for the sum of losses of each of the tasks. Since the losses of both tasks are of nearly the same magnitude, we do not have to worry about imbalance and a simple sum suffices.[5] We experiment with both types of losses.

In the alternating loss setting, we randomly choose a task from the given tasks and then randomly choose a batch of sentences along with their annotations from that task before calculating the loss of that batch and backpropagating the errors. In a given epoch we chose sentences without replacement. For joint loss, we randomly choose a batch of the same sentences from both the tasks, along with their different annotations. Losses are calculated based on those annotations and summed together before backpropagating the errors. We posit that joint loss should allow for faster convergence as both the tasks affect the parameter updates of the shared layers simultaneously, thus helping the optimization process to move towards the goal more quickly.

The two choices of losses combined with the op-

[4] Our code is available at `https://github.com/zeeshansayyed/multiparser`

[5] When losses in an MTL setting do not have comparable magnitude, then the joint loss tends to more influenced by the task with larger loss; thus, producing a learning bias.

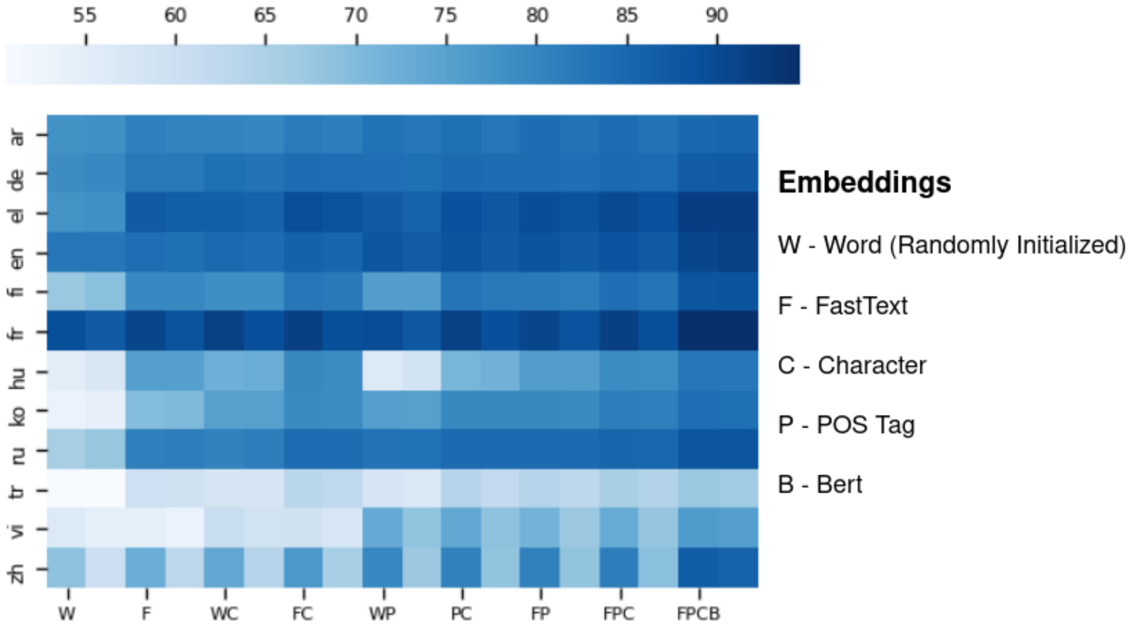

Figure 3: Heatmap illustrating the mean LAS scores for the four MTL settings across all languages and embedding types. UD-LAS is represented in the left column and SUD-LAS in the right column for each embedding input.

tional sharing of MLP layers gives rise to four different experimental settings: alternating-unshared, alternating-shared, joint-unshared, and joint-shared. In addition, we experiment with internally randomly initialized word and POS[6] embeddings, external embeddings (FastText; Bojanowski et al. (2017)) and BERT (Devlin et al., 2019)), and their concatenations as inputs to the BiLSTM layers. All results are reported on the dev sets using the CoNLL 2018 Shared Task Scorer (Zeman et al., 2018).

4 Results

The overall performances of the four experimental settings, namely alternating vs joint loss and shared vs unshared MLP layers, are very close to each other. The convergence statistics for joint and alternating loss settings are reported in Table 2.[7] It can be noted that despite taking a greater number of epochs to converge when compared to alternating loss, joint loss converges faster in terms of time because it performs the forward propagation through the shared layers only once for both tasks, whereas alternating loss has to perform it separately for each task.

As we are more interested in the MTL parser behavior across experimental settings, we report the mean LAS score over the four MTL settings in all our experiments to capture the general trends of the MTL parser.

Parameter	# Epochs	Time (seconds)
Joint Loss	342	2 774
Alternating Loss	297	3 907

Table 2: Convergence statistics for Joint and Alternating Loss

To analyze the impact of different embedding types on the MTL parsing setup, we change the specificity of information by using different embedding types with the MTL parser as discussed in section 3.2, results of which are presented in Fig 3. We see that adding more information yields in higher LAS across languages (moving from left to right on the heatmap) with the concatenation of all embeddings (rightmost columns) performing the best.

However, given that we are more interested in examining whether the parallel UD-SUD treebanks can benefit from an MTL setup, we choose instead to focus on how the MTL parsers compare to the single UD and SUD baseline parsers across the different embedding choices. Fig. 4 shows a heatmap depicting the difference of the mean LAS of all four settings with respect to the corresponding single

---

[6] We use gold POS tags.

[7] All experiments were performed on Nvidia V100 GPUs. Tables 2 and 3 analyses do not include BERT experiments.

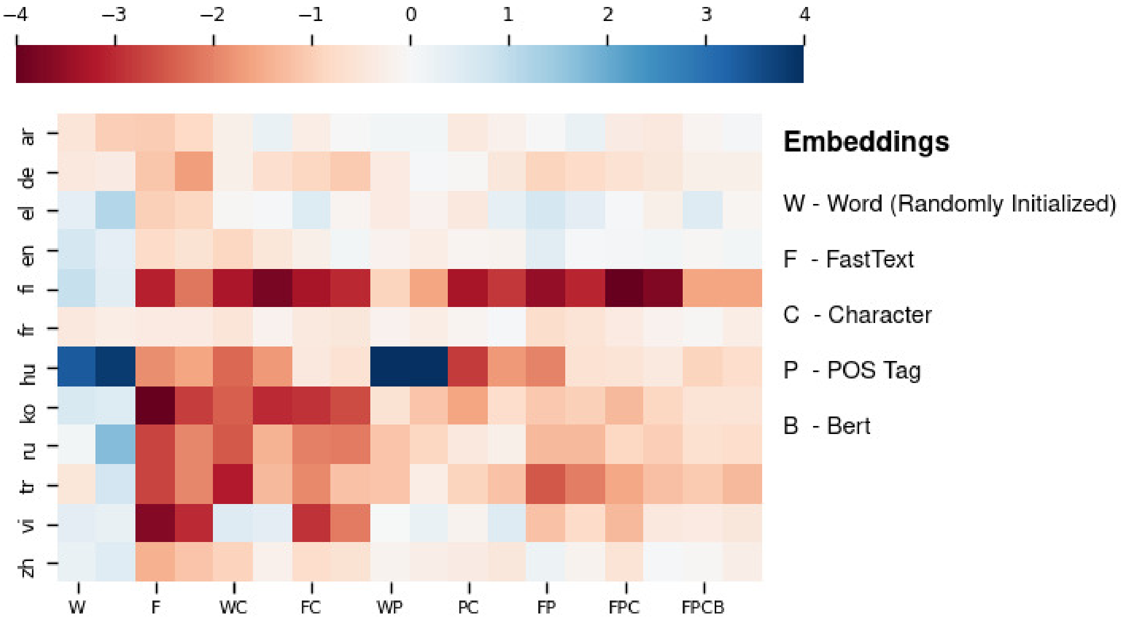

Figure 4: Heatmap illustrating the performance difference between MTL parsers compared to corresponding single task baseline parser. Each block represents the difference between the mean LAS score of four MTL settings and the respective single task baseline LAS score.

baseline parser, for each embedding input.[8]

The mean drop in LAS scores for MTL settings when compared to the baselines across all languages and all the different feature embeddings (432 runs) are reported in Table 3, with lower numbers indicating better performance. No particular setting shows a significant improvement over the other. Keeping this in consideration, we still see that joint loss performs slightly better than alternating loss. Sharing of MLP layers seems to help a little compared to the setting where we have task specific layers. As mentioned in section 3.2, the role of dimension reducing MLPs is to remove all the information that is not necessary for performing the task at hand. This would indicate that the two tasks remove similar unnecessary information, thereby sharing the signal necessary for making parsing decisions.

One of the most striking observations is that randomly initialized word embeddings (seen in the far left two columns) are noticeably lighter across all languages. This stands in stark contrast to the subsequent FastText (FT), word+char and FT+char embeddings. Hungarian shows particularly noticeable improvements, though it may be due to its size. However, given that we also see some moderate improvements for English, Greek and Russian, the size of the treebanks is not the only contributing factor.

Parameter	Mean Drop (LAS)
Joint Loss	0.70
Alternating Loss	0.75
Shared MLP	0.69
Unshared MLP	0.76

Table 3: Mean drop in LAS compared to baseline

Once inputs include word embeddings initialized with FT embeddings or randomized char embeddings, we see some interesting trends. Finnish, Hungarian, Korean, Turkish, and Russian show consistent degradation in performance with any inclusion of character-based embeddings. Some languages show more stable results, regardless of the input embeddings, namely Greek, English, French, and Chinese. Vietnamese clearly performs worse when using FT embeedings to initialize the word embeddings, but otherwise is rather stable in other settings. However, even with BERT (B) embeddings, we do not see any noticeable improvement over the baselines.

---

[8] We also experimented with task-specific fine-tuning following Liu et al. (2019) on MTL parsers. While it did lead to improvements, the overall distribution across all the different settings and languages was not considerably different. Also see Appendix for additional heatmaps contrasting shared vs unshared and alternating vs joint loss settings. The overall pattern remains the same.

When we begin incorporating POS tag embeddings, we see that drops relative to the baseline for these languages become less pronounced, but few languages ultimately show improvements, with Hungarian being the noticeable exception. The pattern in the reduction in degradation of performance when including POS tag embeddings continues across all settings. The exception being Finnish, which still shows large drops in almost all settings, but show slightly reduced drops when including BERT embeddings.

5 Discussion

5.1 UD vs SUD

We see, in general, a systematic decrease in performance when using parallel UD and SUD treebanks in an MTL setup across many languages. When looking for linguistic behaviors, we can clearly see that agglutinative languages (Hungarian, Finnish Turkish, and Korean) all suffer severe performance drops when using character-based embeddings, but the concatenation of POS embeddings helps mitigate the degradation. The absolute differences of Hungarian and Finnish are noticeably different compared to one another. This may be somewhat unexpected, given they are in the same language family. However, the modern forms are quite different and treebank sizes may play a role, as input embeddings pattern similarly overall between the two.

The morphological complexity of other languages in relation to their behavior is not necessarily a good predictor of behavior. However, if we view the other eight remaining languages on a continuum of fusional and analytical properties, we can see some general patterns.

Russian, a fusional language, patterns with the agglutinative languages in its behavior with character embeddings, but is also one of the more morphologically rich languages (MRL) of the non agglutinative languages. The other more fusional MRLs, German and Greek, also do not see as much volatility, although German tends to be worse respective to the baseline, while Greek shows some more positive results, but this could again be due to treebank sizes. English and French are more analytical than the other fusional languages and contain far less morphology. While both show rather consistent minimal degradation regardless of the input embedding, English occasionally shows some improvement, while French virtually none.

Arabic and Vietnamese, however, are somewhat odd cases. Arabic is both fusional and an MRL, whereas Vietnamese is much more analytical. Vietnamese, though, patterns more with the other MRLs, while Arabic patterns more like the analytical language, particularly with its less overall performance degradation compared to baselines across settings. Vietnamese shows one of the larger performance drops relative to the baseline compared to the other eight languages when using FT embeddings in the input, but this is diminished when combined with additional embeddings.

Chinese, an extremely analytical language, presents an additionally interesting case. The LAS for SUD is usually on average 10% absolute lower than its UD counterpart, which can be seen in Fig. 3. This probably is a direct result of the SUD treebank having 40% absolute more non-projective trees. However, this massive disparity in non-projectivity has seemingly not resulted in additional performance degradation in the MTL setup (as seen in Fig. 4), suggesting that sharing between treebanks that show large differences in non-projectivity is not necessarily detrimental.

Given the general behavior across settings, performance degradation can most likely be attributed to negative transfer derived from the different annotation preferences UD and SUD encode, which is not seen in the single model baselines. When different embeddings are used, the negative transfer is either accentuated depending upon the language, as seen with character embeddings, or some embeddings seem to help mitigate the negative transfer, as with POS embeddings. Interestingly, although character-based embeddings show significant improvements in the single baseline models compared to word embeddings, the signals they encode seem to be detrimental in an MTL setting, as performances drops relative to their respective single model baselines. This would seemingly suggest that in an MTL setup, word and POS embeddings are encoding more beneficial signals that help both annotation schemes, reducing possible negative transfer from each treebank, whereas character embeddings are maximally beneficial when used to train a single model. This is in line with recent work showing that the linguistic information POS tags convey, when highly accurate or gold, still have value for specific use cases, and are beneficial in certain dependency parsing architectures or as auxiliary tasks (Anderson and Gómez-Rodríguez,

Table 4: Results for MTL experiments with SPMRL dataset. All MTL experiments are trained with the alternating batch loss setting to allow for comparison with experiments involving SPMRL. We cannot use joint loss when training SPMRL with either UD or SUD as they are not parallel treebanks. The UD-SUD experiment shows results for UD and SUD when they are trained together in an MTL setting, whereas the SPMRL experiment shows results for UD and SUD when each of them is separately trained along with the corresponding SPMRL dataset instead of each other (UD-SPMRL & SUD-SPMRL).

2020; Zhou et al., 2020).

One specific often overlooked annotation issue that helps convey this point is punctuation.[9] In both annotation schemes, punctuation attachment is rather straight forward. However, as seen in Fig 1, it is one of the competing annotation decisions. In both annotation schemes, punctuation is simply attached directly to the root. However, in UD the root is a content word, while in SUD the root is a function word. Thus, while straight forward form an annotation perspective for both schemes, an MTL system is now learning both attachment possibilities simultaneously and preferences and errors regarding both are now being encoded in the global attachment decisions. When looking at specific attachment errors, across almost all examined experiments, there were substantial increases in punctuation attachment errors. This can be seen as a direct result of switching the content versus function oriented headedness and creates systematic, competing attachment decisions for an MTL parser exposed to both attachment possibilities.

5.2 UD and SUD vs SPMRL

To further explore whether the competing annotation decisions between UD and SUD are indeed contributing to the noticeable performance degradation, we choose to compare a subset of languages in an MTL setup but with a differently annotated treebank. Using a different treebank runs the risk of adding additional domain issues into our experiments; however, character-level embeddings have proven effective at handling OOV words (Ballesteros et al., 2015; Vania et al., 2018), thus domain differences should be reduced.

We perform experiments where we use the Arabic (Habash and Roth, 2009), German (Brants et al., 2004), and Hungarian (Vincze et al., 2010) treebanks from the SPMRL Shared task (Seddah et al., 2013, 2014), each of which were annotated with language specific linguistic phenomena in mind.[10] To mitigate size difference issues as the smaller treebank tends to benefit more in a multi-treebank setup (Johansson, 2013), we randomly select a train and dev set from the SPMRL data respectively to match the corresponding size of the UD-SUD treebanks.[11]

Results for the SPMRL experiments using char+FT embeddings are presented in Table 6.[12] All results in UD-SPRML and SUD-SPMRL MTL experiments show improved performance over the baseline. Importantly, this includes settings in which the UD-SUD MTL experiments show noticeable decreases relative to the baseline, and specifically we see that character-based embeddings are able to yield benefit in an MTL setup relative to the baseline.

These results suggests that the annotation

---

[9] The CoNLL 2018 evaluation scores punctuation. We are not, however, making a claim as to whether punctuation is or is not a linguistic issue, rather simply highlight it is an annotation attachment issue that illustrates different possible attachment distributions between the annotation schemes. From a linguistic perspective, punctuation can be argued to be irrelevant, from a parsing perspective, unless removed, it still influences attachment decisions.

[10] We refer to the reader to the cited papers for more detailed information on the individual treebank annotations.

[11] We note that the both German and Hungarian UD-SUD Treebanks are derived from a small section of the TiGer and Szeged Treebanks respectively, which are also the treebanks for the SPMRL data, thus there is a possibility of sentence overlap in the random selection. The UD-SUD Arabic treebank is derived from the Prague Arabic Dependency Treebank (Hajič et al., 2004) but is also annotated on newswire.

[12] Results using word+POS embeddings are provided in the Appendix.

schemes are indeed contributing to why UD and SUD make poor tasks for each other in an MTL setup, and not strictly the embeddings themselves. Rather, the information conveyed by each individual annotation scheme is important in terms of the possible gains that MTL parsers can make over the baseline parsers. It may simply be that how the annotations are embedded into the architecture and shared are more influential in what signals are encoded in the network than the embeddings themselves in terms of how they benefit treebanks in an MTL setup. If the annotations themselves encode information that results in negative transfer in the network due to their competing nature, an MTL setup cannot benefit as effectively.

6 Conclusion

We implemented an MTL architecture leveraging parsing UD and SUD as separate tasks to examine how their syntactic annotation overlaps and differences influence parser behavior. We find that models from an MTL setup perform generally worse than their single model baselines, regardless of input embeddings. Interestingly, POS embeddings seemingly help mitigate some of the performance loss caused from negative transfer as the POS information may help resolve possible linguistic ambiguities with which character embeddings struggle (Vania et al., 2018; Smith et al., 2018b). This stands in contrast to much multi-treebanking research which has yielded positive performance gains when using multiple treebanks, particularly if they are of the same language, though this is not always the case (Barry et al., 2019).

We then further investigated the possible influence annotations have in an MTL setup by training a subset of SPMRL treebanks against their UD-SUD counterparts, finding increases in performance across the chosen languages and input embeddings not seen when pitting UD and SUD together. We argue that this indicates that in an MTL setup, simply adding another treebank is not inherently going to yield better performance, rather the information that each additional treebank can learn from the other, specifically from their annotation schemes, and how this is then subsequently encoded in the network is a more pivotal factor in yielding performance gains.

We conclude that the syntactic annotation schemes are pertinent when determining performance gains in an MTL parsing setup, as extensive competing annotations provides too many mixed signals in an MTL architecture, hampering the ability of both parsers to benefit from shared information, yielding worse results.

Future research will include incorporating more treebanks with different annotation schemes to examine in which directions and annotations parsers will optimize towards in MTL. We also wish to further explore how constituency parsing and dependency parsing can be leveraged against each other in similar MTL setups.

Table 6: Results for MTL experiments with SPMRL dataset. All MTL experiments are trained with the alternating batch loss setting to allow for comparison with experiments involving SPMRL. We cannot use joint loss when training SPMRL with either UD or SUD as they are not parallel treebanks. The UD-SUD experiment shows results for UD and SUD when they are trained together in an MTL setting, whereas the SPMRL experiment shows results for UD and SUD when each of them is separately trained along with the corresponding SPMRL dataset instead of each other (UD-SPMRL & SUD-SPMRL).

Generating Informative Conclusions for Argumentative Texts

Abstract

The purpose of an argumentative text is to support a certain conclusion. Yet, they are often omitted, expecting readers to infer them rather. While appropriate when reading an individual text, this rhetorical device limits accessibility when browsing many texts (e.g., on a search engine or on social media). In these scenarios, an explicit conclusion makes for a good candidate summary of an argumentative text. This is especially true if the conclusion is *informative*, emphasizing specific concepts from the text. With this paper we introduce the task of generating informative conclusions: First, Webis-ConcluGen-21 is compiled, a large-scale corpus of 136,996 samples of argumentative texts and their conclusions. Second, two paradigms for conclusion generation are investigated; one extractive, the other abstractive in nature. The latter exploits argumentative knowledge that augment the data via control codes and finetuning the BART model on several subsets of the corpus. Third, insights are provided into the suitability of our corpus for the task, the differences between the two generation paradigms, the trade-off between informativeness and conciseness, and the impact of encoding argumentative knowledge. The corpus, code, and the trained models are publicly available.[1]

1 Introduction

A conclusion of an argument is a statement that conveys a stance towards a specific target (Bar-Haim et al., 2017; Alshomary et al., 2020b). Drawing conclusions is an integral part of argumentation, but often various conclusions may be drawn from a set of premises. Consider the following argumentative text on caffeine adapted from the web:[2]

> *"Caffeine stimulates the nervous system, signaling fat cells to break down body fat. It also increases epinephrine (adrenaline) levels, a fight-or-flight hormone preparing the body for physical exertion. With free body fat acids as fuel, on average, 12% higher performance is attainable."*

Consider further these alternative conclusions:

1. *Caffeine is good.*
2. *Caffeine improves physical performance.*

The first conclusion conveys a pro stance towards the target, caffeine. The second, conveys a pro stance towards caffeine, too, but it also emphasizes a specific concept ("physical performance"). The former conclusion is generic, only *indicating* the stance, while the latter is *informative*; a distinction also made in text summarization (Section 3).[3]

Argumentative texts include short arguments, such as forum posts and reviews, as well as long-form texts, such as essays, blogs, and editorials. Most of these typically have an intended conclusion of which the authors seek to persuade their readers.[4] While the conclusion may be already implied in a given text, authors often choose not to explicitly provide one, either for rhetorical reasons (Habernal and Gurevych, 2015; Al-Khatib et al., 2016), or to encourage critical thinking (Martin et al., 2003). However, when browsing many argumentative texts (e.g., via a search engine or on a social media timeline), having an explicit conclusion helps human readers (and by extension also machines) to quickly process the texts.

In this paper, we introduce the task of generating informative conclusions for argumentative texts, and take the first steps with four key contributions: (1) Adaptation of the notion of informativeness from text summarization as a desired

---

[2] https://www.healthline.com/nutrition/top-13-evidence-based-health-benefits-of-coffee

[3] Other works on argumentation use the term *specificity* to express a similar idea (Durmus et al., 2019; Ke et al., 2019).

[4] An exception is an argumentative text dedicated to deliberation, which merely surveys the argument landscape on a given topic without trying to influence the reader's opinion.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3482–3493
August 1–6, 2021.

property of a conclusion besides stating a target and the stance towards it. (2) Compilation of Webis-ConcluGen-21, a corpus of 136,996 pairs of argumentative texts and associated conclusions, creating the first large-scale ground truth for conclusion generation. (3) Modeling conclusion generation as an end-to-end task by finetuning a pretrained sequence-to-sequence model, and augmenting the corpus with three types of argumentative knowledge: topic, target, and aspect. (4) Extensive quantitative and qualitative (crowdsourced) evaluation of both the quality of our dataset and the effectiveness of two paradigms for conclusion generation, namely extractive and abstractive approaches.

We present three key findings: (a) Finetuning pretrained language models on our dataset shows strong in-domain performance compared to the extractive approach. (b) Qualitative evaluation shows that the extractive approach generates more informative conclusions, demonstrating a trade-off between conciseness and informativeness. (c) Encoding argumentative knowledge guides the finetuning towards generating argumentative sentences; however, more sophisticated encoding techniques than just using the conventional control codes are needed to generate informative conclusions.

2 Related Work

Our work complements and builds on that of Alshomary et al. (2020b), who introduced a conceptual model for conclusion generation, outlining a three-step process: inferring the conclusion's target from the argument's premises, inferring the author's stance towards this target, and generating the conclusion based on these two pieces of information. But Alshomary et al. focused only on the first step of target inference, whereas we model conclusion generation as an end-to-end task.

Conclusion generation can be viewed as a complementary task to summarizing argumentative texts. Previous approaches to the summarization of such texts have been primarily extractive. Egan et al. (2016) proposed summarizing online discussions via "point" extraction, where a point is a verb and its syntactic arguments. Similarly, Bar-Haim et al. (2020) compiled the *ArgKP* corpus (which we also sample from in Section 4) comprised of arguments for a given topic mapped to *key points*, composing a summary from a large collection of relevant arguments. Wang and Ling (2016) proposed a data-driven approach using sequence-to-sequence models (Sutskever et al., 2014; Bahdanau et al., 2015) for summarizing movie reviews and debate portal arguments from idebate.org. Several argument mining approaches have also been applied to identify the main claim from arguments (Petasis and Karkaletsis, 2016; Daxenberger et al., 2017). Recently, Alshomary et al. (2020a) proposed a graph-based model using PageRank (Page et al., 1999) that extracts the argument's conclusion and the main supporting reason as an extractive snippet. This model is the core of our extractive summarization approach (Section 5).

A key difference between conclusion generation and general text summarization is the constraint that a conclusion must have a clear stance towards a certain topic. A similar constraint applies to high-quality summaries of long-form argumentative texts such as editorials (Syed et al., 2020), where the persuasiveness of the editorial should be preserved alongside its thesis. Therefore, existing summarization corpora (although large-scale) are unsuitable for studying conclusion generation. A majority of them contain only non-argumentative texts (e.g., news reports) which are more suitable to general-purpose summarization (Kryscinski et al., 2019). Moreover, intrinsic evaluation of summarization corpora has revealed a lower-quality and/or inconsistent ground-truth, rendering them partially unfit for their intended purpose (Bommasani and Cardie, 2020). To fill this gap, we compile Webis-ConcluGen-21, a large-scale corpus of argumentative texts and their conclusions on diverse topics.

Pre-trained language models have significantly advanced the state-of-the-art in neural text summarization (Liu and Lapata, 2019; Zhang et al., 2019a; Rothe et al., 2020; Huang et al., 2020). However, they have been applied to the domain of argumentation only recently, specifically for argument generation. Gretz et al. (2020) proposed a pipeline based on GPT-2 (Radford et al., 2019) for generating coherent claims for a given debate topic. A more controlled approach for argument generation was developed by Schiller et al. (2020), which performs argument generation with fine-grained control of topic, aspect (core reasoning), and stance. Conclusion generation can be viewed as supplementing argument generation. Ideally, given a conclusion, an argument can be generated constrained by the conclusion's target and stance. To the best of our knowledge, studies investigating pretrained language models for end-to-end conclusion generation do not exist. Besides providing a suitable corpus, we analyze the impact of encoding argumentative knowledge in pretrained language models and assess the popular method of control codes (Keskar et al., 2019; Cachola et al., 2020) for encoding the knowledge in our dataset. Furthermore, our qualitative evaluation highlights three key errors (Section 6) arising in the generated outputs that disqualify them as conclusions.

3 On Informative Conclusions

In the literature, the conclusion of an argument is the statement that depicts a particular stance towards a certain concept, the target (Walton et al., 2008; Alshomary et al., 2020b). Such a statement is also referred to as the *claim* of the argument (Toulmin, 2003; Daxenberger et al., 2017). For a long-form argumentative text with multiple claims, the conclusion is the *main claim* that conveys the overall stance towards the subject matter under discussion. The main claim is also known as *thesis*, or *central claim* in different genres (Van Dijk, 1995; Burstein and Marcu, 2003; Stab and Gurevych, 2014; Peldszus and Stede, 2015).

The quality of the conclusion of an argumentative text can be assessed in terms of several dimensions, including strength, clarity, and specificity (Ke et al., 2019). Here, a strong connection between argumentation and text summarization can be observed, where the dimension corresponding to specificity is called *informativeness*. Text summarization distinguishes between indicative and informative summaries. An indicative summary only hints at the principal subject matter of a document to help decide whether to read it (Hovy and Lin, 1998; Kan et al., 2001). An informative summary, on the other hand, covers the main information in the source document, ideally serving as its surrogate (Maybury, 1999).

The conceptual connection between argumentation and summarization could be described as follows: the *informativeness* of a conclusion is closely connected to the specificity dimension, in the sense that an informative conclusion must be specific to allow for a better understanding of an argumentative text's gist. Seeing that "specificity" and "informativeness" may be used interchangeably, we opted for the latter and the term "informative conclusion" here, to underline the connection.

In contrast to *indicative* conclusions, which broadly convey (implicitly or explicitly) the stance towards a topic (e.g., "Caffeine is good."), informative conclusions also discuss specific concepts from (or implied by) the argumentative text (e.g., "Caffeine improves physical performance."). Concepts of the argumentative text exemplified in Section 1 may refer to the topic (e.g., "Is coffee beneficial?"), the target of the conclusion (e.g., "caffeine"), or a specific aspect (e.g.,"energy levels").

4 The Webis-ConcluGen-21 Corpus

This section details the construction of the Webis Conclusion Generation Corpus 2021 (Webis-ConcluGen-21), a corpus of 136,996 pairs of argumentative texts and conclusions covering diverse topics. The corpus is derived from two reliable sources, where the conclusions of argumentative texts are explicitly identifiable: Reddit's ChangeMyView forum and debate corpora.

4.1 Data Source: Reddit's ChangeMyView

ChangeMyView (CMV) is an online forum for persuasive discussions that start with a user who presents a view and asks others to challenge it. The forum's rules strictly enforce that (1) users' posts must contain sufficient reasoning, (2) posts must take a stance (and not be neutral), and (3) the title of a post must sufficiently sum up an author's view (as a statement and not a question).[5] Given these constraints, the original post of a discussion can be operationalized as an *argumentative text*, and the corresponding title as its (intended) *conclusion*. Starting from the Reddit crawls provided by Baumgartner et al. (2020), we compiled 61,695 such pairs by processing all CMV discussions up until August 2019. The included posts are those whose argumentative text was longer than ten words, the conclusion longer than two words, and the title includes the "CMV" tag.[6] An average argumentative text is 312 words long and a conclusion 15 words.

To better understand the relation of the conclusions to their respective argumentative texts, and the expected difficulty of generating them, we analyzed a sample of 200 pairs manually.[7] Table 1

---

[5] https://reddit.com/r/changemyview/wiki/rules

[6] These heuristics reflect manual inspections, and the fact that we did not wish to compile a representative sample of ChangeMyView's discussions, but a purposeful selection of high-quality pairs of argumentative texts and their conclusions: In light of this, the lower bounds are still quite inclusive with respect to extremely short samples.

[7] These examples were taken from the Dec-2019 Reddit submissions to ensure a truly-hidden sample as BART was originally trained on the OpenWebText dataset containing samples

Type	Description	%
Extractive	Conclusion is present verbatim in the argumentative text.	12.8
Paraphrase	Conclusion is synonymous to, or a fusion of a part of the argumentative text.	24.1
Abstractive	Conclusion is inferred from the argumentative text.	57.8
No conclusion	Conclusion cannot be derived from the argumentative text.	5.3

Table 1: Different types of conclusions in 200 CMV samples, and their relative proportion.

shows the proportion of extractive, paraphrased, and abstractive conclusions in our sample, where the former only need to be extracted, and the latter demand actual text synthesis. Paraphrases share aspects of both, though arguably, extracting the paraphrased part would suffice. Altogether, CMV provides for 94.7% valid pairs of argumentative texts and conclusions at sufficiently low noise (5.3%). The amount of non-trivial conclusions (abstractive + paraphrase) are sufficiently challenging, as found in our qualitative evaluation (Section 6).

4.2 Data Source: Debate Corpora

Online debate portals facilitate semi-structured debates on controversial topics, where pro and con arguments or argumentative texts are collected. Conclusions are clearly stated even for individual arguments. Given their high-quality curation, debate portals constitute the majority of argument corpora. We utilized the following existing corpora:

Kialo is a debate platform that enables "visual reasoning" in complex debates via a tree-based structure (Chaudoin et al., 2017). A key advantage here is the role of moderators in curating accepted arguments, rendering it a rich resource (Durmus et al., 2019). As debates progress, the arguments are reorganized into multiple hierarchies, each with a conclusion at its root.[8] We compiled this corpus from scratch in accordance with the website's terms and conditions. In 1,640 English discussions, at each level of the discussion tree, all pro arguments were matched to the corresponding root conclusion, obtaining a total of 82,728 examples.

Args.me is a search engine (Wachsmuth et al., 2017) indexing the Args.me Corpus (Ajjour et al., 2019b), comprised of argumentative texts, their conclusions and their stance from four debate portals: debatewise.org, idebate.org, debatepedia.org, and debate.org. We used the "cleaned" version of this corpus containing 387,606 samples and applied further post-processing. On manual inspection, we observed that a number of examples from debate.org contained spam, sarcasm, or ad hominem attacks, or they were not self-contained due to references to previous turns. To avoid noise, we excluded all examples from this portal. Next, we removed arguments with con stance towards a conclusion.[9] This is due to the fact that considering these examples for training would first require negating their conclusions to reflect the con stance. We leave such automatic claim negation (Bilu et al., 2015) for future work. Finally, to favor informative conclusions, we excluded arguments whose conclusion was the same as the discussion topic (which is generally indicative). This heavy filtering resulted in a total of 23,448 argument-conclusion pairs.

ArgsKP is a corpus of arguments and a set of key points written by domain experts on 28 topics (Bar-Haim et al., 2020). For each topic, the corpus contains multiple arguments which have been mapped via crowdsourcing to their respective key points. From this corpus, we obtained 2,341 pairs; again, only pro arguments and those that have been mapped to a specific key point, the conclusion.

Postprocessing. The structure of debate portals allows for multiple arguments to be mapped to a single conclusion. This happens when different users independently contribute pro and con arguments, which is acceptable, since the same conclusion can be drawn from different arguments with different frames (Ajjour et al., 2019a). Apart from the ones filtered in preprocessing the debates corpora, we preserved duplicate conclusions across debates as their arguments are still unique. Similar to CMV, the included argumentative texts were those whose length exceeded ten words. Also, argumentative texts shorter than their conclusion were excluded. This removed many pairs from the Kialo discussions. Altogether, we retained 75,301 usable examples from all three corpora.

4.3 Corpus Statistics

The argumentative texts are on average longer in CMV (312 words) compared to those in debates (44.5 words). A reason is that, on debate portals, each argumentative text seems to be a self-contained argument. CMV posts, by comparison,

---

from Reddit (Liu et al., 2019; Radford et al., 2019).

[8] For an example, see: https://www.kialo.com/pro-life-vs-pro-choice-should-abortion-be-legal-5637

[9] This does not exclude conclusions that are already negations.

often contain multiple arguments and/or preface the actual argument with additional background. However, the corresponding conclusions are of similar length (15 words for CMV and 18.4 words for debates on average, about the length of an average English sentence). For both data sources, we measured the percentage of words in a conclusion that do not occur in the argumentative text as a measure of "novelty" (Narayan et al., 2018). For CMV, the average novelty is 33.2%, and for debates, the novelty is 81.6%, which is due to the fact that multiple arguments have been mapped to a single conclusion, and that arguments supporting (or attacking) a conclusion during an ongoing discussion are usually not directly derived from it.

5 Generating Informative Conclusions

Given the mixture of conclusion types shown in Table 1, we approach the generation of informative conclusions according to two paradigms, one extractive approach combined with paraphrasing, and one abstractive approach combined with state-of-the-art argument mining technology.

5.1 Paraphrased Conclusion Generation

Paraphrased conclusions are fundamentally extractive in nature, where an extracted sentence is reformulated to improve it. To extract conclusions, we employ the graph-based approach of Alshomary et al. (2020a), originally designed to generate snippets for argument search results. Given an argument, a snippet is generated as follows: (1) related arguments are retrieved as context, (2) all argument's sentences and those from the retrieved ones are embedded, (3) the PageRank of the sentences is computed, and lastly (4) the argument's two top-ranked sentences are returned. Underlying this approach is the hypothesis that an extractive snippet for an argument should comprise its conclusion and its most important supporting premise. Sentences are thus scored regarding their centrality in context of other arguments and their argumentativeness.

Our goal is to generate a single conclusion statement, thus we consider only the top-ranked sentence as the conclusion from the approach of Alshomary et al. (2020a). This sentence is automatically paraphrased using PEGASUS (Zhang et al., 2020a), finetuned on the Google PAWS dataset (Zhang et al., 2019b).[10] For instance, consider the top-ranked sentence from a post questioning the use of hormone blockers on transgender kids:[11]

> *"I don't see it as anything different, and I think it is scandalous to permanently change a child's entire life on a whim rather than treating their mental health."*

After paraphrasing, it reads as follows:

> *"I think it's scandalous to change a child's life on a whim, rather than treating their mental health, and I don't see it as anything different."*

The paraphraser primarily rearranges the sentence; and shared phrases with the original are typical in the paraphrased sentences we reviewed. This approach, called `Arg-PageRank`, represents an advanced extractive paradigm.

5.2 Abstractive Conclusion Generation

Abstractive conclusions can be formulated freely, provided they capture the main pieces of information required for an informative conclusion: topic, targets, stance, and aspects. In this regard, our approach is three-fold (see Figure 1): (1) Automatic extraction of the aforementioned pieces of information from a given argumentative text; (2) augmentation of the training examples in Webis-ConcluGen-21 using control codes, and (3) domain transfer of a pretrained abstractive news summarization model via finetuning on the augmented corpus.

Argumentative Knowledge Extraction. This step details our respective approaches at providing the prerequisite pieces of information to formulate an informative conclusion, namely topic, targets, and aspects. Table 2 shows an example.

Topic: An argumentative text's topic is a description of what it is about. For argumentative texts from debates, we use the associated debate title as the topic. For CMV posts, their titles are also their conclusions; here, topic information is considered missing (denoted as 'NA' token).

Targets: The target of a conclusion is typically a controversial concept or statement (Bar-Haim et al., 2017). For an argumentative text, though, an overlap with its topic is possible, different targets can also be found in its premises. Moreover, when not explicitly stated, the targets of a conclusion can be inferred from either the targets of premises, or external knowledge bases. A set of possible targets

---

[11] https://www.reddit.com/r/changemyview/comments/e97sir/cmv_giving_children_puberty_blockers_to_allow/

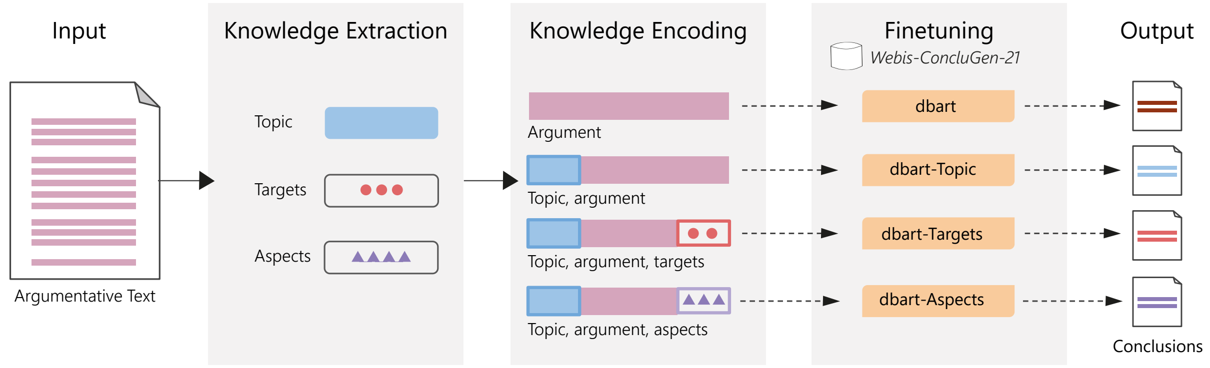

Figure 1: The three steps of our approach to abstractive conclusion generation: For all examples in the Webis-ConcluGen-21 corpus (1) different pieces of argument knowledge are extracted namely the discussion topic, possible conclusion targets, and covered aspects, (2) this knowledge is encoded using control codes, and (3) knowledge-specific variations are finetuned of the distilled BART model to generate informative conclusions.

Argument	Feminism as a 'linguistic term' often misses clarity, universal definition and regularly incorporates opposite goals at the same time in regard to key feminist issues as gender equality, gender-neutrality, non-binary and gender-related rights. The linguistic term thereby clouds public debate and hampers the setting of clear social and political goals in society.
Conclusion	Feminism is an umbrella of ideologies first and foremost, and consequently, it muddies the discussion of gender equality with its ideological baggage.
Topic	Is Feminism a Force For Good?
Aspects	clouds, gender equality, non-binary, opposite goals, public debate, gender-related rights, clarity, gender-neutrality, social and political goals, universal definition
Targets	The linguistic term, Feminism as a ' linguistic term'
Encoded Representation	<|*TOPIC*|>Is Feminism a Force For Good?<|*ARGUMENT*|>Feminism as a 'linguistic term' often misses clarity, universal definition and regularly incorporates opposite goals at the same time in regard to key feminist issues as gender equality, gender-neutrality, non-binary and gender-related rights. The linguistic term thereby clouds public debate and hampers the setting of clear social and political goals in society.<|*TARGETS*|> The linguistic term, Feminism as a ' linguistic term<|*CONCLUSION*|>

Table 2: Example argument-conclusion pair along with topic, targets, and aspects. The last row shows the representation for finetuning models on specific types of encoded external knowledge (here, on conclusion targets).

for every argumentative text in the corpus are automatically identified using the target identification model of Alshomary et al. (2020b).

Aspects: Text spans that contribute to the core reasoning of an argument are called its aspects (Schiller et al., 2020). Aspects can be viewed as subtopics related to the main topic of an argumentative text, encoding a stance. Including aspects into a conclusion can render it more specific and, thus, informative. We identify aspects for all samples in the corpus, using the model of Schiller et al. This model trains a BERT-based (Devlin et al., 2019) ranker on a corpus containing 5,032 high-quality argumentative sentences that are manually labeled with aspects at the token level.

Stance is excluded as an explicit input to our models. For CMV, by design, a post supports its title. For debate portals, only argumentative texts with pro stance towards their conclusion have been considered. Nevertheless, argumentative texts and their conclusions in our corpus may, implicitly or explicitly, express their own stance towards implicit or explicit targets. Implicit stance can be encoded via the aspects.

Argumentative Knowledge Encoding. The extracted pieces of knowledge are encoded into a training example with control codes using special tokens (Cachola et al., 2020): <|*TOPIC*|>, <|*ARGUMENT*|>, <|*ASPECTS*|>, <|*TARGETS*|>, and <|*CONCLUSION*|>. Table 2 shows a corresponding example input sequence encoding the topic and the conclusion targets. To examine the impact of individual knowledge types, we create three versions of Webis-ConcluGen-21: *topic-encoded*, *aspect-encoded*, and *target-encoded*. Presuming the availability of a topic in nearly all real-world applications, it is also encoded in the latter two versions. Since aspects and targets overlap in 38.3% of the case in the corpus, they are independently encoded.

Model	Data	#Train	#Valid
`dbart-XSum`	XSum	204,045	n/a
`dbart-CMV`	CMV	55,768	5,577
`dbart-Debates`	Debates	67,770	6,777
`dbart`	All	123,538	12,354
`dbart-Topic`	All+topic	123,538	12,354
`dbart-Aspects`	All+topic+aspects	122,040	12,192
`dbart-Targets`	All+topic+targets	110,867	11,068
`Arg-PageRank`	*none, unsupervised model*		

Table 3: Corpus splits for all six variants. 'All' refers to the entire Webis-ConcluGen-21 corpus. Models were automatically evaluated on a test set of 1,000 examples, and qualitatively on 300 examples (Section 6).

Parameter	Value
max_target_length	100
warmup_steps	500
eval_steps	500
attention_dropout	0.1
label_smoothing	0.1
sampling	sortish_sampler
seed	5153
num_beams	6
length_penalty	0.5
gradient_accumulation_steps	1
lr_scheduler	linear

Table 4: Hyperparameters for finetuning BART.

Finetuning. As conclusion generation is closely related to abstractive text summarization, we picked BART (Lewis et al., 2020), a pretrained state-of-the-art summarization model, for finetuning on the three augmented versions of Webis-ConcluGen-21. However, BART has approximately 10% more parameters than BERT, which makes it resource-intensive for finetuning. To account for this, we used the distilled checkpoint derived using the "shrink-and-finetune" approach of Shleifer and Rush (2020), where large sequence-to-sequence models are compressed by extracting "distilled student models" (Sanh et al., 2019) from a teacher model (here, BART). We used distilled BART finetuned on the XSum corpus (Narayan et al., 2018) (`dbart-XSum`) provided by the Transformers library (Wolf et al., 2020),[12] since the average length of our ground-truth conclusions is similar to the summaries in XSum. Additionally, we also added our control codes as special tokens to the BART tokenizer during finetuning in order to avoid splitting them into sub-word tokens while processing the encoded sequences.

We first applied `dbart-XSum` on the held-out test set of 200 examples analyzed for Table 1 to evaluate the domain transfer from news reports to argumentative texts. On manual evaluation, 79.1% of the outputs were invalid conclusions, primarily due to being non-argumentative (Section 6). This demonstrates that existing summarization models are ineffective when applied on argumentative texts and must be trained on task-specific data.

Model	BERTScore (F1)	Rou.-1	Rou.-2	Rou.-L
`dbart-XSum`	0.21	15.28	3.10	13.31
`dbart-CMV`	0.32	20.35	7.11	18.80
`dbart-Debates`	0.23	15.38	4.85	14.22
`dbart`	**0.39**	**31.73**	**19.48**	**30.87**
`dbart-Topic`	0.34	23.74	9.56	22.14
`dbart-Aspects`	0.33	23.47	9.46	22.01
`dbart-Targets`	0.34	23.80	9.63	22.25
`Arg-PageRank`	0.20	15.35	3.20	13.37

Table 5: Automatic evaluation of models on the internal test set consisting of 1,000 pairs (500 each from CMV and Debates). BERTScore is the re-scaled F1 score; in addition, average Rouge-1, -2, and -L are reported.

5.3 Training Details

We compiled six variations of the corpus (with and without encoded knowledge) for finetuning the The `dbart-XSum` model with 306M parameters.[12] Table 3 shows the training and validation splits for each model variant and the corresponding data subsets, and Table 4 shows the chosen hyperparameters. The standard finetuning regimen was employed from the Transformers library[13] to train each model on a V100 GPU for 6 epochs with batch size 1, dropout rate 0.1, adafactor optimizer, learning rate of 3e-5, and beam search for inference. For `dbart-<CMV|Debates|All>` the maximum source sequence length was set to 512 tokens, while for `dbart-<Topic|Aspects|Targets>` we increased it to 750 tokens to account for the appended knowledge in the input sequence. On a single V100 GPU, the runtime varies between 3 to 5 days per model, depending on their corresponding training splits.

6 Evaluation

Our models are evaluated via both: (1) An automatic evaluation on a large test set using standard metrics, and (2) a manual evaluation on a smaller test set via crowdsourcing.

6.1 Automatic Evaluation

On a test set of 1,000 examples with known ground-truth (500 each from CMV and from the debate corpora), we computed ROUGE (Lin, 2004)[14] and BERTScore (Zhang et al., 2020b)[15] for all models.

[13] https://github.com/huggingface/transformers/tree/master/examples/legacy/seq2seq

[14] https://github.com/pltrdy/rouge

[15] https://github.com/Tiiiger/bert_score

Table 5 shows that `dbart-XSum` performs poorly on argumentative texts. Inspecting the reasons for this shortcoming, we found several outputs of the model to be either neutral sentences (despite having the right target), or hallucinations with artifacts from the XSum corpus (e.g., "*In our series of letters from African journalists* [...]" or "*This week I've been writing about* [...]"). Among the finetuned models, `dbart`, trained on the entire corpus without any encoded knowledge, performs best across all metrics. The knowledge-encoded models exert a drop in effectiveness, but still outperform models trained on the sub-datasets `dbart-CMV` and `dbart-Debates`.

All finetuned models generate concise outputs of similar lengths (average 12 words), while `Arg-PageRank` extracts longer spans (25 words). Outputs of the knowledge-encoded models are somewhat similar to each other (average pairwise Jaccard similarity of 0.43), compared to those from `dbart` (0.27 with any knowledge-encoded model).

6.2 Manual Evaluation

Given the results of the automatic evaluation, only the models trained on the entire corpus were manually evaluated against our baseline approach `Arg-PageRank`. A test set of 300 examples was employed, 100 each from debates and CMV posts, plus 100 comments to CMV posts. The latter include only comments with at least 100 words and exclude non-argumentative ones as per automatic claim-detection (Chakrabarty et al., 2019). This part of the test set corresponds to an unsupervised evaluation of the conclusions, since no ground truth for the comments is available.

Two expert writers, both native English speakers, were hired via Upwork.com.[16] For every given argumentative text in the test set, all candidate conclusions generated by the different models were shown to the annotators in random order, and without revealing the respective model's name. Assessment was cast as a series of binary decisions: first, whether a given candidate is a conclusion, and if yes, whether it is fluent, and whether it is informative. To simplify judging informativeness, we only asked if the conclusion was too generic. For each candidate judged not to be a conclusion, we asked whether it either has the (1) *wrong target* (WT), conveys the (2) *wrong stance* (WS), or whether it is (3) *non-argumentative* (NA).

Table 6 shows the percentage of cases on which both annotators agreed. For CMV and debates, finetuning outperforms `Arg-PageRank` at generating conclusions that convince the experts: `dbart` performs best on CMV (36%), and `dbart` and `dbart-Topic` on debates (14%).

Model	**Concl.**	**Inform.**	**Error Types**		
			WT	WS	NA
CMV Posts					
`dbart`	36%	4%	56%	22%	22%
`dbart-Topic`	28%	0%	59%	23%	18%
`dbart-Aspects`	33%	6%	69%	23%	8%
`dbart-Targets`	27%	4%	69%	23%	8%
`Arg-PageRank`	11%	7%	0%	0%	100%
Debates					
`dbart`	14%	6%	65%	9%	26%
`dbart-Topic`	14%	3%	76%	12%	12%
`dbart-Aspects`	7%	2%	77%	13%	10%
`dbart-Targets`	11%	2%	71%	17%	12%
`Arg-PageRank`	10%	6%	7%	0%	93%
Comments					
`dbart`	12%	2%	52%	18%	30%
`dbart-Topic`	6%	2%	58%	24%	18%
`dbart-Aspects`	7%	3%	52%	33%	15%
`dbart-Targets`	8%	3%	55%	35%	10%
`Arg-PageRank`	17%	9%	5%	5%	90%

Table 6: Full agreement percentages of two annotators on 300 examples, grouped by the example type (posts, debates, comments). The first column is the % of valid conclusions, the second the % of informative conclusions, followed by the % distribution of error types (lower is better) of a model. On average, all models were judged to be fluent for 97% of the conclusions.

Comments appear to be a particularly difficult type of test cases. This is because comments to the first post may not be self-contained but refer back to the post, they may have a mixed stance (supporting only part of the post while opposing the rest), and they may introduce new targets and aspects (different concepts)—based on our inspection of the comments. In such cases, extracting the conclusion from the comment (and paraphrasing it) using `Arg-PageRank` performs best (17%).

Encoding knowledge slightly impacts the effectiveness. Across all example types, knowledge-encoded models perform equally well, sometimes worse, sometimes better than `dbart`. Encoding topic with aspects or targets performs better on posts and comments.

As for *informativeness*, `dbart-Aspects` generates a higher number of informative conclusions for posts, while `dbart` does best in debates, among the finetuned models. In all domains, `Arg-PageRank` performs similar to or better than all approaches due to extracting claims that are twice as long on average (24 words) compared to the finetuned models (12 words), hence capturing more information.

---

[16] An hourly rate of about 30 USD was paid.

Inspecting the error types, encoding argumentative knowledge increases the number of argumentative candidate conclusions, validating its positive impact. All knowledge-encoded models have fewer non-argumentative (NA) errors compared to `dbart`. However, this affects target inference; the knowledge-encoded models generate more wrong targets (WT). The mixed stance of comments (supporting part of the original post, while opposing the rest) leads to a higher number of stance errors (WS) for `dbart-Aspects` and `dbart-Targets`. Finally, for `Arg-PageRank`, almost all errors were non-argumentative sentences (NA).

6.3 Discussion

Our qualitative evaluation indicates that generating informative conclusions is challenging, and that our data is well-suited for the task, due to a mix of conclusion types (Table 1), and diverse data sources. Leveraging external knowledge, though a promising feature for guiding finetuning, may benefit from better encoding strategies compared to the conventional method of using control codes in text. However, given that the identified knowledge is extractive and that we encoded multiple aspects and targets per example in contrast to related controlled text generation approaches (Keskar et al., 2019; Schiller et al., 2020; Gretz et al., 2020; Cachola et al., 2020), further investigations with importance sampling of argumentative knowledge are advised. Ideally, such sampling would be tailored to a specific domain or target audience.

Likewise, regarding the informativeness of the generated conclusions, a trade-off between conciseness and specificity must be decided. Our experiments suggest that long extractive conclusions capture more information compared to the more concise (and fluent) abstractive one of the finetuned models, rendering them preferable to the annotators when sufficient background is missing. Finally, for comments, modeling the argumentative context supplemented by explicit stance identification is necessary to generate valid conclusions.

7 Conclusion

The notion of an informative conclusion is introduced and discussed in the context of computational argumentation as well as text summarization. Informative conclusions are to argumentation what brief summaries are to text: they concisely convey its main points. We lay the foundation for studying the conclusions of argumentative texts, compiling the Webis-ConcluGen-21 corpus, comprising 136,996 pairs of argumentative texts and corresponding conclusions.

Conclusions are diverse and typically depart significantly from the argumentative text they are derived from, paraphrasing it, and more than half the time abstracting over it. Authors typically tailor their conclusions to the occasion; and in many cases, they are not necessarily made explicit. This is where we contribute by tackling the task of generating an informative conclusion. The two main paradigms we study—paraphrased (incl. extractive) vs. abstractive conclusion generation—compete closely with each other.

8 Ethics Statement

Our dataset is a collection of opinionated texts obtained from sources that are available publicly and acknowledged appropriately. We respected their terms and conditions.

We did not employ any author-specific features in our approaches and instead processed only the corresponding arguments, although representing personal views of anonymous authors.

The proposed technology will be applicable to an English-speaking audience. While failures in generating valid conclusions may mislead a reader's initial interpretation of an argument, we do not aim at applications that prevent readers from reading the complete arguments. Rather, we seek to simplify the consumption of public discussions comprising several arguments by providing explicit, informative conclusions especially for longer arguments.

Finally, in terms of computational resources, we restricted ourselves to the smaller, distilled checkpoints of a large pretrained model that can be trained with (comparably) smaller resources and are accessible to majority of the researchers.

Acknowledgments

We thank the reviewers for their valuable feedback. This work was supported by the German Federal Ministry of Education and Research (BMBF, 01/S18026A-F) by funding the competence center for Big Data and AI (ScaDS.AI Dresden/Leipzig). Computations for this work were done (in part) using resources of the Leipzig University Computing Centre, who we sincerely thank for their support.

Substructure Substitution: Structured Data Augmentation for NLP

Haoyue Shi **Karen Livescu** **Kevin Gimpel**
Toyota Technological Institute at Chicago, IL, USA, 60637
{freda,klivescu,kgimpel}@ttic.edu

Abstract

We study a family of data augmentation methods, substructure substitution (SUB^2), that generalizes prior methods. SUB^2 generates new examples by substituting substructures (e.g., subtrees or subsequences) with others having the same label. This idea can be applied to many structured NLP tasks such as part-of-speech tagging and parsing. For more general tasks (e.g., text classification) which do not have explicitly annotated substructures, we present variations of SUB^2 based on text spans or parse trees, introducing structure-aware data augmentation methods to general NLP tasks. For most cases, training with a dataset augmented by SUB^2 achieves better performance than training with the original training set. Further experiments show that SUB^2 has more consistent performance than other investigated augmentation methods, across different tasks and sizes of the seed dataset.[1]

1 Introduction

Data augmentation has been found effective for various natural language processing (NLP) tasks, such as machine translation (Fadaee et al., 2017; Gao et al., 2019; Xia et al., 2019, *inter alia*), text classification (Wei and Zou, 2019; Quteineh et al., 2020), syntactic and semantic parsing (Jia and Liang, 2016; Shi et al., 2020; Dehouck and Gómez-Rodríguez, 2020), semantic role labeling (Fürstenau and Lapata, 2009), and dialogue understanding (Hou et al., 2018; Niu and Bansal, 2019). Such methods enhance the diversity of the training set by generating examples based on existing ones, and can make the learned models more robust against noise (Xie et al., 2020). Most existing work focuses on word-level manipulation (Kobayashi, 2018; Wei and Zou, 2019; Dai and Adel, 2020, *inter alia*) or global sequence-to-sequence style generation (Sennrich et al., 2016).

In this work, we study a family of general data augmentation methods, substructure substitution (SUB^2), which generates new examples by substituting same-label substructures (Figure 1). While some instances within this family have been proposed before for certain tasks, we generalize the idea and investigate it for a variety of tasks and settings. SUB^2 naturally fits structured prediction tasks such as part-of-speech tagging and parsing, where substructures exist in the annotations of the tasks. For more general NLP tasks such as text classification, we present variations of SUB^2 which (1) define substructures based on text spans or parse trees for existing examples, and (2) generate new examples by substructure substitution based on the substructures and various kinds of constraints.

While data augmentation methods can often be task-specific or have inconsistent performance, extensive experiments show that SUB^2 consistently helps models achieve competitive or better performance than training on the original dataset across structured prediction tasks and original dataset sizes. We further study the effect of different constraints for the variations of SUB^2 in text classification. While there is no consistently winning combination of constraints, SUB^2 remains dominant on both investigated few-shot text classification datasets.

In addition, when combined with XLM-R (Conneau et al., 2019), a cross-lingual pretrained language model, SUB^2 establishes new state-of-the-art results for sentiment analysis and low-resource part-of-speech tagging. Finally, the experimental setups we define can serve as a benchmark for future work on NLP with little annotated data.

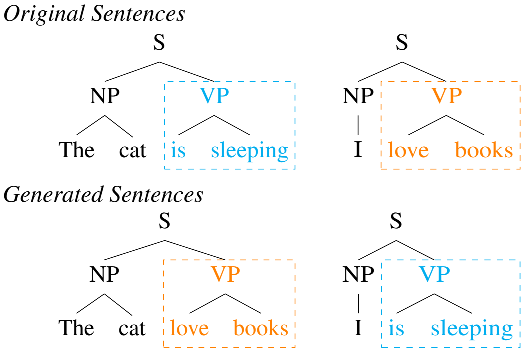
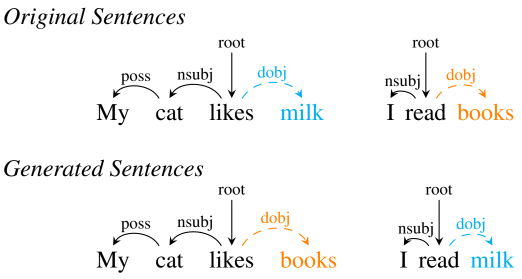
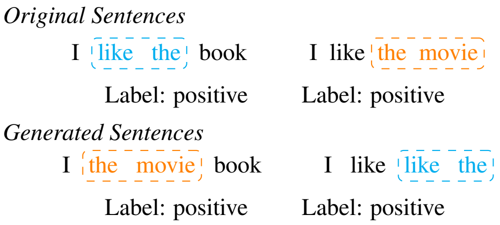
(a) Part-of-speech tagging.



(b) Constituency parsing.



(c) Dependency parsing.



(d) Text classification. To apply SUB^2, we use text spans as substructures, with both the *number of words* in the span and the *text classification label* as constraints (see Sec. 3.2).

Figure 1: Illustration of SUB^2 for investigated tasks. We generate new examples by same-label substructure substitution, whether or not the generated examples are semantically or syntactically acceptable. Best viewed in color.

2 Related Work

Data augmentation aims to generate new examples based on available ones, without actually collecting new data. Such methods reduce the cost of dataset collection, and usually boost model performance on desired tasks. Most existing data augmentation methods for NLP tasks can be classified into the following categories:

Token-level manipulation. Token-level manipulation methods have been widely studied in recent years. They typically create new examples by substituting (word) tokens with ones having the same desired features, such as synonym substitution (Zhang et al., 2015; Wang and Yang, 2015; Fadaee et al., 2017; Kobayashi, 2018) or substitution with words having the same morphological features (Silfverberg et al., 2017). Such methods have been applied to generate adversarial or negative examples which help improve the robustness of neural network–based NLP models (Belinkov and Bisk, 2018; Shi et al., 2018a; Alzantot et al., 2018; Zhang et al., 2019; Min et al., 2020, *inter alia*), or to generate counterfactual examples which help mitigate bias in natural language (Zmigrod et al., 2019; Lu et al., 2020).

Other token-level manipulation methods introduce noise, such as random token shuffling and deletion (Wang et al., 2018; Wei and Zou, 2019; Dai and Adel, 2020). Models trained on the augmented datasets are expected to be more robust against the considered noise.

Constrained text generation. Recent work has explored generating new examples by training a conditional text generation model (Bergmanis et al., 2017; Liu et al., 2020a; Ding et al., 2020; Liu et al., 2020b, *inter alia*), or applying post-processing on the examples generated by pretrained models (Yang et al., 2020; Wan et al., 2020; Yoo et al., 2020). In the data augmentation stage, given task-specific constraints, such models generate associated text accordingly. The generated examples, together with the original datasets, are used to further train models for the primary tasks. A representative method is back-translation (Sennrich et al., 2016), which is effective for not only machine translation, but also style transfer (Prabhumoye et al., 2018; Zhang et al., 2020a), conditional text generation (Sobrevilla Cabezudo et al., 2019), text classification (Iyyer et al., 2018), and grammatical error correction (Xie et al., 2018). Relatedly, automatic question generation has been used in data augmentation for question answering (Yang et al., 2017; Song et al., 2018).

Another approach to example generation is to generate new examples based on predefined templates (Kafle et al., 2017; Asai and Hajishirzi, 2020), where the templates are designed following heuristic, and usually task-specific, rules.

Soft data augmentation. As an alternative to explicit generation of concrete examples, soft augmentation directly represents generated examples in a continuous vector space: Gao et al. (2019) propose to perform soft word substitution for machine translation; recent work has adapted the mixup method (Zhang et al., 2018), which augments the original dataset by linearly interpolating the vector representations of text and labels, to text classification (Guo et al., 2019; Sun et al., 2020), named entity recognition (Chen et al., 2020), and compositional generalization (Guo et al., 2020).

Structure-aware data augmentation. Existing work has also sought potential gain from structures associated with natural language: Xu et al. (2016) improve word relation classification by dependency path–based augmentation. Şahin and Steedman (2018) show that subtree cropping and rotation based on dependency parse trees can help part-of-speech tagging for low-resource languages, while Vania et al. (2019) demonstrate that such methods also help dependency parsing when very limited training data is available.

SUB^2 also falls into this category. The idea of same-label substructure substitution has been used to improve performance on structured prediction tasks such as semantic parsing (Jia and Liang, 2016), constituency parsing (Shi et al., 2020), dependency parsing (Dehouck and Gómez-Rodríguez, 2020), named entity recognition (Dai and Adel, 2020), meaning representation–based text generation (Kedzie and McKeown, 2020), and compositional generalization (Andreas, 2020). To the best of our knowledge, however, SUB^2 has not been systematically studied as a general data augmentation method for NLP tasks. In this work, we not only extend SUB^2 to part-of-speech tagging and structured sentiment classification, but also present a variation that allows a broader range of NLP tasks (e.g., text classification) to benefit from syntactic parse trees. We evaluate SUB^2 and several representative general data augmentation methods, which can be widely applied to various NLP tasks.

When constituency parse trees are used, there is a connection between SUB^2 and tree substitution grammars (TSGs; Schabes, 1990), where the approach can be viewed as (1) estimating a TSG using the given corpus and (2) drawing new sentences from the estimated TSG.

3 Method

We introduce the general framework we investigate in Section 3.1, and describe the variations of SUB^2 which can be applied to text classification and other NLP applications in Section 3.2.

3.1 Substructure Substitution (SUB^2)

As shown in Figure 1, given the original training set $\mathcal{D}$, SUB^2 generates new examples using same-label substructure substitution, and repeats the process until the training set reaches the desired size. The general SUB^2 procedure is presented in Algorithm 1.

Algorithm 1: SUB^2.

```
Input: Original dataset $\mathcal{D}$,
desired dataset size $N > |\mathcal{D}|$
Output: Augmented dataset $\mathcal{D}'$
$\mathcal{D}' \leftarrow \mathcal{D}$;
repeat
    Uniformly draw $s \in \mathit{substructure}(\mathcal{D}')$
    $S \leftarrow \mathit{example}(s)$
    Uniformly draw $u \in \{v \mid v \in \mathit{substructure}(\mathcal{D}), \mathit{label}(v) = \mathit{label}(s), v \neq s\}$
    $S' \leftarrow$ replace $s$ with $v$ in $S$
    $\mathcal{D}' \leftarrow \mathcal{D}' \cup \{S'\}$
until $|\mathcal{D}'| = N$;
```

For part-of-speech (POS) tagging, we let text spans be substructures and use the corresponding POS tag sequences as substructure labels (Figure 1a); for constituency parsing, we use subtrees as the substructures, with constituent labels as the substructure labels (Figure 1b); for dependency parsing, we also use subtrees as substructures, and let the dependency arc labels, which link the heads of subtrees to their parents, be the substructure labels (Figure 1c).

3.2 Variations of SUB^2 for Text Classification

Text classification examples do not typically contain explicit substructures. However, we can obtain them by viewing all text spans as substructures (Figure 1d). This approach may be too unconstrained in practice, so we consider constraining substitution based on matching several features of the spans:

- **Text classification label**: when considering this constraint, we can only substitute a span with another span that comes from text annotated with the same class label as the original one; otherwise we can choose the alternative from any example text in the training corpus.
- **Constituency**: when considering this constraint, we can only substitute a constituent with another constituent (according to a constituency parse of the text, whether they have the same constituent label or not); otherwise the considered spans do not necessarily need to be constituents.
- **Annotated text span label**: in our experiments, this constraint is valid only when the previous constraint (constituency) is considered. When considering this constraint, we can only perform substitution between text spans with the same annotated label (e.g., constituent label).[2]
- **Number of words**: when considering this constraint, we can only substitute a span with another having the same number of words; otherwise we can substitute a span with any other span.

Shi et al. (2018b) argue that binary balanced trees are better backbones for recursive neural networks (Zhu et al., 2015; Tai et al., 2015) on text classification; inspired by them, we introduce the following constraint in this work:

- **"Constituency" in binary balanced tree.** we use binary balanced trees, analogously to constituency parse trees, as the backbone for SUB^2: we (1) generate balanced trees by recursively splitting a span of n words into two consecutive groups, which consist of $\lfloor \frac{n}{2} \rfloor$ and $\lceil \frac{n}{2} \rceil$ words respectively, and (2) treat each nonterminal in the balanced tree as a substructure to perform SUB^2.

We also investigate combinations of the above constraints, where we require all the chosen constraints to be the same to perform SUB^2. For example, combining *text classification label* and *number of words* (Figure 1d) requires the original and the alternative span to have the same text label and the same number of words.

4 Experiments

We introduce our experimental setups (Section 4.1), and evaluate SUB^2 and several data augmentation baselines (Section 4.2) on four tasks: part-of-speech tagging (Section 4.3), dependency parsing (Section 4.4), constituency parsing (Section 4.5), and text classification (Section 4.6).

4.1 Setup

For part-of-speech tagging and text classification, we add a two-layer perceptron on top of XLM-R (Conneau et al., 2019) embeddings, where we calculate contextualized token embeddings by a learnable weighted average across layers. We use endpoint concatenation (i.e., the concatenation of the first and last token representation) to obtain fixed-dimensional span or sentence features, and keep the pretrained model frozen during training.[3] For dependency parsing, we use the SuPar implementation of Dozat and Manning (2017).[4] For constituency parsing, we use Benepar (Kitaev and Klein, 2018).[5]

For all data augmentation methods, including the baselines (Section 4.2), we only augment the training set, and use the original development set. If not specified, we introduce 20 times more examples than the original training set when applying an augmentation method. When introducing $k\times$ new examples, we also replicate the original training set k times to ensure that the model can access sufficient examples from the original distribution.

All models are initialized with the XLM-R base model (Conneau et al., 2019) if not specified. We train models for 20 epochs in high-resource settings (i.e., high-resource part-of-speech tagging, sentiment classification trained on the full training set) or when applying data augmentation methods, and for 400 epochs in the low-resource settings without augmentation; we select the one with the highest accuracy or F_1 score on the development set. All models are optimized using Adam (Kingma and Ba, 2015), with learning rates cho-

---

[2] There can be other text span labels such as sentiment labels of constituents (Socher et al., 2013).

[3] We did not observe significant improvement by finetuning the large pretrained language model, and for most cases, the performance is much worse than the current scheme we apply.

[4] `https://github.com/yzhangcs/parser`

[5] `https://github.com/nikitakit/self-attentive-parser`

sen from $\{5 \times 10^{-4}, 5 \times 10^{-5}\}$. For the hidden layer size (i.e., the hidden size of the perceptron for part-of-speech tagging and text classification, the dimensionality of span representation and scoring multi-layer perceptron for constituency parsing, and the dimensionality of token representation and scoring multi-layer perceptron for dependency parsing), we vary it between 128 and 512. We apply a 0.2 dropout ratio to the contextualized embeddings in the training stage. All other hyperparameters are the same as the default settings in the released codebases.

4.2 Baselines

We compare Sub^2 to the following baselines:

- **No augmentation** (NoAug), where the original training and development set are used.

- **Contextualized substitution** (CtxSub), where we apply contextualized augmentation (Kobayashi, 2018), masking out a random word token from the existing dataset and using multilingual BERT (mBERT; Devlin et al., 2019) to generate a different word.

- **Knowledge based guided synonym substitution** (Syno), where we substitute a random word token by its synonym defined in an existing knowledge base.[6]

- **Random shuffle** (Shuf), where we randomly shuffle all the words in the original sentence, while keeping the original structured or non-structured labels. It is worth noting that for dependency parsing, we shuffle the words, while maintaining the dependency arcs between individual word tokens; for constituency parsing, we shuffle the terminal nodes, and insert them back into the tree structure. Our Shuf method for constituency parsing is arguably more noisy than that for dependency parsing.

All of the data augmentation baselines are explicit augmentations where concrete new examples are generated and used. The methods above are generally applicable to a wide range of NLP tasks.

Table 1: Part-of-speech tagging accuracy (×100) on the standard test set of UD 1.2 high-resource (top) and low-resource (bottom) languages, across different pretrained models and augmentation methods. The best numbers in each row are bolded. SoTA: previous state of the art, i.e., the best test accuracy for each language among all methods reported by Heinzerling and Strube (2019), where all numbers in the SoTA column are not necessarily produced by the same model. † denotes new state-of-the-art results.

4.3 Part-of-Speech Tagging

We conduct our experiments using the Universal Dependencies (UD; Nivre et al., 2016, 2020)[7] dataset.

First, we compare both NoAug and Sub^2 to the previous state-of-the-art performance (Heinzerling and Strube, 2019) to ensure that our baselines are strong enough (Table 1).[8] Heinzerling and Strube (2019) take the token-wise concatenation of mBERT last-layer representations, byte-pair en-

---

[6] Specifically, we use the lexical PPDB-XL (Ganitkevitch and Callison-Burch, 2014; Pavlick et al., 2015) of the appropriate language when applicable.

Table 2: Part-of-speech tagging accuracy (×100) on the standard test set of selected UD 2.6 low-resource treebanks. The best number in each row is bolded.

coding (BPE; Gage, 1994)–based LSTM hidden states and character-LSTM hidden states as the input to the classifier, and fine-tune the pretrained mBERT during training. We find that using our framework with frozen mBERT and extra learnable layer weight parameters, we are able to obtain competitive or better results than those reported by Heinzerling and Strube (2019); the gains grow larger when using XLM-R, which is trained on larger corpora than mBERT. In addition, by augmenting the training set with Sub^2, we achieve better average accuracy on low-resource languages (paired, one-tailed t-test p-value$=0.028$) while remaining competitive on high-resource languages (no statistically significant difference).

We further test the part-of-speech tagging accuracy on 5 selected low-resource treebanks in the UD 2.6 dataset (Table 2), following the official splits of the dataset. For four of the five treebanks, Sub^2 achieves the best performance among all methods, while also maintaining competitive performance on the Telugu treebank. In contrast, other augmentation methods (CtxSub and Shuf) are harmful compared to NoAug on all treebanks.

4.4 Dependency Parsing

We evaluate the performance of models using the standard Penn Treebank dataset (PTB; Marcus et al., 1993), converted by Stanford dependency converter v3.0,[9] following the standard splits.

We first compare the performance of Sub^2 and baselines in the low-resource setting (Table 3). All methods sometimes, though not always, improve performance over NoAug. Shuf achieves the best LAS when there is only an extremely small training set (e.g., 10 examples) available; however, when the size of the original training set becomes larger, Sub^2 begins to dominate, while CtxSub and Shuf start to sometimes hurt the performance. In addition, a larger augmented dataset does not necessarily lead to better performance, but CtxSub and Shuf often hurt performance as the augmented set size gets too large while Sub^2 does not. Although there is not a consistently best configuration, throughout our experiments, augmenting by 10×–50× the original dataset size produces good improvements over NoAug for both development and test sets. When tuning the augmentation factor k using small development sets, Sub^2 improves over NoAug for four out of five seed dataset sizes. CtxSub, in contrast, improves performance for only one out of five.

$\|\mathcal{D}'\| = k \times \|\mathcal{D}\|$	10	50	$\|\mathcal{D}\|$ 100	500	1,000
2× (CtxSub)	38.3	55.1	$\underline{62.9}$	78.1	80.1
5× (CtxSub)	35.5	$\underline{55.9}$	62.1	81.4	$\underline{81.0}$
10× (CtxSub)	$\underline{\mathbf{39.8}}$	55.1	61.7	$\underline{81.7}$	80.8
50× (CtxSub)	31.2	52.3	60.9	79.3	78.0
100× (CtxSub)	32.0	53.1	58.2	77.1	75.9
2× (Shuf)	32.8	$\underline{55.9}$	62.5	76.7	78.4
5× (Shuf)	34.4	52.7	60.5	77.5	81.6
10× (Shuf)	$\underline{\mathbf{39.8}}$	53.1	$\underline{\mathbf{63.7}}$	77.9	$\underline{81.9}$
50× (Shuf)	34.0	52.7	60.9	79.1	79.6
100× (Shuf)	39.1	55.9	61.3	$\underline{80.4}$	77.4
2× (Sub^2)	$\underline{38.3}$	54.3	61.7	81.0	80.0
5× (Sub^2)	35.9	54.7	62.9	$\underline{\mathbf{82.5}}$	80.4
10× (Sub^2)	32.0	53.9	$\underline{\mathbf{63.7}}$	81.7	80.6
50× (Sub^2)	33.2	$\underline{\mathbf{57.0}}$	62.5	81.4	$\underline{\mathbf{82.5}}$
100× (Sub^2)	38.3	52.7	62.5	78.8	82.1

Table 3: Labeled attachment scores (LAS) on the standard PTB development set (PTB Section 22). We start with an original training set $\mathcal{D}$, which consists of $|\mathcal{D}| \in \{10, 50, 100, 500, 1000\}$ examples, and augment it $k \in \{2, 5, 10, 50, 100\}$ times. For each training set $\mathcal{D}$, the corresponding development set consists of $\max\left(10, \frac{|\mathcal{D}|}{10}\right)$ examples. Underlined results correspond to k values tuned to maximize development set LAS for each combination of augmentation method and $|\mathcal{D}|$ (if there are multiple k values with the same development LAS, we choose the smallest). The best number in each column is bolded.

When training on the full WSJ training set, Sub^2 does not necessarily help improve over NoAug, but it also does not hurt performance (Table 4).[10]

---

[9] `https://nlp.stanford.edu/software/stanford-dependencies.shtml`

[10] An additional finding here is that a simple biaffine dependency parsing model (Dozat and Manning, 2017) with XLM-R initialization is able to set a new state of the art for dependency parsing with only in-domain annotation.

Model	UAS	LAS
Mrini et al. (2020)† (NoAug)	97.4	96.3
Zhang et al. (2020b)‡ (NoAug)	96.1	94.5
BiAffine+XLM-R (NoAug)	96.7	95.2
BiAffine+XLM-R+Sub^2	96.6	95.2

Table 4: Unlabeled attachment score (UAS) and labeled attachment score (LAS) on the PTB dependency test set. Models are trained with the full PTB training set. †: the previously best result using any kind of annotation (e.g., constituency parse trees); ‡: the previously best result using only dependency annotations. BiAffine: the bi-affine dependency parsing model proposed by Dozat and Manning (2017).

4.5 Constituency Parsing

Shi et al. (2020) have shown that Sub^2 can significantly improve few-shot constituency parsing on the Penn Treebank dataset; in this work, we extend the few-shot parsing evaluation to other domains, using the Foreebank (FBank; Kaljahi et al., 2015) and NXT-Switchboard (SWBD; Calhoun et al., 2010) datasets. Foreebank consists of 1,000 English and 1,000 French sentences; for either language, we randomly select 50 sentences for training, 50 for development, and 250 for testing.[11] We follow the standard splits of NXT-Switchboard, and randomly select 50 sentences from the training set and 50 from the development set for training and development respectively.

We compare data augmentation methods using the setup of few-shot parsing from scratch (Table 5). Among all settings we tested, Sub^2 achieves the best performance, while all augmentation methods we investigated improve over training only on the original dataset (NoAug). Surprisingly, we find that the seemingly meaningless Shuf, which randomly shuffles the sentence and inserts the shuffled words back into the original parse tree structure as the nonterminals, also consistently helps few-shot parsing by a nontrivial margin.[12]

For domain adaptation (Table 6), we first train Benepar (Kitaev and Klein, 2018) on the Penn Treebank dataset, achieving an F_1 score of 95.1 on the PTB standard development set, and use the pretrained model as the initialization. While compared to few-shot parsing trained from scratch, the gain by data augmentation generally becomes smaller, Sub^2 still works the best across datasets.

Method	FBank(en)	FBank(fr)	SWBD
NoAug	33.1	27.3	29.1
CtxSub	64.8	59.9	51.1
Syno	62.9	60.8	52.1
Shuf	55.9	48.8	37.0
Sub^2	**71.8**	**70.8**	**64.6**

Table 5: Labeled F_1 scores ($\times 100$) on the test set of each constituency treebank, in the setting of few-shot parsing. The best number in each column is bolded.

Method	FBank(en)	FBank(fr)	SWBD
PTB	82.3	30.8	74.3
NoAug$\rightarrow$	83.1	70.1	77.2
CtxSub $\rightarrow$	84.0	71.1	78.2
Syno $\rightarrow$	84.2	71.0	77.9
Shuf $\rightarrow$	83.5	70.1	75.6
Sub^2 $\rightarrow$	**84.6**	**72.6**	**78.3**

Table 6: Labeled F_1 scores ($\times 100$) on the test set of each constituency treebank, in the setting of domain adaptation. PTB: directly testing the model trained on the Penn Treebank; $\rightarrow$: transferring a model trained on PTB to each domain. The best number in each column is bolded.

4.6 Text Classification

We take text classification as a representative of a wider range of NLP tasks, and evaluate the methods introduced in Section 3.2 and baselines on low-resource versions of two text classification datasets: SST (Socher et al., 2013) and a sentence version of the AG News dataset (Zhang et al., 2015).[13] To avoid over-fitting to the small development set and tuning on test set issues, we introduce small "development test" (devtest) sets for each task, and only evaluate on the test sets using Sub^2 variations with the best devtest performance. For settings requiring constituency parse trees, we generate them using Benepar (Kitaev and Klein, 2018) trained on the standard PTB dataset.

Across the two datasets, any data augmentation technique usually improves over NoAug (Table 7).[14] While methods in the Sub^2 family usually lead to the best performance on both tasks, there is not a consistently best-performing combination of constraints. Surprisingly, Sub^2 without constraints

---

[11] We leave the other 650 sentences for future use.

[12] This trend may be explained by benefits in learning/optimization stability in this few-shot setting, but we leave a richer exploration of potential explanations for future work.

[13] We only keep the single-sentence instances among all examples in each split of the original AG News dataset, following Shi et al. (2018b).

[14] To measure variance due to random selection of data from the full sets, results on additional randomly-sampled few-shot datasets for both tasks can be found in Appendix A.

Dataset	Method	Constraints				Accuracy		
		Text Label	*Constit.*	*Span Label*	*#Words*	*Dev*	*Devtest*	*Test*
AG News-1%	NoAug	N/A	N/A	N/A	N/A	55.2	44.8	44.8
$\lvert\mathcal{D}_{train}\rvert = 0.6$K	CtxSub	N/A	N/A	N/A	N/A	91.0	89.6	86.0
$\lvert\mathcal{D}_{dev}\rvert = 0.06$K	Syno	N/A	N/A	N/A	N/A	89.6	89.6	85.6
$\lvert\mathcal{D}_{devtest}\rvert = 0.06$K	Shuf	N/A	N/A	N/A	N/A	91.0	88.1	86.3
	Sub^2 (balanced tree)	✗	N/A	N/A	✓	88.1	**92.5**	86.7
	Sub^2	✓	✓	✗	✗	91.0	**92.5**	**87.0**
SST-10%	NoAug	N/A	N/A	N/A	N/A	27.3	35.5	23.3
$\lvert\mathcal{D}_{train}\rvert = 0.8$K	CtxSub	N/A	N/A	N/A	N/A	40.0	53.6	44.9
$\lvert\mathcal{D}_{dev}\rvert = 0.1$K	Syno	N/A	N/A	N/A	N/A	40.0	39.1	39.0
$\lvert\mathcal{D}_{devtest}\rvert = 0.1$K	Shuf	N/A	N/A	N/A	N/A	37.3	44.5	38.9
	Sub^2 (balanced tree)	✗	N/A	N/A	✗	40.0	50.0	44.6
	Sub^2	✓	✓	sentiment	✗	40.0	**55.5**	**45.8**

Table 7: Accuracy (×100) on the low-resource sentence AG News and SST datasets, together with the corresponding constraints, where *Constit.* denotes constituency labels. We enumerate multiple constraints for data augmentation with Sub^2, and only test the obtained model with the highest devtest accuracy – results for all investigated combinations of constraints can be found in Appendix A. The best devtest accuracies and the best test accuracy for each dataset are bolded.

Method	Dev. Acc.	Test Acc.
XLM-R (NoAug)	56.1	55.7
XLM-R (Sub^2)	**56.6**	**56.6**
Brahma (2018)	N/A	56.2

Table 8: Accuracy (×100) on the SST standard development and test set.

on the text label, which may introduce more noise than having the constraint, does not necessarily hurt the performance much.

While constituency parse tree–based Sub^2 typically achieves competitive performance among all investigated combinations of constraints, the gain over Sub^2 with balanced trees is not consistent. Our results are in line with Shi et al. (2018b).

We further use Sub^2 with constraints of (1) text label, (2) phrase, and (3) phrase sentiment label, to augment the full SST training set, since it is the best augmentation method for few-shot sentiment classification, in terms of devtest accuracy (Table 7). In addition to sentences, we also add phrases (i.e., subtrees) as training examples, following most existing work (Socher et al., 2013; Kim, 2014; Brahma, 2018, *inter alia*),[15] to boost performance. In this setting, we find that Sub^2 helps set a new state of the art on the SST dataset (Table 8).

5 Conclusion and Future Work

We investigate substructure substitution (Sub^2), a family of data augmentation methods that generates new examples by same-label substructure substitution. Such methods help achieve competitive or better performance on the tasks of part-of-speech tagging, dependency parsing, constituency parsing, and text classification in the few-shot setting, where the number of annotated examples is limited. While other data augmentation methods (e.g., CtxSub and Shuf) sometimes improve the performance, Sub^2 is the only one that consistently improves performance for low-resource NLP across tasks and seed dataset sizes. The experimental setups used in this work can further serve as a standard benchmark for future work on NLP with limited annotations.

There are two open questions remaining to be addressed. First, it is still unclear why Shuf, which requires the model to recover the correct constituency parse tree of a sentence while only accessing shuffled words, consistently helps improve few-shot constituency parsing by a nontrivial margin. Second, while constituency parse tree–based Sub^2 sometimes achieves better performance than Sub^2 without the constituency constraint, the advantage is not large: whether explicit constituency parse trees are useful for NLP applications in the neural network era remains an open question. We leave the above questions, as well as applications of Sub^2 to more NLP tasks, for future work.

---

[15] That is, unlike in Table 7, we apply the same settings as most existing work to produce numbers in Table 8.

6 Acknowledgment

We thank Jiayuan Mao, Shane Settle and Bowen Shi for helpful suggestions on this work, Yu Zhang for fruitful discussion regarding dependency parsing, as well as anonymous reviewers for their valuable feedback.

Towards Protecting Vital Healthcare Programs by Extracting Actionable Knowledge from Policy

Abstract

In challenging economic times, obtaining value for money by ensuring financial integrity and fairer distribution of services are among the top priorities for social and health-care systems globally. However, healthcare billing policies are complex and identifying non-compliance is often narrow-scope, manual and expensive. Maintaining 'integrity' is a challenge - ensuring that scarce resources get to those in need and are not lost to fraud and waste. Our approach fuses recent advances in dependency parsing with a policy ontology to convert the content of regulatory healthcare policy into human-friendly policy rules, that are amenable to machine-execution, with human oversight. We describe the ontology-guided transformation of textual patterns into a semantically-meaningful knowledge graph of rules, outline our experiments and evaluate results against policy rules obtained from professional investigators. The aim is to make a policy-compliance 'landscape' visible to healthcare programs - helping them identify Fraud, Waste or Abuse.

1 Introduction

The WHO (World Health Organization, 2010) lists fairness, financial integrity ["Program Integrity"] and access in healthcare among the top global healthcare priorities. In the U.S., an estimated annual amount of USD$20-30B is lost to **Fraud, Waste and abuse (FWA)** (Shrank et al., 2019). These vital funds never make it to the vulnerable citizens that they were intended to serve.

To combat this, countries with insurance-based healthcare programs (e.g. Medicaid, Medicare), employ claim investigators to validate the integrity of reimbursement claims submitted by providers. Investigators verify these claims against the program's policies, with the goal of reducing wasteful practices, identifying fraud or abuse and closing policy gaps. This is a labor-intensive task – claim volumes are high, policies are complex and investigative resources are limited.

More broadly, governments regulate a wide range of sectors, with extensive rules and policies. These policies drive significant spending by the regulated organizations. e.g., a European Union Commission study (2019) found that the annual cost of complying with EU financial regulations is around EUR€11.3B. In Australia, Deloitte (2014) estimated the costs of administering and complying with public sector rules at AUD$94B.

In this paper we propose a methodology for automatically extracting knowledge from healthcare policy documents, in the form of **Benefit Rules (BRs)** that are both human-understandable and machine consumable. These BRs can be applied automatically to flag discrepancies in claims, with limited human effort. This paper focuses on the extraction of these rules, and not their execution.

Policy rules have a major impact both on the health of the citizens they serve, and the financial integrity of the Programs that pay the Service Providers. Human-understanding, oversight and control are first-class AI-design concerns for this domain. Model 'explainability' is not enough. Transparency is needed anywhere that provider or citizen coverage is at stake. Users need to see and influence which rules are being applied, and on what policy basis decisions are being made.

To achieve this, we anchor our methodology in an ontology[1], that both guides and constrains AI extraction tasks. We build on recent NLP advances

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3509–3521
August 1–6, 2021.

to identify patterns in dependency paths that connect relevant entities.

Finally, we transform the dependent entities into knowledge-graph fragments, which are assembled into graphs that represent actionable Benefit Rules. Users can curate these rules as they are well-structured and expressed in familiar terms.

Automated extraction of these rules from high-volume policies (e.g., Medicaid), will enable the emergence of a new generation of tools for safeguarding Program Integrity, e.g. execution of these rules against claims data enables an overview of the 'policy-compliance landscape' that does not exist today.

Section 2 presents Rules as Code and related work in knowledge extraction for social good. Section 3 describes domain requirements. Section 4 presents the architecture for our 'Claim Audit' extraction pipeline. Section 5 describes how dependency parsing and the ontology are used to extract semantically-rich rule fragments. In Section 6 we evaluate our results with professional policy investigators using dental policies, and in Section 7, we present future work.

2 Related Work

2.1 Rules As Code (RaC)

Organizations need novel approaches to help with regulatory compliance, and **Rules as Code (RaC)** is an initiative that envisages *"an official version of rules (e.g., laws and regulations) in a machine-consumable form, which allows rules to be understood and actioned by computer systems in a consistent way"* (Mohun et al., 2020). It forms part of a broad movement towards digital government and has garnered broad public-sector interest.

Approaches to achieving machine-executable RaC rules for published legislation run from manual coding by multi-disciplinary teams to automatic code-generation from natural-language legislation (Mohun et al., 2020). The former approach brings legislative drafters, policy analysts and software developers together to co-produce human and machine-consumable versions of rules. Examples include the New Zealand Better Rules Discovery initiative (Digital Government NZ, 2018) and OpenFisca (OpenFisca.org, nd) in France. The latter approach uses NLP technology to assist policy experts in converting policy texts to machine-consumable forms, helping scale the RaC process, and is being explored by the AustLII's DataLex Project *(*Greenleaf et al., 2020*)* and CSIRO Data61's Regulation as a Platform project (Data61, 2019*)*. Our work involves taking this latter approach for government healthcare insurance policy.

2.2 Knowledge Extraction for Social Good

Related to our work, Kiyavitskaya et al. (2018) extracts right, obligation, exception and constraints from legal documents by annotating entities with a domain-specific ontology consisting of entity vocabulary and normative phrasal templates built manually by domain experts. Dragoni et al. (2016) parses sentences into grammar trees using Stanford NLP, and annotates legal concepts with a manually-built ontology. The annotation is turned into rules using a set of hand-crafted rules.

Our work is similar, but we extract tuples from dependency trees and reason over the ontology to produce a Benefit Rule knowledge graph.

Recent efforts to build graphs for social good include (Assom, 2020) - constructing knowledge graphs to extract food-trading activities for sustainable food trading and security. Puri et al. (2020) discusses challenges in extracting knowledge graphs from UN datasets for sustainable development goals. Khetan et al. (2020) describes the use of NLP tools like Spacy, CoreNLP, ClausIE and OpenIE to extract information from unstructured text provided by the UN. Kejriwal et al. (2017) constructs a knowledge graph that supports a semantic search engine for investigators in human-trafficking.

AI for social good is a broad research topic as described in Shi et al. (2020). For public health, Nordon et al. (2019) uses biomedical knowledge graph for drug discovery. Finally, Percha and Altman (2018) connect entity-pair dependency paths to extract relations between chemicals, genes and diseases.

Our focus is on AI and knowledge-extraction to help combat FWA in healthcare programs. Today, FWA detection generally relies on two approaches. Firstly, traditional data mining to identify outliers and anomalous billing patterns in claims (Joudaki et al., 2015). While valuable, this approach presents challenges when building legal cases, as it is not innately grounded in policy. Secondly, hand-coded algorithms written by analysts to find claims that are not compliant with policy. These are labor-intensive to develop and maintain in the face of ever-evolving policy. Worse, they cover only a small fraction of the policy ‘landscape’, resulting in a prioritization catch-22 - algorithms are needed in order to know which areas most need algorithms.

3 Background and Requirements

Despite the variety of ways that Benefit Rules (BRs) are expressed across healthcare policies, experts know the common entities, relationships and logical constraints that underpin them. To extract BRs that are correct, human-friendly and executable, we need to account for these semantics. Popular generic language models do not capture such implicit knowledge and expert-labeled datasets are expensive to develop (and small).

We apply these semantics via a BR ontology co-created with domain experts as described in (Lopez et al., 2019). The ontology guides the extraction of well-structured, consistent knowledge graphs from the policy. It links relevant entities together with their context in sentences, e.g., take the policy paragraph and its ontology subset shown in Figure 1. To extract the two distinct Benefit Rules shown in Figure 2, the two distinct roles of the service ‘*full-mouth debridement*’ must be recognized. Widely-adopted medical terminology standards (e.g. UMLS, CPT, HCPCS) can be attached to ontology concepts for consistent representation and mapping of billing codes/values in a BR.

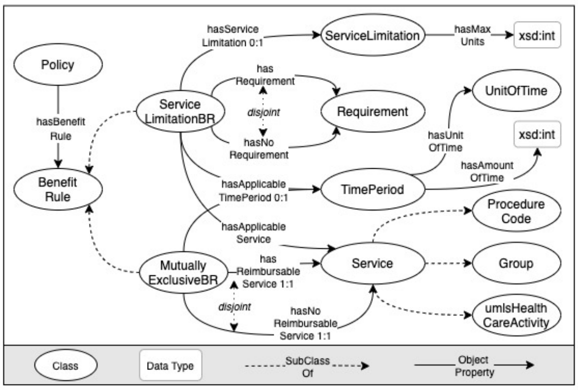

Figure 1: Ontology subset describing the policy: *Full-mouth debridement to enable comprehensive periodontal evaluation and diagnosis is a covered service and does not require prior approval. It is payable once in a 24-month period. Full-mouth debridement is not payable on the same date of services as other prophylactic or preventative procedures*

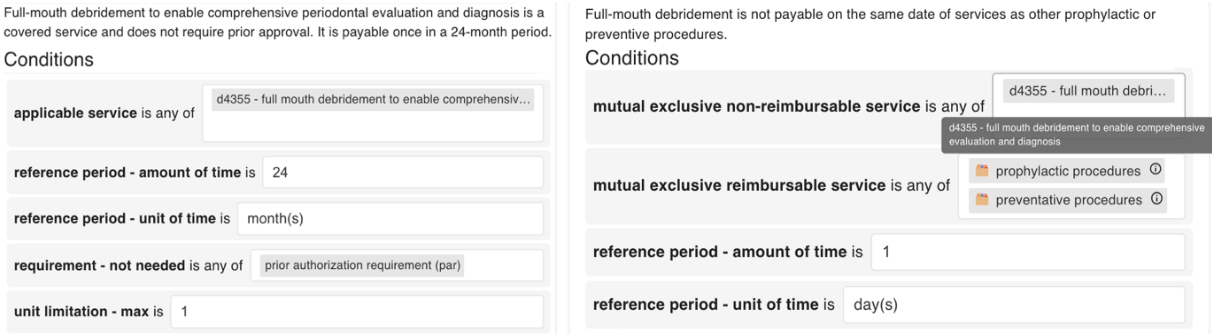
Human understanding and control are also key requirements. Policy can be challenging to interpret, and amenable to mis-interpretation or mis-application. Expert operators must be able to understand the policy provenance and correct any incorrectly-extracted BRs. The ontology powers this 'explainability' in two ways. Firstly, by enabling consistently-structured knowledge graphs to be extracted from inconsistent policy representations, removing ambiguities between the rules interpretation and policy intent. Secondly – by expressing them simply, using familiar user concepts. All our graphs can be presented as a set of simple, editable condition-value pairs, as in Figure 2. This is achieved by 'flattening' the graph - taking only the leaf properties and values. While our UI needs visual design, users report that these representations 'feel right' and that correcting extraction errors/omissions is straightforward.

Finally, extracted BRs must be amenable to execution - i.e., converted into a form that can automatically label claims as policy-compliant (or not). Here again, the ontology helps by mapping each condition to consistent constraints - this time for the selection, filtering and aggregation of claims data. While beyond the scope of this paper, our work to-date suggests that ontology-conforming BRs execute with similar accuracy to algorithms hand-written by claim investigators. (Of course, execution accuracy will still also depend on accuracy of automated extraction and human curation).



Full-mouth debridement to enable comprehensive periodontal evaluation and diagnosis is a covered service and does not require prior approval. It is payable once in a 24-month period.

On the right: a Mutually Exclusive BR on services that cannot be billed together in a given period

4 Proposed Extraction Pipeline

We propose a methodology to extract Benefit Rules from policy automatically. Figure 3 presents the main components, from policy enrichment to ontology-guided knowledge extraction and user validation. All steps in the pipeline are configurable - similar functional components can easily be replaced/added. We give an overview for each step, the functionality and data requirements:

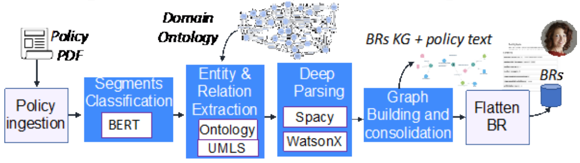

Figure 3. Pipeline from extraction of Benefit Rules

Data preparation and Policy ingestion: all domain information is captured in the ontology, so the technical components remain domain agnostic. While the ontology schema generalises across many policies, instance data is domain-specific and must be prepared ('lifted'). Some instances are common across policy areas and states, such as an eligible 'Place of Service' (e.g. *hospital)* (Centers for Medicare & Medicaid, n.d.). Other instance data is specific to the target domain, such as 'body parts' for tooth identifiers in dental claims. These can be automatically 'lifted' into the ontology from tabular data sources containing a main entity, a list of surface forms (to address vocabulary heterogeneity) and other attributes. They are added as individuals of a given entity type on application startup, and according to a user-configurable mapping. The lexicalizations are made available when processing policy text and identifying entity mentions. New instance data can be added as the need arises

Next, PDF policies are transformed into enriched HTML using an off-the-shelf conversion tool (compare and comply, n.d.), outlining headings, passages and paragraphs for later use at passage-level by annotators and extractors, as well as at paragraph-level by the classification and consolidation.

Segment Classification: a classifier optionally filters incoming paragraphs, deciding whether they are likely to contain BRs. This can significantly reduce compute-time and can also improve Precision, at the cost of some Recall. This is the only component in the pipeline that requires enough ground truth data on (validated) BRs and the associated paragraphs to fine-tune deep learning models. In section 6 we evaluate a fine-tuned, BERT-based classifier.

Entity & Relation Extraction: Here, candidate ontology entities/types are annotated in the text by two complementary annotators. The first is based on WatsonX (Kalyanpur et al., 2012) , a generic entity and UMLS-based clinical annotator. A Lucene search index is used to find approximate matches for any annotated entities (verbs, noun-phrases, etc.), in the ontology lexicalizations. It is also used to retrieve semantic types (e.g. diseases) relevant to benefit rules, from terminology services such as UMLS (UMLS semantic hierarchy, nd).

The second - SystemT (Chiticariu et al., 2018), extracts entity mentions from dictionaries and regular expressions. These are built automatically, from the instances 'lifted' into the ontology at initialization time, as described earlier. This enables entity mentions to be matched with complex labels, like '*Full-mouth debridement to enable comprehensive periodontal evaluation and diagnoses'*. All lexicalizations in the ontology are useful to address vocabulary heterogeneity.

Annotators label these textual spans with specific ontology labels (URIs) and other useful information (lemma, POS, UMLS type, etc). These annotations can later be used to simplify the dependency trees of sentences containing complex entities. Since there can be overlapping annotations and competing annotations for the same span, heuristics are used – e.g. 'longest span', or preferring exact matches to approximate ones. Disambiguation is otherwise performed later.

Deep Parsing and Graph Building: In this step, BR knowledge graphs are obtained by combining dependency trees together with the annotations, in an ontology-guided way. First, linguistic links are identified between annotated entities. Then, these are converted into semantic triples and linked together into knowledge graph fragments by reasoning over the ontology. Fragments from different sentences in a paragraph are **consolidated** together to produce a set of well-formed Benefit Rule knowledge graphs that respect the ontology semantics. Finally, to enable human oversight and control, all knowledge graphs are 'flattened' into a user-friendly, editable format. The ability to do this flattening is a key 'explainability' property of the ontology structure and thus, of knowledge graphs derived from it. The extracted and curated rules are then stored in a Knowledge Base.

User Validation: extracted BRs are shown to investigators in a prototype workbench. Here they can be reviewed against the corresponding policy text and corrected when necessary. Validated BRs form a shared store of high-quality, machine-readable rules, making the rule creation and consumption process more transparent. In a related work, we execute these rules on claims data to discover inappropriate payments. This shortens the investigator's workflow by giving them an immediate view of policy-relevant claims data (normally obtained through time-consuming data requests, spreadsheets and algorithm coding). It also grounds their work to specific policy clauses, helping them build a watertight case for recovery.

5 Knowledge Extraction Approaches

Dependency parsing has been frequently used to support relation extraction by capturing words that are close in context, even if far in sentence distance. Given a dependency tree, a set of subtree extraction rules identifies linguistically-connected terms, in the form of Predicate Argument Structure (**PAS**) tuples (Section 5.1). PAS tuples represent dependencies between textual entities, such as binary or ternary relations. They provide an easy intermediate representation to match text sentences to triples (subject, predicate, object) constituting a knowledge graph. The ontology can then be used to check if the linguistic tuples make sense semantically. Transformation of PAS tuples into Knowledge Graph fragments (sets of ontology triples) is done following a set of semantic templates (Section 5.2.).

To extract PAS tuples, we first implemented a deterministic baseline using WatsonX general-purpose deep parsing engine (Kalyanpur et al., 2012), which builds dependency trees for sentences. WatsonX provides a *Pattern Matching* library to characterize subtrees via handcrafted rules. Table 1 shows an example of two rules, based on the simple dependency tree in Figure 4. The rule assigns a *syntactic* role to tokens/spans in the sentence – e.g., 'subject', 'predicate' or 'object' (also referred to as 'slot types'). Other roles such as 'complement', can also be applied as necessary.

However, hand-coding these syntactic rules requires knowledge of computational linguistics. Our aim is for non-linguistic experts (e.g., application developers) to be able to apply this process to new domains. To reduce dependence on hard-to-acquire dependency parsing skills, we have developed an approach based on Spacy (Honnibal et al., 2020) for learning these rules from curated examples (Section 5.1). In Section 6, we compare performance of these learned rules to the baseline hand-coded rules.

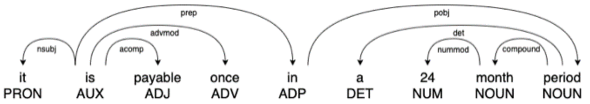

Figure 4. Dependency tree for an example sentence

pattern1→verb[hasPOS('verb'), hasLemma('be')] { nsubj -> **subj** [hasPOS("pron")] } { acomp-> **pred** [ ] } { advmod -> **comp** [hasPOS ("noun")] } { prep -> prepVar [ ] { pobj -> **obj** [hasPOS ("noun")] } } **pattern2** -> **subj** [hasPOS ("noun")] { compound -> **obj** [] { num_mod -> **comp** [] }}
PAS[pattern1]:subj=it,pred=payable,obj=once,comp=period PAS[pattern2]:subj=period, pred=[], obj=month, comp=24

Table 1: Example of written rules to extract PAS.

5.1 PAS Extraction Based on Learned Rules

Using a curated set of sentences with labelled PAS tuples, our framework generates dependency parsing rules that can obtain corresponding tuples from other, similarly-structured sentences. Specifically, we use Spacy's pattern builder to extract *Semgrex* patterns between fully-connected tokens, based on the shortest dependency path between tokens. This path usually contains the necessary information to identify their relation. Semgrex syntax allows us to characterize a subtree (Chambers et al., 2007), it describes nodes with normal token attributes, and how these nodes connect to other nodes in the dependency tree.

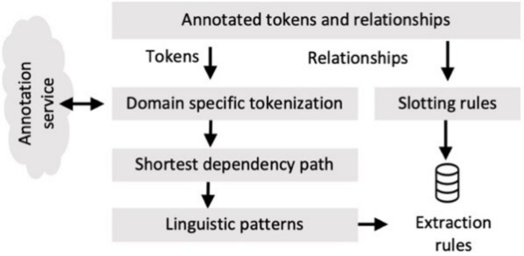

Figure 5. Extraction rule learning phase

We begin by obtaining a collection of sentences that represent the linguistic relationships we want to extract. We then annotate these sentences, identifying the interesting tokens and their syntactic roles (PAS 'slots'). Every annotated example is used to learn extraction rules, as depicted in Figure 5.

To learn the extraction rules for one curated sentence, we start by applying domain-specific tokenization, using the ontology-based entities annotated during Entity Extraction. We then build a dependency tree for the sentence. These annotations help subsequent dependency parsing by letting the parser know when a complex, multi-token term (e.g., the service name "*Full-mouth debridement to enable comprehensive* ..") can be treated as a simple, single named-entity. The re-tokenization simplifies and lends a degree of consistency to the resulting dependency tree (Finkel and Manning, 2009). The dependency tree is then parsed to find the shortest dependency path between the interesting (annotated) roles/slots for a PAS. Once the subtree consisting of all the desired tokens for a PAS has been identified, we extract a linguistic pattern characterizing that subtree. In addition to the linguistic properties of the tokens, we also extract slotting rules. A slotting rule is used in conjunction with linguistic patterns to assign a syntactic role to an extracted token. This is based on (Choi and Palmer, 2012) where dependency labels can be assigned to arguments – i.e, they indicate the Slot type (subject, predicate, object, etc.) Finally, an extraction rule (linguistic -semgrex - pattern + slotting rules) is captured for every PAS in an annotated sentence.

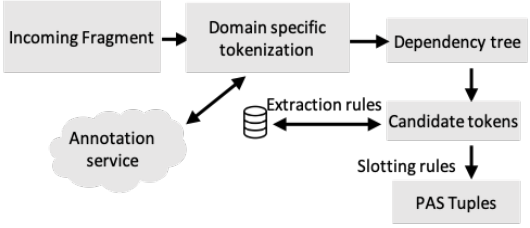

Figure 6. Runtime extraction of candidate PAS tuples

At runtime, incoming sentences are processed to extract PAS tuples (Figure 6). As before, domain-specific tokenization is applied to the sentence prior to building a dependency tree. The extraction rules learned earlier are then applied, to obtain candidate PAS tokens. Lastly, syntactic role labels are assigned to these candidate tokens by applying slotting rules.

5.2 Graph Building from PAS

PAS tuples enable us to extract meaningful relationships, even in text with challenging, long-range dependencies. However, PAS tuples require some translation to match ontology entities and relationships, e.g., a linguistic predicate may not directly translate to an ontological property. Implicit arguments may also be missing from a PAS. PAS can contain ternary relations that need to be aligned to one or more binary relations. And finally, not all PAS tuples are relevant.

To translate PAS tuples into semantically consistent Knowledge Graph fragments, we start by only keeping PAS that contain one or more ontology-based entity annotations. Then, for each subset of connected PAS tuples, we search for non-ambiguous semantic paths in the ontology that connect these entities, based on *parametrized* templates - implemented using the Jena API (Carrol et al., 2004). We use the annotated semantic types of the PAS entities (e.g.: class, instance, property, datatype, etc.) to select the templates to be executed. If a PAS token was annotated with more than one ontology annotation, then all combinations are tried. Non-relevant candidates will likely not yield any meaningful graph fragments. In here we provide an illustrative example of the process. Further details on the different templates can be found in Appendix C.

Consider the example in Figure 1, the first sentence yields the following PAS (among others):

```
<:d4355, :hasApplicableService, :Service>
<:d4355,    :hasNoRequirement,     :PAR>
```

The first PAS fires a template pattern that checks if the class *Service* is both the type of the instance *d4355* and the range of the object property *hasApplicableService*. If so, these entities are semantically connected and can be translated into the corresponding knowledge graph fragments. The following semantic triples are created:

`:br1 rdf:type :ServiceLimitationBR`

`:br1 :hasApplicableService :d4355`

For the second PAS, the range of the property *hasNoRequirement* corresponds to the type of the object instance *PAR*. This PAS links to the previous through the subject instance *:d4355* and can be translated into the knowledge graph fragment:

`:br1 :hasNoRequirement :PAR`

Thus, a knowledge graph is built by joining together all graph fragments obtained from the subset of connected PAS tuples.

Finally, a consolidation step pulls together the collection of graphs extracted from different portions of a policy paragraph. Here, all the constraints expressed in the ontology are enforced, e.g. *disjointness* between two properties, *min* and *max cardinality,* to ensure semantically-meaningful rules and discard nonsense rules (e.g. there can only be one applicable time period per BR – due to max cardinality = 1). Graph fragments are also merged, if the resulting BR graph does not violate any ontological constraint. Since there can more than one extractor, any duplicate graphs derived from the same policy text are discarded, partial graphs can also be merged if doing so does not violate any ontological constraint.

Figure 7 shows the consolidated graph extracted from sentence 1 and 2. This graph can be 'flattened' to obtain human-readable 'Benefit Rules' – such as the Service Limitation rule shown on the left of Figure 2 and Mutually Exclusive rule shown on the right. Both subtypes inherit the properties of their parent Benefit Rule class, but are not merged, because each contains conditions that are only meaningful for that rule subtype, e.g., the property *hasServiceLimitation* is only relevant for a 'Service Limitation' rule.

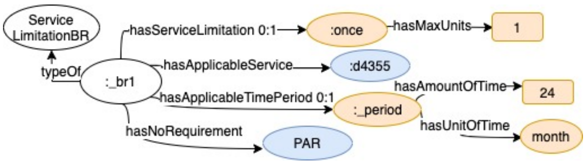

Figure 7. Consolidated graph from sentence 1 and 2

6 Evaluation Methodology

We concentrate on the system's ability to exploit the rich information contained in both a domain ontology and dependency trees with respect to a gold-standard created in consultation with our policy investigators. In particular, we aim to compare the impact of first addressing the need for dependency rules to extract PAS by proposing an approach that generates these rules from examples, which fit the domain-specific characteristics of new policy text. Policy-aware users can add these examples as there is no requirement to manually write new dependency parsing rules. Second, the impact of using a BERT-based classifier. Labeled training data is expensive to acquire as it requires domain expertise. However, as policy investigators review Benefit Rules, we investigated the use of this curated, small labeled dataset to fine-tune a classifier that filters out paragraphs that do not appear to contain any rules.

6.1 Set up: Data and Metrics

The proposed extraction pipeline was evaluated using Benefit Rules extracted from unstructured policies from two different states in the US. The ground truth of BRs for each policy was manually created by a team of three FWA investigators using our prototype User Interface: 90 rules were provided for State1 and 51 rules for State 2.

The ontology used in the experiments consists of 34 classes and 43 properties. Once the domain-specific instance data is 'lifted' in, 4954 individuals are added along with 23250 lexicalizations (i.e., labels used to annotate textual entities). The ground truth Benefit Rules presented in the experiments (not commercially sensitive or in production) are made available together with the ontology.

Each BR comprises of a policy text and a corresponding set of condition-values describing the text. Precision (P) measures the proportion of extracted rules that match the ground truth (GT) for the same policy text. Recall (R) measures the proportion of GT rules correctly extracted. F_1 combines the two. In addition, each matched rule gets a pairing 'score'. When all extracted condition-value pairs for a rule exactly match the GT, the score is 1. For partial matches, the score is between 0 and 1. A score of 0 indicates a missed rule. Table 2 shows the average pairing score across all rules. Details on the calculation and execution environment can be found in the appendixes A and B.

Jupyter notebooks showcasing the dependency tree (before and after tokenization) and PAS tuple extraction implementation with the learned rule for the example used in this paper, can be found in the git repository.

6.2 Results and Discussion

We run the evaluations using the two approaches presented for the PAS tuple extraction. The first – based on 54 manually-coded linguistic rules in WatsonX - acts as a baseline. The second are the learned syntactic rules described in Section 5.1. A total of 55 sentences were annotated with PAS examples.

State	Extractor	R	P	Avg score	F1
1	Learned rules	0.51	0.90	0.56	**0.65**
	Manual rules	0.48	0.73	0.57	0.58
2	Learned rules	0.45	0.82	0.41	0.58
	Manual rules	0.57	0.71	0.54	**0.62**

Table 2: Metrics when different extractors are applied over policies from different states

Results are summarized in Table 2. Overall, figures indicate that the proposed pipeline is a promising step towards automated extraction of BRs from unstructured policies. Extraction using learned rules is comparable to using manual rules. Considering the number of curated examples and rules added to both extractors, there is a potential to further improve this by identifying missed rules and adding them as examples. This requires far less skill than manually hand-crafting linguistic extraction rules. We believe this takes a distinct step towards empowering development teams to tailor extraction to customer needs.

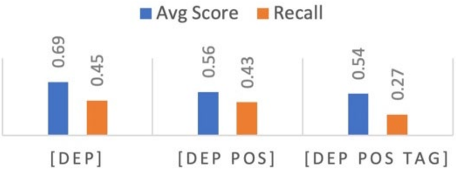

Table 3: Performance when various combinations of linguistic features are used to characterize subtree

Spacy provides several linguistic features on which to characterize a subtree, including syntactic dependency (DEP), part-of-speech (POS) and detailed part-of-speech (TAG). When settling on which of these to use (Table 3), we used Recall as the key metric and found that syntactic dependency (DEP) yielded best performance.

The use of a filtering classifier increases both performance (execution times shown in appendix A) and Precision (from 0.88 to 0.96 in State 1 and 0.82 to 0.95 in State 2) at the cost of a small drop in Recall (from 0.51 to 0.48 in State 1 and 0.45 to 0.41 in State 2). This is expected, since there are inevitably some false negatives in the classification. The model used is a BERT-based text classifier, fine-tuned on 70% of the paragraphs of the two policies, with the remaining 30% used for validation and early stopping during training. The hyperparameters were selected using Optuna (Takuya et al., 2019) optimization framework using 5-fold cross validation settings. The generalization capacity of the model is difficult to assess due to the small amount of labelled ground truth. With that caveat, it has been verified with cross-validation, where the model obtains an average accuracy of 96% on the various folds. The training data size is currently small due to the cost of manual policy labelling. However, it is expected this will expand as users review and curate extractor output.

While these benefit rule extraction results are promising, there is clearly scope to enhance our models and extractors to improve coverage. Most Benefit Rules are self-contained across one or more sentences in a paragraph, However, further work is needed to automatically capture the knowledge from headings, tables or co-references that span paragraphs. Improvements in service annotation could also reduce the incidence of partially-extracted rules being discarded during consolidation. Of course, there can always be implicit information, available in the minds of policy consumers but not present in the policy text for extractors to see. For example, the meaning of *'fair to good'* expressed in the rule *"Restorative services are payable when there is a fair to good prognosis for maintaining the tooth"*. While these details cannot currently be extracted automatically, our system gives policy analysts the ability to capture them in other consistent ways. For example, simple options like attaching a 'medical necessity' label can make cases like these amenable to machine learning and offer real benefits to Program Integrity workers seeking to size and prioritize work.

Various approaches can be used to look beyond co-occurrence of entities in sentences and explore how the terms are linguistically and semantically connected. For instance (Roth and Lapata, 2015) (Lopez et al., 2019) use semantic role labeling to identify actions and roles in a sentence (agent, theme, polarity, etc.) and reason over these to expose relation-entity/value pairs. Other complementary extraction approaches can be leveraged to look beyond co-occurrence of entities in the sentence and explore how the terms are linguistically and semantically connected, which could improve further on rule extraction coverage, such deep learning models. While the training data set is currently small, due to the cost of manual policy labeling, it is expected this will expand as users review and curate the extractors' output.

In this paper, we have explored building over dependency PAS, which can be exploited to capture fine-grained and distant relationships. Using a 'learned-rule' approach to obtain intermediate representations from a sentence enables non-linguistic experts to extend this process to more policies, without requiring manual production of syntactic-rules to address syntactical variability.

We made a small analysis to quantify the similarity between our two dental policy texts P_1 and P_2. We extracted sentences (removing stop words) from P_1 and P_2 using a standard sentence tokenizer (NLK Tokeniser, n.d.). Following (Reimers et al., 2019), we computed embeddings for each sentence using a model optimized for

Semantic Textual Similarity (STS) (specifically, we used stsb-roberta-large -STSb performance:86.39 (SBert, n.d.)). Let Ei be the list of sentence embeddings for the sentences of policy Pi. We have computed pairwise cosine similarity between E_1 and E_2. Let E_{12_max} be the list of the maximum values of the cosine similarity between each embedding in E_1 and all the embeddings in E_2 (the i-th value of E_{12_max} gives the best cosine similarity between the i-th sentence in P_1 and some sentence in P_2). We found that the mean of E_{12_max} is 0.65 with a standard deviation of 0.12; about 45% of the sentences in P_1 have a cosine similarity score with some sentence in P_2 that is above the average value. We repeated the same experiment using a third policy text from a different domain P_3, and found that the similarity scores for sentences in P_1 with respect to P_3 were consistently lower than between P_1 and P_2. This small experiment gives an indication that policy texts from different states but in the same domain (e.g., dental) have a good degree of similarity. The Benefit Rule Ground Truth built for each of the two policies can be seen in the git repository, each Benefit Rule shows the policy paragraph of text from where it is extracted and condition-values.

7 Conclusions and Future Work

Within regulated organizations, visibility over any part of the 'compliance landscape' is valuable information for identifying Program Integrity risks and prioritizing follow-up. With healthcare insurance policies, typically only a small fraction policy is automated (hand-coded), and the rest of the landscape remains opaque. So, unlike many AI applications that require high Recall before they are useful, any Recall here provides concrete, actionable value that claim workers can use both for prioritization and for follow-up. In a dark room, all light helps.

The ontology abstraction supports transferability, e.g. from one US state to another that semantically express similar compliance rules concepts or conditions (e.g.: eligible members, places of service, maximum billable units of service, services that should not be billed together, etc.) even if the wording differs between the texts. It also supports incremental enhancement to cover more rules and/or policy areas, which enables a scalable market. Dependency trees capture fine-grained, distant connections, which guided by the ontology are used to automatically build and consolidate a semantically meaningful Knowledge Graph. This increases precision by allowing for paragraphs that mention relevant entities, but which don't contain Benefit-Rules, to be discarded. If syntactical variability is high, using a 'learned rule' approach to obtain PAS representation enables non-linguistic experts to apply this process to more policies without requiring manual production of syntactic rules.

We see interesting avenues for follow-up NLP / AI work that combines neural and symbolic approaches, e.g., training deep learning models as our users validate more policy rules, to recognize rule fragments (spans), then assemble them into rules using the ontology as a blueprint. We also plan to perform user-based evaluations to measure how our pipeline impacts the time taken by investigators to identify and resolve FWA leads, as well as the quality and scope of the compliance information provided.

Finally, while our methodology is shown in a Healthcare setting, we believe it is applicable to other regulated domains, such as Finance. These extracted computable policy representations have the potential to open up many new opportunities – from reducing compliance costs through automated checking (particularly where common regulations apply to many) to 'what-if' analyses of proposed policy to automatically identifying gaps/loopholes that undermine Program Integrity.

Acknowledgments

We would like to acknowledge our business developers, offering managers, subject matter experts and accredited fraud investigators that make this project and its evaluation possible: Morten Kristiansen, Conor Cullen, Denisa Moga, Jillian Scalvini, John Davis, Shannon Ware, Mark Gillespie and Mark Goodhart.

Ethics / Broader Impact Statement

Governments must routinely automate policy rules in order to deliver services at population-scale, and this brings opportunities for both good and harm. Consistent application of policy rules at population-scale ensures fairer distribution of healthcare and social care services, as well as defending limited resources from Fraud, Waste and Abuse. (This latter point is often missed, but is critical to ensuring that resources are available when vulnerable people need them). At the same time, defects in the code increase the potential for failure to reimburse healthcare providers for delivering necessary services. Getting from policy, to business requirements, to coded rules is a long, multi-translation process, with error and omission failure modes at every step. Gaps or biases in the original policy may also remain unnoticed through this long journey, only to be discovered at the end when vulnerable people are impacted.

A recent global movement known as '*Rules as Code'* (Mohun et al., 2020) identifies several methods to tackle this. The one our system uses involves extracting rules from policy text via NLP, to minimize translation steps. There is potential for misuse here, should machine-extracted rules be executed blindly, without checking they faithfully represent policy intent. Hence, our system treats human-in-the-loop oversight as an essential, non-optional part of the process. Together - automated extraction plus human oversight have the potential to reduce translation failures, as well as enable discovery of *policy* errors and biases (by facilitating earlier testing and iteration).

Further to this, we believe that effective oversight demands more than a review process or 'AI explainability' add-on. It requires human-understanding and ability-to-correct to be first-class design goals. To this end, we use an ontology to represent extracted rules in a form (Figure 2) that policy-aware users find familiar, understandable and correctable (as well as traceable back to their policy origin). This representation is at the heart of the system. When presented side-by-side with the policy text to a reviewer, both success and failure scenarios are clearly visible. For example, in a failure scenario (ontology does not model the policy well), few rules are extracted, and rule conditions are missing. Here the reviewer can discard the rule, or fill-in the missing information. Whether well-formed or poorly formed, at no point are rules blindly applied to citizen data automatically.

We believe that shifting the focus towards validation of policy and its digital expression will facilitate the production of better-quality, more humane policy.

Supplementary Material

Appendix A. Evaluation environment

Our experiments were run using multiple microservices representing the modules described in the paper. Kubernetes was used to orchestrate the deployment of containers (microservices) in a cloud infrastructure with approximately 16 CPUs, 16 GB of RAM, and 64 GB of disk space.

The processing time of the policy for state 1 (27 pages) is approximately 74 minutes using the "learned rules" approach, while if using the classifier, the time is reduced to 41 minutes. The "manual rules" approach instead takes 42 minutes without classifier and 23 minutes with the classifier. For the policy of state 2 (35 pages), the times of the "learned rules" approach with and without classifier are 104 minutes and 35 minutes respectively. For the "manual rules" approach the processing time with and without classifier are 70 minutes and 10 minutes respectively.

Appendix B. Definition of metrics

Precision (P) measures the proportion of extracted rules that match the GT. Recall (R) measures the proportion of GT rules correctly extracted. f_1 combines these two. Specifically, they are defined as follows:

$$\boldsymbol{Precision} = \frac{\boldsymbol{n°exact\ matches + n°\ partial\ matches}}{\boldsymbol{n°\ extracted\ rules}}$$

$$\boldsymbol{Recall} = \frac{\boldsymbol{n°exact\ matches + n°\ partial\ matches}}{\boldsymbol{n°\ GT\ rules}}$$

$$\boldsymbol{f_1} = 2 * \frac{\boldsymbol{P * R}}{\boldsymbol{P + R}}$$

For a pair consisting of a ground truth Benefit Rule (BR) and an output BR we calculate a similarity score as follows, assuming each BR is a list of conditions c_i with corresponding values v_i taken out of a set with cardinality C_i.

For every pair of partial matches BR (R_j^{GT}, R_i^E), a similarity score s_{ji} is calculated based on:

$$s_{ji} = \frac{\min(L_i,L_j)}{\max(L_i,L_j)} * \frac{1}{L_j} * \sum_{k=1}^{L_j} score_{c_k}$$

where L_j and L_i correspond to the sizes of R_j^{GT} and R_i^E (i.e., how many conditions each BR consists of), and $\frac{\min(L_i,L_j)}{\max(L_i,L_j)}$ represents a penalizing factor when the sizes of the two BR are not the same (rule length similarity).. The score $score_{c_k}$ for each condition value pair $\{c_k: v_k\}$ is calculated as:

$$0, \quad if\ c_k\ is\ captured\ in\ R_j^{GT}, but\ not\ in\ R_i^E$$

$$1, if\ c_k\ is\ captured\ in\ both\ R_j^{GT}, R_i^E\ and\ v_k is\ the\ same$$

$$0.5 + 0.5 * f_1 * \left(1 - \frac{1}{Ca_k}\right), if\ c_k\ is\ in\ R_j^{GT}, R_i^E\ and\ v_k differ$$

Here, f_1 is the harmonic P-R mean generated by comparing the values of c_k in R_j^{GT} and R_i^E and $\{Ca_k\}$ is the number of semantically compatible candidate values a condition may have in the ontology (i.e., instances of the same type, such as all known medical programs), for datatypes where $Ca_k\ is\ 1$

Appendix C. Semantic patterns - templates

For each PAS tuple containing at least two entities annotated with the ontology model (as classes, instances, properties or datatype), consistent semantic statements (subject, predicate, object) are created to build the knowledge graph. Connections are found across the entities according to their semantic types and the templates described in Table 1. Different templates are executed for each meaningful combination of candidate matches in the PAS.

Table 4: semantic templates to check if entities of the given types can be semantically connected. They consist of parameters to substitute by the candidate entities of the type sought - a class, property, instance or datatype (in between <>) - and variables (preceded by '?') that must bind to an ontological resource. If all the constraints apply (that is semantically consistent), the pattern executes to build new statements, creating anonymous resources (blank nodes) as needed.

Pattern 1: <class, object property, instance>

- <class> is one of the domains of <property>
- <instance> type is on the range of <property>

If consistent, create a blank resource _:b such:

_:b rdf:type <class>. _:b <property> <instance>

- <class> is in the range of <property>
- <class> is the type of <instance> (or a superclass, that is <instance> rdf:type <class>)
- <obj property> has a domain ?domain

If consistent, create a blank resource _:b such:

_:b rdf:type <domain>. _:b <property> <instance>.

Pattern 2: <class, data property, datatype>

- <class> is one of the domains of <property>
- the range of <property> is consistent with the <datatype> (e.g., string, numerical, currency)

If consistent, create an blank resource _:b such:

_:b rdf:type <class>. _b: <property> 'datatype'

Pattern 3: <class, object property, datatype>

- <class> is one of the ranges of <property>
- <class> is the domain of a ?property2, which range is compatible with <datatype>
- <property> has a domain ?domain

If consistent, create two blank resources _:bi such:

_:bx rdf:type <domain>. _:bx <property> :_by.

_:by rdf:type <class >. _:by <property2> <datatype>.

Pattern 5: <instance, data property, datatype>

- the <instance> type is one of the domains of <property>
- the range of <property> is compatible with <datatype>

If consistent, create a new statement such:

<instance> <property> 'datatype'

- <property> has a range consistent with the datatype
- <property> has a domain ?domain
- ?domain is the domain of ?property2, which range ?range is compatible with the type of < instance>

If consistent, create a blank resource _:b such:

_:b1 <property> 'datatype'. _:b1 rdf:type <domain>

_:b1 <property2> <instance>

Pattern 6: <instance1, object property, instance2>

- <property> has <instance2> as value
- <property> has a domain ?domain
- ?domain is the domain of ?property2, which range ?range is compatible with the type of < instance>

If consistent, create a blank resource _:b such:

_:b <property> <instance2>. _:b rdfs:type <domain>.

__:b <property2> <instance2>

Pattern 7: <class1, object property, class2>

- <class1> is the domain of <property>
- <class2> is the range of <property>

If consistent, create a blank resource _:bi such:

_:bx rdf:type <class1>. _:by rdf:type <class2>

:bx <property>:by.

Pattern 8: <class, instance1, instance2>

- <class> is the domain of ?property1 and ?property2
- ?property1 has as range the type of <instance1>
- ?property2 has as range the type of <instance2>

If consistent, create a blank resource _:b1 such:

_:b1 rdf:type <class>. _:b1 <property1> <instance1>.
_:b1<property2> <instance2>

Not Far Away, Not So Close: Sample Efficient Nearest Neighbour Data Augmentation via MiniMax

Abstract

In Natural Language Processing (NLP), finding data augmentation techniques that can produce high-quality *human-interpretable* examples has always been challenging. Recently, leveraging kNN such that augmented examples are retrieved from large repositories of unlabelled sentences has made a step toward interpretable augmentation. Inspired by this paradigm, we introduce *MiniMax-kNN*, a sample efficient data augmentation strategy tailored for Knowledge Distillation (KD). We exploit a semi-supervised approach based on KD to train a model on augmented data. In contrast to existing kNN augmentation techniques that blindly incorporate all samples, our method dynamically selects a subset of augmented samples that maximizes KL-divergence between the teacher and student models. This step aims to extract the most efficient samples to ensure our augmented data covers regions in the input space with maximum loss value. We evaluated our technique on several text classification tasks and demonstrated that MiniMax-kNN consistently outperforms strong baselines. Our results show that MiniMax-kNN requires fewer augmented examples and less computation to achieve superior performance over the state-of-the-art kNN-based augmentation techniques.

1 Introduction

Knowledge distillation (KD) (Buciluǎ et al., 2006; Hinton et al., 2015) has been successful in improving the performance of various NLP tasks such as language modelling (Jiao et al., 2020; Sanh et al., 2019; Turc et al., 2019), machine translation (Tan et al., 2019; Wu et al., 2020), natural language understanding (Passban et al., 2020; Rashid et al., 2021), and multi-task learning (Clark et al., 2019). It aims to transfer the knowledge embedded in a model—called teacher—to another succedent model—called student, without compromising on accuracy (Furlanello et al., 2018).

Data plays a significant role in the success of KD. The importance of data becomes even more crucial when dealing with large teacher models (Lopez-Paz et al., 2015) or managing tasks with small amount of labelled data (Rashid et al., 2020; Nayak et al., 2019). The training objective of KD focuses on minimizing the discrepancy between representations of a teacher model and a student model. However, this might not be the case for regions which are not covered by training data in the input space. Data augmentation comes into play as a natural solution for such circumstances.

Most existing data augmentation techniques are not tailored for KD as the dynamics of teacher and student models are not considered in generating augmented data. Moreover, other model-based data augmentation techniques such as adversarial approaches do not generate interpretable samples for NLP tasks (Du et al., 2021). In this work, inspired by the success of retrieval-based augmentation techniques (Guu et al., 2020; Khandelwal et al., 2020; Du et al., 2021; Kassner and Schütze, 2020), we propose *MiniMax-kNN*, an interpretable data augmentation methodology. Our technique is interleaved with KD training to generate realistically-looking training points. For this purpose, we use a massive external respostiory of unlabelled sentences. In contrast to previous kNN augmentation techniques which naively extract and incorporate k samples, we propose a minimax approach to adapt kNN augmentation to KD and select our augmented samples more efficiently.

Experimental results show that our technique requires significantly fewer samples, reaches the state-of-the-art kNN augmentation technique (Du et al., 2021), and improves generalization to unseen

data.[1]

Our key contributions can be summarized as follows:

- We tailor kNN-based data augmentation for KD via MiniMax to select more impactful augmented samples for training.
- We significantly improve sample efficiency of kNN-based data augmentation.
- We conduct extensive experiments to evaluate our proposed method and manifest that we can maintain the test performance with training on only influential augmented examples.

2 Background

2.1 Data Augmentation in KD

KD (Hinton et al., 2015) is a training method that incorporates the knowledge of a teacher network in training a student network. The teacher can be trained on the same dataset as the student and often provides a suitable approximation of the underlying distribution of data. The training loss of the student using KD is formulated as in Eq. (1).

$$\begin{aligned}
&\mathcal{L} = (1-\lambda)\mathcal{L}_{CE} + \lambda\mathcal{L}_{KD} \\
&\mathcal{L}_{CE} = CE\Big(y, \sigma(z_s(x)\Big) \\
&\mathcal{L}_{KD} = \mathcal{T}^2 KL\Big(\sigma(\frac{z_t(x)}{\mathcal{T}}), \sigma(\frac{z_s(x)}{\mathcal{T}})\Big)
\end{aligned} \tag{1}$$

where z_s and z_t refer to the logits of the student and teacher networks, $\sigma(.)$ is the softmax prediction, CE and KL refer to cross entropy and KL-divergence loss, respectively. λ is a hyperparameter which controls the contribution of the KD loss with respect to the original cross entropy loss, and $\mathcal{T}$ is the temperature parameter which determines the smoothness of the output probability.

Although KD has been shown to be successful in model compression (Buciluǎ et al., 2006) and improving the performance of neural networks (Furlanello et al., 2018), the core prerequisites for effective KD are often overlooked. Lopez-Paz et al. (2015) give a good insight about these conditions using the VC-dimension analysis:

$$O(\frac{|\mathcal{F}_s|_c + |\mathcal{F}_t|_c}{n^\alpha}) + \varepsilon_t + \varepsilon_l \leq O(\frac{|\mathcal{F}_s|_c}{\sqrt{n}}) + \varepsilon_s \tag{2}$$

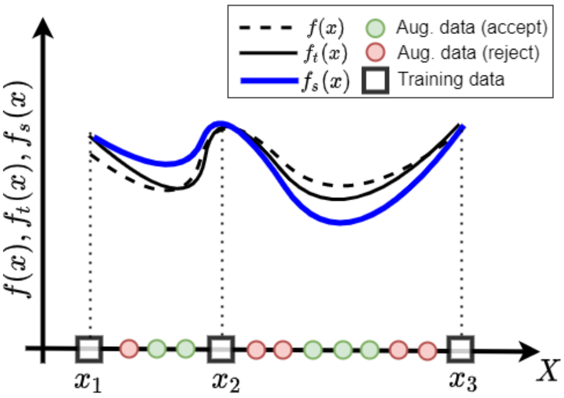

Figure 1: Data sparsity problem in KD; f, f_t, and f_s are representing the underlying function, teacher, and student outputs respectively. We show 10 augmented samples around x_2 with small circles on the X-axis. The green circles show the augmented samples which are selected by our MiniMax-kNN because these points correspond to maximum divergence regions of the teacher and student networks. The red circles are rejected augmented samples.

where $\mathcal{F}_s$ and $\mathcal{F}_t$ are the function classes corresponding to the teacher and student; $|.|_c$ is a function class capacity measure; $O(.)$ is the estimation error of training the learner; ε_s is the approximation error of the best estimator function belonging to the $\mathcal{F}_s$ class with respect to the underlying function; ε_t is a similar approximation error for the teacher with respect to the underlying function; ε_l is the approximation error of the best student function with respect to the teacher function; n is the number of training samples, and $\frac{1}{2} \leq \alpha \leq 1$ is a parameter related to the difficulty of the problem.

According to Eq. (2), it is clear that when the capacity of the teacher is large or when the number of the training samples is small, training with KD can be less beneficial. Figure 1 illustrates this problem through a synthetic example that KD loss forces the student to follow the teacher on training samples but there is no guarantee for such phenomenon to happen in regions in the input space that are not covered by training data. Therefore, the chance of a mismatch between two networks would be higher if training data is sparse or when there is a large gap between two networks.

Data augmentation can be considered as a remedy for this problem. To the best of our knowledge, most existing techniques are not sample efficient and blindly consider all generated samples in their training. As illustrated in Figure 1, different augmented samples might have different contribution to the final teacher/student loss. Moreover, these

---

[1] Source code is available at `https://github.com/ehsk/Minimax-kNN`

augmentation techniques are not tailored for KD. Our MiniMax-kNN solution addresses these two problems.

2.2 Nearest Neighbour Data Augmentation

The kNN augmentation strategy consists of two main stages: (a) a paraphrastic nearest neighbour retrieval engine, and (b) a training method using augmented samples.

Initially, training examples are queried over a large sentence repository using a general-purpose paraphrastic encoder. The aim of this stage is to find interpretable unannotated augmented samples that are semantically close to training data. For this purpose, we use one of the sentence repositories from SentAugment (Du et al., 2021), comprising 100M sentences collected from Common Crawl. We also employ the same paraphrastic sentence encoder, namely SASE, introduced in SentAugment. SASE is an XLM model (Lample and Conneau, 2019), fine-tuned on a number of well-known paraphrase datasets using a triplet loss to maximize the cosine similarity between representations of paraphrases. The similarity between a pair of sentence representations obtained from SASE can be adopted for unsupervised semantic similarity. Du et al. (2021) show that SASE achieves high correlation (0.73 on average) with human judgment on several STS benchmarks. Consequently, the kNN operation can be summarized as follows: Suppose a dataset $\{x_i, y_i\}_{i=1}^{N}$ where x_i and y_i denote an example and its corresponding label respectively. Given a large sentence repository $\mathcal{R}$ encoded using SASE, kNN is determined via top k sentences with respect to $\cos(\text{SASE}(x_i), \text{SASE}(s_j))$ where $s_j \in \mathcal{R}$.

Next, in step (b), a model is trained on the original data by minimizing $\mathcal{L}_{CE}$ from Eq. (1). The trained model learns task-specific knowledge that is further useful in finding relevant augmented examples. To this end, retrieved examples that are close to original examples within the teacher's space are retained to form augmented data. Augmented examples are subsequently incorporated into training via KD. A student model is then distilled from the teacher by leveraging teacher's soft labels on the combination of original data and augmented samples. In particular, for original examples $\{x_i, y_i\}$, $\mathcal{L}$ from Eq. (1) is minimized during training, whereas for the augmented examples, we only minimize $\mathcal{L}_{KD}$.

3 Related Work

3.1 KD in Tandem with Data Augmentation

Adaptive data augmentation can strengthen the capacity of the teacher in transferring knowledge to the student during distillation (Fu et al., 2020). Numerous studies (Chen et al., 2020b; Xie et al., 2020b) have applied KD for self-training in image classification tasks. In NLP, however, generating semantically plausible examples that can be easily inspected by humans is more challenging. In TinyBERT (Jiao et al., 2020), a contextual augmentation method is used along with KD, but such augmentation does not take the advantages of teacher or student's knowledge. A recent paradigm that heavily relies on data augmentation is zero-shot KD (Nayak et al., 2019; Rashid et al., 2020). In contrast, we explore the interpretability of augmentation in KD, which distinguishes our approach from the literature.

3.2 Data Augmentation in NLP

Word-level methods (Zhang et al., 2015; Xie et al., 2017; Wei and Zou, 2019) are heuristic based and do not necessarily yield natural sentences. More recently, contextual augmentations (Kobayashi, 2018; Yi et al., 2021) that substitute words for other words, is shown effective in text classification. However, these approaches do not produce diverse syntactic forms. Similarly, inspired by denoising auto-encoders, augmented examples can be sampled from the reconstruction distribution of corrupted sentences via Masked Language Modelling (Ng et al., 2020). Back-translation (Sennrich et al., 2016) is also another strategy to obtain augmented data (Yu et al., 2018; Xie et al., 2020a; Chen et al., 2020a; Qu et al., 2021).

Another line of work that mainly targets model robustness is to create new data or counterfactual examples via human-in-the-loop perturbations (Kaushik et al., 2020; Khashabi et al., 2020; Jin et al., 2020). Nonetheless, these strategies are task-specific and not scalable to generate data at massive scale. Besides, our method diverges from these studies in that we intend to build a semi-supervised system with minimal human intervention.

Several models (Miyato et al., 2017; Zhu et al., 2020; Jiang et al., 2020; Cheng et al., 2020; Qu et al., 2021) leveraged adversarial training for data augmentation. These methods manipulate the input embedding space to construct synthetic examples. Neighbourhoods around training instances in

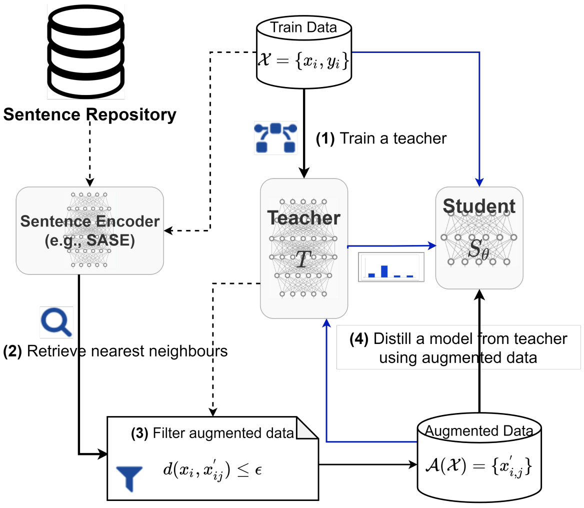

Figure 2: A schematic view of MiniMax-kNN

the embedding space cannot be translated back to text and thus are not interpretable. Although we advocate for interpretable data augmentation, we do not compete with these techniques and in fact, gradient-based augmentation is complementary to our method.

Finally, kNN, a non-parametric search algorithm that probes an external data source to find nearest neighbours is employed in several NLP tasks such as language modelling (Khandelwal et al., 2020), machine translation (Khandelwal et al., 2021), cloze question answering (Kassner and Schütze, 2020), and open-domain question answering (Lewis et al., 2020). kNN offers access to explicit memory that can retrieve factual knowledge from a data store. kNN is highly interpretable as knowledge is stored in raw text, an easy format for humans to understand. Recently, SentAugment (Du et al., 2021) introduced a semi-supervised strategy with unlabelled sentences. It retrieves augmented samples from a universal data store using kNN. Our proposed strategy is in line with SentAugment at heart, but different in leveraging the augmented examples during training. We focus on sample efficiency and show that we can reduce the size of the augmented data—e.g., by 60% in sentiment classification as reported in Section 5.6—while reaching a competitive performance.

4 MiniMax-kNN Data Augmentation for KD

Inspired by Volpi et al. (2018) and Madry et al. (2018), we apply minimax framework to tailor a sample efficient kNN data augmentation for KD. Minimizing the maximum expected risk is used in adversarial training (Volpi et al., 2018) and it is shown to have guaranteed good performance on distributions (P) within a particular distance (ρ) from a source distribution (P_0):

$$\min_{\theta} \sup_{\mathcal{D}(P,P_0)\leq\rho} \mathbf{E}[l(x', y'; \theta)] \tag{3}$$

where $\mathcal{D}$ is a notion of distance between distributions, l refers to the loss function, θ represents the parameters of the estimator model, and in our framework, (x', y') are augmented data samples.

Let us define the set of kNN augmented samples corresponding to the training sample $x_i \in \mathcal{X}$ from the training set, $\mathcal{X}$, to be $\mathcal{A}(x_i) = \{x'_{i1}, x'_{i2}, ..., x'_{ik}\}$. In the maximization phase, we define the loss $l(x', y'; \theta) = \mathrm{KL}\big(T(x'), S(x'; \theta)\big)$ between the softmax output of the teacher $T(x')$ and that of the student network $S(x'; \theta)$ with trainable parameters θ, with respect to the given augmented samples. Note that the augmented samples are unlabelled in the maximization phase. Then, we sort the augmented samples based on their loss value and form our MiniMax-kNN augmentation set $\bar{\mathcal{A}}(x_i)$ by selecting the top n out of the k samples in $\mathcal{A}(x_i)$. n is a hyper-parameter in our method that determines the sample efficiency of MiniMax-kNN. In order to enforce $\mathcal{D}(P, P_0) \leq \rho$ on the distance between the two distributions in Eq. (3), in our kNN search, we set a maximum radial semantic distance ϵ between the sentence representation of accepted augmented samples in $\bar{\mathcal{A}}(x_i)$ and the sentence representation of their corresponding input x_i based on the angular distance metric:

$$d(x_i, x'_{ij}) = \frac{1}{\pi} \cos^{-1} \frac{< h^t_{cls}(x_i).h^t_{cls}(x'_{ij}) >}{\|h^t_{cls}(x_i)\| \|h^t_{cls}(x'_{ij})\|} \leq \epsilon \tag{4}$$

where h^t_{cls} refers to the teacher's last layer hidden representation of the `[CLS]` token, and $<\cdot>$ denotes the dot product of two vectors. The discussion on how to adjust ϵ is given in Section 5.3.

In summary, our technique equips kNN augmentation with minimax to improve its sample efficiency. In contrast to adversarial data augmentation methods, our approach uses the minimax loss for selecting augmented samples. The overall structure of our augmentation strategy is visualized in Figure 2. We essentially follow three steps in each iteration during training:

(1) We construct teacher logits and student logits for augmented samples to measure KL-divergence between the two models.

(2) Out of all kNN samples, n samples with highest KL-divergence will be selected.

(3) KD loss is minimized for training data and selected augmented samples.

Our experiments reveal that this modification to KD underscores sample efficiency while retaining the test performance.

4.1 FLOPs Analysis of MiniMax-kNN

Minimax computations in MiniMax-kNN incur additional overhead costs during training, but how much precisely do minimax operations curtail the runtime performance? To answer this question, we analyze the logical compute complexity of our algorithm in terms of floating point operations (FLOPs) because it can be measured regardless of hardware considerations (Clark et al., 2020).

To this end, we compare FLOPs corresponding to each augmented example from MiniMax-kNN with vanilla kNN within an epoch. Suppose a forward pass and a backward pass for one batch takes F and B FLOPs, respectively. The number of matrix operations between the forward pass and the backward pass is not considerably different and hence, $F \approx B$ (Clark et al., 2020). For simplicity, we assume batch size is 1. Considering k_1 is the number of retrieved NNs, vanilla kNN requires $k_1F + k_1B$ additional FLOPs per epoch.

On the other hand, MiniMax-kNN selects n neighbours from k_2 retrieved nearest neighbours—i.e., $n < k_2$. The algorithm first takes the logits of all k_2 neighbours to compute KL-divergence vectors, which needs k_2F FLOPs, similar to vanilla kNN. The extra operations of MiniMax-kNN occur in the maximization step in which top n neighbours are determined with respect to their KL-divergence values. This operation can be carried out by sorting the KL-divergence vector, which costs S FLOPs. Note that $S \ll F$ because obtaining an output from a deep neural network model is far more costly than a sorting operation. The backward pass is then computed only for the n selected neighbours. Accordingly, the overall FLOPs for MiniMax-kNN is $k_2F + S + nB$. The difference between the FLOPs is:

$$\begin{aligned}\Delta_{\text{FLOPs}} &= \text{FLOPs}_{\text{vanilla-}k\text{NN}} - \text{FLOPs}_{\text{MiniMax-}k\text{NN}} \\ &= (k_1 - k_2)F + (k_1 - n)B + S\end{aligned}$$

Given that B can be approximated with F (as mentioned earlier) and $S \ll F$:

$$\Delta_{\text{FLOPs}} = (2k_1 - k_2 - n)F$$

Dataset	#class.	#train	#dev	#test	avg. #tokens
SST-2	2	67.3K	872	1.8K	12.4
SST-5	5	8.5K	1.1K	2.2K	22.6
TREC	6	5K	500	500	11.4
CR	2	2.5K	640	642	21.4
IMP	2	3.9K	2.2K	2.6K	50.0

Table 1: Downstream tasks used for evaluation

Thus, as long as $k_2 + n < 2k_1$, MiniMax-kNN is more efficient than vanilla kNN. In experiments, we illustrate that how MiniMax-kNN surpasses vanilla-kNN while satisfying the FLOPs condition.

5 Experiments

5.1 Datasets

We evaluate MiniMax-kNN on five datasets: SST-2 and SST-5 (Socher et al., 2013) for sentiment analysis, TREC (Li and Roth, 2002) for question type classification, CR (Hu and Liu, 2004) for product review classification, and Impremium's hate-speech detection dataset (IMP)[2]. Information related to all datasets is summarized in Table 1.

5.2 Experimental Setup

We adopt the publicly available pre-trained RoBERTa$_{\text{Large}}$ (Liu et al., 2019) and DistilRoBERTa (Sanh et al., 2019)—using the Huggingface Transformers library (Wolf et al., 2020) and the Pytorch Lightning library[3]—for evaluating our approach. For KD, RoBERTa$_{\text{Large}}$ is selected as the teacher. For training, we adhere to findings in Mosbach et al. (2021) and Zhang et al. (2021) to circumvent the fine-tuning instability problem by training for longer iterations—i.e., 100 epochs—with early stopping and use Adam optimizer with bias correction. The model is evaluated on the development data at the end of each epoch and the best performing model is chosen for testing. Our learning rate schedule follows a linear decay scheduler with a warm-up on {10%, 20%} of the total number of training steps. The learning rate is tuned for each task separately out of {1e-5, 2e-5, 3e-5}, and the batch size is chosen from [16, 128] depending on the dataset size. For KD hyperparameters, we use grid search to choose the best λ and $\mathcal{T}$ from {0.3, 0.4, 0.5, 0.6} and {5, 10, 12, 20}. We also schedule augmentation to start after a certain number of epochs in the training. On SST-5, SST-2, and

$n = 6$	**55.6**	94.4	96.6	**91.8**	87.9

Table 3: Test accuracy (↑) of DistilRoBERTa on the downstream tasks varying the number of selected NNs (n) in MiniMax-8NN (**bold** numbers indicate the best result for each task).

TREC, augmentation takes effect at epochs 8, 6, and 6, respectively, whereas on IMP, and CR, augmentation starts at the beginning of training. All experiments were conducted on two Nvidia Tesla V100 GPUs.

Few-shot learning setup We follow Du et al. (2021) to setup the environment for few-shot learning experiments. In particular, we sample 2 training subsets with replacement from the original training set for each task. Each subset is balanced and consists of 20 examples per label. The development set is reduced to 200 examples for all tasks except CR in which we keep all of the original set. The label distribution is retained in the reduced development data. Evaluation is conducted on the actual test dataset. To obtain reliable results, we repeat training with 10 different seeds on each sampled dataset and report the average across all runs—i.e., 20 runs per task. Few-shot experiments were run on a single Nvidia Tesla V100 GPU.

5.3 MiniMax-kNN Results

First, we investigate the impact of kNN data augmentation at test time and compare MiniMax-kNN with vanilla kNN data augmentation. To this end, we train a RoBERTa$_{\text{Large}}$ as teacher on the original data. Then, we distill a small size student based on DistilRoBERTa from the teacher using the augmented data and the original data.

In Table 2, we report the performance of MiniMax-kNN as well as the vanilla-kNN on the downstream tasks. In this experiment, the number of nearest neighbours (k) is set to 8 and for MiniMax-kNN, we empirically select the minimum number of augmented examples (n) out of 8-NNs such that MiniMax-kNN exceeds vanilla-kNN. We observe that using KD alone leads to a marginal improvement on all tasks. Adding more data results in further improvements but comes at the expense of substantially longer training time. On the other hand, MiniMax-kNN reduces the cost of training as it learns through less than half of the NNs and yet, consistently outperforms vanilla-kNN.

Varying the number of selected examples (n) in MiniMax-kNN We explore the number of selected augmentations by varying $n \in \{1, 2, 4, 6\}$ for 8-NNs on the downstream tasks. Results are reported in Table 3. Interestingly, picking n as small as either 1 or 2 results in superior performance of MiniMax-kNN, compared to vanilla-kNN, on all tasks. In TREC, and SST-2, the sweet spot is $n = 4$. In SST-5, and CR, MiniMax-kNN performs better as n grows. On the contrary, in IMP, accuracy declines by increasing n.

Varying the number of nearest neighbours (k) In order to investigate the optimal number of NNs, we assess the effect of k on the downstream tasks. The Results are reported in Table 4. We observe that more data sometimes makes the training noisy and as a result, performance deteriorates—e.g., $k = 2$ in SST-5 and IMP. Nonetheless, when the augmentation size is sufficiently large, test results improve—i.e., $k = 8$ in all datasets except CR. Apart from three cases—i.e., $k = 2, 4$ in SST-2, and $k = 4$ in CR—MiniMax-kNN is superior to vanilla-kNN by incorporating roughly 50% fewer

Task	KD	$k = 1$	$k = 2$		$k = 4$		$k = 8$	
		vanilla	vanilla	MiniMax	vanilla	MiniMax	vanilla	MiniMax
SST-5	53.2	53.9	52.0	52.5	54.7	55.0	55.2	**55.4**
SST-2	93.6	93.7	94.7	94.2	94.6	93.8	94.7	**95.2**
TREC	96.6	96.2	96.4	96.6	96.8	96.8	97.0	**97.4**
CR	92.1	91.9	92.1	92.2	**92.4**	91.6	91.3	91.9
IMP	87.7	87.2	87.1	87.6	86.0	87.8	88.4	**88.6**

Table 4: Test accuracy (↑) of DistilRoBERTa on the downstream tasks varying the number of nearest neighbours (k). **KD** refers to knowledge distillation with no data augmentation. For MiniMax, n is equal to half of k neighbours for $k = 2, 4$ and when $k = 8$, n is selected as in Table 2 (**bold** and underline indicate best and second best results per task).

Model	SST-5		SST-2		TREC		CR		IMP	
vanilla-8NN	162.1		484.5		78.4		43.7		99.4	
MiniMax-8NN*	158.8	2% ↓	634.4	31% ↑	101.1	29% ↑	30.8	30% ↓	38.6	61% ↓

Table 5: Training time (in seconds) for one epoch (↓), averaged across epochs during training, on the downstream tasks along with the percent of reduction compared to vanilla-8NN. MiniMax-8NN and vanilla-8NN refer to the models we used for Table 2 (*denotes our approach).

examples.

Adjusting the maximum radial distance (ϵ) in MiniMax-kNN We plot the distance distribution of augmented data for two cases: (a) when the teacher predicts the same label as the original examples for augmented ones (*matched labels*) (b) when the predicted label for augmented examples do not match that of original examples (*mismatched labels*). Figure 3 illustrates a clear distinction between these two groups. Considering these insights, we find an empirical heuristic to set ϵ. When the overlap between groups is infinitesimal, we tune ϵ in the vicinity of the maximum distance of *matched labels*. The rationale here is to avoid altering the skewness of the original label distribution. Throughout our experiments, ϵ is set to 0.22, and 0.4 for SST-5, and SST-2, respectively. However, we find $\epsilon = \infty$ works best on CR, IMP, and TREC.

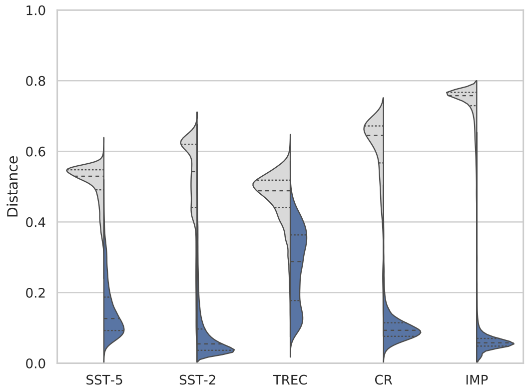

Figure 3: Distance distribution of augmented examples for each dataset (Left: *mismatched labels* / Right: *matched labels*)

5.4 Runtime Efficiency

In §4.1, we showed that MiniMax-kNN is computationally more efficient than vanilla-kNN when $k_2 + n < 2k_1$. Given the number of nearest neighbours is identical ($k_1 = k_2$) in our experiments, any choice of n makes MiniMax-kNN more efficient than vanilla-kNN in theory. However, in our implementation of MiniMax, we feed selected examples again to the student, thereby triggering a redundant forward pass[4]. Although this change reduces the efficiency of MiniMax-kNN in practice, it significantly simplifies the implementation. Thus, the above condition evolves to $k_2 + 2n < 2k_1$ in our experiments. Nonetheless, in Table 2, this new efficiency constraint still holds on all tasks except SST-2, and TREC. To calculate the exact amount of speed-up, we measure the average training time corresponding to one epoch for each task. The results are outlined in Table 5. On IMP, MiniMax-kNN saves more than 60% of training time and on CR, MiniMax-kNN brings almost 30% speed-up. Also, MiniMax-kNN is slightly faster than vanilla-kNN on SST-5. However, MiniMax-kNN trains around 30% slower on SST-2 and TREC.

5.5 Ablation Study

We analyze each component of our augmentation strategy to understand how they impact the overall

---

[4] All augmented examples are initially fed to the student within a PyTorch `no_grad` block. Since we want to backpropagate through only selected examples, they should be fed again to the student.

Model	SST-5	SST-2	TREC	CR	IMP
SIZE	100	40	120	40	40
SentAugment (Du et al., 2021)	44.4 ± 1.0	86.7 ± 2.3	92.1 ± 2.4	89.7 ± 2.0	81.9 ± 1.4

RoBERTa$_{\text{Large}}$ + MiniMax-10NN ($n = 6$)*	46.8 ± 1.4	86.5 ± 1.8	91.8 ± 1.0	88.3 ± 1.5	81.7 ± 2.3
AUG. SIZE (#forward / #backward pass)	1030 / 700	380 / 280	835 / 720	400 / 280	360 / 280

Table 6: Few-shot learning results of MiniMax-kNN on the downstream tasks (*denotes our approach). Compared to SentAugment, our proposed approach achieves competitive performance, but with the use of fewer augmented examples.

#	Model	SST-5	Δ
1	DistilRoBERTa	52.9	-
2	+ KD	53.2	+0.3
3	+ KD + random-8	54.4	+1.2
4	+ KD + random-8 + reranked	54.2	-0.2
5	+ KD + random-8 + reranked + ϵ	52.3	-1.9
6	+ KD + 8NN	54.7	+1.5
7	+ KD + 8NN + reranked (=vanilla)	55.2	+0.5
8	+ vanilla-8NN + ϵ	55.0	-0.2
9	+ MiniMax-8NN + ϵ	55.4	+0.4

Table 7: Ablation study of MiniMax-kNN on SST-5. Δ denotes the performance difference with respect to the previous row, but for the first row in each section, it indicates the difference with the accuracy of KD—i.e., row 2.

effectiveness of MiniMax-kNN. To this end, three components of our strategy are targeted for an ablation study. First, the effect of nearest neighbours is measured by replacing them with random examples from the sentence repository. Then, to determine whether reranking neighbours by teacher is helpful, we preserve the order of nearest neighbours returned by the SASE. Finally, we relax the maximum radial distance to include all nearest neighbours.

In Table 7, we report the results on SST-5. Surprisingly, random augmentation (row 3) scores only 0.3% lower than kNN augmentation (row 6). Reranking nearest neighbours by the teacher further boosts the results by 0.5% (row 7). The presence of maximum radial distance is not helpful for vanilla-kNN as it leads to 0.4% drop in the accuracy (row 8). Finally, our selection mechanism in MiniMax-kNN (row 9) leads to a 0.2% improvement compared to vanilla-kNN (row 7).

5.6 Few-shot experiments

Our data augmentation strategy can be applied to few-shot learning scenarios where a minuscule number of labelled data is available. Therefore, we simulate a few-shot learning setting as described in Section 5.2. In addition to vanilla-kNN and no augmentation baselines, we compare our results with SentAugment (Du et al., 2021), the state-of-the-art method in kNN data augmentation. In SentAugment, experiments are conducted on 5 randomly sampled small datasets and top 3 results of 10 different runs are averaged across sampled datasets, which means average over 15 runs in total. To be comparable to SentAugment, we average across all 10 runs for 2 sampled datasets, average over 20 runs in total, to report our results. In SentAugment, augmented few-shot datasets contain 1000 examples including the original data. For MiniMax-kNN, we use 10-NNs in this experiment with a maximum radial distance.

Table 6 shows the few-shot learning results. The performance of our baselines follows a similar trend in the full-size data experiments. In particular, KD without augmentation slightly improves the test accuracy; Vanilla-kNN brings almost 1.9% improvement on average, and MiniMax-kNN consistently surpasses vanilla-kNN by 0.7% on average. Compared to SentAugment, MiniMax-kNN reaches a competitive performance. The key advantage of MiniMax-kNN lies in sample efficiency. Specifically, MiniMax-kNN falls short by only 0.3% on SST-2, and IMP with using less than 40% of the SentAugment augmented data on average. On CR, MiniMax-kNN lags behind by 1.4%, but again on roughly 40% of the SentAugment data size. Moreover, SentAugment outperforms our approach by 0.3% on TREC, while the size of augmentation is reduced by almost 20%. Lastly, MiniMax-kNN outperforms SentAugment in SST-5 by 2.4% with almost same amount of data.

5.7 Qualitative Analysis

We study the quality of augmented examples retrieved from the sentence repository. Table 8 presents four examples from SST-5, CR, and TREC along with the corresponding top 3-NNs. The top

(i) **SST-5:** this is a stunning film, a one-of-a-kind tour de force.	**very positive**
Here is masterful film-making in action. (5)	*very positive*
It's an expertly-crafted spectacle-event movie. (1)	*very positive*
This is a unique cinematographic experience. (6)	*very positive*
(ii) **CR:** one also exhibited extremely slow speed when going to the menu.	**negative**
No menu appears to make it very quick and easy to use. (15)	*negative*
Switching between options in the main menu is relatively slow. (13)	*negative*
the only niggle i have found is that the menus are a bit slow at times. (8)	*negative*
(iii) **SST-5:** final verdict: you've seen it all before.	**very negative**
Below is the final result. (15)	*neutral*
The final verdict: Go ahead and buy (4)	*positive*
Nut in the end, the final result always pays out. (7)	*positive*
(iv) **TREC:** What causes the body to shiver in cold temperatures?	**DESC**
How is it possible that a higher minimum wage could actually lead to more inequality within a country? (11)	*DESC*
How did the minimum wage increase come about? (13)	*DESC*
How is the new minimum wage hike impacting them? (7)	*DESC*

Table 8: Examples, derived from the augmented CR, SST-5, and TREC, after teacher reranking (the numbers in the bracket indicate the initial rank by SASE). For the nearest neighbours, the teacher's *predictions* are also provided, although soft labels will be used during training. Row (iii) shows an example of label mismatch and row (iv) highlights a mediocre paraphrase retrieval despite matching labels.

two rows show clear-cut examples that the nearest neighbours are in fact paraphrased forms of original samples. Also, the teacher predicts the same label as the original examples for these augmented examples. We observe task-specific knowledge that the teacher has learned from original data helps to rank retrieved sentences—e.g., in the second row, reranking pushes the neighbours at ranks 15 and 13 to the top 3.

However, the augmented data is not always perfect. To identify the limitations of kNN augmentation, we manually inspect 20 samples, randomly drawn from SST-5 and TREC. We find that inaccurate paraphrase retrieval undercuts the quality of augmented examples shown in the bottom rows of Table 8. A side effect of this weakness is the domain mismatch, denoting that augmentation can introduce out-of-domain data. For instance, the input data in TREC is expected to be in interrogative mood, but the retrieval may return declarative sentences. A potential solution to this problem could be utilizing a different repository, entirely comprised of questions in this case, similar to that of Perez et al. (2020). However, curating such repository for specialized domains can be challenging. Moreover, the improvements we observe in the experiments show that this issue is not prevalent in our selected tasks.

6 Conclusion

In this paper, we presented a sample efficient semi-supervised data augmentation technique, namely MiniMax-kNN. The augmentation procedure is framed as finding nearest neighbours from a massive repository of unannotated sentences. The crucial aspect of kNN augmentation is interpretability as augmented examples are written in natural language. We adopt KD to learn from unlabelled data. The key ingredient of our approach is to find the most impactful examples that maximize the KL-divergence between the teacher and the student models. We show that MiniMax-kNN can reduce the augmented data size by 50% while improving upon vanilla augmentation.

Abstract

Commonsense reasoning is one of the key problems in natural language processing, but the relative scarcity of labeled data holds back the progress for languages other than English. Pretrained cross-lingual models are a source of powerful language-agnostic representations, yet their inherent reasoning capabilities are still actively studied. In this work, we design a simple approach to commonsense reasoning which trains a linear classifier with weights of multi-head attention as features. To evaluate this approach, we create a multilingual Winograd Schema corpus by processing several datasets from prior work within a standardized pipeline and measure cross-lingual generalization ability in terms of out-of-sample performance. The method performs competitively with recent supervised and unsupervised approaches for commonsense reasoning, even when applied to other languages in a zero-shot manner. Also, we demonstrate that most of the performance is given by the same small subset of attention heads for all studied languages, which provides evidence of universal reasoning capabilities in multilingual encoders.

1 Introduction

Neural networks have achieved remarkable progress in numerous tasks involving natural language, such as machine translation (Bahdanau et al., 2014; Kaplan et al., 2020; Arivazhagan et al., 2019), language modeling (Brown et al., 2020), open-domain dialog systems (Adiwardana et al., 2020; Roller et al., 2020), and general-purpose language understanding (Devlin et al., 2019; He et al., 2021). However, the fundamental problem of commonsense reasoning has proven to be quite challenging for modern methods and arguably remains unsolved up to this day. The tasks that aim to measure reasoning capabilities, such as the Winograd Schema Challenge (Levesque et al., 2012), are deliberately designed not to be easily solved by statistical approaches, which are a foundation of most deep learning methods. Instead, these tasks require implicit knowledge about properties of real-world entities and their relations in order to resolve inherent ambiguities of natural language.

The town councilors refused to give *the demonstrators* a permit because they feared violence.
Answer: The town councilors

Figure 1: Example of a Winograd Schema problem. The resolved pronoun is underlined, two options are highlighted with an italic font.

Figure 1 illustrates the gist of this task: given a sentence and a pronoun (they), the goal is to choose the word that this pronoun refers to from two options (*The town councilors* or *the demonstrators*). While picking the right answer is straightforward for humans, the lack of explicit clues makes it hard for machine learning algorithms to perform better than majority vote or random choice.

Recently large Transformer-based masked language models (MLMs) (Devlin et al., 2019) were shown to achieve impressive results on several benchmark datasets for commonsense reasoning (Sakaguchi et al., 2020; Kocijan et al., 2019; Klein and Nabi, 2020). However, the best-performing methods frequently involve finetuning the entire model on large enough corpora with varying degrees of supervision; apart from providing initial parameter values, the pretrained trained language model is not used for predictions.

Moreover, these methods have mostly been evaluated on English language datasets, despite increasing interest in multilingual evaluation for NLP (Hu et al., 2020) and the existence of multilingual encoders (Conneau et al., 2020; Conneau and Lample, 2019). The XCOPA dataset (Ponti et al., 2020) was recently proposed as a benchmark for multilingual

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3534–3546
August 1–6, 2021.

commonsense reasoning, yet its task is different from the pronoun resolution problem described above. Versions of Winograd Schema Challenge exist in different languages, but each version comes with slight differences in task specification. This makes holistic cross-lingual evaluation of new commonsense reasoning approaches a quite difficult problem for researchers in the area.

In this work, we propose a simple supervised method for commonsense reasoning, which trains a linear classifier on the self-attention weights between the pronoun and two answer options. To evaluate our method and facilitate research in multilingual commonsense reasoning, we aggregate existing Winograd Schema datasets in English, French, Japanese, Russian, Portuguese, and Chinese languages, converting them to a single format with a strict task definition. Our approach performs comparably to supervised and unsupervised baselines in this setting with both multilingual BERT and XLM-R models as backbone encoders.

Moreover, we find that the same set of attention heads can be used to solve reasoning tasks in all languages, which hints at the emergence of language-independent linguistic functions in cross-lingual models and supports the conclusions made by prior work (Chi et al., 2020; Li et al., 2020). Interestingly, when using an unsupervised attention-based method (Klein and Nabi, 2019), we observe that restricting the choice of heads to this set also improves the results of this baseline. This result suggests that the key to improved performance of such approaches might lie in the right choice of heads rather then the exact attention values.

To summarize, our contributions are as follows:

- We offer a simple supervised method to utilize self-attention heads of pretrained language models for commonsense reasoning.
- We compile a multilingual dataset of Winograd schemas in six languages, bringing all tasks to the same format[1]. When evaluated on this dataset, our method performs competitively to strong baselines from prior work.
- We demonstrate that in cross-lingual models, there exists a small subset of attention heads specializing in *universal* commonsense reasoning. This reveals new linguistic properties of masked language models trained on multiple languages.

2 Related work

2.1 Winograd Schema challenges

The Winograd Schema Challenge (WSC) was proposed as a challenging yet practical benchmark for evaluation of machine commonsense reasoning (Levesque et al., 2012). Since its introduction, several English-language benchmarks of varying difficulty and size were also proposed: notable examples include Definite Pronoun Resolution (Rahman and Ng, 2012) and Pronoun Disambiguation Problem (Morgenstern et al., 2016) datasets, as well as WinoGrande, which consists of 44k crowdsourced examples (Sakaguchi et al., 2020). A version of WSC is also included in the popular SuperGLUE language understanding benchmark (Wang et al., 2019a), where it is reformulated as a natural language inference problem.

There also exist variations of WSC in other languages: French (Amsili and Seminck, 2017), Japanese (Shibata et al., 2015), Russian (Shavrina et al., 2020), Portuguese (Melo et al., 2019), and Chinese (Bernard and Han, 2020). We use these datasets in our study to create a multilingual dataset for commonsense reasoning.

Although in general the task definition of Winograd Schema Challenge was formalized to some degree, both succeeding datasets and methods proposed by users of these datasets have introduced various changes to the task specification and even the input format. In particular, a work by Liu et al. (2020) provides a thorough comparison of different ways to formalize the task for WSC and shows that the same model can give widely varying results depending on the evaluation framework. We describe our efforts to convert different datasets to a single format in Section 4.

2.2 Language models applied to commonsense reasoning

Several works attempt to solve Winograd Schema Challenge by utilizing pretrained language models. For example, Trinh and Le (2018) propose to rank possible answers with an ensemble of RNN language models by substituting the pronoun with each of the options. Recently, Klein and Nabi (2019) introduced Maximum Attention Score (MAS) for commonsense reasoning. This method uses the outputs of multi-head attention from each layer and scores each candidate answer based on the number of heads for which this answer has the highest attention value. We use the first (adapted to

---

[1] Our datasets and code are available at `github.com/yandex-research/crosslingual_winograd`

masked language models as proposed by Salazar et al., 2020) and the second approaches as baselines in the experiments. In essence, our method can be compared to MAS, but as we demonstrate in Section 5, several algorithm design differences along with task supervision allow us to significantly improve the commonsense reasoning performance.

Large pretrained Transformer models, such as BERT (Devlin et al., 2019), have also enabled rapid progress of supervised methods for WSC. One such method is given by Sakaguchi et al. (2020): the authors propose to concatenate the sentence and one of the options and to use the [CLS] token representation of the resulting sequence for binary classification. Also, Kocijan et al. (2019) propose a margin-based loss function which aims to increase the log-probability of the correct answer as a replacement for the masked pronoun. We evaluate these methods in our experiments without training on large in-domain datasets; as we show, both methods are prone to overfitting when applied to several hundreds of examples.

2.3 Cross-lingual encoder models

Multilingual representations have been a longstanding goal of the research community: they allow to serve fewer models for a wide range of languages and to improve the results on low-resource languages. Ruder et al. (2019) gives a detailed survey of different cross-lingual word embedding approaches, as well as the history of cross-lingual representations in general.

In this work, we are interested in the latest developments in multilingual Transformer masked language models (Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2020; Siddhant et al., 2020) that were driven by the advances in transfer learning for NLP (Howard and Ruder, 2018; Devlin et al., 2019). In particular, we use pretrained multilingual BERT (mBERT, Devlin et al., 2019) and XLM-RoBERTa (XLM-R, Conneau et al., 2020) for all our experiments.

Recently, there has been increasing interest in the evaluation of multilingual models: as a result, several benchmarks, including XTREME (Hu et al., 2020), XNLI (Conneau et al., 2018) and XCOPA (Ponti et al., 2020) were introduced. Although XCOPA is a commonsense reasoning dataset, it is meant to serve as a multilingual version of the COPA dataset (Roemmele et al., 2011), which offers a problem different from pronoun resolution. In this work, we aimed to create a multilingual counterpart of more widely used Winograd Schema Challenge, so that any future methods for commonsense reasoning can be easily evaluated on languages other than English.

2.4 Functions of Transformer heads

Previous works have demonstrated that it is possible to perform unsupervised zero-shot consistency parsing with attention heads of pretrained cross-lingual models (Kim et al., 2020; Li et al., 2020). In our work, we extend these findings to a conceptually different task of commonsense reasoning. This task has significant overlap with coreference resolution, which was shown to be encoded in specific heads of monolingual BERT (Clark et al., 2019; Tenney et al., 2019).

Motivated by similar results for monolingual models, several works have previously demonstrated that models such as multilingual BERT encode grammatical relations (Chi et al., 2020) and can perform zero-shot entity recognition, as well as POS-tagging (Pires et al., 2019). Besides presenting evidence for universality in pronoun resolution, which was not studied before, our analysis relies on attention heads instead of extracting representations from intermediate layer outputs.

3 Common sense from attention

In this section, we first give a formal definition of the commonsense reasoning task, most commonly encountered in Winograd Schema Challenge and its successors. Then, we provide necessary background information about the Transformer architecture for transfer learning and describe our proposed solution for this task.

3.1 Exact task specification

It is known that commonsense reasoning performance can vary greatly due to changes in task formulation: for example, recent work by Liu et al. (2020) reports improvements of up to 6 points when posing the task as multiple choice instead of binary classification. Thus, as per recommendations from this work and in order to create a unified dataset, we choose the definition of the Winograd Schema problem which is as strict as possible.

The definition is as follows: the system receives a sentence with a pronoun and has to choose the noun (or noun phrase) that this pronoun refers to. For this choice, the system has two options; both of which, along with the pronoun, are always included as substrings of the initial sentence. We intentionally do not restrict the choice of sentence representation or the framing of the task in order to evaluate a diverse range of solutions.

Although the requirements listed above are quite general and intuitive when working with WSC, some of the datasets we employ have samples that do not conform to them. For example, it might be the case that the pronoun occurs at several positions in the sentence without explicit indication of the one to be resolved. For all such examples, we attempt to convert them to standardized instances by hand and drop them only if it is not possible via simple means: otherwise, the right answer to the problem is misspecified. We give a detailed description of our solution in Section 4.2.

3.2 Transformers for sentence representations

Our method heavily relies on the specifics of the Transformer architecture (Vaswani et al., 2017), which has attracted increased interest in NLP recently due to its generation (Raffel et al., 2020; Brown et al., 2020) and transfer learning (Devlin et al., 2019; Liu et al., 2019) capabilities.

This architecture consists of several sequential layers, where each layer contains a feed-forward block and a self-attention block. Inside the self-attention block, there are multiple *attention heads*: each head first linearly projects the input sequence $z = [z_1, \ldots, z_i, \ldots, z_n]$ into sequences of queries q_i, keys k_i and values v_i, then computes the attention weights as softmax-normalized values of pairwise dot products between all keys and all queries:

$$\alpha_{ij} = \frac{\exp(q_i^T k_j)}{\sum_{l=1}^{n} \exp(q_i^T k_l)} \quad (1)$$

These weights are then used to combine the values into a single vector for each input vector, and the layer output is a linear combination of all attention head outputs.

3.3 Our approach

The method proposed in this work uses intermediate outputs of a Transformer masked language model with L layers and H heads in each layer. Given an instance of the Winograd Schema problem, we take the input sentence and mask the pronoun that needs to be resolved. After that, we feed the resulting sentence to the language model and obtain the activations of each self-attention layer as a tensor $L \times H \times T$, where T is the number of tokens that constitute the candidate answer. Here, we can either take the attention from the pronoun to the candidate or vice versa.

After aggregating the attention outputs by computing the mean or the maximum over T, we have two matrices for each of two possible answers, which are then flattened into vectors. Combining these vectors, we obtain an input for the binary classification task with class 0 corresponding to the first answer being correct and class 1 corresponds to the second one. Given a dataset of such inputs, we can train a logistic regression to predict the class from the multi-head attention weights α.

There are several design choices which define the exact implementation of our method. We describe them below; for each design choice, we underline the best-performing option as found by the ablation study in Section 5.4.

Feature combination: With two feature vectors for candidate answers, we can either concatenate them or subtract the vector of the second candidate from the vector of the first one.

Pooling over tokens: As the candidates can have different length, we need to transform the attention outputs to feature vectors of the same size. This can be done by one of two simple forms of aggregation: mean- or max-pooling.

Attention direction: Observe from Equation 1 that in general, $\alpha_{ij} \neq \alpha_{ji}$. To find the optimal configuration, we evaluate both options of either attending to the candidate or the pronoun.

4 Dataset

In this section, we describe our procedure of building a multilingual commonsense reasoning benchmark using Winograd Schema Challenge problems. We create this benchmark by combining several monolingual collections for six languages, each described in previously published works.

We intentionally do not use XCOPA (Ponti et al., 2020) as it is aimed at a different problem: instead of operating at the word level, the task of this dataset is to connect the premise and one of two hypotheses, both of which are complete sentences. Because direct application of attention-based reasoning to sentence-level tasks is a non-trivial research question, we leave it to future work.

4.1 Languages

For the English language, we work with the data from the original WSC task[2] (Levesque et al., 2012), as well as the SuperGLUE benchmark (Wang et al., 2019a) and the Definite Pronoun Resolution dataset (Rahman and Ng, 2012). For French and Japanese, we use datasets published by Amsili and Seminck (2017) and Shibata et al. (2015) respectively. We also include the corresponding part from the Russian SuperGLUE benchmark (Shavrina et al., 2020), a collection of Winograd Schemas in Chinese from the WSC website[3], and the Portuguese version of WSC (Melo et al., 2019) into our multilingual benchmark.

In addition, we attempted to use Mandarinograd (Bernard and Han, 2020) — a Mandarin Chinese version of WSC. However, this dataset contains questions instead of pronouns that need to be resolved. As such, we were unable to incorporate its contents without significantly changing the task.

4.2 Preprocessing and filtering

As the datasets for different languages were released in several different formats, in order to have a unified evaluation framework, we needed to convert them all to the same schema. Unfortunately, due to the differences in task formalization we were unable to convert certain examples without completely changing them; as a result, these examples had to be removed from the dataset. Still, our main priority was to maintain the same task format while keeping as many examples as possible; to this end, we fixed minor annotation inconsistencies by hand wherever possible.

Below we describe the steps of our pipeline. First, several examples had more than two candidate choices, i.e. more than one incorrect option is given. We convert these examples into several binary choice problems and report the original dataset sizes after executing this step. Next, the main issue we faced was that the right answer is not included as a substring of the input sentence. Often this can be explained by missing articles, typos or differences in word capitalization. We attempt to fix all such errors in these cases.

The resulting dataset sizes are listed in Table 1; it can be seen that our conversion pipeline discards approximately 29% of data. In the future, more effort could be directed towards constructing a linguistically diverse, large-scale and balanced multilingual Winograd Schema dataset. Yet, as shown in Section 5, this collection of datasets already allows us to distinguish recent commonsense reasoning models by their performance.

Language	Before	After	Remaining, %
English	2605	2325	89.25
French	214	83	38.79
Japanese	1886	959	50.85
Russian	569	315	55.36
Chinese	18	16	92.28
Portuguese	285	263	88.89
Total	5577	3961	71.02

Table 1: Dataset sizes before and after filtering.

5 Experiments

Below we describe the experimental setup used to evaluate cross-lingual transfer capabilities of different approaches to commonsense reasoning and report the results. Note that we also aim to study the universal reasoning properties of attention heads, and thus we do not evaluate our method on common monolingual Winograd Schema datasets.

5.1 Setup

Models We use multilingual BERT (Devlin et al., 2019) and XLM-R-Large (Conneau et al., 2020), as these models are frequently used in other multilingual evaluation literature. The first model has 12 layers with 12 attention heads each, whereas the second model is a 24-layer Transformer with 16 attention heads on each layer. We do not evaluate XLM-R-Base or multilingual translation encoders (Siddhant et al., 2020) because we take two best-performing models according to the XTREME benchmark (Hu et al., 2020).

For our method, we use an implementation of logistic regression from scikit-learn (Pedregosa et al., 2011) with default hyperparameters as a linear classifier over attention weights.

Evaluation For unsupervised methods, we directly apply each method to each language subset and report the classification accuracy. For supervised methods, we first choose a single language for training and generate random train-validation-test splits, leaving 10% of data both for validation and testing subsets. For each language, we create 5

random train-validation splits to estimate the standard deviation of metrics, while keeping the same test set to keep the results comparable. Additionally, we test each trained model for a language on all other languages in a zero-shot setting, reporting averaged performance as well.

5.2 Baselines

To compare our approach with currently popular methods, we also evaluate a wide set of well-performing approaches described in earlier works:

Unsupervised We use three entirely unsupervised baselines inspired by prior work. For the first approach, we replace the pronoun by the number of `[MASK]` tokens equal to the length of each candidate answer and compare the MLM probabilities. For the second approach, we replace the pronoun with each of the answers and rank the candidates by "pseudo-perplexity" (Salazar et al., 2020), inspired by the results of Trinh and Le (2018). Both baselines use normalized scores with respect to the candidate word length.

The third unsupervised baseline is Masked Attention Score (MAS), described in Klein and Nabi (2019). Similarly to our method, this approach relies on attention weights for prediction; however, they are utilized differently and the model is unable to discover an optimal subset of heads.

Supervised First, we evaluated the masked language model finetuning approach suggested by the authors of WinoGrande (Sakaguchi et al., 2020). However, in our experiments there are no additional large-scale datasets; we found that with reference hyperparameters, the authors' implementation quickly overfits the training data for all languages in our relatively small benchmark, achieving less than 50% zero-shot accuracy on average.

In addition, we used the margin-based classification approach described in (Kocijan et al., 2019). This method achieves competitive results and outperforms unsupervised baselines in most setups, so we include it in our comparison.

5.3 Results

The results of our experiments for multilinual BERT and XLM-R-Large are shown in Tables 2 and 3 respectively. It can be seen that despite using only the attention weights as features, our method can outperform unsupervised approaches and performs competitively with a state-of-the-art supervised approach in several setups. Notably, the quality improves significantly when going from BERT to XLM-R: this goes in line with previous work on evaluation of cross-lingual encoders (Hu et al., 2020). At the same time, the quality of our method improves more significantly than of that suggested by Kocijan et al. (2019): this may be explained by a greater parameter count and a higher number of attention heads with more distinct specializations.

5.4 Ablation study

Here we compare several algorithm versions listed in Section 3.3. We train all models on the English part of the dataset and evaluate on all other languages, using validation subset performance as our

Figure 2: Averaged attention from the pronoun when using top-5 common heads.

target metric. As the Table 4 demonstrates, each choice leads to drops in performance, with the most influential being the choice of feature concatenation instead of taking the difference and attention direction being the least important decision.

6 Analyzing the attention heads

In this section, we intend to analyze the reasons behind competitive generalization performance of our approach. Mainly we compare the subsets of heads learned on different languages and measure their impact on the prediction quality.

6.1 Universal commonsense reasoning

For the first experiment, we rank the heads for models trained on all languages with the XLM-R[4] representations by the absolute value of the weight. Then, we consider the top-5 heads which are ranked highest on average across all languages. These common heads are located in the higher layers of the model, which was shown previously to encode mainly semantic features (Raganato and Tiedemann, 2018; Jo and Myaeng, 2020), which intuitively corresponds to the tasks the model needs to solve for pronoun resolution. Figure 2 shows the average attention weights of these heads for each word in several example sentences.

After we locate the most important common heads, we train linear classifiers restricted to these heads as features only for every language. To evaluate the importance of head choice, we also provide the performance of linear classifiers trained on a fixed subset of 5 random heads. The results of this experiment can be seen in Table 5; we observe that using the same top-5 heads (only 1.3% of the total number) across all languages preserves or even improves the results. The only exception is Chinese, which might not have enough labeled data to extract a sufficient amount of task-specific in-

---

[4] The results for mBERT are available in Appendix B.

Table 5: Performance of models trained with different subsets of XLM-R-Large attention heads.

formation. It means that a very small subset of attention weights is required to perform commonsense reasoning in all evaluated languages. This further supports the previous results on the analysis of linguistic universals in cross-lingual models (Chi et al., 2020; Wang et al., 2019b).

Moreover, restricting the subset of heads used in the MAS baseline to those selected by the classifiers significantly improves the quality of this unsupervised method as well, nearly closing the gap with the results obtained with supervision. This leads us to the conclusion that initially the poor performance of MAS might be caused by the suboptimal choice of attention heads; when the right heads are selected, their weights do not impact the predictions as significantly. Future unsupervised methods for commonsense reasoning can use that information to pay more attention to the choice of heads, which is currently a less explored subject.

6.2 The impact of number of heads

In this experiment, we directly study the connection between the number of heads and the quality of predictions. Specifically, after training a model with a full set of attention heads, we order them by the absolute value. Then, we retrain the model while keeping only the top-N important heads.

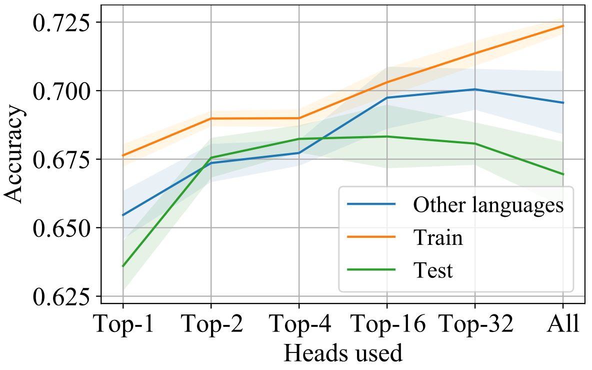

Figure 3: Effect of the number of XLM-R attention heads used when training on English data. Shaded areas show standard deviation across runs.

Figure 3 displays the results of our study for the English language; results for other languages can be seen in Appendix C. From these results, we find that although the training accuracy monotonically increases with the number of used attention weights, the optimal amount of heads for cross-lingual generalization is approximately equal to 16. This number is optimal or near-optimal for other languages as well, which might mean that as the number of features grows, the model either simply overfits the data or starts relying on features that are not universal for all languages.

7 Conclusion

In this work, we offer a simple supervised method to utilize pretrained language models for commonsense reasoning. It relies only on the outputs of self-attention and outperforms complete finetuning in a zero-shot scenario.

We also create a multilingual dataset of Winograd schemas that contains tasks from English, French, Japanese, Russian, Chinese, and Portuguese languages with the same specification. We want to encourage research on commonsense reasoning in languages other than English and release our benchmark to facilitate the development and analysis of new methods for this problem.

Lastly, we demonstrate that the reasoning capabilities of cross-lingual models are concentrated in a small subset of attention heads located in higher layers of the model. Furthermore, this subset of heads is language-agnostic, which sheds light at another facet of linguistic universals encoded in models such as multilingual BERT and XLM-R.

A In-language metrics for supervised methods

Here, we provide the metrics of our method and the finetuning baseline described by Kocijan et al. (2019) that were obtained on the training, validation and test data for the same language that the models were trained. Tables 6 and 7 demonstrate the results: it can be seen that although our approach performs less well on the same language that was used for training, the issue of overfitting on train data is less noticeable, which might be the reason for better zero-shot metrics.

B Analysis of common heads for multilingual BERT

Table 8 shows the evaluation results of models using top-5 attention heads of multilingual BERT. It can be seen that leaving only 5 heads out of 144 improves average accuracy in all cases and per-language accuracy in 18/30 cases without any significant decreases in quality.

C Impact of number of heads for other languages

In this section, we analyze the changes in both supervised and zero-shot performance for our method that follow from changes in the number of used attention heads. Figure 4 displays the results for French, Japanese, Russian, and Portuguese language; we omit the results for the Chinese language due to high variance from the small training dataset size. From this figure, we observe the same trend: increasing the number of used heads past 16 can favorably affect the accuracy on the training set, but negatively impacts the resulting quality both for the test set and for other languages.

Abstract

Pre-trained language models induce dense entity representations that offer strong performance on entity-centric NLP tasks, but such representations are not immediately interpretable. This can be a barrier to model uptake in important domains such as biomedicine. There has been recent work on general interpretable representation learning (Onoe and Durrett, 2020), but these domain-agnostic representations do not readily transfer to the important domain of biomedicine. In this paper, we create a new entity type system and training set from a large corpus of biomedical texts by mapping entities to concepts in a medical ontology, and from these to Wikipedia pages whose categories are our types. From this mapping we derive *Biomedical Interpretable Entity Representations* (BIERs), in which dimensions correspond to fine-grained entity types, and values are predicted probabilities that a given entity is of the corresponding type. We propose a novel method that exploits BIER's final sparse and intermediate dense representations to facilitate model and entity type debugging. We show that BIERs achieve strong performance in biomedical tasks including named entity disambiguation and entity label classification, and we provide error analysis to highlight the utility of their interpretability, particularly in low-supervision settings. Finally, we provide our induced 68K biomedical type system, the corresponding 37 million triples of derived data used to train BIER models and our best performing model.

1 Introduction

In modern NLP systems, entities are embedded in the same dense vector space as words using vectors from pre-trained (masked) language models (Devlin et al., 2019) that yield contextualized embeddings of tokens. These representations are used as inputs for downstream models built for particular tasks. One issue with such learned representations is that we do not actually know what information they encode. Recent work has shown that deep pre-trained models implicitly learn factual knowledge about entities (Petroni et al., 2019; Roberts et al., 2020), but the embeddings that they provide do not explicitly maintain representations of this knowledge (i.e., the dimensions in learned representations have no *a priori* semantics); consequently, are not directly interpretable. This has motivated the design of knowledge *probing tasks* to measure a factual knowledge implicit in embeddings (Petroni et al., 2019; Poerner et al., 2019).

Recent work (Onoe and Durrett, 2020) has proposed learning interpretable entity representations using an entity typing model and corresponding fine-grained type system that accepts an entity mention and its context. The output represents a high-dimensional sparse embedding whose values correspond to the model's (independently) predicted probabilities that the entity possesses the respective properties defined by the fine-grained type system.

This past work proposed general domain pre-trained Transformer-based (Vaswani et al., 2017) entity typing models trained on Wikipedia or the ultra-fine entity typing system (Choi et al., 2018), yielding 60k and 10k dimensional embeddings, respectively, which can then be used directly in downstream tasks. Such representations can achieve strong results without learning task specific representations. Thus, in addition to providing interpretability, such representations may be particularly useful for tasks with limited supervision.

Such interpretable entity representations for text can be valuable in domains such as biomedicine, because they afford model transparency which may help with model debugging, or simply to instill confidence in model outputs. For example, if one defines a linear layer on top of entity-type representations, learned coefficients are interpretable as

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3547–3561
August 1–6, 2021.

weights assigned to specific entity types. One could debug an incorrect prediction by inspecting the induced representation for potentially erroneous types assigned to it. This sort of insight is particularly important in biomedical NLP, given the potential sensitivity of the tasks in the domain, and the high-level expertise of the 'end-users'.

Motivated by these observations, we extend (Onoe and Durrett, 2020) to learn sparse Biomedical Interpretable Entity Representations (BIERs) in which values encode predicted probabilities of an entity belonging to a type from a fine-grained entity type system. Starting from a corpus of PubMed[1] articles on cancer and drugs as our training data, we induce an entity type system by mapping entities in the articles to their associated UMLS concepts, and then mapping the concepts to Wikipedia pages whose categories we use as our types.

We show that learning a typing model on top of such a system realizes strong performance on a variety of biomedical tasks including named entity disambiguation (NED) and entity label classification using simple cosine similarity or Euclidean distance based methods, and we provide an analysis of the results from an interpretabilty perspective. In addition, we propose a simple technique that facilitates debugging and provides a mechanism by which to improve model performance by exploiting both the proposed sparse interpretable type representations and their internal underlying dense counterparts. Finally, we introduce and release a new medical-centric Wikipedia dataset based on (Rosenthal et al., 2019) for use in the task of biomedical NED.

Our specific contributions[2] are as follows:

- We create (and will release) a biomedical entity typing system comprising Wikipedia Categories from pages mapped to UMLS concepts linked to PubMed article entities and learn a model that produces sparse entity representations in which dimensions are imbued with known semantics. We show that these achieve strong performance on biomedical NED and entity label classification tasks.

- We conduct an interpretability analysis and demonstrate a new debugging method that uses the proposed representation's performance on downstream tasks to gain insights into the entity typing model and system.

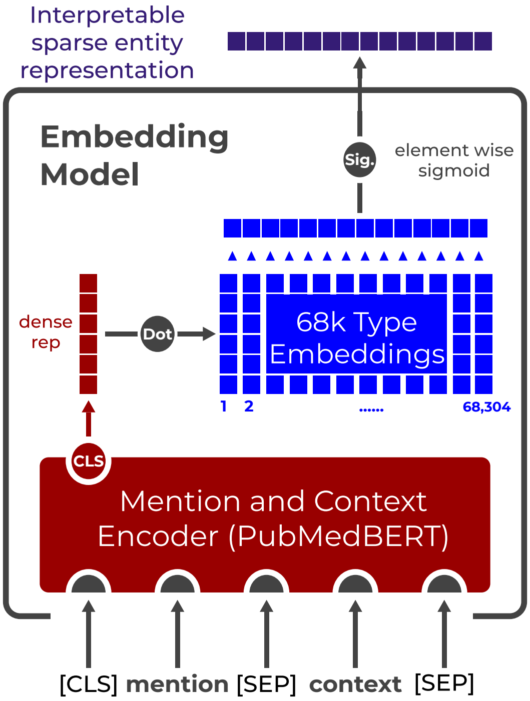

Figure 1: Model architecture from (Onoe and Durrett, 2019) using our 68k biomedical entity type system. A BERT based encoder embeds a mention and context and the output entity embedding contains probabilities for each type.

- We release a medical literature centric Wikipedia dataset for use in the task of biomedical NED.

2 Background: Interpretable Entity Model

We first review the interpretable entity model architecture we extend from (Onoe and Durrett, 2020).

Let $s = (w_1, ..., w_N)$ denote a sequence of input context words, $m = (w_i, ..., w_j)$ denote an entity mention span in s, and $\mathbf{t} \in [0, 1]^{|\mathcal{T}|}$ denote a vector whose values are predicted probabilities corresponding to fine-grained entity types $\mathcal{T}$ from a predefined type system with higher values identifying types most pertaining to m and s .

Given a labeled dataset $\mathcal{D} = \{(m, s, \mathbf{t}^*)^{(1)}, ..., (m, s, \mathbf{t}^*)^{(k)}\}$ the objective is to learn parameters θ of a function f_θ that maps the mention m and its context s to a vector $\mathbf{t}$ that captures salient features of the entity mention within its context. The basic idea is that the

---

[1] A repository of biomedical literature: `http://www.pubmed.gov/`.

[2] Code and datasets available at `http://github.com/diegoolano/biomedical_interpretable_entity_representations`

resultant entity embeddings $\mathbf{t}$ (wherein individual dimensions have explicit semantics) can be used as embeddings in downstream tasks, for example by using basic similarity measures such as dot products or cosine similarities.[3]

The simple model f_θ that produces these embeddings is shown in Figure 1. First, a BERT-based encoder (Devlin et al., 2019) maps inputs m and s to an intermediate dense vector representation. Specifically, the encoder takes as input a token sequence formatted as $\mathbf{x} = \texttt{[CLS]}\ m\ \texttt{[SEP]}\ s\ \texttt{[SEP]}$, where the mention m and context s are segmented into WordPiece tokens (Wu et al., 2016). The hidden vector output corresponding to the `[CLS]` token can be treated as the intermediate dense mention and context representation: $\mathbf{h}_{\texttt{[CLS]}} = \textsc{BertEncoder}(\mathbf{x})$.

A type embedding layer then projects this intermediate representation to a vector whose dimensions correspond to the entity types $\mathcal{T}$ using a single linear layer whose parameters may be viewed as a matrix of type embeddings $\mathbf{E} \in \mathbb{R}^{|\mathcal{T}| \times d}$, where d is the dimension of the mention and context representation $\mathbf{h}_{\texttt{[CLS]}}$. Finally, we apply a sigmoid function to each unnormalized score in the vector to obtain the predicted probabilities that form our entity representation $\mathbf{t}$ (top of Figure 1). We obtain these output probabilities $\mathbf{t}$ by multiplying $\mathbf{E}$ by $\mathbf{h}_{\texttt{[CLS]}}$, followed by an element-wise sigmoid function: $\mathbf{t} = \sigma\left(\mathbf{E} \cdot \mathbf{h}_{\texttt{[CLS]}}\right)$

Following Choi et al. (2018), the training loss we minimize is a sum of binary cross-entropy losses over all entity types $\mathcal{T}$ over all training examples $\mathcal{D}$. That is, we treat each type prediction for each example as an independent binary decision, with shared parameters in the BERT encoder. Our loss $\mathcal{L}$ is:

$$-\sum_i \sum_j t^*_{ij} \cdot \log(t_{ij}) + (1 - t^*_{ij}) \cdot \log(1 - t_{ij}),$$

where i are the data indices, j are indices over types, t_{ij} is the jth component of $\mathbf{t_i}$, and t^*_{ij} is the jth component of $\mathbf{t_i}^*$ that takes the value 1 if the jth type applies to the current entity mention. We fine-tune all parameters in BERT and the type embedding matrix.

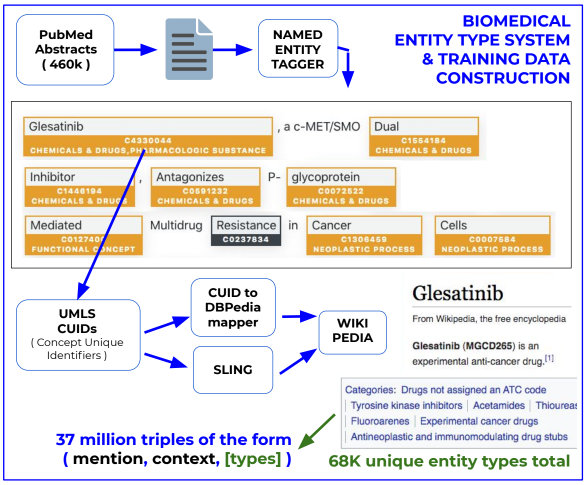

Figure 2: Biomedical Entity Type System and dataset construction. Appendix Fig 4 contains example output.

3 Biomedical Interpretable Entity Representations

Biomedical Entity Typing To train an interpretable entity embedding model tailored specifically for biomedical tasks, we must first construct a suitable biomedical entity type system and dataset. PubMed indexes over 30 million biomedical citations across a wide range of topics. To curate a topically focused set of literature, we first used the PubTator tool (Wei et al., 2019) to query PubMed for articles related to drugs used as treatment for cancer; this yielded 461,404 unique citations (titles and abstracts).[4]

We used an off the shelf NER tagger available in `SciSpacy` (Neumann et al., 2019) to identify entity spans within abstracts, and used the `Entity Linker` component to link those entities to concept unique IDs (CUIDs) within the Unified Medical Language System (UMLS) ontology[5].

Next we had to decide on the specific entity type system to use, i.e., the set of labels to attach to entities, and chose Wikipedia as our knowledge base. We used this general knowledge base instead of a specialized ontology (for example, MeSH or SNOWMED CT) primarily because it yielded (many) more diverse entity types per mention, comparatively.

To connect UMLS concepts to Wikpedia pages

---

[3] Fine-tuning the representations would destroy their interpretability.

[4] We selected the topic of cancer because our work is motivated by a larger project aimed at finding existing evidence that supports repurposing generic drugs for cancer.

[5] UMLS defines around 3 million concepts from a combined 200 source ontologies. Concepts may be identified as having one or more of 127 semantic types which can be used to place them into groupings such as diseases or drugs.

we use the mapping from Cuzzola et al. (2018), which is accurate but incomplete: It provides exact wikipage matches for 221,690 concepts and "close matches" for 26,276 of them, out of a possible 3 million concepts in UMLS. For concepts for which no exact or close match was found, we used SLING (Ringgaard et al., 2017), a framework for frame semantic parsing which allows for querying and resolving wikipages given a search string (in our case, mention surface forms). For high confidence exact or close matches, we return the set of categories found for their combined results. While these results can be slightly noisy, they mostly lead to satisfactory performance.

We filter the entity mentions that compose our final set, as follows. If multiple concept CUIDs are found for a given entity, we include the highest scoring matches within two points of each other provided they all exceed a minimum score threshold of 0.8;[6] Additionally, we only include results that are linked to at least one concept CUID and where an associated Wiki link was mapped to directly via Cuzzola et al. (2018) or via SLING. A schematic of this process is shown in Figure 2. An example working through the entity filtering process is shown in the text of Appendix A. In the end about 12.5% of the mappings from PubMed mentions to Wikipedia categories come via SLING.

After processing, linking and filtering the corpus of PubMed abstracts, we were able to extract 37,357,141 triples of the form (mention, context, [list of categories]). This list of triples contains 68,304 unique categories which we use as the entity type system for training BIERs. Appendix 8 contains a list of the top 100 entity types that appear over these articles and Appendix 5 shows a histogram of entity types per mention. As one contribution, we will release this set of derived triples.

To assess the quality of this dataset, we chose 500 triples at random and asked 4 experts (researchers in biomedicine and ML) to score them on a Likert scale from 1 (low) to 5 (high) for accuracy. Experts assessed how well a PubMed mention from a context sentence maps onto a Wikipedia URL. Average expert scores for the triples were [4.01, 4.13, 4.18, 4.20] (overall mean of 4.13) out of 5. The Fleiss-Kappa score which measures inter-annotator agreement was strong at .69. Additionally 77% of scores are $>=4$, and for 93% of the examples at least 3/4 experts agree (73% have unanimous agreement).

BIER entity typing model training and test results We split our derived dataset of biomedical triples into train, validation, and test sets of sizes 31,340,000, 376,071, and 5,641,070, respectively. For comparison, the total data size used by Onoe and Durrett (2020) is 6.1 million and based on the most popular categories of Wikipedia whereas ours only uses categories on pages linked to UMLS.

We trained different BIER models using variants of BERT as an encoder for mentions and contexts. Specifically we considered BioBERT (Lee et al., 2019), SciBERT (Beltagy et al., 2019) and BLURB (Gu et al., 2020) (we will refer to this as PubMedBERT), which constitute the current state of the art for many biomedical tasks.We compute entity typing macro F1 using development examples to check model convergence and use the hyperparameters from Onoe and Durrett (2020).

Debugging BIERs by combining dense and sparse embeddings We propose a technique for debugging using BIER representations that is in part inspired by prior work that used intermediate layer representations of training examples as additional features (Papernot and McDaniel, 2018). Specifically, we propose to debug BIER performance on downstream tasks by examining instances where dense and sparse representations yield different outputs. For each example, BIER models produce an intermediate dense $\mathbf{h}_{\texttt{[CLS]}}$ and interpretable sparse output embeddings t (red and purple, respectively, in Figure 1). We will refer to the two seperate models which use these dense and sparse BIERs embeddings for downstream tasks as `BIERDense` and `BIERSparse` respectively.

After performing inference initially, we gather all test examples where the `BIERDense` makes a correct prediction but `BIERSparse` does not and we place their mention values into a set $\mathcal{Z}$. Additionally, as a diagnostic measure, we consider an 'oracle' approach in which we use the `BIERDense` prediction for all instances in $\mathcal{Z}$, and the `BIERSparse` output otherwise. The intuition is that $\mathcal{Z}$ contains examples for which the intermediate dense embeddings better represent a mention-context than the more interpretable sparse output embeddings from the BIER model.

Because the sparse embeddings are interpretable, this analysis affords fine-grained analysis of which

---

Table 1: Comparison of BioMed Linked Datasets. BIERs and ClinicalWikiNED datasets described in Section 3 and 4.1 respectivtely

entity types lead to incorrect predictions by the sparse model (but correct predictions using a dense representation). This diagnostic can be used as a benchmark for how well the model could have done had the entity typing model's output better represented the mention-context, or if the model had known to fallback to using the intermediate dense embedding; the former case might be ameliorated via more supervised examples or changes to the type system while the latter could motivate a dynamic approach to making predictions that is a function of model confidence. We show results and analysis using these methods in Section 5.

4 Experimental Setup

To evaluate the utility of the proposed biomedical entity representations, we use them for the tasks of biomedical entity label classification (ELC) and named entity disambiguation (NED). We highlight that these models perform well even without fine-tuning, which is critical in low- or zero-supervision scenarios.

4.1 NED on Biomedical Wikipedia articles

The NED task connects entity mentions in text with real world entities in a knowledge base by disambiguating the true entity from a list of candidates. We consider the local resolution setting in which each instance features a single entity mention span in the input text and several possible candidates with corresponding descriptions (e.g., the first paragraph of their Wikipedia article).

NED dataset construction While there exist multiple biomedical named entity recognition and linking datasets (Mohan and Li, 2019; Basaldella et al., 2020), we did not find much in the way of publicly available biomedical NED corpora, and we therefore constructed a new dataset, which we will release for use by other researchers. The dataset is based on the set of Wikipages used by Rosenthal et al. (2019), as relevant medical literature which consists of 34,692 medically relevant articles under the 'Clinical Medicine' category [7]. We used SLING[8] to process these articles and were able to retrieve around 1.5 million training examples (mention, context, [categories]) from them.

After obtaining these examples for each entity mention we used the CrossWikis dictionary (Spitkovsky and Chang, 2012) to try to gather between 3 to 5 challenging candidate entities for the example. This range in terms of number of candidates was selected because we wanted to include salient biomedical terms that are difficult to disambiguate; setting a higher number of potential candidates for use with CrossWikis largely gives general and short "popular" candidates (i.e., those that appear often in Wikipedia). This behavior makes sense since many biomedical terms are quite specific and usually only have a few high quality alternative candidates to select from. Additionally, we filter out redirect pages and pages that no longer match the wiki version used to create CrossWikis.

This candidate generation and data content acquisition step filters out considerably the number of available examples. We additionally subsample the dataset to reduce the instances where the "popular" candidate is the correct entity so as to make the task more difficult and to allow for more rare entities to appear in our set. After all the filtering, our ClinicalWikiNED dataset consists of a train/dev/test split of size 5332, 3730, and 800 respectively. Table 1 shows a comparison of the two datasets introduced in this paper with that of one of the largest publicly available linked biomedical datasets(Murty et al., 2018).

Using BIERs for NED Using the BIER architecture, we first train a separate `WikiDescription` model that takes as input a wikipage title as its mention, its first paragraph as the context, and outputs a sparse embedding that predicts the page's categories. As training data, we use any Wikipedia page that contains categories in our biomedical entity type system. We use 2.5 million such (title, descriptions, [categories]) as our training data, and we check for model convergence on a small development set. This model is used so that candidate embedding dimensions will align with our BIER mention-context embeddings.

For each mention m and context s in the test set, we use a BIER model to induce a sparse rep-

resentation t. We then go through each candidate c_i for the current test example and use the `WikiDescription` model to retrieve the candidate's sparse output embedding t_{c_i}. Finally, we compute both the cosine similarity and dot product of t with each candidate t_{c_i} and predict the candidate c_i that achieves the highest score for each metric as the true one.

Baseline model for NED We use the EntEval (Chen et al., 2019) framework for our experiments and train a logistic regression classifier using a feature vector composed of the mention-context embedding x_1 and current candidate wiki description embedding x_2 from the set of candidates C_m as a concatenation of x_1, x_2, element-wise product, and absolute difference: $[x_1, x_2, x_1 \odot x_2, |x_1 - x_2|]$. Both x_1 and x_2 are obtained via BERT based models. Training minimizes binary log loss using all negative examples. At test time, inference combines this classifier result with the prior probability of how frequently candidates occur in Wikipedia as follows: $arg\ max_{c \in C_m} [p_{prior}(c) + p_{classifier}(c)]$ to obtain the final candidate prediction. Directly using the most likely prior as predictions yields an accuracy of 73.9%. We emphasize that these baselines are fine-tuned on the task data while the BIER models only do inference on the test set.

Results Table 2 shows the results of the NED experiments. The biomedical BIER model affords improvements over the prior general domain interpretable model (Onoe and Durrett, 2020), showing that the biomedical type system and training is beneficial for this type of task. In addition, the BIER models outperform the baselines without fine-tuning on the training data.

4.2 ELC on Cancer Genetics data

For our entity label classification task we use the Cancer Genetics dataset (Pyysalo et al., 2013) which consists of 10,935 training, 3,634 dev, and 6,955 test examples from 300, 100, and 200 unique PubMed articles, respectively.[9] Given an article title and abstract, mention, and the corresponding entity label, the objective is to predict this label from 16 available coarse labels (see Table 7 in the Appendix for label distribution information).

To assess how well the learned BIER representations fare against comparable baselines, we perform a simple nearest neighbor classification technique using the proposed BIER model variants, the general domain model from Onoe and Durrett (2020), and non-BIER fine-tuned pre-trained language models as standalone encoders.

We first induce dense embeddings for all training examples by passing the mention m and context s through the encoders as `[CLS]` m `[SEP]` s `[SEP]`, and we store the resultant contextualized `[CLS]` embedding $\mathbf{h}_{\texttt{[CLS]}}$ as our dense embedding. For the BIER and Onoe and Durrett (2020) models we also save the final sparse entity embedding $\mathbf{t}$.

We iterate over the test examples and similarly induce dense representations for these $\mathbf{h}^{test}_{\texttt{[CLS]}}$ and (if applicable) sparse representations $\mathbf{t}^{test}$. We find their nearest neighbor (under either $\ell 2$ distance or dot product similarity) from the saved training set of embeddings, and use its label as the prediction. We use the FAISS semantic indexer (Johnson et al., 2017) for storing embeddings and finding nearest neighbors quickly. We are interested in evaluating the off-the-shelf utility of learned representations, and, as such, we do not train or fine-tune the models in any of these cases; rather, training examples are used only for nearest neighbor retrieval.

That said, for completeness we also performed additional experiments in which we do fine-tune models on the task data, with varying amounts of supervision; we are interested especially in low-supervision settings. For the fine-tuning experiment, we add a linear layer on top of the best performing BIER and baseline models, using cross entropy loss as our objective and fine-tuning them for 4 epochs on the training data before performing inference. For the low supervision regime experiment, we show how the best nearest neighbor and

fine-tuned models perform when given K examples per class for $K \in [5, 10, 25, 50, 75, 100, 200]$

Results Table 3 shows the results for our first experiment, in which we use untuned representations. We observe that the baseline language model encodings all perform worse than the proposed BIER sparse and dense models, with the exception of SciBERT, which fares better than the sparse BIER model based on SciBERT. Additionally, we see that BERT and Onoe and Durrett (2020) (which is based on BERT) both perform poorly in this biomedical task compared to the other baselines.

Importantly, we notice that the sparse interpretable embedding results for our top performing models (both BIER-PubMedBERT and BIER-BioBERT) perform near the level of their dense, non-interpretable counterparts. In the next section we will look at some illustrative test examples cases along with a simple technique to leverage both the dense and sparse embeddings that a BIER model can give to improve performance on the task and gain insight into where the entity type model and system may be underperforming.

Table 4 shows the results of our fine-tuning experiment. Freezing the model and allowing only the classification layer to learn weights doesn't allow enough capacity for either case, while fully fine-tuning both models gives improved performance in both models. However because the BIER model is no longer tied in, the interpretability component of our representations is eliminated, a limitation left for future work.

Figure 3 shows BIER-PubMedBERT performs better than the fine-tuned and non-interpretable PubMedBERT model when there are fewer than 100 examples per class (which is the case for 6 out of the 16 test classes in the dataset as seen in table 7 in the appendix).

5 Debugging with BIERs

One of the claimed advantages of BIERs is their ability to facilitate model debugging. In this section we provide illustrative examples where the interpretability of the underlying representations offers insights into model behavior and suggests avenues for improvements.

Entity Type and Mention Analysis We illustrate the debugging strategy proposed in the context of entity label classification. Recall that this entails inspecting test examples for which the dense model yields a correct prediction, while the sparse variant does not (implying that the former somehow better represents the instance). We can inspect these cases to understand what entity types are leading to such behavior. Appendix Table 11 and 12 enumerate such mentions and their most probable types. We note the inclusion of many people's names (e.g., "Anthony Campbell", "Tony Walsh") which have been assigned at least some incorrect types in their sparse representations. This highlights a general failure mode of the model: It is assigning incorrect types to person names, which may be causing downstream prediction errors. This is actionable information, as we could remedy the issue via rules, additional, targeted supervision or by down weighting probabilities given to common erroneous types for these mentions.

To better characterize entity type errors, we gather the set of the 20 most probable entity types for all mentions incorrectly predicted by the BIER sparse model and sort types by frequency. We do the same for those predicted correctly. The resulting two lists share many of the same top popular types, but looking at relative rankings and only displaying those that are comparatively far apart[10] reveals some interesting results. Tables 9 and 10 report entity types correlated with correct and incorrect predictions, respectively. We emphasize this type of analysis is only possible due to the interpretable nature of the proposed BIER embeddings.

As a final illustrative debugging example, we consider a test example mention "thyroid carcinomas" with label "Cancer", along with the predictions made by the sparse model, "thyroid" with the incorrect label "Organ", and the dense model,"esophageal carcinoma" with the correct label "Cancer". We also retrieve the first correct prediction from the nearest neighbors of the sparse model embedding "medullary thyroid carcinoma" which we refer to as the *counterfactual* sparse prediction.[11] We take the dot product of the mention-context embedding with these three prediction's embeddings and inspect the top types which lead to their selection in Figure 6 in Appendix C. Both the incorrect sparse and correct counterfactual sparse predictions, at the surface level are quite similar to the test mention, but have lower scores for the entity type 'thyroid cancer' compared with the dense prediction which gives the correct label, but is semantically less similar to the test mention than the counterfactual sparse prediction. Additionally, the noisy type "rtt" erroneously plays more of a role in the sparse model predictions as well.

Diagnosing task results In analyzing errors made by the highest performing BIER dense and sparse nearest neighbor models for the entity label classification task, we noticed that while there was high concurrence for correct predictions (i.e., of the 88% true predictions made by the dense model overall, the sparse model agreed with the prediction 95% of the time), the cases where the model predictions disagreed, but where one of them still predicted the true label, were quite varied. In other words, the sparse model gave many correct results on test cases when the dense model gave incorrect ones and vice versa. Applying the diagnostic technique from Section 3, we see the classifier's overall performance could have improved from 88.2 to 91.9 had the model known when to utilize its intermediate dense representation over its sparse output.

	Test Acc.			
Task	Dense	Sparse	Combined	Δ
NED	84.0	81.0	**91.7**	+7.7
ELC	87.5	88.2	**91.9**	+3.7

Table 5: Results for both tasks showing improvements that could have been achieved by combining intermediate dense and interpretable sparse output embeddings generated by the same BIER-PubMedBERT model.

Similarly we applied the diagnostic technique to the NED task and leave more details in Appendix B. Incorporating mentions that the dense dot product BIER model handles better than the cosine similarity based sparse one does would have given an improvement from our prior accuracy of 84.0 to 91.7. Table 5 shows the possible improvement in task accuracies for both tasks.

6 Related Work

In this work we have introduced a predefined fine-grained biomedical type system comprising 68k types, explicitly tied to PubMed. Instead of using a fixed type system, Raiman and Raiman (2018) seek to dynamically learn a 100 dimensional type system from a much larger general domain type system in order to optimally disambiguate entities.

Aside from work on biomedical NLP and entities specifically, there exists a line of work on interpretable word embeddings (Subramanian et al., 2017; Faruqui et al., 2015). A common approach here is to identify the groups of words most associated with vector components globally, somewhat akin to topic models. This differs from our approach, which is based on an external type system and provides immediate, instance-level interpretable probabilities for each entity type. Hu et al. (2020) proposes transforming dense to sparse representations independent of entity typing.

Another related line of work tests a models' ability to induce syntactic or type information by the measuring accuracy of a probe (Peters et al., 2018; Hewitt and Manning, 2019; Hewitt and Liang, 2019). There is significant uncertainty about how

---

[10] We chose to highlight entity types that are farther than 50 rankings apart to have a small set to display.

[11] Had the mention under consideration instead mapped to this sparse representation, the prediction would have been different, and correct.

to calibrate such post-hoc probing results (Voita and Titov, 2020) whereas our model's representations are directly interpretable.

While many interesting biomedical entity representation and linking task oriented works (Murty et al., 2018; Vashishth et al., 2020; Mondal et al., 2019; Sung et al., 2020; Liu et al., 2020) leverage PubMed or UMLS for semantic type, entity synonym, or self alignment purposes, our work is the first to incorporate interpretable embeddings that are linked to a biomedical entity type system.

7 Conclusions

We have introduced a new biomedical entity typing system and training set from a large corpus of biomedical texts. We will release this dataset, which comprises 37 million derived triples. Exploiting this data, we proposed *Biomedical Interpretable Entity Representations* (BIERs), in which dimensions correspond to fine-grained entity types, and values are predicted probabilities that a given entity is of the corresponding type.

Using two downstream biomedical tasks, we showed that BIER representations yield predictive performance that is competitive with dense (uninterpretable) representations, and that such representations are particularly beneficial in zero-shot or low-supervision settings. We also demonstrated that BIER representations can facilitate meaningful model debugging both at the mention and entity type level.

Acknowledgements

This material is based upon work supported in part by the National Science Foundation (under Grants No. NSF 1901117 and NSF 1750978) and in part by a grant from the Office of Naval Research (ONR N00014-17-1-2143). The project was conducted under the auspices of the IBM Science for Social Good initiative.

Ethical Considerations

NLP models are increasingly used in biomedicine, where some applications can be quite high-stakes. Establishing trust in such models is therefore paramount; unfortunately, deep neural networks tend to be opaque in their operations, potentially precluding their use in certain areas of biomedicine where they might otherwise be beneficial. This work is a step towards more transparent models for biomedical NLP.

A BIER system level specifics

To better illustrate the process of which mentions are retained during our filtering process, Table 6 shows the 6 concepts associated with an example mention of ”phase II clinical trial” found in a PubMed article. We see all 6 concepts score higher than our minimum threshold and we use the two highest scoring matches that are within 2 points of each other: CUIDs C0282460 and C1096779. the former C0282460 has a WikiPedia data item Q7180990 that corresponds to the page “wiki/Phases_of_clinical_research” whose associated categories are “Clinical research”, “Design of experiments”, “Life sciences”, “industry”. The second result C1096779 has no direct WikiPedia match and the results we get from SLING include “Clinical trial”, “Scientific control”, “Medicine”, “Topical medication”, “Observational study”, “Literature”. Hence for this mention and context from a PubMed abstract, we are able to extract a (mention, context, list of types) triple of the form (“phase II clinical trial”, context, [“Clinical research”, “Design of experiments”, “Life sciences” industry”, “Clinical trial”, “Scientific control”, “Medicine” ....]].

CUID	**Concept Name**	**Score**	**DBPedia**
C0282460	Phase 2 Clinical Trials	0.9999	Q7180990
C1096779	Clinical Trial, Phase II	0.9999	none
C0282461	Phase 3 Clinical Trials	0.9496	Q7180990
C0920321	Phase I Clinical Trials	0.8707	Q7180990
C1096780	Clinical Trial, Phase III	0.8635	none
C0282462	Phase 4 Clinical Trials	0.8208	Q7180990

Table 6: Using an NER tagger we find 6 associated concepts in UMLS for the mention “phase II clinical trial” in a context sentence “Unraveling the molecular mechanism of BNC105, a phase II clinical trial vascular disrupting agent, provides insights into drug design.”

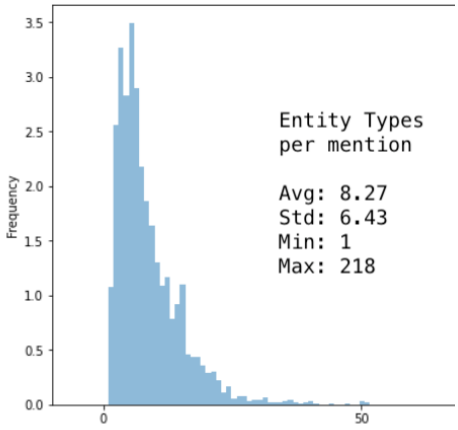

Figure 5: Entity Types per mention on Training set for BIER

B NED diagnostic details

For the NED task we used the BIER’s sparse embeddings of test mentions in their contexts and took cosine similarity with a separate BIER model’s sparse embeddings of candidate wiki descriptions to make our predictions. To use the diagnostic technique we first get task predictions using the dense embeddings from the BIER models which gives results of 81 and 79.25 percent test accuracy using dot product and cosine similarity respectively. Although the prior sparse cosine similarity BIER model in this case gave a higher 84.0 percent test accuracy, using the diagnostic technique in this case by incorporating mentions the dense dot product BIER model handles better would have given an improvement in accuracy from 84.0 to 91.65.

Learning Robust Latent Representations for Controllable Speech Synthesis

Shakti Kumar[*†] **Jithin Pradeep**[*] **Hussain Zaidi**[*]

[*]Vanguard Center for Analytics and Insights
[†]Computer Science, University of Toronto

{shakti_kumar, jithin_pradeep, hussain_zaidi}@vanguard.com

Abstract

State-of-the-art Variational Auto-Encoders (VAEs) for learning disentangled latent representations give impressive results in discovering features like pitch, pause duration, and accent in speech data, leading to highly controllable text-to-speech (TTS) synthesis. However, these LSTM-based VAEs fail to learn latent clusters of speaker attributes when trained on limited or noisy datasets. Further, different latent variables are found to encode the same features, limiting the control and expressiveness during speech synthesis. To resolve these issues, we propose REMMI (Reordered transformer Encoder with Minimal Mutual Information) where we minimize the mutual information between different latent variables and devise a modified Transformer architecture with layer reordering to learn controllable latent representations in speech data. We show that REMMI reduces the cluster overlap of speaker attributes by at least 30% over LSTM-VAE.

1 Introduction

Learning disentangled latent representations in speech is an active area of research (Hsu et al., 2017; Chou et al., 2018; Park et al., 2020) with applications in controlling the style (for example, pitch, pause duration, and accent) of synthesized speech. Recurrent architectures like Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997) networks in Variational Autoencoders (VAE) have been state-of-the-art in discovering disentangled latent representations in speech (Wang et al., 2018; Jia et al., 2018; Skerry-Ryan et al., 2018) as well as sequential data more generally. For example Li and Mandt (2018) attempt to disentangle global and local features of video/speech in different latent variables. Hsu et al. (2019) disentangled different dimensions of the latent variables to discover meaningful representations and hence proposed a speech synthesis model with controllable pitch, pause duration, and speed.

These papers as well as several others (Chung et al., 2015; Hsu et al., 2019; Leglaive et al., 2020; Hono et al., 2020; Sun et al., 2020) make one limiting assumption— the availability of hundreds of hours of speech data for training deep learning networks. As we show in our experiments, state-of-the-art VAEs fail to learn meaningful separation of speaking styles in speech data when presented with small datasets. In addition, different latent variables learned by the VAE are no longer uncorrelated. Both these shortcomings lead to poor control of speaking styles during synthesis.

While LSTMs are state-of-the-art in learning latent variables in speech, Transformers have been used for understanding latent representations for text completion (Wang and Wan, 2019) and Transformer-based VAEs were used in Jiang et al. (2020) to model independent style attributes in music generation.

Inspired by these limitations of LSTM-based VAEs and the promise of more ”attentive” networks, we modify the loss function of the state-of-the-art VAEs (Hsu et al., 2019) by explicitly minimizing the mutual information between latent variables, thereby penalizing common learned features between different representations. We then modify Transformer architecture for learning robust disentangled latent representations of speech from limited and noisy data. We show that our proposed architecture– REMMI (Reordered transformer Encoder with Minimal Mutual Information) discovers compact stable latent representations of speaker attributes even on datasets as small as 4 hours of total speech samples while state-of-the-art fails. Our proposed VAE outperforms LSTM and vanilla Transformers even on challenging dataset like Common Voice which has considerable background noise, low recording quality and large num-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3562–3575
August 1–6, 2021.

ber of speakers with the same style or accent. To summarize, following are the main contributions of our work,

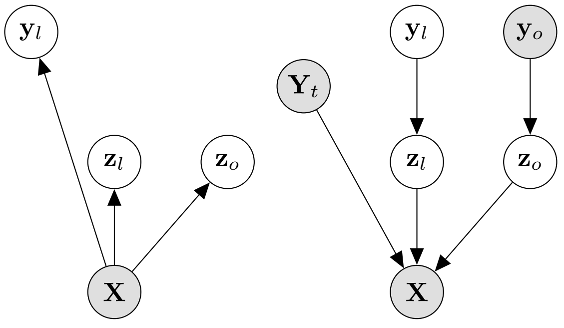
1. Formulate a modified VAE loss function for speech data and a novel Transformer-based VAE for learning uncorrelated latent variables, thereby allowing more precise control over synthesis compared to the existing state-of-the-art.
2. Show that our latent clusters of speaking styles are better separated than existing LSTM and vanilla Transformer based VAEs on noisy and small datasets.
3. Show that the our modified Transformer architecture allows a faster convergence of the variational lower bound compared to both vanilla Transformer and LSTM based VAEs.

2 Related Work

Multiple previous work have targeted this problem of learning latent representations for sequential data like speech (Wang et al., 2018; Jia et al., 2018; Skerry-Ryan et al., 2018). As discussed, the main advantage of learning such representations is that it allows creating diverse examples during reconstruction by manipulating the encoded latent variable. Li and Mandt (2018) propose two sets of latents which learn global features like the generated sequence contents and local dynamic features such as pitch, speed etc. However, a limitation of this approach is the lack of interpretability of the learnt dimensions— it is known that the different dimensions of the latent variables are learning some features but there is little to no visibility into what those actual features are.

Modifying Text-to-Speech systems by introducing additional encoders has been a standard way to discover meaningful representations. Zhang et al. (2019) build on top of Tacotron-2 (Shen et al., 2018) architecture and use Gaussians to model their latent variables. An improved version can be seen in Hsu et al. (2019) where a hierarchical latent with mixture of Gaussians is used. Hsu et al. (2019) propose adversarial training to further improve latent variables and the features discovered by disentangling the background noise and reverberation along with speaker identity from the recording conditions.

While all these prior work aim to discover latent representations, there is a lot of room for improving those representations especially in cases where we have very limited hours of speech dataset. As we show in our experiments, in the absence of explicit restrictions on the training objective these VAEs easily collapse when presented with smaller datasets. Thus we focus on improving the representations, specifically latent clusters of speaker attributes, in cases of extremely limited datasets. Our contributions, however are not limited to smaller datasets and we see similar improved performance on larger and noisy datasets too.



(a) Encoder (b) Generator

Figure 1: Graphical model of controllable TTS system. Note that $q(\mathbf{y}_l|\mathbf{X})$ in the Encoder can be approximated in terms of $q(\mathbf{z}_l|\mathbf{X})$, in which case node $\mathbf{y}_l$ will have an edge from $\mathbf{z}_l$ instead of $\mathbf{X}$ as done in Hsu et al. (2019).

3 Background

Controllable text-to-speech (TTS) VAE-based systems like in Hsu et al. (2019) take an input text sequence $\mathbf{Y}_t$ and an optional observed categorical label $\mathbf{y}_o$ (e.g., speaker identity or accent) as input and learn to synthesize a sequence, usually mel-spectrogram frames $\mathbf{X}$ as output. Additional latent variables $\mathbf{z}_o$ and $\mathbf{z}_l$ can be introduced to discover meaningful representations during this process. Here $\mathbf{z}_o$ is a continuous latent learnt on top of shown labels $\mathbf{y}_o$, hence $\mathbf{z}_o$ captures the variation in features correlated with the speaker attribute $\mathbf{y}_o$. $\mathbf{z}_l$ is a completely unsupervised continuous variable learnt on top of standard Expectation-Maximization style latent mixture components $\mathbf{y}_l$. This graphical model is depicted in Figure 1. The objective function for learning such model, i.e. synthesizing sequence $\mathbf{X}$ given $\mathbf{Y}_t$ and $\mathbf{y}_o$, can be formulated as the variational lower bound[1],

---

[1] Complete derivation is given in the Appendix A.

$$
\begin{aligned}
&log\ p(\mathbf{X}|\mathbf{Y}_t, \mathbf{y}_o) \geq\ log\ p(\mathbf{X}|\mathbf{Y}_t, \widetilde{\mathbf{z}_o}, \widetilde{\mathbf{z}_l}) \\
&\quad - \sum_{\mathbf{y}_l=1}^{K} q(\mathbf{y}_l|\mathbf{X}) D_{KL}[\ q(\mathbf{z}_l|\mathbf{X})\ ||\ p(\mathbf{z}_l|\mathbf{y}_l)\ ] \\
&\quad - D_{KL}[\ q(\mathbf{y}_l|\mathbf{X})\ ||\ p(\mathbf{y}_l)\ ] \\
&\quad - D_{KL}[q(\mathbf{z}_o|\mathbf{X})\ ||\ p(\mathbf{z}_o|\mathbf{y}_o)\ ] \\
&\quad = -L_{mel} - L_{KL}
\end{aligned}
$$

where $L_{mel} = -log\ p(\mathbf{X}|\mathbf{Y}_t, \widetilde{\mathbf{z}_o}, \widetilde{\mathbf{z}_l})$ and L_{KL} refers to the remaining terms. Here $\widetilde{\mathbf{z}_o}, \widetilde{\mathbf{z}_l}$ are sampled points and are reparameterized (Kingma and Welling, 2014) as $\widetilde{\mathbf{z}_o} = \hat{\mu_o} + \hat{\sigma_o} \odot \epsilon_o$ and $\widetilde{\mathbf{z}_l} = \hat{\mu_l} + \hat{\sigma_l} \odot \epsilon_l$ with $\hat{\mu_o}, \hat{\mu_l}, \hat{\sigma_o}, \hat{\sigma_l}$ as the mean and standard deviation of the posterior distributions $q(\mathbf{z}_o|\mathbf{X})$ and $q(\mathbf{z}_l|\mathbf{X})$ respectively and with auxiliary noise variable $\epsilon_o, \epsilon_l \sim \mathcal{N}(0, I)$. Following Higgins et al. (2017) the loss L can be written in a more general form as,

$$L = L_{mel} + \beta L_{KL} \tag{1}$$

with β balancing the relative weighing between the latent channels and reconstruction accuracy. Here L_{mel} is the mel loss which controls the quality of the mel-spectrograms produced and L_{KL} refers to the total KL Loss controlling the features learnt in latent variables.

This VAE can be used in the Tacotron-2 architecture (Hsu et al., 2019) as shown in Figure 2(a) to learn the text to mel-spectrogram mapping and the latent features controlled by L_{KL}.

4 Methodology

We now describe the two main components, 1) Minimizing mutual information and 2) Layer reordering in our proposed REMMI architecture.

4.1 Minimizing Mutual Information

The latent $\mathbf{z}_l$ in Figure 1 is unsupervised while the latent $\mathbf{z}_o$ learns features correlated with the shown label $\mathbf{y}_o$. Our experiments showed that both $\mathbf{z}_l, \mathbf{z}_o$ can end up encoding the same set of features, which leads to poor control in synthesizing speech. An intuition into why this happens lies in the fact that $\mathbf{z}_l$ is an unsupervised variable and it can discover any feature hidden in the input speech sequence. There is no term in the loss function (1) which prevents the features of $\mathbf{z}_l$ from being correlated with the observed labels $\mathbf{y}_o$ (Klys et al., 2018).

This can be resolved by minimizing the mutual information I between latents $\mathbf{z}_o$ (equivalently $\mathbf{y}_o$) and $\mathbf{z}_l$. We can formulate this as,

$$
\begin{aligned}
&min\ I(\mathbf{y}_o; \mathbf{z}_l) \triangleq max\ H(\mathbf{y}_o|\mathbf{z}_l) \\
&= min \int_{\mathbf{z}_l} \int_{\mathbf{y}_o} p(\mathbf{z}_l)\ p(\mathbf{y}_o|\mathbf{z}_l)\ log\ p(\mathbf{y}_o|\mathbf{z}_l) d\mathbf{y}_o d\mathbf{z}_l \\
&= min \int_{\mathbf{X}} \int_{\mathbf{z}_l} \int_{\mathbf{y}_o} \begin{matrix} p(\mathbf{X})\ p(\mathbf{z}_l|\mathbf{X})\ p(\mathbf{y}_o|\mathbf{z}_l) \\ log\ p(\mathbf{y}_o|\mathbf{z}_l)\ d\mathbf{y}_o\ d\mathbf{z}_l\ d\mathbf{X} \end{matrix}
\end{aligned}
$$

Since integral over $\mathbf{z}_l$ is intractable, we replace $p(\mathbf{z}_l|\mathbf{X})$ with an approximate posterior $q(\mathbf{z}_l|\mathbf{X})$. Further, since the true distribution $p(\mathbf{y}_o|\mathbf{z}_l)$ is unknown, we approximate it by introducing a new network $q_\psi(\mathbf{y}_o|\mathbf{z}_l)$ leading to $min\ I(\mathbf{y}_o; \mathbf{z}_l)$

$$
\begin{aligned}
&\approx min \int_{\mathbf{X}} \int_{\mathbf{z}_l} \int_{\mathbf{y}_o} \begin{matrix} p(\mathbf{X})\ q(\mathbf{z}_l|\mathbf{X})\ q_\psi(\mathbf{y}_o|\mathbf{z}_l) \\ log\ q_\psi(\mathbf{y}_o|\mathbf{z}_l) d\mathbf{y}_o\ d\mathbf{z}_l\ d\mathbf{X} \end{matrix} \\
&= min\ E_{D(\mathbf{X})q(\mathbf{z}_l|\mathbf{X})} \left[\int_{\mathbf{y}_o} \begin{matrix} q_\psi(\mathbf{y}_o|\mathbf{z}_l) \\ log\ q_\psi(\mathbf{y}_o|\mathbf{z}_l)\ d\mathbf{y}_o \end{matrix} \right] \\
&\approx min\ \frac{1}{N} \sum_a \left[\begin{matrix} q_\psi(\mathbf{y}_o = a|\mathbf{z}_l{}') \\ log\ q_\psi(\mathbf{y}_o = a|\mathbf{z}_l{}') \end{matrix} \right]
\end{aligned} \tag{2}
$$

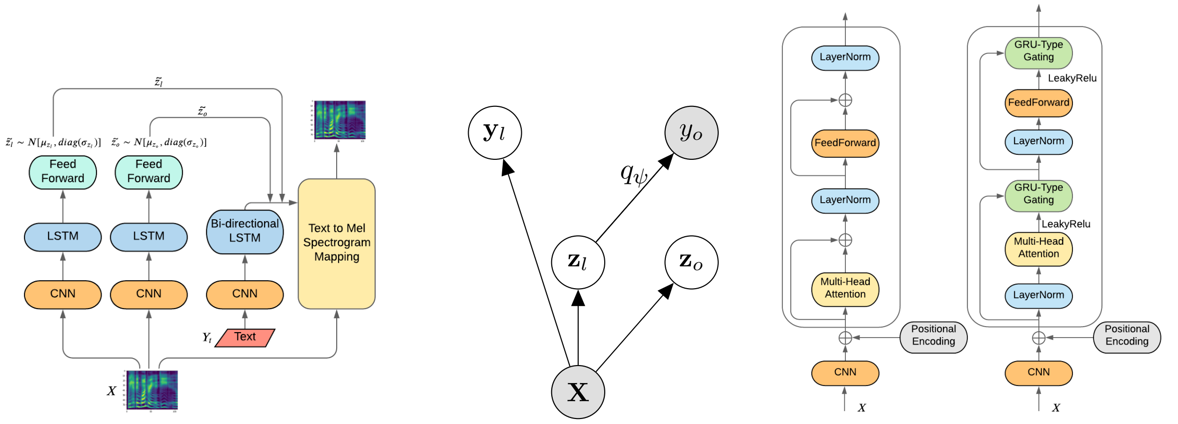
where $\mathbf{z}_l{}' \sim q(\mathbf{z}_l|\mathbf{X})$, $a \in \{0, 1, 2...A\}$, A is total number of unique classes of $\mathbf{y}_o$, N is the number of samples used for Monte Carlo estimates, and $D(\mathbf{X})$ is the underlying distribution of the input points $\mathbf{X}$. Our proposed encoder is depicted in Figure 2(b). Since we are using q_ψ to make predictions for $\mathbf{y}_o$, this network needs to be learnt itself. Hence we need to subtract an additional $q_\psi(\mathbf{y}_{o_T}|\mathbf{z}_l{}')$ from the loss function, where $\mathbf{y}_{o_T}$ is the ground truth $\mathbf{y}_o$ for the input $\mathbf{X}$. With $N = 1$ our proposed term is,

$$
\begin{aligned}
L_{MI} = &\sum_a q_\psi(\mathbf{y}_o = a|\mathbf{z}_l{}') log\ q_\psi(\mathbf{y}_o = a|\mathbf{z}_l{}') \\
&- q_\psi(\mathbf{y}_{o_T}|\mathbf{z}_l{}')
\end{aligned} \tag{3}
$$

Combining equations (1) and (3), the total loss function in our proposed model is,

$$
\begin{aligned}
L_{total} &= L_{mel} + \beta L_{KL} + \gamma L_{MI} \\
&= L_{mel} + L_{cond}
\end{aligned} \tag{4}
$$

To summarize, L_{mel} controls the quality of the mel-spectrogram produced during decoding, L_{KL} controls the features learnt in the latent variables $\mathbf{z}_l, \mathbf{z}_o$ and L_{MI} makes sure that $\mathbf{z}_l, \mathbf{z}_o$ encode different features. We will be referring to L_{mel} as the reconstruction or mel loss, L_{KL} as the KL loss and $L_{cond} = \beta L_{KL} + \gamma L_{MI}$ as the conditional loss respectively throughout this paper.



(a) Tacotron Architecture (b) Proposed Encoder (c) Original versus Proposed Transformer

Figure 2: **Left**: The Tacotron-2 architecture. VAE consists of two left parts where LSTMs predict mean μ and variance σ^2 of multivariate Gaussians $\mathcal{N}(\mu_{\mathbf{z}_l}, diag(\sigma^2_{\mathbf{z}_l})), \mathcal{N}(\mu_{\mathbf{z}_o}, diag(\sigma^2_{\mathbf{z}_o}))$. $\widetilde{\mathbf{z}_l}, \widetilde{\mathbf{z}_o}$ from this distribution are sampled and concatenated to the text encoding to conditionally learn the text to mel-spectrogram mapping. **Center**: Proposed encoder with the network q_ψ. The generator stays the same as in Figure 1. **Right**: The original and the proposed Transformers replace the LSTMs shown in the VAE of Tacotron-2 architecture.

4.2 Layer Reordering in Transformer

Introducing the above loss helps disentangle the learning of $\mathbf{z}_o$ and $\mathbf{z}_l$, but there is another problem that remains. Our experiments on MAILABS and Common Voice data, discussed in section 5.3, indicated that clusters of $\mathbf{z}_o$ corresponding to different shown labels $\mathbf{y}_o$ start sharing regions in the latent space. Hence for any given label $\mathbf{y}_o$ the sampled $\hat{\mathbf{z}_o} \sim p(\mathbf{z}_o|\mathbf{y}_o)$ may or may not belong to the style which $\mathbf{y}_o$ denotes. This leads to speech samples where the style correlated with the shown attribute $\mathbf{y}_o$ is not under control while sampling from the priors.

We tackle this problem by replacing LSTMs with Transformers. We expected that the ability of Transformers to attend to specific frames of interest where features could be localized or have a higher expression density, with a higher weight in the input speech sequence should bring down the dataset volume required for convergence by a considerable amount. Hence the lower bound on dataset size needed for modelling non overlapping clusters of $\mathbf{z}_o$ should be smaller while still keeping the sampled style under control. This should also accelerate the separation between latent clusters for larger datasets. Our experiments with vanilla Transformer-based VAEs confirm our predictions.

We next drew some inspiration from Parisotto et al. (2019) and modified the Transformer encoder. This was an attempt at changing the learning paradigm— instead of directly learning to translate $\mathbf{Y}_t$ to $\mathbf{X}$ in different $\mathbf{y}_o$ styles, we first learn to synthesize a general representation for all $\mathbf{X}$, and then learn specific deviations of each style $\mathbf{y}_o$ from this general representation. For example, instead of learning directly to speak in different accents first we learn to speak, and then we learn the subtleties of different accents. Our hypothesis was that learning different $\mathbf{y}_o$ styles should be a lot faster if a common understanding of all $\mathbf{X}$ in the dataset is gained first. The accent specific speech frames $\mathbf{X}$ (or style specific as per $\mathbf{y}_o$) should just be a slight deviation from this common representation.

Our proposed architecture is shown in Figure 2c where we switch the order of `LayerNorm` forming a direct connection between the input and the output. Due to this layer reordering if we make sure that all the modules `MHA`, `LayerNorm`, `FeedForward` are initialized with their expectation near 0, a direct path is formed early in training allowing a general representation of speech to be learnt independent of the shown labels $\mathbf{y}_o$. Now as training progresses and these modules warm up, the accent or $\mathbf{y}_o$ specific features will be learnt by conditioning the encoder.

We also introduce GRU-type gating (Chung et al., December 2014) to stabilize learning by minimizing the maximum gradient norms produced, and apply a small nonlinearity via $LeakyRelu$ at the outputs of the `MHA` and `FeedForward` modules to balance the observed trade-off between frequent gradient updates and maximum gradient

d	**Feature**	$\mu_{\mathbf{z}_l,d} - 3\sigma_{\mathbf{z}_l,d}$	$\mu_{\mathbf{z}_l,d}$	$\mu_{\mathbf{z}_l,d} + 3\sigma_{\mathbf{z}_l,d}$
0	Speaking Rate (sec)	3.0 ± 0.2	3.7 ± 0.3	4.4 ± 0.3
1	F_0 (Hz)	240.5 ± 12.57	211.4 ± 15.66	184 ± 10.43
2	Pause Duration (msec)	70 ± 3.40	79 ± 3.30	91 ± 3.50

Table 1: Length of the mel-spectrogram synthesized and pause durations increase while pitch decreases with increasing dth dimension of $\mathbf{z}_l$ from its marginal prior mean in REMMI.

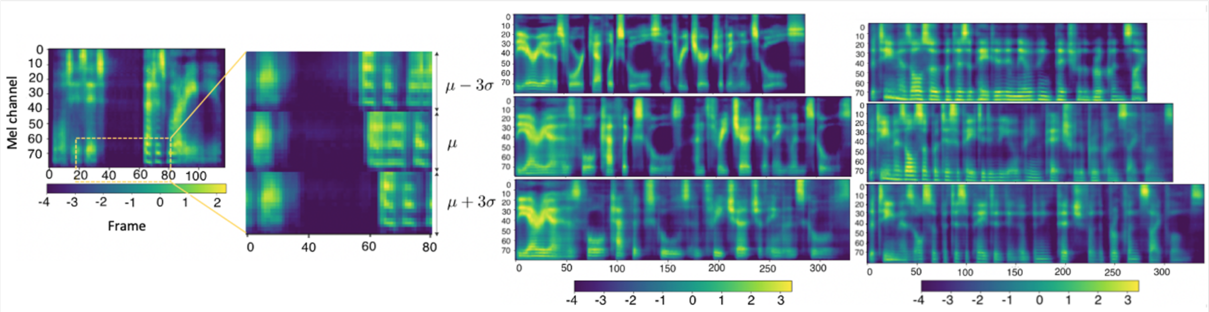


Figure 3: **Left**: Synthesized mel spectrogram for *"What is it, that is worrying you today?"* The stack of 3 mel spectrograms on the right are zoomed areas from frames 20 to 80 for each of their original mel-spectrogram. It can be seen that the pause duration denoted by the dark region increases as you synthesize the same text moving from $\mu_i - 3\sigma_i$ to $\mu_i + 3\sigma_i$. **Center**: Three mel-spectrograms synthesized for the text *"The area has four catholic schools and three church of England schools"*, corresponding to three random sampling of $\tilde{\mathbf{z}}_o, \tilde{\mathbf{z}}_l$ from their posteriors. First synthesis is considerably shorter than the second and third. Notice the different positions of voids between frames 50 and 100, and at frame 150 in the third spectrogram being considerably different. **Right**: Mel-spectrograms synthesized for the text *"The team has also participated in the opening pitch of the Brooklyn Cyclones"*. The third spectrogram shows smooth areas in the higher mel channels compared to the second and the first. These random latent sampling affects intonation and spectrogram texture.

norm[2].

5 Experiments

We refer to our proposed VAE with modifications from sections 4.1 (L_{MI} term) and 4.2 as REMMI, the vanilla Transformer with L_{MI} term as Transformer-VAE and the LSTM based state-of-the-art Tacotron-2 without L_{MI} term (Hsu et al., 2019) as LSTM-VAE. We trained each model on two datasets— 1) MAILABS (Solak, 2018 (accessed November 11, 2020) with a total 35hrs of UK and 39hrs of US speech in studio quality recorded by 4 professional speakers, 2) Common Voice (Ardila et al., 2020) with 4hrs of UK and 19hrs of US speech crowd-sourced from 477 volunteers with varying background noise, microphone qualities and other recording conditions. The input feature $\mathbf{X}$ were mel-scale spectrograms, the label $\mathbf{y}_o$ was set to be 0 for all $\mathbf{X}$ belonging to US and 1 for all UK. Dimension of $\mathbf{z}_o$ and $\mathbf{z}_l$ were picked to be 2 and 3 respectively and K = 3 for all experiments [3].

5.1 Features Learnt

Before we demonstrate our latent cluster improvements over Transformer-VAE and LSTM-VAE, we show that REMMI does learn important latent features in speech. Our experiments (focused on learning the speaking rate, the fundamental frequency F_0, and the pause duration) are summarized in Table 1. $\mu_{\mathbf{z}_l,d}$ and $\sigma_{\mathbf{z}_l,d}$ are the dth dimension mean and standard deviations of the marginal prior $p(\mathbf{z}_l) = \sum_k p(\mathbf{z}_l|\mathbf{y}_l = k)p(\mathbf{y}_l = k)$. All other dimensions of $\mathbf{z}_l$ are kept fixed at their own marginal priors while analyzing dth dimension.

For demonstrating control on speaking rate, we did 25 different synthesis for the text *"We had been wandering, indeed, in the leafless shrubbery an hour in the morning"*. It can be seen from Table 1 that the length of the synthesized mel-spectrogram increases as the value of $\mathbf{z}_l$ dimension 0 increases.

Next, we synthesized 25 texts, with 10 samples for each text to show control on pause duration and

---

[2] Importance of Gates and the specific choice of $LeakyRelu$ is discussed in the Ablation Study in Appendix D.

[3] Other hyperparameters of our VAE and training details of Tacotron-2 are given in Appendix F, G, H.

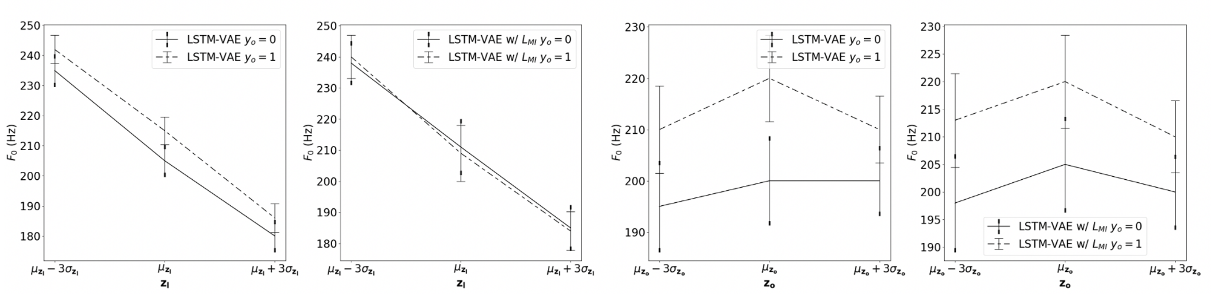

Figure 4: In LSTM-VAE F_0 encoded by $\mathbf{z}_l$ is significantly different for $\mathbf{y}_o = 0, 1$ showing that y_o specific information is encoded by $\mathbf{z}_l$. However this difference is no longer significant once we include our proposed L_{MI} terms in LSTM-VAE w/ L_{MI} experiment. $\mathbf{z}_o$ keeps showing different values of F_0 for $y_o = 0, 1$ in both LSTM-VAE and LSTM-VAE w/ L_{MI} experiments demonstrating learnt features which are conditional on y_o.

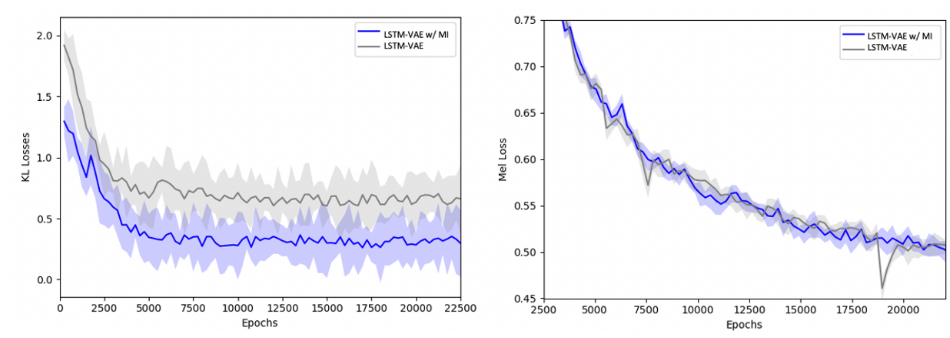

Figure 5: **Left**: Test L_{KL} versus epochs. Including L_{MI} in loss function decreases L_{KL} pointing to improved latent variables. **Right**: Test L_{mel} versus epoch. The L_{mel} remains the same even upon including L_{MI} demonstrating our proposed L_{MI} does not hurt the synthesized mel-spectrogram quality.

pitch (or the fundamental frequency F_0). For pause duration experiments each text contained at least one comma and we measured the maximum period of intermediate silence for each synthesis. To calculate F_0 we used the YIN algorithm (Guyot, 2018). In Table 1 it can be seen that the pause duration increases and F_0 decreases with increasing values of 2nd and 1st dimensions of $\mathbf{z}_l$, respectively.

Furthermore the sampled variables $\widetilde{\mathbf{z}_o}, \widetilde{\mathbf{z}_l}$ from their respective posterior distributions $q(\mathbf{z}_o|\mathbf{X}), q(\mathbf{z}_l|\mathbf{X})$ in L_{mel} gives the effect of different intonations with different speakers every time we synthesize a given text $\mathbf{Y}_t$. We demonstrate concrete examples in Figure 3.

5.2 Importance of L_{MI}

Our experiment on MAILABS dataset shows that the latent variable $\mathbf{z}_l$ starts encoding $\mathbf{y}_o$ specific features in the absence of an explicit L_{MI} term in the total loss, contrary to the expectation that $\mathbf{z}_l$ should not encode any $\mathbf{y}_o$ style specific information. As shown in Figure 4, $\mathbf{z}_l$ shows different values of F_0 for classes $\mathbf{y}_o = 0, 1$ in the absence of L_{MI}, while $\mathbf{z}_o$ continues to show accent specific values for both $\mathbf{y}_o$ classes with and without L_{MI} terms. The values in Figure 4 are plotted for a synthesis of 25 different texts with 10 samples for each text. We show similar trends for speaking rate in the Appendix.

A consequence of including L_{MI} in the loss function (4) can also be seen in the test curve of L_{KL}. We can see in Figure 5 that LSTM-VAE w/ MI has a lower value of L_{KL}. Also note that as shown in Figure 5, L_{mel} remains the same in both the experiments hence there is an overall decrease in the total loss value. We also observe that the two terms of L_{MI} in equation (3) are in contention to each other. The first term tries to learn a representation $\mathbf{z}_l$ such that it does not have any information about label $\mathbf{y}_o$ whereas the second term tries to maximize the probability of predicting true label $\mathbf{y}_o$ given $\mathbf{z}_l$. We verify from our experiments that at convergence $\mathbf{z}_l$ acts as a complete random input for estimating $\mathbf{y}_o$ with $q_\psi(\mathbf{y}_o|\mathbf{z}_l) = 0.5$ for both $\mathbf{y}_o = 0, 1$.

Table 3: REMMI performs at least 4% better (DI for 4hrs US+4hrs UK Common Voice compared to Transformer-VAE) on all sizes of noisy Common Voice dataset than all existing LSTM and Transformer-VAE architectures.

Model	Overlap on MAILABS 4+4	Overlap on MAILABS 20+20	Overlap on MAILABS 39+35	Overlap on Common Voice 4+4	Overlap on Common Voice 10+4	Overlap on Common Voice 19+4
LSTM-VAE	30%	11%	0%	92%	94%	96%
Transformer-VAE	7%	0%	0%	52%	65%	81%
REMMI	**0%**	0%	0%	**47%**	**56%**	**65%**

Table 4: Overlap percentages for datasets of size $M + N$ with M hrs US and N hrs UK speech. REMMI reduces the overlap percentage by 30% for limited MAILABS dataset and by half for limited Common Voice dataset. The reduction difference for entire Common Voice dataset is 31% compared to LSTM and 16% compared to Transformer-VAE.

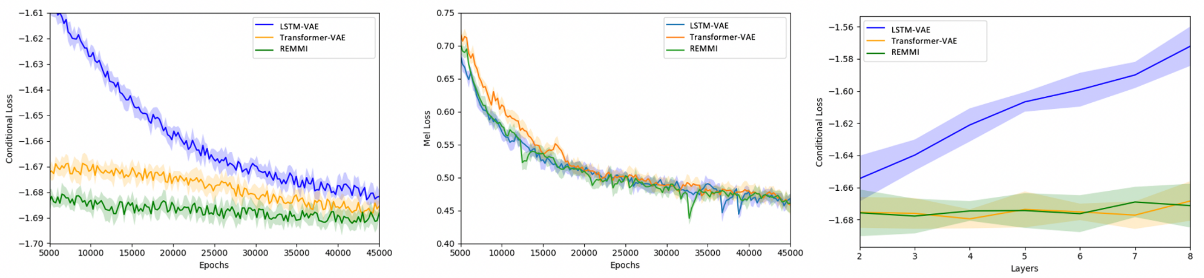

Figure 6: Loss Curves on MAILABS dataset. **Left**: Test L_{cond} versus Epochs. REMMI converges faster compared to both Transformer-VAE and LSTM-VAE. **Center**: Test L_{mel} versus Epochs. REMMI accelerates L_{cond} without compromising the mel-spectrogram quality or L_{mel}. **Right**: Test L_{cond} versus model depth. Transformer and REMMI do not overfit to a given dataset with increasing model depth unlike LSTM-VAE.

5.3 Cluster Quality

As discussed in section 4.2, we want clusters of $p(\mathbf{z}_o|\mathbf{y}_o = 0)$ and $p(\mathbf{z}_o|\mathbf{y}_o = 1)$ to be far from each other with no overlaps so that we can control $\mathbf{y}_o$ styles during synthesis. Hence we objectively measured the cluster quality with Dunn Index (DI) (Bezdek and Pal, 1995) and DB Index (DBI) (Davies and Bouldin, 1979) where $DI{=}\frac{min_{1\leq i<j\leq n} d(i,j)}{max_{1\leq k\leq n} d'(k)}$, $DBI{=}\frac{1}{n}\sum_{i=1}^{n} max_{j\neq i}\left(\frac{\sigma_i+\sigma_j}{d(\mu_i,\mu_j)}\right)$, j, i are cluster indices, $d(i,j)$ denotes the distance between the clusters i and j, n is the total number of points, $d'(k)$ is the maximal intra-cluster distance and $\mu_i, \sigma_i, \mu_j, \sigma_j$ are the means and standard deviations of the clusters i, j respectively. Thus DI is the ratio of minimal inter-cluster distance to the maximal intra-cluster distance. Similarly, DBI is the ratio of spread in each cluster to the distance between their means.

In Tables 2 and 3, we compare the test DI and DBI for different dataset sizes between

Dataset	CMOS	CS
MAILABS4hrs US+4hrs UK	0.2581 +- 0.1249	0.576 +- 0.0947
CommonVoice 4hrs US+4hrs UK	0.0541 +- 0.0966	0.327 +- 0.0888

Table 5: Positive CMOS confirms that REMMI produces speech that sounds more British than LSTM-VAE. A higher CS also shows that REMMI has better control over synthesized accent than LSTM-VAE.

REMMI, Transformer-VAE and LSTM-VAE. We see that REMMI performs consistently better than Transformer-VAE and LSTM-VAE for both MAILABS and Common Voice dataset. We also observe that as dataset size decreases, the performance gap between our REMMI and LSTM-VAE increases.

In Table 4 we calculate the percentage of overlap between clusters with test points $\hat{\mathbf{z}_o} \sim p(\mathbf{z}_o|\mathbf{y}_o = i)$ marked as overlapping with cluster $p(\mathbf{z}_o|\mathbf{y}_o = j)$ if they fall within $[\mu_{p(\mathbf{z}_o|\mathbf{y}_o=j)} - \sigma_{p(\mathbf{z}_o|\mathbf{y}_o=j)}, \mu_{p(\mathbf{z}_o|\mathbf{y}_o=j)} + \sigma_{p(\mathbf{z}_o|\mathbf{y}_o=j)}]$, with $i, j = 0, 1$. We observe that our REMMI consistently decreases the overlap regions by large margins even on challenging datasets like Common Voice, where more than 90% overlap exists for existing state-of-the-art. As discussed earlier this better separation provides improved control on synthesis and prevents uncontrolled styles when sampling speech from the priors.

5.4 Synthesis Quality

To get opinion scores on the quality of the synthesized British accent between LSTM-VAE and REMMI, we used Griffin-Lim reconstruction (Griffin and Lim, 1983) to convert the Mel spectrograms to waveforms for models trained on Common Voice 4hrs US+4hrs UK and MAILABS 4hrs US+4hrs UK data. To compare the accents, we synthesized 30 pairs of speech samples (LSTM was sample 1, REMMI was sample 2) and asked 20 Mechanical Turk (MTurk) (Crowston, 2012) participants to rate which sample sounded more British. The rating scale given to MTurk participants was: +2: 2nd sample sounds more British than 1st, +1: 2nd sounds slightly more British than 1st, 0: 2nd and 1st sound equally British, -1: 1st sounds slightly more British than 2nd, -2: 1st sounds more British than 2nd. We repeated the experiment with REMMI as sample 1 and LSTM as sample 2 (reversing the corresponding rating scale) and averaged the scores of the experiments to counter any ordering bias. We calculated the CMOS by averaging the difference in the mean scores for REMMI and LSTM-VAE.

Second, to check if REMMI provided more control on synthesized accent (whether US or British) than LSTM-VAE and provide human verification that the separation in latent clusters led to controllable synthesis, we generated 50 random pairs of (US sample, UK synthesized sample) using LSTM-VAE and REMMI each. We asked 10 MTurk participants to rate if the US and UK samples sounded different. The scale was: 0- Samples sound the same, 1- Samples sound slightly different, 2- Samples sound different. We calculated the Control Score (CS) by averaging the difference in the mean scores for REMMI and LSTM-VAE.

The resulting CMOS and CS with 95% confidence intervals in Table 5 show that in MAILABS 4hrs US+4hrs UK our approach is superior in both producing speech that sounds more British and providing controlled synthesis. In Common Voice due to noisy synthesis, LSTM-VAE and REMMI produce nearly the same accent quality, but a significantly positive CS provides better synthesis control for REMMI. In practice, this means that LSTM-VAE cannot be controlled at test time to produce US/British speech, while REMMI can be better controlled at this task.

5.5 Loss Curves

The conditional loss L_{cond} in equation (4) controls the latent variables being modelled namely $\mathbf{z}_l, \mathbf{z}_o$ and $\mathbf{y}_l$. The trend in Figure 6 for MAILABS dataset shows that REMMI has an accelerated convergence compared to both Transformer-VAE and LSTM-VAE. It can also be seen in Figure 6 that L_{mel} remains the same in all the 3 experiments, LSTM-VAE, Transformer-VAE and REMMI. This shows that while our REMMI is successful in lowering L_{cond}, it does so without hurting L_{mel} or the synthesized mel-spectrogram quality.

We also observed that for a given dataset size in LSTM-VAE, L_{cond} increases with increasing model depth which points towards inferior latent features. This trend is summarized in Figure 6 and shows that Transformer-VAE and REMMI do not overfit to a given dataset size with increasing layers.

6 Conclusion

In this work we showed that REMMI discovers disentangled latent representations of speech with uncorrelated latent variables allowing better control of speech synthesis. Our layer reordering in Transformers produces notably improved latent clusters of speaker attributes keeping the speaker styles under control on varying dataset sizes with different noise conditions. We can generate mel spectrograms for different text with controllable pitch, pause durations, speaking speed and accent. We also showed that there is a significant boost both in convergence and in the stability of the learnt representations with our proposed method. Going forward we would like to explore the application of REMMI beyond speech, e.g, image captionining with sentiments or text to image rendering with different emotions.

Appendix

A Variational Lower Bound

For an input text sequence Y_t and an observed categorical label y_o frames X can be learnt via the joint distribution $log\ p(X, Y_t, y_o)$. Additional latent variables z_o and z_l can be introduced to discover meaningful representations during this process. Here z_o is a continuous latent learnt on top of shown labels y_o, hence the features z_o discovers is correlated with what is shown to the model via y_o, while z_l is a completely unsupervised continuous variable learnt on top of standard Expectation-Maximization style latent mixture components y_l. Note that y_l is a K-way categorical discrete variable. The variational lower bound can then be formulated as,

$$\begin{aligned}
&log\ p(X|Y_t, y_o) \geq \mathbb{E}_{q(z_o|X)q(z_l|X)q(y_l|X)} \\
&\quad \left[log \frac{p(X|Y_t, z_o, z_l)p(z_o|y_o)p(z_l|y_l)p(y_l)}{q(z_o|X)q(z_l|X)q(y_l|X)} \right] \\
&\quad = \mathbb{E}_{q(z_o|X)q(z_l|X)}[log\ p(X|Y_t, z_o, z_l)] \qquad (5) \\
&\quad - D_{KL}(q(z_o|X) \;||\; p(z_o|y_o)) \\
&\quad - \mathbb{E}_{q(y_l|X)}[D_{KL}(q(z_l|X) \;||\; p(z_l|y_l))] \\
&\quad - D_{KL}(q(y_l|X) \;||\; p(y_l)) \\
&\quad \approx \ log\ p(X|Y_t, \widetilde{z_o}, \widetilde{z_l}) \qquad (6) \\
&\quad - \sum_{y_l=1}^{K} q(y_l|X) D_{KL}[\ q(z_l|X) \;||\; p(z_l|y_l)\ ] \\
&\qquad\qquad\qquad\qquad\qquad\qquad (7) \\
&\quad - D_{KL}[\ q(y_l|X) \;||\; p(y_l)\ ] \\
&\quad - D_{KL}[q(z_o|X) \;||\; p(z_o|y_o)\ ] \\
&\quad = -L_{mel} - L_{KL}
\end{aligned}$$

B Gated Architecture

In the past multiplicative interactions have been successful at stabilizing learning across different architectures (Cho et al., 2014; Srivastava et al., 2015). This motivated us to try out GRU-type gating at the heads of the proposed Transformers. The outputs at the GRU-type gating is controlled by the following equation,

$$\begin{aligned}
r &= \sigma(W_r^{(l)} y + U_r^{(l)} x), \\
z &= \sigma(W_z^{(l)} y + U_z^{(l)} x - b_g^{(l)}), \\
\hat{h} &= tanh(W_g^{(l)} y + U_g^{(l)} (r \odot x)) \\
g^{(l)}(x, y) &= (1 - z) \odot x + z \odot \hat{h}
\end{aligned}$$

where r stands for the reset gates, z is the update gates, $\hat{h}$ is the candidate activation similar to other recurrent units (Bahdanau et al., 2016). The overall gate activation $g(x, y)$ takes input x as the residual connection and y the output of the `FeedForward` or `Multi-Head Attention` modules. $g(x, y)$ is basically an interpolation between the previous activations $\hat{h}$ and the residual input x.

C Speaking Rate for $\mathbf{y}_o = 0, 1$

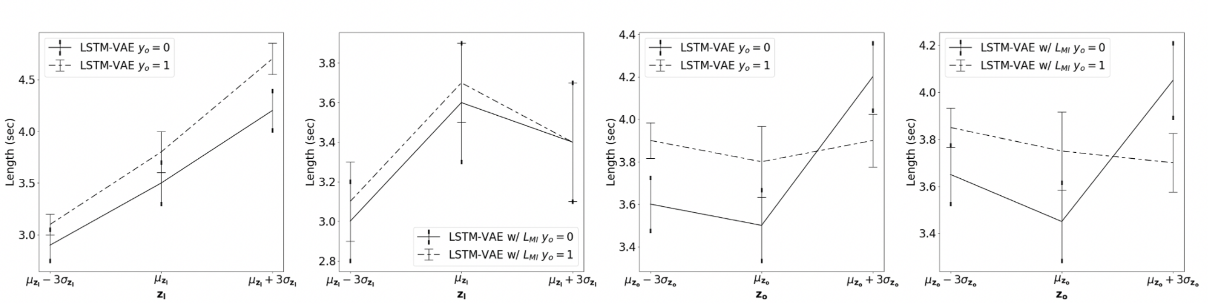

Figure 7: Length of mel-spectrogram synthesized by $\mathbf{z}_l$ in LSTM-VAE for MAILABS is significantly different for $\mathbf{y}_o = 0, 1$ showing that y_o specific information is encoded by $\mathbf{z}_l$. However this difference is no longer significant once we include our proposed L_{MI} terms in LSTM-VAE w/ L_{MI} experiment. $\mathbf{z}_o$ keeps showing different lengths for $y_o = 0, 1$ in both LSTM-VAE and LSTM-VAE w/ L_{MI} experiments demonstrating learnt features which are conditional on y_o.

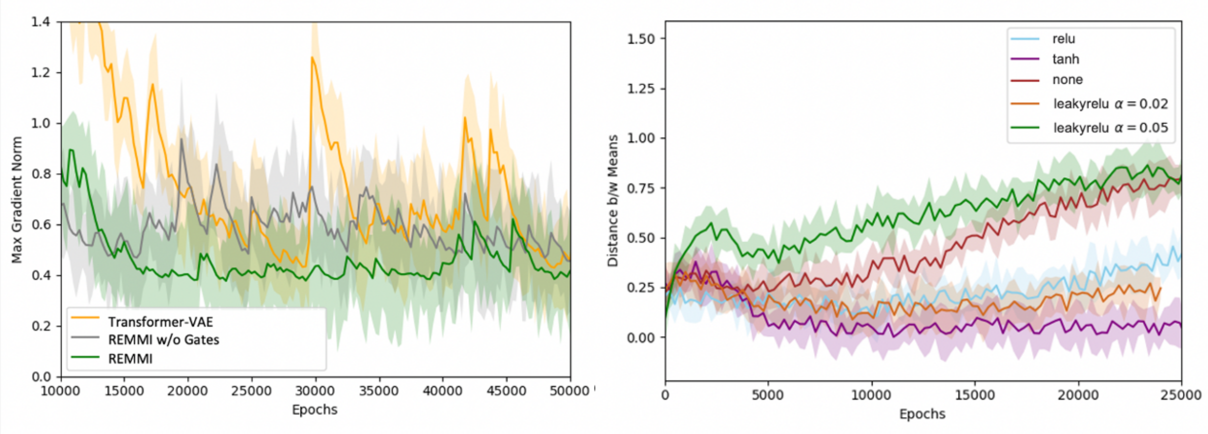

Figure 8: **Left**: Lower gradient norm for REMMI w/ Gates along with smaller variance compared to Transformers-VAE and REMMI w/o Gates. **Right**: Distance between the means of $z_o|y_o$ for $y_o = 0, 1$ for different activation functions at the output of `Multi-Head Attention` and `FeedForward` modules. We see that $LeakyRelu$ with $\alpha = 0.05$ performs the best in segregating the prior clusters among all experiments.

D Ablation Study

D.1 Importance of Gates

Our comparison of Gated architectures with non-Gated ones in Figure 8 shows that the maximum gradient norm which directly influences the convergence is much lower and stable with a lower variance for REMMI (which includes gates) compared to REMMI without (w/o) Gates and Transformer-VAE.

D.2 Choosing the Right Activation

In Figure 8 we see that the distance between $z_o|y_o$ cluster means is very small when the output from `Multi-Head Attention` and `FeedForward` modules are fed to `GRU-Type Gating` layers without any non linearity. Hence our choice of this non linearity was inspired by the trade-off between number of gradient updates and the maximum gradient norm. We see in Table 6 that $relu$ has a high maximum gradient norm ∇_{norm} which led to convergence instability and small distance between $z_o|y_o$ cluster means. But for $tanh$, almost all activations were producing gradient updates and this frequent update was leading to small cluster distance as shown in Figure 8. Hence we needed a function somewhere between $relu$ and $tanh$, which has a small gradient norm while also having fewer gradient updates. $LeakyRelu$ turns out to be the best candidate for this with its high distance between means as shown in Figure 8.

Experiment	% activation	max ∇_{norm}
relu	84.5 (< 0)	40.96
tanh	0 (>+2,<-2)	10.68
leakyrelu	-	7.17

Table 6: Comparing the percentage of activations for which gradient saturates and maximum gradient norm ∇_{norm}

E Compute Information

We ran all our experiments on NVIDIA Tesla V100 GPU with 16GB of GPU memory. Our LSTM-VAE (both with and without L_{MI}) experiments take average 5.81sec/step (seconds per step) with convergence near 40k steps. Transformer-VAE takes an average 2.81sec/step with convergence near 25k steps, and REMMI takes average 2.81sec/step with convergence near 25k steps. Total number of parameters are 28.03mn (million) for LSTM-VAE w/ and w/o MI, 27.84mn for Tranformer-VAE and 28.03mn for REMMI.

How to Split: the Effect of Word Segmentation on Gender Bias in Speech Translation

Abstract

Having recognized gender bias as a major issue affecting current translation technologies, researchers have primarily attempted to mitigate it by working on the data front. However, whether algorithmic aspects concur to exacerbate unwanted outputs remains so far under-investigated. In this work, we bring the analysis on gender bias in automatic translation onto a seemingly neutral yet critical component: word segmentation. Can segmenting methods influence the ability to translate gender? Do certain segmentation approaches penalize the representation of feminine linguistic markings? We address these questions by comparing 5 existing segmentation strategies on the target side of speech translation systems. Our results on two language pairs (English-Italian/French) show that state-of-the-art sub-word splitting (BPE) comes at the cost of higher gender bias. In light of this finding, we propose a combined approach that preserves BPE overall translation quality, while leveraging the higher ability of character-based segmentation to properly translate gender.

Bias Statement.[1] We study the effect of segmentation methods on the ability of speech translation (ST) systems to translate masculine and feminine forms referring to human entities. In this area, structural linguistic properties interact with the perception and representation of individuals (Gygax et al., 2019; Corbett, 2013; Stahlberg et al., 2007). Thus, we believe they are relevant gender expressions, used to communicate about the self and others, and by which the sociocultural and political reality of gender is negotiated (Hellinger and Motschenbacher, 2015).

Accordingly, we consider a model that systematically and disproportionately favours masculine over feminine forms to be biased, as it fails to properly recognize women. From a technical perspective, such behaviour deteriorates models' performance. Most importantly, however, from a human-centered view, real-world harms are at stake (Crawford, 2017), as translation technologies are unequally beneficial across gender groups and reduce feminine visibility, thus contributing to misrepresent an already socially disadvantaged group.

This work is motivated by the intent to shed light on whether issues in the generation of feminine forms are also a by-product of current algorithms and techniques. In our view, architectural improvements of ST systems should also account for the trade-offs between overall translation quality and gender representation: our proposal of a model that combines two segmentation techniques is a step towards this goal.

Note that technical mitigation approaches should be integrated with the long-term multidisciplinary commitment (Criado-Perez, 2019; Benjamin, 2019; D'Ignazio and Klein, 2020) necessary to radically address bias in our community. Also, we recognize the limits of working on binary gender, as we further discuss in the ethic section (§8).

1 Introduction

The widespread use of language technologies has motivated growing interest on their social impact (Hovy and Spruit, 2016; Blodgett et al., 2020), with gender bias representing a major cause of concern (Costa-jussà, 2019; Sun et al., 2019). As regards translation tools, focused evaluations have exposed that speech translation (ST) – and machine translation (MT) – models do in fact overproduce masculine references in their outputs (Cho et al., 2019; Bentivogli et al., 2020), except for feminine asso-

---

†The authors contributed equally.

[1] As suggested by (Blodgett et al., 2020) and required for other venues (Hardmeier et al., 2021), we formulate our bias statement.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3576–3589
August 1–6, 2021.

ciations perpetuating traditional gender roles and stereotypes (Prates et al., 2020; Stanovsky et al., 2019). In this context, most works identified *data* as the primary source of gender asymmetries. Accordingly, many pointed out the misrepresentation of gender groups in datasets (Garnerin et al., 2019; Vanmassenhove et al., 2018), focusing on the development of data-centred mitigating techniques (Zmigrod et al., 2019; Saunders and Byrne, 2020).

Although data are not the only factor contributing to generate bias (Shah et al., 2020; Savoldi et al., 2021), only few inquiries devoted attention to other technical components that exacerbate the problem (Vanmassenhove et al., 2019) or to architectural changes that can contribute to its mitigation (Costa-jussà et al., 2020b). From an algorithmic perspective, Roberts et al. (2020) additionally expose how "taken-for-granted" approaches may come with high overall translation quality in terms of BLEU scores, but are actually detrimental when it comes to gender bias.

Along this line, we focus on ST systems and inspect a core aspect of neural models: word segmentation. Byte-Pair Encoding (BPE) (Sennrich et al., 2016) represents the *de-facto* standard and has recently shown to yield better results compared to character-based segmentation in ST (Di Gangi et al., 2020). But does this hold true for gender translation as well? If not, why?

Languages like French and Italian often exhibit comparatively complex feminine forms, derived from the masculine ones by means of an additional suffix (e.g. en: *professor*, fr: *professeur* M vs. *professeure* F). Additionally, women and their referential linguistic expressions of gender are typically under-represented in existing corpora (Hovy et al., 2020). In light of the above, purely statistical segmentation methods could be unfavourable for gender translation, as they can break the morphological structure of words and thus lose relevant linguistic information (Ataman et al., 2017). Indeed, as BPE merges the character sequences that co-occur more frequently, rarer or more complex feminine-marked words may result in less compact sequences of tokens (e.g. en: *described*, it: *des@@critto* M vs. *des@@crit@@ta* F). Due to such typological and distributive conditions, may certain splitting methods render feminine gender less probable and hinder its prediction?

We address such questions by implementing different families of segmentation approaches employed on the decoder side of ST models built on the same training data. By comparing the resulting models both in terms of overall translation quality and gender accuracy, we explore whether a so far considered irrelevant aspect like word segmentation can actually affect gender translation. As such, **(1)** we perform the first comprehensive analysis of the results obtained by 5 popular segmentation techniques for two language directions (en-fr and en-it) in ST. **(2)** We find that the target segmentation method is indeed an important factor for models' gender bias. Our experiments consistently show that BPE leads to the highest BLEU scores, while character-based models are the best at translating gender. Preliminary analyses suggests that the isolation of the morphemes encoding gender can be a key factor for gender translation. **(3)** Finally, we propose a multi-decoder architecture able to combine BPE overall translation quality and the higher ability to translate gender of character-based segmentation.

2 Background

Gender bias. Recent years have seen a surge of studies dedicated to gender bias in MT (Gonen and Webster, 2020; Rescigno et al., 2020) and ST (Costa-jussà et al., 2020a). The primary source of such gender imbalance and adverse outputs has been identified in the training data, which reflect the under-participation of women – e.g. in the media (Madaan et al., 2018), sexist language and gender categories overgeneralization (Devinney et al., 2020). Hence, preventive initiatives concerning data documentation have emerged (Bender and Friedman, 2018), and several mitigating strategies have been proposed by training models on *ad-hoc* gender-balanced datasets (Saunders and Byrne, 2020; Costa-jussà and de Jorge, 2020), or by enriching data with additional gender information (Moryossef et al., 2019; Vanmassenhove et al., 2018; Elaraby and Zahran, 2019; Saunders et al., 2020; Stafanovičs et al., 2020).

Comparatively, very little work has tried to identify concurring factors to gender bias going beyond data. Among those, Vanmassenhove et al. (2019) ascribes to an algorithmic bias the loss of less frequent feminine forms in both phrase-based and neural MT. Closer to our intent, two recent works pinpoint the impact of models' components and inner mechanisms. Costa-jussà et al. (2020b) investigate the role of different architectural designs in multilingual MT, showing that language-specific encoder-decoders (Escolano et al., 2019) better translate gender than shared models (Johnson et al., 2017), as the former retain more gender information in the source embeddings and keep more diversion in the attention. Roberts et al. (2020), on the other hand, prove that the adoption of beam search instead of sampling – although beneficial in terms of BLEU scores – has an impact on gender bias. Indeed, it leads models to an extreme operating point that exhibits zero variability and in which they tend to generate the more frequent (masculine) pronouns. Such studies therefore expose largely unconsidered aspects as factors contributing to gender bias in automatic translation, identifying future research directions for the needed countermeasures.

To the best of our knowledge, no prior work has taken into account if it may be the case for segmentation methods as well. Rather, prior work in ST (Bentivogli et al., 2020) compared gender translation performance of cascade and direct systems using different segmentation algorithms, disregarding their possible impact on final results.

Segmentation. Although early attempts in neural MT employed word-level sequences (Sutskever et al., 2014; Bahdanau et al., 2015), the need for open-vocabulary systems able to translate rare/unseen words led to the definition of several word segmentation techniques. Currently, the statistically motivated approach based on byte-pair encoding (BPE) by Sennrich et al. (2016) represents the *de facto* standard in MT. Recently, its superiority to character-level (Costa-jussà and Fonollosa, 2016; Chung et al., 2016) has been also proved in the context of ST (Di Gangi et al., 2020). However, depending on the languages involved in the translation task, the data conditions, and the linguistic properties taken into account, BPE greedy procedures can be suboptimal. By breaking the surface of words into plausible semantic units, linguistically motivated segmentations (Smit et al., 2014; Ataman et al., 2017) were proven more effective for low-resource and morphologically-rich languages (e.g. agglutinative languages like Turkish), which often have a high level of sparsity in the lexical distribution due to their numerous derivational and inflectional variants. Moreover, fine-grained analyses comparing the grammaticality of character, morpheme and BPE-based models exhibited different capabilities. Sennrich (2017) and Ataman et al. (2019) show the syntactic advantage of BPE in managing several agreement phenomena in German, a language that requires resolving long range dependencies. In contrast, Belinkov et al. (2020) demonstrate that while subword units better capture semantic information, character-level representations perform best at generalizing morphology, thus being more robust in handling unknown and low-frequency words. Indeed, using different atomic units does affect models' ability to handle specific linguistic phenomena. However, whether low gender translation accuracy can be to a certain extent considered a by-product of certain compression algorithms is still unknown.

3 Language Data

As just discussed, the effect of segmentation strategies can vary depending on language typology (Ponti et al., 2019) and data conditions. To inspect the interaction between word segmentation and gender expressions, we thus first clarify the properties of grammatical gender in the two languages of our interest: French and Italian. Then, we verify their representation in the datasets used for our experiments.

3.1 Languages and Gender

The extent to which information about the gender of referents is grammatically encoded varies across languages (Hellinger and Motschenbacher, 2015; Gygax et al., 2019). Unlike English – whose gender distinction is chiefly displayed via pronouns (e.g. *he/she*) – fully grammatical gendered languages like French and Italian systematically articulate such semantic distinction on several parts of speech (gender agreement) (Hockett, 1958; Corbett, 1991). Accordingly, many lexical items exist in both feminine and masculine variants, overtly marked through morphology (e.g. en: *the tired kid sat down*; it: *il bimbo stanco si è seduto* M vs. *la bimba stanca si è seduta* F). As the example shows, the word forms are distinguished by two morphemes (*–o*, *–a*), which respectively represent the most common inflections for Italian masculine and feminine markings.[2] In French, the morphological mechanism is slightly different (Schafroth, 2003), as it relies on an additive suffixation on top of masculine words to express feminine gender (e.g. en: *an expert is gone*, fr: *un expert est allé* M vs.

---

[2] In a fusional language like Italian, one single morpheme can denote several properties as, in this case, gender and singular number (the plural forms would be *bimbi* vs. *bimbe*).

une experte est allée F). Hence, feminine French forms require an additional morpheme. Similarly, another productive strategy – typical for a set of personal nouns – is the derivation of feminine words via specific affixes for both French (*e.g. –eure, –euse*)[3] and Italian (*–essa, –ina, –trice*) (Schafroth, 2003; Chini, 1995), whose residual evidence is still found in some English forms (e.g. *heroine, actress*) (Umera-Okeke, 2012).

In light of the above, translating gender from English into French and Italian poses several challenges to automatic models. First, gender translation does not allow for one-to-one mapping between source and target words. Second, the richer morphology of the target languages increases the number of variants and thus data sparsity. Hereby, the question is whether – and to what extent – statistical word segmentation differently treats the less frequent variants. Also, considering the morphological complexity of some feminine forms, we speculate whether linguistically unaware splitting may disadvantage their translation. To test these hypotheses, below we explore if such conditions are represented in the ST datasets used in our study.

3.2 Gender in Used Datasets

MuST-SHE (Bentivogli et al., 2020) is a gender-sensitive benchmark available for both en-fr and en-it (1,113 and 1,096 sentences, respectively). Built on naturally occurring instances of gender phenomena retrieved from the TED-based MuST-C corpus (Cattoni et al., 2020),[4] it allows to evaluate gender translation on qualitatively differentiated and balanced masculine/feminine forms. An important feature of MuST-SHE is that, for each reference translation, an almost identical "wrong" reference is created by swapping each annotated gender-marked word into its opposite gender. By means of such wrong reference, for each target language we can identify ∼2,000 pairs of gender forms (e.g. en: *tired*, fr: *fatiguée* vs. *fatigué*) that we compare in terms of *i)* length, and *ii)* frequency in the MuST-C training set.

As regards frequency, we asses that, for both language pairs, the types of feminine variants are less frequent than their masculine counterpart in over 86% of the cases. Among the exceptions, we find words that are almost gender-exclusive (e.g. *pregnant*) and some problematic or socially connoted activities (e.g. *raped, nurses*). Looking at words' length, 15% of Italian feminine forms result to be longer than masculine ones, whereas in French this percentage amounts to almost 95%. These scores confirm that MuST-SHE reflects the typological features described in §3.1.

4 Experiments

All the direct ST systems used in our experiments are built in the same fashion within a controlled environment, so to keep the effect of different word segmentations as the only variable. Accordingly, we train them on the MuST-C corpus, which contains 492 hours of speech for en-fr and 465 for en-it. Concerning the architecture, our models are based on Transformer (Vaswani et al., 2017). For the sake of reproducibility, we provide extensive details about the ST models and hyper-parameters' choices in the Appendix §*A*.[5]

4.1 Segmentation Techniques

To allow for a comprehensive comparison of word segmentation's impact on gender bias in ST, we identified three substantially different categories of splitting techniques. For each of them, we hereby present the candidates selected for our experiments.

Character Segmentation. Dissecting words at their maximal level of granularity, **character-based** solutions have been first proposed by Ling et al. (2015) and Costa-jussà and Fonollosa (2016). This technique proves simple and particularly effective at generalizing over unseen words. On the other hand, the length of the resulting sequences increases the memory footprint, and slows both the training and inference phases. We perform our segmentation by appending "@@ " to all characters but the last of each word.

Statistical Segmentation. This family comprises data-driven algorithms that generate statistically significant subwords units. The most popular one is **BPE** (Sennrich et al., 2016),[6] which proceeds by merging the most frequently co-occurring characters or character sequences. Recently, He et al. (2020) introduced the Dynamic Programming Encoding **(DPE)** algorithm, which performs

---

[3] French also requires additional modification on feminine forms due to phonological rules (e.g. en: *chef/spy*, fr: *cheffe/espionne* vs. *chef/espion*).

[4] Further details about these datasets are provided in §8.

[5] Source code available at `https://github.com/mgaido91/FBK-fairseq-ST/tree/acl_2021`.

[6] We use SentencePiece (Kudo and Richardson, 2018): `https://github.com/google/sentencepiece`.

competitively and was claimed to accidentally produce more linguistically-plausible subwords with respect to BPE. DPE is obtained by training a mixed character-subword model. As such, the computational cost of a DPE-based ST model is around twice that of a BPE-based one. We trained the DPE segmentation on the transcripts and the target translations of the MuST-C training set, using the same settings of the original paper.[7]

Morphological Segmentation. A third possibility is linguistically-guided tokenization that follows morpheme boundaries. Among the unsupervised approaches, one of the most widespread tools is **Morfessor** (Creutz and Lagus, 2005), which was extended by Ataman et al. (2017) to control the size of the output vocabulary, giving birth to the **LMVR** segmentation method. These techniques have outperformed other approaches when dealing with low-resource and/or morphologically-rich languages (Ataman and Federico, 2018). In other languages, they are not as effective, so they are not widely adopted. Both Morfessor and LMVR have been trained on the MuST-C training set.[8]

	en-fr	**en-it**
# tokens[9]	5.4M	4.6M
# types	96K	118K
BPE	8,048	8,064
Char	304	256
DPE	7,864	8,008
Morfessor	26,728	24,048
LMVR	21,632	19,264

Table 1: Resulting dictionary sizes.

For fair comparison, we chose the optimal vocabulary size for each method (when applicable). Following (Di Gangi et al., 2020), we employed 8k merge rules for BPE and DPE, since the latter requires an initial BPE segmentation. In LMVR, instead, the desired target dimension is actually only an upper bound for the vocabulary size. We tested 32k and 16k, but we only report the results with 32k as it proved to be the best configuration both in terms of translation quality and gender accuracy. Finally, character-level segmentation and Morfessor do not allow to determine the vocabulary size. Table 1 shows the size of the resulting dictionaries.

	en-fr			**en-it**		
	M-C	M-SHE	Avg.	M-C	M-SHE	Avg.
BPE	**30.7**	25.9	**28.3**	21.4	**21.8**	21.6

DPE	29.8	25.3	27.6	21.9	21.7	**21.8**
Morfessor	29.7	25.7	27.7	21.7	21.4	21.6
LMVR	30.3	**26.0**	28.2	**22.0**	21.5	**21.8**

Table 2: SacreBLEU scores on MuST-C tst-COMMON (M-C) and MuST-SHE (M-SHE) for en-fr and en-it.

4.2 Evaluation

We are interested in measuring both *i)* the overall translation quality obtained by different segmentation techniques, and *ii)* the correct generation of gender forms. We evaluate translation quality on both the MuST-C *tst-COMMON* set (2,574 sentences for en-it and 2,632 for en-fr) and MuST-SHE (§3.2), using SacreBLEU (Post, 2018).[10]

For fine-grained analysis on gender translation, we rely on gender accuracy (Gaido et al., 2020).[11] We differentiate between two categories of phenomena represented in MuST-SHE. Category (1) contains first-person references (e.g. *I'm a student*) to be translated according to the speakers' preferred linguistic expression of gender. In this context, ST models can leverage speakers' vocal characteristics as a gender cue to infer gender translation.[12] Gender phenomena of Category (2), instead, shall be translated in concordance with other gender information in the sentence (e.g. *she/he is a student).*

5 Comparison of Segmentation Methods

Table 2 shows the overall **translation quality** of ST systems trained with distinct segmentation techniques. BPE comes out as competitive as LMVR for both language pairs. On averaged results, it exhibits a small gap (0.2 BLEU) also with DPE on en-it, while it achieves the best performance on en-fr. The disparities are small though: they range within 0.5 BLEU, apart from Char standing ∼1 BLEU below. Compared to the scores reported by Di Gangi et al. (2020), the Char gap is however smaller. As our results are considerably higher than theirs, we believe that the reason for such differences lies in a sub-optimal fine-tuning of their hyper-parameters. Overall, in light of the trade-off between computational cost (LMVR and DPE require a dedicated training phase for data segmen-

[12] Although they do not emerge in our experimental settings, the potential risks of such capability are discussed in §8.

tation) and average performance (BPE achieves winning scores on en-fr and competitive for en-it), we hold BPE as the best segmentation strategy in terms of general translation quality for direct ST.

Turning to **gender translation**, the gender accuracy scores presented in Table 3 exhibit that all ST models are clearly biased, with masculine forms (M) disproportionately produced across language pairs and categories. However, we intend to pinpoint the relative gains and losses among segmenting methods. Focusing on overall accuracy (ALL), we see that Char – despite its lowest performance in terms of BLEU score – emerges as the favourite segmentation for gender translation. For French, however, DPE is only slightly behind. Looking at morphological methods, they surprisingly do not outperform the statistical ones. The greatest variations are detected for feminine forms of Category 1 (1F), where none of the segmentation techniques reaches 50% of accuracy, meaning that they are all worse than a random choice when the speaker should be addressed by feminine expressions. Char appears close to such threshold, while the others (apart from DPE in French) are significantly lower.

These results illustrate that target segmentation is a relevant parameter for gender translation. In particular, they suggest that Char segmentation improves models' ability to learn correlations between the received input and gender forms in the reference translations. Although in this experiment models rely only on speakers' vocal characteristics to infer gender – which we discourage as a cue for gender translation for real-world deployment (see §8) – such ability shows a potential advantage for Char, which could be better redirected toward learning correlations with reliable gender meta-information included in the input. For instance, in a scenario in which meta-information (e.g. a gender tag) is added to the input to support gender translation, a Char model might better exploit this information. Lastly, our evaluation reveals that, unlike previous ST studies (Bentivogli et al., 2020), a proper comparison of models' gender translation potentialities requires adopting the same segmentation. Our question then becomes: What makes Char segmentation less biased? What are the tokenization features determining a better/worse ability in generating the correct gender forms?

Lexical diversity. We posit that the limited generation of feminine forms can be framed as an issue of data sparsity, whereas the advantage of Char-based segmentation ensues from its ability to handle less frequent and unseen words (Belinkov et al., 2020). Accordingly, Vanmassenhove et al. (2018); Roberts et al. (2020) link the loss of *linguistic diversity* (i.e. the range of lexical items used in a text) with the overfitted distribution of masculine references in MT outputs.

	en-fr				
	ALL	1F	1M	2F	2M
BPE	65.18	37.17	75.44	61.20	80.80
Char	**68.85**	48.21	74.78	65.89	**81.03**

Morfessor	65.46	36.61	81.04	56.94	79.61
LMVR	69.77	39.64	**89.00**	63.85	83.03

Table 3: Gender accuracy (%) for MuST-SHE Overall (ALL), Category 1 and 2 on en-fr and en-it.

To explore such hypothesis, we compare the lexical diversity (LD) of our models' translations and MuST-SHE references. To this aim, we rely on Type/Token ratio **(TTR)** – (Chotlos, 1944; Templin, 1957), and the more robust Moving Average TTR **(MATTR)** – (Covington and McFall, 2010).[13]

As we can see in Table 4, character-based models exhibit the highest LD (the only exception is DPE with the less reliable TTR metric on en-it). However, we cannot corroborate the hypothesis formulated in the above-cited studies, as LD scores do not strictly correlate with gender accuracy (Table 3). For instance, LMVR is the second-best in terms of gender accuracy on en-it, but shows a very low lexical diversity (the worst according to MATTR and second-worst according to TTR).

	en-fr		**en-it**

though to different extent, longer and less frequent than their masculine counterparts. In light of such conditions, we expected that the statistically-driven BPE segmentation would leave feminine forms unmerged at a higher rate, and thus add uncertainty to their generation. To verify if this is the actual case – explaining BPE's lower gender accuracy – we check whether the number of tokens (characters or subwords) of a segmented feminine word is higher than that of the corresponding masculine form. We exploit the coupled "wrong" and "correct" references available in MuST-SHE, and compute the average percentage of additional tokens found in the feminine segmented sentences[14] over the masculine ones. Results are reported in Table 5.

At a first look, we observe opposite trends: BPE segmentation leads to the highest increment of tokens for feminine words in Italian, but to the lowest one in French. Also, DPE exhibits the highest increment in French, whereas it actually performs slightly better than Char on feminine gender translation (see Table 3). Hence, even the increase in sequence length does not seem to be an issue on its own for gender translation. Nonetheless, these apparently contradictory results encourage our last exploration: *How* are gender forms actually split?

Gender isolation. By means of further manual analysis on 50 output sentences per each of the 6 systems, we inquire if longer token sequences for feminine words can be explained in light of the different characteristics and gender productive mechanisms of the two target languages (§3.1). Table 6 reports selected instances of coupled feminine/masculine segmented words, with their respective frequency in the MuST-C training set.

Starting with Italian, we find that BPE sequence length increment indeed ensues from greedy splitting that, as we can see from examples **(a)** and **(c)**, ignores meaningful affix boundaries for both same length and different-length gender pairs, respectively. Conversely, on the French set – with 95% of feminine words longer than their masculine counterparts – BPE's low increment is precisely due to its loss of semantic units. For instance, as shown in **(e)**, BPE does not preserve the verb root (*adopt*), nor isolates the additional token (-*e*) responsible for the feminine form, thus resulting into two words with the same sequence length (2 tokens). Instead DPE, which achieved the highest accuracy results for en-fr feminine translation (Table 3), treats the feminine additional character as a token *per se* (**f**).

Based on such patterns, our intuition is that the proper splitting of the morpheme-encoded gender information as a distinct token favours gender translation, as models learn to productively generalize on it. Considering the high increment of DPE tokens for Italian in spite of the limited number of longer feminine forms (15%), our analysis confirms that DPE is unlikely to isolate gender morphemes on the en-it language pair. As a matter of fact, it produces the same kind of coarse splitting as BPE (see **(b)** and **(d)**).

Finally, we attest that the two morphological techniques are not equally valid. Morfessor occasionally generates morphologically incorrect subwords for feminine forms by breaking the word stem (see example **(g)** where the correct stem is *sicur*). Such behavior also explains Morfessor's higher token increment with respect to LMVR. Instead, although LMVR (examples **(h)** and **(i)**) produces linguistically valid suffixes, it often condenses other grammatical categories (e.g. tense and number) with gender. As suggested above, if the pinpointed split of morpheme-encoded gender is a key factor for gender translation, LMVR's lower level of granularity explains its reduced gender accuracy. Working on character' sequences, instead, the isolation of the gender unit is always attained.

---

[14] As such references only vary for gender-marked words, we can isolate the difference relative to gender tokens.

6 Beyond the Quality-Gender Trade-off

Informed by our experiments and analysis (§5), we conclude this study by proposing a model that combines BPE overall translation quality and Char's ability to translate gender. To this aim, we train a multi-decoder approach that exploits both segmentations to draw on their corresponding advantages.

In the context of ST, several multi-decoder architectures have been proposed, usually to jointly produce both transcripts and translations with a single model. Among those in which both decoders access the encoder output, here we consider the best performing architectures according to Sperber et al. (2020). As such, we consider: *i) Multitask direct*, a model with one encoder and two decoders, both exclusively attending the encoder output as proposed by Weiss et al. (2017), and *ii)* the *Triangle* model (Anastasopoulos and Chiang, 2018), in which the second decoder attends the output of both the encoder and the first decoder.

For the triangle model, we used a first BPE-based decoder and a second Char decoder. With this order, we aimed to enrich BPE high quality translation with a refinement for gender translation, performed by the Char-based decoder. However, the results were negative: the second decoder seems to excessively rely on the output of the first one, thus suffering from a severe *exposure bias* (Ranzato et al., 2016) at inference time. Hence, we do not report the results of these experiments.

Instead, the *Multitask direct* has one BPE-based and one Char-based decoder. The system requires a training time increase of only 10% and 20% compared to, respectively, Char and BPE models. At inference phase, instead, running time and size are the same of a BPE model. We report overall translation quality (Table 7) and gender accuracy (Table 8) of the BPE output (BPE&Char).[15] Starting with gender accuracy, the Multitask model's overall gender translation ability (ALL) is still lower, although very close, to that of the Char-based model. Nevertheless, feminine translation improvements are present on Category 2F for en-fr and, with a larger gain, on 1F for en-it. We believe that the presence of the Char-based decoder is beneficial to capture into the encoder output gender information, which is then also exploited by the BPE-based decoder. As the encoder outputs are richer, overall translation quality is also slightly improved (Table 7). This finding is in line with other work (Costa-jussà et al., 2020b), which proved a strict relation between gender accuracy and the amount of gender information retained in the intermediate representations (encoder outputs).

Overall, following these considerations, we posit that target segmentation can directly influence the gender information captured in the encoder output. In fact, since the Char and BPE decoders do not interact with each other in the Multitask model, the gender accuracy gains of the BPE decoder cannot be attributed to a better ability of a segmentation method in rendering the gender information present in the encoder output into the translation.

Our results pave the way for future research on the creation of richer encoder outputs, disclosing the importance of target segmentation in extracting gender-related knowledge. With this work, we have taken a step forward in ST for English-French and English-Italian, pointing at plenty of new ground to cover concerning *how to* split for different language typologies. As the motivations of this inquiry clearly concern MT as well, we invite novel studies to start from our discoveries and explore how they apply under such conditions, as well as their combination with other bias mitigating strategies.

7 Conclusion

As the old IT saying goes: *garbage in, garbage out*. This assumption underlies most of current attempts to address gender bias in language technologies. Instead, in this work we explored whether technical choices can exacerbate gender bias by focusing on

---

[15] The Char scores are not reported, as they are not enhanced compared to the base Char encoder-decoder model.

the influence of word segmentation on gender translation in ST. To this aim, we compared several word segmentation approaches on the target side of ST systems for English-French and English-Italian, in light of the linguistic gender features of the two target languages. Our results show that tokenization does affect gender translation, and that the higher BLEU scores of state-of-the-art BPE-based models come at cost of lower gender accuracy. Moreover, first analyses on the behaviour of segmentation techniques found that improved generation of gender forms could be linked to the proper isolation of the morpheme that encodes gender information, a feature which is attained by character-level split. Finally, we propose a multi-decoder approach to leverage the qualities of both BPE and character splitting, improving both gender accuracy and BLEU score, while keeping computational costs under control.

Acknowledgments

This work is part of the "End-to-end Spoken Language Translation in Rich Data Conditions" project,[16] which is financially supported by an Amazon AWS ML Grant. The authors also wish to thank Duygu Ataman for the insightful discussions on this work.

8 Ethic statement[17]

In compliance with ACL norms of ethics, we wish to elaborate on *i)* characteristics of the dataset used in our experiments, *ii)* the study of gender as a variable, and *iii)* the harms potentially arising from real-word deployment of direct ST technology.

As already stated, in our experiments we rely on the training data from the TED-based MuST-C corpus[18] and its derived evaluation benchmark, MuST-SHE. Although precise information about various sociodemographic groups represented in the data are not fully available, based on impressionistic overview and prior knowledge about the nature of TED talks it is expected that the speakers are almost exclusively adults (over 20), with different geographical backgrounds. Thus, such data are likely to allow for modeling a range of English varieties of both native and non-native speakers.

As regards gender, from the data statements (Bender and Friedman, 2018) of the used corpora, we know that MuST-C training data are manually annotated with speakers' gender information[19] based on the personal pronouns found in their publicly available personal TED profile. As reported in its release page,[20] the same annotation process applies to MuST-SHE as well, with the additional check that the indicated (English) linguistic gender forms are rendered in the gold standard translations. Hence, information about speakers' preferred linguistic expressions of gender are transparently validated and disclosed. Overall, MuST-C exhibits a gender imbalance: 70% vs. 30% of the speakers referred by means of *he/she* pronoun, respectively. Instead, allowing for a proper cross-gender comparison, they are equally distributed in MuST-SHE.

Accordingly, when working on the evaluation of speaker-related gender translation for MuST-SHE category (1), we proceed by solely focusing on the rendering of their linguistic gender expressions. As per (Larson, 2017) guidelines, no assumptions about speakers' self determined identity (GLAAD, 2007) – which cannot be directly mapped from pronoun usage (Cao and Daumé III, 2020; Ackerman, 2019) – has been made. Unfortunately, our experiments only account for the binary linguistic forms represented in the used data. To the best of our knowledge, ST natural language corpora going beyond binarism do not yet exist,[21] also due to the fact that gender-neutralization strategies are still object of debate and challenging to fully implement in languages with grammatical gender (Gabriel et al., 2018; Lessinger, 2020). Nonetheless, we support the rise of alternative neutral expressions for both languages (Shroy, 2016; Gheno, 2019) and point towards the development of non-binary inclusive technology.

Lastly, we endorse the point made by Gaido et al. (2020). Namely, direct ST systems leveraging speaker's vocal biometric features as a gender cue have the capability to bring real-world dangers, like the categorization of individuals by means of biological essentialist frameworks (Zimman, 2020). This is particularly harmful to transgender individuals, as it can lead to misgendering (Stryker, 2008) and diminish their personal identity. More generally, it can reduce gender to stereotypical ex-

pectations about how masculine or feminine voices should sound. Note that, we do not advocate for the deployment of ST technologies *as is*. Rather, we experimented with unmodified models for the sake of hypothesis testing without adding variability. However, our results suggest that, if certain word segmentation techniques better capture correlations from the received input, such capability could be exploited to redirect ST attention away from speakers' vocal characteristics by means of other information provided.

A Models

Our direct ST models are built with the Fairseq library (Ott et al., 2019) and are based on the Transformer (Vaswani et al., 2017). They have 11 encoder and 4 decoder layers (Potapczyk and Przybysz, 2020). The encoder layers are preceded by 2 3x3 convolutional layers with 64 filters that reduce the input sequence length by a factor of 4 and their attention weights are added a logarithmic distance penalty (Di Gangi et al., 2019). The models are optimized on label smoothed cross-entropy (Szegedy et al., 2016) – the smoothing factor is 0.1 – with Adam using β_1=0.9, β_2=0.98 and the learning rate is linearly increased during the warm-up phase (4k iterations) up to the maximum value 5×10^{-3}, followed by decay with inverse square root policy. The dropout is set to 0.2 and each mini-batch consists of 8 sentences, while the update frequency is 8. The source audio is augmented with SpecAugment (Park et al., 2019; Bahar et al., 2019) that is applied with probability 0.5 by masking two bands on the frequency axis (with 13 as maximum mask length) and two on the time axis (with 20 as maximum mask length).

LMVR	74M	72M
BPE&Char	77M	77M

Table 9: Number of parameters (in millions). For BPE&Char, the reported number is the total of the training parameters, but at inference time only one decoder is used, so the size is the same of BPE.

The systems are trained on MuST-C (Cattoni et al., 2020). We filtered from the training set all the samples whose audio length is higher than 20s. So to avoid rewarding models' potentially biased behaviour, as a validation set we rely on the MuST-C gender-balanced dev set (Gaido et al., 2020). The target text was tokenized with Moses.[22] We normalized audio per-speaker and extracted 40 features with 25ms windows sliding by 10ms with XNMT[23] (Neubig et al., 2018).

Trainings are stopped after 5 epochs without improvements on the validation loss and we average 5 checkpoints around the best on the validation set. They were performed on 8 K80 GPUs and lasted 2-3 days.

Abstract

Natural language processing (NLP) methods for analyzing legal text offer legal scholars and practitioners a range of tools allowing to empirically analyze law on a large scale. However, researchers seem to struggle when it comes to identifying ethical limits to using NLP systems for acquiring genuine insights both about the law and the systems' predictive capacity. In this paper we set out a number of ways in which to think systematically about such issues. We place emphasis on three crucial normative parameters which have, to the best of our knowledge, been underestimated by current debates: (a) the importance of academic freedom, (b) the existence of a wide diversity of legal and ethical norms domestically but even more so internationally and (c) the threat of moralism in research related to computational law. For each of these three parameters we provide specific recommendations for the legal NLP community. Our discussion is structured around the study of a real-life scenario that has prompted recent debate in the legal NLP research community.

1 Introduction

Developing computational methods for analyzing legal text is an emerging area in natural language processing (NLP) with various applications such as legal topic classification (Nallapati and Manning, 2008), court opinion generation (Ye et al., 2018) and legal judgment prediction (Aletras et al., 2016; Luo et al., 2017; Zhong et al., 2018; Chalkidis et al., 2019). *Legal NLP* holds the promise of improving access to justice and offers to legal scholars the tools that allow for an empirical analysis of law on a large scale (Katz, 2012; Zhong et al., 2020).

The development and use of legal text processing technologies also raise a series of ethical questions, on which we focus in this paper. For example, following the publication at EMNLP 2019 of a paper on automatic prison term prediction (Chen et al., 2019) using a dataset constructed from published and publicly available records of past cases of the Supreme People's Court of China, a debate ensued about the ethical limits of legal NLP. More specifically, Leins et al. (2020) queried in a systematic way whether papers such as that of Chen et al. (2019) should be published. Leins et al. (2020) invoked a number of arguments including considerations to do with the construction of the dataset (Bender and Friedman, 2018), and so-called 'dual use' arguments (Radford et al., 2019), i.e. the possibility of using a system developed for some purpose for another, potentially harmful, purpose. Following a rich discussion, Leins et al. (2020) asked whether it is ethically permissible that legal NLP should be used at all to predict items such as prison terms.

We believe that the kind of ethical query put forth by Leins et al. (2020) is vital for the future of legal NLP and computational law in general. However, we also contend that it is essential that a more general discussion should be conducted about the pertinent normative principles and concepts at play. References to more general principles can often curb the temptation to make decisions on the basis of ad hoc moral intuitions which might not be and probably are not, as we explain later on, universally shared. The contributions of this paper are as follows:

- In this paper we make no claim to cover all the ethical ground in a comprehensive way. Instead, we focus on three crucial ethical parameters that, to the best of our knowledge, have not been extensively debated so far: (a) the role of *academic freedom* (§2); (b) the existence of a wide *diversity of legal and ethical norms* applicable to or endorsed by the global NLP scholarly community (§3); and (c) the

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3590–3599
August 1–6, 2021.

threat of moralism in legal NLP research (§4);

- We illustrate the practical difference that the first two factors would make, when taken into account, on the basis of the study of real-case scenarios of developing or using legal NLP technology;
- Moreover, for each of the three normative parameters (i.e. academic freedom, norms diversity and moralism), we provide specific recommendations for the legal NLP community.

2 Academic Freedom

2.1 What is academic freedom?

The idea of academic freedom has a long and important pedigree in the history of the Western university (Newman, 1976; Searle, 1972). Still, despite the importance of the idea, there is currently no commonly accepted definition accepted across domestic jurisdictions and scholars (Barendt, 2010). Be that as it may, for the purposes of this paper we provide the following working definition: *academic freedom is the freedom of scholars, whether employed by universities or not, to decide without undue external pressure or coercion the topics of their research, the standards of such research and the application of such standards to the scholars' peers*.

Academic freedom is both similar to and different from the more general right to freedom of speech (Barendt, 2010). It is similar in that it involves communicating freely chosen and conducted research to pertinent audiences. It is different in that: (a) it also applies to non-expressive research activities; (b) it is more circumscribed because scholars are bound by certain professional standards; and (c) it has both an individual-rights dimension and an institutional dimension, both being bound to the idea of the university as an intellectual space of free and uncoerced pursuit of truth. Academic freedom is recognized as a distinctive right by a number of national constitutions, such as Article 5(3) of the German Basic Law, as well as by some transnational legal instruments, such as Article 13 of the EU Charter of Fundamental Rights.

2.2 What is the value of academic freedom?

Two different tacks could be taken. First, one could provide a consequentialist argument. Consequentialist arguments identify right and wrong actions solely on the basis of their good or bad consequences (Driver, 2012). Accordingly, academic freedom could be justified by invoking the beneficial results of research undertaken, conducted and debated freely by researchers.

Second, one could opt for a deontological argument. Deontological ethical arguments identify permissible actions on the basis of (absolute) rules and irrespective of the consequences that actions may bring about (Alexander and Moore, 2007). Under a deontological construal, the guarantees of academic freedom would not be justified solely by the (expected) outcomes of the research actions they would allow but also: (a) because the pursuit of truth and knowledge for their own sake is a good in itself and irrespective of whether its (expected) consequences are good or bad (under some criterion of 'goodness' and 'badness'); and (b) because preserving academic freedom also preserves the integrity and inviolability of the very person of the researcher (Nagel, 1995).

We hasten to add for the sake of completeness that one could perhaps also opt for a virtue ethical approach to academic freedom (Hursthouse and Pettigrove, 2018). We refrain from doing so in this paper because, to the best of our knowledge, no comprehensive literature on a virtue ethics approach to academic freedom exists. Therefore, whatever the merits of such an approach, it falls outside the scope of this paper, which focuses on more entrenched within the pertinent research community ethical parameters.

2.3 Academic freedom and legal NLP

One first thing to note is that, despite its importance, academic freedom does not seem to be recognized as a distinctive ethical value in many codes related to the community of computer science researchers. For example, the ACM Code of Ethics refrains from specifically referring to that freedom in its first section, which is devoted to 'General Ethical Principles'.[1] While explaining this gap is beyond the scope of the present paper, we contend that academic freedom should be taken as seriously as the other ethical principles and values invoked therein, especially if one is to accept, as we think one should, that academic freedom's scope of application does not just include the 'academia' in the

---

[1] ACM Code of Ethics – `https://www.acm.org/code-of-ethics`

narrow institutional sense (i.e. universities or other kinds of tertiary education institutions) but virtually anyone who engages in research and scholarship with a view to discovering the truth about a subject matter.

If we begin with the widespread assumption that academic freedom is indeed a fundamental right, certain things seem to follow. First, in the assessment of the ethics of legal NLP, academic freedom will have to be taken into due account and then balanced against other values, such as the value of privacy of data subjects or the value or disvalue of certain further potential applications of systems (e.g. for legal judgment prediction) than those for which they were initially developed ('dual-use'). When values are balanced against each other, the all-things-considered permissibility of taking an action (in our case proceeding with a research project or publishing a paper in legal NLP) ultimately depends on taking all relevant contextual factors into account. We thus contend that there is no automatic general rule to apply to all cases. Still, we believe that, for example, in most imaginable scenarios where there is minimal interference with the rights of data subjects insofar as data such as court judgments are harvested from the public domain, pursuing an otherwise cognitively valuable research project should be permitted. More generally, taking academic freedom seriously renders the ethical permissibility of legal NLP projects more complex than sometimes acknowledged, since academic freedom will have to be taken seriously into account as an independent ethical factor, something which rarely (if ever) seems to happen as things currently stand, and despite the fact that almost all researchers pledge some kind of commitment to some version of academic freedom.

Second, and more importantly, ethical assessments of legal NLP research will also depend on the particular interpretation of the value of academic freedom (Barendt, 2010). For example, deontological interpretations of that value radically circumscribe the permissibility of invoking certain kinds of consequentialist reasons to block particular types of legal NLP research (Waldron, 2000). Invoking such reasons, we contend, is a direct violation of the integrity and equal freedom of researchers in the same way that, say, invoking people's tendency to be offended by certain kinds of artistic creations (for example, 'blasphemous' art) to block dissemination of art is a violation of the dignity of the artist. At the very least, under a robust understanding of the right to academic freedom (Dworkin, 1977), arguments to the effect that a certain piece of legal NLP research will have 'bad' consequences (whatever these are) will not be enough unless the risk of the consequences actually (as opposed to merely speculatively) obtaining is clear, present and significant. Again, we stress that there is no easily applicable general ethical rule here. Researchers should apply their ethical judgment in a contextual way by trying to account for all the relevant factors. We provide in the discussion that follows a concrete illustration of what a deontological understanding of academic freedom might entail in a particular scenario.

We also argue that even consequentialist interpretations of the value of academic freedom will place emphasis on the benefits of allowing researchers, at least *prima facie*, to freely conduct research, even when such research is ethically controversial. These benefits consist, among other things, in the possibility of maximizing the chances of getting to the truth about a certain subject-matter (in our case, law) through the proliferation of different research perspectives, thus promoting the public good.[2] Moreover, in this case again, the merely speculative possibility of certain adverse effects obtaining (e.g. systems designed by the researchers being used by others to pursue unethical goals) is not enough to render such research unethical in itself. There must be a real probability, not just a theoretical possibility, that these effects might in fact materialize.

2.4 Specific scenarios

These points can be readily illustrated by reference to the article by Leins et al. (2020) with which we began our discussion. We have said that, at the very least, academic freedom should be taken into account as an independent ethical value. We contend that this would modify significantly at least the structure of the argument provided by Leins et al. (2020). We stress, of course, that this in no way implies that academic freedom 'wins by default'. In fact, we have already highlighted that academic freedom is not the only pertinent ethical value and we have stressed that we do not believe that a generally applicable rule exists. All we intend to do is to argue that academic freedom as such should be

---

[2] ACM Code of Ethics – `https://www.acm.org/code-of-ethics#h-1.2-avoid-harm`

taken seriously into account and balanced against other pertinent ethical factors. However, we think that in the context of the particular case under consideration, academic freedom tips the balance in favor of the ethical permissibility of the research by Chen et al. (2019). Thus, the 'dual-use' and 'dataset construction' concerns voiced by Leins et al. (2020) will not be sufficient on their own to call the shots in ethics assessment in favor of rejecting either conducting or publishing the scrutinized research for the following reasons.

Dual-use Regarding the 'dual-use' concerns, we think that Leins et al. (2020) overestimate the dangers of an algorithm designed by academics being used to decide real cases with adverse consequences for real people. In particular, Leins et al. (2020) provide no reason to worry that any such use might happen anytime soon, nor evidence that there is, for example, a serious standing intention on the part of Chinese authorities to implement what would amount to a radical reform of the judicial system. Accordingly, the chance of an ethically unacceptable use of the designed algorithm seems, on the face of it, rather small (not to say almost completely theoretical). If this should be accepted, then both deontological and consequentialist interpretations of academic freedom tip the balance in favor of conducting and publishing the scrutinized research. Deontological interpretations place a very high premium on curtailments of the freedom and dignity of researchers. Arguably, this premium is not met by just the theoretical possibility of some bad consequence eventually resulting somewhere downstream from the research. But even consequentialist interpretations of academic freedom would concur in the case at point. This is because the expected probability of the occurrence of the bad consequences highlighted in the paper by Leins et al. (2020) (use of a potentially biased algorithm by the judiciary to help make inequitable decisions) seems in this case particularly low (or perhaps even nonexistent).

Of course, we fully acknowledge that we might be wrong in our assessment about the probability of a potentially evil 'dual-use'; we are in no way experts about Chinese legal and political affairs or of impending developments in the Chinese legal system. Still, the reasoning we have outlined also has a dimension to do with accruing and assessing evidence for ethical assessment. Thus, we hold that, in cases of doubt or where adequate evidence is neither available nor forthcoming, the value of academic freedom grounds at least a presumption in favor of proceeding with the research, the burden of proof in 'dual-use' scenarios been shifted to those who believe that there is a serious reason not to undertake a given piece of research. It is crucial for academic freedom that this burden should not be met by the researchers themselves. Arguably, in the case at hand the evidential burden has not been met by Leins et al. (2020).

Dataset Construction Similar considerations apply when it comes to assessing concerns to do with the construction of any particular dataset for legal NLP. The argument put forth by Leins et al. (2020) stresses that the dataset exposes people to harm because the defendants of past cases are identifiable. But arguably the probability of exposing people to harm through the construction of a dataset consisting of already decided cases by some domestic Supreme Court seems so low as to be practically non-existent. On the one hand, Leins et al. (2020) do not provide any evidence in favor of their argument. On the other hand, and to the best of our knowledge, the probability of these cases reopening together with that of some judge being specifically influenced by the dataset if such reopening occurs is practically non-existent. In all jurisdictions that we know about, cases by courts at the top of the judicial hierarchy are mostly, even if not uniquely, to do with the past, since by definition Supreme Courts issue the final judgment on some case. Thus, in order for considerations of potential harm to defendants to trump academic freedom, the risk of harm must be real, even under a generous understanding of the latter term, not merely imaginary or speculative. We stress, moreover, that this kind of understanding of harm coheres well with the ACM Code of Ethics that we have already cited. Thus, here again academic freedom, under any reasonable interpretation, should normally tip the balance in favor of proceeding with the research.

In a similar way, contending that some dataset 'unfairly advantages or disadvantages', as Leins et al. (2020) claim, appears to hugely overstate the real degree to which academic research might impact on the actual workings of judicial and political institutions. This is even more the case with respect to the specific dataset in question, since the latter was created by using documents already available in the public domain. In fact, it is the availability of the documents in the public domain itself, for which researchers bear no ethical responsibility, that creates certain risks to data subjects, if at all. Furthermore, such a contention bypasses the obvious fact that the dataset merely indicates the existence of unfair treatment that happened, if it did, at the level of what some Supreme Court did and not at the level of converting the activity of this Court into a dataset.

Last, but not least, here again the cases refer to facts that have already happened and no details are provided in Leins et al. (2020) as to whether there is, within the Chinese legal and social order, a concrete and standing threat for individuals to be unfairly treated on the basis of past cases (whether these led to convictions or not). Thus, we repeat that a merely theoretical or speculative possibility should not be considered sufficient, absent other factors, and especially concrete and real, not just imagined, reasons to trump academic freedom.

2.5 Recommendations

In decisions about the ethics of legal NLP research, deliberation should begin by commencing with a (rebuttable) presumption to the effect that academic freedom should not be curtailed lest there be compelling, to wit, clear and present or at least significantly probable (not purely theoretical or speculative) reasons to decide otherwise.

3 Diversity of Ethical and Legal Norms

3.1 Norms Diversity: The general problem

The community of legal NLP researchers is now global, ranging from the Global North to the Global South. However, a number of ethical standards on how to conduct legal NLP research in many cases seem to be either local or of local origin. Moreover, different ethical and legal standards may be found across different jurisdictions or cultures. Moral diversity is thus an issue that crops up in a variety of contexts to do with legal NLP. Below, we shall concentrate on the specific issue of privacy and data protection in the construction of datasets. Still, similar issues could also arise in other areas, such as the definition of what counts as 'unfairness' towards a specific group.

Privileging a particular ethical or legal standard over another (or a particular interpretation of a common standard) could fuel the suspicion that, instead of reflecting a perspective of detached and 'pure rationality', such standards and interpretations are in fact just entrenching local (and, for that matter, Western European or, more generally, Global Northern) prejudices and preconceptions, imposing them as mandatory norms on researchers who might not reflectively endorse them. There are two distinct but interrelated issues here. First, as a matter of fact, there appears to be a wide diversity of ethical standards that are accepted by different communities, with some of them being endorsed by some and rejected by others and vice versa (Prinz, 2007). Second, even when ethical or legal standards are shared across communities, there is often more or less widespread and reasonable disagreement about their 'best' or 'proper' interpretation (Gowans, 2015).

Now, the above facts do not immediately lead to what might seem like an unacceptable ethical relativism, i.e. the idea that no universal valid ethical standards could ever exist (Gowans, 2015). A discussion about the merits of ethical relativism is outside the scope of this paper, and we wish neither to endorse nor to criticize it. Our only point here is that, irrespective of the stand one takes on the issue of ethical relativism, the reality of diversity of ethical and legal opinion gives rise to an issue that cannot be avoided, to wit, the kind of position that researchers may take when confronted with research based on ethical rules and norms that significantly diverge from their own. Thus, ethical diversity points to the need to submit the content of the researcher's own standards, especially when they are used to evaluate the research of scholars who do not necessarily endorse them or reside in parts of the globe where they are considered neither legally nor perhaps even morally binding, to a much more searching examination. Accordingly, it should not be taken for granted that, say, historically and geographically contingent conceptions of a particular concept (e.g. data privacy in the EU, or the ban of judge analytics in France[3]) should always and without further argument take normative priority in ethical assessments.

Like in the previous section on academic freedom, we hasten to add that this does not amount to an easily applicable rule or 'formula' (which in our case could be either 'pay no heed to alien rules and norms and stick to what you think is right' or its exact opposite such as 'accept diversity no matter how unethical the alien rules or norms appear to be'). In fact, we do not think that there exists

---

[3] `https://www.artificiallawyer.com/2019/06/04/france-bans-judge-analytics-5-years-in-prison-for-rule-breakers/`

any easy, uncontroversial and unequivocal way by which to resolve such ethically complicated issues. As everywhere in life, a lot will depend on the particulars of each case and on the researcher's capacity to manifest a sensitivity to these particulars and of the specific ways in which they mesh in each scenario. All that we are suggesting is that issues to do with diversity of ethical and legal outlooks should be brought to the attention of researchers and, in the end, may only be resolved by the exercise of contextual and inherently controversial ethical judgment. At the very least, the actual presence of a diversity of different outlooks requires a willingness to engage seriously with 'alien' rules and norms, trying to understand their point and justification from the other's point of view, instead of easily and sometimes even complacently dismissing them out of hand as straightforwardly unethical.

3.2 Specific Scenario

To better apprehend how such a relatively abstract discussion may play out in a particular context and scenario, let us once again revisit the initial example with which we began our discussion, i.e. the paper by Leins et al. (2020).

Data Privacy: The ethical factors at play A large part of the argument put forth by Leins et al. (2020) consists in querying the process of construction of the dataset used by Chen et al. (2019) by invoking the rights of data subjects to privacy (similarly, Aletras et al. (2016), Chalkidis et al. (2019), Chalkidis et al. (2020) and Chalkidis et al. (2021) use publicly available data that contain private information in the context of the European Court of Human Rights). Thus, Leins et al. (2020) raise issues to do with the use of 'sensitive and confidential data', such as data to do with prison time served. They also refer to the fact that the people represented in the dataset do not seem to have been informed about data collection. The question then is whether these research practices are ethically problematic. While it seems self-evident, at least for a researcher accustomed to the practices of late twentieth century European states, to answer in the affirmative, an issue that Leins et al. (2020) do not address is that any answer to this question will presuppose a particular prior understanding of the content of the right of data subjects to privacy, an understanding, moreover, that may only be available to certain kinds of legal and ethical cultures and not to others.

The discussion may progress by reference to the simple observation that, when it comes to the legal and ethical status of datasets composed of data already available in the public domain (such as those in the papers by Chen et al. (2019) and Chalkidis et al. (2019)), there appears to be no global universal consensus as to the scope of the privacy rights of the data subjects involved.[4] A few jurisdictions deploy very demanding definitions of data privacy, coupled with special protection provided with respect to 'sensitive data': the EU and Australia are prime examples. Still, there also exist major divergences between state practices, some states being much more permissive in those respects than others.

The invocation of privacy as an ethical consideration thus raises a distinctive problem: how should privacy be understood in view of the fact that there is no universal consensus on its nature and its protection across states? Should particular definitions of data privacy constitute the appropriate normative benchmark? And why? As we have already said, some of these definitions might be significantly more demanding than others, reflecting different local conventions about the value of rights that data subjects have under the law.

We contend that the documented divergences in the attitudes towards data protection and the right to privacy, differences reflected in the law of different jurisdictions, in fact stem from a more fundamental phenomenon, i.e. the diversity of ethical, moral and legal outlooks both across time and across states, cultures and peoples. (Prinz, 2007). In fact, as we have already shown, it is arguable that the high standard of data protection that Leins et al. (2020) use, which also appears to be the standard used by the ACM Code of Ethics[5] is in the minority from a global point of view (Renteln, 1988). Moreover, the construction of datasets from databases containing publicly available court judgments appears to at least count in favor of the prima facie permissibility of that research practice.

The availability of court judgments in the public domain even in core Western countries that otherwise protect private data in other domains and with respect to international courts such as the European Court of Human Rights still belies an older conception of privacy: one in which the publicity of court trials as a rule of law guarantee trumps

---

[4] `https://www.cnil.fr/en/data-protection-around-the-world`

[5] `https://www.acm.org/code-of-ethics`

the individual's wish to hide oneself from others in public space (Langford, 2009). Under this older conception of privacy, not only is it possible to retrieve the names of litigants in past cases, but also that possibility is protective of the rule of law in the same way that, say, secret trials of terrorist or other suspects are still widely thought to undermine it (Resnik, 2011). The above comments thus suffice to show that the high standard of privacy protection that is sometimes used to scrutinize research practices in legal NLP, exemplified by Leins et al. (2020), is not only geographically but also historically contingent.

Under these conditions, the following question becomes ethically pressing: Why should any local and geographically restricted conception of stricter data privacy and protection be preferred to, say, a more relaxed and minimal one? Granted, researchers conducting legal NLP research in locations where that particular conception is prevalent and legally obligatory, such as the European Union or Australia, should of course abide by it; but why should other researchers, such as those residing, say, in Singapore, the United States or Africa, be held to that same particularly demanding standard? Moreover, is it even fair and ethical, given what was already stated above with respect to academic freedom, to hold researchers (e.g. non-European and non-Australian) to a peculiarly local, and by no means universally acknowledged, standard?

Data Privacy: Application to the case at hand On the basis of the above considerations, we believe that this kind of contextually informed thinking could argue in favor of the ethical acceptability of the research practices used by Chen et al. (2019) in the construction of their dataset. There are two important variables at play here. On the one hand, the data is already in the public domain. Under these circumstances, the interference of the researchers with the data subjects' rights appears minimal at worst: in fact, even under a demanding definition of privacy, the main interference with privacy rights is due to the availability of the publicly available database itself and not to the researcher's activity of constructing a dataset for research purposes out of it. But, second, we could even go further and ask why what appears like a specifically European definition of privacy and data protection, and moreover one which, at least as things stand nowadays seems to be more of an outlier on a global level, should be adopted as a normative yardstick by researchers working in a completely different ethical and regulatory environment.

As we have already said, there is a long and venerable Western and European tradition which lays stress on the importance of the publicity of court judgments. For a long time, it was considered not unethical but utterly normal to make court trials and their outcomes public, so as to control through public scrutiny the exercise of state coercion on individuals. While this consideration might now seem dated in some parts of the world, especially those that have entrenched traditions of judicial independence and a high degree of trust to the judicial system, we should be sensitive to its importance in other parts of the world. It thus becomes difficult to resist the conclusion that the absence of respect of (putatively European) data protection norms by Chen et al. (2019)) is not a fatal ethical objection to either conducting or publishing their research.

3.3 Recommendations

Forging genuine universal ethical standards requires a global conversation between researchers engaged from a plurality of standpoints and traditions. When such standards do not exist or exist only to a minimal degree, ethical assessment for global conferences, journals and reviews should be appropriately flexible and respectful of differences and reasonable disagreements. No automatic assumptions should be made that a 'one-size-fits-all' model is sufficient to make informed decisions about the ethical status of research practices.

4 The Threat of Moralism in Legal NLP

We believe that the previous discussion points to a more general issue, that we treat under the heading of the 'threat of moralism' in legal NLP. While this issue is more theoretical than the previous ones (which had practical ramifications), we think it should be treated on its own, insofar as it allows us to propose a more general and comprehensive conceptual framework that allows us to make wider sense of the ethical issues at play. This section of our paper thus has the function of both subsuming the previous discussion and further advancing it, albeit without this time focusing on the discussion of a specific scenario.

4.1 How to characterize moralism?

Moralism can be intuitively understood as 'the vice of overdoing morality' (Coady, 2015). In the context of qualitative research, Hammersley and Traianou (2011) has contended that moralism can take two different forms. First, it might involve the belief that substantive ethical values, other than the disinterested pursuit of knowledge for its own sake, should be integral goals of research. Second, it might involve the requirement that researchers adhere to 'high' or even the 'highest possible' ethical standards (Hammersley and Traianou, 2011).

Here, and with no ambition of a comprehensive discussion, we roughly define moralism as the idea that substantive moral values and constraints more demanding than mere adherence to valid legal norms or to relatively uncontroversial and in any event minimal ethical norms, such as the requirement not to harm others, must be taken into account when assessing research outputs, including legal NLP research. Our argument is that moralism of this sort threatens academic freedom and the equal dignity of researchers as bearers of such freedom.

4.2 Why moralism might be a problem in legal NLP?

To think clearly about why moralism in the sense of the pursuit of substantive moral values might be a problem in legal NLP, we might make an analogy with moralism in the setting of ordinary social and political life. At least liberal democracies take seriously John Stuart Mill's idea (Mill, 2015) that people should be free to pursue various ends that they themselves set, so long as they keep within certain reasonable limits circumscribed by the so-called 'harm' principle, i.e. the requirement not to harm others equally engaged in the pursuit of their proper ends.

A political community that attempts to impose substantive ends on individuals, say on the assumption that certain forms of life are 'higher' or 'more important' than others is guilty of disrespecting the autonomy of individuals. We contend that, in an analogous way, a research community that attempts to instill in its members specific ethical ends other than the disinterested pursuit of truth and knowledge, especially by ethically assessing the very content of research endeavors, is risking falling into a kind of moralism which fails to take the freedom of researchers seriously. In particular, the mere fact that certain members of the research community subjectively find a piece of research to be unacceptable on other than professionally defined and accepted methodological grounds or basic and flagrant disrespect of moral norms such as the no-harm principle, should not be deemed automatically sufficient for ethical condemnation of the research.

4.3 Recommendations

The primary moral duty of legal NLP researchers, like all researchers, is to the disinterested pursuit of truth as they understand it, and not to substantive ends which are extrinsic to that pursuit.

5 Conclusions

In this paper we have contributed to the ongoing discussion on the ethics of legal NLP (Leins et al., 2020). We laid emphasis on three normative factors whose importance, to the best of our knowledge, has not been sufficiently acknowledged, i.e. academic freedom, diversity of ethical and legal norms of the global NLP community and the wider and more abstract issue of moralism in research ethics. Moreover, we illustrated how the first two factors might make a practical difference to ethical decision-making by a detailed discussion of a specific scenario. We also stressed that these factors do not amount to any automatically applicable general rule but require the exercise of contextual ethical thinking on the part of researchers. Final decisions should be made by taking all ethically relevant factors into account.

We believe that the ethical factors we identified can help the legal NLP community become more reflective and tolerant of a wider variety of approaches whilst at the same time remaining fully committed to the academic ideal of disinterested pursuit of truth for its own sake.

Abstract

In this paper, we analyze the interplay between the use of offensive language and mental health. We acquired publicly available datasets created for offensive language identification and depression detection and we train computational models to compare the use of offensive language in social media posts written by groups of individuals with and without self-reported depression diagnosis. We also look at samples written by groups of individuals whose posts show signs of depression according to recent related studies. Our analysis indicates that offensive language is more frequently used in the samples written by individuals with self-reported depression as well as individuals showing signs of depression. The results discussed here open new avenues in research in politeness/offensiveness and mental health.

1 Introduction

The use of offensive language is pervasive in social media and it has been studied from different perspectives. A popular line of research is the study of computational models to identify offensive content online relying on traditional machine learning classifiers (e.g. naive bayes and SVMs) (Xu et al., 2012; Dadvar et al., 2013), neural networks (e.g. LSTMs, GRUs) with word embeddings (Aroyehun and Gelbukh, 2018; Majumder et al., 2018), and more recently, transformer models like ELMO (Peters et al., 2018) and BERT (Devlin et al., 2019) which have shown to obtain competitive scores topping the leaderboards in recent shared tasks on offensive language and hate speech detection (Liu et al., 2019).

Offensive language is related to the notion of impoliteness (Culpeper, 2011) and it can take various forms from general and often harmless profanity to abusive language intended to cause harm, such as cyberbullying and hate speech (Waseem et al., 2017). Computational models have been applied not only to identify the various types of offensive content (Basile et al., 2019) but also to, for example, study the relation between profanity and hate speech (Malmasi and Zampieri, 2018) and the different functions and intentions of vulgarity in social media (Holgate et al., 2018).

Most of the datasets used in the aforementioned studies contain data sampled from the general population and therefore very little light has been shed on the use of offensive language in online communication by specific groups such as individuals with mental health conditions. A notable exception is the recent study by Birnbaum et al. (2020) which shows that users with mood disorders (bipolar disorder, major depressive disorder) and schizophrenia spectrum disorders use more swear words in their Facebook messages than healthy users.

To address this shortcoming, in this paper, we build on recent work on offensive language identification and apply it to mental health datasets. More specifically, we look at the role of offensive language in the communication of users with depression using two publicly available datasets containing posts by individuals with self-reported depression diagnosis.

To the best of our knowledge, this study is the first to apply state-of-the-art offensive language identification models to mental health datasets. We aim to answer two research questions:

RQ1: Are posts from individuals suffering from depression more likely to contain offensive language in existing datasets?

RQ2: Are there differences in the nature of offensive language used by individuals with depression compared to control groups?

WARNING: This paper contains offensive words.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3600–3606
August 1–6, 2021.

2 Related Work

Offensive language identification is a popular topic in NLP. Researchers have been working to improve the performance of systems trained to identify conversations that are likely to go awry (Zhang et al., 2018) and to detect the various types of offensive posts in social media (Basile et al., 2019; Kumar et al., 2020). More recently, with the goal of improving explainability, offensive language identification at the token-level has received more attention (Mathew et al., 2021; Ranasinghe and Zampieri, 2021). A number of computational models have been applied to this task ranging from traditional machine learning classifiers, most notably SVMs (MacAvaney et al., 2019), to various deep learning models (Liu et al., 2019). While the clear majority of studies on this topic deal with English, some studies have addressed offensive language in other languages like Greek (Pitenis et al., 2020) and Turkish (Çöltekin, 2020) while a few others have applied cross-lingual models to take advantage of existing English datasets when making predictions in languages with fewer resources (Ranasinghe and Zampieri, 2020).

Several studies have applied machine learning and NLP methods to address research questions related to mental health in social media such as identifying users with a particular mental health condition and predicting the risk of self-harm or suicide ideation (De Choudhury et al., 2013; Preoţiuc-Pietro et al., 2015; Malmasi et al., 2016; De Choudhury et al., 2016; Chancellor and De Choudhury, 2020). The CLPsych workshop co-located with international NLP conferences has hosted multiple competitions on these topics providing participants with important benchmark datasets and attracting a large number of teams (Coppersmith et al., 2015; Milne et al., 2016; Zirikly et al., 2019).

There have been multiple studies on the impact of offensive and hateful speech on the individual's psychological mental health and well-being (Bannink et al., 2014; Saha et al., 2019). The use of offensive language by individuals with mental health conditions, however, has not been substantially studies with the exception of Birnbaum et al. (2020) that analyzed the use of offensive language in Facebook messages from individuals with mood disorders. Our work fills this important gap by providing further empirical evidence of the use of offensive language by individuals with diagnosed depression or showing signs of depression.

3 Data

In our experiments, we use three publicly available English datasets with data collected from social media: one with offensive language annotation, and two datasets with posts from users with self-reported depression diagnosis.

Offensive Language We use the Offensive Language Identification Dataset (OLID) (Zampieri et al., 2019a) to train offensive language identification models. OLID contains a total of 14,100 manually annotated posts from Twitter and it was released as the official dataset of SemEval-2019 Task 6 (OffensEval) (Zampieri et al., 2019b). We chose OLID due to its general hierarchical annotation taxonomy with the following levels:

Level A: Offensive language identification: offensive (OFF) vs. non-offensive (NOT)

Level B: Categorization of offensive language: targeted insult or threats (TIN) vs. untargeted profanity (UNT).

Level C: Offensive language target identification: individual (IND) vs. group (GRP) vs. other (OTH).

This hierarchical taxonomy provides us with a flexibility as it represents multiple types of offensive content in a single annotation scheme (e.g. posts targeted at an individual are often *cyberbullying* and posts targeted at a group are often *hate speech*) making it a great fit for this kind of analysis. In our experiments, we consider level A (offensive vs. non-offensive) and level B (target vs. untargeted).

Mental Health We run all our experiments on the Reddit Self-reported Depression Diagnosis (RSDD) dataset (Yates et al., 2017) and on the Early Risk Prediction on the Internet (eRisk) 2018 dataset (Losada and Crestani, 2016), two publicly available datasets containing posts from Reddit. The RSDD dataset consists of users annotated as having depression by their mention of diagnosis and control users, which are users who do not suffer from depression (there is not any mention of diagnosis in their posts). To prevent users labeled with depression to be easily identified by specific keywords, the authors removed posts containing depression terms (e.g. *depression, depressive*) or belonging to mental health related subreddits. The authors made the training, validation, and test splits available and in our experiments we use the training split, which contains over 5 million posts from users with depression and over 30 million posts from users in the control group.

The eRisk 2018 dataset contains users labeled with depression by their mention of diagnosis and control users. In this paper, we use both train and test splits, consisting of a total of approximately 90,000 submissions from users annotated as having depression and 985,000 posts and comments from the users in the control group. As opposed to the RSDD dataset, the authors removed only the posts containing the exact mention of diagnosis.

4 Methods

Offensive Language Detection and Categorization We address **RQ1** and **RQ2** by studying the language of users from the two groups, self-reported depression diagnosis and control, in social media. We start by computing an offensive score, which measures the extent to which a post is offensive, and whether it is a targeted insult or an untargeted post (most often profanity). These two tasks correspond to OLID levels A and B respectively Zampieri et al. (2019a).

For the task of offensive language detection, we fine-tune a BERT model on the OLID dataset on level A. We train the model for 2 epochs, with a small learning rate of 0.00001 and Adam optimizer (Kingma and Ba, 2015). We use an 80:20 split of the training data to choose the best performing model in terms of F1 score. The model obtains 0.85 Precision, 0.74 Recall and 0.77 F1 score on the test data from the OLID dataset. These numbers are consistent with the baselines reported in (Zampieri et al., 2019a). The offensive score is computed as a probability taken from the softmax output of the BERT model.

For the task of offensive language categorization (targeted insult or untargeted profanity) we also choose a transformer-based approach, using another BERT model trained on OLID level B. We fine-tune BERT for 7 epochs with the same aforementioned train-validation split, with a learning rate of 0.00002 with Adam optimizer and a linear warm-up schedule with a 0.05 warm-up ratio, as proposed by Rosenthal et al. (2020). To account for the class imbalance, we use cross-entropy loss with balanced class weights. The effectiveness of the model is also evaluated on the OLID test data, using the same metrics and achieving 0.78 Precision, 0.84 Recall and 0.80 F1 score.

Signs of Depression Detection Furthermore, we are interested in distinguishing the posts that show signs of depression from all the posts of individuals from the depression group. This way, we filter out the noise added by the texts which do not contain any cues of depression. We are using the Semantic Polarity Score heuristic (H_s heuristic) proposed by Ríssola et al. (2020) to detect posts showing signs of depression written by individuals with a self-reported depression diagnosis.

H_s uses a mix of sentiment polarity, depression score, and emotion detection. The authors use TextBlob[1] to obtain the polarity score of each post, ranging between -1 and 1. The terms from EmoLex (Mohammad and Turney, 2013) are used in order to detect the emotions (anger, fear, anticipation, trust, surprise, sadness, joy, and disgust) contained in the texts. The depression score of each post is computed using the NRC Affect Intensity Lexicon (Mohammad, 2017), ranging from 0 to 1. In order to distinguish the posts showing signs of depression from other posts of users with self-reported depression diagnosis, we follow the criteria from Ríssola et al. (2020). Posts are labeled as showing signs of depression if the texts have a negative polarity, if sadness or disgust emotions are present, and if they have a depression score higher than 0.1.

5 Results and Discussion

Using the H_s heuristic, we demonstrate that there is a statistically significant difference (Welch t-test, p-value <0.001) in terms of offensive language use between individuals with self-reported depression diagnosis that manifest signs of depression in their posts and users who do not show any signs of depression. Posts containing signs of depression have a higher offensive score than posts from users diagnosed with depression without any signs, in both eRisk 2018 and RSDD datasets, as shown in Figure 1.

For labeling the offensive posts, we use the same 0.50 threshold as used during training. We show in Table 1 that more posts from users diagnosed with depression are labeled as offensive than from control. Using the H_s heuristic, we filter the posts containing signs of depression and find that there is a higher percentage of posts with signs of depression labeled as offensive. These findings are consistent for both eRisk 2018 and RSDD datasets. The higher degree to which depressed individuals use offensive language in comparison to individuals in the control group can be explained via the

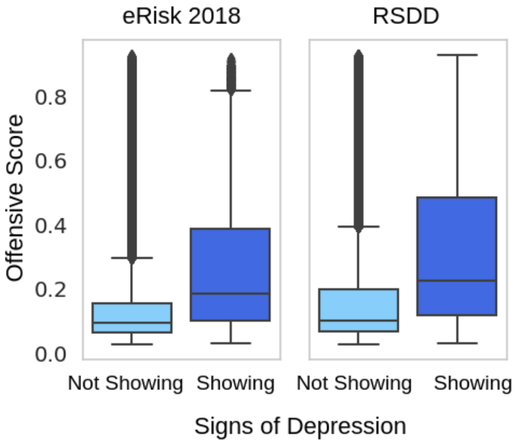

Figure 1: Distribution of the offensive language score for posts written by users with self-reported depression diagnosis and showing or not showing signs of depression measured with the H_s heuristic.

	Self-reported		Signs of depression	
Dataset	**Depression**	**Control**	**Showing**	**Not showing**
eRisk 2018	8.24%	5.91%	18.50%	7.40%
RSDD	11.31%	8.91%	24.33%	10.10%

Table 1: Percentage of posts labeled as offensive from total posts of self-reported individuals and of individuals showing/not-showing signs of depression measured with the H_s heuristic.

emotion regulation framework (Gross, 1999). The use of offensive language could be an emotion regulation strategy through which depressed individuals relieve some of their distress. Similarly, pain and distress studies indicate that the use of offensive language when experiencing pain significantly diminishes the level of pain experienced (Stephens and Robertson, 2020), suggesting that the use of offensive language can relieve distress.

Although there are more posts with signs of depression labeled as offensive, the majority of them are untargeted (containing swears, profanity) and only 10.71% and 10.72%, respectively, are targeted insults (Table 2).

	Self-reported		Signs of depression	
Dataset	**Depression**	**Control**	**Showing**	**Not showing**
eRisk 2018	24.12%	21.72%	11.48%	26.68%
RSDD	16.63%	23.94%	8.29%	18.48%

Table 2: Percentage of posts labeled as targeted insult from the offensive posts of self-reported individuals and of individuals showing/not showing signs of depression measured with the H_s heuristic.

The fact that depressed individuals tend to use more self-deprecating content and less deprecation of others, as evidenced in our analysis, is a result that is in line with the broad spectrum of cognitive studies, which indicates that negative evaluation of the self is a main interpretation bias in depressed individuals (Everaert et al., 2017). Depressed individuals tend to view themselves as less valuable than others. By self-deprecating language, we use the definition from Speer (2019). This broader definition includes, but is not limited to, insults towards self, if they have a negative intention. Finally, studies show that there is also a self-focused attention tendency in depressed individuals (Brockmeyer et al., 2015), where just like in other conditions (e.g. anxiety), individuals tend to be unable to detach from their own perspective focusing primarily on their side of the story, their pain, etc.

In order to further understand the differences in the use of offensive language, we analyze the words from posts written by individuals with depression. We compute the keyness score (Kilgarriff, 2009; Gabrielatos, 2018) of content words (removing stop words) from posts labeled as offensive written by users with self-reported diagnosis. The keyness is computed in order to show which words occur more often in the texts from depressed individuals showing signs of depression (target corpus) in comparison to the texts from users diagnosed with depression that do not show signs of depression (reference corpus). We calculate the frequencies of words from the two corpora and then the log-likelihood Ratio (G^2) (Dunning, 1993) for each word. In Figure 2 we present the top 20 words, ordered by G^2 from each corpus, in the two datasets.

We show that, while users without signs of depression refer more to sexual and profane terms, posts by users showing signs of depression include more negative words such as *bad, hate, sick, death*. This result corroborates the findings described in the literature on cognitive errors or biases in depression (Beck and Haigh, 2014). It is well known that depressed individuals tend to view life events more negatively than their non-depressed peers (Everaert et al., 2017). Furthermore, depressed individuals are more likely to recall negative life events than positive events and also more likely to pay closer attention to negative information (Beck and Haigh, 2014). Signs of this biased view of life are expected to be noticeable in language and there are studies that indicate that depressed individuals tend to have a more negative discourse than their non-depressed depressed peers (Rude et al., 2004). Keywords with a negative polarity, such as *bad, die* or *pain*, seem to be pervasive in the speech of depressed individuals as confirmed in our study. Finally, the reduced sexual drive is a well-known indication of depression (Manohar et al., 2017), therefore, it is to be expected that depressed individuals tend to use fewer words with sexual connotation as confirmed in our study.

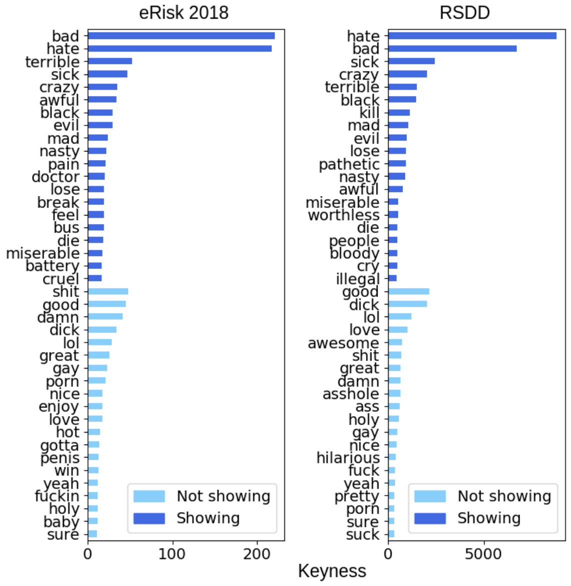

Figure 2: Keyness for words from posts showing/not showing signs of depression.

6 Conclusion and Future Work

This paper is the first to apply offensive language identification techniques to posts by individuals with a mental health condition with the purpose of interpreting the use of profanity and offensive language by this group. We showed how the offensive language use differs substantially between individuals with depression (in samples with self-reported diagnosis or showing signs of depression) answering our **RQ1**. Our findings indicate that users with self-reported depression diagnosis are more likely to use offensive language in their posts compared to the control group. From the posts of individuals with depression, the ones showing signs of depression contain more offensive language than the ones not showing any signs.

In terms of the nature of offensive content, our results indicate that posts from individuals with signs of depression are less likely to contain targeted offensive language. Furthermore, while analyzing the texts of users with depression, we observed a larger frequency of words with negative polarity (e.g. *bad, hate, sick, suffer*) in the posts of users showing signs of depression, where the discourse of users not showing any signs contains more sexual-related content, addressing our **RQ2**. These findings are consistent with the existing literature from psychology (Stephens and Robertson, 2020; Everaert et al., 2017; Beck and Haigh, 2014).

While it is clear that depressed users are more likely to write posts with negative polarity, the interplay between offensive language and polarity in the mental health datasets used in this paper has not yet been explored. A polarity score has been used in the heuristic by Ríssola et al. (2020) suggesting that using NLP models to investigate the interplay between polarity and depression is a promising future work direction. Other future work directions include the analysis of the targets of offensive posts using the OLID Level C annotation and a more detailed analysis on the function of profanity and vulgarity in these datasets (Holgate et al., 2018). Finally, we would like to carry out a similar analysis for other languages taking advantage of existing datasets and available cross-lingual embedding models.

Acknowledgments

We would like to thank Ioana Podină for providing us with helpful feedback and suggestions for the results analysis. We further thank the anonymous ACL reviewers for the insightful feedback provided. Finally, we thank the dataset creators for making the data used in this study available.

Liviu P. Dinu was partially supported by a grant of the Ministry of Research, Innovation and Digitization, CNCS/CCCDI – UEFISCDI, project number 108, within PNCDI III.

Ethics Statement

This paper uses publicly available datasets on offensive language and mental health to train computational models with the purpose of carrying out both quantitative and qualitative data analysis. We are primarily interested in quantifying and analyzing the use of offensive language in the texts included in the two mental health datasets and we do not attempt to predict mental health status or condition from these datasets. Potential biases in our model predictions and in our analysis may arise from the annotation and sampling techniques of these two datasets and are not intentional. Finally, we did not use any form of demographic information in our models or in our analysis.

Transforming Term Extraction: Transformer-Based Approaches to Multilingual Term Extraction Across Domains

Christian Lang*, Lennart Wachowiak*, Barbara Heinisch, Dagmar Gromann
University of Vienna, Center for Translation Studies
`[christian.lang,lennart.wachowiak]@univie.ac.at`

Abstract

Automated Term Extraction (ATE), even though well-investigated, continues to be a challenging task. Approaches conventionally extract terms on corpus or document level and the benefits of neural models still remain underexplored with very few exceptions. We introduce three transformer-based term extraction models operating on sentence level: a language model for token classification, one for sequence classification, and an innovative use of Neural Machine Translation (NMT), which learns to reduce sentences to terms. All three models are trained and tested on the dataset of the ATE challenge TermEval 2020 in English, French, and Dutch across four specialized domains. The two best performing approaches are also evaluated on the ACL RD-TEC 2.0 dataset. Our models outperform previous baselines, one of which is BERT-based, by a substantial margin, with the token-classifier language model performing best.

1 Introduction

Automated Term Extraction (ATE) aims at extracting terms, i.e., single- or multi-word sequences, from domain-specific text. ATE plays a role in many NLP tasks, such as information extraction, knowledge graph learning, and text summarization. In a corpus-level setting, methods range from frequency-based to utilizing Wikipedia links, where no single method has been found to perform consistently best across domains in English (Astrakhantsev, 2018). In document-level ATE, KeyConceptRelatedness (Astrakhantsev, 2014), which relies on keyphrase extraction and semantic relatedness, outperforms other methods (Šajatović et al., 2019). The use of neural networks in these methods is mostly limited to generating embeddings.

A first use of BERT-based language models is documented by Hazem et al. (2020), the winning system of the recent ATE challenge TermEval 2020 (Rigouts Terryn et al., 2020) and the baseline for the proposed approaches. Inspired by this first success of transformer-based models, we compare two variations of the multilingual pretrained language model XLM-RoBERTa (XLM-R) (Conneau et al., 2020) with an innovative use of the multilingual pretrained NMT model mBART (Liu et al., 2020) on the Annotated Corpora for Term Extraction Research (ACTER) dataset (Rigouts Terryn et al., 2019) utilized in TermEval 2020 as well as on the ACL RD-TEC 2.0 dataset (QasemiZadeh and Schumann, 2016). Since masked language and NMT models take sentences as input, the proposed ATE methods operate on sentence level. In spite of this reduced context of sentence input rather than documents or corpora, the models achieve F1 scores of up to 69.8% on ACTER, strongly outperforming the previous baseline of 48.1% .

An XLM-R-based sequence classifier relies on positive (term) and negative (non-term) samples, which are generated based on all n-grams up to a length of six of a given sentence. A second XLM-R-based token classifier decides for each word in a sequence whether it can be considered (part of) a term. Since the second model operates without upfront n-gram generation and only processes each sentence once, it is considerably more time-efficient than the first. Finally, the pretrained NMT model mBART is adapted to transform input sentences to sequences of comma-separated terms, an approach inspired by NMT-based ontology learning (Petrucci et al., 2018).

Analyses of results reveal interesting insights into the performance of the different input processing strategies and transformer-based models, including their ability to handle multi-word terms, training time required, and a comparison between baseline monolingual and multilingual language models in ATE. To achieve sentence-level ATE

the ACTER dataset had to be preprocessed aligning terms with their occurrences in sentences, which we made publicly available together with our source code.[1]

In summary, our main contributions are: (i) We show that transformer-based models can be successfully applied to ATE across three languages and five domains, without the need for text preprocessing or feature extraction; (ii) We show that ATE can be performed successfully on sentence level; (iii) We conduct robust experiments to show that our models outperform competitive baselines; (iv) We investigate the models' abilities to handle single- and multi-word terms, distinct term types, and differences in performance depending on train and test language combinations.

2 Related Work

An initial classification of ATE methods into statistical, linguistic or hybrid (e.g. by Kageura and Umino (1996)) has recently been refined by Astrakhantsev (2018) to methods based on term occurrence frequencies (e.g. C/NC-value Frantzi et al., 2000), occurrence contexts (e.g. Bordea et al., 2013), domain-specific corpora combined with general language corpora (e.g. Weirdness (Ahmad et al., 1999)), topic modeling (e.g. Li et al., 2013), and those utilizing Wikipedia. Methods are additionally categorized by the type of context, i.e., corpus-level (e.g. Zhang et al., 2008; Astrakhantsev, 2018) and document-level (e.g. Šajatović et al., 2019) settings.

These classifications cannot easily accommodate recent neural ATE methods that generally operate on sentence level. An approach most closely related and our baseline by Hazem et al. (2020) utilized RoBERTa (Liu et al., 2019) for English and CamemBERT (Martin et al., 2020) for French and won the TermEval 2020 challenge. In their work, pretrained language models clearly outperformed a classification method based on a variety of features, such as statistical descriptors and the domain-specificity measure termhood (Kageura and Umino, 1996). A recently published approach (Rokas et al., 2020) relies on LSTM, GRU and BERT embeddings and achieves high F1 scores for ATE of Lithuanian terms in the cybersecurity domain. Several approaches build on word embeddings to perform ATE on specific domains, such as medicine (e.g. Bay et al., 2020), or to separate general-language from domain-specific embeddings (Hätty et al., 2020). In contrast, our models perform ATE on four domains and in three languages utilizing a pretrained language and a pretrained NMT model. Extracting terms is also vital to learning expressive ontologies from text, for which Petrucci et al. (2018) train an NMT model to transform sentences to Description Logic formulas, an idea that inspired our NMT-based ATE model.

3 Language Models and NMT

Neural Language Models, which create contextualized language representations, were responsible for many of the recent improvements in NLP. Such models acquire rich contextualized language representations in a pretraining stage in which they learn to predict a masked word in a sentence, a task for which large amounts of training data are readily available. The thereby learned representations can be reused for various downstream tasks in the so-called fine-tuning stage, where task-specific layers are added on top of the pretrained language model. One of the most popular language models is BERT (Devlin et al., 2019), utilizing the transformer architecture (Vaswani et al., 2017). XLM-R (Conneau et al., 2020) is a multilingual variant of BERT, which was pretrained in 100 languages using 2.5 terabytes of Common Crawl data. Moreover, it makes use of the improved training routine introduced by RoBERTa (Liu et al., 2019).

Despite the widespread use of neural language models for NLP, adoption of such self-supervised pretraining approaches in NMT has only recently started to gain traction. NMT is traditionally performed with sequence-to-sequence encoder-decoder models that generate a target language output sequence based on a source language input sequence. Conventional language models trained on predicting masked words from a sequence, such as BERT, have only recently been incorporated into NMT (Zhu et al., 2020). A very interesting alternative is to pretrain an NMT transformer architecture, as done by Lewis et al. (2020) in form of a Bidirectional and Autoregressive Transformer (BART) (Lewis et al., 2020). This is achieved by combining a bidirectional encoder similar to that of BERT with an autoregressive decoder, as seen in GPT (Radford et al., 2018). Thereby, contextualized language representations are trained and

---

[1] `https://github.com/Text2TCS/Term-Extraction-With-Language-Models` and `https://github.com/Text2TCS/mBART-termextraction`

a model that is proficient in text generation and translation is created. Liu et al. (2020) applied the BART architecture to large-scale monolingual corpora across 25 languages, creating multilingual BART (mBART) that can be directly fine-tuned for machine translation (MT).

4 Dataset

In order to compare to a strong baseline, we train and test on the ACTER dataset (Rigouts Terryn et al., 2019) utilized in the recent TermEval 2020 challenge. The domains wind energy and corruption represent the training set, dressage (equitation) the validation set, and heart failure the hold-out test set, for which the count of words and unique gold standard terms including named entities for English, French and Dutch are presented in Table 1.

In the ACTER dataset, words were labeled as specific, common, and out-of-domain (OOD) terms, and named entities (NE). Specific terms are understood by domain experts, while common terms might also be additionally understood by laypersons. OOD terms might be specific to a different domain, but used in the domain at hand, e.g. statistical terms in the medical domain.

Since the time of the challenge the dataset has undergone some minor updates, that is, unicode encoding, dash and quote normalization.[2] We believe that these minor normalization changes do not significantly impact comparability to TermEval results, which is confirmed by the fact that our most similar model to the baseline, the sequence classifier, achieves comparable results. Furthermore, the ACTER dataset provides terms as a single list for all documents in a domain. However, we required inline sentence-level term annotation, which we generated. In rare cases, this generation of inline annotations might have lead to erroneous results for single-word terms. For instance, the term "gain" as in "private gain" lead to the verb "gain" as in "gain acceptance" to be erroneously annotated in the corruption domain. We manually analyzed 300 inline annotated sentences and since the above example was the only error found, we consider this a negligible issue.

The fully inline annotated dataset ACL RD-TEC 2.0 (henceforth ACLR2) dataset provides cleaner training and test data and could therefore potentially further boost model performance as we show in Section 7.2. The ACLR2 dataset provides a total of 471 inline human annotated abstract texts from articles in the ACL Anthology Reference Corpus. As shown in the split of numbers in Table 1, two separate annotations by two human experts are provided. Since no official train/val/test split is provided, we chose to split the ACLR2 dataset with a 60/20/20 split per annotator. In contrast to the ACTER dataset, ACLR2 is only available in English and exclusively covers scientific abstracts in the domain of computational linguistics. In terms of baseline, previous work generally reported precision at *k* top terms extracted (P@k) (Zhang et al., 2018b) or F1 on Recoverable True Positives (F1@RTP) (Zhang et al., 2018a), due to the necessity to define an arbitrary cut-off point with traditional ATE methods. In another work attempting ATE with neural networks, due to the lack of an official data split and a restriction to domain specific terms, F1 scores are reported on arbitrary parts of the dataset (Kucza et al., 2018).

5 Neural Language Model-based ATE

We introduce two possible architectures for ATE based on the multilingual language model XLM-R. For the experiments we use the base-size model version in form of the implementation made available by the transformers library (Wolf et al., 2019).

5.1 Sequence Classifier

As with the winning approach of TermEval 2020 (Hazem et al., 2020), our first architecture utilizes language models for binary sequence classification by using a fully connected layer to classify the representation of the special classification token `<s>`,

---

[2] This normalized version 1.4 is available at `https://github.com/AylaRT/ACTER`

which encoded by XLM-R carries information regarding the whole input sequence. Instead of using language specific models, however, we make use of the multilingual model XLM-R, which enables the use of a single model for all languages and has the ability to generalize to unseen languages.

The model receives pairs consisting of a term candidate and a context sentence in which the candidate appears as input as exemplified in Table 2. Term candidates are created by producing all possible n-grams of a given sentence. Due to performance reasons and the term length distribution in the dataset (mostly <5 words), n-grams were only created up to a length of 6 words. For instance, given the input sentence "We meta-analyzed mortality using random-effect models" a positive sample, i.e., one labeled as term, is "random-effect models. We meta-analyzed mortality using random-effect models", while a negative sample is "mortality using. We meta-analyzed mortality using random-effect models". For training the model, we undersample the negative samples so that their amount matches the amount of positive samples to compare to Hazem et al. (2020). For the evaluation on the validation and test set we use all possible n-grams for each input sentence, thus, creating a set of extracted terms which we can evaluate against the gold standard. The model was trained for 4 epochs with a batch size of 32 using the Adam optimizer with a learning rate of 2e-5.

5.2 Token Classifier

The second architecture we use for experimentation classifies each token of an input sentence separately, utilizing the same fully connected layer for all tokens after they have been processed by XLM-R. This leads to a significant reduction in training and inference time as each sentence has to be only processed once by XLM-R. This type of architecture is usually utilized in tasks like Named Entity Recognition (NER) (Devlin et al., 2019), where each word of a sequence needs to be classified.

The input provided to the model now simply consists of the sentences of the document which we want to process. The model then assigns each input token one of three possible output labels: "B-T" for the beginning of a term, "T" for the continuation of a term, and "n" in the case the token is not part of a term. For instance, the input sentence "We meta-analyzed mortality using random-effect models." would be labeled as 'n', 'B-T', 'B-T', 'n', 'B-T', 'T', 'n', with the last label annotating the punctuation at the end of the sentence.[3] Table 2 compares this input and output pattern with the other two methods. Since XLM-R's tokenizer is a SentencePiece tokenizer that splits the input into tokens on a subword level, the output labels obtained from the model are also subwords and have to be matched to the original words of the sentence afterwards. For training we used the Adam optimizer with a learning rate of 2e-5. Moreover, we used a batch size of 8 evaluating the model every 100 steps to be able to load the best model at the end.

6 NMT-based ATE

As a third experiment, we present a novel approach to ATE building on a recent sequence-to-sequence denoising auto-encoder model trained for NMT. We chose the recent and robust mBART model trained on the Common Crawl corpus in 25 languages (mBART25) (Liu et al., 2020) available in the Fairseq library (Ott et al., 2019).

6.1 Data Preprocessing for NMT-based ATE

Since we construct the downstream task of ATE as an MT task, we required parallel text data for supervised fine-tuning of mBART. We opted for a sentence-level approach, which specifically requires sentence-aligned parallel data. Sentence tokenization was performed with the Punkt tokenizer of NLTK and terms were inline annotated with the flashtext algorithm (Singh, 2017). For the ACLR2 dataset, individual sentences and the terms within were extracted with an XML parser. In order to distinguish single- and multi-word terms in the model's output sequence, a separator between terms or a unifying character between components of multi-word terms was required. Preliminary testing showed that using a semicolon surrounded by white-spaces (` ; `) as separator would achieve the same final F1 score as using more complex separators like a tag (for example `<term>`). Notably using an underscore (w_w) to connect the individual constituents of a term (w) lowered the score of the output significantly, that is, F1 performance of the best model was 5.3% lower on average across all test languages when compared to utilizing semicolons. Irrespective of the separator, the model would at times add or omit a white-space between separator and term, which had the effect that the

---

[3] The separation of "meta-analyzed" and "mortality" as distinct terms corresponds to the gold standard.

Model	Input Example	Output Example
Sequence Classifier	random-effect models. We meta-analyzed mortality using random-effect models	Term
Token Classifier	We meta-analyzed mortality using random-effect models	['n', 'B-T', 'B-T', 'n', 'B-T', 'T', 'n']
NMT	We meta-analyzed mortality using random-effect models	meta-analyzed ; mortality ; random-effects models

Table 2: Input and output examples for all three transformer-based models

term would not be considered in the evaluation. This was remedied in the process of extracting individual terms from the output sequence and the results reported in Section 7 are with unwanted white-spaces removed. Tokenization during training was performed with SentencePiece (Kudo and Richardson, 2018) and data was binarized with the *fairseq-preprocess* CLI tool.

6.2 NMT Model Fine-Tuning

The pretrained mBART model was fine-tuned with the preprocessed data described in Section 6.1. Input to the encoder model was a given sentence, such as “Codes of conduct forbid corruption, irrespective of its intended purpose.”, while the decoder would be shown the expected term labels, such as “codes of conduct ; corruption”. No language-specific tags were added to input or output, which is compared to the other methods in Table 2. For faster and more memory-efficient training we used automated mixed precision training of Fairseq with the Fused Adam Optimizer of the NVIDIA Apex PyTorch extensions.[4] We fine-tuned a separate model for each language of the dataset and a single model with all languages combined. Following the original publication of the pretrained model, each model was fine-tuned with 0.3 dropout, 0.2 label smoothing, 2500 warm-up steps and a learning rate of 3e-5. Furthermore, we opted for a dynamic batch size by limiting the maximum tokens per batch to 768, while updating the gradients every 4 steps (more details in Section 7.4).

While preliminary testing showed faster convergence and slightly higher final scores with higher tokens per batch, availability of the V100 GPU was not guaranteed and therefore training hyperparameters had to be adjusted to also run on an RTX2080Ti GPU, which limited the maximum tokens per GPU to 768. Model performance was evaluated every full epoch. Results were generated using the standard generation parameters of Fairseq.

7 Results

This section first presents the results on ACTER including an analysis per language (combination) and the results on ACLR2, then details the term length and type behavior of the models, and finally compares their training time efficiency. We additionally report on the validation performance of the best performing token classifier in Table 4, which shows some performance differences to the test domain, especially with French as training and validation language. For further comparability we also provide precision, recall and F1 scores at k top terms of 15 methods offered by the term extraction toolkit ATR4S, which implements a large range of existing ATE methods, in Appendix A.

7.1 Results on ACTER

To compare our results to the strongest participant of TermEval 2020, we report precision, recall and F1 scores in Table 3. These metrics are calculated on the basis of the available annotation in the original ACTER dataset, where we opted for the more comprehensive list of terms including named entities. All three models are evaluated on different combinations of training and test languages as shown in Table 3, where the heart failure domain is the hold-out test set as done for the SOTA baseline. The overall best results are marked in bold for each test language, while the best results of each model (if not bold) are highlighted in italics.

The overall best result for our approaches was an F1 score of 69.8%, which could be achieved by training the token classifier model on English and testing it on Dutch. With the exact same settings as the baseline (Hazem et al., 2020) that is based on RoBERTa (Liu et al., 2019) for English as training and test language, the token classifier

achieves an 11.6% higher F1 score and the NMT model an improvement of 6.5% on the F1 score. The sequence classifier struggles with precision and cannot outperform the baseline in this setting. Best performance for English as test language can be achieved by the token classifier trained on Dutch and by the NMT model trained on all languages.

When testing on French, the sequence classifier is on par with the F1 baseline (Hazem et al., 2020) building on CamemBERT (Martin et al., 2020), while the token classifier outperforms it by 9.5% and the NMT model obtains an additional 7.8%. Best performance on French as a test language is achieved by the token classifier when trained on English and by the NMT model when trained on all languages again. The baseline for Dutch is provided by a bidirectional LSTM with GLOVE.[5] With Dutch as a test language, the sequence and token classifier achieve their best result when trained on English, the NMT model when trained on Dutch.

A significant result is the substantial improvement of precision of the token classifier and NMT model over the baseline, even though the recall for English as test language lags behind. For French, the recall could be improved with the NMT model and matched by the token classifier when trained on English. Interestingly, the sequence classifier achieves a remarkable improvement on recall, however, lags behind on precision for all settings.

This can be explained by the fact that we perform undersampling of the negative samples to match the number of positive samples, a strategy adopted from Hazem et al. (2020) to obtain comparable results. If undersampling is reduced, the precision and recall scores are more balanced and closer to the performance of the token classifier, however, training time is considerably increased. Another reason for the higher number of extracted phrases by the sequence classifier compared to the other models is that it can extract multi-word terms as well as words which are part of these multi-word terms separately, since both are used as input in the form of potential term candidate n-grams.

All three models show remarkable zero-shot transfer learning capabilities, i.e., they are trained on one language and show strong test scores on another. This is especially true for the token classifier, where models trained on a single language often outperform those trained on all three languages. This transfer learning ability across languages can also be observed in the overall highest F1 scores

---

[5] No system description paper was submitted for this approach after participation in the challenge.

for the English test set, which was achieved by a model trained on Dutch, and for the French test set, which was achieved by a model trained on English.

7.2 Results on ACLR2

In addition to evaluating our models on the ACTER dataset, we compared the two best performing architectures, i.e., the token classifier and the NMT model, on the ACLR2 dataset. Both models achieve similar test scores as reported in Table 5 and higher than the scores achieved on the ACTER dataset. As with the ACTER dataset, we additionally report validation performance of the best performing token classifier model in Table 4, which is in line with the test performance.

Data	**Token Classifier**			**NMT**		
	Prec	Rec	F1	Prec	Rec	F1
An.1	74.4	77.2	75.8	73.2	77.2	75.2
An.2	80.1	79.3.	80.0	79.4	80.7	80.0

Table 5: Test set results of token classifier on data from Annotator 1 and 2 of the ACLR2 dataset.

7.3 Term-based Analysis

A qualitative analysis of the lists of false positives and false negatives based on the ACTER dataset demonstrated that all models handle acronyms well. This may be due to the text type in ACTER, which is partially based on scientific abstracts that frequently introduce acronyms in brackets. If acronyms are part of the term, e.g. "LV strain rate", there was a high number of false negatives in both models. Moreover, false negatives occurred in all models if a term included a proper name and an apostrophe, e.g. "Chaga's disease" or "Cronbach's α", or frequently if it included a figure, e.g. "p38alpha" or "6-min walk test". In addition, named entities that included version numbers or consisted of multiple words often resulted in false negatives, e.g. "Self-Care of Heart Failure Index Version 6.2", "Multicenter Automatic Defibrillator Implantation Trial-Cardiac Resynchronization Therapy". In the token classifier and NMT model, the class of named entities of cities, e.g. "New York" and "Seattle", were frequently not identified as terms. False negatives also occurred in all models if it was a particularly long multi-word term, e.g. "resynchronization reverses remodeling in systolic left ventricular dysfunction". A tendency by the token classifier to split longer terms could be observed, e.g. splitting adjectives and nouns.

To quantitatively evaluate how well the different model types handled terms of different lengths, we computed the F1 scores individually for terms of a specific length, based on the terms in the ACTER test set. The results in Table 6 were computed using the best model of each method, i.e., the model trained in English for the token and the sequence classifier and the model trained on all language for the NMT model. We can see that the scores of all models decrease with term length. Secondly, we observer that for English and Dutch the token classifier has the strongest results for all term lengths. However, for French the token classifier scores strongly decrease for multi-word terms, even though it is still the best model for unigrams. This is due to a very low recall, e.g. for 4-grams and higher the token classifier recalls only 7% of all French terms. The NMT model shows more consistency between languages, thus, performing strongest for French multi-word terms. As already the case with the overall scores the sequence classifier shows the highest recall values for both single-word and multi-word terms, however, lagging behind in precision, which leads to an overall lower F1 score.

Furthermore, based on the ACTER term type annotation (see Section 4), we could compare the types of terms extracted by the individual models. As can be seen in Fig. 1, the models all achieve a very similar distribution of extracted term types when compared to the gold test set distribution. We can observe, however, that the sequence classifier showed a slight tendency to extract more common and OOD terms and noticeably less NEs than the other models. All models tended to extract more specific terms, with the token classifier and the NMT model interestingly extracting comparatively few OOD terms.

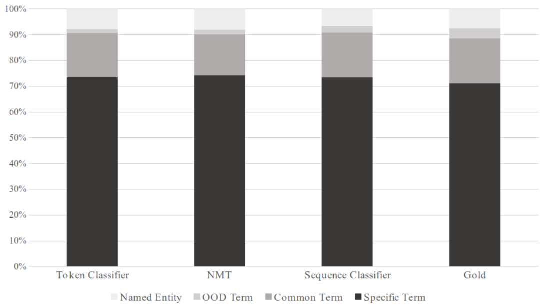

Figure 1: Distribution of term types across languages in the models' true positives and the ACTER gold test dataset.

Term Length	Sequence Classifier (F1)			Token Classifier (F1)			NMT (F1)		
	EN	FR	NL	EN	FR	NL	EN	FR	NL
Unigram	61.6	61.2	68.0	**63.3**	**69.1**	**73.8**	61.7	61.8	70.4
Bigram	38.0	41.0	39.8	**55.9**	43.0	**58.4**	52.2	**57.6**	56.3
Trigram	37.0	35.4	40.4	**55.4**	31.3	**49.1**	51.6	**52.4**	47.7
$\geq$ 4-gram	32.2	22.6	30.3	**44.3**	12.2	**42.9**	43.4	**33.4**	38.8

Table 6: F1 Scores based on different term lengths using the overall best model for each method on the ACTER dataset. In bold the best scores per row for each language.

7.4 Training Time Efficiency

Looking at the epochs required to reach the best score on the ACTER validation set, we can observe that in most cases the token classifier model requires not even a single training epoch. Training with the English dataset required 300 steps with a full epoch consisting of 432 steps. The model trained on French was the only model with its best performance being reached during the second epoch after 700 steps while a full epoch consists of 437 steps. The model trained on Dutch performed best after 400 steps while one epoch takes 553 steps. The multilingual model converged the quickest needing only 200 steps whereas a full epoch consists of 1,421 steps. The token classifier models trained on the ACLR2 dataset need more epochs and achieve their highest scores after 3 and 5 epochs respectively. However, due to the lower training set size of the ACLR2 corpus, this also corresponds to less than 500 steps, thus, being similar with the training times reported for the models trained on the ACTER data. In comparison, the sequence classifier achieved its best performances on the ACTER validation set after 4 epochs of training.

The NMT model also required several epochs to reach the best performance. Initially, all models were trained for 80 epochs, with the model having the lowest validation loss being loaded at the end. The models trained on monolingual data benefited from longer training compared to the models trained on the combined multilingual data. For completeness, we report the training epochs, label smoothed cross entropy loss, and log perplexity on the validation set for the best models. For the English dataset the reported score was achieved at epoch 49 with a loss of 5.82 and perplexity of 3.94. For the French dataset peak performance was reached at epoch 40, with a loss of 5.82 and perplexity of 3.78. Like the French model, the Dutch model achieved its best performance at epoch 40 having a loss of 5.69 and a perplexity of 3.37. When trained on one language, model performance was observed to drop for unseen languages when training beyond the best validation score. For instance, while the English model at epoch 49 obtained F1 scores of 53.2%, 54.4%, 55.4% for the English, French, and Dutch test data respectively, at epoch 80 these scores were at 53.6%, 50.6% and 52.1% respectively, gaining little for English and losing for unseen languages. Finally, for the multilingual dataset the model reached the reported peak performance already at epoch 22 as it trains on a lot more data per single epoch. Loss and perplexity were at 5.50 and 2.89 respectively. The training and validation times as well as the used GPUs are reported in Table 7. Training times denotes the full training time over all epochs without any validations. Validation time denotes the time for a single validation. The token classifier is the most efficient.

Model	Train Time	Val Time	GPU
Seq.	19	44	P100
Tok.	9	1	P100
NMT	49	2	V100

Table 7: Training/validation times in minutes on the English ACTER data and GPUs used.

8 Discussion

Although the ACLR2 dataset is smaller in size than the ACTER dataset, the resulting F1 scores are considerably higher. Apart from the fact that it only covers a single domain, ACLR2 already provides inline annotations and more consistent term annotations, which seems to facilitate learning the task. Inconsistencies in the ACTER annotations were mainly noted when analyzing false positives of the models. For instance, “patient” is considered a common term in the heart-failure domain, but “serum” is not annotated at all, although in our view it would also qualify as common term.

We also noted that more training data does not necessarily increase model performance. As indicated by the training times on the ACTER dataset, the token classifier achieved its best evaluation scores long before training for a whole epoch, i.e., having seen only a small fraction of the available data before reaching its strongest performance.

In this paper we compare the performance of a pretrained monolingual language model baseline with pretrained multilingual language models. Previous work indicates that monolingual language models like RoBERTa or CamemBERT outperform multilingual language models on tasks posed in a single language (Rönnqvist et al., 2019). The difference increases the higher the complexity of the given task but is negligible on simple tasks that mostly rely on syntactic features. Since in our case the multilingual model XLM-R in form of a sequence classifier performs very similar to the sequence classifier-based RoBERTa model winning TermEval 2020, it indicates that successful ATE does not require very strong language understanding but corresponds more to simpler tasks relying mostly on syntactic features. Nevertheless, the remarkable zero-shot transfer learning of the multilingual models fine-tuned on a single language would also suggest that the multilingual pretraining might aid the model in defining what a term is, as highly domain-specific terms might be similar between languages tested, e.g. rooted in Latin. In the NMT output analysis, we found that the knowledge transfer between languages could cause curious side-effects, where at times terms are predicted by the model in a semi-translated way. For instance, when training on English the model would at times invent “toxicity cardiaque ” for the French test set instead of extracting “toxicité cardiaque”.

Besides stronger performance, the NMT model as well as the token classifier have a higher potential to better handle the possible extension of the term extraction task to include discontinuous entities, which, however, are so far not annotated in the datasets we used. An example of a discontinuous entity can be found in the expression “left and right ventricular failure”, where “right ventricular failure” but also “left ventricular failure” are terms, the latter not being continuous in the original expression. While the NMT model does not require any special adaptations to deal with such an addition, the sequence classifier would have to consider many more n-gram combinations leading again to even higher training and inference times per sentence. To consider discontinuous entities with the token classifiers labels, the annotation and training process would have to be adapted to a multi-label token classification, e.g. the above phrase would be labeled as [B-T, n, n, T, T] and [n, n, B-T, T, T]. Since in the first label “ventricular” and “failure” are labeled as “T” they still clearly belong to the word “left” labeled as “B-T”, which could be considered in a post processing step.

9 Conclusion

In this paper, we adapt and evaluate three transformer-based models on the task of ATE, building on pretrained multilingual language and NMT models. In this evaluation, these multilingual models outperform a baseline of monolingual language models and show remarkable zero-shot abilities. A token classification strategy building on a language model achieved the best performance, however, the NMT-based model seemed to be able to handle multi-word expressions more consistently across languages and not lag far behind in performance. One aspect that became very clear is a prevalence for quality over quantity when fine-tuning pretrained models to the task of ATE.

Recently, both NMT and masked language models show a trend towards increased input sequence capacity. Thus, it would be interesting to evaluate the impact of context length on the proposed models by testing with more domain context than only single sentences. Furthermore, to test the ability of the token classifier and the NMT model to handle discontinuous terms, such as elliptical expressions, a dataset containing and annotating such terms would be interesting.

Impact Statement

Automatically extracting domain-specific terms across domains and languages with high accuracy provides a valuable means to reduce time and resource effort in creating terminological resources. Such resources are important to ensure terminological consistency in specialized communication, such as communication between different groups in times of crisis, and to avoid misunderstandings.

From a technological perspective, we introduce multilingual pretrained language models to the field of Automated Term Extraction (ATE) with detailed tests on three different transformer-based models across four domains and three languages. Since these models support considerably more languages than tested, the approach can be transferred to other languages. This transfer capability has been tested by training in a specific language and then testing models in another language. Transfer capabilities extend to domains, since we trained and validated on three domains and achieved results strongly outperforming previous approaches on a previously unseen test domain. Up to this point, such flexibility has been achieved by statistical approaches, however, with considerably lower results in precision and recall. In contrast to previous ATE methods performing on corpora, our models extract terms on sentence level. This makes ATE more flexible since neither large domain-specific nor reference corpora are required.

From a societal perspective, terminological inconsistencies are a major source of misunderstanding in the communication among experts, between experts and laypersons, and between laypersons in reference to a specialized domain. This issue can be mitigated by publishing agreed upon designations for real-world phenomena in a specialized domain that can be consulted for domain-specific communication. However, manually preparing a collection of natural language terms is extremely human resource- and time-intensive. We reduce this workload for governmental institutions, private and public organizations, and private persons by providing a method to automate the detection of such domain-specific terms in natural language texts across languages and domains.

In terms of risk, such a highly flexible solution to automated term extraction fully depends on the quality of the input text. Misleading, erroneous, or biased contents will inevitably be propagated to the resulting terminologies. Relying on terminologies extracted from such problematic contents can negatively impact specialized communication or conclusions drawn from it. Thus, it is of vital importance for any user of this approach to mitigate the uncertainty of the reliability of extracted terms by only considering high-quality and reliable sources in the term extraction process and have domain experts carefully review the outcome prior to utilizing it in communication. We cannot guarantee that in a real-life setting all important terms have been extracted and all extracted terms are indeed central to the domain at hand. Furthermore, training neural network models is a process known to leave an environmental footprint, which we try to mitigate by fine-tuning pretrained models. Fine-tuning is less resource- and time-intensive than training from scratch, but still requires high-performance computing clusters.

A Appendix

For further comparability, we provide results of 15 prior term extraction methods provided by the ATR4S toolkit (Astrakhantsev, 2018). All methods provided by ATR4S are re-ranking methods based on a previous term candidate extraction process.

Table A1 shows the results of ATR4S on the ACTER heart-failure domain in English. While some methods achieve good precision, most methods show precision scores below our best models, even at only 100 terms extracted. Increasing the manually specified amount of k terms to extract results in a decrease of precision in favor of recall. The scores of the different methods level out towards the maximum of 2,000 terms extracted. The best F1 score is achieved by the DomainPertinence method at 2,000 terms extracted with an F1 score of 30.32%.

Table A2 shows the results of ATR4S on our ACLR2 test splits. One major drawback of prior methods is the required corpus size. The small test set in ACLR2 does not provide enough data for many of the statistical approaches or in fact the reranking to be effective at all after a certain amount of terms extracted. For the smaller Annotator 1 test set, we can observe virtually identical scores between all methods from 300 extracted terms onwards. For Annotator 2, this phenomena can be observed at 400 extracted terms. Best overall results are an F1 score of 21.83% for Weirdness at 200 terms extracted on the Annotator 1 test set and and F1 Score of 18.28% for Weirdness, PU and DomainPertinence at 300 terms extracted on the Annotator 2 test set. In comparison, our best models achieve an F1 score of over 75% for both Annotators.

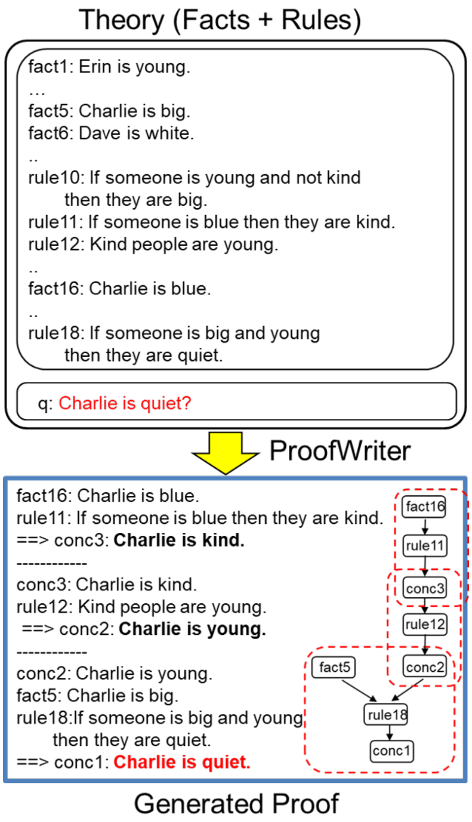
ProofWriter: Generating Implications, Proofs, and Abductive Statements over Natural Language

Oyvind Tafjord, Bhavana Dalvi Mishra, Peter Clark
Allen Institute for AI, Seattle, WA
{oyvindt,bhavanad,peterc}@allenai.org

Abstract

Transformers have been shown to emulate logical deduction over natural language theories (logical rules expressed in natural language), reliably assigning true/false labels to candidate implications. However, their ability to *generate* implications of a theory has not yet been demonstrated, and methods for reconstructing proofs of answers are imperfect. In this work we show that a generative model, called ProofWriter, can reliably generate both implications of a theory and the natural language proofs that support them. In particular, iterating a 1-step implication generator results in proofs that are highly reliable, and represent actual model decisions (rather than post-hoc rationalizations). On the RuleTaker dataset, the accuracy of ProofWriter's proofs exceed previous methods by +9% absolute, and in a way that generalizes to proof depths unseen in training and on out-of-domain problems. We also show that generative techniques can perform a type of abduction with high precision: Given a theory and an unprovable conclusion, identify a missing fact that allows the conclusion to be proved, along with a proof. These results significantly improve the viability of neural methods for systematically reasoning over natural language.[1]



fact1: Erin is young.

rule18: If someone is big and young then they are quiet.
==> conc1: **Charlie is quiet.**

Figure 1: Given facts, rules, and a question all expressed in natural language, ProofWriter answers the question and generates a proof of the answer.

1 Introduction

A fundamental goal for AI, dating back to its earliest years, is automated reasoning: the ability to draw valid conclusions from explicitly provided knowledge (McCarthy, 1959). However, approaches relying on expressing knowledge in a formal representation language have sometimes proved challenging (Musen and Van der Lei, 1988). Recent work on RuleTaker (Clark et al., 2020) demonstrated a modern approach to this goal, in which transformers emulate deductive reasoning over statements expressed in *natural language*, by reliably assigning true/false labels to candidate implications. However, simply assigning true/false labels is limiting. For practical purposes, systems should also generate proofs of those labels, so that their conclusions can be verified and a human-understandable rationale be produced.

Recent work on PRover, by Saha et al. (2020), provided first results towards this goal, assembling proofs by first classifying which facts, rules, and connections should be in the proof tree then using an Integer Linear Programming (ILP) module to enforce consistency constraints. However, the gen-

August 1–6, 2021.

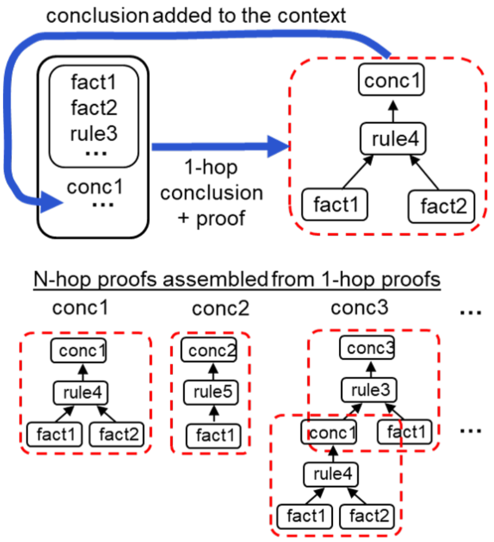

Figure 2: ProofWriter iteratively generates 1-step implications and their proofs, and adds implications back into into the context for deeper reasoning. The stepwise proof fragments are assembled into full proofs of N-hop conclusions.

erated proofs were imperfect, and there were no guarantees that the model "believed" the proofs that it was reciting, i.e., that its QA module would agree with the steps shown in the proof. In this paper, we adopt a different approach, based on generation rather than classification. Our system, ProofWriter, generates proofs such as that shown in Figure 1 by iteratively generating 1-hop inferences and their (simple) proofs, adding implications back into the context for deeper reasoning, and assembling more complex proofs from the 1-hop fragments (Figure 2). As the accuracy of 1-hop inference is highly reliable, the accuracy of deeper inference and their proofs is also high. This results in proofs that substantially exceed the earlier method's accuracy, and also reflect the model's internal decisions, rather than a post-hoc rationalization (i.e., is a "faithful" proof (Subramanian et al., 2020)).

The generative approach also affords two other new capabilities. First, ProofWriter generates implications that logically follow from a NL (natural language) theory, allowing enumeration of consequences (rather than only assigning truth values to pre-conjectured hypotheses). Second, we demonstrate (a constrained form of) abduction: Given a theory and an unprovable conclusion, identify a missing fact (if any) that allows the conclusion to be proved when added to the theory, plus its proof.

We evaluate our work on a collection of natural language reasoning datasets, including the RuleTaker datasets as well as several new variants. We achieve state-of-the-art results in proof generation, and strong new baselines for implication enumeration and abduction over natural language theories. Our contributions are thus:

1. A new method for proof generation for logical reasoning over natural language, that obtains state-of-the-art results and is faithful to the model's internal decisions.
2. A method and baseline results for *generating* logical implications of statements in NL.
3. A method and baseline results for performing abduction over natural language statements.
4. New datasets to promote further research.

These results significantly improve the viability of neural methods for formal reasoning over language.

2 Related Work

Our work builds on the RuleTaker line of research, in which transformers learn to emulate a deductive reasoning *algorithm* (Clark et al., 2020). Unlike other approaches to reasoning such as parsing to a formal language (Kamath and Das, 2019), implementing a reasoning algorithm with neural components (Weber et al., 2019; Rocktäschel and Riedel, 2017), or SAT solving (Selsam et al., 2019), these transformers emulate reasoning over language directly, bypassing a formal representation.

PRover (Saha et al., 2020), mentioned earlier, was the first system to also produce proofs in this context, although its post hoc approach meant that proofs did not necessarily represent the actual model decisions. Gontier et al. (2020) also explored the generation of answers and proofs, but in the context of rule *induction* with ($\approx$ 10) fixed rules to induce. In contrast, ProofWriter generates proofs from explicit NL rules (which may differ for each problem). Similarly, formal theorem proving has explored proving mathematical theorems from fixed, fundamental axioms, e.g., (Polu and Sutskever, 2020; Wang and Deng, 2020), while ProofWriter performs inference with differing sets of rules expressed in natural language.

Our work is also distinct from the large body of work on rationales and explanation. Work on rationales aims to identify sentences (or phrases) that caused a model to make a particular decision, but without an explanation of *why* that rationale led to the answer (the model's reasoning is opaque), e.g., (DeYoung et al., 2019; Narang et al., 2020). Similarly, work on explanations has sought to gen-

Proof (and Answer)	$CQ \rightarrow AP$	Given theory C and hypothesis fact Q, determine Q's truth A and proof P (if any)
Enumeration	$C \rightarrow I_1, ..., I_n$	Given C, generate all implications I_i that logically follow.
Abduction	$CQ \rightarrow f_m$	Given C and an unprovable fact Q, identify a new fact f_m that, when added to C, would make Q true.

Table 1: The three tasks that ProofWriter performs.

erate human-style justifications, which again are typically supporting evidence rather than a fully-formed line of reasoning, and without explicit reasoning rules (Camburu et al., 2018; Jhamtani and Clark, 2020; Inoue et al., 2020). In contrast, ProofWriter produces a deductive chain of reasoning from what is known to what is concluded, using a transformer retrained to reason systematically.

3 Approach

3.1 Definitions

Let:

- C be a *theory*, a set of English sentences C consisting of facts F and rules R, each expressing a logical fact or rule in English. (We also refer to C as the *context*).
- Q be a *question*, a hypothesis fact in English whose truth is to be determined based solely on the information in C.
- A be an *answer*, where $A \in \{True, False\}$ (if reasoning using a closed-world assumption) or $A \in \{True, False, Unknown\}$ (open-world assumption).
- P be a *proof*, described shortly.
- I be an *implication*, a fact that logically follows from C.

We define three tasks (also see Table 1):

1. **proof (inc. QA):** $CQ \rightarrow AP$: Given C and hypothesis fact Q, what is the truth A and proof P (if any) of Q?
2. **enumeration:** $C \rightarrow I_1, ..., I_n$: Which I_i follow from C?
3. **abduction**(restricted form) $CQ \rightarrow f_m$: Which extra fact f_m will make Q true given C?

We reuse (and add to) the RuleTaker datasets for our work, which include all five elements above. An example of a RuleTaker theory (facts and rules), a query, and a proof generated by ProofWriter are shown in Figure 1. Facts and rules are English statements, and implications are English statements that logically follow from those facts and rules. The original datasets were generated from synthetic logic programs and their implications, using natural language patterns to produce the English forms.

3.2 Semantics

Following prior work, we adopt the semantics of Datalog (Ceri et al., 1989): A fact is true if it is either known (i.e., explicitly stated in the context C), or (recursively) is the conclusion of a rule whose conditions are true (is "supported"). For handling negation, we use two alternative Datalog semantics: The first, following prior work, makes the closed-world assumption (CWA) and uses negation as failure (NAF), so that any fact not provable is assumed false. Under this semantics, negated facts and negative rule conclusions are not allowed (redundant under the CWA). The second makes an open-world assumption (OWA), and does allow negative facts and rule conclusions. Under this semantics, a third truth value *Unknown* is also possible.

3.3 Proof Representation

We define a proof P of a fact f_q as a directed acyclic graph (N, E) with nodes $n \in N$ and (directed, untyped) edges $e \in E$. Each node in P is either a fact f (a ground literal) or a rule r (a logical implication), expressed in English. Each edge in the proof either connects a fact to a rule, denoting that the fact helps satisfy the rule's condition, or connects a rule to a fact, denoting that the fact follows from the instantiated rule. Thus nodes in any branch of the proof will alternate between facts and rules. Note this definition differs from (and is richer than) that in PRover, where intermediate conclusions were not part of the proof.

Facts in the proof are one of three types: known facts $f_i \in F$, negated facts f_{naf} that cannot be proven (false under negation-as-failure (NAF)), and facts f_{conc} that are the conclusions of rules. f_i and f_{naf} are leaf nodes of the proof, while the f_{conc} are intermediate nodes within the proof. Note that f_{naf} and f_{conc} are by definition not in F. Example proofs are shown in Figures 1 and 3.

3.4 Proof Encoding

As we wish to generate proofs, we need to encode P as a linear structure that can be output by a generative model. Facts and rules in the context are explicitly labeled with identifiers (fact1, ..., rule1,

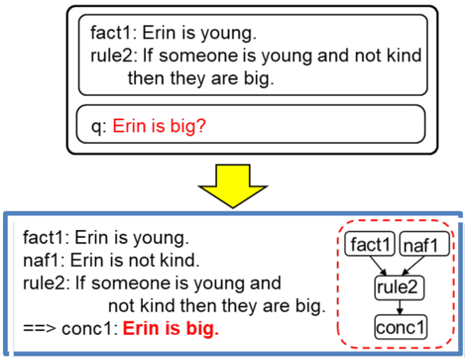

Figure 3: An example proof that includes a negated (negation-as-failure) fact.

...) that the proof can refer to, see Figures 1 and 3.[2] Then, in the linear proof, rule nodes are denoted by their identifier (rule1, ...), while fact nodes are denoted by three types of identifiers: fact1, fact2, ... for facts in the context; naf1, naf2, ... for facts *not* in the context and assumed false; and conc1, conc2, ... for facts concluded by rules. To decode the naf* and conc* identifiers (which by definition are not in the context), an additional sequence of the form "with conc1: *sentence1*. conc2: *sentence2*. ..." is appended to the proof.

To linearize the proof in a format convenient for a generative model, we conjoin rules and their conclusions using a "%" symbol, express conjunctive rule conditions with a "&" symbol, and use "#" to denote the inverse implication ("←"). We then express the tree using Polish notation. E.g., the proof tree "((fact1 & fact2) → rule1 → conc1)" (i.e., fact1 and fact2 satisfy rule1, concluding conc1) would be expressed "# rule1%conc1 & fact1 fact2". Thus the 3-step proof from Figure 1 is encoded:

> # rule18%conc1 & fact5 # rule12%conc2 # rule11%conc3 fact16 ; with conc1: Charlie is quiet. ; conc2: Charlie is young. ; conc3: Charlie is kind.

If the question is a known fact, the "depth 0 proof" is simply the fact itself (e.g., fact1). If no proof exists, the symbol "None" is used.

3.5 Models

The ProofWriter models are built on top of the text-to-text pretrained T5 transformer (Raffel et al., 2020) (T5-11B). We use different textual prompts for the different tasks. For the task of generating an answer and a proof, the input to the model is of the form: " \$question\$ = *question* ; \$context\$ = *theory-sentences*", for example: "\$question\$ = Erin is big. ; \$context\$ = sent1: Erin is young. sent2: If ..." The output is of the form: "\$answer\$ = *True/False/Unknown* ; \$proof\$ = *proof* ;", where *proof* is encoded as described in Section 3.4. For training instances where multiple outputs are valid, we select a single one at random (for multiple proofs, we select among the shortest proofs). Appendix D lists the hyperperameters and gives input/output examples for each task.

3.6 Task 1: Proof Generation

We evaluate two methods of proof generation:

All-At-Once: We train a model to generate the full proof and answer in one go (theory + question → answer + proof).

Iterative: We first train a model to generate a single 1-step implication (theory → implication + 1-step-proof), where the implication follows from a single rule application. Then at test time, we apply this model iteratively, adding each implication to the theory and repeating until no more implications can be found (i.e., exhaustive forward-chaining). The proof for any given implication can then be assembled from the 1-step-proof fragments (Figure 2).

3.6.1 All-At-Once ProofWriter ("All")

The All-At-Once model is trained directly on $CQ \rightarrow AP$ examples in the datasets (P = "None" if there is no proof of Q). Section 3.5 describes the i/o format, and Appendix D.1 shows an example.

3.6.2 Iterative ProofWriter ("Iter")

Training: To train the Iterative model, for each theory C in the training data, we create an augmented set of training examples with one sequence of iteratively inferred facts in turn, each using C plus the previously inferred facts. For example, if theory C_1 implies I_1, I_2, and I_3, then we create four training examples $C_1 \rightarrow I_1$, $C_1 \cup \{I_1\} \rightarrow I_2$, $C_1 \cup \{I_1, I_2\} \rightarrow I_3$, and $C_1 \cup \{I_1, I_2, I_3\} \rightarrow$ "None". The order of adding the I_i is random but constrained such that if a later implication depends on an earlier one, the earlier one must be inferred first. For example, if the proof of I_3 depends on I_2 (determined by inspecting the gold proofs), I_2 must be in the context before I_3 is inferred. This ensures that all example inferences are depth 1 (i.e., a single rule application). An example input/output for one step is shown in Appendix D.2.

---

[2] In practice we name these sent1, sent2, ... without a fact/rule distinction, but for expository purposes it is helpful to use different identifiers.

Testing: To answer and provide the proof for a particular question/implication, the model generates all implications and their proofs by iteratively applying the model until no more implications (the implication "None") is generated. It then looks for the question among them. If found, the answer is *True* with the proof given. The model also looks for the negation of the question[3] and its proof. If found, the answer is *False* with the proof given. Otherwise, there is no proof (proof = "None") and the answer is *False* (for positive questions, CWA), *True* (for negative questions, CWA), or *Unknown* (any question, OWA).

3.7 Task 2: Implication Enumeration

A second desirable reasoning skill is *enumerating* implications of a theory (rather than just assign *True/False* to a hypothesis). This capability is important for practical application of the technology. In fact, the Iterative ProofWriter already does this by design, a substantial advantage. To evaluate this (later), we compare this with an "all at once" strategy of generating *all* implications as a single output string, analogous to the All-At-Once strategy for generating the full proof as a single string. For training this All-At-Once enumerator, and testing both, we gather the list of *all* implications I_i of each theory C in the train/test data. Each train/test example is of then of the form: given C, predict all the I_i. An example input/output is in Appendix D.3.

3.8 Task 3: Abduction (Single Fact)

A third desirable reasoning skill is *abduction* over natural language theories, again made possible by generative models. Abduction has previously been studied extensively in formal logic, e.g., (Konolige, 1997), and in NLP, e.g., (Hobbs et al., 1993; Bhagavatula et al., 2020). Here we evaluate whether a generative approach can combine logic and NLP, performing logical abduction over natural language knowledge. We do this for a restricted form of abduction, namely single-fact abduction: Given a theory C and a possible implication Q not provable from C, identify a new fact f_m (other than the trivial Q itself) such that $C \cup \{f_m\}$ implies Q.

We restrict this task to the OWA (open-world) setting where questions can naturally have unknown truth values. To train and test an abductive model over our datasets, we create an abductive version as follows: For each theory C in the train/test data, for each unprovable fact Q, identify all alternative "missing facts" $factM$ that, when added to C, make Q True. To do this, recall that each NL theory was originally generated from a formal one C_{formal} in a formal representation language (Datalog). We first exhaustively enumerate all possible Q_{formal} and $factM_{formal}$ in the formal language (this is feasible as the space of predicates and individuals is small), then use a theorem prover to test if $C_{formal} \cup \{factM_{formal}\}$ implies Q_{formal} for all pairs $(factM_{formal}, Q_{formal})$. For each success, we generate the NL equivalents Q and $factM$ using simple NL generation templates. We then collect the alternative $factM$s for each Q. The abduction task is then, given C and Q, identify the set of all alternative $factM$s, i.e.:

$$C, Q \rightarrow factM_1, ..., factM_i$$

If there is no single $factM$ that can be added to make Q true, then the symbol "None" is output.

4 Datasets

We now evaluate ProofWriter on these three tasks. We use the original RuleTaker D* datasets (Clark et al., 2020), plus we create two new variants: The first (CWA) is similar to the original except it fixes some minor inconsistencies concerning negation (details in Appendix A.2). The second (OWA) is also similar to the original, except reasoning uses an open-world assumption.

We denote these as D*(orig), D*(CWA), and D*(OWA). Each example in each dataset contains a theory C, a question Q, the answer A (*True/False/Unknown*), and all possible proofs $P_1, ..., P_n$ for that answer (if provable).[4] Each theory is also accompanied with all possible proofs of all possible implications, as auxiliary annotations.

The D* datasets comprise five datasets, named **D0, D1, D2, D3, D5**, each containing 100k questions. In each dataset, theories and questions are expressed in templated English (e.g., Figure 1), questions can be positive or negated facts (e.g., "Charlie is not quiet?"), and answers are equally divided into *True/False* (and *Unknown*, for the OWA versions). Each dataset contains questions whose answers require reasoning up to depths D (D = 0, 1, 2, 3, 5). Thus, for example, all questions in D0

---

[3] To negate a question, a model can be trained for this straightforward task. Here, as our question language is simple, a simple regex to add/remove a "not" suffices.

[4] The domain is small enough that all proofs can be enumerated. However, there still can be a large number, e.g., some D5 questions have over 3000 possible proofs.

All	5270	86.5	85.5	97.0	80.5	84.5	97.0

Table 3: [Task 1: Proof Generation] Training on D5, test on Birds-Electricity. Both ProofWriter versions ("**All**" for All-At-Once, "**Iter**" for Iterative) outperform PRover overall in both answer and proof correctness. The Iterative model is also significantly more robust.

are lookup questions, requiring no inference. Each dataset is split 70/10/20 into train/dev/test.

To test generalization, we also use two other datasets from the original RuleTaker work:

Birds-Electricity: These 6 test-only datasets use small, real-world theories written by hand (one per dataset) to test out-of-distribution model performance. Details are in Appendix A.3.

ParaRules: This dataset contains 40k questions against 2k theories expressed in paraphrased natural language, obtained through crowdsourcing. This dataset tests transfer to more natural expressions of knowledge. Details are in Appendix A.4.

5 Experiments and Results

5.1 Task 1: Proof Generation (Comparison with Prior Work)

First, we compare ProofWriter's ability to generate proofs with PRover, the current state-of-the-art. We evaluate both answer accuracy and proof correctness. For proof correctness, for a fair comparison, we ignore the intermediate conclusion nodes (which PRover does not generate). We then use the same strict scoring metric as in PRover (called FA or Full Accuracy in the PRover paper): the proof graph must *exactly* match a gold proof (i.e., be perfectly correct); otherwise, the proof scores 0.

5.1.1 Generating Answers and Proofs

We use the same IID (independent, identically distributed) data used for PRover (train/test on dataset D5(orig)). The results are in Table 2, showing accuracies for questions requiring increasingly deeper depths of reasoning to answer. The ProofWriter's results are for the All-At-Once model. (The Iterative model scores are almost identical, see later Table 4.) While answer accuracy is almost perfect for both systems, ProofWriter generates **substantially more correct proofs** (last line, +9% absolute), and without the complexity of PRover's heuristic assembly of proof graphs using ILP.

5.1.2 Performance on OOD Rulesets

We compared ProofWriter's and PRover's ability to generalize to the hand-authored Birds-Electricity rulesets, zero shot. These rulesets are out-of-domain (OOD), as their English is not templated and is stylistically different to the training data. We compare the PRover and All-At-Once ("All") ProofWriter models trained on D5, plus the Iterative ProofWriter ("Iter") trained on D0-D3 theories. The models do not see any Birds-Electricity examples during training. The results in Table 3 show that ProofWriter's proof generation transfers well zero-shot to these hand-authored datasets, with 84.5% proof correctness for All-At-Once, and 97% for the Iterative ProofWriter, indicating better out-of-domain generalization for the Iterative version. Both ProofWriter models significantly outperform PRover (80.5%).

We also find ProofWriter obtains more correct proofs (+3%) than PRover on the ParaRules dataset. Details are in Appendix B.1.

5.2 Task 1: Proof Generation (All-At-Once vs. Iterative)

Second, we compare our two approaches to proof generation, All-At-Once vs. Iterative, in more detail. We show that although they have almost identical performance for proofs with depths seen in training, **the Iterative model generalizes better to proofs of longer depths** than seen in training. For these comparisons, we use the new D*(CWA) datasets (which fix some minor errors in D*(orig)), and also the D*(OWA) datasets to explore performance in an open-world setting.

	Answer				**Proof**			
	CWA		OWA		CWA		OWA	
Depth	All	Iter	All	Iter	All	Iter	All	Iter
N/A	99.0	99.7	99.4	99.9	99.0	99.7	99.4	99.9
0	100	100	100	100	100	100	100	100
1	99.9	99.8	100	99.3	99.6	95.4	99.7	97.8
2	99.9	99.5	99.9	99.7	98.3	91.7	98.6	97.3
3	100	99.7	100	99.2	95.8	90.4	96.9	97.1
4	100	99.7	99.9	99.1	93.1	88.9	94.8	96.5
5	99.9	98.9	100	98.8	89.3	87.8	91.4	86.4
All	99.6	99.7	99.7	99.6	97.2	95.4	98.0	97.6

Table 4: [Task 1] Comparison of All-At-Once ("**All**") vs. Iterative ("**Iter**") ProofWriter models, trained on D5 and D0-D3 respectively, and tested on D5.

5.2.1 Comparison (IID Test Set)

We train the All-At-Once model on D5 (train), and the Iterative model using the method described in Section 3.6.2, using the (∼ 5k) theories from D3 (train) plus ∼ 20% of the D0-D2 (train) theories.[5] We then test both models on D5 (test). We measure both answer and proof accuracies, and also break down the results by proof depth (using "N/A" as the proof depth for questions that are not provable). The D5 test set has 2k questions at each proof depth, plus 8k unprovable questions (proof = "None", depth = "N/A').[6]

The results are shown in Table 4, and show that **both ProofWriter versions have similar, high proof correctness (95%+)** on the test set, even though some proofs are highly complex.

5.2.2 Generalization to Unseen Depths

We also wish to see how well the models can generate proofs at depths unseen during training. To do this, we train an All-At-Once model on D3, and use the same Iterative model as earlier (trained on iterative examples from theories up to depth 3). We test on D5. As D5 contains problems at greater depths than those seen during training, we can observe the models' ability to generalize. We compare with both the CWA and OWA versions of our datasets.

The results are shown in Table 5. As can be seen, the All-At-Once model has quite poor generalization for generating longer proofs than seen in training, while **the Iterative model is more robust** (red box).

	Answer				**Proof**			
	CWA		OWA		CWA		OWA	
Depth	All	Iter	All	Iter	All	Iter	All	Iter
N/A	99.6	99.7	99.4	99.9	99.6	99.7	99.4	99.9
0	100	100	100	100	100	100	100	100
1	99.9	99.8	99.9	99.3	99.7	95.4	99.8	97.8
2	99.4	99.5	99.8	99.7	98.2	91.7	98.8	97.3
3	99.2	99.7	99.8	99.2	93.4	90.4	94.5	97.1
4	95.4	99.7	99.3	99.1	69.9	88.9	71.4	96.5
5	72.9	98.9	93.7	98.8	27.4	87.8	35.1	86.4
All	96.6	99.7	99.0	99.6	88.9	95.4	90.2	97.6

Table 5: [Task 1] Comparison of the All-At-Once vs. Iterative ProofWriter models, trained on D3 and tested on D5. While scores are mostly similar throughout, the iterative model generalizes substantially better to generate proofs of depths unseen during training (red box).

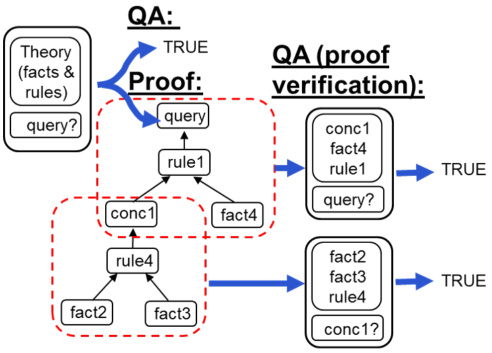

Figure 4: [Task 1] All-At-Once proofs can be verified by checking each step as a separate QA query.

5.3 Verifying All-At-Once Proofs

Proofs from the Iterative ProofWriter have an additional desirable property: each proof step is one that the model explicitly took during the iteration, i.e., the model "believes" the step. In contrast, the All-At-Once proofs are a post hoc generated string of symbols, and may not reflect steps that ProofWriter would actually make. However, because proofs include intermediate conclusions, we can alleviate this concern by *verifying* individual steps in the All-At-Once proofs. For example, if a generated proof step states that fact2 + fact3 + rule4 implies conc1, we can simply ask ProofWriter in QA mode if this is true (Figure 4). Given the almost perfect performance for such simple depth 1 questions in QA mode (with no distractor facts or rules), the ability to verify a correct proof corresponds to the accuracy of correctly generating the correct intermediate conclusions conc* in the first place. (Note that an unverified proof is not necessarily wrong, rather cannot be verified as right). OWA proofs can be fully verified in this way. For CWA theories with NAFs, the verification is only partial as NAFs are presumed negative statements

---

[5] We include D0-D2 theories to have more examples of theories with fewer conclusions. The derivative iterative training data is included in our dataset release.

[6] Note this breakdown is slightly different from the one in Table 2 where the depth used the original RuleTaker annotations which included a depth for questions without proofs, based on the deepest proof search that fails. We retained that convention in Table 2 for best comparison with PRover.

	Verified Proofs			
	CWA		OWA	
	Train on:		Train on:	
Depth	D3	D5	D3	D5
N/A	99.6	99.0	99.4	99.4
0	100	100	100	100
1	99.8	99.6	99.7	99.7
2	98.2	98.3	98.6	98.6
3	93.2	95.8	94.3	96.8
4	66.7	92.9	66.1	94.6
5	13.8	89.3	16.4	90.8
All	87.2	97.2	87.9	97.9

Table 6: [Task 1: Proof Generation] The All-At-Once model's ability to verify its proofs. For proofs within depths seen during training, almost all correct proofs (Tables 5 and 4, columns 5 and 7) can be verified. However, for proofs at unseen depths, the proportion that can be verified drops rapidly (trained on D3, test on depths 4,5). In contrast, Iterative ProofWriter's proofs are always verified, by definition of its algorithm.

which require the full theory to verify.

We measured the percentage of correct, verified proofs, shown in Table 6. Provided proofs are within the depths seen during training, almost all correct proofs can be verified. However, at depths deeper than seen at training, the proportion that can be verified drops rapidly. In contrast, the Iterative ProofWriter's proofs are always verified, as by definition they are assembled from single step inferences that the model actually took.

5.4 Task 2: Implication Enumeration

Third, we evaluate ProofWriter's performance on a new task, namely *enumerating* implications of a theory (rather than just assign *True/False* to a hypothesis). We compare the All-At-Once and Iterative strategies as described in Section 3.7.

To train All-At-Once, and test both, we created an enumerative dataset of $C \rightarrow \{I_1, ..., I_n\}$ examples (Section 3.7). For this we sample theories C in the D0-D3 datasets and gather the list of all implications I_i for each theory C. We call this enumerative dataset **D3+Enum**. We similarly create a **D5-Enum** dataset from theories in (only) D5 to test OOD conclusion generation. We create CWA and OWA versions of both.

We train All-At-Once on D3-Enum (train), then test both models on D3-Enum (test) and D5-Enum (test). For metrics, we measure F1 scores by comparing the individual predicted implications with the gold I_i, as well as the exact-match correctness of the predicted *set* of implications $\{I_1, ..., I_n\}$ (one point if the set *exactly* matches the gold, bar ordering, zero otherwise). The results are shown in Table 7, and show that the **Iterative ProofWriter is better at implication enumeration** than the simple All-At-Once strategy. In particular, the All-At-Once strategy struggles for problems at depths unseen in training (second row), although it does well on its own test set despite the complicated unordered output it has to generate (up to 16 different implications in D3, 21 in D5).

	F1				Accuracy			
Enum	CWA		OWA		CWA		OWA	
Test	All	Iter	All	Iter	All	Iter	All	Iter
D3+	98.9	99.8	99.4	99.6	92.5	98.8	95.5	99.0
D5	94.5	99.5	94.8	99.4	44.6	93.9	48.9	94.8

Table 7: [Task 2: Enumeration] Iterative ProofWriter is better at generating all implications than an All-At-Once strategy. (All-At-Once is trained on D3+Enum, Iterative ProofWriter is the same model as earlier.)

Test:	Count	F1	Acc
D3-Ab	7067	97.4	94.5
D5-Ab	7181	97.3	93.5

Table 8: [Task 3: Abduction] Given a theory C and an unprovable conclusion Q, predict all alternative facts that, when added to C, make Q provable.

5.5 Task 3: Abduction (Single Fact)

Fourth and finally, we evaluate performance on a second new task, namely *abduction* over natural language theories, again made possible by generative models. Analogous to implication enumeration, we create a derivative abductive dataset of $C, Q \rightarrow factM_1, ..., factM_i$ examples, where $C \cup \{factM_i\}$ results in Q becoming provable as described in Section 3.8. We create such D*-Ab datasets from the D*(OWA) datasets.

5.5.1 Results (IID)

We trained a model on D3-Ab (train), and then tested on both D3-Ab (test) and D5-Ab (test). We evaluate the results by comparing the predicted and gold $factM$s, measuring both F1 and "perfect match" Accuracy (1 when F1=1, 0 otherwise). The results are shown in Table 8, and indicate that the model performs well overall (85%+ scores). We also broke down the recall of $factM$s by proof depth required to prove Q given C and $factM$. This is shown in Table 9, indicating that it is harder to identify a $factM$ that completes a deeper proof. The similarity of D3-Ab and D5-Ab scores suggests that D5-Ab is not out-of-domain for this task: Although depths for *provable* D5 facts are deeper than D3, this task concerns *unprovable* facts, which may not be distributed differently to D3-Ab.

Gold Proof Depth	Test on D3-Ab		Test on D5-Ab	
	# Gold	Acc (recall)	# Gold	Acc (recall)
N/A	2155	97.73	2170	97.74
1	4813	98.46	4731	98.73
2	1719	96.22	1986	96.17
3	688	90.26	915	92.79
4	153	75.82	330	82.73
5	19	36.84	96	78.13

Table 9: [Task 3: Abduction] Recall of abduced facts by proof depth. The data suggests that it is harder to identify a $factM$ that completes a deeper proof.

5.5.2 Generalization to New Tasks

To assess out-of-domain generalization, we also evaluate how well the trained abductive model performs on an abductive version of the Birds-Electricity(OWA) theories, zero-shot (created using the same approach, Section 3.8). We find that ProofWriter has perfect zero-shot performance for the simple Birds rulebases, but progressively reduced performance for the Electricity theories as they get more complex (dropping to 64% F1, 62% Accuracy for one rulebase), indicating that the abductive task is only partly solved (Appendix B.2).

6 Discussion

6.1 All-At-Once vs. Iterative Strategies

While the All-At-Once approach to proof generation is simple, efficient, and effective, it does not generalize as well to proofs of greater depth than seen at training. In contrast, the Iterative approach is robust to generalization. Even though errors at each iteration accumulate, the reliability of 1-step inference is so high that such error accumulations remain small. The Iterative architecture, namely a simple model embedded in a recursive loop (rather than single seq2seq model), illustrates how transformers can be used in a "scale-invariant" way, i.e., performance is largely unchanged by the scale (here reasoning depth) of the problem. In addition, as proofs are built from actual inference steps taken by the model, they are by definition "faithful" to the model's inference steps, rather than being a post hoc rationalization.

However, there are also some drawbacks to the Iterative approach: First, it is inefficient and unguided, proving everything possible and only then looking for the answer and proof for a particular question. In fact, this is a limitation of unconstrained forward-chaining in general, hence established techniques for guiding forward-chaining could be applied, e.g., a best-first expansion strategy, or using a backward-chaining strategy instead (which would similarly need to be controlled). Second, as the theory grows by one fact per iteration, there is a risk of exceeding the transformer's input token limit (512 tokens by default), hence limiting the size of theories that can be handled. For larger theories, a retrieval mechanism might be needed to manage the facts and rules available to the reasoner.

6.2 Abduction and Implicit Knowledge

Recently, LeapOfThought (Talmor et al., 2020) showed that RuleTaker-like models could be retrained to reason with a combination of explicit and implicit knowledge, rather than requiring all rules to be stated explicitly (the implicit knowledge coming from the latent knowledge acquired during pretraining (Petroni et al., 2019)). Now, given an abductive capability such as the one we have presented, we have a mechanism for materializing the implicit knowledge used to answer a question, and hence generating the full proof of its answer: Given a LeapOfThought conclusion, first abduce the "missing" (implicit) fact(s) required for an explicit proof, then use ProofWriter to generate that proof. This is a significant step forward to help understand a model's decisions when both implicit and explicit knowledge has been used.

7 Summary and Conclusion

While it is remarkable that transformers can learn to systematically reason over language, such methods will have limited impact if they cannot also explain their answers. In this work, we showed the first application of generative techniques to this task, and demonstrated how proofs, implication enumerations, and abductive inferences can be generated, exceeding the prior state-of-the-art in proof generation by +9% (absolute). In addition, the Iterative ProofWriter robustly generalizes to deeper proofs and more varied language than seen in training, and produces proofs that reflect (i.e., are faithful to) the model's actual inference decisions. Finally, the abductive capability offers the potential for generating proofs when both explicit and implicit knowledge are used, by materializing the implicit knowledge needed to complete the proof. Together, these significantly improve the viability of neural methods for systematically reasoning over language in practical settings. The ProofWriter datasets are available at https://allenai.org/data/proofwriter

A Datasets: Additional Details

A.1 Statistics

Some overall statistics for the updated RuleTaker CWA and OWA datasets are in Table 10. The number of implications per theory can reach 20 and above, and the proof depths go up to 10, even though the proof depths of the associated questions are limited to the dataset depth (e.g., depth 3 for D3).

Dataset	# th	# qns	# impl min/mean/max	depth max
CWA:				
D0	27020	100002	0/1.0/18	8
D1	12965	100012	1/1.9/17	6
D2	9138	100014	2/3.3/18	5
D3	7067	100024	3/5.1/16	7
D5	4935	100030	5/9.8/21	10
Birds/Elec	140	5270	0/2.0/6	4
ParaRules	2403	40022	3/4.3/14	5
OWA:				
D0	26978	100000	0/0.8/18	5
D1	12933	100014	1/1.7/14	6
D2	9033	100010	2/3.1/14	5
D3	6940	100036	3/4.8/16	6
D5	4752	100030	5/9.1/21	10
Birds/Elec	140	5270	0/1.2/6	3
ParaRules	2403	40022	3/4.3/14	5

Table 10: Statistics for the CWA and OWA datasets, giving the number of theories, questions and implications per theory. Note that the maximum implication proof depth can go higher than the maximum proof depth for the included questions (e.g., for D5 the maximum questions depth is 5, but there are implications up to depth 10 which are include in the enumeration task).

Table 11 describes overall statistics for the datasets for Task 3: Abduction. Each abduction question can have zero or more missing facts as answer, and the proof depths can go up to 11.

Dataset	# th	# qns	# missing facts min/mean/max	max proof depth
D0-Ab	18011	85705	0/0.8/15	6
D1-Ab	10448	49808	0/0.8/12	7
D2-Ab	7092	37245	0/0.9/11	6
D3-Ab	5633	34915	0/1.1/11	8
D5-Ab	4362	35213	0/1.2/9	11
Birds-Electricity-Ab	140	3940	0/0.24/4	4

Table 11: Statistics for the Abduction datasets, giving the number of theories, abduction questions, number of missing facts per question and maximum proof depth.

A.2 Repairs to the RuleTaker Datasets

The original RuleTaker theories were intended to be full Datalog theories, but contained three occasional violations in the with-negation theories:

1. Some theories contained negated facts (e.g., "Bob is not red") and/or rules with negated conclusions. Such statements are redundant under a CWA, and not allowed according to formal Datalog specifications.
2. Some theories included rules with a free variable in a negated condition (e.g., "If someone is not blue then Bob is happy."). Such rules are not allowed according to formal Datalog specifications, as the possible groundings of the variable require meta-information about the theory as a whole.
3. A bug in the stratification checker led to a few theories being included that were not stratifiable, and hence may have multiple, valid truth assignments for their facts.

As a result, the theories were regenerated (with the same distribution over number of facts, rules, condition, etc.) to create the D*(CWA) datasets, avoiding these issues.

The D*(OWA) datasets are similar to the D*(orig) datasets, but evaluated without a CWA, i.e., negation-as-failure (NAF) is replaced with hard negation. The theories with negation were again regenerated to ensure they were stratifiable (to avoid negation cycles), but they still retain negated facts and rule conclusions. The truth values of the questions were recomputed using an OWA, resulting in answers *True/False/Unknown*.

A.3 The Birds-Electricity Datasets

The RuleTaker "birds" rulebase is a well-known logic problem illustrating the use of "abnormality" predicates (McCarthy, 1984),[7], and converted into English by hand. The dataset contains a single theory of six rules (e.g., "If someone is a bird and wounded then they are abnormal.") and seven facts (e.g., "Bill is wounded"), and forty questions against this theory (i.e., 40 test examples total). Birds1 and Birds2 differ solely in the English wording (e.g., "Bill is flying" vs. "Bill can fly").

		Answer		**Proof**	
	# qns	PRover	ProofWriter	PRover	ProofWriter
D=0	2968	99.7	99.9	99.4	99.9
1	2406	98.6	99.3	97.3	99.3
2	1443	98.2	98.3	88.7	97.7
3	1036	96.5	98.2	89.9	96.5
4	142	88.0	91.5	76.1	83.1
All	8008	98.4	99.1	95.1	98.5

Table 12: [Task 1: Proof Generation] Train on D3 + ParaRules, test on (only) ParaRules. Both systems demonstrate robustness to more complex linguistic expressions in the theories, with ProofWriter obtaining 3% higher proof correctness.

The four RuleTaker "electricity" datasets contain examples of reasoning about toy electrical cicuits using a small set of general rules about circuits. Examples in each dataset are built using a fixed set of general rules per dataset, ranging from five rules (Elec1) to twelve rules (Elec4). Each example in these datasets contains the general rules, plus between two and five facts describing a particular circuit, with a set of questions about the circuit, e.g., Q: "The light bulb is glowing?" A: *True*.

A.4 The ParaRules Dataset

The RuleTaker "ParaRules" dataset contains 40k questions against 2k theories expressed in paraphrased natural language, obtained by having crowdworkers rephrase the templated English facts and rules from sampled original theories into more varied natural language. For example, "Bob is cold." might be rephrased "In the snow sits Bob, crying from being cold"; or "Alan is round. Alan is blue. Alan is kind." might be rephrased "Alan, who is round and also kind, tends to be rather blue"; or "If someone is kind then they are young." might be rephrased "A kind person will certainly be young.". While the previous datasets contain synthetic language, ParaRules tests the models' ability to reason over more human-like paraphrased language.

B Additional Results

B.1 Results on the OOD ParaRules Dataset

We also test the robustness of ProofWriter's proof generation to theories that use more varied natural language, summarized in Section 5.1.2. Following (Clark et al., 2020) and (Saha et al., 2020), we train on the combined training partitions of D3(orig) and ParaRules, then test on the ParaRules test partition. The results in Table 12 show that PRover and ProofWriter (All-At-Once) are robust to more complex natural language in the input, with ProofWriter obtaining 3% higher proof correctness.

Test Dataset:	**# qns**	**F1**	**Acc**
Birds1-Ab	14	100.00	100.00
Birds2-Ab	14	100.00	100.00
Elec1-Ab	114	89.47	89.47
Elec2-Ab	126	90.25	88.89
Elec3-Ab	456	81.79	76.32

All	3940	85.66	83.53

Table 13: [Task 3: Abduction] Zero-shot scores of the D3-Ab model on the Birds-Electricity-Ab rulebases.

B.2 Abduction: Generalization to New Tasks

Section 5.5.2 summarized the results of testing abductive reasoning on abductive versions of the Birds-Electricity(OWA) theories. The detailed results are shown in Table 13, showing perfect zero-shot performance for the simple Birds rulebases, but progressively reduced performance for the Electricity theories as they get more complex. This indicates that the abductive task remains only partially solved by our generative model.

C Results with T5-large

In the main part of the paper we trained ProofWriter starting from the largest available T5-11B model (11 billion parameters). If we instead use the more manageable T5-large model (770 million parameters), the scores generally go down, but typically by a small amount.

In Tables 14 and 15 we show two examples of this, for the All-At-Once and Iterative ProofWriter models respectively, when training on the D3 dataset and evaluating on D5. We see the T5-large model is a bit worse on higher depth proof accuracy in the All-At-Once model, but is otherwise quite competitive.

D Hyperparameters and I/O Examples

We fine-tune the models on the training set using the default hyperparameters (including the Adafactor optimizer) in the T5 library.[8] We use the largest T5-11B model for the main results, fine-tuned for 40k steps (batch size 8), selecting the checkpoint with highest validation score (usually the final step). See Appendix C for results using the smaller T5-large.

Table 15: [Task 1] Comparing T5-large vs T5-11B for the Iterative ProofWriter trained on D0-D3 and evaluated on D5. T5-11B is systematically slightly better.

For all tasks in this paper, the model input and output are plain textual strings in a certain format. The format is slightly more verbose than strictly necessary, as it is compatible with a more general framework combining different views of the task. This is not typically an issue, although there are a few cases where the iterative model reaches the default 512 token limit of T5 when adding implications to the theory. We now show input/output examples for proof generation (All-At-Once and (one step of) the Iterative approaches), implication generation (All-At-Once approach; Iterative implication generation is a side-effect of Iterative proof generation), and abduction.

D.1 All-At-Once Proof Generation

In this task we are given a theory and question, and need to produce an answer (True/False/Unknown) and proof with intermediates.

INPUT: $answer$; $proof$; $question$ = The lion is not nice? ; $context$ = sent1: The tiger chases the lion. sent2: The lion is not big. sent3: If something visits the dog and it is kind then it visits the mouse. sent4: The dog chases the lion. sent5: If something is big then it visits the dog. sent6: The tiger eats the dog. sent7: If something visits the tiger and the tiger is not red then it is not nice. sent8: If something chases the dog then it is not red. sent9: The mouse does not chase the tiger. sent10: If something visits the mouse then the mouse is red. sent11: The tiger visits the lion. sent12: The tiger does not eat the mouse. sent13: The mouse is nice. sent14: The lion does not eat the tiger. sent15: If the tiger visits the dog and the dog is not big then the dog chases the mouse. sent16: The lion visits the tiger. sent17: If something chases the lion and it visits the dog then it chases the dog. sent18: The dog is nice. sent19: If something chases the lion then it is big. sent20: If something eats the lion then it is not cold.
OUTPUT: $answer$ = True ; $proof$ = # sent7@int1 & sent16 # sent8@int2 # sent17@int3 & sent1 # sent5@int4 # sent19@int5 sent1 ; with int1: The lion is not nice. ; int2: The tiger is not red. ; int3: The tiger chases the dog. ; int4: The tiger visits the dog. ; int5: The tiger is big.

If we translate back from Polish Notation, this proof corresponds to ((sent16 & ((((sent1 & ((sent1 → sent19 → int5) → sent5 → int4)) → sent17 → int3)) → sent8 → int2)) → sent7 → int1)

D.2 Iterative Proof Generation (one step)

In this task we ask the model to generate one valid implication of the theory with proof of depth 1. If no such implication exists, instead generate ”None” as the answer.

INPUT: $answer$; $proof$; $question$ = What is one single-hop inference? ; $context$ = sent1: If something eats the cow and it is big then the cow sees the bald eagle. sent2: If something likes the bald eagle then it is rough. sent3: If something eats the dog then it likes the cow. sent4: Big things are young. sent5: If something likes the cow then it eats the cow. sent6: If something sees the bald eagle then the bald eagle eats the cow. sent7: If something likes the bald eagle then the bald eagle is kind. sent8: If something sees the bald eagle then the bald eagle eats the dog. sent9: The bald eagle eats the cow. sent10: The bald eagle sees the dog. sent11: The dog is big. sent12: The cow likes the bald eagle. sent13: The bald eagle is young. sent14: The dog sees the cow. sent15: The bald eagle is kind. sent16: The dog is young. sent17: The bald eagle sees the cow. sent18: The bald eagle is rough. sent19: The cow eats the bald eagle. sent20: The dog is cold. sent21: The dog likes the cow. sent22: The dog eats the bald eagle. sent23: The dog eats the cow. sent24: The bald eagle likes the dog. sent25: The bald eagle likes the cow. sent26: The cow sees the bald eagle. sent27: The cow sees the dog.
OUTPUT: $answer$ = The cow is rough. ; $proof$ = # sent2 sent12

During evaluation time, we would then take this output and append it to the theory as ”sent28: The cow is rough.” and repeat the question. If a subsequent proof then references ”sent28”, we know already that this was derived using the proof ”# sent2 sent12”.

D.3 All-At-Once Implication Enumeration

In this task we ask the model to simply output all valid implications of a theory, without generations proofs in this case.

INPUT: \$answer\$; \$proof\$; \$question\$ = What are all the inferences? ; \$context\$ = sent1: The tiger chases the lion. sent2: The lion is not big. sent3: If something visits the dog and it is kind then it visits the mouse. sent4: The dog chases the lion. sent5: If something is big then it visits the dog. sent6: The tiger eats the dog. sent7: If something visits the tiger and the tiger is not red then it is not nice. sent8: If something chases the dog then it is not red. sent9: The mouse does not chase the tiger. sent10: If something visits the mouse then the mouse is red. sent11: The tiger visits the lion. sent12: The tiger does not eat the mouse. sent13: The mouse is nice. sent14: The lion does not eat the tiger. sent15: If the tiger visits the dog and the dog is not big then the dog chases the mouse. sent16: The lion visits the tiger. sent17: If something chases the lion and it visits the dog then it chases the dog. sent18: The dog is nice. sent19: If something chases the lion then it is big. sent20: If something eats the lion then it is not cold.
OUTPUT: \$answer\$ = The dog is big. The tiger is big. The dog visits the dog. The tiger visits the dog. The dog chases the dog. The tiger chases the dog. The dog is not red. The tiger is not red. The lion is not nice.

This particular theory has 9 valid implications, around average for D5 theories. (The number of implications can be as high as 21).

D.4 Iterative Implication Enumeration

Iterative implication generation is a side-effect of Iterative proof generation, hence the input/output (one step) is the same as in Appendix D.2.

D.5 Abduction

In this task we ask the model to output all alternative missing facts, separated by a comma, that can be (separately) added to a theory so as to prove the given implication to be True.

INPUT: \$answer\$; \$question\$ = Dave is rough. ; \$context\$ = triple1: Anne is white. triple2: Charlie is young. triple3: Dave is round. triple4: Erin is quiet. rule1: If someone is rough and young then they are blue. rule2: Rough, white people are smart. rule3: All smart people are rough. rule4: All white people are smart. rule5: If someone is young then they are smart. rule6: All smart people are rough.
OUTPUT: \$answer\$ = Dave is young. , Dave is smart.

This particular abduction question has 2 alternative missing facts. Any one of them when added to the input theory is sufficient to prove the implication 'Dave is rough'.

Probing Image–Language Transformers for Verb Understanding

Lisa Anne Hendricks Aida Nematzadeh
DeepMind
`{lmh, nematzadeh} @google.com`

Abstract

Multimodal image–language transformers have achieved impressive results on a variety of tasks that rely on fine-tuning (*e.g.*, visual question answering and image retrieval). We are interested in shedding light on the quality of their pretrained representations – in particular, if these models can distinguish different types of verbs or if they rely solely on nouns in a given sentence. To do so, we collect a dataset of image–sentence pairs (in English) consisting of 421 verbs that are either visual or commonly found in the pretraining data (*i.e.*, the Conceptual Captions dataset). We use this dataset to evaluate pretrained image–language transformers and find that they fail more in situations that require verb understanding compared to other parts of speech. We also investigate what category of verbs are particularly challenging.

1 Evaluating Verb Understanding

The success of image–language models in real-world applications relies on their ability to relate different aspects of language (such as verbs or objects) to images, which we refer to as multimodal understanding. For example, an image-retrieval model needs to distinguish between "eating an apple" and "cutting an apple" and a captioning model must accurately describe the actions in a scene.

Previous work shows that image–language benchmarks do not always fully measure such multimodal understanding: object retrieval models fail to account for linguistic structure (Akula et al., 2020), visual question answering (VQA) models overly rely on language priors (Goyal et al., 2017; Agrawal et al., 2018), and captioning metrics do not always measure if captions "hallucinate" objects in an image (Rohrbach et al., 2018). Inspired by this, prior work introduced tasks to specifically examine whether models can relate objects to images (Shekhar et al., 2017) or classify frequent interactions associated with objects (Chao et al., 2015). However, both these datasets are limited to the 80 objects in the MSCOCO detection challenge (Lin et al., 2014).

To address this gap, we design a benchmark focused on verbs called SVO-Probes for examining **s**ubject, **v**erb, **o**bject triplets; more specifically, we collect a set of image–sentence pairs (in English) where each pair is annotated with whether the sentence corresponds to the image or not. As shown in Fig. 1, for a given sentence, in addition to a *positive* image that matches the sentence, our dataset includes controlled *negative* images that do not correspond to specific aspects of the sentence (*i.e.*, subject, verb, and object). These controlled examples enable us to probe models for their understanding of verbs as well as subjects and objects. Our dataset consists of 421 verbs and includes over $48,000$ image–sentence pairs.

We use our benchmark to evaluate the recent family of multimodal (image–language) transformers that have shown impressive results on benchmarks like VQA and image retrieval (Lu et al., 2019; Chen et al., 2020; Tan and Bansal, 2019; Li et al., 2020b,a; Huang et al., 2020). Our goal is to investigate if the good performance of these models is due to learned representations that successfully relate different aspects of language to images. More specifically, we evaluate a few architectural variations of these models in a zero-shot way by using the pretrained models to classify if image–sentence pairs from SVO-Probes match.

Our results show that the performance of all evaluated models is worst on verbs, with subjects being easier than verbs but harder than objects. We find that this observation does not depend on the frequency of test examples in pretraining data. Moreover, it is considerably harder for all models to correctly classify image–sentence pairs that do not

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3635–3644
August 1–6, 2021.

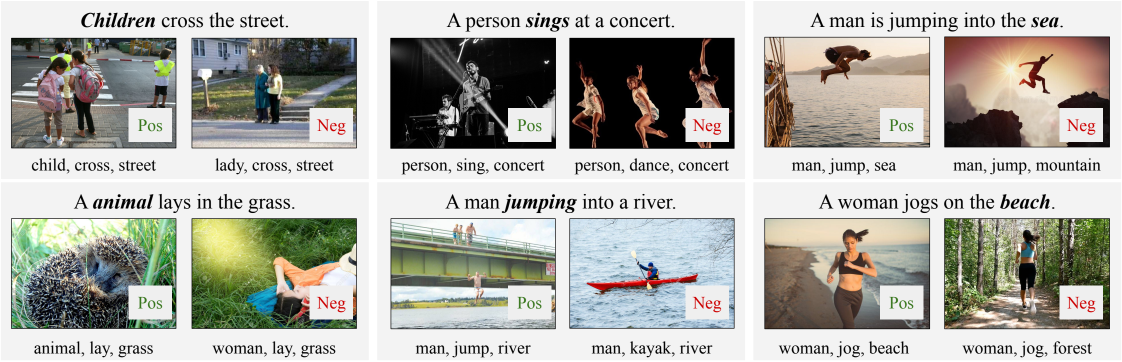

Figure 1: Examples from SVO-Probes. Images on the left and right show positive and negative image examples for each sentence. Below each image is the ⟨subject, verb, object⟩ triplet corresponding to the image.

match; the image–language transformers overpredict that sentences corresponds to images.

Additionally, we compare an image–language transformer pretrained on a large automatically-curated dataset (*i.e.*, Conceptual Captions, Sharma et al., 2018) with one pretrained on the smaller but manually-annotated MSCOCO (Chen et al., 2015). Conceptual Captions is more noisy than MSCOCO in that its sentences do not necessarily correspond to its images. Interestingly, we observe that the model pretrained on MSCOCO performs better. This result shows that the image–language transformers are not robust to dataset noise as they learn to predict that somewhat-related image–sentence pairs correspond to each other.

Despite their good performance on downstream tasks, image–language transformers fail on our task that requires multimodal understanding since they cannot distinguish between finer-grained differences between images. Our results highlight that there is still considerable progress to be made when training multimodal representations, and that verbs in particular are an interesting challenge in image–language representation learning.

2 Related Work

Image–language transformers build on the transformer architecture (Vaswani et al., 2017) by incorporating additional loss functions (to learn image features and align image and language modalities), using self-attention to combine modalities, and training on paired image–text data (Lu et al., 2019; Chen et al., 2020; Tan and Bansal, 2019; Li et al., 2020b,a; Huang et al., 2020). The impressive performance of these models on many image–language benchmarks has inspired recent work that studies different architectural choices made in these models (Cao et al., 2020; Hendricks et al., 2021).

Compared to previous image–language models, multimodal transformers both use a new architecture and are frequently trained on a much larger dataset – the Conceptual Captions dataset consisting of $3m$ image–text pairs (Sharma et al., 2018). Singh et al. (2020) show that on fine-tuned tasks, the performance of multimodal transformers (*i.e.*, Lu et al., 2019; Li et al., 2019) are less sensitive to dataset size; the domain match between pretraining and fine-tuning datasets is more important.

Datasets. Our proposed dataset is most similar to the FOIL benchmark (Shekhar et al., 2017) which tests if image–language models can differentiate between sentences that vary with respect to only one noun. FOIL consists of $64,300$ images from MSCOCO (Chen et al., 2015); each image is paired with a corresponding sentence that describes the image (*i.e.*, a *positive* example) and one that does not (*i.e.*, a *negative* example). Negative sentences are collected by replacing object words in the positive sentences with a similar object (*e.g.*, changing the word “dog” to “cat” in “The dog ran.”). Shekhar et al. (2017) use the FOIL dataset in a few tasks including a classification task where the model is asked to classify if a sentence matches the image or not. We use the same task setup because it allows us to probe image–language transformers in a zero-shot setting as these models are generally trained to classify whether an image–text pair match. Our work is different than FOIL in that we focus on verb understanding as opposed to noun understanding; moreover, our dataset provides different negative types (by replacing subjects, verbs, or objects).

Other datasets focus on relationship or interaction detection (*e.g.*, HICO and VRD; Chao et al., 2015; Lu et al., 2016a). These datasets are evalu-

dataset	Ims	Subjs	Verbs	Objs	Sents	Negs
FOIL	32k	n/a	0	70	✓	✓
HICO	10k	n/a	117	80	✗	✓
VRD	1k	100	70	100	✗	✗
V-COCO	5k	n/a	26	48	✗	✗
ImSitu	25k	950	504	1840	✗	✗
SVO-Probes	14k	100	421	275	✓	✓

Table 1: **Im**ages, **Subj**ects, Verbs, **Obj**ects, **Sent**ences, and **Neg**atives in other datasets and SVO-Probes. Image numbers are for the *evaluation* set.

ated in a classification setting in which the input is an image and the output is a detected relationship (for HICO, an object and interaction, for VRD two objects and their relationship) and have a limited number of verbs and objects. V-COCO (Gupta and Malik, 2015) and ImSitu (Yatskar et al., 2016) both includes verbs but do not provide negatives for a controlled evaluation of verb (or noun) understanding. Finally, other work has explored how creating hard negatives (*e.g.*, by substituting words in train examples) leads to better test performance (Gupta et al., 2020; Hendricks et al., 2018; Faghri et al., 2017). In contrast, our work focuses on creating hard evaluation examples to probe learned representations.

In summary, SVO-Probes is unique as it tests understanding of a broad range of verbs as well as subjects and objects in a controlled way. Furthermore, our dataset includes image–sentence pairs; thus, it can be used to evaluate image–language transformers that process image–sentence pairs. Finally, SVO-Probes is designed as a zero-shot task to evaluate pretrained image–language transformers and is collected to have a similar distribution to Conceptual Captions which is commonly used in pretraining these models. See Table 1 for a comparison between SVO-Probes and other datasets.

3 Task Setup and Dataset Collection

Our goal is to examine *verb-understanding* in *pretrained* multimodal transformers. To do so, we need a task that requires an understanding of a given verb in a sentence, *e.g.*, a model cannot succeed at the task by relying on nouns. We also need to include a diverse set of verbs, and examine each verb in at least a few situations. To test the pretrained representations, we need to examine the models in a zero-shot setting (without fine-tuning).

Inspired by the FOIL setup (Shekhar et al., 2017), we use a zero-shot classification task where a model is asked to identify if a sentence and an image correspond to each other. As a result, we need a dataset that provides "match" or "not match" labels between images and sentences. We collect a dataset of image–sentence pairs (SVO-Probes) that given a sentence, provides such labels for at least two images.[1] Some of these images are *positive* examples, *i.e.*, the sentence correctly describes them. Others are *negative* examples where some aspect of the sentence (*e.g.*, verb) does not match the image. Figure 1 shows some examples from our dataset.

We systematically collect negative examples such that they only differ from the positive image with respect to the subject, verb, or object of the sentence. Finally, we consider sentences whose subjects, verbs, and objects are frequent in the Conceptual Captions (CC) training dataset. Since CC is the dataset most frequently used for pretraining multimodal transformers, we can examine what the pretrained representations capture (in contrast to examining these models' generalization ability). We next describe our pipeline to create SVO-Probes.

Creating a verb list. To ensure that we have a large number of verbs in our dataset, we first created a verb list by considering a subset of verbs that occur in the train split of the Conceptual Captions dataset (CC-train). More specifically, we consider verbs that are visually recognizable in the images; to identify the visual verbs, we use the *imSitu* dataset (Yatskar et al., 2016) that includes verbs that annotators marked as reliably recognizable. Moreover, we include verbs that occur at least 50 times in CC-train.

Curating triplets. Given a positive example, we need to systematically generate negatives by replacing the subject, verb, or the object. As a result, we collect a set of ⟨subject, verb, object⟩ (SVO) triplets from CC-train sentences for our verbs. We extract the subject, verb, and direct object from the dependency parse trees. and remove triplets where subjects or objects are pronouns or have less than two characters. Finally, we discard SVO triplets with frequency smaller than five.

We consider three negative types for a given triplet: a subject-, verb-, or object-negative where respectively, the subject, verb, or object in the triplet are replaced by a different word. For example, given the triplet ⟨girl, lie, grass⟩, examples of subject-negative, verb-negative, and object-

---

[1] We note that our dataset is limited to English sentences; we simply use "sentences" to refer to English sentences.

negative are ⟨puppy, lie, grass⟩, ⟨girl, sit, grass⟩, and ⟨girl, lie, beach⟩.

Since our goal is to examine verb understanding, we only keep the triplets that have at least one verb negative. This enables us to evaluate a model's capacity in distinguishing images that mainly differ with respect to the verb; for example, ⟨girl, lie, grass⟩ vs. ⟨girl, sit, grass⟩. Adding this constraint results in 11230 SVO triplets and 421 verbs. In this set, 1840 SVO triplets (and 53 verbs) have at least two verb and object negatives.

Collecting images. The next step is collecting images that match the curated SVO triplets. We query for SVO triplets using the Google Image Search API. We retrieve 5 images for each triplet, then remove any images with urls in Conceptual Captions. To make sure that these automatically-retrieved images certainly match the triplets, we set up an annotation task where we ask workers on Amazon Mechanical Turk (AMT) to verify if the subject, verb, and object are present in the image. We ask three people to annotate each image, and only keep images where at least two annotators agree that the subject, verb, and object are depicted in the image. Moreover, we discard images marked as a cartoon by annotators. We find that 58% of our images pass this initial annotation process. We pay workers \$0.04 per HIT for all tasks.

Collecting sentences. Multimodal transformer models are trained on pairs of images and *sentences*; to evaluate them, we require image–sentence pairs as opposed to image–SVO pairs. Given an image and an SVO triplet, we next ask annotators to write a sentence that uses all the words in the triplet and describes the image. For example, as shown in Figure 1 top right, given the triplet ⟨man, jump, sea⟩, an annotator might write "A man is jumping into the sea.". We ask annotators to refrain from writing additional information to ensure that a collected sentence examines the words in the SVO (as opposed to words that we are not controlling for). Annotators are given the option to not write a sentence if they do not think the subject, verb, and object can be combined into a grammatical sentence that describes the image. 86% of our images pass this phase of our pipeline.

We observe that for a given SVO, different images elicit slightly different sentences. For example, the triplet ⟨person, jog, beach⟩ resulted in the sentences "A person jogging along the beach." and "A person jogs at the beach.". Additionally, annotators pluralize nouns to ensure the sentence describes the image (*e.g.*, Figure 1 top left, the subject "child" is written as "children" in the sentence).

Confirming the negative image. Finally, given a *positive* triplet (*e.g.*, ⟨girl, lie, grass⟩) and its negative (*e.g.*, ⟨girl, sit, grass⟩), we need to confirm that the positive's sentence does not match the image retrieved for the negative triplet. To do so, we ask three annotators to select which images (positive, negative, neither, or both) match a given sentence. Image–sentence pairs where two out of three annotators agree are accepted into our dataset; 68% of the pairs pass this final annotation stage.

4 Experimental Setup and Results

We investigate if current image–language transformers can relate different aspects of language (and in particular verbs) to images by evaluating these models against both FOIL and SVO-Probes. More specifically, we evaluate a few architectural variations of image–language transformer models (based on the implementation of the models by Hendricks et al., 2021) that differ in their choice of multimodal attention and loss functions; this way we can examine whether our findings are sensitive to these slight differences. The base multimodal transformer (**MMT**) closely replicates the ViLBERT architecture (Lu et al., 2019): this model includes three loss functions, masked language modeling (MLM) and masked region modeling (MRM) losses on the language and image inputs and an image–text matching (ITM) loss that classifies if an image–sentence pair match. Importantly, the multimodal attention of MMT is similar to the hierarchical co-attention in Lu et al. (2016b) where each modality (*i.e.*, image or language) attends *only* to the other modality. More specifically, in the multimodal self-attention layer of transformer (Vaswani et al., 2017), for queries on the language input, keys and values are taken from images and vice versa.

Different interactions of image (language) queries, keys, and values in multimodal self-attention results in variations of image–language transformers. We describe the model variations we study in Table 2. We also consider models that either lack the MLM or MRM loss. Models are pretrained on Conceptual Captions (CC) unless stated otherwise. For reference, we report the Recall@1 performance on the zero-shot image-retrieval task

Name	Multimodal Attention	Similar Model	MLM	MRM	*ZS Flickr*
MMT	Queries from L (I) take values and keys from *only* I (L)	ViLBERT; LXMERT	✓	✓	**41.9**
Merged–MMT	Queries from L (I) take values and keys from *both* L and I	UNITER	✓	✓	**40.0**
Lang–MMT	Queries are *only* from L (Hendricks et al., 2021)		✓	✓	33.6
Image–MMT	Queries are *only* from I (Hendricks et al., 2021)		✓	✓	31.6
SMT	Single-Modality Transformers without multimodal attention		✓	✓	16.9
No-MRM–MMT	The same as MMT		✓	✗	**41.1**
No-MLM–MMT	The same as MMT		✗	✓	20.2

Table 2: Different variants of the image–language transformer architecture we test. L and I stand for language and image, respectively. We note that models with Merged attention (like UNITER) are also referred to as single-stream models. ViLBERT: Lu et al. (2019); LXMERT: Tan and Bansal (2019); UNITER: Chen et al. (2020)

on Flickr (*ZS Flickr*), where a model must retrieve an image from the Flickr dataset (Young et al., 2014) that matches an input sentence. Since MMT performs best on *ZS Flickr*, we do most of our experiments on this model unless stated otherwise.

We first evaluate our image–language transformers on FOIL to examine their noun understanding and then test them on SVO-Probes which probes for subject, verb, and object understanding in learned representations. Following FOIL, we report the accuracy on positive and negative pairs. All our models have an image-text classification output used in pretraining to align images and sentences. We calculate accuracy by passing images through our models and labeling an image–sentence pair as negative if the classifier output is < 0.5 and positive otherwise. We report the average over the two pairs (see Avg columns in Tables 3 and 4) by weighting them equally, since we expect models to perform well on both positive and negative pairs. In FOIL, there are equal positive and negative pairs.

Another possible way to set-up our evaluations is as image-retrieval (reporting recall@1 as a metric). However, the retrieval setting does not highlight the difference in performance between positive and negative pairs. For example, a model might rank the pairs correctly even when their scores are very close (positive score is 0.91 and negative one is 0.9). In this example, the model is wrong about the negative pair (it is assigned a high score) but the retrieval setting does not capture this. However, the classification metric will penalize the model for assigning a high score to a negative pair. As a result, the classification metric better differentiates between the models by examining if they correctly label both the positive and negative pairs.

4.1 Evaluating Nouns with FOIL

We examine noun understanding in image–language transformers with the FOIL dataset (Shekhar et al., 2017). Given image–sentence pairs from FOIL, we evaluate the MMT model in a zero-shot setting by using it to classify if the image and sentence match. Table 3 compares MMT with the best model from the FOIL paper (HieCoAtt Shekhar et al., 2017) and, to our knowledge, the best-performing model on the task without using ground-truth annotations (Freq+MM-LSTM from Madhyastha et al., 2018). Note that these models are trained specifically for the FOIL task (*i.e.*, on the train split of FOIL), whereas the MMT model (pretrained on CC) is tested in a zero-shot setting.

MMT achieves an accuracy considerably worse than the best models on FOIL (Shekhar et al., 2017; Madhyastha et al., 2018) on all pairs; this is surprising given that image–language transformers achieve state-of-the-art results on zero-shot image retrieval tasks based on Flickr (Young et al., 2014) and MSCOCO (Chen et al., 2015). In particular, MMT overpredicts that image–sentence pairs match, resulting in the highest accuracy on the positive pairs (99.0) but the lowest on negative pairs (11.8). Thus MMT cannot distinguish between sentences that only differ with respect to nouns.

We investigate whether this poor performance of MMT is due to mismatch between the pretraining (*i.e.*, CC) and FOIL test (*i.e.*, MSCOCO) datasets. Thus, we compare our MMT model pretrained on Conceptual Captions with one pretrained on MSCOCO (MMT-COCO). As expected, MMT-COCO has considerably higher performance on all pairs (compare to MMT); however, the accuracy is still significantly higher on positive pairs than negative ones, showing that the model overpredicts that image–sentence pairs match. Our result shows that despite their impressive performance on downstream tasks, image–language transformer models perform poorly in distinguishing between semantically similar sentences. Next we examine how well these models perform on our proposed

Model	Avg	Pos.	Neg.
HieCoAtt*	64.1	91.9	36.4
Freq + MM-LSTM †	**87.9**	86.7	**89.0**
MMT	55.4	**99.0**	11.8
MMT-COCO	72.0	95.0	49.0

Table 3: Performance on FOIL averaged over all (Avg), positive (Pos.), and negative (Neg.) pairs. *Shekhar et al. (2017); †Madhyastha et al. (2018).

probing dataset which is designed to have a similar vocabulary to the CC pretraining dataset.

4.2 Comparing Models on SVO-Probes

We evaluate all models (see Table 2) on SVO-Probes and report overall accuracy and accuracy for subject, verb, and object negatives in Table 4.

The MMT model (with the best performance on *ZS Flickr*) performs poorly on SVO-Probes, achieving an overall average accuracy of 64.3. The best overall average accuracy (No-MRM–MMT; 69.5) shows that SVO-Probes is challenging for image–language transformers. In particular, models struggle with classifying negative pairs; Lang–MMT achieves the highest accuracy over negative pairs (56) which is slightly higher than chance at 50. [2]

Though No-MRM–MMT and MMT perform similarly on *ZS Flickr*, No-MRM–MMT performs better on SVO-Probes. This suggests that the masked region modelling loss is not needed for good performance on *ZS Flickr*; also, it impedes the model from learning fine-grained representations needed to perform well on SVO-Probes. More surprisingly, Lang–MMT, which performs worse on *ZS Flickr* than MMT, outperforms MMT on SVO-Probes. The image representations in Lang–MMT are not updated with an attention mechanism. In Sec. 4.4, we explore if the stronger attention mechanism in MMT leads to overfitting of the training images and thus weaker performance.

We crafted SVO-Probes such that it includes words from the pretraining dataset of image–language transformers (*i.e.*, CC), whereas FOIL is collected from MSCOCO. Comparing the performance of MMT (with CC pretraining) on FOIL and SVO-Probes (55.4 in Table 3 vs. 64.3 in Table 4), we see that the domain mismatch between pretraining and test data plays a role in MMT's performance. Interestingly, comparing the performance of MMT-COCO (MMT with COCO pretraining) on FOIL to MMT (with CC pretraining) on SVO-Probes, we find that SVO-Probes is more challenging than FOIL when there is no domain mismatch (72.0 in Table 3 vs. 64.3 in Table 4).

When comparing different negative types across *all* models, we observe that verbs are harder than subjects and objects; compare average accuracy for Subj., Verb, and Obj. Negative columns in Table 4. For example, in MMT, the subject and object negative average accuracies (67.0 and 73.4) are considerably higher than the average accuracy for verb negatives (60.8). Moreover, when breaking down the accuracies for positive and negative pairs (Pos. and Neg. columns in Table 4), we observe that the accuracies of positive pairs are similar (ranging between 80.2 and 94.4) across all models except SMT (which performs close to chance); however, for negative pairs, there is more variation in accuracy across models especially for verb negatives (ranging between 22.4 and 54.6, Neg. columns under "Verb Negative"). These results show that negative pairs are better than positive ones in distinguishing between different model architectures.

We also find that subjects are harder than objects across all models (when comparing average accuracies of subject and object negatives). To better understand this result, we examined 21 nouns that occur both as subjects and objects in SVO-Probes' sentences. Interestingly, over these 21 nouns, for our MMT model, the accuracies of negative pairs are 42.9 and 56.4 for subject and object negatives, respectively. This suggests that the subject position might be more challenging than the object one which we further explore in Sec. 4.3.

4.3 Accuracy and Frequency at Training

Our overall results on SVO-Probes (Table 4) show that for image–language transformers, verb negatives are more challenging than subject and object ones, and also subject negatives are harder than object ones. We examine if this observation is due to properties of SVO-Probes as opposed to differences specific to subjects, verbs, and objects. First, we explore whether the frequency of SVO triplets in pretraining data impacts the accuracy of negative pairs in our MMT model. We focus on negative

---

[2] We focus on image–language transformers, but we also tested a baseline model where image features are embedded with the detector used in our transformers and language features with BERT. Features are pooled using element-wise multiplication. This baseline achieves 66.3% accuracy overall with 75.4% and 57.3% accuracy on positives and negatives. Similar to transformers, performance on verbs is the worst.

	Overall			Subj. Negative			Verb Negative			Obj. Negative		
	Avg	Pos.	Neg.	Avg	Pos.	Neg.	Avg	Pos.	Neg.	Avg	Pos.	Neg.
# Examples	48k	12k	36k	8k	3k	5k	34k	11k	23k	11k	3k	8k
MMT	64.3	*93.8*	34.8	67.0	*94.4*	39.5	60.8	*93.8*	27.8	73.4	*94.4*	52.4

No-MLM–MMT	60.8	92.3	29.3	64.8	93.9	35.8	57.4	92.5	22.4	69.5	93.6	45.5

Table 4: Results on SVO-Probes on different models for subject, verb, and object negatives. Best results are shown in bold; second best results are italicized.

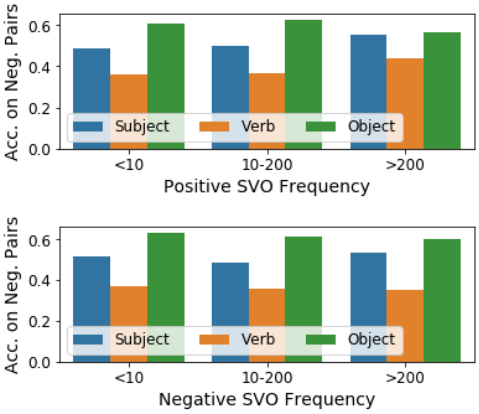

Figure 2: Accuracy of negative pairs for subject, verb, and object negatives given SVO frequencies in CC.

pairs as there is more variation in negative-pair accuracies across both models as well as subject, verb, and object negatives. We consider the frequency of positive and negative SVO triplets: a positive SVO corresponds to a positive image matching a given sentence, but a negative SVO and its extracted negative image do not match the sentence.

We group SVOs based on their frequency in CC-train into low (less than 10), medium (between 10-200), and high (greater than 200) frequency bins. Fig. 2 plots the negative-pair accuracy for subject, verb, and objects across these different frequency bins over positive and negative SVO frequencies. We confirm that our result on the difficulty of negative types does not depend on the frequency of positive or negative SVOs in pretraining data. In both plots of Fig. 2, the negative types in order of difficulty (lower accuracy) are verbs, subjects, and objects independent of the frequency bin.

Similarity between SVOs. We examine if the similarity between the SVO triplets corresponding to the negative and positive images can explain the difference in performance of subject, verb, and object negatives. For example, we expect that distinguishing ⟨child, cross, street⟩ and ⟨adult, cross, street⟩ to be harder than differentiating one of them from ⟨dog, cross, street⟩: "child" and "adult" are more similar to each other than to "dog". To test this, we measure the similarity between subjects, verbs, and objects in their corresponding negative types using the cosine similarity between word2vec (Mikolov et al., 2013) embeddings.

The average similarities between subjects, verbs, and objects are 0.49, 0.29, 0.27, respectively. Thus, subject words in negative examples tend to be more similar than object words. Furthermore, we find that there is a small positive correlation (as measured by Spearman rank correlation) between SVO similarity and classifier scores for negative pairs – .264 and .277 for subjects and objects respectively – suggesting that when SVOs corresponding to the image and sentence are similar, the classifier tends to assign a higher score (more positive) to the pair. This partially explains why accuracy on subjects is lower than on objects in Table 4. Even though verb negatives are harder for our model, the similarity for verb negatives is similar to that of object negatives. The correlation coefficient between similarity and classifier score is weaker (.145) for verbs, suggesting that word similarity factors less in how well the model classifies verb negatives.

4.4 Similarity to Pretraining Data

We next consider the similarity between images in SVO-Probes and CC. To measure the similarity between images, we sample 1 million images from CC. For each image in SVO-Probes, we find the 10 nearest neighbors in the feature embedding space

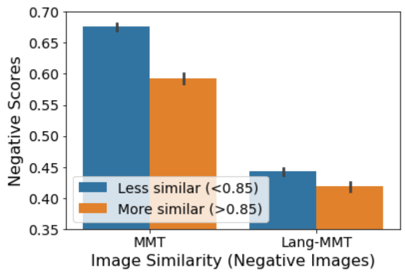

Figure 3: Comparing negative scores on MMT and Lang–MMT for images less or more similar to CC.

of CC, and average the distance to compute a similarity score for the image. Figure 3 plots the average score from our classifier for negative pairs with images that are less or more similar to the pretraining data (since we are classifying negative pairs, the lower score the better). We compare the MMT and Lang–MMT models since they have considerably different performance on SVO-Probes and *ZS Flickr*. The difference in average scores between less similar and more similar examples for MMT is 0.083. This is noticeably greater than the difference in average scores between less and more similar examples for Lang–MMT (0.024), suggesting that the image similarity influences Lang–MMT less than MMT. One hypothesis is that the stronger attention mechanism in MMT overfits to the training images which makes the MMT model less robust.

4.5 The Choice of Pretraining Dataset

In Sec. 4.2, we observe that models perform particularly poorly in classifying negative pairs. We investigate whether the choice of pretraining dataset impacts this observation. Conceptual Captions (CC), the most-common pretraining dataset for image–language transformers, is curated by scraping images and alt-text captions from the web. As a result, compared to manually-annotated datasets such as MSCOCO, CC is noisy – it contains examples where the sentence and its corresponding image do not completely align. For example, a sentence can mention objects that are not in the image or, in extreme cases, does not describe the image at all.

We hypothesize that image–language transformers treat correspondences due to dataset noise as "real" relations; in other words, they learn that if a image–sentence pair is somewhat semantically related, it should be classified as a positive match, even if some aspects of the sentence do not describe the image. At the same time, we can think of negatives in SVO-Probes as examples with noisy correspondences where a specific aspect of a sentence (*e.g.*, the verb) does not match the image. We compare our MMT model (with CC pretraining) to one trained on a manually-annotated and less noisy dataset, MSCOCO (referred to as MMT-COCO).

	Overall			Neg. Acc.		
Train	Avg.	Pos.	Neg.	S	V	O
CC	64.3	93.8	34.8	39.5	27.8	52.4
COCO	68.0	75.2	60.9	66.0	55.5	73.4

Table 5: Comparing performance when training our MMT model on COCO and CC.

Table 5 reports the overall accuracy of the two models on SVO-Probes as well as a breakdown over subject, verb, and object negatives for negative-pair accuracies. MMT-COCO performs better than MMT pretrained on CC (avg. accuracy of 68 vs 64.3). This is surprising since MMT-COCO has a different image and language distribution in its pretraining dataset. The accuracy of positive pairs in MMT-COCO is considerably lower than MMT while it performs noticeably better for negative pairs: unlike MMT, the MMT-COCO model does not overpredict that image–sentence pairs match. Our results show the image–language transformers are not robust to dataset noise. Less-noisy datasets (such as MSCOCO), despite their small size and domain mismatch, are more suitable for learning representations that are sensitive to finer-grained differences in images. Alternatively, models which are more robust to noise in datasets could be beneficial for tasks like ours.

4.6 Which Verbs Are the Hardest?

We investigate which verbs are hardest for MMT. We consider verbs with many examples in SVO-Probes: we keep SVO triplets with at least 30 negative images, resulting in a set of 147 verbs and 887 SVO triplets across $4,843$ images. Table 6 lists the easiest and hardest verbs (with highest and lowest accuracy for negative pairs) for the MMT model. Easy and hard verbs have a diverse set of properties; for example, easy verbs include sporting activities like "tackle" as well as verbs like "lead" that occurs in a variety of contexts. We also examine the 20 most difficult and easiest verbs for *all* our models (described in Table 2). Most difficult verbs for all models include: "cut", "argue", and"break" and the easiest ones include: "direct", "battle", "surround", "skate", and "participate".

Easy	Hard
tackle, reach, arrive, pitch, accept, congratulate, lead, present, celebrate, attend	argue, beat, break, burn, buy, cast, comb, crash, cut, decorate

Table 6: Hard and easy verbs for our MMT model

We test if verbs that occur in both SVO-Probes and imSitu are easier for our model to classify. Verbs in imSitu are considered visual as the dataset collection pipeline for imSitu includes an explicit annotation step to determine if verbs are visual. Surprisingly, we find verbs in imSitu are harder for our MMT model. On closer inspection, some verbs in our dataset but *not* in imSitu (*e.g.*, "swim") are clearly visual. An interesting future direction is to investigate which visual properties of a verb make it harder or easier for image–language models to learn.

5 Conclusions

Although image–language transformers achieve impressive results on downstream tasks, previous work suggests performance on these tasks can be confounded by factors such as over-reliance on language priors (Goyal et al., 2017). We collect a dataset of image–sentence pairs to examine multimodal understanding by testing the ability of models to distinguish images that differ with respect to subjects, verbs, and objects.

Our results show that image–language transformers fail at identifying such fine-grained differences; they incorrectly classify image–sentence pairs that do not match. Surprisingly, a model trained on a manually-annotated and smaller dataset does better on our task, suggesting that models have trouble ignoring noise in larger but automatically-curated pretraining datasets. Additionally, verb understanding is harder than subject or object understanding across all models we study. This motivates the need for researchers to not only examines models on objects, but develop datasets and architectures which allow for better verb understanding as well.

Implications of Using Internet Sting Corpora to Approximate Underage Victims

Tatiana Ringenberg, Kathryn Seigfried-Spellar, and **Julia Rayz**

Abstract

Law enforcement officers (LEOs) and the justice system employ NLP models for classifying and triaging child exploitation cases due to the textual communications between predators and victims. The usefulness of these systems depend on the quality of data that can be used for training. Data in the domain are scarce, sensitive, and emotionally taxing for annotators. NLP researchers approximate victimization conversations using transcripts from internet stings performed by either vigilantes or LEOs, with an implicit assumption that vigilante or LEO conversations represent the victimization process. Psychology research, however, states that underage victim chats differ from internet stings in goal and modus operandi. We present a methodology and observations from annotating a corpus of victim, vigilante, and LEO conversations with convicted predators with the goal of comparing these chats. The corpus is annotated for stages and tactics of the victimization process described within psychology research. As predicted by psychological research, we found significant differences in the three classes of chats that are usually not taken into account in chat classification.

1 Introduction

Child exploitation crimes have expanded over the years to include a wide array of concerns including sextortion (Kopecký, 2017), sex trafficking (Diaz and Panangadan, 2020), sexual solicitation (Briggs et al., 2011), and deep fakes (Albahar and Almalki, 2019). NLP research in understanding these chats is crucial because law enforcement agencies have become overwhelmed with online cases; automated systems are needed in order to sift through the available textual data and transcripts to improve case triage through identification of criminal activity (Inches and Crestani, 2012). In the past, automatic systems have been developed for differentiating predators from non-predators (Misra et al., 2019; Pendar, 2007), predicting level of risk throughout a conversation (Ringenberg et al., 2019), and flagging predatory conversations (Kim et al., 2020; McGhee et al., 2011; Zuo et al., 2018).

While the potential of NLP in the child exploitation domain is substantial, the corpora used to train these models is not always adequate. The data used to train algorithms rely on internet sting operations between an adult predator and a law enforcement officer (LEO) (DeHart et al., 2017), or adult vigilante (Black et al., 2015), impersonating a minor. Psychology research, which serves as the foundation for theory in the child exploitation domain, suggests internet sting operations progress differently than traditional conversations in which an adult seeks to victimize a child (DeHart et al., 2017; Briggs et al., 2011; Bergen et al., 2013; Mitchell et al., 2005). As a result, further research is needed to assess the ways in which these corpora differ and the potential impact the differences have on the resulting models.

We investigate to what extent internet sting operations may be assumed to accurately approximate child victimization. We focus on differences between sting participants and underage victims with respect to the victimization process known as online child grooming: the process an adult uses to gain the trust of a minor for the purpose of sexual fulfillment either online or in a physical meeting (O'Connell, 2003).

According to Stede and Huang (2012), "the most convincing evidence for the value of an annotation task remains to be its direct contribution to the success of one or more NLP applications" (p.92). This work highlights the potential negative impact of untested assumptions related to corpus composition in this domain. We also provide insights into the annotation process which may help others as-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3645–3656
August 1–6, 2021.

sess corpora within child exploitation. Finally we plan to release our code book, coinciding with this paper, as an aid to future work.

2 Online Child Victimization as a Process

The victimization process by which an adult entices a minor is referred to as grooming (O'Connell, 2003), and has been studied within the online (Kloess et al., 2019; O'Connell, 2003) and physical (Colton et al., 2010; Jackson et al., 2015) contexts for decades (Kaufman et al., 1993; Lang and Frenzel, 1988; Leclerc and Tremblay, 2007). We seek to understand the impact to NLP research. Thus, we limited the scope of our investigation to the textual transcripts produced from the online grooming process as originally defined by O'Connell (2003).

2.1 Characteristics of Online Grooming

Online grooming is the process an adult uses, on the Internet, to entice a minor into a sexual scenario (O'Connell, 2003). The process consists of six transient stages which include friendship forming, relationship forming, exclusivity, risk assessment, sexual, and meeting (O'Connell, 2003; Gupta et al., 2012). For a discussion of the grooming stages, see O'Connell (2003); Whittle et al. (2013). The process of grooming is not uniform; it ebbs and flows (Gillespie, 2002) based on the goals of the predator (Beauregard et al., 2012; Briggs et al., 2011; Kloess et al., 2017) and feedback from the victim (Wortley et al., 2019).

Common tactics used during online grooming include bragging (Aitken et al., 2018), compliments (Kloess et al., 2019), fantasy enactment (Kloess et al., 2019; Malesky Jr, 2007), coercion (Kloess et al., 2019; Villacampa and Gómez, 2017), repetition (Kloess et al., 2017), and expression of vulnerability (Barber and Bettez, 2014). For a thorough treatment on online grooming tactics, see Barber and Bettez (2014); Kloess et al. (2019). Predators use grooming tactics in order to further a goal or progress the relationship with the minor (Beauregard et al., 2012; Briggs et al., 2011; Kloess et al., 2017; Wortley et al., 2019).

2.2 Corpora in Online Grooming

To understand how datasets and corpora are built within the child exploitation domain, we performed a systematic review of research on child exploitation from January 2000 to March 2020. We searched for peer-reviewed journal articles in four databases: Medline, PubMed, PsychInfo, and ERIC. In each database, we searched for the terms *online sexual grooming*, *online sexual solicitation*, *child sexual abuse*, and *child molestation*. Results included applied NLP papers and psychology papers. Based on titles and abstracts, we selected papers which met the following criteria: peer-reviewed journal article, published in English, contained adult groomer and underage victims, clear online child grooming tactics component, and articles with empirical focus. Articles which were literature reviews or meta-analyses of grooming were removed.

We identified a total of 32 articles. We analyzed the type of participants and the location of the participants in the sample. Ten papers used vigilante cases, 16 used underage victim cases, one used interactions with LEO, and five contained a mixture of participants. These datasets are problematic because they may not represent the phenomenon being studied (Bowen, 2008; Hovy and Lavid, 2010). A representative corpus would ideally include the space of all participant types and behaviors (Bowen, 2008). However, transcripts from these three groups may differ in length (Briggs et al., 2011; Mitchell et al., 2005), motivation (Briggs et al., 2011; Williams et al., 2013), and modus operandi (Briggs et al., 2011; DeHart et al., 2017; Williams et al., 2013). Additionally, the studies were done on participants from a wide range of geographical jurisdictions including the United States (Black et al., 2015), the United Kingdom (Whittle et al., 2014), Sweden (Shannon, 2008), Spain (de Santisteban et al., 2018), Israel (Katz, 2013), or multiple countries (Quayle et al., 2014). This is problematic due to differences between countries with respect to the age of consent, legal ramifications, and social constructs surrounding child sexual abuse.

Online grooming corpora are generally used by ML researchers to identify specific grooming stages (Cano et al., 2014; Gupta et al., 2012) and classify conversations as predatory (Bogdanova et al., 2012; McGhee et al., 2011). Methods for identifying grooming tactics have included rule-based systems (McGhee et al., 2011), naïve bayes (Bogdanova et al., 2012), support vector machines (Gunawan et al., 2016), and more recently neural networks (Ebrahimi et al., 2016). Some of the common features used for classifying grooming conversations and stages include sentiment polarity

(Bogdanova et al., 2012; Cano et al., 2014), psycholinguistic categories (Cano et al., 2014; Gupta et al., 2012), and n-grams (Bogdanova et al., 2012).

2.3 Underage victims and internet stings: Could they differ?

Internet sting datasets do not represent the underage victimization process (Bergen et al., 2013; Briggs et al., 2011; Chiang and Grant, 2019; DeHart et al., 2017; Gijn-Grosvenor and Lamb, 2016; Mitchell et al., 2005; Schneevogt et al., 2018; Winters et al., 2017) as: 1) the type of predator caught in internet stings versus real victimization cases is different (Briggs et al., 2011; Mitchell et al., 2005); and 2) there are differences between the real vulnerabilities and reactions of at-risk minors versus trained vigilantes and LEOs with a goal of gathering evidence (Briggs et al., 2011; Chiang and Grant, 2019; DeHart et al., 2017; Gijn-Grosvenor and Lamb, 2016; Schneevogt et al., 2018; Williams et al., 2013). The first is impactful for NLP research because it affects the topics the predators pursue and the progress of stages. For instance, looking for sexually-charged language would likely be more effective in internet-stings than in underage victim chats (Briggs et al., 2011). The second is impactful because the data used to train algorithms is not representative of successful grooming techniques, especially if predators caught during stings were not familiar with grooming tactics for luring minors. These factors affect how openness and directness of communication is used by law enforcement and vigilantes in comparison to underage victims (Briggs et al., 2011; Williams et al., 2013).

Conversely, DeHart et al. (2017) found many internet-based predators requested meetings with victims. While more research is needed, empirical evidence shows the predators in internet stings may be different enough to impact how the online grooming process manifests (Briggs et al., 2011; Mitchell et al., 2005).

Psychologists also posited several ways in which the grooming process may differ in terms of modus operandi. Briggs et al. (2011); DeHart et al. (2017); Williams et al. (2013) claimed LEO, or vigilantes, are more likely than victims to be open to online sexual behavior and requests to meet (Briggs et al., 2011; DeHart et al., 2017). Further, authors posit LEOs or vigilantes differ with respect to search criteria (DeHart et al., 2017), reaction to sexual comments (Briggs et al., 2011; Williams et al., 2013), specialized training (Briggs et al., 2011), overt explicitness of profiles (Briggs et al., 2011), and coercion (Chiang and Grant, 2019; Schneevogt et al., 2018). Finally, vigilantes and LEO are limited in what they can say to secure an arrest, as they are discouraged from initiating sexual conversation, contact, and arrangements of meetings (Gijn-Grosvenor and Lamb, 2016). As a result, LEOs and vigilantes may attempt to nudge conversations in this direction (Williams et al., 2013).

Finally, Briggs et al. (2011) highlighted the importance of the difference in goals between underage victims, vigilantes, and LEOs. Briggs et al. (2011) noted vigilantes and LEOs have a goal of collecting evidence and securing a quick arrest. This results in shorter chats with faster progressions and more pointed language than victim chats (Briggs et al., 2011). In LEO and vigilante chats, there was eagerness which is not reflective of either the distrust or language used by at-risk teens (Briggs et al., 2011).

3 Methodology

The annotation protocol described in the following sections follows the annotation pipeline proposed by Hovy and Lavid (2010). Based on research presented above, we hypothesize the greatest actionable differences occur within the grooming stages and grooming tactics actualized by underage victim, vigilante and LEO chats.

3.1 Corpus Composition: Data Subjects

A corpus is considered to be representative once it is *saturated* (Bowen, 2008), such that all relevant aspects of the phenomena are covered (Bowen, 2008; Hovy and Lavid, 2010) to the point of repetition or redundancy (Bowen, 2008). Per our assessment of online grooming literature in the 2000s, datasets in the predator domain consist of underage victims, LEOs, and online vigilantes. As data in the domain is difficult and time-consuming to acquire, we are unable to construct a corpus which would satisfy the saturation metric. However, we are able to construct a small corpus which represents all three participant types within the domain. We constructed a corpus of the three groups to ensure we account for all participants. Our corpus consists of 60 chat transcripts representing an equal number of participants from the three groups: 20 vigilantes, 20 underage victims, and 20 LEOs.

3.2 Data Acquisition and Cleaning

Our data collection and data use practices adhere to our Institutional Review Board (IRB) protocol. Due to the sensitive nature of the data, we submitted a full protocol review, which was approved. All texts in the corpus had all images and identifying information removed.

Underage victim and LEO transcripts were obtained from local, state, and federal agencies within the United States. While previous studies consisted of transcripts from multiple countries (Bergen et al., 2013; Quayle et al., 2014), we focused on transcripts from a single country in order to minimize confounding variables which could influence how participants interact.

The vigilante conversations are publicly available through pervertedjustice.com, an organization of adult vigilantes, trained to pose as minors online. The vigilantes speak with predators and work with LEOs to secure evidence for convictions. Oversight of these individuals is minimal (Williams et al., 2013) and there is little information on their website concerning the content of training for the vigilantes. The chat transcripts are posted to the Perverted Justice website following conviction.

One limitation we identified was incompleteness of the data. Transcripts from LEOs rarely included the full interaction between participants. Additionally, vigilante conversations would occasionally reference a phone call which took place without making the call transcript available. We also found that some chats ended early when LEOs had enough evidence. Other chats took place partway through the interaction. Still others terminated when the LEO switched to a different chat service.

Our mitigation for incomplete transcripts was to request background information from the law enforcement agencies. In the case of Perverted Justice transcripts, case documents and transcript summaries are often linked to the chats on the site. This can be a helpful resource for identifying limitations of individual transcripts.

3.3 Constructing the Initial Code Book

Tactics in our code book were deductively selected from grooming stages and tactics which map to the limitations discussed in Section 2.3.

The consensus from Section 2.3 was the grooming process would be affected by participant goals and investigator tactics (Bergen et al., 2013; Williams et al., 2013). To capture these differences, we considered all stages outlined by O'Connell (2003). The stages included *friendship forming*, *relationship forming*, *exclusivity*, *sexual*, *risk assessment*, and *meeting*. Additionally, as we annotated the stages, we noticed a possible divide between the *sexual stage* and a *non-consensual sexual stage* in which the victim, vigilante, or LEO indicated discomfort or declined sexual advances.

We selected the grooming tactics to operationalize the limitations enumerated in Section 2.3. The tactics are summarized in Table 1.

Openness to sexual comments/behavior. The *bragging* and *personal compliment* tactics are linked to sexual discussions within grooming (Barber and Bettez, 2014). Given LEOs respond to sexual content in a more positive manner than at-risk teens, we posit responses related to *bragging* and *personal compliments* will differ. Roleplay is how some predators act out fantasy, thus making it applicable to assessing openness to sexual behavior (Kloess et al., 2019). Finally, predators often ask for jarring and explicit details about the victim's sexual past (Aitken et al., 2018) which an at-risk teen might find uncomfortable.

Discussion of Meetings. *Willingness* is an assessment of what a participant would consider doing (Barber and Bettez, 2014). Often, this is associated with discussions of the explicit activities a victim would agree to perform in person.

Coercion. *Coercion* has been associated with differences between internet stings and victim conversations in the past, though they often point to more overt forms of coercion (Chiang and Grant, 2019; Schneevogt et al., 2018). We split the *coercion* tactic into *coercion* and *sexual violence* to reflect this distinction.

Naïve and Young/Explicitness of Profile. Vulnerabilities are used by predators to evoke sympathy (Barber and Bettez, 2014). The expression of vulnerabilities by a non-predator may be a good indicator that a sting is taking place, as we hypothesize LEOs and vigilantes will over-emphasize childhood problems. Further, willingness to send images in chat to a stranger could also be an operationalization of naïvety to online dangers. We posit LEOs and vigilantes are more likely to send such pictures than real at-risk minors.

Initial Contact. While we could not find any grooming tactics related to initial contact within the literature, we posit differences in initial contact can be captured by the grooming stages.

Grooming Characteristics	Grooming Tactics
Openness to sexual comments/behavior	Roleplay Bragging Sexual History Personal Compliments
Discussion of Meetings	Willingness
Coercion	Coercion Sexual Violence
Naïve/Explicitness of Profile	Discussion of Images Vulnerabilities (Neg. Life Stories, Neg. Physical Attributes)
Initial Contact	Grooming Stages
Arrest Goal	Age Difference Reverse Power
Speed/Duration	Media Progression (Phone calls, Video Chat)

Table 1: Mapping of grooming characteristics to grooming tactics in this paper.

Arrest Goal. We focused on what an LEO would need to show that a law was broken. Stating the *age difference* would indicate the predator knew the victim was under 18. *Reverse power* is giving the control of the situation to the other participant (Barber and Bettez, 2014). We hypothesize there may be differences with respect to *reverse power* because the vigilantes and LEOs are unable to initiate certain discussions (Gijn-Grosvenor and Lamb, 2016). *Reverse power* may be a way to influence the discussion without explicitly initiating.

Speed/Duration. In typical grooming conversations, participants often switch chatting services multiple times (Quayle et al., 2014). If conversations are shorter and faster in internet stings, we posit there will be fewer forms of communication.

In addition to definitions for each of the tactics and stages from literature, code books often include examples for each tactic (Bada et al., 2012; Kingsbury et al., 2002; Stoyanov and Cardie, 2008) which help to clarify the tactic without over-specifying (Hovy and Lavid, 2010). In the code book we included an initial set of examples for each tactic from the psychology literature (2.1).

3.4 Annotator Selection

Grooming stages and tactics are difficult to annotate, even for those experienced within the domain (Gillespie, 2002). Recommendations of whether to use domain experts or novices differs within NLP literature (Hovy and Lavid, 2010). We used two annotators: the first annotator is an expert within the child exploitation domain while the second annotator was an undergraduate with low levels of experience. Due to the multidisciplinary nature of this domain, we decided to use a non-expert for the second annotator to ensure our corpus was accessible to researchers with multiple backgrounds.

3.5 Annotator Training

Hovy and Lavid (2010) recommends providing a reasonable amount of training in order to familiarize the annotators with the task without overspecifying the task. To accomplish this, the first annotator gave the novice second annotator a short overview of the child exploitation domain to help bridge the gap between skill sets to improve alignment (Bayerl and Paul, 2011).

The first annotator also provided the second annotator with the initial code book to review. The second annotator was able to ask clarifying questions about the grooming stages and tactics in the code book.

Following familiarization with the codebook, both annotators annotated a series of three training chats. Since grooming participants do not use every single grooming stage or tactic in chats, but rather a subset that fits their goals (Beauregard et al., 2012; Briggs et al., 2011; Kloess et al., 2017), annotating three chats ensured exposure of the second annotator to all of the stages and tactics in the code book.

Simple agreement was used to calculate a baseline of agreement on which to measure improvement following training; the target agreement for this study was 80% (Krippendorff, 2011). Per best practices, the annotators met to discuss the training round, answer questions from the second annotator, and resolve inter-annotator disagreements (Hovy and Lavid, 2010).

3.6 Annotation Procedures

3.6.1 Coding Rounds

We initially had six grooming stages and 14 grooming tactics to annotate. Due to the expected complexity of these tactics and stages, we originally split the annotation task into three rounds. Following the training round we re-split the task into four rounds to reduce annotator fatigue in an annotation session (Bayerl et al., 2003).

One recommendation from this is to keep the grain-size of stages or tactics consistent within a single annotation round. In the first round of annotation we had a mixture of stages and tactics. However, this made annotation difficult for two reasons. The first reason was that grooming stages encompassed grooming tactics. For instance, within the *sexual stage* a predator might use *willingness* as a means to gauge interest and *roleplay* to normalize sexual content. We found the difference in granularity between grooming stages and tactics made it difficult to context switch within the same round. The second reason was that grooming stages were complex and impermanent (Gillespie, 2002). There were multiple examples and rules to remember with each grooming stage and changes between grooming stage were often quick and overlapped, making the annotation task complicated. Keeping the number of tactics low made it easier to focus on the stages.

3.6.2 Code Span Identification

The transient nature of grooming makes the beginning and end of a grooming instance difficult to identify (Gillespie, 2002). Known as *code span*, challenges related to identification of the boundaries of an annotation are known issues within annotation literature (Bada et al., 2012; Stoyanov and Cardie, 2008). To mitigate code span issues, we allow partial membership to a tactic or stage to facilitate discussion and identify span issues.

For this study, we defined *partial membership* as (i) non-substantive statements made in reference to a tactic or (ii) lines which do not meet the criteria for a tactic but result in or from the tactic. Full membership was defined as a line which was representative of a tactic. For instance, if a victim indicates their parents will be gone for the weekend and the predator responds by asking if they would like to meet, we would annotate the statements about the meeting as having full membership to the *meeting stage*. We would also annotate the victim's line about their parents as partial membership because the message precipitated the meeting discussion.

Based on annotating the corpora, we did not find a noticeable difference in the code span of topics between victim, vigilante, and LEO transcripts. However, we did notice that for longer spans of sexual tactics such as the *sexual stage*, *sexual history*, and *roleplay*, the intensity and graphic content of the messages would increase. We posit this was due to the predators attempting to gradually sexualize the conversation. Given that LEO and vigilantes respond in a more positive manner that real victims (Briggs et al., 2011; DeHart et al., 2017; Williams et al., 2013), predators may use more graphic and descriptive language when talking to vigilantes and LEOs than real victims. Additionally, we noticed real victims would end uncomfortable conversations more quickly and with more firm language (e.g., "no" versus "idk"). Future research should examine the change in graphical descriptions and responses to them over time in transcripts.

3.6.3 Annotator Protocol and Process

We developed the following guidelines for the annotation process:

- Review the code book before each annotation session.
- Annotation questions should be noted at the time, and discussed between rounds.
- Questions should be directed towards the first annotator and not external works or researchers. Hovy and Lavid (2010) emphasized the issues which could arise from inexperienced annotators not knowing the correct resource to ask for assistance. We mitigate this by having the first annotator, with domain experience, be the sole source of training.
- Annotators should label each round independently; annotations do not depend on previous rounds. We added this rule following the training session because the non-expert annotator began to second-guess tactics and annotations they felt should be related to one another.
- Coding session duration should be limited to reduce fatigue (Bayerl et al., 2003). We limited coding sessions to a maximum of three rounds in an annotation session.
- Each line may be annotated for multiple tactics within the coding round. While limiting annotations to one per tactic per round is desirable (Bada et al., 2012), the complex and transient nature of grooming results in multiple tactics and stages manifesting at the same time (Gillespie, 2002).

Using these guidelines and the finalized code book, both annotators annotated six chat transcripts, which represented 10% of the total number of transcripts. Simple agreement was calculated and found to be greater than the recommended 80% for annotation tasks (Krippendorff, 2011). For the

Group	Total Lines	*M*	*SD*
Vigilante	28505	1425.25	1111.96
Victim	10469	523.45	742.74
LEO	5140	257.00	302.56

Table 2: Summary of corpus composition.

simple agreement calculation, we used the total agreed upon annotations out of the total annotations. For this study, we only took into account full membership annotations as partial membership annotations were created to facilitate discussion. Future work, which incorporates the partial membership annotations into analysis, would require additional agreement measures.

Differences following the agreement calculation were each discussed and resolved through verbal agreement.

Finally, the first annotator annotated the remaining 51 chat conversations using the finalized code book and above guidelines. Future work should use two or greater annotators for the duration of annotation (Bayerl and Paul, 2011). While using a single annotator for the remainder of the annotation is a limitation of this study, we sought to mitigate the limitation by constructing and testing the finalized code book using both annotators.

3.6.4 Comparing Victims, Vigilante, and LEOs

Quantitative Analysis

To compare chat length, we used a one way analysis of variance between the three groups. Levene's F Test indicated unequal variance (F= $10.82, p < .001$). As a result, the Welch Test was performed and showed a significant effect of participant type on length of chat, *Welch's* $F(2, 57) = 10.587, p < .001$, $\omega = .52$. We performed Post-hoc analysis using the Games-Howell test due to the unequal variance. The Games-Howell test indicated the number of lines for a vigilante chat were significantly different than the number of lines for LEO ($p < .001$) and underage victims ($p = .013$).

. A χ^2 test was conducted to examine the presence or lack of each tactic within chats in the three groups. While the majority of chats contained all stages, future work should assess differences in presence and sequencing of grooming stages as well.

When assumptions of a χ^2 test could not be met, a Fisher's Exact test was conducted. Through χ^2 tests, we found *sexual history* ($\chi^2 = 10.40, df = 2, p = .006$), *willingness* ($\chi^2 = 14.55, df = 2, p = .001$), *discussion of phone calls* ($\chi^2 = 10.15, df = 2, p = .006$), and acknowledgement of *age difference* ($\chi^2 = 22.67, df = 2, p < .001$) were significantly different between participant groups. Through Fisher's Exact tests, we found the use of *personal compliments* ($p = 0.011$) and *reverse power* ($p = 0.03$) were significantly different between participant groups. There were no significant differences between the three groups with respect to *coercion*, *discussion of images*, *bragging*,*discussion of video chatting*, *negative physical traits*, *negative life stories*, *roleplay*, or *sexual violence*.

	Vigilante	Victim	LE
Sexual History	95.0%	50.0%	75.0%
Willingness	85.0%	55.0%	25.0%
Phone Calls	75.0%	55.0%	25.0%
Age Difference	95.0%	35.0%	90.0%
Compliments	100.0%	65.0%	83.3%
Reverse Power	100.0%	75%	70%

Table 3: Occurrence of grooming tactics in vigilante, victim, and LEO conversations.

The results of the χ^2 and Fisher's Exact tests are summarized in Table 3.

Within the three groups, grooming tactics were used the most in vigilante conversations. This was consistent for all tactics in Table 3. Most conversations with vigilantes included the use of all of the tactics in Table 3. *Willingness*, *discussion of phone calls*, and *reverse power* were used the least in LEO chats. *Sexual history*, *age difference*, and *compliments* were used the least in victim conversations.

LEO conversations tended to be short and often included a shift to talking in another app. Additionally, LEO responses to direct questions about meeting and sexual activities tended to be vague in comparison to vigilantes and real victims. The vagueness of the LEO responses may have resulted in the predator adjusting tactics.

We posit age difference and sexual history may be used less frequently in victim conversations because the victims often already knew the predator. The sexual history of the victim may already be known by the predator. This is likely the case with age difference as well. The victims and predators often appeared aware of the age gap but would not discuss it. In vigilante and LEO conversations, the conversations were with strangers. The participants would often give their age, sex, and location towards the beginning of the chat.

We originally posited LEO and vigilante conversations would be similar. Both vigilante and LEO groups consist of adults posing as children. Additionally, both groups receive some level of dedicated training on identifying predators. However, from Table 3 we see the groups differ in the tactics used. Some of these differences may be the result of the motivation of the LEO versus the vigilante and some may be a result of the differences in training. In the next section, we will discuss our qualitative observations which may contribute to differences in both how and how often the grooming tactics were used.

Qualitative Analysis

In addition to the analysis of chat length and tactic usage, we also qualitatively noted, and aggregated, annotator observations on language and conversational differences between the three groups. The differences we found between real victims and internet stings were the result of the LEOs and vigilantes attempting to make the predator state intentions explicitly and avoid sexual situations or meetings.

In many cases, individual lines taken out of context would appear innocuous. For instance, it is common for a predator to ask for images of a victim to get to know them and determine level of attraction. However, based on this exchange alone, it would not be possible to determine whether or not one of the participants were a predator. In these cases, LEOs and vigilantes would often ask clarifying questions to determine whether the request was for sexual or non-sexual pictures. At times, the LEOs or vigilantes would go as far as to describe the clothing they were wearing, such as making references to their pajamas, when the predator asked for pictures. We observed this as a priming technique to prompt the user to ask for more graphic images. Additionally, we found real victims were more likely to provide images while vigilantes and LEOs tended to ask clarifying questions around image requests.

Furthermore, it is also common for a predator to request images when attempting to determine if the other participant is an LEO instead of a minor (Kloess et al., 2019). In some cases, the predator will demand pictures taken immediately to ensure the participant is the person in the image.

From the chats we annotated, this appeared to occur more frequently in predator and vigilante chats than in underage victim chats. We hypothesize that the LEOs or vigilantes were being forward in a manner that sparked suspicion in the predator. Additionally, this was often triggered by another tactic in which the officer or vigilante would say they lied about their age in the profile and were actually younger. Statements like this did not occur in victim chats and seemed to cause suspicion and trigger risk assessment questions from the predator.

We also found direct and indirect communication styles used by the predator affected the three participant groups differently. Predators would often use expressions of vagueness about intentions to avoid explicitly stating an interest in sex. Further, we saw examples in which predators would not refer to sexual body parts or sexual acts directly, but instead would use euphemisms.

LEO and vigilantes would respond to vague responses about meetings, sexual intentions, and euphemisms by repetitively asking the predator what they meant or what they would do together. Additionally, the LEOs and vigilantes would act naïve and ask the predator to explain obvious references to body parts or sexual innuendos. We did not see this within underage victim chats. In real victim chats, the predators appeared to do the majority of the prompting related to sexual topics. We did not see much evidence of victims asking predators what they would do when they met. However, this was present in most vigilante and officer chats where meetings were discussed.

The greatest disparities between vigilantes and LEOs were within the *willingness* and *phone call* tactics. *willingness* to assess whether or not the vigilantes would engage in specific sexual activities during a physical meeting. In some instances, predators would also use *willingness* to get the other participant to agree to follow their instructions. We posit the difference in occurrence of the *willingness* tactic may be due to the responses given. Vigilantes and victims appear to respond more positively to *willingness* questions whereas LEOs tend to respond more vaguely. This may lead the predator to adjust tactics when speaking to LEOs.

Finally, LEOs and vigilantes used contrived situations to avoid undesired interactions or unplanned meetings with a predator. Such interactions included roleplaying, sending sexual images, or watching sexual activity on a webcam. Examples of avoidances used for undesirable interactions included an angry parent, a parent in the room, homework, a broken phone or camera, a broken internet connection, tiredness, or plans with friends. Avoidances of meetings were generally framed around other events preventing the meeting. For instance, if a predator wanted to meet the vigilante or LEO but the participant was not ready, the vigilante or LEO would claim to have family plans that were unavoidable. Avoidances were rarely used by underage victims.

3.7 Iterative Changes to Corpus

Neutering is a common strategy to handle disagreement and combine overlapping tactics, and refers to collapsing two or more tactics together in a code book (Hovy and Lavid, 2010). During the annotation process, we chose to neuter two sets of tactics: sexual stage and non-sexual stage; and relationship forming and exclusivity.

As described in 3.5, we treated the *sexual stage* and the *non-consensual sexual stages* as separate stages during annotator training. Following training, we neutered the stages into a single stage as the annotators often could not agree on what constituted an implied denial of an advance. Future research should investigate the possible presence of a *non-consensual sexual stage* where the victim implicitly or explicitly scorns advances.

Given the similarity between *relationship forming* and *exclusivity*, we also neutered these stages into a single stage. *Relationship forming* and *exclusivity* revolve around the construction of foundational trust between the predator and the victim (O'Connell, 2003). While relationship forming can be thought of as the day-to-day interactions, exclusivity revolves around language to intensify the relationship and isolate the victim from their support system (O'Connell, 2003).

In addition to neutering tactics within the code book, we added examples for each tactic. The original stages and tactics in the literature were designed from the perspective of the predator (Barber and Bettez, 2014), kloess2017qualitative, O'Connell. We annotated each of the tactics for all participants. We found the way LEOs, vigilantes, and underage victims used and responded to tactics differed from the predator. For instance, the predators used references to *age difference* to determine the level of comfort of the victim while LEOs used *age difference* to ensure the predator explicitly acknowledged the illegality of the solicitation. Further, underage victims would sometimes reference the age gap as a negative trait of themselves, almost as an insecurity. Having examples of uses of the tactics and stages by multiple types of participants helped the second annotator to generalize the tactics to all participants and not just predators.

4 Conclusion

NLP has contributed to research in the child exploitation domain by developing automated systems for detection of predators (Kim et al., 2020; McGhee et al., 2011; Zuo et al., 2018) and participants (Pendar, 2007). However, the corpora used for training the models are not representative of the criminals or victims involved in actual child exploitation cases (Bergen et al., 2013; Briggs et al., 2011; Chiang and Grant, 2019; DeHart et al., 2017; Gijn-Grosvenor and Lamb, 2016; Mitchell et al., 2005; Schneevogt et al., 2018; Winters et al., 2017). We offered an overview of the problems within the NLP corpora in the domain. We also discussed the impact these problems have on representing the online grooming process. Finally, we provided our methodology and recommendations from annotating a corpus of underage victim, vigilante, and LEO conversations and showed that there are statistical differences between the three groups. While NLP research within the child exploitation domain appears to be expanding, there is a need to ensure that corpora are designed and annotated in such a way that it contributes beneficial solutions.

Acknowledgments

We would like to thank the reviewers for their feedback and recommendations. Additionally, we would like to thank Lin Sun Fa for his assistance as the second annotator for this project.

Abstract

Sentiment lexicons are instrumental for sentiment analysis. One can use a set of sentiment words provided in a sentiment lexicon and a lexicon-based classifier to perform sentiment analysis. One major issue with this approach is that many sentiment words (from the lexicon) are domain dependent. That is, they may be positive in some domains but negative in some others. We refer to this problem as *domain polarity-changes of words* from a sentiment lexicon. Detecting such words and correcting their sentiment for an application domain is very important. In this paper, we propose a graph-based technique to tackle this problem. Experimental results show its effectiveness on multiple datasets from different domains.

1 Introduction

Sentiment words, also called opinion/polar words, are words that convey positive or negative sentiments (Pang and Lee, 2008). Such sentiment-bearing words are usually pre-compiled as word lists in a sentiment lexicon, which is instrumental as well as an important linguistic resource to sentiment analysis (Liu, 2012). So far, numerous studies about how to construct lexicons have been reported, which will be discussed in Section 2.

Despite the fact that there is extensive research on lexicon construction, limited work has been done to solve the problem of identifying and handling sentiment words in a given/constructed lexicon that have domain-dependent polarities. In real-life applications, there are almost always some sentiment words that express sentiments different from their default polarities provided in a general-purpose sentiment lexicon. For example, in the lexicon compiled by Hu and Liu (2004), the word "crush" is associated with a negative sentiment, but it actually shows a positive opinion in domain *blender* because "crush" indicates that a blender works well, e.g., in the sentence "it does crush the ice!". We call this problem *domain polarity-change* of a word in a sentiment lexicon.

The polarity change of words plays a crucial role in sentiment classification. As we will see in the experiment section, without identifying and correcting such domain dependent sentiment words, the performance of sentiment classification could be much poorer. Although some researchers have studied the domain-specific sentiment problem with lexicons, their focuses are quite different and their approaches are not suitable for our task. We will discuss them further in the following sections.

Regarding sentiment classification, it is important to note that our work mainly aims to help *lexicon-based approaches* (Taboada et al., 2011). It does not directly help machine-learning (ML) or supervised learning approaches (Zhang et al., 2018) because the domain-dependent polarities of words are already reflected in the manually labeled training data. Notice that for those ML approaches, the manual annotation for each application domain is required, which is a time-consuming and labor-intensive task, and is thus hard to scale up. In many real-world scenarios, lexicon-based approaches are useful and could be a better alternative (Liu, 2012).

However, to effectively apply a sentiment lexicon to an application domain, the domain-polarity change problem discussed above needs to be addressed. To this end, we propose a graph-based approach named Domain-specific Sentiment Graph (DSG) in Section 4. It works with three steps: (domain) sentiment word collection, (domain) sentiment correlation extraction, and graph construction and inference. Experimental results show its effectiveness in detecting domain polarity-changed words on multiple datasets. We will also see with the detection of those words, a huge performance gain can be achieved in sentiment classification.

2 Related Work

This work concerns domain polarity changes of words in lexicons. So we first discuss the works related to sentiment lexicons, and then domain sentiment, and finally domain sentiment with lexicons.

Extensive studies have been done for sentiment lexicons and the majority of them focus on lexicon construction. These approaches can be generally categorized as dictionary-based and corpus-based.

Dictionary-based approaches first used some sentiment seed words to bootstrap based on the synonym and antonym structure of a dictionary (Hu and Liu, 2004; Valitutti et al., 2004). Later on, more sophisticated methods were proposed (Kim and Hovy, 2004; Esuli and Sebastiani, 2005; Takamura et al., 2007; Blair-Goldensohn et al., 2008; Rao and Ravichandran, 2009; Mohammad et al., 2009; Hassan and Radev, 2010; Dragut et al., 2010; Xu et al., 2010; Peng and Park, 2011; Gatti and Guerini, 2012; San Vicente et al., 2014). Corpus-based approaches build lexicons by discovering sentiment words in a large corpus. The first idea is to exploit some coordinating conjunctions (Hatzivassiloglou and McKeown, 1997; Hassan and Radev, 2010). Kanayama and Nasukawa (2006) extended this approach by introducing inter-sentential sentiment consistency. Other related work includes (Kamps et al., 2004; Kaji and Kitsuregawa, 2006; Wang et al., 2017). The second idea is to use syntactic relations between opinion and aspect words (Zhuang et al., 2006; Wang and Wang, 2008; Qiu et al., 2011; Volkova et al., 2013). The third idea is to use word co-occurrences for lexicon induction (Turney and Littman, 2003; Igo and Riloff, 2009; Velikovich et al., 2010; Yang et al., 2014; Rothe et al., 2016).

However, our work is very different as we focus on detecting domain dependent sentiment words in a given general-purpose sentiment lexicon.

Also related is the existing research about domain and context dependent sentiment. First, despite the fact that several researchers have studied context dependent sentiment words, which are based on sentences and topic/aspect context (Wilson et al., 2005; Ding et al., 2008; Choi and Cardie, 2008; Wu and Wen, 2010; Jijkoun et al., 2010; Lu et al., 2011; Zhao et al., 2012; Kessler and Schütze, 2012; Teng et al., 2016; Wang et al., 2016, 2018a,b; Li et al., 2018a), our work is based on domains. Second, while the studies on transfer learning or domain adaptation for sentiment analysis deal with domain information (Bhatt et al., 2015; Yu and Jiang, 2016; Li et al., 2018b), our work does not lie in this direction. We do not have any source domain and our goal is not to transfer domain knowledge to another domain. Third, most importantly, the above works are either irrelevant to lexicons or not for detecting the sentiment discrepancy between a lexicon and the application domain.

Our work is most related to the following studies that involve both sentiment lexicons and domain sentiment problems. Choi and Cardie (2009) adapted the word-level polarities of a general-purpose sentiment lexicon to a particular domain by utilizing the expression-level polarities in that domain. However, their work targeted at reasoning the sentiment polarities of multi-word expressions. It does not detect or revise the sentiment polarities of individual words in the lexicon for a particular domain, and hence, cannot solve our problem. Du et al. (2010) studied the problem of adapting the sentiment lexicon from one domain to another domain. It further assumes that the source domain has a set of sentiment-labeled reviews. Their technique is therefore more about transfer learning and their learning settings differ from ours intrinsically. (Ortiz, 2017) designed a sentiment analysis application that allows plugin lexicons (if users can provide them) to help predict domain sentiment. It neither detects nor corrects domain polarity-changed words. Perhaps, the most related work is (Hamilton et al., 2016), which uses seed lexicon words, word embeddings, and random walk to generate a domain-specific lexicon. However, their model is for lexicon construction in essence, by (its capability of) functioning on a domain-oriented corpus. It does not aim to detect/change the sentiment polarity from a given lexicon. It is thus not directly applicable to our task. To make it workable for our task, we design a two-step approach, which will be detailed in the experiment section (Section 5).

To the best of our knowledge, this is the first study to detect domain polarity-changes of words in a sentiment lexicon. We will further discuss why this task is important and useful in Section 5.7.

3 Problem Definition

Given a general-purpose sentiment lexicon L (which contains sentiment words and their default polarities) and an application domain review corpus D, the goal (or the task of detecting domain polarity changes of words) is to identify a subset of words in L that carry different sentiment polarities in that domain (different from their default polarities), which we call *domain polarity-changed (lexical*[1]*) words* and denote them as C ($C \subseteq L$).

4 Proposed Solution

To tackle the above problem, we propose a graph-based learning approach named Domain-specific Sentiment Graph (DSG). It works with three major steps: (1) (domain) sentiment word collection, (2) (domain) sentiment correlation extraction, and (3) graph construction and inference.

Specifically, it first collects a set of mentioned sentiment words S ($L \subseteq S$) in the domain corpus D. It then mines multiple types of relationships among sentiment words in S, which are denoted as a relationship set R. The relationships are identified based on different types of linguistic connectivity. Next, it builds a probabilistic graph with each node representing a sentiment word in S and each edge representing a relation (from R) between two words. An inference method is then applied to re-estimate the domain-specific polarities (or beliefs) of sentiment words. With the re-estimated beliefs obtained in the application domain, those sentiment words with changed polarities can be detected, by measuring the sentiment shift of a lexical word between its induced (in-domain) sentiment belief and its original (lexicon-based) polarity.

In this learning manner, the proposed approach requires no prior knowledge or annotated data for a particular domain. It is thus applicable to multiple/different domains. Intuitively, this approach works based on two assumptions:

Assumption 1: Sentiment Consistency (Abelson, 1983; Liu, 2012): a sentiment expression tends to be sentimentally coherent with its context. Notice that sentiment consistency can be reflected in multiple types of conjunction like "and", "or", etc., which will be explained in Section 4.2. In fact, this assumption is common in sentiment analysis and has been used in many studies (Kanayama and Nasukawa, 2006; Hassan and Radev, 2010)

Assumption 2: The number of domain polarity-changed lexical words[1] is much smaller than the number of those (words) whose polarities do not change. This assumption ensures that we can rely on the general-purpose lexicon itself for detection[1]. In other words, the real polarity of a sentiment word in a certain domain can be distilled by its connections with other (mostly polarity-unchanged) words whose polarities are known from the lexicon.

4.1 Sentiment Word Collection

As the first step, DSG collects sentiment words in an application domain corpus, including the sentiment words not present in a lexicon. Specifically, we consider three types of (likely) sentiment words: (1) The word appears in a given lexicon. (2) The word is an adjective in the corpus. (3) The word is an adverb in the corpus and has an adjective form.

We simply accept all lexical words and adjective words as (likely) sentiment words, which does not cause serious problems in our experiments and they were also commonly used in the literature (Liu, 2012). However, we impose constraints on selecting adverbs. While adverbs like "quickly" and "nicely" do express sentiment, some others like "very" and "often" may not function the same. We thus use the adverbs having adjective forms only.

Notice that in the above setting, the sentiment words not present in the lexicon are also collected due to two reasons: first, they are useful for building connection among other lexical words for inference purposes. Suppose that "quick" is a sentiment word (found because it is an adjective) and it is not in the given lexicon. Given its sentiment correlations with other words like "efficient and quick" and "quiet and quick", it can make a path between "efficient" and "quiet" in the graph. Second, in each domain there exist a number of sentiment words uncovered by the given lexicon. Their inferred polarities can also benefit the graph reasoning process, though those words are not the focus of detection in this study (we aim at detecting the polarity change of lexical words, i.e., words from a given lexicon). For instance, if the non-lexical word "quick" is identified as expressing positive sentiment (in the application domain) , "efficient" and "quiet" are more likely to be positive as well, given their in-domain sentiment correlations. We follow (Das and Chen, 2007; Pang and Lee, 2008) to handle the negation problem, where a negation word phrase like "not bad" will be treated as a single word like "not_bad" and its sentiment polarity will be reversed accordingly. Finally, all extracted words are modeled as nodes in the graph.

4.2 Sentiment Correlation Extraction

This step is to extract multiple types of conjunction relationship among sentiment words, which

---

[1] In this paper, we call the words in a given lexicon *lexical words* for short. The term *detection* will generally stand for the detection of domain polarity-changes of (lexical) words.

we refer to as *sentiment correlation*[2]. The key idea here is to use the sentiment consistency (Abelson, 1983; Liu, 2012) (see Assumption 1) for relationship construction among the collected sentiment words from the above step. Specifically, in an application domain, five types of sentiment correlation are considered, each of which is presented in a triple format, denoted as ($word_1$, correlation type, $word_2$). They will be further used in the graph inference process (discussed in the next sub-section). Their definitions are shown in Table 1.

In each sentence, when a specific type of relationship between two (collected) sentiment words is found, a triple is created. For instance, in the sentence "it is efficient and quiet", a triple (efficient, AND, quiet) will be generated. The extraction of OR sentiment correlation is similar to AND. Likewise, a specific BUT triple (powerful, BUT, noisy) will be extracted from the sentence "it is a powerful but noisy machine". The extraction of ALT (abbreviation for although) is similar to BUT. NB means two neighboring sentiment words occur in a sentence, like "reasonably good".

Notice that while five types of relationships are jointly considered, they are associated with different agreement levels (parameterized in the graphical model discussed below). Here the agreement level measures how likely the sentiment polarities of two connecting words are the same. Intuitively, we believe AND gives the highest-level agreement. For instance, "bad and harmful" is very common but "good and harmful" is much unlikely. It is also an intuitive belief that BUT indicates the strongest disagreement between two sentiment words. Note that we only consider pairwise relationships between sentiment words in this study, which already achieve reasonably good results, as we will see.

4.3 Graph Construction and Inference

This subsection presents how our proposed domain-specific sentiment graph is used for detecting polarity-changed words after the above two steps.

4.3.1 Constructing Markov Random Field

Markov Random Fields (MRFs) are a class of probabilistic graphical models that can deal with the inference problems with uncertainty in observed data. An MRF works on an undirected graph G, which is constructed by a set of vertexes/nodes V and edges/links E and denoted as $G = (V, E)$. In the graph G, each node $v_i \in V$ denotes a random variable and each edge $(v_i, v_j) \in E$ denotes a statistical dependency between node v_i and node v_j. Formally, $\psi_i(v_i)$ and $\psi_{ij}(v_i, v_j)$ are defined as two types of potential functions for encoding the observation (or *prior*) of a node and the dependency between two nodes, also called *node potential* and *edge potential* respectively. An MRF thus can model a joint distribution for a set of random variables and its aim is to infer the marginal distribution for all $v_i \in V$. With an inference method used, the estimation of the marginal distribution of a node can be obtained, which is also called *belief*.

The reason why we formulate our domain-specific sentiment graph as an MRF is three-fold: (1) The sentiment correlation between two words is a mutual relationship, as one word w_a can provide useful sentiment information to the other word w_b and vice versa, which can be properly formulated in an undirected graph. (2) From a probabilistic perspective, the polarity changes of sentiment words can be naturally understood as the belief estimation problem. That is, on one hand, we have an initial belief about the polarity of a lexical word (known from the lexicon, like the word "cold" is generally negative), which is essentially the prior. On the other hand, our goal is to infer the real polarity of a word in a specific application domain, which is reflected in its final estimated belief (like "cold" is positive in the domain *fridge*). Concretely, the polarity of a sentiment word is modeled as a 2-dimensional vector, standing for the probability distribution of positive and negative polarities, e.g., $[0.9, 0.1]$ indicates that a word is very likely to express a positive sentiment in an application domain. We can further use p as the parameter to simplify the representation as $[p, 1-p]$. (3) Recall that multiple types of sentiment correlation are used and treated differently in our proposed approach. These *typed sentiment correlations* can be encoded in the MRF model (will be further illustrated below).

4.3.2 Inference over Typed Correlation

As discussed above, the inference task in MRF is to compute the marginal distribution (or posterior probability) of each node given the node prior and edge potentials. Efficient algorithms for exact inference like Belief Propagation (Pearl, 1982) are available for certain graph topologies, but for general graphs involving cycles the exact inference is computationally intractable. Approximate inference is

---

[2] The term *sentiment correlation* used in this paper denotes the correlation between two sentiment words in a domain, which may not have to be the same as used in other studies.

Name	Correlation	Example	Representation	Agreement Level
AND	connecting with "and"	"it is efficient and quiet"	(efficient, AND, quiet)	Strongly Agree
OR	connecting with "or"	"everything as expected or better"	(expected, OR, better)	Agree
NB	neighboring words	"a reasonably quiet fridge"	(reasonably, NB, quiet)	Weakly Agree
ALT	although, though	"too noisy, though it is efficient"	(noisy, ALT, efficient)	Disagree
BUT	but, however	"it is a powerful but noisy machine"	(powerful, BUT, noisy)	Strongly Disagree

Table 1: Five types of sentiment correlation.

thus needed. Loopy Belief Propagation (Murphy et al., 1999) is such an approximate solution using iterative message passing. A message from node i to node j is based on all message from other nodes to node i except node j itself. It works as:

$$m_{i\to j}(x_j) = z \sum_{x_i \in S} \psi_{i,j}(x_i, x_j)\psi_i(x_i) \prod_{k\in N(i)\backslash j} m_{k\to i}(x_i) \tag{1}$$

where S denotes the possible states of a node, i.e., being a sentiment word with positive or negative polarity. x_j indicates that node j is in a certain state. $N(i)$ denotes the neighborhood of i, i.e., the other nodes linking with node i. $m_{i\to j}$ is known as the message passing from node i to node j. z is the normalization constant that makes message $m_{i\to j}(x_j)$ proportional to the likelihood of the node j being in state x_j, given the evidence from i in its all possible states. After iterative message passing, the final belief $b_i(x_i)$ is estimated as:

$$b_i(x_i) = z'\psi_i(x_i) \prod_{k\in N(i)} m_{k\to i}(x_i) \tag{2}$$

where z' is a normalization term that makes $\sum_{x_i} b_i(x_i) = 1$. In this case, $b_i(x_i)$ can be viewed as the posterior probability of a sentiment word being with positive or negative polarity.

However, notice that in the above setting, each edge is not distinguishable in terms of its type of sentiment correlation. In other words, each type of possible connections between words is treated intrinsically the same, which does not meet our modeling requirements. In order to encode the typed sentiment correlation as defined in previous sections, we propose to replace the Eq. 1 with:

$$\begin{aligned} m_{i\to j}(x_j) =& z \sum_{x_i\in S} \sum_{r_{i,j}\in R} \psi_{i,j,r_{i,j}}(x_i, x_j) \\ & \psi_i(x_i) \prod_{k\in N(i)\backslash j} m_{k\to i}(x_i), \end{aligned} \tag{3}$$

where $r_{i,j} \in R$ indicates the specific type of sentiment correlation between node i and node j, which can be any type like AND or NB as defined in Section 4.2. $\psi_{i,j,r_{i,j}}(x_i, x_j)$ thus becomes an edge potential function related to its sentiment correlation type. Each type of a correlation is parameterized as a (state) transition matrix shown in Table 2. The five types of sentiment correlation therefore result in five such tables/matrices but with different ϵ being set. For example, ϵ with AND can be set to 0.3 as it indicates the highest agreement level, while the one with NB can be set to 0.1 as it is regarded as weakly agreement. For BUT, ϵ can be set to -0.3 as it shows strong disagreement.

State	Positive	Negative
Positive	$0.5 + \epsilon$	$0.5 - \epsilon$
Negative	$0.5 - \epsilon$	$0.5 + \epsilon$

Table 2: Transition/Propagation matrix.

For each word, with its estimated beliefs $[b^+, b^-]$ obtained in the application domain, its *polarity change score (pcs)* is defined as:

$$pcs = I(l = +)b^- + I(l = -)b^+ \tag{4}$$

where l denotes the original sentiment polarity of a lexical word (known from the given lexicon), and $I(.)$ is an indicator function. According to the resulting scores of all words, a word list ranked by *pcs* is used to identify the most likely polarity-changed sentiment words, e.g., one can select the top n words or set a threshold for word extraction. In this way, the sentiment words with changed polarities in an application domain can be detected.

4.4 An Illustrating Example for DSG

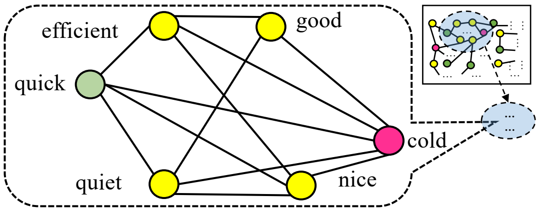

Figure 1: DSG Example. The nodes in pink (or darkest in grayscale) like "cold" represent the polarity-changed words in a domain, while nodes in yellow (or lightest) like "nice" indicate polarity-unchanged words, and nodes in green like "quick" denote non-lexical words.

Figure 1 provides an example to illustrate how DSG works in domain *fridge*. It shows a subgraph with several nodes, such as "quick", "nice", and "cold", representing the words extracted from step 1. The links between them represent their sentiment correlation as discussed in step 2. With the inference performed in step 3, "cold" is detected as a polarity-changed word (e.g., with a high pcs value 0.9 inferred), where its sentiment information is estimated by the (sentiment) message passing from other nodes in the graph. Specifically, in the *fridge* domain, through sentences like "looks nice and quiet", "it is quiet and cold", and "nice to have a quick cold beer or soda" (from the fridge), positive sentiment is directly or indirectly propagated from the words/nodes "nice", "quiet", "quick" to "cold" with their (typed) connections. Therefore, while "cold" was assigned a negative prior $[0.0, 1.0]$ (by default negative in the given lexicon), through the in-domain sentiment inference its final estimated belief becomes $[0.9, 0.1]$, resulting a high pcs score ($psc = 0.9$ by Eq. 4). "cold" is thus detected.

5 Experiments

We conducted experiments on multiple datasets with several candidate solutions. Here we first compare their performance on the word detection task. Sentiment classification will then be another task to evaluate their effect on polarity correction.

5.1 Experimental Setup

Dataset. Four real-world datasets from different domains/products were used, namely, *fridge*, *blenders*, *washer*, and *movie*. The first three datasets contain review sentences of these products. The fourth dataset (*movie*) consists of tweets from Twitter discussing movies. All these datasets are collected by us. The first dataset contains around 36,000 (36k) sentences, the second 16,000 (16k) sentences, and the rest datasets 10,000 (10k). Their sizes can be viewed as large, medium, and small. Such product diversity and variable size settings help evaluate the generality of each solution. Note that only the text is used by all candidate models.

In addition, two other datasets from domains *drill* and *vacuum cleaner* are used as development sets for hyper-parameter selections. *drill* contains 76k and *vacuum cleaner* contains 9k sentences.

Sentiment Lexicon. We used a general-purpose sentiment lexicon from (Hu and Liu, 2004), which contains 2,006 positive and 4,783 negative lexical words. A candidate model will find polarity-changed words from them for each domain/dataset.

Parameter Settings. The hyper-parameters of state priors and the (typed) transition matrices in DSG are shown in Table 3 and 4. They were empirically set based on the word detection performance on the two development datasets. We found this parameter setting works generally well on both datasets, while they are from different domains and with different data sizes. The following reported results for evaluations are based on this setting and as we will see, it already produces quite good results.

Prior	Positive	Non-lexical Words	Negative
$p\ in\ \psi_i(v_i)$	0.70	0.50	0.30

Table 3: Parameters of state prior.

Types	AND	OR	NB	ALT	BUT
ϵ **in** $\psi_{i,j}(v_i, v_j)$	0.20	0.10	0.05	-0.10	-0.20

Table 4: Parameters of typed transition matrix.

5.2 Lexicon-based Sentiment Classifier

Our evaluations include lexicon-based sentiment classification. We briefly illustrate how a lexicon-based sentiment classifier (called *classifier* for short) works here. Clearly, it works with a lexicon, from which each word is associated with a sentiment score (e.g., -1/+1). The classifier then calculates the sentiment score s of each sentence t by summing the score of each word. We follow the lexicon-based classifier design in (Taboada et al., 2011), incorporating sentiment negation and intensity. The sentence sentiment score s is calculated:

$$s = \sum_{w \in t} negation(w) * intensity(w) * polarity(w) \quad (5)$$

where w denotes a word in sentence t. A sentence is classified as positive if the resulting score s is greater than or equal to zero, otherwise negative.

Different lexicons working with this classifier will generate different results. That is, even if their lexical words are the same, the associated sentiment score of a lexical word could vary and Eq. 5 will thus make different predictions. This is how we can utilize the classifier to verify the effect of the word detection, because the classifier will perform differently using the original lexicon and the modified lexicon, whose results can be compared in a *before-and-after* manner. Here the *modified lexicon* means the sentiment polarities of (detected) lexical words are corrected from the original lexicon. For example, "crush" is associated with negative sentiment (-1) in the original lexicon, but it could be associated with positive sentiment (+1) in the modified lexicon (if detected). So the sentence-level sentiment scores will vary accordingly, e.g., "the machine does crush ice!" will be predicted as a positive sentence with the modified lexicon.

5.3 Candidate Models

Original Lexicon (OL): This is a baseline for sentiment classification evaluations only (Section 5.5), which uses the classifier with the original lexicon.
Domain-specific Sentiment Graph (DSG): This is our proposed model introduced in the previous sections. The following two models and DSG will be used for both word detection and classification.
Lexicon-Classifier Inconsistency (LCI): This is a heuristic solution to detecting the polarity-changed sentiment words. It relies on the inconsistency between the sentiment of a lexical word (obtained from the original lexicon) and the sentiment of the sentences containing the word (induced by the classifier). Concretely, it first calculates the sentiment polarities of all sentences using a classifier with the original lexicon. With the polarities of sentences known, it computes an inconsistency ratio for each lexical word. The inconsistency ratio is the ratio of (a) to (b), where (a) is the number of a word appearing in the positive/negative sentences but the word itself is negative/positive, and (b) is the number of all sentences covering that word. Finally, it ranks all lexical words based on their ratio values to produce a list of likely polarity-changed words.
SentProp (SP): SentProp (Hamilton et al., 2016) is a lexicon construction algorithm concerning domain sentiment, which is the most related work to ours. As discussed in Section 2, it is not directly applicable to the detection task. But since it can generate a list of domain-specific sentiment words and those words are associated with positive/negative scores (estimated by SentProp, which can be treated as the in-domain beliefs like DSG), we can design a two-step approach to achieve our goal. First, we download[3] and run the SentProp system to learn the domain-specific lexicon for each domain. Second, we calculate the polarity change scores for all lexicon words like DSG based on the learned domain-specific sentiment scores and the original polarities from the lexicon using Eq. 4. Similar to DSG, it produces a list of words ranked by the polarity change scores (pcs). For its parameter selection, we tried both the system default, following the code instruction and the original paper, and parameter fine-tuning based on the performance on two development sets (same as DSG), so as to achieve its best performance to report.

5.4 Correct Detection of Words

As each candidate model generates a list of words ranked by polarity-change scores, those top-ranked ones are the most likely polarity-changed words and can be used as the detected words. For evaluation, the top-n words from each model are inspected and the number of correct (word) detection is counted, which is denoted as **#C@n** in Table 5.

Specifically, two domain experts who are familiar with the domain sentiments identify and annotate the correct polarity-changed words from the top-20 shortlisted candidate words generated by each model. For each candidate word, we sampled numbers of sentences containing that word for the domain experts to judge. A candidate word needs to be agreed upon by both of them to be correct. Here the Cohen's Kappa agreement score is 0.817.

Model	#C@n	fridge	blender	washer	movie
DSG	#C@5	5	5	4	5
	#C@10	9	10	6	9
	#C@20	12	15	12	15
LCI	#C@5	3	3	3	1
	#C@10	5	3	5	4
	#C@20	5	7	7	9
SP	#C@5	1	0	1	1
	#C@10	2	0	2	4
	#C@20	3	3	3	6

Table 5: Detection of polarity-changed words.

Evaluation results are reported in Table 5, where we can see that DSG achieves outstanding results consistently. LCI also does a decent job, while SP does not perform well on this task.

Next, we will evaluate the impact of such detection from their top 20 words, and the following sub-sections are based on their correctly detected words to give further analyses.

5.5 Sentiment Classification

After the detection of polarity-changed words, we conduct classification tasks on the sentences containing at least one word from the detected words of all models. Because the classification results on the sentences that without containing any detected word would not be affected (same prediction results using either the original or modified lexicon).

For evaluation, we sampled and labeled 925 (around 1k) sentences, from all sentences that could be affected. We used a stratified sampling strategy

---

[3] https://nlp.stanford.edu/projects/socialsent/

and set the minimum number of sentences contained by each word, to make sure each detected word is considered. The numbers of labeled sentences for the four domains are 232, 214, 174, and 305. The Cohen's Kappa agreement score is 0.788.

In regard to the lexicon-based classification, for DSG and LCI, the modified lexicon for each domain is based on the correction of the original lexicon (OL) on that domain. For SP, its self-generated lexicon is used with its inferred sentiment scores.

Model	fridge	blender	washer	movie	AVG
DSG	**74.56%**	**80.84%**	**77.01%**	84.91%	**79.33%**
SP	68.10%	78.97%	66.67%	**87.87%**	75.40 %
LCI	61.63%	68.22%	62.64%	62.95%	63.86%
OL	61.20%	65.42%	62.06%	56.72%	61.35%

Table 6: Sentiment classification accuracy.

Table 6 reports the classification accuracy, from which we have the following observations:

1. Compared to the baseline using the original lexicon (OL), DSG greatly improves the accuracy by 17.98% on average (AVG). We can see the usefulness of detecting polarity change of lexical words for sentiment classification.
2. SP also produces very good results. The reason is, as a lexicon-generation approach (essentially), SP itself creates a bigger lexicon for each domain (around 2 times bigger than OL), including additional sentiment words outside the original lexicon. In other words, discovering more sentiment words (with more sentiment clues provided) could also help better classification. Note that this does not contradict the importance of detecting polarity-change words, as they are two different aspects, which will be discussed in Section 5.7.
3. LCI outperforms OL but its performance gain is small. The reason is, though LCI detects polarity changed words decently, its detected words affect a much smaller number of sentences compared to the ones from DSG and SP, i.e., the words LCI detects are rarer and less frequent, with fewer sentences being affected.

5.6 Example Results

blender	movie
frozen shake cheap crushing	despicable fucking complex
breaks crush lost destroy	insanely damn *sad* crazy
loose crushed breaking	intense funny freaking *creepy*
broken lose grind *clog bulky*	bloody crap shit bad *retarded*
kills wobbled bitter shocked	*mad* insane terribly *eccentric*

Table 7: Example results on *blender* and *movie*. Incorrectly detected words are italicized and marked in red.

Here we show some example results. Table 7 lists the top polarity-changed words detected by DSG on domains *blender* and *movie*; we will explain how they benefit the domain sentiment analysis with example sentences. Below, an underlined word in an example sentence indicates its polarity has changed in a certain domain. In domain *blender*, the words like "crushing" and "breaks" express positive sentiments in "good for crushing ice" and "this breaks down frozen fruit", while they are provided as negative words in the original lexicon. With the detection and correction of those words, their domain-specific sentiments are identified correctly as positive and thus make the classification correct (through the modified lexicon provided by DSG). In domain *movie*, we found that many negative lexical words are in fact commonly used by users to show their love for a movie. For instance, "damn, I wanna watch this movie so bad" and "this movie was insanely brilliant". Similarly, for other domains, we also found "it keeps foods cold and frozen" in *fridge*, "you can also delay your cycle" in *washer*, and "it sucked very well" in *vacuum cleaner*. DSG also detects those words.

5.7 Further Analysis and Discussion

We aim to answer two questions here. Q1: What is the key difference between using SP and DSG? Q2: More generally, what is the relationship between the existing lexicon generation research and the polarity-change detection problem (which is studied in this work)?

First, let us dive a bit deeper into SP. As a lexicon generation approach, its goal is to collect sentiment words from a given corpus and infer their sentiment scores. There are two important notes: (a) while SP could discover more sentiment words, those extracted words could be wrong. For example, SP extracts the word "product" as a sentiment word and assigns it a positive (+ve) sentiment. This could lead to mis-classifications of the negative (-ve) sentences containing "product". (b) while SP directly discovers and estimates sentiment words, it does not know which sentiment words carry important domain-shifted sentiment. For example, SP discovers "excellent", "crush", "terrible" for the domain *blender* and estimates the sentiment scores as 0.9, 0.7, and 0.1 (for simplicity, let us assume all scores are rescaled to [0.0, 1.0], where 1.0 denotes most

+ve and 0.0 most -ve). Those scores indicate their polarities, but do not reflect their importance/effect of polarity change towards that domain.

For DSG, (a) could be avoided because "product" is usually excluded in a general-purpose lexicon. Regarding (b), say the scores of "excellent", "crush" and "bad" are 1.0, 0.0, and 0.0 in the original lexicon; with the domain sentiment re-estimation from DSG, they become 0.9, 0.7, and 0.1. Their polarity-changed scores are thus inferred as 0.1 ($|1.0 - 0.9|$), 0.7, and 0.1, where "crush" can be found as an important domain-sentiment changed word (0.7).

Certainly, one can compare the SP generated lexicon to the original/general lexicon to detect the changes. We already did this for the detection task (Table 5). Here we design a variant SP-dsg-like, following this idea to perform the sentiment classification task. The main difference between SP and SP-dsg-like is that SP directly uses its generated lexicon and sentiment scores, while SP-dsg-like uses its generated lexicon to modify the original lexicon (OL) like DSG does. However, SP-dsg-like performs poorly (Table 8), mainly because the modified lexicon (based on OL) does not fully reflect the whole sentiment words generated by SP.

Model	fridge	blender	washer	movie	AVG
OL	61.20%	65.42%	62.06%	56.72%	61.35%
SP	68.10%	78.97%	66.67%	87.87%	75.40%
SP-dsg-like	67.67%	71.02%	64.36%	63.93%	66.75%
SP-dsg-like+SP	69.40%	77.57%	68.97%	83.28%	74.81%
OL + SP	62.07%	78.04%	70.11%	82.30%	73.13%
CLI + SP	62.07%	77.57%	70.67%	83.61%	73.48%
DSG + SP	**72.41%**	**78.97%**	**79.89%**	**88.85%**	**80.03%**

Table 8: Sentiment classification accuracy.

We then combine two lexicons together to give another variant SP-dsg-like+SP, which means the modified lexicon (based on OL) is expanded by the SP self-generated lexicon, where the SP generated lexicon can contain additional sentiment words (outside OL). Similarly, we can make OL+SP and CLI+SP, but they are all inferior to SP (Table 8). The reason is that the key polarity-changed words in the original lexicon have not been corrected, keeping their wrong sentiments for classification.

However, notice that DSG can effectively detect and correct those words; when we use DSG+SP, the overall results are improved (AVG) and even better than using DSG or SP only (Table 8 and Table 6).

It has been shown that either getting more sentiment words (from SP) or fixing a smaller number of important polarity-changed words (from DSG) can help sentiment classification (Table 6). With DSG+SP working even better, we can view the lexicon generation and the domain polarity-changed (lexical) word detection as two directions for classification improvement. Either one has its own advantage. Lexicon generation methods can induce more words and may help find rarer/infrequent words. The domain polarity-changed lexical word detection can be handy and less risky, as it directly corrects the polarities of important lexical words and would not induce noises (wrong sentiment words).

Finally, the answers to Q1 and Q2 are: using SP/lexicon-generation and DSG/polarity-change-detection can both improve sentiment classification, but in different manners (i.e., two directions as discussed above). Besides, using DSG can effectively detect important polarity-changed words, while SP does not perform very well on this task. These two directions could be complementary, as indicated by DSG+SP. Note that in this work we have shown that incorporating the DSG corrected lexical words (i.e., DSG modified lexicon) into SP can help boost its performance, which can be viewed as injecting clean/reliable domain sentiment knowledge. Another possible enhancement as future work is that, for the additional (non-lexical) sentiment words found by SP (or other domain lexicon generation method), we can use DSG to detect and correct their changed/shifted polarity in domains. However, for that, we will also need to deal with the induced noise (newly identified but wrong sentiment words like "product"), perhaps with some denoising or pruning techniques. We also hope this work and its findings can inspire more future work.

6 Conclusion

This paper studied the problem of detecting domain polarity-changed words in a sentiment lexicon. As we have seen, the wrong polarities seriously degenerate the sentiment classification performance. To address it, this paper proposed a novel solution named Domain-specific Sentiment Graph (DSG). Experimental results demonstrated its effectiveness in finding the polarity-changed words and its resulting performance gain in sentiment classification.

Abstract

Online political advertising is a central aspect of modern election campaigning for influencing public opinion. Computational analysis of political ads is of utmost importance in political science to understand the characteristics of digital campaigning. It is also important in computational linguistics to study features of political discourse and communication on a large scale. In this work, we present the first computational study on online political ads with the aim to (1) infer the political ideology of an ad sponsor; and (2) identify whether the sponsor is an official political party or a third-party organization. We develop two new large datasets for the two tasks consisting of ads from the U.S.. Evaluation results show that our approach that combines textual and visual information from pre-trained neural models outperforms a state-of-the-art method for generic commercial ad classification. Finally, we provide an in-depth analysis of the limitations of our best-performing models and linguistic analysis to study the characteristics of political ads discourse.[1]

1 Introduction

Online advertising is an integral part of modern digital election campaigning (Fulgoni et al., 2016; Fowler et al., 2020a). The increased spending on online political ads (e.g. the 2020 U.S. election campaign spending hit an all-time record[2]) poses a significant challenge to the democratic oversight of digital campaigning,[3] with serious implications about transparency and accountability, for example how voters are targeted and by whom (Kriess and Barrett, 2020).

Political advertising is defined as *'any controlled message communicated through any channel designed to promote the political interests of individuals, parties, groups, government, or other organizations'* (Kaid and Holtz-Bacha, 2006). It is guided by ideology and morals (Scammell and Langer, 2006; Kumar and Pathak, 2012), and often expresses more negativity (Haselmayer, 2019; Iyengar and Prior, 1999; Lau et al., 1999) compared to the aesthetic nature of commercial advertising. Table 1 shows examples of online political ads across different political parties and sponsor types.

While the closely related online *commercial* advertising domain has recently been explored in natural language processing (NLP) for predicting the category (e.g. politics, cars, electronics) and sentiment of an ad (Hussain et al., 2017; Kalra et al., 2020), online *political* advertising has yet to be explored. Large-scale studies of online political advertising have so far focused on understanding targeting strategies rather than developing predictive models for analyzing its content (Edelson et al., 2019; Medina Serrano et al., 2020).

Automatically analyzing political ads is important in political science for researching the characteristics of online campaigns (e.g. voter targeting, sponsors, non-party campaigns, privacy, and misinformation) on a large scale (Scammell and Langer, 2006; Johansson and Holtz-Bacha, 2019). Moreover, identifying ads sponsored by third-party organizations is critical to ensuring transparency and accountability in elections (Liu et al., 2013; Speicher et al., 2018; Fowler et al., 2020b; Edelson et al., 2019). For example, third-party advertising had an increased presence in the U.S. House and Senate races in 2018 considerably more than in 2012 where almost half of the third-

Political Ideology	Ad Sponsor Type	Sample Ad
Liberal	Political Party	Conservative	Political Party	N/A	Third-Party	

Table 1: Examples of online political ads by sponsor political ideology and type.

party sponsored ads were funded by dark-money sources (Fowler et al., 2020b). Finally, computational methods for political ads analysis can help linguists to study features of political discourse and communication (Kenzhekanova, 2015; Skorupa and Dubovičienė, 2015).

In this paper, we present a systematic study of online political ads (consisting of text and images) in the U.S. to uncover linguistic and visual cues across political ideologies and sponsor types using computational methods for the first time. Our contributions are as follows:

1. A new classification task for predicting the political ideology (conservative or liberal) of an ad (§3). We collect 5,548 distinct political ads in English from 242 different advertisers in the U.S., and label them according to the dominant political ideology of the respective sponsor's party affiliation (*Liberal* or *Conservative*);

2. A new classification task to automatically classify ads that were sponsored by official political parties and third-party organizations, such as businesses and non-profit organizations (§3). For this task, we extract 15,116 advertisements in English from 665 distinct advertisers in the U.S., and label them as *Political Party* (i.e. officially registered) and *Third-Party* (i.e. other organizations) following Fowler et al. (2020b);

3. Experiments with text-based and multimodal (text and images) models (§4) for political ideology prediction and sponsor type classification reaching up to 75.76 and 87.36 macro F1 in each task respectively (§6);

4. Analysis of textual and visual features of online political ads (§7) and error analysis to understand model limitations.

2 Related Work

2.1 Political Communication and Advertising

Previous work on analyzing political advertising has covered television and online ads (Kaid and Postelnicu, 2005; Reschke and Anand, 2012; West, 2017; Fowler et al., 2020b). Ridout et al. (2010) analyze a series of YouTube videos posted during the 2008 presidential campaign to understand its influence on election results as well as the actors and formats compared to traditional television ads. Anstead et al. (2018) study how online platforms such as Facebook are being used for political communication and identify challenges for understanding the role of these platforms in political elections, highlighting the lack of transparency (Caplan and Boyd, 2016). Fowler et al. (2020b) explore differences between television and online ads, and demonstrate that there is a greater number of candidates advertising online than on television.

2.2 Political Ideology Prediction

Inferring the political ideology of various types of text including news articles, political speeches and social media has been vastly studied in NLP (Lin et al., 2008; Gerrish and Blei, 2011; Sim et al., 2013; Iyyer et al., 2014; Preoţiuc-Pietro et al., 2017; Kulkarni et al., 2018; Stefanov et al., 2020). Bhatia and P (2018) exploit topic-specific sentiment analysis for ideology detection (i.e. conservative, liberal) in speeches from the U.S. Congress. Kulkarni et al. (2018) propose a multi-view model that incorporates textual and network information to predict the ideology of news articles. Johnson and Goldwasser

(2018) investigate the relationship between political ideology and language to represent morality by analyzing political slogans in tweets posted by politicians. Maronikolakis et al. (2020) present a study of political parody on Twitter focusing on the linguistic differences between tweets shared by real and parody accounts. Baly et al. (2019) estimate the trustworthiness and political ideology (left/right bias) of news sources as a multi-task problem. Stefanov et al. (2020) develop methods to predict the overall political leaning (left, center or right) of online media and popular Twitter users.

Political ideology and communicative intents have also been studied in computer vision. Political images have been analyzed to infer the persuasive intents using various features such as facial display types, body poses, and scene context (Joo et al., 2014; Huang and Kovashka, 2016; Joo and Steinert-Threlkeld, 2018; Bai et al., 2020; Chen et al., 2020). Joo et al. (2015) introduce a method that infers the perceived characteristics of politicians using face images and show that those characteristics can be used in elections forecasting. Xi et al. (2020) analyze the political ideology of Facebook photographs shared by members of the U.S. Congress. Chen et al. (2020) examine the role of gender stereotypical cues from photographs posted in social media by political candidates and their relationship to voter support.

2.3 Computational Analysis of Online Ads

Hussain et al. (2017) propose the task of ad understanding using vision and language. The aim is to predict the topical category, sentiment and rhetoric of an ad (i.e. what the message is about). The latter task has been approached as a visual question-answering task by ranking human generated statements that explain the intent of the ad in computer vision (Ye and Kovashka, 2018; Ahuja et al., 2018). More recently in NLP, Kalra et al. (2020) propose a BERT-based (Devlin et al., 2019) model for this task using the text and visual descriptions of the ad (Johnson et al., 2016). Thomas and Kovashka (2018) study the persuasive cues of faces across ad categories (e.g. beauty, clothing). Zhang et al. (2018) explore the relationship between the text of an ad and the visual content to analyze the semantics across modalities. Ye et al. (2018) integrates audio and visual modalities to predict the climax of an advertisement (i.e. stress levels) using sentiment annotations.

3 Tasks & Data

We aim to analyze the political ideology of ads consisting of image and text, and the type of the ad sponsor for the first time. To this end, we present two new binary classification tasks motivated by related studies in political communication (Grigsby, 2008; Fowler et al., 2020b):

- **Task 1: *Conservative/Liberal*** The aim is to label an ad according to the political party that sponsored the ad either as *Conservative* (i.e. assuming that the dominant ideology of the Republican Party is conservatism), or *Liberal* (i.e. assuming that the dominant ideology of the Democratic Party is social liberalism) (Grigsby, 2008);
- **Task 2: *Political Party/Third-Party*** The goal is to classify an ad according to the type of the organization that sponsored the ad. We distinguish between ads sponsored by official political parties and non-political organizations, such as businesses and non-profit groups, following Fowler et al. (2020b).

To the best of our knowledge, no datasets are available for modeling these two tasks. Therefore, we develop two new publicly available datasets consisting of political ads and ideology/sponsor type labels from the U.S.. We opted to use data only from the U.S. because its Federal Election Commission[4] (FEC) provides publicly available information of political ads sponsors such as official political parties (e.g. Democratic, Republican) via their FEC ID; and third-party organizations can be identified via their Employer Identification Number[5] (EIN) suitable for our study.

3.1 Collecting Online Political Ads

We use the public Google transparency report platform[6] to collect political ads. This platform contains information on verified political advertisers (i.e. sponsors) and provides links to actual political ads from Google Ad Services.

We collect all U.S. available data from the Google platform consisting of ads published from May 31, 2018 up to October 11, 2020 (note that

[6] `https://transparencyreport.google.com/political-ads/region/US`

Sample Ad	
Image Text	FIGHTING FOR WORKING FAMILIES, FOR GOOD JOBS, AND FAIR PAY. PAID FOR BY DEFAZIO FOR CONGRESS
Densecap	the man is wearing glasses, a man holding a red tie, the background is blue

Table 2: Example of text, and visual information extracted from a sample Ad.

there is no data prior to 2018). This corresponds to a total of 168,146 image ads. Each ad is associated with a URL that links to its summary metadata consisting of a URL to the original image file and sponsor information, i.e. name and FEC ID, state elections registration or EIN ID.[7]

We scrape all available image files resulting into a total of 158,599 ads which corresponds to 94.32% of all ads in the Google database. The rest of the ads were either not available due to violations to Google's Advertising Policy, the summary metadata was missing, or the file URL was not included in the metadata.

3.2 Extracting Text and Visual Information

Before, we label the ads with ideology and sponsor type, we extract two types of information from the images: (1) the text contained in each ad (Image Text; IT) using the Google Vision API;[8] and (2) the descriptive caption or denscap (D) of the image using the DenseCap API,[9] following the method proposed by Kalra et al. (2020) for commercial ad classification. This way, we obtain both the actual text appearing on the ad and the textual descriptions of the ad such as entities in the images, their characteristics and relationships. Table 2 shows an example of an ad consisting of an image, text information and the densecap.

We use the textual and visual information to eliminate all duplicate images by comparing the URL of the image, its text and densecap. Finally, we filter out all ads that contain non-English text (i.e. IT).[10] This results in 15,116 unique ads from 665 unique ad sponsors.

3.3 Labeling Ads with Political Ideology

Our aim is to label political ads as *Conservative* or *Liberal* (see Task 1 description). First, we retrieve all the ad sponsors and their corresponding ads that are available in the Google Ads database. Official political committees associated with the Democratic or Republican parties are identified by their FEC ID (included in the sponsor's information in the Google database). However, the name of the political party associated with a sponsor is not available in the Google database. Thus, we query the FEC database to obtain the affiliation for all committees of the Democratic and Republican parties (e.g. Donald J. Trump for President, Inc.). Then, we compare this information with the Google database (FEC ID and exact name), to assign the corresponding affiliation to the sponsors. For example an ad sponsored by the 'Donald J. Trump for President, Inc.' official committee is labeled as *Republican* and subsequently as *Conservative* (in a similar way we label ads for the *Liberal* class).

In total, we collect 242 unique sponsors corresponding to 5,548 ads. *Liberal* ads represent the 39% of the total ads and the rest are *Conservative* (61%).

3.4 Labeling Ads with Sponsor Type

We first label all ads from sponsors that have an associated FEC ID in the Google database as *Political Party*. These sponsors correspond to official political committees affiliated with the Democratic or Republican parties (e.g. Biden for President).

Third-party sponsors of political ads consist of groups not officially associated to any political party such as not-for-profit organizations (e.g. NRDC Action Fund) and businesses (Fowler et al., 2020b). This type of sponsors are identified with their EIN ID (included in the Google database). Thus, we label all ads linked to an EIN ID as *Third-Party*. We collected a total of 15,116 ads where 37% corresponds to *Political Party* and 63% corresponds to *Third-Party*.

---

Table 3: Data set statistics for Task 1: *Conservative* (C)/ *Liberal* (L), and Task 2: *Political Party* (PP)/*Third-Party* (TP).

Avg. Tokens (Train/Dev/Test)			
Task	**IT**	**D**	**IT+D**
T1	17.1/16.5/17.1	38.3/39.9/36.9	55.4/56.4/54.0
T2	16.2/17.6/19.2	36.7/38.9/37.2	52.9/56.5/56.4

Table 4: Average number of tokens in image text (IT), densecaps (D) and both (IT+D) for sponsor ad ideology (T1) and type (T2) prediction.

3.5 Data Splits

We split both datasets chronologically into train (80%), development (10%), and test (10%) sets. Table 3 shows the dataset statistics and splits for each task.

3.6 Data Preprocessing

Text We normalize the text from the image (IT) and the densecap (D) by lower-casing, and replacing all URLs and person names with a placeholder token. To identify the person names we use the Stanford NER Tagger (Finkel et al., 2005). Also, we replace tokens that appear in less than five ads with an 'unknown' token. We tokenize the text using the NLTK tokenizer (Bird et al., 2009). Table 4 shows the average number of tokens in IT and D for each data split.

Image Each image is resized to (300 × 300) pixels represented by red, green and blue color values. Each color channel is an integer in the range [0, 255]. The pixel values of all images are dived by 255 to normalize them in the range [0, 1].

4 Predictive Models

We experiment with textual, visual and multimodal models for political ad classification.

4.1 Linear Baselines

As baseline models, we use logistic regression with bag of n-grams and L2 regularization using (1) the image text (LR_{IT}); (2) densecap (LR_{D}); and (3) their concatenation (LR_{IT+D}) for representing each ad.

4.2 BERT

We also test three models proposed by Kalra et al. (2020) for generic ad classification demonstrating state-of-the-art performance. The models are based on Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019) using a combination of the image text and the densecap. We follow a similar approach and fine-tune BERT for predicting the corresponding class in each task by adding an output dense layer for binary classification that receives the 'classification' [CLS] token as input. We use three types of inputs for each ad: (1) image text (BERT_{IT}); (2) densecap (BERT_{D}); and (3) their concatenation (BERT_{IT+D}).

4.3 EfficientNet

EfficientNet (Tan and Le, 2019) is a family of Convolutional Neural Network (CNN) (LeCun et al., 1995) models which has achieved state-of-the-art accuracy on ImageNet (Deng et al., 2009). In particular, we use EfficientNet-B3 and fine-tune it on political ad classification by adding an output dense layer for each binary classification task.

4.4 BERT+EffN

We finally test two multimodal models by combining: (1) BERT_{IT} and EfficientNet (BERT_{IT}+EffN); and (2) BERT_{IT+D} and EfficientNet (BERT_{IT+D}+EffN). We concatenate the text representation obtained by BERT and the visual information from EfficientNet into a $768 + 1536$ dimensional vector from BERT and EfficientNet respectively. This vector is then passed to an output layer for binary classification. We fine-tune the entire architecture for each task.

5 Experimental Setup

We select the hyperparameters for all neural models using early stopping by monitoring the validation binary cross-entropy loss, and we estimate the

Table 6: Macro Precision (P), Macro Recall (R), and Macro F1-Score (F1) for sponsor type prediction (± std. dev. for 3 runs). Best results are in bold.

class weights using the ’balanced’ heuristic (King and Zeng, 2001) for each task, as both datasets are imbalanced. BERT and EfficientNet models use ADAM optimizer (Kingma and Ba, 2014), and experiments use 1 GPU (Nvidia V100).

LR For LR we use bag of n-grams with $n = (1, 3)$, $n \in \{(1,1),(1,2),(1,3)\}$ weighted by TF.IDF and L2 regularization. The average training time is 30 seconds.

BERT We fine-tune BERT for 20 epochs and choose the epoch with the lowest validation loss. We use the pre-trained base-uncased model for BERT (Vaswani et al., 2017; Devlin et al., 2019) from HuggingFace implementation (12-layer 768-dimensional) trained on English Wikipedia (Wolf et al., 2019). The maximal sequence length is 512 tokens. We fine-tune BERT for 2 epochs and learning rate $\eta = 2e^{-5}$ for ideology prediction; and $\eta = 1e^{-5}$ for advertiser type prediction with $\eta \in \{1e^{-5}, 2e^{-5}, 3e^{-5}, 4e^{-5}\}$. The average training time is 8.1 minutes.

EfficientNet We use EfficientNet-B3 with Noisy-Student weights (Xie et al., 2020). For ideology prediction, we first freeze the layers of the EfficientNet (Tan and Le, 2019) model and train it for 11 epochs with learning rate $\eta = 1e^{-3}$ to learn the parameters of the output layer. We then unfreeze and train the whole network for another 30 epochs with $\eta = 1e^{-4}$, as it has been shown that unfreezing the CNN during the latter stages of training improves the performance of the network (Faghri et al., 2017). For predicting the type of sponsor, we train for 45 epochs and $\eta = 1e^{-2}$ keeping the EfficientNet layers frozen. Unfreezing the base model did not result into lower validation loss. We use dropout rate of 0.2 before passing the output of EfficientNet to the classification layer. The average training time is 37.8 minutes.

BERT+EffN For ideology prediction, we freeze all the layers of the pre-trained models (BERT and EfficientNet) apart from the classification layer and train for 27 epochs with $\eta = 1e^{-3}$. We then fine-tune BERT for 30 epochs with $\eta = 1e^{-5}$. For sponsor type prediction, we freeze all EfficientNet layers and fine-tune BERT for 30 epochs with $\eta = 2e^{-6}$. We train in stages to ensure that the parameters of each part of the model (textual and visual) are properly updated (Kiela et al., 2019). The average training time is 56.65 minutes.

6 Results

This section presents the experimental results for the two predictive tasks, political ideology and sponsor type prediction (§3) using the methods described in §4. We evaluate our models using macro precision, recall and F1 score since the data in both tasks is imbalanced. Note that for all models we report the average and standard deviation over three runs using different random seeds. We also report the majority class baseline for each task.

6.1 Predictive Performance

Task 1: Conservative/Liberal Table 5 shows the results for the political ideology prediction. We first observe that BERT$_{IT}$ (73.16%) which uses as input information the image text outperforms BERT$_{D}$ (57.64%) and EfficientNet (68.15%) in

(a) True: *Lib* - Pred: *Cons* (b) True: *Cons* - Pred: *Lib* (c) True: *PP* - Pred: *TP* (d) True: *TP* - Pred: *PP*

Figure 1: Examples of ads with their true and predicted labels Lib (Liberal), Cons (Conservative), PP (Political Party), TP (Third-Party).

macro F1. This suggests that the text shown on a political ad is the dominant medium for conveying its main message, corroborating findings in related research on commercial ads (Dey et al., 2019; Kalra et al., 2020).

Moreover, combining image text and densecap (BERT$_{IT+D}$), leads to higher performance, than using only image text (BERT$_{IT}$), i.e. 75.49% and 73.16% F1 respectively. This indicates that the combination of textual with visual information (in the form of image descriptions) improves the model performance.

Finally, using all visual information sources, i.e. densecaps and image representation from EfficientNet (BERT$_{IT+D}$+EffN), further improves performance achieving the highest macro F1 (75.76%) across models, followed by BERT$_{IT+D}$ (75.49%).

Task 2: Political-Party/Third-Party Table 6 shows the results for the sponsor type prediction. The best overall performance is obtained by BERT$_{IT+D}$+EffN (87.36%) which combines both image and textual information. BERT$_{IT+D}$ (86.90%) and LR$_{IT+D}$ (86.54%) follow very closely. By inspecting our data, we identified the presence of noise in image text, particularly sentences are interrupted by logos and other aesthetic elements. This negatively affects the performance of BERT because such models are usually pre-trained on 'cleaner' generic corpora (Kumar et al., 2020). On the other hand, LR models trained from scratch can adapt to the noisy text (see § 6.2 for error analysis).

Overall, our results in both tasks suggest that text is a stronger modality for inferring the political ideology and sponsor type of political ads compared to visual information extracted from the images. However, integrating visual information in the form of text descriptions (densecaps) or representations obtained by pre-trained image classification models, enhances model performance.

6.2 Error Analysis

We further perform an error analysis to examine the behavior of our best performing models (BERT$_{IT+D}$+EffN and BERT$_{IT+D}$) and identify potential limitations.

The ad shown in Fig. 1 (a) was misclassified as *Conservative* by BERT$_{IT+D}$ and BERT$_{IT+D}$+EffN. This particular ad requires common knowledge of social issues (e.g. inadequate health support) that are often discussed in political campaigns to inform voters about a party's views on the issue (Scammell and Langer, 2006). This makes the classification task difficult for the models since it requires contextual knowledge. Incorporating external relevant knowledge to the models (e.g. political speeches, interviews or public meetings) might improve performance (Lin et al., 2018).

The ad depicted in Fig. 1 (b) was misclassified by BERT$_{IT+D}$ and BERT$_{IT+D}$+EffN as *Conservative*. After analyzing the densecap descriptions, we found that this information tends to be noisy. For this particular example, it contains descriptions such as 'a man is holding a horse', 'the sign is blue', 'a blue and white stripe shirt', and 'a man wearing a hat'. In fact, BERT$_{IT}$, which only takes the image text into account, classified this ad correctly as *Conservative*. Improving the quality of the image descriptions (e.g. pre-training on advertising or political images, capturing specific attributes such as 'military hat') might be beneficial for these models.

Fig. 1 (c) shows an example of a *Political Party* ad misclassified by BERT$_{IT+D}$+EffN as *Third-Party*. The ad contains the following text:

> *WE CAN'T LET <person> WIN!*
>
> *VOTE EARLY*

The message has a confrontational and divisive tone that is common in *Third Party* ads (Edelson

et al., 2019), but is typically used as a political tactic for negative campaigning (Skaperdas and Grofman, 1995; Gandhi et al., 2016; Haselmayer, 2019).

Finally, Fig. 1 (d) shows an example of a *Third-Party* ad misclassified as *Political Party* by BERT$_{IT+D}$+EffN. The text content promotes voter participation (e.g. *Vote*), a characteristic of *Political Party* advertising (see Table 8). However, one of the aims of the *Third-Party* advertising is precisely to encourage voting and activism (Dommett and Temple, 2018).

There is a considerable difference between the models using visual information only (LR$_D$, BERT$_D$, EfficientNet), and those that also use the ad text as input (IT, IT+D). Our intuition is that models get confused by the appearance of shapes, colors and other aesthetic features that are domain specific and appear frequently in political advertisements (Sartwell, 2011). For instance, several ads that belong to the *Third-Party* category, include buttons linking to websites (see Fig, 1 (c), (d)). However, *Political Party* ads, also make use of these type of buttons to link users to donation or informative websites (Edelson et al., 2019).

7 Linguistic Analysis

We perform an analysis based on our new data set to study the linguistic characteristics of political ads. We first analyze the specific features of each class for both tasks. For this purpose, we use a method introduced by Schwartz et al. (2013) to analyze uni-gram features from image text (see §4) using univariate Pearson correlation. Features are normalized to sum up to unit for each ad. For each feature, we compute correlations independently between its distribution across ads and its label (*Conservative/Liberal*), or *Political Party/Third Party*).

7.1 Conservative vs. Liberal

Table 7 presents the top unigrams correlated with *Liberal* and *Conservative* ads. We first notice that the top words in the *Conservative* category are closely related to its ideology such as 'conservative' and 'republican'. Other prominent terms in these categories are words related to current political issues, such as immigration (e.g. 'border') and taxation (e.g. 'taxes'). In fact, these are examples of emotionally evocative terms (e.g. anger about taxes) that are frequently used in political campaigns to influence voters (Brader, 2005).

Top terms of *Liberal* ads include 'necessary', 'end','values', and 'win'. For example, the following ads belong to the *Liberal* class:

> *I'm supporting <person> because he has the same* ***values*** *that I do and he's an honest person.*
>
> *<person> FOR CONGRESS*
>
> *To* ***End*** *Gun Violence*

These are examples of ads containing a combination of moral and controversial topics (e.g. gun regulation) which are typical characteristics of political advertising (Kumar and Pathak, 2012).

7.2 Political Party vs. Third-Party

Table 8 shows the top unigram features correlated with the sponsor type of an ad (*Political*

Party/Third-Party). We observe that some top terms in the *Political Party* class also belong to the top terms of the political ideology task (see Table 7) such as 'committee', 'republican' and 'senate'. Messages calling for vote and donation support ('vote', 'donate', '$') are also prevalent in *Political Party* ads (Fulgoni et al., 2016), as in the next example (See Fig. 1 (b)):

> *Making sure our veterans*
>
> *get the care they've earned*
>
> ***VOTE** FOR <person>*

On the other hand, top features from the *Third-Party* category (e.g. 'action', 'protect') share common characteristics with the rhetoric used by media outlets focused on promoting specific political messaging (Edelson et al., 2019; Dommett and Temple, 2018). Many of these ads direct people to websites to read about a particular topic. For example:

> *Is <person> HIDING ANTI-GUN VIEWS? **Learn** More*

This ad belongs to the *Third-Party* class and points the viewer to an external website for reading further details.

8 Conclusion

We have presented the first study in NLP for analyzing the language of political ads motivated by prior studies in political communication. We have introduced two new publicly available datasets containing political ads from the U.S. in English labeled by (1) the ideology of the sponsor (*Conservative/Liberal*); and (2) the sponsor type (*Political Party/Third Party*). We have defined both tasks as advertisement-level binary classification and evaluated a variety of approaches, including textual, visual and multimodal models reaching up to 75.76 and 87.36 macro F1 in each task respectively.

In the future, we aim to incorporate other modalities such as speech, and video, and explore other methods of acquiring and integrating multimodal information. In addition, we aim to extend our work for analyzing political advertising discourse across different regions, languages and platforms.

Acknowledgments

We would like to thank Kate Dommett, Alexandra Boutopoulou, Mali Jin, Katerina Margatina, George Chrysostomou, Peter Vickers, Emily Lau, and all reviewers for their valuable feedback. DSV is supported by the Centre for Doctoral Training in Speech and Language Technologies (SLT) and their Applications funded by the UK Research and Innovation grant EP/S023062/1. Abstract

Inspired by evidence that pretrained language models (LMs) encode commonsense knowledge, recent work has applied LMs to automatically populate commonsense knowledge graphs (CKGs). However, there is a lack of understanding on their generalization to multiple CKGs, unseen relations, and novel entities. This paper analyzes the ability of LMs to perform generalizable commonsense inference, in terms of *knowledge capacity*, *transferability*, and *induction*. Our experiments with these three aspects show that: (1) LMs can adapt to different schemas defined by multiple CKGs but fail to reuse the knowledge to generalize to new relations. (2) Adapted LMs generalize well to unseen subjects, but less so on novel objects. Future work should investigate how to improve the transferability and induction of commonsense mining from LMs.[1]

1 Introduction

Large-scale commonsense knowledge graphs (CKGs), like ConceptNet (Speer et al., 2017) and ATOMIC (Sap et al., 2019), store structured knowledge that can benefit various knowledge-driven applications. Given the usefulness of CKGs, but also their inability to flexibly provide information, (Paulheim, 2018), recent work has paid much attention to populating CKGs with commonsense knowledge mined from pretrained language models (LMs) (Wang et al., 2020c; Bosselut et al., 2019). Enhancing the knowledge of CKGs is essential to support reasoning on downstream tasks (Talmor et al., 2019; Wang et al., 2020b; Young et al., 2018).

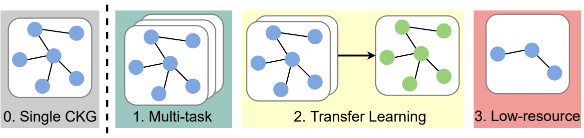

Figure 1: Unlike previous studies that adapt LM on one single CKG (0), we investigate LM's three aspects of **generlizability**: (1) *knowledge capacity* by multi-task learning, (2) *transferability* by transfer learning and (3) *induction* by controlled low-resource learning.

The task of completing CKGs has typically been posed as *commonsense knowledge inference*, where the goal is to predict the object of a fact triplet, given its *subject* and a *relation* (*predicate*) (Petroni et al., 2019; Bosselut et al., 2019). Commonsense inference techniques, such as COMET (Bosselut et al., 2019), typically fine-tune an LM, like GPT (Radford et al., 2018), over the training set from a single CKG. While such methods are able to dynamically enhance the completeness of CKGs, their application so far has been limited to the relation set of the source (training) CKG (Da et al., 2021). In addition, the generated object concepts are found to be largely biased towards the ones in the training set (Wang et al., 2020a). It remains unclear to which extent LMs can generalize to multiple CKGs, new relations, and novel objects. To this end, we pose the question: *do language models perform generalizable commonsense inference?*

To answer this question, we study three aspects of the LM generalizability for commonsense inference, namely: knowledge capacity, transferability, and induction. To measure the *knowledge capacity* ability of LMs, we examine whether LMs can be adapted to multiple CKGs simultaneously, and tested on each of the CKGs. We test their *transferability* by assessing whether an initial adaptation of a LM on multiple source CKGs can reduce the effort on further adapting it to a new CKG. The *inductive* power of LMs is measured by varying the overlap between the objects in the training and test splits of a CKG. The overview of our analysis is depicted in Figure 1. Our results show that LMs are able to infer knowledge for multiple CKGs simultaneously without loss of performance on the

August 1–6, 2021.

target inference task, though the transferability of knowledge across tasks is limited. In addition, we observe that the inductive power of LMs for commonsense inference relies heavily on whether an object is observed during training.

2 Analysis Setup

To shed light on the LM's generalizability for commonsense inference, we investigate: whether LMs have the capability to adapt to multiple CKGs (*Q1: capacity*), whether LMs can reuse the knowledge learned from source CKGs to efficiently adapt to a target CKG (*Q2: transferability*), and whether LMs can predict unseen objects or mainly repeat the observed ones (*Q3: induction*). In this Section, we define the task, the CKGs we consider, our experimental settings, and relate to prior studies.

2.1 Task Formulation

Following Hwang et al. (2020); Da et al. (2021), we formalize *commonsense inference* as a task of predicting the object of a triplet, given a pair of *(subject, relation)* as input. The subject s and the object o are both expressed as free-form phrases, while the relation r is a predefined relation type from the CKG. A training example from ConceptNet could have `(go to a concert, MotivatedByGoal)` as input, and `listen to music` as output. Assuming that a CKG is given, the goal is to leverage the commonsense triplets in the CKG as training examples to adapt the LM for commonsense inference.

2.2 CKG Datasets

We consider three large and popular CKGs, with different foci:(1) **ConceptNet**'s broad set of commonsense knowledge includes taxonomic (e.g., `IsA`), utility (e.g., `UsedFor`), and temporal knowledge (e.g., `HasPrerequisite`). It combines crowdsourced knowledge with that from existing sources, such as WordNet. We use its ConceptNet-100K subset, collected by Li et al. (2016). (2) **TupleKB** (Dalvi Mishra et al., 2017) focuses on scientific commonsense knowledge like `(salt, dissolve in, water)`. It is constructed through an information extraction pipeline. (3) **ATOMIC** (Sap et al., 2019) has social commonsense knowledge about causes and effects of everyday events, and mental states (e.g., `xIntent`) of their participants. It is created by crowdsourcing.

As indicated by Jastrzebski et al. (2018), a large proportion of the subjects in the test set of ConceptNet-100K overlap with its training set, while TupleKB does not provide an official split. Thus, we (re-)split these two datasets to ensure that the subjects of testing triplets do not appear in the training set. This criterion is also consistent with how the ATOMIC dataset is constructed.

2.3 Experimental Settings

Multi-task Learning To answer Q1, we adapt an LM with balanced training data from ConceptNet, TupleKB, and ATOMIC. We sample 8 triplets from each dataset to form one training batch.

Transfer Learning To provide insight into Q2, we adopt transfer learning under a leave-one-out strategy. In this setting, we adapt an LM on two of the three CKGs, and then we further adapt it on the third target CKG. Moreover, we study the data efficiency of this transfer learning by down-sampling each training set to $x = \{1, 20, 50\}\%$, in order to see whether the LM can adapt to the target CKG with less training effort. Fine-tuning on data as small as 1% training set may suffer from instability, and results may change dramatically given a new split of training data (Gao et al., 2020). To control the randomness, we re-sample the 1% training data 5 times with a fixed set of random seeds and report the average performance instead.

Controlled Low-resource Learning To answer Q3, we design a controlled experiment, where we first split the training set into two disjoint subsets depending on whether the triplets in the original training set contain objects that exist in the test set or not. We denote the subset where the objects of the triplets appear in testing data as Ω. We sample $x = \{0, 25, 50, 100\}\%$ of the training triplets in Ω for adapting the LM. During the evaluation, we also separate the test set into two disjoint subsets, according to whether the objects are seen in the original full training set. The results on these two split test sets are reported separately for each adapted LM.

Evaluation Protocol For each *(subject, relation)* pair in the test set, we treat all their objects as ground truth references for evaluating the model inference. We report scores for commonly used automatic evaluation metrics for text generation: BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), and METEOR (Banerjee and Lavie, 2005), which are shown to be consistent with human judgements (Hwang et al., 2020). During experiments, we observe a high correlation among these differ-

Adaptation method	**Input**	**Learnable params**
Zero-shot (ZS)	(s, r)	N/A
ZS+demo	$(s^{'}, r, o^{'}, s, r)$	N/A
Fine-tuning (FT)	(s, r)	Transformer (LM)
FT+demo	$(s^{'}, r, o^{'}, s, r)$	Transformer (LM)
Adapter tuning (AT)	(s, r)	Adapter

ent metrics and choose to report METEOR in the main text and other metrics in the appendix.

2.4 Connections to Prior Studies

Earlier works (Li et al., 2016; Jastrzebski et al., 2018; Davison et al., 2019) poses the CKG completion task as triplet classification, where the goal is to score the plausibility of a complete triplet. COMET (Bosselut et al., 2019) is the first to cast this task as commonsense inference with LMs. Follow-up contributions utilize COMET as a commonsense provider in various downstream tasks (Bosselut and Choi, 2021; Ammanabrolu et al., 2021; Chakrabarty et al., 2020), thus providing evidence for LM's generalization to previously unseen scenarios. Further efforts include Hwang et al. (2020), which show that the quality of the training triplets is a key factor of adapting LMs, and (Da et al., 2021), which investigates how to learn COMET in a few-shot learning setting. Meanwhile, the study by Wang et al. (2020a) indicates the limited generalization of COMET. Ma et al. (2021) also adapt LMs simultaneously on multiple CKGs, albeit their goal is to improve downstream performance rather than CKG inference. In this paper, we aim to provide a more comprehensive study of a LM's generalizability for CKG inference.

3 Method

While a set of pretrained LMs exists, we adopt a widely used generative model, GPT2 (Radford et al., 2019), as our baseline LM. The investigation of other generative LMs is orthogonal to our analysis. We experiment with its largest version, GPT2-XL, which contains 48 transformer layers (Vaswani et al., 2017), ensuring sufficient capacity for storing knowledge acquired during its pretraining. We introduce our experimental method as follows.

Commonsense Inference with LMs Given a training triplet *(s,r,o)*, we represent s and o as sequences of tokens, $\mathbf{x}_s$ and $\mathbf{x}_o$, which is trivial given that they are already expressed as phrases. As for the relation r, we convert it by using a template taken from the literature (Davison et al., 2019) into a natural-language phrase $\mathbf{x}_r$, e.g., `IsA` is converted to "is a". This has been shown to facilitate efficient adaptation of LMs (Da et al., 2021). Note that we do not explicitly provide the LMs with the information about the source CKG of the triplet as input (e.g., prepending a related special token to the triplet).

Adapting LMs with Commonense Knowledge The training objectives for adapting LMs is to maximize the probability of generating the object phrase $\mathbf{x}_o$ given the tuple $(\mathbf{x}_s, \mathbf{x}_r)$. During inference, we adopt greedy decoding to obtain the predicted object from the adapted LM.

There have been various techniques developed for adapting pretrained LMs to downstream tasks (Howard and Ruder, 2018; Chen et al., 2020). Moreover, previously only the vanilla **Fine-tuning**, i.e., updating the whole LM architecture during training, has been employed to adapt LMs for commonsense inference (Bosselut et al., 2019; Hwang et al., 2020; Da et al., 2021). To obtain comprehensive results that are not specific to one particular way of fine-tuning, here we investigate two more alternatives, each of which has their own advantage when considered in different contexts.

Fine-tuning with Demonstration (FT+demo) Combining the ideas of fine-tuning and in-context learning (Brown et al., 2020), this technique (Gao et al., 2020) adds a demonstration to each input as additional context and fine-tunes the whole LM as usual. Incorporating demonstrations is shown to boost performance when the amount of training data is extremely limited. In our case, a demonstration is a top-1 training triplet $(s^{'}, r, o^{'})$, ranked according to the cosine similarity between the embedding of the input tuple (s, r) and the embeddings of the training tuples with the same relation type r. The tuple embeddings are given by a pretrained Sentence-BERT (Reimers and Gurevych, 2019). For instance, a demonstration (`go to restaurant`, `UsedFor`, `eat out`) would be added before the input (`go to pub`, `UsedFor`). With the demonstrated triplets, the LM could learn to understand the schema of the CKG instead of simply learning the knowledge from the training data.

Adapter Tuning (AT) Unlike fine-tuning, adapter tuning (Houlsby et al., 2019) fixes the entire LM and adds one trainable adapter right before the skip connection in each transformer layer of the LM,

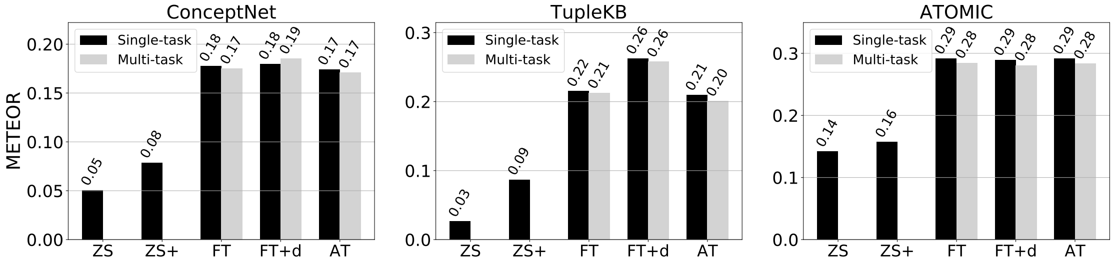

Figure 2: **Results (METEOR) for *knowledge capacity* of LMs. ”FT+d” refers to FT+demo.** We find no notable performance drop for any method trained in the multi-task setting.

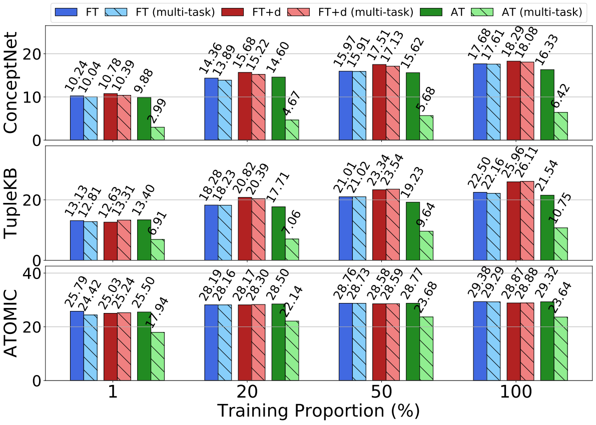

Figure 3: **Results (METEOR) for LM *transferability*.** ”FT+d” refers to FT+demo. Across datasets, we do not observe that adapting to the source CKGs would enable the LMs to adapt to the target CKG better or more easily.

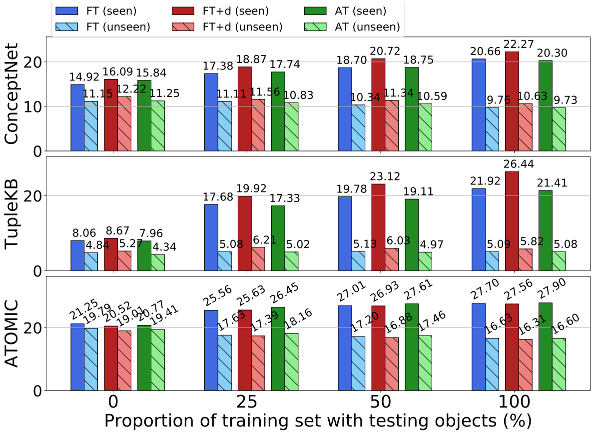

Figure 4: **Results (METEOR) for LM *induction*.** ”FT+d” refers to FT+demo. All the methods perform better on predicting facts that contain seen objects, while the performance degrades when less objects are seen during training.

which is more parameter-efficient. Each adapter is a two-layer bottleneck network with a skip-connection internally. Following Houlsby et al. (2019), the parameters of the bottleneck network are initialized close to zero so that the adapter approximates an identity function from the beginning.

We compare to two additional baselines, both using GPT2-XL in a zero-shot setting: **Zero-shot (ZS)** is fed with the same input as Fine-tuning, while zero-shot with demonstrations (**ZS+demo**) combines the input plus demonstration, as in the FT+demo method. By investigating all these methods, we aim to understand the influence of different adaptation techniques on the models' performance. Table 1 summarizes the set of methods which we consider in this paper.

4 Results and Discussion

Knowledge Capacity (Q1) The results that quantify the knowledge capacity of LMs for commonsense inference over multiple CKGs with METEOR scores are shown in Figure 2. The complete results including other metrics can be found in the appendix. All adaptation methods perform considerably better than the zero-shot baselines, indicating the benefit of adaptation. There is no clear distinction between the adaptation methods, though FT+demo performs slightly better than the others across CKGs. Most importantly, we find no notable performance drop for any method in the multi-task training setup despite the challenge that there is limited overlap between these CKGs. Only 10.0% of the facts from ATOMIC can be found in ConceptNet (Hwang et al., 2020) while 8.4% of the facts from ConceptNet can be found in TupleKB (Dalvi Mishra et al., 2017) [2]. This indicates the prominent capacity of LMs to simultaneously adapt to different CKGs. Nevertheless, the results reveal that learning different CKGs jointly do not interfere with each other positively (via knowledge sharing) or negatively (due to overfitting).

Transferability (Q2) Figure 3 shows the obtained results regarding the transferability of LMs. Across different CKGs and for any training data size, we observe no indications that adapting to the source CKGs enhances the performance on the target CKG. On the contrary, adapting from source CKGs

---

[2] We also try to breakdown the results by relation types and do not observe correlation between the relation-wise performance and the extent of overlap.

even hurts the performance of the Adapter-tuning method, revealing that this method overfits to the source CKGs. Overall, we conclude that LMs cannot reuse the knowledge learned from the source CKGs to improve the performance on the target CKG or achieve the same performance with less training data. Thus, we call for future study on developing more effective adaptation methods.

Induction (Q3) The results in Figure 4 show that without down-sampling ($x = 100\%$), all methods perform much better on predicting facts that contain seen objects, and their performance degrades more when less object entities are seen to training. Meanwhile, the performance on facts with unseen objects stays roughly unaffected. This indicates a key limitation of the LMs: they adapt notably better on seen objects. Since the training set and test set do not share subjects, we conclude that the generalizability of the LM is largely dependent on finding the relationship between unseen subjects and observed objects. We thus posit that a novel strategy for adapting LMs while retaining the knowledge acquired during pre-training is necessary for better generalizability. Promising directions here are prefix tuning (Li and Liang, 2021) or including an additional objective during adaptation which would encourage the generation of novel objects.

5 Conclusion

This work conducted a focused study of three aspects of the generalizability of LMs for commonsense inference: knowledge capacity, transferability, and induction. We experiment with five methods of using a generative LM and three representative CKGs. Despite their capability to accommodate multiple CKGs, we have observed that LMs have limited ability to transfer knowledge across CKGs. Moreover, their adaptation relies heavily on whether the objects to predict are seen during training. These findings help our understanding of LMs' adaptation behavior on commonsense inference, and highlight the need for future work to improve their transferability and induction.

A.2 Implementation Details

The GPT2-XL language model we adopted in this work has 1558M parameters in total. We train all the models on a V100 GPU. As for hyper-parameters, we adopt the commonly-used learning rate (1e-5) and batch size (16) for adapting GPT2, except that in the multi-task learning setting, the batch size is 24 (8 samples from each CKG).

A.3 Additional Results

Probing Multi-modal Machine Translation with Pre-trained Language Model

Yawei Kong, Kai Fan
Alibaba DAMO Academy
{yawei.kyw,k.fan}@alibaba-inc.com

Abstract

Multi-modal machine translation (MMT) aimed at using images to help disambiguate the target during translation and improving robustness, but some recent works showed that the contribution of visual features is either negligible or incremental. In this paper, we show that incorporating pre-trained (vision) language model (VLP) on the source side can improve the multi-modal translation quality significantly. Motivated by BERT, VLP aims to learn better cross-modal representations that improve target sequence generation. We simply adapt BERT to a cross-modal domain for the vision language pre-training, and the downstream multi-modal machine translation can substantially benefit from the pre-training. We also introduce an attention based modality loss to promote the image-text alignment in the latent semantic space. Ablation study verifies that it is effective in further improving the translation quality. Our experiments on the widely used Multi-30K dataset show increased BLEU score up to 6.2 points compared with the text-only model, achieving the state-of-the-art results with a large margin in the semi-unconstrained scenario and indicating a possible direction to rejuvenate the multi-modal machine translation.

1 Introduction

Joint models of language and vision have achieved remarkable results, such as in image caption (Karpathy and Fei-Fei, 2015) and visual question answering (Antol et al., 2015). Multi-modal machine translation (MMT) was first introduced as a shared competition task at the 2016 Conference on Machine Translation (WMT16) (Specia et al., 2016) as an interdisciplinary study to incorporate a visual element into the multilingual translation task. This task continued for three years until WMT18, and the findings presented by the organizers suggest that the text-only systems remain competitive, and that the contribution of visual modality is not entirely convincing (Specia et al., 2016; Elliott et al., 2017; Barrault et al., 2018). Moreover, the experiments in (Elliott, 2018) find that a publicly available MMT system produces great translations with random, incongruent images, further undermining the importance of visual features. The empirical results have so far raised doubts about whether the visual features can really help MMT, and there is evidence pointing to a negative answer.

Table 1: Different unconstrained scenarios in MMT.

We hypothesize that one reason is the data scale of the benchmarking Multi-30K (Elliott et al., 2016) – it is likely insufficient for a deep model to learn better cross-modality or cross-lingual representations. However, the pre-training techniques such as BERT (Devlin et al., 2019) or cross-lingual language model (XLM) (Conneau and Lample, 2019) can capture rich representations of the inputs from languages and be applied to various downstream tasks by providing context-aware embeddings, leading to remarkable improvements even on small datasets. Furthermore, the pre-trained vision and language model LXMERT (Tan and Bansal, 2019) pioneers the cross-modality pre-training and sets an influential record in vision and language reasoning tasks. These advances lead us to believe that a better cross-modality representation can help multi-modal machine translation as well.

In this work, we discuss the unconstrained scenario of MMT, but unlike previous setting in most WMT 2018 submissions (Grönroos et al., 2018; Helcl et al., 2018), we did not include any external data of the parallel source and target textual corpus. Since we want to incorporate a pre-trained (vision)

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3689–3699
August 1–6, 2021. ©2021 Association for Computational Linguistics

language model as an encoder backbone into the transformer architecture (Vaswani et al., 2017) for neural machine translation, our used external data only contains the images and the source texts.

Particularly, our model is initialized with the widely used BERT, and pre-trained on large scale image-text dataset (about six million pairs), expecting to learn a better cross-modality representation between the image and the source language. Next, we stack a regular transformer decoder on top of the pre-trained (vision) language model and proceed to the task of MMT. Meanwhile, we design another modality loss in addition to the traditional sequential cross entropy loss. The modality loss is to minimize the difference between source-target cross attention and image-target cross attention. Intuitively, minimizing this loss function can promote the modality alignment among the three possible pairwise configurations in the latent semantic space. In other words, differences among (source, target), (source, image), and (target, image) alignments can be reduced. Our experimental section also presents a detailed analysis of how each factor separately contributes to the overall gains.

In summary, this paper makes the following contributions. **(1)** We propose to integrate a pre-trained vision language model into multi-modal machine translation, aiming at learning and utilizing better cross-modality representations. **(2)** We address the importance of the modality loss which can further boost the model performance. **(3)** We conduct extensive experiments on the benchmark Multi-30K dataset, and our results outperform strong baselines by a large margin.

2 Related Works

Constrained Scenario Most works like (Calixto et al., 2017; Zhou et al., 2018; Ive et al., 2019; Yao and Wan, 2020) in MMT prefer to use Multi-30K dataset alone. For example, a standard paradigm of MMT explored by many previous works is to simultaneously learn the vision language interaction and the target language generation (Calixto et al., 2017; Zhou et al., 2018; Ive et al., 2019; Yang et al., 2020). However, training on such a limited dataset, the benefits provided by visual features of these methods are quantitatively marginal w.r.t. automatic evaluation metrics BLEU and METEOR.

Unconstrained Scenario In the submissions of WMT 2018 (Grönroos et al., 2018; Helcl et al., 2018) as shown in Table 1, either images / source texts or the source / target texts parallel dataset (or back-translation) are added to improve the model performance. However, as they discovered, training with the large scale parallel textual corpus will shift the machine translation model towards the pure textual domain, further weakening the effect of visual features. The additional target data will also make the fair comparison difficult. A special unconstrained scenario by (Su et al., 2019b) leverages large monolingual language data to pre-train an unsupervised translation model. It considers the cross representation of the source-target in an unsupervised manner, but the image domain is still isolated without proper training.

We will discuss another unconstrained scenario that only allows to use additional images and source texts. Zhu et al. (2019) investigates the representation from pre-trained BERT by feeding it into all layers of a text-only translation model. This work, to a large extent, encourages us to explore how the (vision) language pre-trained model can benefit the MMT. However, we found that a direct architecture of feeding cross-modality representations (from LXMERT) to multi-modal translation model does not work well.

To our best knowledge, Yin et al. (2020) currently achieves the state-of-the-art on Multi-30K. It employed a common encoder-decoder framework by hard-encoding a multi-modal graph to guide the learning of the image-text cross attention, where the graph structure is annotated by a pre-trained visual grounding model (Yang et al., 2019). The external data is not explicitly used in this work, but the pre-trained visual grounding model uses BERT as part of its backbone. Instead of relying on a pre-defined graph to prevent the attention between the word and visual feature without connection, we obtain a soft cross attention from large-scale vision-language data pre-training. It is also worth mentioning that we make the BERT based visual grounding and multi-modal machine translation into an end-to-end trainable architecture.

3 Our Method

3.1 Initial Trial

The overall architecture of our proposed approach is based on the commonly used transformer (Vaswani et al., 2017), which is the basic unit of most pre-trained (vision) language model. Our initial experiment is to adopt pre-trained (vision) language model as the encoder. The baseline is to train

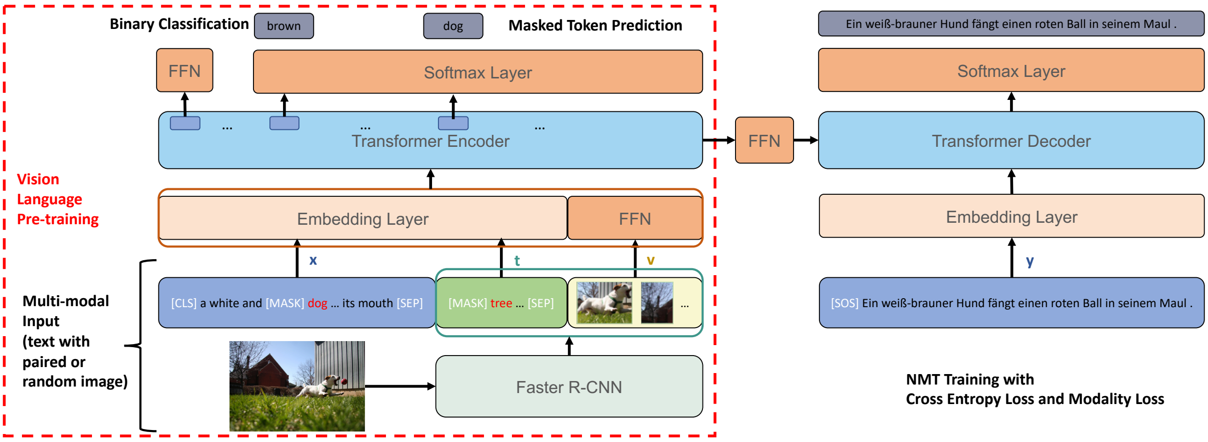

Figure 1: The overall architecture of our proposed multi-modal NMT with pre-trained vision language model. Note that the [MASK] tokens and random images are merely applied during vision language pre-training.

Encoder	visual feature	Test2016 EnDe		Test2016 EnFr	
		BLEU	Meteor	BLEU	Meteor
Transformer	-	38.3	56.6	59.6	74.6
BERT	-	39.1	57.1	61.0	75.3
LXMERT	✓	37.4	55.2	57.7	68.6

Table 2: BERT/LXMERT are frozen.

a transformer NMT from scratch. The first competitive system is simply BERT, and the second one is the pre-trained vision language model LXMERT. LXMERT claimed that the initialization with pre-trained BERT will harm the performance of their downstream tasks. Table 2 shows the preliminary results indicating that the pre-trained LXMERT as the encoder performs surprisingly worse than text-only BERT. Does the table suggest that the visual features are equally marginalized in MMT equipped with pre-trained language model? However, since BERT encoder can bring more improvements, we can abandon LXMERT's conclusion and return to the paradigm with BERT initialization.

3.2 Vision Language Pre-training (VLP)

Ive et al. (2019) finds that integrating both object-based embedding features and image features into the NMT model results better performance in human evaluation on comprehensibility. We therefore favor the object-semantics alignment whose interaction is composed of text embedding, object tag embedding and object image features.

We visualize the training rationale of the VLP in the red dashed box of Figure 1. Suppose that an image and its description $\mathbf{x}$ are presented as the input, where $\mathbf{x}$ represents a sequence of n tokens $(x_1, ..., x_n)$, i.e., the sentence of the source language in our following NMT system. We first process the image with the efficient object detection model Faster-RCNN (Ren et al., 2015) to detect the object regions, box positions, object tags and attribute tags. Particularly, two sets of features are extracted. One is the image visual features of all detected objects, denoted as $\mathbf{v}$. The other is the classification tags of the corresponding objects, denoted as $\mathbf{t}$, as textual features.

Since the backbone of our transformer encoder is pre-trained BERT, the input text $\mathbf{x}$ and object tags $\mathbf{t}$ are both language tokens that can be easily concatenated. However, there is a dimensionality mismatch between the BERT embedding layer and the visual features. For dimension reduction, a fully-connected layer is necessary with input $\mathbf{v}$, and its task is to learn cross modality transferring. The final input fed into the multiple transformer layers of BERT can be written as follows.

$$\mathrm{Cat}\left[\mathrm{Emb}\left(\mathrm{Cat}[\mathbf{x},\mathbf{t}]\right), \mathrm{FFN}(\mathbf{v})\right] \qquad (1)$$

We now face two similar tasks as BERT.

Task 1: Masked LM Same as the standard BERT, our training objective employs the masking token prediction, where 15% of the input text tokens are randomly selected and replaced with the special token [MASK]. Then, only the masked token will be predicted.

Task 2: Paired Image Prediction Analogous to the standard BERT, we pre-train the binarized paired image prediction task that mimics predicting the next sentence, where the training data can be trivially generated for each batch. Specifically, for a given text input, we choose its paired image or

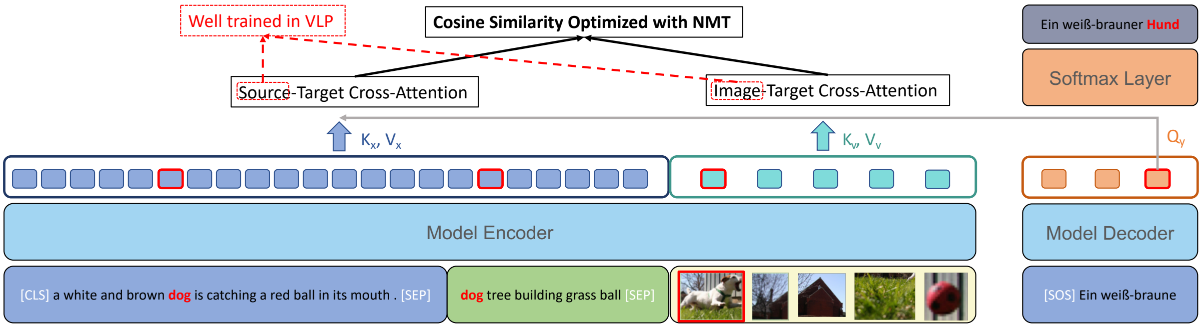

Figure 2: The visualization of modality loss for an input sentence-image pair. It exemplifies the computational flow of the modality loss w.r.t. the last layer of the decoder when decoding “Hund” in German.

a random image each with probability 50%. The output vector of the first special token [CLS] is used as the aggregate multi-modal representation for this classification task.

3.3 Multi-modal NMT

Once the vision language model has been fully trained on a large paired image-text dataset, it is reasonable to assume that the obtained cross-modality representations between the source text and the image are more powerful than those training on the limited Multi-30K. The (key, value) pairs of both the textual and visual features participate in the dot-product attention of the transformer decoder. But there is another dimensionality mismatch between the BERT output and the decoder hidden size. To close this gap, we append an additional fully connected layer after the last layer of BERT. In this section, we also introduce a novel modality loss that is potential to benefit the multi-modal representation learning while but incurs only a few extra model parameters.

Modality Loss To train a multi-modal machine translation task, i.e., generating the tokens in the target language $\mathbf{y} = (y_1, ..., y_m)$, a common objective is the sequential cross entropy loss $\mathcal{L}_{\text{XENT}} = -\sum_{j=1}^{m} \log p(y_j|\mathbf{y}_{<j}\mathbf{x}, \mathbf{v})$, which is the sum of the negative log-likelihoods of the auto-regressive text generation task. Our proposed auxiliary modality loss can be intuitively depicted as Figure 2.

Concretely, when generating the j-th token in the target, the output textual and visual (key, value) pairs from the encoder are separately used to compute the cross-lingual and cross-modality attention with the query vector of the l-th layer in the decoder. The derived vectors can be written as follows.

$$\mathbf{h}_{x,j}^{(l)} = \text{Softmax}\left(K_x \mathbf{q}_j^{(l)} / \sqrt{d}\right) V_x \tag{2}$$

where d is the hidden size of the model decoder, and similar attention holds for visual features $\mathbf{h}_{v,j}^{(l)} = \text{Softmax}\left(K_v \mathbf{q}_j^{(l)} / \sqrt{d}\right) V_v$. Thus, the modality loss can be represented as

$$\mathcal{L}_{\text{M}}^{(l)} = \sum_{j=1}^{m} (1 - \cos(\mathbf{h}_{x,j}^{(l)}, \mathbf{h}_{v,j}^{(l)})) \tag{3}$$

where the cosine similarity is defined as $\cos(\mathbf{a}, \mathbf{b}) = \frac{\mathbf{a}^\top \mathbf{b}}{\|\mathbf{a}\|, \|\mathbf{b}\|}$. Consequently, the overall training objective is a weighted combination of two loss functions.

$$\mathcal{L} = \mathcal{L}_{\text{XENT}} + \sum_{l=1}^{L} \lambda^{(l)} \mathcal{L}_{\text{M}}^{(l)} \tag{4}$$

where L is total number of transformer layers in decoder. Empirically, we found that only using the modality loss of the last layer is sufficient to improve the model performance. Intuitively, the query vector will be directly fed into the softmax layer for decoding the target tokens, making the last layer more informative than other remote layers.

A common method of choosing the weighting parameter λ is to run cross validation on the held-out development data. For the task at hand, this is a time-consuming process. We instead discard the layer-wise $\lambda^{(l)}$ in Eq. (4) and introduce a self-tuning module with respect to the generation process of every single target token. Mathematically, the refined modality loss can be formulated as,

$$\widetilde{\mathcal{L}}_{\text{M}}^{(l)} = \sum_{j=1}^{m} \lambda_j^{(l)} (1 - \cos(\mathbf{h}_{x,j}^{(l)}, \mathbf{h}_{v,j}^{(l)})). \tag{5}$$

where the token level λ_j is learnable and derived from a feedforward neural network.

$$\lambda_j^{(l)} = \text{Sigmoid}(\mathbf{w}_y^\top \text{Emb}(y_j) + \mathbf{w}_x^\top \mathbf{h}_{x,j}^{(l)} + \mathbf{w}_v^\top \mathbf{h}_{v,j}^{(l)})$$

where $\mathbf{w}_y, \mathbf{w}_x, \mathbf{w}_v$ are three d-dimensional vectors shared cross different decoder layers and required

Algorithm 1 Training Pipeline

```
Require: Image, source text paired data $\mathcal{D}_{\text{VLP}}$; Image, source/target text triple data $\mathcal{D}_{\text{MMT}}$.
  Initialize the transformer encoder of NMT with pre-trained BERT.
  Pre-train the transformer encoder on $\mathcal{D}_{\text{VLP}}$ with masked language model task and pair image prediction task.
  Extract the image, source text paired from $\mathcal{D}_{\text{MMT}}$.
  Continue the vision language pre-training on above extracted data.
  Freeze the transformer encoder, and optimize other parameters on $\mathcal{D}_{\text{MMT}}$ with cross entropy loss and modality loss until convergence.
  Optimize all model parameters on $\mathcal{D}_{\text{MMT}}$ with cross entropy loss and modality loss until convergence.
```

to jointly optimize with the model parameters, but useless during inference. We expect the model to dynamically adjust the weight parameters of the tokens with different importance. For example, there is a good chance that the content words also appear as detected objects by the Faster R-CNN. If the term $\mathbf{w}_v^\top \mathbf{h}_{v,j}^{(l)}$ can positively increase its scale for such words, the corresponding λ_js become larger and therefore reinforce the maximization of the cosine similarity. In contrast, although it happens that a mapping exists between the source and target functional words, the image-target cross attention may become weak, making it less necessary to promote the similarity. The term $\mathbf{w}_x^\top \mathbf{h}_{x,j}^{(l)}$ is intended to model the importance of the source contribution. Our results, however, show that in the current experiment setup its effect is not quite as significant.

3.4 Two-Stage Training

When BERT is applied to the downstream tasks, the task-specific module parameters are usually plugged into BERT and all the trainable parameters are simultaneously fine-tuned (Devlin et al., 2019). However, we found this is not the optimal strategy of training our downstream task – multi-modal machine translation. The large number of untrained parameters in the transformer decoder almost account for half of the model size. We conjecture that the encoder parameters have already reached a flat plateau after the pre-training, and it is difficult to set the consistent optimization hyper-parameters (such as learning rate, decay rate or warm-up steps) for both the encoder and decoder.

Therefore, we adopt a two-stage training schedule. In the first stage, the encoder parameters are frozen and only the decoder parameters are optimized w.r.t. the cross entropy and modality loss. In the second stage, all model parameters become trainable and are updated concurrently. This step simulates the regular BERT fine-tuning procedure, and its convergence is expected to lead to a better performance. To this end, we have elaborated the key ideas of our proposed method and summarize the training pipeline of the entire model training process in Algorithm 1.

4 Experiments

In this section, we describe the datasets, the detailed settings as well as the compared baselines.

4.1 Datasets and Settings

Multi-30K We conduct experiments on the Multi-30K dataset (Elliott et al., 2016), where each image is paired with one English(En) description and human translations of German(De) and French(Fr). It has 29,000 instances for training and 1,014 instances for development. Besides, we evaluate our model on various testing sets, including the Multi-30K 2016 test set, the WMT17 test set and the ambiguous MSCOCO test set, which contain 1,000, 1,000 and 461 instances, respectively.

External Data We use about 6 million image and English text paired data for our vision language model pre-training, including MSCOCO (Lin et al., 2014), Im2text (Ordonez et al., 2011), visual7w (Zhu et al., 2016), VQA 2.0 (Goyal et al., 2017), Conceptual captions (Sharma et al., 2018), GQA (Hudson and Manning, 2019). We first process the image with a popular off-the-shelf Faster-RCNN toolkit[1] (Ren et al., 2015; Anderson et al., 2018; Wu et al., 2019). The Faster R-CNN (Ren et al., 2015) network is pre-trained on the MSCOCO dataset and fine-tuned on the Visual Genome (Krishna et al., 2017) dataset to detect salient visual objects, where the number of visual objects ranges from 10 to 100 with the highest prediction probability and 2048 is the dimension of the flattened last pooling layer in the ResNet (He et al., 2016) backbone. Then, we obtain the position-sensitive

visual features by concatenating the region features and the corresponding positions.

For the English text, we follow the same pre-processing as the open-source BERT toolkit[2]. The BERT base model with hidden size 768 is utilized as initialization. Note that unlike (Grönroos et al., 2018; Helcl et al., 2018), we never include any external data related to the target languages for both vision language pre-training and machine translation training. For notation simplicity and differentiating their setting, we define our scenario as **semi-constrained**.

4.2 Baselines

We mainly compare with the following representative and competitive frameworks. The constrained methods include **Doubly-Att** (Calixto et al., 2017), **Fusion-conv / Trg-mul** (Caglayan et al., 2017), **VAG** (Zhou et al., 2018), **VMMT** (Calixto et al., 2019) and **Multimodal-Att** (Yao and Wan, 2020). **MeMAD** and **CUNI** (Grönroos et al., 2018; Helcl et al., 2018) mainly discussed the unconstrained scenario of MMT. In addition, VMMT and Multimodal-Att attempted to adding in-domain back-translation data. We prefer to include them into semi-unconstrained methods as well. **Graph-Fusion** (Yin et al., 2020) uses BERT based visual ground model to hard-code a unified multi-modal graph and performs semantic interactions by graph fusion layers, achieving the current state-of-the-art performance.

4.3 Main Results

In Table 3 and 4, we report the main experimental results of our proposed method with previous research works. All reported numbers of our approach are evaluated on the best performed model for the validation set. Note that when optimizing the parameters, we only use the modality loss calculated from the last layer with learnable token level $\lambda_j^{(6)}$. In other words, the reported numbers are obtained by minimizing $\mathcal{L}_{\text{XENT}} + \widetilde{\mathcal{L}}_{\text{M}}^{(6)}$. In the ablation study, we demonstrate this simplification not only reduces the computational complexity, but also achieves better result than our initial proposal.

Both tables show that our multi-modal translation outperforms the existing models and baselines, especially the recent state-of-the-art algorithm Graph Fusion, which also leveraged the pre-trained BERT based visual grounding model from large scale paired image-text data. However, it only hard-coded the inferred multi-modal graph by visual grounding to construct the mask matrix of cross modality attention in the transformer encoder. One advantage of our work is that we directly build our NMT model on top of the pre-trained vision language BERT, making the most of pre-trained cross modality attention. Another advantage is that our end-to-end trainable model can spontaneously avoid the error accumulation.

Since our multi-modal translation model is implemented based on the text-only transformer, we also report the text-only results with our own implemented transformer for a fair comparison. Our text-only transformer is a surprisingly strong baseline and very competitive with most cited works. For English to German translation task, our text-only baseline almost beats all previous works on the ambiguous MSCOCO test set, and is only inferior to two systems on Multi-30K test sets with less than 2 BLEU score difference. For English to French translation task, only the Graph Fusion algorithm significantly outperforms our text-only transformer. In contrast, on the three test sets of English to German, our final multi-modal translation model can on average achieve approximately +4.6 BLEU and +4.2 METEOR over the text-only baseline. On the two test sets of English to French, the averaged gains of our model are about +5.85 and +4.45 on BLEU and METEOR.

Table 5: Comparison with variants of text-only models. 1st and 2nd means the 1st and 2nd stage of training.

4.4 Probing Textual Language Model

Our implemented text-only transformer only uses the source-target parallel corpus extracted from Multi-30K, which overlooks the power of the pre-training on the source side. Because our multi-modal encoder has been fully pre-trained, we systematically compare it with another two text-only baselines. The first baseline virtually has the same architecture as multi-modal framework but without vision language pre-training, denoted as BERT-enc. The second one is **BERT-NMT** (Zhu et al., 2019) by incorporating the output of BERT into the attention module of the transformer. We directly run the experiments with their released codebase[3]. Without image data, all text-only models only optimize the cross entropy loss, so we also present the result of our model without the modality loss.

As shown in Table 5, the BERT-NMT is sometimes even worse than the regular transformer. We hypothesize that the existence of too many untrained parameters in the encoder makes the model difficult to optimize on the limited Multi-30K dataset. When we directly use the pre-trained BERT as the encoder and train the model with two-stage schedule, we observe a consistent improvement on the metrics over the regular transformer, i.e., +1.1 BLEU at 1st-stage and +2.7 BLEU at 2nd-stage. Thus, we argue that with the proper 2-stage training strategy, the pre-trained BERT can account for one half of the overall gains in our final model.

4.5 Ablation Study

To validate the contribution of each component in our approach, we conduct a series of incremental experiments to observe the model performances in different scenarios, summarized in Table 6.

Table 6: Ablation study of MMT training on the En⇒De dataset after VLP. Different modality losses are exclusive.

Two-Stage Training In previous analysis, we've seen how the 2-stage training can benefit the text-only model. In Table 6, we present the metrics of different multi-modal models. The end-to-end training, similar to the traditional fine-tuning strategy in (Devlin et al., 2019), optimizes all model parameters of the downstream task once the VLP is finished. We found it leads even worse result than optimizing the decoder alone (i.e., 1st-stage training) on the metric BLEU. In addition, the result after the 2nd-stage fine-tuning produces significant performance increase. We also plot the learning curve of BLEU on development dataset in Figure 3. The apparent gap between two curves confirms the contribution of 2-stage training.

Modality Loss Note that the results in the first three lines of Table 6 are achieved by optimizing the cross entropy loss alone. In this study, we will verify the effectiveness of the modality loss in 3 different setups. We found only optimizing the modality loss of the last layer can achieve the best performance. As we discussed before, the query vector of the last layer will directly and maximally influence the generation of the target token, while the vectors from remote layers seem not important. We can use the statistics of the learnable λ to avoid the time-consuming cross-validation. For example, we set λ as the approximate mean 0.4 in the original modality loss Eq. (4). Although a slightly performance drop appears, we can get rid of 3 trainable vectors.

4.6 Case Studies

Actually, the translation performance of the MMT with vision language model only exceeds about 2 BLEU scores compared with the NMT with BERT language model. So we cannot guarantee that all sentences in the testsets can be better translated by MMT with VLP. We only exemplify two cases with better translation quality for MMT with VLP, to indicate the potential benefits.

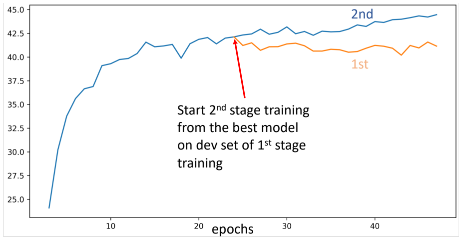

Figure 3: Learning curve of two-stage training w.r.t. BLEU on development set.

In the first case, German words "personen" and "leute" both mean "people", where leute is a general expression and can't be in singular, and "personen" is a formal expression when stating how many people. In object detection model, the tag "person" possibly enhances the NMT model to produce a similar German word "personen". In addition, person is also a German word.

The second case comes from the Ambiguous COCO testset. The NMT with BERT language model cannot miss the translation of the word pizza. The detected object "pizza" may also emphasize the word and help the MMT, though MMT translated the rectangular pizza to stein-pizza (stone-pizza).

4.7 Discussion

The major limitation of our method is that the training pipeline cannot easily generalize to other source languages other than English, because the image-text paired data is unavailable in other languages. Liu et al. (2020) presented a sequence-to-sequence denoising auto-encoder pre-trained on large-scale monolingual corpora in many languages, and successfully applied to multi-lingual translation. Hopefully, we can explore the similar unsupervised cross-lingual or zero-shot transfer learning techniques, which help adapt the multi-lingual BERT

Table 7: Case Studies

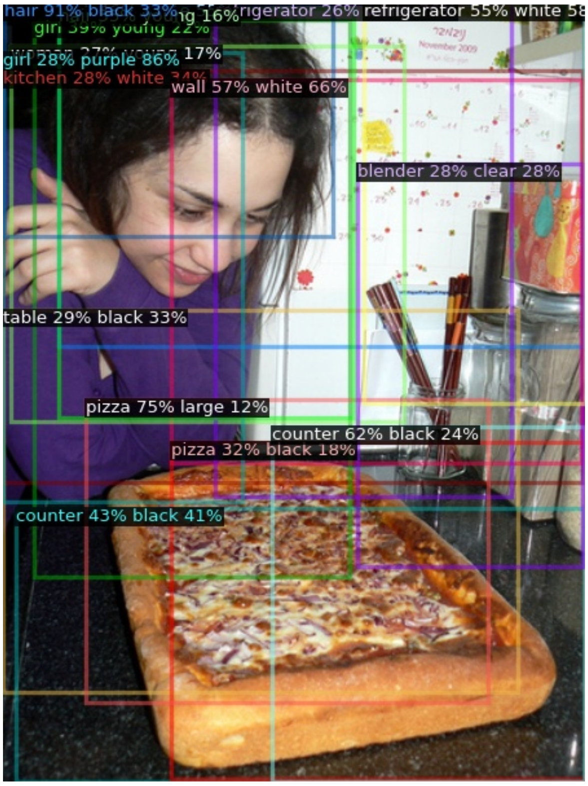

Figure 4: The image for the second case

to a vision multi-lingual model. We will leave this direction as our future work. The main purpose is not to design a better vision language model for other downstream tasks such as VQA. Note that the contemporary works including ViLBERT (Lu et al., 2019) and Oscar (Li et al., 2020) may share the same idea to utilize pre-trained BERT. Our idea is mostly enlighten by (Ive et al., 2019). Another different approach is VL-BERT (Su et al., 2019a), which required to mask sub-regions of the image and introduced masked ROI classification loss, rather than mimicking the NSP loss in traditional BERT.

5 Conclusion

In this paper, we found the vision language pre-training on the source side can significantly improve the multi-modal machine translation, even without additional target corpus. Although the model architecture is as simple as the regular encoder-decoder transformer, our proposed training pipeline can help the MMT system outperform previous works by a large margin on the Multi-30K dataset. The success of the source-image cross-modality representation learning encourages us to design the modality loss that aims at transferring the pre-trained representations to the target-image pair. The quantitative analysis also demonstrates its effectiveness.

Impact Statement

Vision language pre-training has achieved great success in many NLP tasks. We believe it would definitely benefit the multi-modal translation and expect this work can indicate a new unconstrained scenario.

The interplay between language similarity and script on a novel multi-layer Algerian dialect corpus

Samia Touileb

jeremycb@uio.no

Abstract

Recent years have seen a rise in interest for cross-lingual transfer between languages with similar typology, and between languages of various scripts. However, the interplay between language similarity and difference in script on cross-lingual transfer is a less studied problem. We explore this interplay on cross-lingual transfer for two supervised tasks, namely part-of-speech tagging and sentiment analysis. We introduce a newly annotated corpus of Algerian user-generated comments comprising parallel annotations of Algerian written in Latin, Arabic, and code-switched scripts, as well as annotations for sentiment and topic categories. We perform baseline experiments by fine-tuning multi-lingual language models. We further explore the effect of script vs. language similarity in cross-lingual transfer by fine-tuning multi-lingual models on languages which are a) typologically distinct, but use the same script, b) typologically similar, but use a distinct script, or c) are typologically similar and use the same script. We find there is a delicate relationship between script and typology for part-of-speech, while sentiment analysis is less sensitive.

1 Introduction

Cross-lingual transfer has shown promising results for several tasks, however the effect of and the interplay between typologically related languages and languages that do not share the same script has seen less focus. This is especially true for under-resourced vernacular languages and dialects. In this paper, we focus our work on the Algerian language, a non-standardized vernacular Arabic variety, characterized by the heavy use of both code-switching and borrowings. The existing code-switching can be anything from local Algerian dialects (e.g. region based Algerian or Berber), French, English, Spanish, Modern Standard Arabic (MSA), or other Arabic dialects. The borrowings depend on the speakers' background, but is usually heavily French-based.

Algerian is a spoken language with no standardized writing, and with the rise of social media, it has become a language extensively used to communicate online. Algerian can be written in both Arabic and Latin scripts, and code-switching can therefore occur in a mixture of scripts, or within one same script. Arabic varieties written in Latin script are referred to as Arabizi, with north African languages referred to as North African Arabizi, NArabizi in short (Seddah et al., 2020). For the remainder of the paper, we will refer to Algerian written in Latin script as NArabizi (NA) and Algerian written in Arabic script as Algerian Arabic (DZ).

The broad usage of Algerian results in large amounts of data, with no resources or tools to automatically process them. To address this issue and further investigate which of scripts and typological differences influence the results the most, we use a corpus of user comments that reflect the nature of the Algerian vernacular dialect: with heavy use of non-standardised spellings and code-switching.

Our main contributions are (i) a new layer of annotations (transliteration, sentiment analysis, topic classification) that build on the Algerian NArabizi treebank corpus (Seddah et al., 2020), (ii) we investigate the interplay of script and typology on cross-lingual transfer for the two tasks part-of-speech (POS) tagging and sentiment analysis (SA); (iii) we give a baseline model for topic categorization for Algerian. All of the data, annotations, and models are made freely available[1].

To the best of our knowledge, the corpus we present in this work is the first dataset of parallel Algerian texts written in NArabizi and DZ, anno-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3700–3712
August 1–6, 2021.

tated on the morphological and syntactic levels, and for which the interplay between typology and script can be investigated. We also believe that it can help developing approaches to tackle the heavy code-switched nature of the language.

In what follows, in Section 2, we give a brief overview of related works. In Section 3, we describe our dataset and annotations, the annotation processes, and give detailed statistics of the data. We start with some benchmark experiments in Section 4, and present in Section 5 our experiments for POS tagging, SA, and topic classification. In Section 6, we summarize and discuss our results, and conclude in Section 7 with our main findings and future plans.

2 Related work

The vernacular Algerian language is under-resourced, and few freely available corpora and tools exist. Despite work in recent years on this language (Adouane et al., 2020; Moudjari et al., 2020; Adouane et al., 2018; Adouane and Dobnik, 2017; Cotterell et al., 2014), there is only one corpus manually annotated for morphological and syntactical analysis (Seddah et al., 2020).

As pointed out by Seddah et al. (2020), Algerian is a non-codified spoken Semitic language. It is a morphologically-rich language (Tsarfaty et al., 2010), although less so than MSA (Saadane and Habash, 2015). Similarly to other north African languages, it uses heavy code-switching and borrowings, which can either be lexicalized borrowings that receive Arabic-like morphology, or borrowings that remain invariant or take the morphology of the borrowings' original language (*e.g.,* French). Furthermore, Algerian exhibits high variance at the morphological and phonological levels, as well as the lexicon and conventions (Seddah et al., 2020). As shown in Table 1, the Arabic name of the country "*Algeria*" can be written in various ways in both NArabizi and DZ scripts.

As in other North African languages written in Latin script, phonemes that do not exist in the Latin alphabet are represented by digits that are visually similar. For example Table 2 shows how the digits *3* and *9* are used to represent the Arabic letters "*ayin*" and "*qāf*" respectively. The nature of the language makes it therefore an interesting avenue to explore the interplay between language similarity and differences in script on cross-lingual transfer.

NArabizi	DZ
al-dzayer	الدزاير
dzayer	دزاير
jazayer	جزاير
al-jazayer	الجزاير
al-jazaair	الجزائر

Table 1: Lexical variations of the word "*Algeria*" in Algerian written in NArabizi and DZ scripts.

Gloss	NArabizi	Arabic	D	Letter
why	we3lach	وعلاش	3	ع (ayin)
he said	9alli	قالي	9	ق (qāf)

Table 2: Example of non-Latin phonemes represented as digits in NArabizi.

The script of NArabizi differs from the more resourceful MSA and French languages, which can be seen as its culturally closest languages. However, Muller et al. (2020) show that transfer learning approaches can be used on NArabizi, both for POS-tagging and dependency parsing. They show that multilingual BERT (Xu et al., 2019) trained on Maltese, French, and English can successfully transfer to NArabizi, despite not being included in pretraining. This shows the potential for multilingual language models to transfer to unseen dialects across scripts.

The effect of language similarity on NLP tasks is well known (Ponti et al., 2019), with several dedicated workshop series (Nicolai et al., 2020; Zampieri et al., 2018). More recently, attention has turned to larger scale analyses of morphological typology effects on language modeling (Gerz et al., 2018; Cotterell et al., 2018; Mielke et al., 2019). Cross-lingual transfer between languages with related typology is more successful than between languages that do not share similar scripts (Murikinati et al., 2020; Anastasopoulos and Neubig, 2019), especially for the study of morphological inflection. Finally, regarding difference in script, Murikinati et al. (2020) find that using high-quality transliteration as preprocessing can improve the accuracy of such models.

However, in contrast to these previous works, we are interested in the interplay between similar typology and difference in script on *cross-lingual transfer* for two *supervised tasks*, namely POS tag-

NArabizi	*ycombati la misere li las9at fina welat kiste*
Arabic transliteration	يكومباطي لا ميزار لي لسقت فينا ولات كيست
Code-switched transliteration	يكومباطي *la misère* لي لسقت فينا ولات *kyste*
English translation	he fights the misery that sticks to us and which has become a cyst

Table 3: Example of transliteration annotations into Arabic and code-switched scripts. The NArabizi is from (Seddah et al., 2020). The translation to English is added for readers' comprehension.

ging and sentiment analysis. More precisely, we are interested in investigating if there are differences in performance based on the various Algerian scripts.

3 Data and Annotations

The underlying dataset we use is the NArabizi treebank presented in Seddah et al. (2020). This dataset comprises approximately 1,500 sentences: 1,300 NArabizi sentences extracted from an Algerian newspaper's web forum (Cotterell et al., 2014), and 200 sentences from lyrics of songs collected manually from the web. Each NArabizi sentence has five annotation layers: tokenization, morphology, identification of code-switching, syntax, and translation to French (Seddah et al., 2020). The corpus is in *conllu* format, and is freely available[2].

To investigate the interplay between script and typology for cross-lingual transfer on POS tagging and SA, we extend the annotations of Seddah et al. (2020) by adding two levels of annotations:

Token level: for each token of the NArabizi sentences we:

1. transliterate each NArabizi token to Arabic script (*i.e.,* DZ).
2. transliterate each NArabizi token to code-switched scripts (Arabic or Latin) based on the origin of the token (and the code-switch annotation label of the treebank).

Sentence level: we annotate each sentence of the NArabizi corpus for:

1. sentiment: each sentence is annotated as POS (positive), NEG (negative), NEU (neutral), or MIX (a mix of two or more of the three previous classes).
2. topic: each sentence is annotated as belonging to *one* of the following topics: Politics, Prayer, Religion, Societal, Sport, or NONE.

All the annotations were carried out by native speakers of Algerian, Arabic, and French. Two annotators worked on the token-level annotations, and three annotators for the sentence-level annotations. Before starting the annotations, we did a common annotation round to agree on the guidelines, and discuss possible issues. During this, we identified a set of errors in the NArabizi treebank, we therefore started by preprocessing the data and correct some of the recurring errors. More details about our preprocessing of the dataset is given in Section 3.1, the transliteration annotations are described in Section 3.2, and sentiment and topic annotations are described in respectively Section 3.3 and Section 3.4.

3.1 Annotation Preprocessing

The NArabizi treebank dataset (Seddah et al., 2020) contains duplicates both in document IDs and in sentences (strings), both across splits and within splits. Duplicate IDs refer to the same sentences, and therefore duplicate IDs imply duplicate sentences. However, duplicate sentences represent same strings with different IDs. There are far more sentence duplicates than ID duplicates.

All duplicates were removed. However, as the corpus is already quite small, we attempt to avoid removing duplicates from the dev and test splits. If there are duplicates between the train and the dev splits, then we keep the sentences in the dev and remove them from the train set. The same is done with the test split. For the inter-split duplicates, we identified 9 duplicated IDs and 46 (12 unique) duplicated sentences. Intra-split duplicates were only present in train split, with 9 duplicated IDs, and 28 (8 unique) duplicated sentences. We kept

Table 4: Normalization of some of the Latin characters that do not have equivalent phonemes in Arabic.

one occurrence of each as it seems that most of these duplicates come from the chorus of the song lyrics, and short common utterances as *e.g.,* "viva Algeria".

3.2 Transliteration to Arabic and code-switched scripts

Two annotators expanded the annotations of the NArabizi treebank by Seddah et al. (2020) by adding for each token of each sentence a transliteration into Arabic script, and a code-switched version that includes both Latin and Arabic scripts. The Latin script is used for tokens that originate from Latin-scripted languages.

For example, Table 3 shows how the NArabizi sentence is transliterated into the corresponding DZ and code-switched scripts. The first word, "يكومباطي", is actually a borrowing from French. However, borrowings that are integrated into the Algerian language lexicon, and that are influenced by Arabic verbal inflections, were not written in Latin script in the code-switched annotations.

The two annotators were given a subset of 300 sentences to transliterate, *i.e.,* these were doubly annotated. Due to the lack of codification, we do not compute any inter-annotator agreement. The subset of the 300 sentences were mainly used to set the annotation guidelines, and were extensively discussed by the annotators.

We decided to normalize some of the Latin characters that do not have equivalent pronunciations in Arabic, these were transliterated into what the native annotators deemed to be the corresponding Arabic characters. In Table 4 we show the Latin letters and the Arabic form they were transliterated to. Even so, we decided to transliterate the last letter (phoneme *gu*) into a non-native Arabic letter. This letter is vastly used in various Algerian dialects, it represents the dialectal pronunciation of *qāf*, and is also used in names of places and persons.

We are aware of the various efforts to develop guidelines for conventional orthography of Algerian and other Arabic dialects (Saadane and Habash, 2015; Habash et al., 2018; Adouane et al., 2019), but we decided to keep the transliterations as identical as possible to the original NArabizi pronunciations and spellings, to reflect the distinctiveness of the language and its use in normal settings in social media.

During the transliteration annotations, several issues were identified in the original NArabizi treebank by Seddah et al. (2020). However, since our annotators were not trained to alter the dependency treebank, only a small selection of the identified errors were corrected.

The first problem encountered is a lack of consistency in the tokenization. For example, the definite article "ال" ("*el*") can be found both as a standalone token, or attached to a word. The same applies to the adposition "*in/on*" ("fi" – "في") where it can be found both as a stand-alone token, and attached to the next word. For example, it was kept with the token in "*f'doute*" ("*in doubt*"), while it was tokenized as "*f+almarikhe*" for the word "*falmarikhe*" ("*on Mars*"). All tokenization errors were not corrected, as this would lead to altering the dependency trees, and as previously mentioned, our annotators were not trained for this task.

Secondly, there were also errors in the translations from NArabizi to French. This is likely due to non-native Algerian speakers translating some parts of the NArabizi treebank. We only corrected the translations that did not alter the tree, *i.e.,* the POS did not change. Some examples of these types of errors can be found in Table 10 in Appendix A.

Finally, we also found some errors in the marker for code-switching (label *lang* in the data). Some Algerian tokens were marked as French, and vice-versa. This also happened with other languages present in the data (as Spanish, English, and MSA). One of the typical errors was the acronyms of football clubs which were all labeled as Algerian. These were corrected to French, since the acronyms come from their names in French. For example the football club "*MCA*" stands for "*Mouloudia Club d'Alger*", while the Arabic name is "نادي مولودية الجزائر" ("*Nadi mouloudiat al-jazair*").

3.3 Sentiment annotations

The sentences were classified based on their polarities into four different classes: POS (positive),

		Train	Dev	Test
Sentiment	POS	291	32	59
	NEG	274	44	34
	NEU	191	21	20
	MIX	242	40	31
Topic	NONE	300	34	36
	Politics	80	11	16
	Prayer	38	9	9
	Religion	17	4	1
	Societal	204	25	31
	Sport	359	54	51

Table 5: Distribution of sentiment and topic annotations.

NEG (negative), NEU (neutral), and MIX (mixed). The annotation guidelines were quite simple, and annotators were asked to use POS and NEG in clear positive and negative cases respectively. If a sentence does not express any kind of polarity, then NEU was assigned. When sentences express a combination of two or more of the POS, NEG, or NEU polarities, annotators were asked to assign the MIX label. The inter-annotator agreement using *Cohen's kappa coefficient* κ is 0.71 on the doubly annotated subset of 300 sentences. Table 5 shows the distribution of the four labels across the training, development, and test sets. The distribution is unbalanced, and the large amount of sentences categorized as MIX can be problematic as it can contain all other polarities. However, the difference between the POS and NEG classes is relatively small, which we believe should be suitable for binary sentiment classification tasks.

3.4 Topic annotations

After a first round of common analysis in collaboration with the annotators, we identified five topics. However, some sentences were difficult to classify and we therefore decided to include the category "*NONE*". The final dataset is annotated for the following six categories: (1) *Politics*: contains all sentences referring or discussing political events or issues; (2) *Prayer*: all sentences representing prayers; (3) *Religion*: sentences discussing religious issues or issues related to religion in general; (4) *Societal*: societal related discussions. Covers everything from schools and teaching, to terrorism and extremism; (5) *Sport*: mainly covering football events, but spans all types of sports and related events; (6) *NONE*: sentences that were impossible to categorize. This was mainly due to the lack of context, as some sentences were comments responding to either articles or other comments. The final κ score for the triply annotated 300 sentences was 0.70.

		NA	DZ	CS
Sentiment	BOW	47.5	45.1	**49.5**
	AVE	52.5	43.2	36.7
	CNN	50.2	**50.4**	46.2
	BiLSTM	**53.9**	45.9	45.6
Topic	BOW	25.8	34.9	**38.1**
	AVE	40.9	44.6	22.8
	CNN	24.4	33.4	27.4
	BiLSTM	**49.4**	**57.0**	36.4

Table 6: Benchmark results for Sentiment Analysis and Topic classification on the three varieties of the dataset: NArabizi (NA), Algerian Arabic (DZ), and a code-switched version (CS). Sentiment and Topic are both Macro F_1.

Table 5 also shows the distribution of topics across the three splits. Most sentences were classified as "Societal" and "Sport". A large amount of sentences could not be categorised, and few sentences were related to "Religion" and "Prayer". Due to the size of the two latter, one could argue that they could be collapsed into a single topic, as done in our benchmarking experiments (see Section 4). However, we decided to keep them separate in the annotations, to facilitate further annotations in the future.

4 Benchmarking experiments

We perform benchmark experiments for SA and topic classification. Specifically, we use the setup from Barnes et al. (2017), who perform experiments with a logistic regression classifier with bag-of-words features (BOW) and averaged embedding features (AVE), as well as a CNN and BiLSTM. We use their default value for hyperparameters (c=1, hidden dimension = 100, dropout = 0.3) and train for 20 epochs, finally testing the best model on the dev set. As the label distribution for both tasks is highly skewed, we use Macro F_1 to evaluate. Given the size of the categories "Prayer" and "Religion", we collapse them to a single topic, converting the topic classification task into a 5-class multi-class problem.

		UPOS		Sentiment			
group	language	# sents.	avg. len.	# docs.	avg. len.	pos	neg
Original	NArabizi	1,276	16.1	731	14.4	380	351
`Script`	Persian	5,997	26.3	879	49.6	419	460
`Script`	Urdu	5,130	27.0	980	17.5	480	500
`Typology`	Hebrew	6,216	30.6	12,434	24.0	8,512	3,922
`Typology`	Maltese	2,074	21.8	719	18.7	237	482
`Both`	MSA	7,664	42.3	51,051	60.8	42,828	8,223

Table 7: Statistics of UPOS and binarized sentiment data.

For the NArabizi and code-switched experiments, we create 100-dimensional fasttext embeddings (Bojanowski et al., 2017) on the unlabeled NArabizi data made available by Seddah et al. (2020). For the DZ experiments, we use available 300-dimensional MSA fasttext embeddings[3] trained on Wikipedia articles.

Table 6 shows the results. On the sentiment task, the BiLSTM performs best on NArabizi, the CNN best on DZ, and BOW best on the code-switched data. For topic classification the performance is similar, but BiLSTM is also best on DZ. The fact that BOW performs best on code-switched data is largely due to the large amount of out-of-vocabulary words for all other methods, which require embeddings. These baseline experiments show that the dataset is challenging, and the variation means that no single model is always best. The code-switched setting is particularly challenging.

5 The interplay between language similarity and script

The transliteration and further sentiment and topic annotations allow us to explore what interplay there is between typology and script in cross-lingual transfer. Muller et al. (2020) perform experiments on zero-shot cross-lingual transfer for POS tagging on NArabizi. They find that the best transfer language is Maltese, a Semitic language which is written in Latin script, rather than MSA, which performs poorly. This begs the question: *is it mainly similar typology or a shared script that leads to this result?* The transliterated dataset, along with the further sentiment annotations, allow us to investigate this question in more depth, as we are able to control for the script choice.

We choose Persian and Urdu, languages written in Arabic script, but morphologically distinct from DZ (we refer to this group as `Script`), Hebrew and Maltese, two Semitic languages written in other scripts (`Typology`) , and MSA, which is both morphologically similar and written in Arabic script (`Both`). These languages are both available in UD (Zeman et al., 2020) and also have available sentiment analysis datasets (Hebrew (Amram et al., 2018), Maltese (Dingli and Sant, 2016), MSA (Nabil et al., 2015; Abdulla et al., 2013), Urdu (Khan and Nizami, 2020), Persian (Hosseini et al., 2018)). As not all sentiment datasets have the same labels as the NArabizi dataset, we remove all neutral and mixed labels and create binary sentiment data for all languages.

Table 7 gives an overview of the statistics of the POS and SA datasets, respectively. The NArabizi data is the smallest POS data (1,276 sentences), followed by Maltese (2,074), Urdu (5,130), Persian (5,997), Hebrew (6,216), and finally MSA (7,664). The average sentence lengths in tokens range between 16.1 for NArabizi and 42.3 in MSA. The sentiment datasets have a larger variance, ranging from 719 sentences for Maltese to 51,051 for MSA. The distribution of polarity is also skewed to a different degree in each dataset.

5.1 Modeling

We model universal POS (UPOS) tagging as a sequence labeling task and SA as a classification task using multilingual BERT (Xu et al., 2019). We finetune each model on the available training data in each language, using a shared set of hyperparameters which were selected from recommended values according to the characteristics of our data. We set the learning rate to 2e-5, max sequence length of

---

[3] Available at `https://fasttext.cc/docs/en/pretrained-vectors.html`.

256, batch size of 8 or 16[4], and perform early stopping once the validation score has not improved in the last epochs, saving the model that performs best on the dev set. We then test each model on its own dev and test data, the NArabizi test set, and finally the transliterated data. We use accuracy as our metric for POS and macro F_1 for sentiment, as the latter often contains unbalanced classes, and define a baseline as the result of predicting the majority class.

6 Results and Discussion

In order to quantify the zero-shot loss, we define a measure of average transfer loss between a group in Equation 1:

$$TL_{x \to y} = S_{x \to x} - S_{x \to y} \tag{1}$$

where $TL_{x \to y}$ is the transfer loss experienced by a model fine-tuned in language x when transferring to language y and $S_{x \to y}$ is the score[5] achieved when testing a model fine-tuned in language x on language y. Thus, it is a measure of the performance lost in the transfer process.

We also define its averaged variant:

$$\overline{TL}_{A \to B} = \frac{1}{N_A} \sum_{i \in A} \overline{TL}_{i \to B} \tag{2}$$

where $\overline{TL}_{A \to B}$ refers to the average transfer loss experienced by languages from any group A to languages from group B (*group-to-group* transfer loss) and N_A is the number of languages included in the experiment that belong to group A (in our case, either languages that have similar typology, or have the same script).

6.1 POS

Table 8 shows the results for the POS tagging. For completeness, we compare with the results from Seddah et al. (2020), who use a feature-based alVWTagger, described in more detail in de La Clergerie et al. (2017) and Muller et al. (2020), who use mBERT and the StanfordNLP tagger (Qi et al., 2018).

Hebrew has the best test accuracy (96.8) and Maltese the worst (93.8), while the others are somewhere between. All models perform better on the transliterated data than the original NArabizi, although training on Urdu performs lower than the majority baseline. This suggests that even though mBERT was not pretrained on NArabizi or DZ, there is a preference for DZ. This is likely due to the fact that at least *some* of the words have been seen in pretraining, *i.e.,* through MSA. An analysis of the tokenization shows that mBERT splits NArabizi words at a much higher rate than DZ (see Figure 1), breaking it into smaller pieces, which may account for some of the differences between the two. The fact that training on Maltese achieves the best score on both NArabizi (37.8) and DZ (38.4), however, suggests that there is still an effect of typology.

The monolingual model trained and tested on DZ performs better (82.5 acc.) than the one trained

	Dev	Test	NA	DZ
Maj.	–	–	19.9	19.9
1-NArabizi		–	80.4	–
2-NArabizi	–	–	81.6	–
2-Maltese	–	–	35.1	–
NArabizi	77.1	–	76.3	43.6
Algerian (DZ)	83.2	–	39.9	82.5
Persian	95.8	95.5	22.7	26.5
Urdu	94.0	93.4	18.7	21.6
Hebrew	97.4	96.8	32.7	38.2
Maltese	93.6	93.0	**37.8**	**38.4**
MSA	97.0	96.7	20.0	30.5

Table 8: POS accuracy when training on Train Lang. Dev Acc. and Test are in-language, while Test Acc. on Narabizi and Algerian (DZ) is zero-shot cross-lingual. 1-Seddah et al. (2020), 2-Muller et al. (2020).

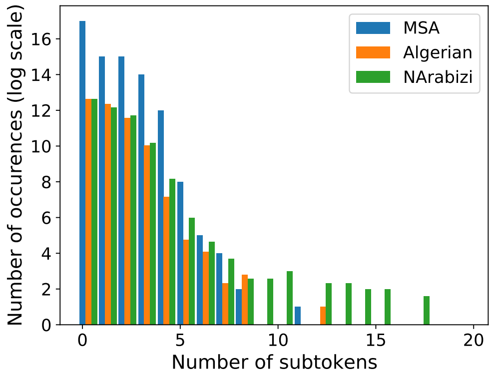

Figure 1: The effect of mBERT tokenization on MSA, Algerian Arabic (DZ), and NArabizi.

---

[4] Depending on the size of the training set, model architecture, and available GPU memory.

[5] The score metric will depend on the task: accuracy in POS and macro F_1 in sentiment analysis.

and tested on NArabizi (76.3). When each of these models is tested on the other, they have significant transfer losses (32.7 for NArabizi → DZ, and 42.6 for DZ → NArabizi). Here too, transfer to DZ script seems easier.

On POS, the effect of language typology is stronger than script, with the best results achieved by training on Maltese and Hebrew. The average transfer loss from Persian and Urdu to DZ is 70.4 while for Hebrew and Maltese to NArabizi it is 59.6, showing less transfer loss from `Typology`. MSA has higher transfer loss on NArabizi (76.7) than DZ (66.2). The differences between average transfer loss on NArabizi and DZ are also slightly larger for `Script` (3.4) compared to `Typology` (3.1) or MSA (3.1).

All of this points to a complicated relationship between script and typology on POS. First of all, it is clear that mBERT prefers the Arabic script seen in pretraining. At the same time, typological similarity also plays a strong role in cross-lingual transfer in POS, although even in this case, the best scores are found on DZ.

6.2 Sentiment

Table 9 shows the results for sentiment analysis. Training in-language again produces the best results (72.1 and 80.3 on NArabizi and DZ, respectively). The transfer loss from NArabizi to DZ is relatively low (9.0), while inversely it is immense (52.6).

Like on POS, most models perform better on DZ and the best zero-shot results do not come from training on `Typology`. In fact, quite the opposite, as these lead to the worst scores and have the highest average transfer loss (34.8/27.9). The best models are MSA for NArabizi (62.4) and Urdu for DZ (63.9), which curiously performs better than NArabizi → DZ. MSA has transfer losses of 12.8/25.1, while `Script` have the lowest average transfer loss (9.2/4.2). This suggests that cross-lingual transfer for a more semantic task, *e.g.*, sentiment analysis, is less reliant on both typological and script similarities.

6.3 Analysis of results

As domain differences between datasets could also lead to transfer loss, we control for this variable by first translating all data to English (to use as a pivot language) and calculating domain difference using Proxy A-distance. Proxy A-distance (Glorot et al., 2011) measures the generalization error of a linear SVM trained to discriminate between two domains. We translate 1,000 sentences from each dataset to English using GoogleTranslate and then compute the proxy A-distance[6] We show heat maps for the domain distances in Figure 2.

	Dev	Test	NA	DZ
Maj.	–	–	39.0	39.0
NArabizi	78.8	–	72.1	63.1
Algerian (DZ)	84.9	–	27.7	80.3
Persian	65.9	66.2	56.9	56.2
Urdu	59.0	62.4	53.3	**63.9**
Hebrew	88.4	88.7	47.2	52.2
Maltese	63.7	61.8	33.8	42.5
MSA	74.2	75.2	**62.4**	50.1

Table 9: Macro F_1 on the zero-shot cross-lingual sentiment task. Note that these results are not comparable to the benchmark experiments, as the data has been converted to binary sentiment classification in order to perform the cross-lingual experiments.

For POS tagging, there are small but insignificant negative effects of proxy A-distance on results (a Pearson coefficient of -0.264, $p > 0.05$). On the sentiment task, there is no significant domain effect (0.264, $p > 0.05$). This suggests that most of the transfer loss is not due to domain mismatch.

7 Conclusion and Future work

In this paper we have described the process of annotating an available Algerian corpus with sentiment and topics, as well as the transliteration to Arabic and code-switched scripts, and finally some aspects of corpus cleanup. We performed benchmark experiments on the three script varieties and show that they are a challenging testbed for future experiments.

We used this new resource to explore a valuable research question in cross-lingual transfer: namely, what is the interplay between language similarity and script when choosing a source language? We found there is a delicate interplay between similar typology and script for transfer in part-of-speech tagging, where typology is more important, but having seen the script in pretraining also influences results. Sentiment analysis, on the other hand, is less

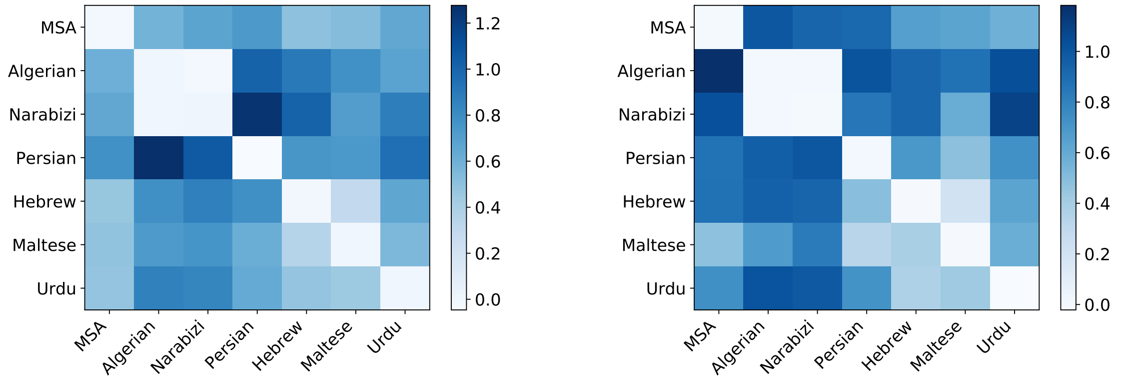

Figure 2: Pairwise proxy A distance between English translations of sentiment (left) and POS (right) datasets.

sensitive to typological differences, while still preferring the script seen in pretraining. This suggests that choice of transfer language is task-specific and that surprising differences can appear from one task to another.

In the future, we would like to address data related issues, and correct the tokenization and translation issues discussed in Section 3.1. Moreover, we plan to focus more concretely on the code-switching aspect of our dataset. The challenges of code-switched data to NLP techniques are numerous, and we would like to focus on the syntactic analysis of our code-switched data, and to explore in more details language modeling approaches to processing it.

Few-Shot Upsampling for Protest Size Detection

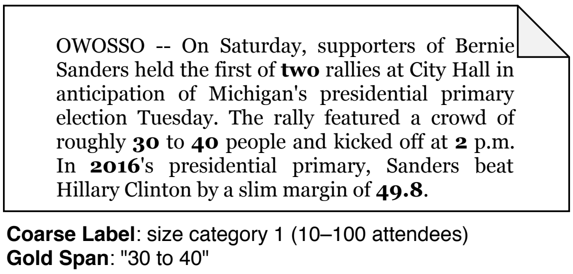
Abstract

We propose a new task and dataset for a common problem in social science research: "upsampling" coarse document labels to fine-grained labels or spans. We pose the problem in a question answering format, with the answers providing the fine-grained labels. We provide a benchmark dataset and baselines on a socially impactful task: identifying the exact crowd size at protests and demonstrations in the United States given only order-of-magnitude information about protest attendance, a very small sample of fine-grained examples, and English-language news text. We evaluate several baseline models, including zero-shot results from rule-based and question-answering models, few-shot models fine-tuned on a small set of documents, and weakly supervised models using a larger set of coarsely-labeled documents. We find that our rule-based model initially outperforms a zero-shot pre-trained transformer language model but that further fine-tuning on a very small subset of 25 examples substantially improves out-of-sample performance. We also demonstrate a method for fine-tuning the transformer span on only the coarse labels that performs similarly to our rule-based approach. This work will contribute to social scientists' ability to generate data to understand the causes and successes of collective action.

1 Introduction

A common data collection task in social science is applying fine-grained labels to documents, including extracting specific passages from text. In many cases, social scientists already have many coarsely-labeled documents and a small number of hand-annotated documents. An automated technique for "upsampling" from coarse labels to more detailed information could help researchers produce better tailored datasets. However, this process does not fit the tools that applied researchers have access to: training a document classifier on coarse labels will not produce the fine-grained answers. Innovations in zero-shot and few-shot classifiers and information extraction (IE) techniques show promise, but new methods are required that can also draw on the existing coarse document annotations to improve fine-grained extraction.



OWOSSO -- On Saturday, supporters of Bernie Sanders held the first of **two** rallies at City Hall in anticipation of Michigan's presidential primary election Tuesday. The rally featured a crowd of roughly **30** to **40** people and kicked off at **2** p.m. In **2016**'s presidential primary, Sanders beat Hillary Clinton by a slim margin of **49.8**.

Coarse Label: size category 1 (10–100 attendees)
Gold Span: "30 to 40"

Figure 1: Documents in our corpus have "coarse labels" reporting the order of magnitude of the protest size and "gold spans" reporting the exact size of the protest. The frequency of number words (in bold) shows why this task is not trivial.

We introduce a new task and dataset for improving information extraction systems' performance when given many coarsely-labeled documents and a small number of documents annotated with the spans of interest.[1] We draw on a dataset on dissent and collective action (hereafter, "protests") in the United States compiled by the Crowd Counting Consortium (2020) (CCC) to construct our training and evaluation data. Protests are an important avenue for social change and of major interest for social science researchers. Current work suggests that attendance is a major factor in the success of a protest movement (Chenoweth and Margherita, 2019), but good data on protest attendance is difficult to collect. CCC compiles structured data about protests from expert annotators using news report-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3713–3720
August 1–6, 2021.

ing, including the exact text span from the article that describes the protest's size and the order of magnitude of the crowd size. An example is given in Figure 1. The task we propose is to locate the span within a document that reports the size of a protest, given a training set of documents labeled with the order of magnitude of the protest ("*coarse labels*") and a small number of document pieces (25) with exact span information ("*gold spans*").

Drawing on recent work in question answering, we repurpose existing models to generate fine-grained labels given a large set of coarsely-labeled documents and a small set of documents with fine-grained labels. We provide results from three baseline models, finding that a heuristic, rule-based system outperforms a zero-shot transformer-based question-answering (QA) model. Fine tuning on a small set (25) of gold spans substantially improves performance. We also introduce a new multitask model that reaches equivalent performance despite fine-tuning on *no* gold spans.

2 Task and Data

For each protest in the CCC dataset, we collect the following data: the raw article text (scraped from the CCC-provided URLs), the exact string reporting the protest size, and a "size category" provided by CCC that reports the order of magnitude size of the crowd. The task is to predict the size text string, given plentiful training data with the size category and the gold spans for a small set of partial documents (25 paragraphs). The test set includes only the full article texts and order-of-magnitude information. To make the task tractable, we exclude protests that are coded from multiple documents and documents from which multiple protests are coded. From 48,736 total protests reported by CCC between January 21, 2017 and October 31, 2020, we eliminate multi-document/multi-protest reports and successfully scrape text for 11,005 protests. We eliminate documents where the CCC-reported size text is not located within the document, leaving 3,849 protests/documents. We split these data into four parts:

- **Coarse label training set**: text with coarse, order-of-magnitude labels {0,1,2,3} but no exact answer spans (2,694 full articles).
- **Gold span training set**: short texts with exact answer spans but no order-of-magnitude labels (25 paragraphs).
- **Validation set**: documents with order-of-magnitude labels and exact answer spans (200 full articles).
- **Test set**: documents with order-of-magnitude labels and exact answer spans (930 full articles).

The task is challenging because models are not evaluated on the largest portion of the data (coarse document labels) but rather on a fine-grained span prediction task for which only limited data is available. The task can thus be framed in several ways, depending on which parts of the data are used and in what ways:

- **Zero shot**: use an off-the-shelf model to detect protest sizes without any fine tuning on our data, either coarse or fine.
- **Few-shot on gold spans**: fine tune a baseline model on the small number of gold span labelled data.
- **Coarse labels**: use a coarse-to-fine model to identify spans given only document-level labels.
- **Coarse labels + gold spans**: train a model using both coarse order-of-magnitude labels and limited fine-grained span data.

3 Related Work

The task we propose relates to several strands of research. One framing is as a *question-answering* task (QA), where the same question ("How many people protested?") is asked about each document. A large set of NLP tasks can be framed as question-answering models (McCann et al., 2018) and QA models trained on language models can generalize to new domains with few or no labeled examples (Brown et al., 2020; Radford et al., 2019). QA models have also been successfully used when the training data is noisy (Lin et al., 2018). Given the flexibility of QA models and their strong performance in new domains, we use one as the base of our models.

A different framing is as a *"rationale"* problem for a document classifier. Lei et al. (2016) train a classifier on document-level labels and use attention weights to extract rationales for the classification. Our task differs from the canonical document classification task because a responsive model is evaluated on the extracted spans, not on the coarse label prediction task.

Distant supervision uses noisy labels, often applied automatically or with heuristic labels, to train systems (Ratner et al., 2017). The classic example of distant supervision uses a database of relations to label binary relations in text (Mintz et al., 2009). Weak supervision, more generally, uses labels that are noisy or coarse to train fine-grained models (Khetan et al., 2018; Robinson et al., 2020). Some work on "noisy labels" relates to our task, where labels are presented at a higher level of aggregation rather than with noise. Nayak et al. (2020) propose a model that uses coarse, document-level sentiment labels to train a fine-grained, sentence-level sentiment classifier. Their task differs from ours in the nature of their labels: in moving from document-level to sentence-level labels, they predict labels of the same type (sentiment scores). In our task, we also change the labels themselves, from a crowd size order of magnitude to a token-level label of whether a word describes the exact protest size.

4 Modeling Strategy

We first attempt the task using a rule-based model (the "heuristic keyword model") and an off-the-shelf zero-shot QA system. We then introduce a multi-task neural network model based on a pre-trained transformer language model. We fine-tune and evaluate this model on the coarse labels and gold spans, as well as on noisy labels we generate through a rule-based procedure.

The two standard performance metrics for question answering tasks are exact match and F_1 (Rajpurkar et al., 2018). We compute exact match as the sum of exact matches (predicted spans exactly matched in the set of correct target spans) divided by the total number of documents. We compute F_1 per document based on token-level precision and recall, then average across documents.

4.1 Heuristic Keyword Model

Our heuristic model is a rule-based system that uses keyword matching and dependency parses to return a single number-containing phrase from the article. We first locate all number-containing phrases (digits or number words) in the text with regular expressions. Using a rule-based system, we convert these number phrases to a numeric form (e.g. "several dozen" → 36) and then compare the phrase's numerical value to the protest's reported order of magnitude. If the phrase does not match the order of magnitude, we eliminate it from our candidate list. To further reduce the candidate list, we look for number phrases that occur within the same sentence as a set of keywords such as "crowd", "gathered", or "protesters".[2] If multiple sentences have keyword matches, we return the first one. The CCC data's size spans include modifiers alongside the raw numerical values (e.g. "*about* 20", "*more than* 50"). We use dependency parse information generated by spaCy to extract the wider span.[3]

4.2 Zero-Shot QA Model

We begin with a pre-trained RoBERTa model (Liu et al., 2019) that we subsequently fine-tune for question answering using the Stanford Question Answering Dataset (SQuAD) 2.0 as described in Appendix A (Rajpurkar et al., 2018).[4] The QA model architecture is depicted on the left side of Figure 2. Because we do not tune this model on our dataset, we consider its predictions to be zero-shot.

Model	Exact	F_1
Heuristic rules	0.54	0.61
RoBERTa QA		
zero-shot	0.17	0.27
+ gold spans	0.67	0.65
+ *coarse labels*	0.48	0.54
+ *coarse labels + heuristic spans*	0.66	0.63

Table 1: Exact match ("Exact") and F_1 performance on test set data. All RoBERTa QA and multitask models are fine-tuned on SQuAD 2.0. Multitask models italicized. Full results given in Appendix B.

4.3 Fine-tuned QA Model

To use the coarse labels, we add an additional objective to the QA model that is trained to predict the crowd size order of magnitude. The model first predicts the start and end token vectors for a given context-question pair. We compute the cumulative sum (over tokens) of the predicted start token vector and the reverse cumulative sum for the predicted end token vector. The resulting vectors are element-wise multiplied to produce an attention mask with high values in the range of tokens between the predicted start and end tokens. We apply

---

[2] The complete list is "protesters", "demonstrators", "gathered", "crowd", "rallied", "attended", "picketed", "protest".

[3] Specifically, (1) for each sentence matching a keyword (2) identify the word in the sentence that is a number word or numeric, and (3) also include child nodes that had the following labels: adjectival modifier, modifier of quantifier, compound, adverbial modifier. We used spaCy version 2.3.2 with the `en_core_web_lg` model to perform the dependency parsing and sentence segmentation.

[4] We use `roberta-base` from HuggingFace (Wolf et al., 2020).

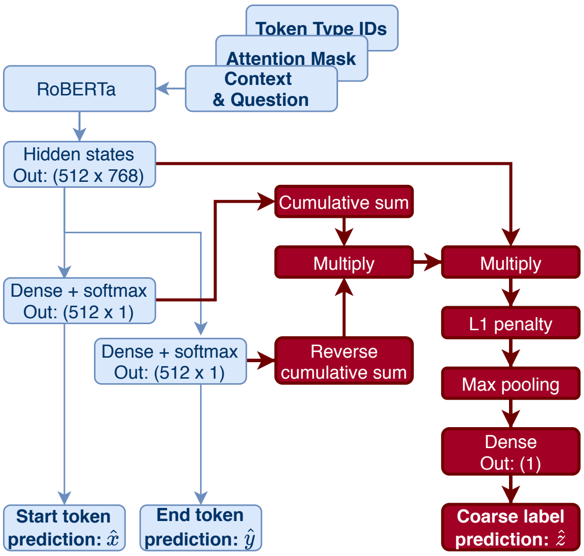

Figure 2: Multitask model architecture: standard RoBERTa QA (left) and attention mask-based regression for coarse label prediction (right).

an L1 penalty to this mask to ensure the attention focuses on a small number of tokens. The attention mask is then element-wise multiplied with the token hidden states produced by RoBERTa. Global max pooling and a single linear regression layer applied to these attended-to hidden states predict the coarse label (as shown in the right side of Figure 2).

The loss function for the multitask model, an unweighted combination of cross-entropy loss and mean squared error, is $-\sum_{i=1}^{n}\{x_i\log(\hat{x}_i)+y_i\log(\hat{y}_i)\} + (\hat{z}-z)^2$, where $x_i \in \{0,1\}$ indicates whether token i is the start of an answer span, $y_i \in \{0,1\}$ indicates whether token i is the end of an answer span, z is the document's coarse label, and n is the number of tokens (512, here). The model can be fit to data including any combination of these three targets.

5 Results

Results on the test set are given in Table 1. RoBERTa QA refers to RoBERTa fine-tuned on SQuAD 2.0. With only fine-tuning on SQuAD 2.0, the model scores 17% exact match accuracy and 27% F_1. On their own, the heuristic-derived spans outperform zero-shot RoBERTa QA. "+ Heuristic spans" indicates that the given model was fine-tuned on the spans identified by the heuristic model.

Fine-tuning the multitask model on the coarse labels alone results in a 180% increase in exact match accuracy and 100% increase in F-score. An example prediction made by the multitask coarse labels model is shown in Figure 3.[5] However, the highest scores are achieved by fine-tuning the RoBERTa QA model on just the 25 gold spans: 67% exact match accuracy and 65% F-score.

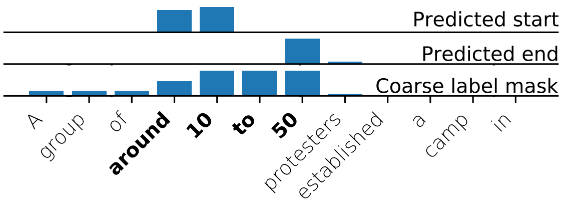

Figure 3: Example target span from document excerpt with predicted start tokens (top), predicted end tokens (middle), and attention mask (bottom). Results from model *c* in Table 1. Actual span in bold.

The greatest performance by a multitask model without any gold spans is achieved by the model fine-tuned on both the coarse labels and the heuristic spans: 66% exact match and 63% F_1, just below the top performing model with access to the gold spans. We interpret the success of this model and the coarse labels model over the base RoBERTa QA model as evidence that our attention masking strategy was successful at upsampling from coarse document-level labels to specific token-level spans.

6 Discussion and Conclusion

Social scientists often find themselves with coarsely-labeled text data for which upsampling may provide valuable additional information. We anticipate applications in extracting fine-grained policy proposals from party manifestos with document-level annotations (Lehmann et al., 2017), the specific armed actors engaged in civil war violence from documents labeled with "rebel" or "government" (Lyall, 2010), or the specific phrases in news text that lead to their censorship (King et al., 2013). We also see applications in upsampling ranges of causalities from NGO reports or Wikipedia articles to the exact sizes, upsampling years to more specific dates, or using rounded numbers from financial disclosures or government reports as coarse supervision for extracting the exact amount from text.

Improvements in zero- and low-shot models should encourage applied researchers to explore computational approaches to text analysis even when training data is scarce, noisy, or coarse—

---

[5] The model just misses an exact match by omitting "around" from the predicted span.

common challenges that are often perceived as intractable. At the same time, NLP researchers should continue to improve models that can learn to extract fine-grained information given coarse training data. Multitask QA models show promise in doing so, but future work can further integrate work from the weak/distant supervision literature, including modeling the noisiness of the labels.

Acknowledgments

We thank Jay Ulfelder of the Crowd Counting Consortium for helpful discussions. Halterman gratefully acknowledges the support of an NSF Graduate Research Fellowship.

Impact Statement

Studies of protests have the potential for serious ethical concerns. Some tasks, such as identifying or de-anonymizing the participants in a protest could produce major harms. Our application, identifying the number of attendees at a protest, has less potential for harm. Our collection of information on the size of protests will generally accord with the desires of protesters. Social scientists have long seen protests as an important tool for social movements to overcome collective action problems: by making support for a position visible in the streets, a protest assures potential supporters of the protest that their opinions are held by others and that the group could potentially achieve its ends with more support (Kuran, 1989; Petersen, 2001; Tarrow, 2011). Providing better information on the size of protests furthers the signalling and information-disseminating objectives of the protesters themselves. While we might not agree with the causes of all protesters in the United States, we believe that on-balance, our work benefits those with less power more than it does those with greater power, who can likely already collect the information they seek manually.

The data that we draw on was collected by the Crowd Counting Consortium, which relies on volunteers and paid research assistants to collect the data. Their protocol was reviewed by the University of Denver IRB and deemed exempt because they do not collect personally identifiable information and use only public data.[6]

A second consideration in our work involves the role of copyrighted news text in our project. Our method uses copyrighted news text that we scraped from the web. While scraping websites is legal in the United States,[7] redistributing copyrighted text is more difficult to justify and depends on how the use fits into the fair use doctrine. Balancing copyright holders' rights with public and educational benefit is at the core of the fair use doctrine.[8] Our attempt to balance the harms to copyright holders and the harms to broader public and scientific benefit is to publish a URL list and scraper so that our corpus can be re-created by future researchers. Additionally, in cases where a researcher is attempting to replicate our work for educational purposes, we will make our scraped corpus available for the narrow purpose of replicating our work.

A Fine-tuning RoBERTa on SQuAD 2.0

A.1 SQuAD 2.0 Fine-Tuning

In order to facilitate extensions to the standard QA model, we perform the fine-tuning of RoBERTa on SQuAD 2.0 ourselves (Abadi et al., 2015). We fine-tune on the SQuAD 2.0 training set for three epochs using the settings recommended by Nandan (2020). We use a batch size of 12 due to memory limitations. We use the Adam optimizer with a learning rate of $5e-5$. Our model achieves 0.78 and 0.74 exact match on the training and evaluation sets, respectively. We use this model only as a basis for subsequent fine-tuning and therefore do not attempt to match state-of-the-art performance on the SQuAD 2.0 evaluation set. The model is trained on two RTX 2080 Ti GPUs. Model size and training time details are provided in Table 2.

We allow the QA model to identify impossible-to-answer questions by predicting the sequence start token ("<s>") as both the answer span start and end token.

To fit within the RoBERTa base model's 512 token limit, we pre-process all text inputs via a shingling procedure. We limit contexts to 450 tokens thereby allowing questions of up to 62 tokens in length. We then pad to a uniform 512 tokens. When contexts exceed 450 tokens, we use a sliding window of 450 tokens that we step through the context 225 tokens at a time. We guarantee all samples generated from large contexts contain precisely 450 tokens by adjusting the first and last window positions such that they do not extend before or after the first or last context token, respectively. We aggregate predictions across shingles by assuming one predicted span per document and selecting the predicted span from the shingle for which $\max_{i\in[1,\ldots,512]}(\hat{x_i})+\max_{i\in[1,\ldots,512]}(\hat{y_i})$ is the greatest.

A.2 Task-Specific Fine-Tuning

The selection of learning rate for these models, 5e-6 (exactly one order of magnitude lower than the default used for SQuAD fine-tuning), was due to our sensitivity to overfitting on the very small set of span examples. All models were trained for 150 batches, each batch comprising 12 samples chosen from the training datasets with replacement. When multiple datasets are used to train the same model, batches alternate between them. We selected the number of batches for training by observing exact match accuracy on the validation set over a range of iteration steps from 1 to 400 and selecting the earliest batch iteration at which validation set accuracy appeared to plateau.

B Results

The full set of fine-tuning data combinations is given in Table 3. All models c through i are trained using the same hyperparameters and strategy (Adam optimizer, 5e-6 learning rate, and 150 batches of size 12 examples each).

		Parameters	Training Time
(a)	Heuristic rules	–	–
(b)	RoBERTa + SQuAD 2.0 (zero-shot)	1.25M	200 min
(c)	+ coarse labels	1.25M	+ 20 min
(d)	+ heuristic spans	1.25M	+ 20 min
(e)	+ coarse labels + heuristic spans	1.25M	+ 20 min
(f)	+ *gold spans*	1.25M	+ 20 min
(g)	+ *gold spans* + coarse labels	1.25M	+ 20 min
(h)	+ *gold spans* + heuristic spans	1.25M	+ 20 min
(i)	+ *gold spans* + coarse labels + heuristic spans	1.25M	+ 20 min

Table 2: Model size in parameters. Training time (approximate) on 2× RTX 2080 Ti GPUs. "+ 20 min" indicates the model takes an additional 20 minutes to fine-tune after the initial fine-tuning on SQuAD 2.0. These estimates may be high due to our validation set performance evaluation between batches.

		Test set		Validation set	
		Exact Match	F_1	Exact Match	F_1
(a)	Heuristic rules	0.54	0.61

Abstract

The unigram distribution is the non-contextual probability of finding a specific word form in a corpus. While of central importance to the study of language, it is commonly approximated by each word's sample frequency in the corpus. This approach, being highly dependent on sample size, assigns zero probability to any out-of-vocabulary (oov) word form. As a result, it produces negatively biased probabilities for any oov word form, while positively biased probabilities to in-corpus words. In this work, we argue in favor of properly modeling the unigram distribution—claiming it should be a central task in natural language processing. With this in mind, we present a novel model for estimating it in a language (a neuralization of Goldwater et al.'s (2011) model) and show it produces much better estimates across a diverse set of 7 languages than the naïve use of neural character-level language models.

1 Introduction

Neural networks have yielded impressive gains in sentence-level language modeling across a typologically diverse set of languages (Mikolov et al., 2010; Kalchbrenner et al., 2016; Merity et al., 2018; Melis et al., 2018; Cotterell et al., 2018). Similarly, neural networks constitute the state of the art in modeling the distribution over a language's word types (Pimentel et al., 2020), outperforming non-neural generative models such as Futrell et al.'s (2017) with character-level models. This paper focuses on a less-researched task that is halfway between sentence-level language modeling and word type distributions: Modeling the **unigram distribution**, the distribution over word tokens in a language consisting of the probability of a word's form as well as its frequency in the language. In particular, as opposed to sentence-level modeling, the unigram distribution does not consider contextual information.

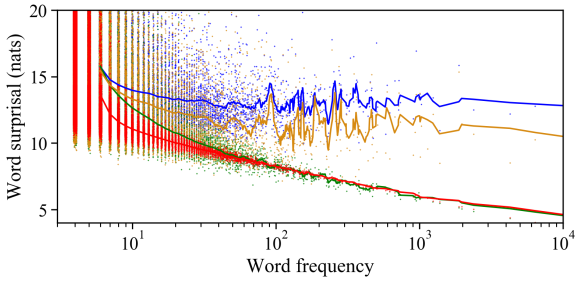

Figure 1: Word-level surprisal in Finnish under our **two-stage** model, two baseline LSTMs trained with either word **type** or **token** data, and another LSTM called the **generator**, trained on an interpolation of both. Lines depict rolling averages.

The unigram distribution is a central object in the science of language from historical linguistics to psycholinguistics and beyond (Baayen et al., 2016; Diessel, 2017; Divjak, 2019). However, the majority of research on unigram distributions is based on identifying this distribution with sample frequency. This approach results in poor estimates, as it assigns zero probability to out-of-vocabulary words.[1] Further, it is highly dependent on sample size (Baayen, 2002)

The core contribution of our work is motivating the unigram distribution as a worthwhile objective for scientific inquiry—one which is currently understudied in the field. With that in mind, we also present a neuralization of Goldwater et al.'s (2011) two-stage model.[2] The gist of this approach is using two components to model the Zipfian distribution of word tokens in a language (Zipf, 1935) separately from its phono- or graphotactic distribution. The first component, termed the **adaptor**, is

---

[*] Equal contribution

[1] In the Turkish Wikipedia, for example, considering a training set of 8 million and a test set of 1 million tokens, 27.4% of test types and 5.3% of test tokens are out-of-vocabulary. Note that, according to Heaps' law, a similar behavior would be expected from corpora of any size (Herdan, 1960; Heaps, 1978).

[2] While Goldwater et al. (2011) acknowledge that their model could be used in various tasks of learning linguistic structure, they only present results in modeling morphology.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3721–3729
August 1–6, 2021.

based on the Pitman–Yor process (PYP; Pitman and Yor, 1997), and has the ability to model the power-law behavior of word tokens. The second, termed the **generator**, leverages a character-level neural language model to capture structural patterns in written words, e.g. graphotactics and morphology.

Critically, naïvely training a character-level neural model in either types (i.e. unique word forms) or tokens (i.e. word forms in their original frequencies) should lead to degenerate results. Models trained on natural corpora (i.e. token data) should excel in modeling the most common words of a language, but might poorly approximate the set of infrequent word forms which individuals dynamically produce (e.g. through compositional morphology). On the other hand, training models on the collection of unique word forms (i.e. type data) would give equal weight to typical and atypical productions, potentially leading to poor performance on the most frequent forms, which any individual would recognize as part of their language. In the two-stage model, as we will show, our generator is trained on a dataset interpolated between types and tokens—modeling the nuance between frequent and infrequent word forms better.

By testing our model on a set of languages with diverse morphological and phonological characteristics, we find that it is capable of modeling both frequent and infrequent words, thus producing a better estimate of the unigram distribution than a character-level LSTM. The empirical superiority of our two-stage model is shown in Fig. 1, where the surprisal (i.e. the negative log-probability, measured in nats here) of each token is plotted under four different models for Finnish. Our proposed two-stage model achieves a lower or similar surprisal to the baselines on tokens with all frequencies—with similar patterns arising in all analyzed languages.[3]

2 The Unigram Distribution

The unigram distribution is a probability distribution over the possible word forms in a language's lexicon. This probability takes the frequency of a token into account, assigning larger probabilities to word forms which are more likely to be encountered in a language's utterances, thus differing from word type distributions, such as in Pimentel et al. (2020). It is also not conditioned on a word's context, as it considers each word token as a stand-alone unit, as opposed to the task of language modeling, e.g. Mikolov et al. (2010).

2.1 Complex Vocabularies

The composition of spoken vocabularies is structured according to a host of factors. Stemming from articulatory biases, each language has a set of constraints on what sequences of speech sounds can be valid words in it; this is termed the **phonotactics** of a language. Languages also exhibit small but non-negligible biases in the regular match of forms and meanings (Dingemanse et al., 2015; Pimentel et al., 2019, 2021b). Additionally, expectations about morphology can constrain the production or processing of a given word as belonging to a particular word class (as shown for instance in Jabberwocky- and wug-type tasks, Berko 1958, Hall Maudslay and Cotterell 2021).

While individuals often have strong intuitions about these patterns, their judgments are typically gradient rather than categorical (Hayes and Wilson, 2008; Gorman, 2013). The effective set of words that naturally occur in linguistic productions are known to be extremely diverse in their composition. Models deployed to explain and predict typical word forms in a given language might fail at capturing these corners of the space of possible forms. If the goal is to produce ecologically valid models that could approximate actual cognitive processes, these atypical forms should be efficiently learned in addition to the most typical productions.

2.2 Imbalanced Frequencies

Zipf (1935) popularized the observation that the frequency of a word in a corpus is inversely proportional to its rank, approximately following a power-law distribution. As such, a small subset of the most common word types dominate the corpus. These extremely frequent words tend to be short in length and exceptionally archaic, in the sense that they preserve traces of previous phonotactic and phonological profiles that might have ceased to be productive. This is particularly relevant when we consider scenarios where substantial portions of the vocabulary might have been borrowed from different sources over time. English is a textbook example: Williams (1986) reports that French, Latin, Germanic and Greek account for

---

[3] As a final contribution of our work, the code used in this paper is available at `https://github.com/irenenikk/modelling-unigram`. We hope this will encourage future work in psycholinguistics to use the model to accurately investigate the effects of unigram probabilities in rare words.

29%, 29%, 26% and 6% of all words' origins in the vocabulary (plus a remaining 10% of diverse origin). The most frequent portion of the vocabulary preserves the most the original West Germanic forms, consisting largely of articles, prepositions, pronouns, and auxiliaries. Further, irregular inflections tend to be more common in these highly frequent words (Ackerman and Malouf, 2013; Cotterell et al., 2019). This observation might invite one to omit frequency information from training data, i.e. to use types, in order to balance out the role of the most frequent words.

On the other side of the frequency scale, however, any natural language data would have plenty of low-frequency words that reflect the open boundaries of the vocabulary. These might include nonce words (*blick*), expressive transformations of other words (*a loooooooooooong summer*), specialized terms (*onabotulinumtoxina*), and names, among others. In addition, genuine orthographic misproductions (*langague*) will be present to some degree.

Finally, acronyms (*HTML*) will be present in all frequency bands. These should be particularly problematic to model, since they do not necessarily follow the language's graphotactics to any degree. There are also frequent and infrequent loanwords with different degrees of adjustment to the grapho- and phonotactics of the rest of the vocabulary. For instance, it has been estimated that 96% and 21% of English speakers know the Afrikaans-originated words *aardvark* and *aardwolf*, respectively (Brysbaert et al., 2019).[4] These are the only written word forms in English with a non-negligible frequency that display two letter '*a*'s in word-initial position.

This whimsical nature of the vocabulary of a language makes modeling the unigram distribution challenging: Naïvely training a model to capture word forms at either the token or type level is likely to give disproportionate emphasis to phonotactically unrepresentative words. However, this is also why its modeling is a worthwhile task—it captures both frequent and rare productions, combining form probability with frequency information.

3 Modeling the Unigram Distribution

Our work neuralizes Goldwater et al.'s (2011) two-stage model and employs it to modeling the unigram distribution.[5] The first component, termed the **generator**, is a model used to produce a set of i.i.d. word forms $\{\boldsymbol{\ell}_k\}_{k=1}^{K}$. The second component is termed **adaptor**, and it assigns each instance in the training set to a cluster $\{z_n\}_{n=1}^{N}$. Under this model, each token in a dataset has a corresponding cluster z_n which defines the token's word form $\boldsymbol{w}_n = \boldsymbol{\ell}_{z_n}$. We note that both word forms $\boldsymbol{\ell}$ and clusters $\mathbf{z}$ are latent variables, and only tokens $\boldsymbol{w}$ are observed during training.

Generator. The generator is a model which produces word forms; we use a character-level LSTM here (Hochreiter and Schmidhuber, 1997), as in:[6]

$$\{\boldsymbol{\ell}_k\}_{k=1}^{K} \sim p_\phi(\boldsymbol{\ell}) = \mathrm{LSTM}(\boldsymbol{\ell}) \tag{1}$$

These word forms $\boldsymbol{\ell}_k$ are sampled i.i.d.—thus, the same word may be sampled more than once.

Adaptor. Each word form sampled from the generator corresponds to a cluster. The adaptor then assigns a frequency to each of the clusters according to a Pitman–Yor process:

$$p(z_n \mid \mathbf{z}_{<n}) \tag{2}$$
$$\propto \begin{cases} c_{<n}^{(z_n)} - a & 1 \le z_n \le K_{<n} \text{ (old cluster)} \\ a \cdot K_{<n} + b & z_n = K_{<n} + 1 \text{ (new cluster)} \end{cases}$$

where $0 \le a < 1$ and $0 \le b$ are hyperparameters of the PYP, $\mathbf{z}_{<n}$ are the previous cluster assignments, $K_{<n}$ is the current number of clusters with at least one token and $c_{<n}^{(z_n)}$ is the number of tokens previously assigned to cluster z_n. This adaptor, as a Pitman–Yor process, allows us to model the power-law distribution of word tokens.

Two-stage Model. Given a cluster assignment and the list of word forms, defining a token's form is deterministic: $p(\boldsymbol{w}_n \mid z_n, \boldsymbol{\ell}) = \mathbb{1}\{\boldsymbol{w}_n = \boldsymbol{\ell}_{z_n}\}$. Thus, our model factorizes a new token's probability into two terms:

$$p_{\text{model}}(\boldsymbol{w}) = \tag{3}$$
$$\underbrace{\frac{c_{\boldsymbol{w}} - \overbrace{n_{\boldsymbol{w}} \cdot a}^{\text{smoothing factor}}}{|\mathbf{z}| + b}}_{\text{smoothed 1-gram}} + \underbrace{\frac{(a \cdot K + b)}{|\mathbf{z}| + b}}_{\text{interpolation weight}} \cdot \underbrace{p_\phi(\boldsymbol{w})}_{\text{LSTM}}$$

where $c_{\boldsymbol{w}}$ is the number of occurrences of word form $\boldsymbol{w}$ in our training corpus and $n_{\boldsymbol{w}}$ is the number

---

[4] Aardvarks and aardwolves are African mammals.

[5] This same model was used in our contemporary work investigating lexicons' (non-)optimality (Pimentel et al., 2021a).

[6] See Pimentel et al. (2020) for more details on this graphotactics generative model.

of distinct clusters to which it has been assigned:

$$c_{\boldsymbol{w}} = \sum_{n=1}^{N} \mathbb{1}\{\boldsymbol{w} = \boldsymbol{\ell}_{z_n}\}, \tag{4}$$

$$n_{\boldsymbol{w}} = \sum_{k=1}^{K} \mathbb{1}\{\boldsymbol{w} = \boldsymbol{\ell}_{k}\} \tag{5}$$

In practice, the two-stage model acts as an interpolation between a smoothed 1-gram model, i.e. corpus frequencies, and an LSTM character model. Notably, this model learns per-word smoothing factors and its interpolation weight in an unsupervised manner through the PYP parameters' inference. The adaptor is fit using Gibbs sampling, and the generator is trained using a cross-entropy loss on the set of non-empty clusters produced by the adaptor. The generator is thus trained using a more balanced corpus where the proportion of the most frequent words is reduced; this can be seen as an interpolation between a type and a token dataset.[7]

4 Experiments.

Dataset. We use Wikipedia data and evaluate our model on the following languages: English, Finnish, Hebrew, Indonesian, Tamil, Turkish and Yoruba. These languages represent a typologically diverse set—with different levels of morphology, ranging from rich (e.g. Finnish) to poor (e.g. Yoruba), as well as distinct scripts and graphotactic patterns. In preprocessing, we first split the data into sentences and then into tokens using spaCy (Honnibal et al., 2020). We then sample 10^6 tokens as our training set for each language (except for Yoruba for which we had less data, see App. F for more details). From these, we build two distinct datasets: a **token dataset**, which corresponds to the list of word forms with their corpus frequency, and a **type dataset** containing the set of unique word forms in the data.

Evaluation. We measure the cross-entropy of our models on a held-out test set; this is the standard evaluation for language modeling. We approximate this cross-entropy using a sample mean estimate

$$\begin{aligned} \mathrm{H}(p) &\leq \mathrm{H}(p, p_{\text{model}}) \\ &\approx -\frac{1}{N}\sum_{n=1}^{N} \log p_{\text{model}}(\boldsymbol{w}_n) \end{aligned} \tag{6}$$

where we assume instances $\boldsymbol{w}_n$ are sampled from the true unigram distribution $p(\boldsymbol{w})$. Specifically, these token samples $\{\boldsymbol{w}_n\}_{n=1}^{N}$ take the form of the token dataset. The model with the lowest cross-entropy is the one that diverges the least from the true distribution.

	Evaluated Model			
Language	Type	Token	Two-stage	Generator
English	12.50	9.04	**8.34**	11.86
Finnish	15.07	12.94	**11.85**	14.16
Hebrew	12.62	10.71	**10.20**	11.76
Indonesian	13.28	10.33	**9.55**	11.89
Tamil	14.24	12.66	**11.76**	13.29
Turkish	14.00	11.77	**10.86**	12.95
Yoruba	11.13	10.04	**9.19**	9.88

Table 1: Cross-entropy on the **unigram distribution**.

Baseline Models. As neural networks yield state-of-the-art performance in language modeling tasks, we expect them to also do well with the unigram distribution. In fact, pseudo-text generated by LSTM-based language models reproduces Zipf's law to some extent (Takahashi and Tanaka-Ishii, 2017; Meister and Cotterell, 2021). Thus, we view state-of-the-art LSTM models as a strong baseline. We train a character-level LSTM language model (Pimentel et al., 2020) to directly approximate the unigram distribution by training it on the token dataset—modeling these tokens at the character level. As a second baseline, we train an LSTM on the type dataset. However, we expect this model to be outperformed by the token one in the unigram distribution task, as the information on word frequency is not available during its training. We do not use a word-level 1-gram model (i.e. the words' sample frequency) as a baseline here, since it results in an infinite cross-entropy for any test set containing oov words. We empirically compare four models: **two-stage**, **generator**, **token**, and **type**.

Modeling Tokens. Cross-entropy on the token test sets can be found in Tab. 1. These results show our two-stage model indeed creates a more accurate estimate of the unigram distribution, producing the smallest cross-entropy across all languages.

Frequent vs Infrequent Words. The weaknesses of the token and type models are evinced by Fig. 1. In line with our hypothesis, the token model achieves lower cross-entropy on the most common words, but fails to model the rare ones accurately.

---

[7] This model's training is detailed in App. E. For a detailed description of the adaptor see Goldwater et al. (2011).

	Evaluated Model

Yoruba	11.13	11.97	**10.36**	11.16

Table 3: The average surprisal for **non-singleton** types.

The cross-entropy achieved by the type model does not change as much with word frequency, but is higher than the one achieved by the token model for most of the vocabulary. We also see that the two-stage model performs well across all word frequencies. Indeed, this model appears to behave similarly to the token model with frequent words, but obtains a lower cross-entropy on the rare ones, where the role of the generator in the estimated probability is emphasized. We suspect this is the reason behind the two-stage model's success.

The Long Tail. Fig. 1 also demonstrates that the entropy estimate for the rare words grows quickly and exhibits a large variance across models. This reflects the heterogeneous nature of the words that only appear a few times in a corpus. This part of the vocabulary is where the type model achieves the best results for all languages except Yoruba (see Tab. 2).[8] The fact that singletons (also known as *hapax legomena*), i.e. word forms which occur only once in the test set, form a large portion of the type dataset boosts the type model's performance on rare words. However, in the case of words appearing more than once (see Tab. 3) the two-stage model achieves the best results across languages. Furthermore, in these non-singleton words, the generator outperforms the type and token models in all languages except for Yoruba. This shows the utility of training the generator on an interpolation between types and tokens. In addition, we note that one may justifiably question whether properly modeling singletons is a desirable feature, since they are likely to contain unrepresentative word forms, such as typos, as discussed previously. Indeed, it appears that the two-stage model not only leads to tighter estimates of the unigram distribution, but also allows us to train a better graphotactics model; capable of modeling both frequent word forms as well as new productions.

Future Work. The results we present focus on analyzing the two-stage model. The generator, though, produces interesting results by itself, modeling non-singleton word forms better than the type and token models in most languages. This suggests that it might be better at modeling the graphotactics of a language than either of these baselines. Future work should explore if this indeed is the case.

5 Conclusion

In this work, we motivate the unigram distribution as an important task to both the psycholinguistics and natural language processing communities that has received too little attention. We present a two-stage model for estimating this distribution—a neuralization of Goldwater et al.'s (2011)—which is motivated by the complex makeup of vocabularies: This model defines the probability of a token by combining the probability of its appearance in the training corpus with the probability of its form. We have shown, through a cross-entropy evaluation, that our model outperforms naïve solutions and is capable of accurately modeling both frequent and infrequent words.

A Tuned hyperparameres for the two-stage model

Language	a	b
English	0.33	3,000
Finnish	0.36	90,000
Hebrew	0.40	55,000
Indonesian	0.48	180,000
Tamil	0.70	37,000
Turkish	0.33	95,000
Yoruba	0.08	156,000

Table 4: The optimized values of a and b for the analyzed languages.

B Hyperparameter Search

The same hyperparameters are used for both our baseline LSTMs and the generator. We use 3 layers, where embedding size is 128, hidden size is 512, and dropout probability is 0.33. Training the two-stage model takes a considerable amount of time (see Tab. 5). We are thus not capable of doing exhaustive hyperparameter tuning. Random search (Bergstra and Bengio, 2012) is used in tuning the values for a and b, where we run five training procedures considering ranges $a \in [0, 1)$, and $b \in [100, 200{,}000)$. We tune the hyperparameters for each language by minimizing the model's cross-entropy on the development set, training them on a subset of the training data with only $100{,}000$ tokens. The found optimal values of a and b are rounded to two decimal places and the thousands respectively. Our two-stage model is trained for five iterations of expectation–maximization.

C Training time with the two-stage model for each language

Language	Minutes
English	164
Finnish	170
Hebrew	175
Indonesian	173
Tamil	166
Turkish	174
Yoruba	56

Table 5: The training times for the two-stage model in each language. These times were obtained with a single NVIDIA Tesla P100 GPU.

D The development set cross-entropies on the unigram distribution

	Evaluated Model			
Language	Type	Token	Two-stage	Generator
English	12.50	9.04	**8.34**	9.18
Finnish	15.08	12.94	**11.88**	13.05
Hebrew	12.62	10.71	**10.20**	10.78
Indonesian	13.27	10.30	**9.53**	10.42
Tamil	14.22	12.65	**11.76**	12.75
Turkish	13.99	11.74	**10.83**	12.92
Yoruba	11.10	10.00	**9.13**	9.83

Table 6: Development set cross-entropy for the baseline models as well as our two-stage model evaluated on the **unigram distribution**.

E Inference

Unfortunately, there is no closed form solution for inferring the parameters of our two-stage model. In order to obtain a sample of cluster assignments and train the generator to match their labels, we estimate the parameters of both the generator and the adaptor concurrently, freezing one's parameters while training the other. We use a regime corresponding to the Monte Carlo Expectation-maximization (EM) algorithm to train the model (Wei and Tanner, 1990), which can be found in Algorithm 1. In the E-step, the function GIBBSSAMPLER returns the cluster assignments $\mathbf{z}$ and the dampened word dataset $\boldsymbol{\ell}$ obtained via Gibbs sampling from the PYP. We then use this dampened dataset to train the generator in the M-step.

Algorithm 1 Training the two-stage model

```
for $i$ in RANGE(# Epochs) do
    // E-Step
    $\mathbf{z}, \boldsymbol{\ell} \sim$ GIBBSSAMPLER$(a, b, p_\phi, \{\boldsymbol{w}_n\}_1^N)$
    // M-Step
    for $t = 1$ up to $T$ do
        $\boldsymbol{\phi} \leftarrow \eta_t \sum_{k=1}^{|\boldsymbol{\ell}|} \nabla_{\boldsymbol{\phi}} \log p_\phi(\boldsymbol{\ell}_k \mid \boldsymbol{\phi})$
    end for
end for
```

E.1 Gibbs Sampler For Cluster Assignments

The Pitman–Yor process does not have a well-defined posterior probability. Nonetheless, we can use Gibbs sampling to obtain a sample from this posterior distribution over cluster assignments defined by the two-stage model.[9] We build our sampler after the morphological sampler presented by Goldwater et al. (2011).

Gibbs sampling is a Markov Chain Monte Carlo (MCMC) method which approximates the posterior of a multivariate distribution. It iteratively samples from the conditional distribution of a variable, given the values of the other dimensions (Neal, 1993). We use the conditional distribution defined in eq. (7) (presented in Fig. 2) in the Gibbs sampler where we know the word form $\boldsymbol{w}_n$ of token n—since it is observable in the corpus— and where the values for all other cluster assignments are fixed. Note that, according to eq. (7), we only assign word tokens to clusters with the same form or create a new cluster—and when a new one is created, its word form is assigned to $\boldsymbol{w}_n$. As such, each cluster contains a single shared word form. For each adaptor training iteration, we run the Gibbs sampler for six epochs, and choose the cluster assignments that have the best performance on a development set. Furthermore, we persist the adaptor state across iterations, warm starting the Gibbs sampler with the cluster assignments of the previous iteration.

E.2 Training the generator

In order to train the generator on word form data with more balanced frequency distributions, a new training set is dynamically created. In this dataset, each token appears as many times as it has been assigned as a cluster label, noted with $\boldsymbol{\ell}$ in Algorithm 1.[10] A regime similar to using the inverse-power transformed counts of the tokens in the corpus (Goldwater et al., 2011).

This new training set allows us to train the generator in an interpolation between a purely type- or token-based dataset; this interpolation can be controlled through its parameters a and b. Setting the values of a and b to zero will cause the model to favor existing clusters to creating new ones, resulting in assigning every token with the same form to a single cluster. In this case, the generator parameters would be estimated using the equivalent of a *type* corpus. Similarly, when a approaches one, or in the limit of $b \to \infty$, less tokens will be assigned per cluster and the number of single token clusters grows. This is effectively equivalent to training the generator using *tokens*. Consequently, non-extreme

---

[9] This is possible due to the exchangeability of the cluster assignments.

[10] We hotstart the generator model by training it on a type-level dataset before the first adaptor training iteration.

$$p(z_n \mid \mathbf{z}_{<n}, \boldsymbol{w}_n) \propto p(z_n, \boldsymbol{w}_n \mid \mathbf{z}_{<n}) \propto \begin{cases} (c_{<n}^{(z_n)} - a) \cdot \mathbb{1}\{\boldsymbol{w}_n = \boldsymbol{\ell}_{z_n}\} & 1 \leq z_n \leq K_{<n} \\ (a \cdot K_{<n} + b) \cdot p_\phi(\boldsymbol{w}_n) & z_n = K_{<n} + 1 \end{cases} \tag{7}$$

Figure 2: The probability of assigning token $\boldsymbol{w}_n$ to cluster z_n in the two-stage model given all other cluster assignments $\mathbf{z}_{<n}$.

value of a and b are a middle ground.

We train the character-level LSTM used as our generator with stochastic gradient descent using a cross-entropy loss function. This model is trained with early stopping; it is evaluated every 200 batches, and training stops when the development set loss has increased for 5 consecutive epochs.

E.3 Training Optimizations

The naïve implementation of the Gibbs sampler for table assignments quickly becomes computationally expensive in practice. Consequently, we use the optimized algorithm designed by Blunsom et al. (2009) for the hierarchical Dirichlet process in our implementation, extending it to Pitman–Yor processes with the additional parameter a.

F Dataset

As noted in the main text, we use Wikipedia data in our experiments. The amount of sentences used in our experiments is capped to one billion after shuffling them. Additionally, we define an upper bound to the amount of tokens used in each experiment. In case the training data exceed this limit, we construct a corpus by re-sampling (with replacement) the desired number of tokens using the corpus frequencies calculated from the original training corpus. The number of types and tokens used in training and evaluation are presented in Tab. 7. Noise in the Wikipedia data is somewhat reduced by hand-defining an alphabet for each language, and removing any sentence which includes words with invalid graphemes in it.[11]

	Train		Test	
	# Types	# Tokens	# Types	# Tokens
English	76,589	10^6	67,148	759,412
Finnish	208,498	10^6	108,020	332,220
Hebrew	131,288	10^6	105,550	619,685
Indonesian	102,739	10^6	72,250	507,848
Tamil	206,512	10^6	116,165	388,257
Turkish	154,185	10^6	85,074	331,072

Abstract

With the ever-increasing complexity of neural language models, practitioners have turned to methods for understanding the predictions of these models. One of the most well-adopted approaches for model interpretability is *feature-based interpretability*, i.e., ranking the features in terms of their impact on model predictions. Several prior studies have focused on assessing the fidelity of feature-based interpretability methods, i.e., measuring the impact of dropping the top-ranked features on the model output. However, relatively little work has been conducted on quantifying the robustness of interpretations. In this work, we assess the robustness of interpretations of neural text classifiers, specifically, those based on pretrained Transformer encoders, using two randomization tests. The first compares the interpretations of two models that are identical except for their initializations. The second measures whether the interpretations differ between a model with trained parameters and a model with random parameters. Both tests show surprising deviations from expected behavior, raising questions about the extent of insights that practitioners may draw from interpretations.

1 Introduction

In recent years, large scale language models like BERT and RoBERTa have helped achieve new state-of-the-art performance on a variety of NLP tasks (Devlin et al., 2019; Liu et al., 2019). While relying on vast amounts of training data and model capacity has helped increase their accuracy, the reasoning of these models is often hard to comprehend. To this end, several techniques have been proposed to interpret the model predictions.

Perhaps the most widely-adopted class of interpretability approaches is that of *feature-based interpretability* where the goal is to assign an importance score to each of the input features. These scores are also called *feature attributions*. Several methods in this class (e.g., SHAP (Lundberg and Lee, 2017), Integrated Gradients (Sundararajan et al., 2017)) possess desirable theoretical properties making them attractive candidates for interpretability.

Benchmarking analyses often show that these methods possess *high fidelity*, i.e., removing features marked important by the interpretability method from the input indeed leads to significant change in the model output as expected (Atanasova et al., 2020; Lundberg and Lee, 2017).

However, relatively few investigations have been carried out to understand the *robustness* of feature attributions. To explore the robustness, we conduct two tests based on randomization:

Different Initializations Test: This test operationalizes the *implementation invariance* property of Sundararajan et al. (2017). Given an input, it compares the feature attributions between two models that are identical in every aspect—that is, trained with same architecture, with same data, and same learning schedule—except for their randomly chosen initial parameters. If the predictions generated by these two models are also identical, one would also expect the feature attributions to be the same for such *functionally equivalent* models. If the attributions in two cases are not the same, two users examining the *same input* may deem the same features to have *different importance* based on the model that they are consulting.

Untrained Model Test: This test is similar to the test of Adebayo et al. (2018). Given an input, it compares the feature attributions generated on a fully trained model with those on a randomly initialized untrained model. The test evaluates whether feature attributions on a fully trained model differ from the feature attributions computed on an

---

[*] Work done during internship at Amazon.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3730–3740
August 1–6, 2021.

untrained model as one would expect.

We conduct the two tests on a variety of text classification datasets. We quantify the feature attribution similarity using *interpretation infidelity* (Arras et al., 2016) and *Jaccard similarity* (Tanimoto, 1958). The results suggest that: (i) Interpretability methods fail the different initializations test. In other words, two functionally equivalent models lead to different ranking of feature attributions; (ii) Interpretability methods fail the untrained model test, i.e., the fidelity of the interpretability method on an untrained model is better than that of random feature attributions.

These findings may have important implications for how the prediction interpretations are shown to the users of the model, and raise interesting questions about reliance on these interpretations. For instance, if two functionally equivalent models generate different interpretations, to what extent can a user act upon them, e.g., investing in a financial product or not. We discuss these implications and potential reasons for this behavior in §4.

Related work. Model interpretability has different aspects: local (e.g. Lundberg and Lee, 2017) vs. global (e.g. Tan et al., 2018), feature-based (e.g. Lundberg and Lee, 2017) vs. concept-based (e.g. Kim et al., 2018) vs. hidden representation-based (Li et al., 2016). See Gilpin et al. (2018); Guidotti et al. (2018) for an overview. In this paper, we focus on feature-based interpretability, which is a well-studied and commonly used form (Bhatt et al., 2020; Tjoa and Guan, 2020). Specifically, this class consists of a relatively large number of methods, of which some have been shown to satisfy desirable theoretical properties (e.g., SHAP (Lundberg and Lee, 2017), Integrated Gradients (Sundararajan et al., 2017), and DeepLIFT (Shrikumar et al., 2017)).

There are several important aspects of interpretation robustness. Some prior studies have considered interpretability in the context of *adversarial robustness* where the goal often is to actively fool the model to generate misleading feature attributions. See for instance Anders et al. (2020); Dombrowski et al. (2019); Ghorbani et al. (2019); Slack et al. (2020). In this work, rather than focusing on targeted changes in the input or the model, we explore robustness of feature attribution methods to various kinds of randomizations.

Several prior works have focused on quantifying quality of interpretations. See for instance, Adebayo et al. (2020); Alvarez-Melis and Jaakkola (2018); Chalasani et al. (2020); Chen et al. (2019); Hooker et al. (2019); Lakkaraju et al. (2020); Meng et al. (2018); Ribeiro et al. (2016); Tomsett et al. (2020); Yang and Kim (2019). Closest to ours is the work of Adebayo et al. (2018), which is based on checking the saliency maps of randomly initialized image classification models. However, in contrast to Adebayo et al., we consider text classification. Moreover, while the analysis of Adebayo et al. is largely based on visual inspection, we extend it by considering automatically quantifiable measures. We also extend the analysis to non-gradient based methods (SHAP).

2 Setup

We describe the datasets, models, and interpretability methods considered in our analysis.

Datasets. We consider four different datasets covering a range of document lengths and number of label classes. The datasets are: (i) **FPB:** The Financial Phrase Bank dataset (Malo et al., 2014) where the task is to classify news headlines into one of three sentiment classes, namely, positive, negative, and neutral. (ii) **SST2:** The Stanford Sentiment Treebank 2 dataset (Socher et al., 2013). The task is to classify single sentences extracted from movie reviews into positive or negative sentiment classes. (iii) **IMDB:** The IMDB movie reviews dataset (Maas et al., 2011). The task is to classify movie reviews into positive or negative sentiment classes. (iv) **Bios:** The Bios dataset of De-Arteaga et al. (2019). The task is to classify the profession of a person from their biography. Table 5 in Appendix A shows detailed dataset statistics.

2.1 Models

We consider four pretrained Transformer encoders: BERT (**BT**), RoBERTa (**RB**), DistilBERT (**dBT**), and DistilRoBERTa (**dRB**). The encoder is followed by a pooling layer to combine individual token embeddings, and a classification head. Appendix B.1 describes the detailed architecture, training and hyperparameter tuning details. After training and hyperparameter tuning, the best model is selected based on validation accuracy and is referred to as `Init#1`.

Different Initializations Test. Recall from §1 that this test involves comparing two identical models trained from different initializations. The second model, henceforth referred to as `Init#2`, is trained using the same architecture, hyperparameters and training strategy as `Init#1`, but starting from a different set of initial parameters. Since we start from pretrained encoders, the encoder parameters are not intialized. For each layer in the rest of the model, a set of initial parameters different from those in `Init#1` is obtained by calling the parameter initialization method of choice for this layer—*He initialization* (He et al., 2015) in this case—but with a different random seed.

Untrained Model Test. Recall that this test involves comparing the trained model (`Init#1`) with a randomly initialized untrained model, henceforth called `Untrained`. To obtain `Untrained`, we start from the `Init#1`, and randomly initialize the fully connected layers attached on top of the Transformer encoders (the encoder weights are not randomized). The initialization strategy is the same as in Different Initializations Test.

2.2 Interpretability methods

We consider a mix of gradient-based and model agnostic methods. Specifically: Vanilla Saliency (**VN**) of Simonyan et al. (2014), SmoothGrad (**SG**) of Smilkov et al. (2017), Integrated Gradients (**IG**) of Sundararajan et al. (2017), and KernelSHAP (**SHP**) of Lundberg and Lee (2017). We also include random feature attribution (**RND**) which corresponds to each feature being assigned an attribution from the uniform distribution, $\mathcal{U}(0, 1)$. Appendix B.2 provides details about the parameters chosen for the interpretability methods.

Given an input text document, we tokenize the text using the tokenizer of the corresponding encoder. Finally, for each input feature (that is, token), the feature attribution of the gradient-based methods is a vector of the same length as the token input embedding. For scalarizing these vector scores, we use the L2-norm strategy of Arras et al. (2016) and the Input $\odot$ Gradient strategy of Ding et al. (2019).

2.3 Interpretability Metrics

To compare the feature attributions by various interpretability methods, we use the following metrics.

(In)Fidelity: Given an input text which has been split into L tokens, $\mathbf{t} = [t_1, \ldots, t_L]$, get the vector $\mathbf{\Psi}(\mathbf{t}) = [\psi(t_1), \ldots, \psi(t_L)]$ of feature attributions of the corresponding tokens using the interpretability method to be evaluated. Drop the features from $\mathbf{t}$ in the decreasing order of attribution score until the model prediction changes from the original prediction (with all tokens present). Infidelity is defined as the % of features that need to be dropped until the prediction changes. A better interpretability method is expected to need a lower fraction of features to be dropped until the prediction change. We simulate feature dropping by replacing the corresponding input token with the model's unknown vocabulary token.

	BT	RB	dBT	dRB
FPB	0.83	0.85	0.82	0.84
SST2	0.87	0.91	0.88	0.90
IMDB	0.92	0.95	0.93	0.94
Bios	0.86	0.86	0.86	0.86

Table 1: Test accuracy with `Init#1`. For any given dataset, all encoders lead to a similar accuracy.

The infidelity metric has appeared in many closely related forms in a number of studies evaluating model interpretability (Arras et al., 2016; Atanasova et al., 2020; DeYoung et al., 2020; Fong et al., 2019; Lundberg and Lee, 2017; Samek et al., 2017). All of these forms operate by iteratively hiding features in the order of their importance and measuring the change in the model output, e.g., in predicted class probability, or the predicted label itself. We chose number of tokens to prediction change, which is closely aligned with (Arras et al., 2016), due to its simplicity as compared to more involved metrics relying on AUC-style measures (Atanasova et al., 2020; Samek et al., 2017).

Jaccard Similarity: It is common to show top few most important features to users as model interpretations. See for instance, Ribeiro et al. (2016) and Schmidt and Biessmann (2019). In order to measure the similarity between feature attributions generated by different methods, we use the Jaccard@K% metric. Given an input $\mathbf{t}$, let $\mathbf{s}_i$ be the set of top-K% tokens, when the tokens are ranked based on their importance as specified by an attribution output $\mathbf{\Psi}_i$. Then, given two attribution outputs $\mathbf{\Psi}_i$ and $\mathbf{\Psi}_j$, Jaccard@K% measures the similarity between them as: $J(i, j) = \frac{|\mathbf{s}_i \cap \mathbf{s}_j|}{|\mathbf{s}_i \cup \mathbf{s}_j|}$. If the top-K% tokens by the two attributions $\mathbf{\Psi}_i$ and $\mathbf{\Psi}_j$ are the same, then $J(i, j) = 1$. In case of no overlap in the top-K% tokens, $J(i, j) = 0$.

Appendix D shows some examples of Jaccard@K% computation.

3 Results

Table 1 shows the test set accuracy of `Init#1` model with different encoders on all the datasets. For all the datasets, different encoders lead to a very similar accuracy. Tables 7 in Appendix C.1 shows the prediction accuracy for `Untrained`.

Infidelity. Table 2 shows the infidelity of different interpretability methods on the best performing models (`Init#1`). The table shows that: (i) As expected, the infidelity of all interpretability methods is better than RND; (ii) SHP provides the best performance, followed by IG; (iii) For a given dataset, even though different encoders have very similar accuracy (Table 1), the infidelity of the same interpretability method for different encoders can vary widely, e.g., SHP on IMDB; (iv) There is no particularly discernable correlation between the models and their infidelity, for instance, with FPB dataset, the distilled Transformers provides same or lower infidelity as compared to the original counterparts (BERT, RoBERTa), whereas the trend is reversed for SST2 data.

Moreover, gradient-based methods in Table 2 use the L2-norm reduction (§2.2). Table 8 in Appendix C.2 shows that in most cases, the performance is much worse when using the Input ⊙ Gradient reduction. Hence, for the rest of the analysis, we only use L2-norm reduction.

Different Initializations Test. Comparing `Init#1` and `Init#2` in Table 6 in Appendix C.1—two otherwise identical models with only difference being the random initial parameters, shows that a vast majority of predictions are common between the two models: meaning that the *two models are almost functionally equivalent*.

We now compare the similarity in feature attributions of two functionally equivalent models. Since the feature attributions are generated w.r.t. the predicted class, our similarity analysis is limited to samples where both models generate the same prediction. Figure 1 shows Jaccard@25% when comparing the feature attributions of `Init#1` vs. `Init#2`, and `Init#1` vs. `Untrained`. The figure shows that (i) for the functionally equivalent models `Init#1` vs. `Init#2`, Jaccard@25% is far from the ideal value of 1.0 — in fact, for IG, the value drops to almost 0.5; (ii) When comparing the top-ranked feature attributions of `Init#1` vs. `Init#2`, and `Init#1` vs. `Untrained`, the former should show a much bigger overlap than latter, but this is not the case, except for SHP.

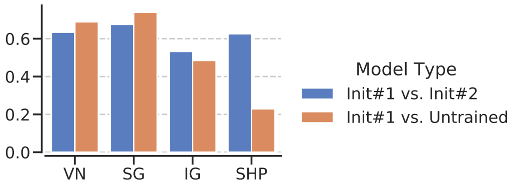

Figure 1: [**BT** on SST2 data] Comparing the mean Jaccard@25 between different model types (`Init#1` vs. `Init#2` and `Init#1` vs. `Untrained`).

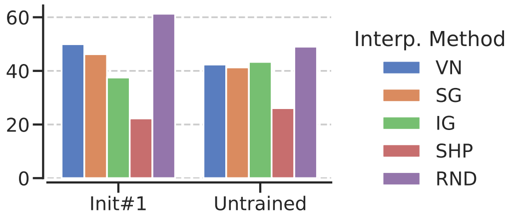

Figure 2: [**BT** on SST2 data] Mean infidelity of interpretability methods on `Init#1` and `Untrained`.

Tables 3 and 4 show the results for rest of the cases, revealing similar insights. Specifically, the Jaccard@25% between `Init#1` and `Untrained` for VN averaged over all 16 cases (four datasets, four models in Table 3) is 68, whereas the same is 69 when comparing `Init#1` and `Untrained` (Table 4). The same comparison yields 67 vs. 64 for SG, 56 vs. 50 for IG and 65 vs. 29 for SHP. Moving beyond averages, we also counted for each of the cases in Table 3, the number of times Jaccard@25% between `Init#1` and `Init#2` is within 10 units (Jaccard@25% ranges from 0-100) of the Jaccard@25% between `Init#1` and `Untrained` for the corresponding

pair in Table 4. The numbers are 14/16 for VN, 12/16 for SG, 7/16 for IG and 0/16 for SHP.

We selected K=25 as it corresponds to comparing the 25% most important features between the two models. Selecting K=10 (comparing 10% most important features) leads to similar outcomes: 13/16 for VN, 11/16 for SG, 6/16 for IG and 0/16 for SHP.

In other words, *the attribution overlap between two functionally equivalent models can be similar to that between a trained vs. an untrained model.*

Untrained Model Test. Figure 2 shows the infidelity of different methods on SST2 dataset with a **BT** model. We note that the performance of RND is better (lower infidelity) for the untrained model (`Untrained`) than for the trained model (`Init#1`). Furthermore, even for the untrained model (`Untrained`), all interpretability methods have a better fidelity than RND. In fact, for SHP, the infidelity is almost half of RND. Table 9 in Appendix C shows a similar pattern for the rest of the datasets and models.

In short, *even for an untrained model, the interpretability methods lead to better-than-random-attribution fidelity.* The insights highlight the need for baselining the fidelity metric with untrained models before using it as an evaluation measure.

4 Conclusion & Future Work

We carried out two tests to assess robustness of several popular interpretability methods on Transformer-based text classifiers. The results show that both gradient-based and model-agnostic methods can fail the tests.

These observations raise several **interesting questions**: if the fidelity of the interpretations is reasonably high on even an untrained model, to what extent does the interpretability method reflect the data-specific vs. data-independent behavior of the model? If two functionally equivalent models lead to different feature attributions, to what extent can the practitioners rely upon these interpretations to make consequential decisions?

One cause of the non-robust behavior could be the redundancy in text where several input tokens may provide evidence for the same class (e.g., several words in input review praising the movie). Another reason, related to the first, could be the pathologies of neural models where dropping most of the input features could still lead to highly confident predictions (Feng et al., 2018).[1] Dropping individual features can also lead to out-of-distribution samples, further limiting the effectiveness of methods and metrics that rely on simulating feature removal (Kumar et al., 2020; Sundararajan and Najmi, 2020). Systematically analyzing the root causes, and designing interpretability measures that are cognizant of the specific characteristics of text data—preferably with human involvement (Chang et al., 2009; Doshi-Velez and Kim, 2017; Hase and Bansal, 2020; Nguyen, 2018; Poursabzi-Sangdeh et al., 2021; Schmidt and Biessmann, 2019)—is a promising research direction. Similarly, extending the Untrained Model Test to study the effect of randomization of pre-trained embedding models on interpretability is another direction for exploration.

---

[1] Note, however, that the insights of Feng et al. relate to *dropping least important tokens first*, whereas when computing infidelity, one drops the most important first.

Appendix A Datasets

	N	K	D	Δ_K
FPB	4,846	3	22±10	47
SST2	9,613	2	19±9	3
IMDB	50,000	2	227±168	0
Bios	397,907	28	61±28	30

Table 5: Dataset details. The columns are: # of samples (N), # of classes (K), average ± standard deviation # of words per document (D), and Class Imbalance (Δ_K). Class imbalance is measured as % prevalence of the most prevalent minus the least prevalent class.

Appendix B Reproducibility

B.1 Architecture, data & training details

We insert a classification head on top of the pretrained encoder. The end-to-end classifier has the following architecture: Encoder → Avg. pooling → FC-layer (512-units) → RELU → FC-layer (K units), where K is the number of classes. The maximum sequence length of the encoder is set to 128 for FPB and SST2 datasets, 512 for IMDB reviews and 200 for the Bios data.

Each dataset is split into a $80\% - 20\%$ train-test set. 10% of the training set is used as a validation set for hyperparameter optimization. Accuracy and overlap statistics are reported on the test set.

We used the following hyperparameter ranges: learning rate $\{10^{-2}, 10^{-3}, 10^{-4}, 10^{-5}\}$ and the number of last encoder layers to be fine-tuned $\{0, 2\}$. Fine tuning last few layers of the encoder, as opposed to all the layers, has been shown to lead to superior test set performance (Sun et al., 2019).

We use the AdamW optimizer (Loshchilov and Hutter, 2019). The maximum number of training epochs is 25. We use early stopping with a patience of 5 epochs: if the validation accuracy does not increase for 5 consecutive epochs, we stop the training. The model training was done using PyTorch (Paszke et al., 2019) and HuggingFace Transformers (Wolf et al., 2020) libraries.

B.2 Interpretability methods implementation

Owing to the large runtime of methods like SHAP and Integrated Gradients, interpretations are only computed for a randomly chosen 1000 subsample from the test set. Consequently, metrics like fidelity and Jaccard@K% are reported only on this subset.

	BT	**RB**	**dBT**	**dRB**
FPB	88	94	90	89
SST2	94	96	93	94
IMDB	98	97	97	98
Bios	95	95	95	95

Table 6: A vast percentage of predictions are common between the `Init#1` and `Init#2`, indicating that the models are almost *functionally equivalent*.

	BT	**RB**	**dBT**	**dRB**
FPB	0.19	0.19	0.34	0.34
SST2	0.21	0.22	0.30	0.80
IMDB	0.27	0.51	0.20	0.46
Bios	0.03	0.02	0.01	0.01

Table 7: Test accuracy with `Untrained`.

Vanilla Saliency and SmoothGrad are implemented using the PyTorch `autograd` function. Integrated Gradients and SHAP are implemented using Captum (Kokhlikyan et al., 2020). The parameters of these methods are:

SmoothGrad. Requires two parameters. (i) Number of iterations: Following AllenNLP Interpret (Wallace et al., 2019), we use a value of 10. (ii) Variance of the Gaussian noise $\mathcal{N}(0, \sigma^2)$. The default value of 0.01 leads to attributions that are almost identical to Vanilla Saliency. So we try different values of $\sigma \in \{0.01, 0.05, 0.1, 0.2\}$ and select the one with the lowest infidelity.

Integrated Gradients. Requires setting two parameters. (i) Number of iterations: we use Captum (Kokhlikyan et al., 2020) default of 50. (ii) Feature Baseline: IG requires specifying a baseline (Sundararajan et al., 2017) that has the same dimensionality as the model input, but consists of 'non-informative' feature values. We construct the baseline by computing the embedding value of the unknown vocabulary token and repeating it N times where N is the maximum sequence length of the model.

KernelSHAP. Requires two parameters. (i) Number of feature coalitions: Following the author implementation,[2] we use a value of $2L + 2^{11}$, where L is the number of input tokens in the text. (ii) Dropped token value: SHAP operates by dropping subsets of tokens and estimating model output on these perturbed inputs. We simulate dropping of a

Table 9: Mean infidelity of different interpretability methods for `Untrained` (shown as %). Lower values are better.

token by replacing its embedding value with that of the unknown vocabulary token.

Appendix C Additional results

C.1 Accuracy & prediction commonality

Table 6 shows the fraction of predictions common between `Init#1` and `Init#2`.

Table 7 shows the accuracy of `Untrained`. As expected, the accuracy of `Untrained` is much smaller than with trained models.

C.2 Input ⊙ Gradient reduction

Table 8 shows the infidelity of gradient-based interpretability methods when using the Input ⊙ Gradient dot product reduction of Ding et al. (2019). When comparing the results to those with L2 reduction in Table 2, we notice that in *all except two cases* (VN and SG on **dBT** with IMDB data), the performance is worse.

C.3 Infidelity with `Untrained` model

Table 9 shows the infidelity for the `Untrained` model. Much like Figure 2, the table shows that in several cases, the performance of the feature attribution methods (most notably SHP) can be much better than random attribution (RND).

The table also shows an exception for **dBT** on IMDB dataset where for all methods, the infidelity is near 100. This behavior is likely an artefact of the particular initial parameters due to which the model always predicts a certain class irrespective of the input.

Appendix D Examples of top-ranked tokens

We now show some examples of Jaccard@K% computation. The examples show the input text, different models, and top-K% tokens ranked w.r.t. their importance. The attribution method used was VN.

Example 1: SST2 data. Comparing `Init#1` and `Init#2`. Both models predict the sentiment to be positive.
Text. at heart the movie is a deftly wrought suspense yarn whose richer shadings work as coloring rather than substance
Top-25% w.r.t. `Init#1`. {‘substance’, ‘rather’, ‘at’, ‘yarn’, ‘coloring’, ‘movie’}
Top-25% w.r.t. `Init#2`. {‘heart’, ‘##tly’, ‘suspense’, ‘at’, ‘yarn’, ‘def’}
Jaccard@25%. 20

Example 2: SST2 data. Comparing `Init#1` and `Init#2`. Both models predict the sentiment to be positive.
Text. an infectious cultural fable with a tasty balance of family drama and frenetic comedy
Top-25% w.r.t. `Init#1`. {‘fable’, ‘infectious’, ‘cultural’, ‘balance’, ‘an’}
Top-25% w.r.t. `Init#2`. {‘cultural’, ‘balance’, ‘infectious’, ‘fable’, ‘an’}
Jaccard@25%. 100

Example 3: FPB data. Comparing `Init#1` and `Untrained`. Both models predict the sentiment to be negative.

Text. nokia shares hit 13.21 euros on friday , down 50 percent from the start of the year in part because of the slow introduction of touch-screen models
Top-25% w.r.t. `Init#1`. { ‘,’, ‘.’, ‘down’, ‘friday’, ‘shares’, ‘euros’, ‘nokia’, ‘hit’ }
Top-25% w.r.t. `Init#2`. { ‘,’, ‘.’, ‘down’, ‘euros’, ‘friday’, ‘hit’, ‘shares’, ‘nokia’ }
Jaccard@25%. 100

In second and third examples, even though the rankings are different, the set of top-25% tokens is the same leading to a perfect Jaccard@25%.

Multimodal Graph-based Transformer Framework for Biomedical Relation Extraction

Sriram Pingali, Shweta Yadav[*], Pratik Dutta[*], Sriparna Saha

{1801cs37, shweta.pcs14, pratik.pcs16, sriparna}@iitp.ac.in

Abstract

The recent advancement of pre-trained Transformer models has propelled the development of effective text mining models across various biomedical tasks. However, these models are primarily learned on the textual data and often lack the domain knowledge of the entities to capture the context beyond the sentence. In this study, we introduced a novel framework that enables the model to learn multi-omnics biological information about entities (proteins) with the help of additional multi-modal cues like molecular structure. Towards this, rather developing modality-specific architectures, we devise a generalized and optimized graph based multi-modal learning mechanism that utilizes the GraphBERT model to encode the textual and molecular structure information and exploit the underlying features of various modalities to enable the end-to-end learning. We evaluated our proposed method on Protein-Protein Interaction task from the biomedical corpus, where our proposed generalized approach is observed to be benefited by the additional domain-specific modality.

1 Introduction

The biomedical scientific articles hold the valuable knowledge of biomedical entities (such as protein, drug, gene) and their relationships. However, with the exponential increase in the volume of biomedical articles (Lu, 2011), it is imperative to advance the development of an accurate biomedical text mining tool to extract and curate meaningful information from huge unstructured texts automatically.

One of the cardinal tasks in biomedical document processing is Protein-protein interaction (PPI), where the relation ('*interaction*' or '*non-interaction*') between two protein mentions is identified from the given biomedical text. The knowledge about protein interactions is critical in understanding the biological processes, such as signaling cascades, translations and metabolism, that are regulated by the interactions of proteins that alter proteins to modulate their stability (Elangovan et al., 2020).

Majority of the existing works on PPI in the literature primarily focused only on the textual information present in the biomedical article. However, these approaches lack in capturing **(1)** multi-omnics biological information regarding protein interactions, and **(2)** genetic and structure information of the proteins. A few works (Dutta and Saha, 2020; Asada et al., 2018; Jha et al., 2020; Jha and Saha) have been reported in the literature where the researchers have considered different modalities of the biomedical corpus. However, these multi-modal architectures are modality-specific and thus are very complex. Hence, there is a surge to develop a generalized and optimized model that can understand all the modalities rather than developing various architectures for different modalities.

Towards this, we explore Graph-based Transformer model (GraphBERT) (Zhang et al., 2020) to learn the modality independent graph representation. This enables the model to acquire the joint knowledge of both the modalities (textual and protein structure) under a single learning network. The main contributions of this work are:

1. Besides the textual information of the biomedical corpus, we have also utilized protein atomic structural information while identifying the protein interactions.
2. Developed a generalized modality-agnostic approach that is able to learn the feature representations of both the textual and the protein-structural modality.
3. Our analysis reveals that addition of protein-structure modality increases the efficiency of

model in identifying the interacted protein mentions.

Related Work: Existing studies have adopted traditional statistical and graphical methods (Miyao et al., 2008; Chang et al., 2016) to identify the protein interactions from the textual content. Later, with the success of deep learning, several techniques based on Convolutional Neural Network (Choi, 2018; Peng and Lu, 2017; Ekbal et al., 2016), Recurrent Neural Network (Hsieh et al., 2017; Ahmed et al., 2019), Long Short Term Memory network (Yadav et al., 2019; Ningthoujam et al., 2019; Yadav et al., 2020), and language models (Yadav et al., 2021) based methods are proposed for extracting the relationships from biomedical literature and clinical records. Fei et al. (2020) proposed a span-graph neural model for jointly extracting overlapping entity relationships from biomedical text. The recent advancement of the Transformer model (Lee et al., 2020; Beltagy et al., 2019) in the biomedical domain has also led to significant performance improvement in biomedical relation extraction task (Giles et al., 2020). Recently, the use of multi-modal dataset in BioNLP domain (Dutta and Saha, 2020; Asada et al., 2018) draws the attention of the researchers due to its better performance than the traditional approaches. In contrast, our model is independent of handling multiple modalities without relying on modality-specific architectures.

2 Proposed Method

In this section, we introduce our proposed method and its detailed implementation. The proposed deep multi-modal architecture is illustrated in Figure-1, that consists of four main components: **(1)** *Multi-modal Graph Constructor*, **(2)** *Multi-modal Graph Fusion*, **(3)** *Multi-modal Graph Encoder*, **(4)** *PPI Predictor*. Below we briefly describe each of the model components.

Problem Statement: Given a biomedical input text $S = \{w_1, w_2, \ldots, w_n\}$ having n words, and a pair of protein mentions $p_1, p_2 \in S$, we aim to predict, whether the protein mentions will *'interact'* or *'non-interact'*.

2.1 Multi-modal Graph Constructor

This component consists of two distinct graph constructors for two different modalities, which are Textual Graph Constructor and Protein Structure Graph Constructor. The former, constructs the graph by considering the textual content that aims to capture the lexical and contextual information present in the input. The later, exploits the atomic structure (3D PDB structure) of the protein molecules to build the graph.

Textual Graph Constructor: To generate the textual graph, we begin by first constructing the vocabulary from the training corpus. For each input text S, we use one-hot-encoding mechanism to encode them as a vector representation $R_S \in \mathcal{R}^{|V|}$. However, the representation R_S suffers from the data sparsity as the vocabulary size can become very large for the entire training corpus. To deal with this, we utilized the Principal Component Analysis (PCA) (Wold et al., 1987) to reduce the vector dimensionality. The textual graph $\mathcal{G}_T = \{\mathcal{V}_T, \mathcal{E}_T\}$ is formulated by the nodes $\mathcal{V}_T = \{\hat{R}_{S_1}, \hat{R}_{S_2}, \ldots, \hat{R}_{S_{|N|}}\}$, where $|N|$ is the number of input sentences in the training dataset and $\hat{R}_{S_i} \in \mathcal{R}^{|\hat{V}|}$ is reduced vector representation of size $|\hat{V}|$ for sentence S_i. The link $e_{i,j}$ between nodes $\hat{R}_{S_i}$ and $\hat{R}_{S_j}$ is determined by the common entities (*protein*) present in both the sentences S_i and S_j, if there is no common entity, then link does not exist between the nodes. The edges $\mathcal{E}_T = \{e_{i,j} \mid i, j \in \mathcal{V}_T, \text{ and } protein \in i,\ j\}$ are the set of all the links that exist between any two nodes in the graph, $\mathcal{G}_T$.

Protein Structure Graph Constructor: For the protein structural modality, we created a graph where each node represents an atom and the edge represents the connection between the atoms. To obtain the atomic information about the proteins, first we have mapped the proteins into genes and utilized the PDB (Protein Data Bank)[1] for each associated protein mention. Each protein information obtained from PDB consists of set of atoms $\{a_1, a_2, \ldots, a_A\}$, and a node feature matrix, $N_p \in \mathcal{R}^{A \times d_p}$. The node feature matrix for each protein k undergoes the convolutional operation *CNN(.)* followed by the max-pooling operation, *pool*(.). Formally, $P_k = pool(relu(CNN(N_{p_k})))$. The final protein representation, P_{S_i}, for both the proteins present in the given input sentence S_i is computed as follows: $P_{S_i} = P_1 \oplus P_2$. Following this, the protein structure graph $\mathcal{G}_P = \{\mathcal{V}_P, \mathcal{E}_P\}$ is formulated by the nodes $\mathcal{V}_P = \{P_{S_1}, P_{S_2}, \ldots, P_{S_{|N|}}\}$, where $|N|$ is the number of input sentences in the training dataset and $P_{S_i} \in \mathcal{R}^{d_s}$ is the protein structure

---

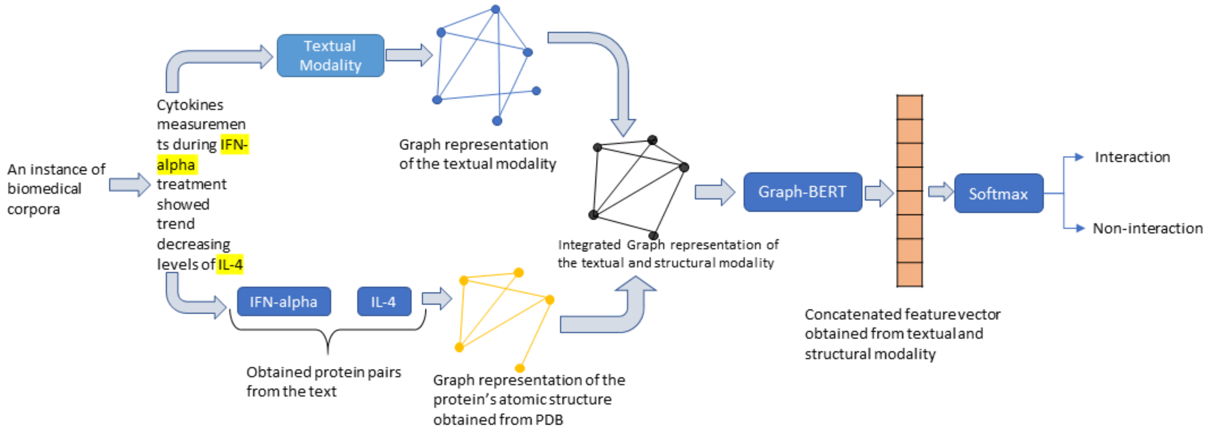

Figure 1: An outline of the proposed deep multi-modal architecture for PPI.

representation of size d_s for sentence S_i.

2.2 Multi-modal Graph Fusion

In this component, we fused the textual graph $\mathcal{G}_T$ and protein structure graph $\mathcal{G}_P$ with the aim of generating a joint representation that is capable of capturing the contextual, lexical, and multi-omnics information. Towards this, we expanded the node information of textual graph with the node information obtained in the protein-structure graph. Specifically, we created a multi-modal graph $\mathcal{G}$ with the nodes $\mathcal{V}$ having concatenated vector representations from the respective nodes of textual graph and protein structure graph. Formally,

$$\mathcal{V}_i = \hat{R}_{S_i} \oplus P_{S_i} \tag{1}$$

The link information remains intact in the multi-modal graph fusion, thus, $\mathcal{E} = \mathcal{E}_{\mathcal{T}}$.

2.3 Multi-modal Graph Encoder

Majority of the existing works on multi-modal relation extraction have treated multiple modalities separately and exploited the modality-specific architectures to learn the respective feature representations. However, these strategies inhibit the learning of inherent shared complementary features, that are often present across the modalities. To address this, we present an end-to-end multi-modality learning mechanism that exploits the single expanded multi-modal graph (obtained from the Multi-modal Graph Expansion component) with the Graph-based Transformer encoder. Specifically, we utilized the Graph-BERT (Zhang et al., 2020) encoder over the other dominants graph neural networks (GNNs) primarily due to its capability to avoid the **(a)** *suspended animation problem* (Zhang and Meng, 2019), and **(b)** *over-smoothing problem* (Li et al., 2018) that hinders the applications of GNNs for deep graph representation learning tasks. For a given multi-modal graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ with the set of nodes ($\mathcal{V}$) and edges ($\mathcal{E}$), Graph-BERT sampled set of graph batches for all the nodes as set $\mathcal{G} = \{g_1, g_2, \ldots, g_{|\mathcal{V}|}\}$. For all the nodes v_j in sub-graph g_i, the Graph-BERT computes raw feature vector embedding e_j^x, role embedding e_j^r, position embedding e_j^p and distance embedding e_j^d. The initial input vector for node v_j is computed as follows: $h_j^{(0)} = e_j^x + e_j^r + e_j^p + e_j^d$. Furthermore, the initial input vectors for all the nodes in g_i can be organized into a matrix $H^{(0)} = [h_i^{(0)}, h_{i,1}^{(0)}, \ldots, h_{i,k}^{(0)}]^\top$, where k is a hyper-parameter. The Graph-Transformer (Zhang et al., 2020) computes the vector representation of D layers of transformers. The final feature (z_i) for node v_j is computed as follows:

$$\begin{aligned} H^{(0)} &= [h_i^{(0)}, h_{i,1}^{(0)}, \cdots, h_{i,k}^{(0)}]^\top \\ H^{(l)} &= \textit{G-Transformer}\left(H^{(l-1)}\right) \\ z_i &= \sum_{m=0}^{m=D} H^{(m)} \end{aligned} \tag{2}$$

2.4 PPI Predictor

The final feature (z_i) of each node i is used to predict the PPI category. Towards this, we employed a feed-forward network with *softmax* activation layer to predict the input text into one of the two classes *interaction* or *non-interaction*. Formally,

$$prob(c = interact|\mathcal{G}, S, \theta) = \frac{exp(\boldsymbol{W}^T z_i^{\text{interact}} + \boldsymbol{b})}{\sum_{k=1}^{K} exp(\boldsymbol{W}^T z_i^k + \boldsymbol{b})} \tag{3}$$

where, $\boldsymbol{W}$ and $\boldsymbol{b}$ are the weight matrix and bias vector, respectively. K denotes total number of

distinct classes, which are *'interaction'* and *'non-interaction'* in our case.

3 Datasets and Experimental Analysis

Datasets: In this work, we have collected two exemplified multi-modal protein protein interaction datasets (Dutta and Saha, 2020). In these datasets, the authors exemplified two popular benchmark PPI corpora, namely BioInfer[2] and HPRD50[3].

Experimental Setup We have utilized the pre-trained Graph-BERT[4] in our experiment. The initial vocabulary for BioInfer and HPRD50 datasets are 6561 and 1277, respectively. We have projected them into 1000 and 1185 dimension vectors using PCA, respectively. We have kept maximum of 5052 and 1185 number of words in both the datasets, respectively. The filter-size of CNN is set to $3, 4$. We have obtained 1185 length node feature representation for protein structure graph. The nodes of multi-modal graph received the 2185 sized feature representation. We have obtained 2500 and 25859 number of nodes and edges from HPRD50 dataset and 13675 and 15930214 number of nodes and edges from BioInfer dataset for the Graph-BERT training, respectively. We have used all the hyper-parameters of Graph-BERT model in our proposed model. We have kept following hyper-parameters values: subgraph size = 5, hidden size = 32, attention head number = 2, Transformer layers, D = 2, learning rate = 0.01, weight decay = 5e 4, hidden dropout rate = 0.5, attention dropout rate = 0.3, loss = cross entropy, optimizer = adam (Kingma and Ba, 2014). The hyper-parameters are chosen based on the 5-fold cross-validation experiments on both the datasets.

Results and Analysis: We have compared the performance (*c.f.* Table-1,3) of our proposed model with the existing state-of-the-art methods on PPI for both the datasets. These existing methods are based on different techniques like kernel-based (Choi and Myaeng, 2010; Tikk et al., 2010; Qian and Zhou, 2012; Li et al., 2015), deep neural network-based (Zhao et al., 2016; Yadav et al., 2019), multi-channel dependency-based convolutional neural network model (Peng and Lu, 2017), semantic feature embedding (Choi, 2018), shortest dependency path (Hua and Quan, 2016) and a recent deep multi-modal approach (Dutta and Saha, 2020). It is to be noted that our results on BioInfer and HPRD50 are not directly comparable with the existing approaches as other methods have utilized different test sets for evaluation. From the above comparative study, it is evident that our proposed multi-modal approach identifies the protein interactions in an efficient way and can be further improved in different ways.

Discussion: To analyze the role of each modality, we conducted ablation study as shown in Table 2. We performed the experiments with the textual modality. Here, we could not consider the protein-structural modality alone as it would bring the conflicting labeling relation. For example, consider two sentences that contain same pair of proteins

---

[3] https://goo.gl/M5tEJj

[4] https://github.com/jwzhanggy/Graph-Bert

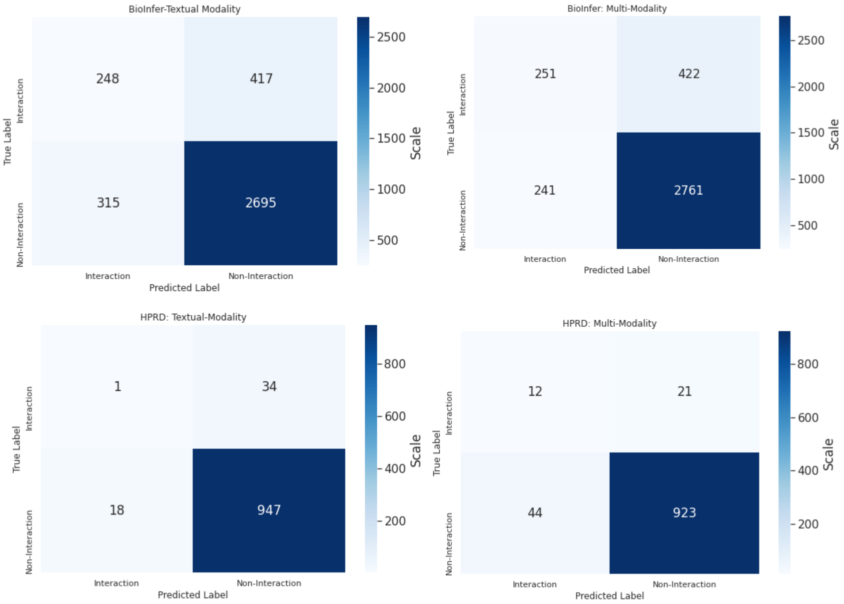

Figure 2: Confusion matrices of our proposed approach on both HPRD and BioInfer datasets with only textual modality and text+structure modality.

but these proteins can have conflicting relations (interacting or non-interacting) depending on the context of sentences in which they appear. Hence, we could not consider the protein-structural modality alone. Though the structural modality is unable to draw any conclusion alone, however the integration of both the modalities demonstrates the improvements (3.78% and 1.8%, in terms of F-score for HPRD50 and BioInfer, respectively) over the textual modality alone.

4 Error Analysis

The comparative confusion matrices with only textual-modality and multi-modality for both the datasets are shown in Figure-2. We have performed error analysis to postulate possible reasons and areas with scope of improvement in our experiments. After careful study on false positive and false negative classes, following observations can be made.
1) Instances with a large number of protein mentions in a single sentence can cause misclassification. For example, the maximum number of proteins in any instances of BioInfer and HPRD50 datasets are 26 and 24, respectively. These large number of proteins present in a single instance may lead the network to misclassificaton.
2) Few samples contain repeated mentions of the same protein. This adds noise and might lead to losing useful contextual information.
3) To get a consistent graph from molecular structure, the nodes were required to be of the same length. This is done by padding the vectors with zeros, and when the PDB is not available, a null vector is used for consistency. A better handling of missing data will help in learning the proposed model.

5 Conclusion

This work presents a novel modality-agnostic Graph-based framework to identify the interactions between the proteins. Specifically, we explored two modalities: *textual*, and *molecular structure* that enable the model to learn the domain-specific multi-omnics information complementary with the task-specific contextual information. A detailed comparative results and analysis proves that our proposed multi-modal approach can capture underlying molecular structure information without relying on sophisticated modality-specific architectures. Future work aims at extending this study to the other related tasks like drug-drug interactions.

Abstract

Many conversation datasets have been constructed in the recent years using crowdsourcing. However, the data collection process can be time consuming and presents many challenges to ensure data quality. Since language generation has improved immensely in recent years with the advancement of pre-trained language models, we investigate how such models can be utilized to generate entire conversations, given only a summary of a conversation as the input. We explore three approaches to generate summary grounded conversations, and evaluate the generated conversations using automatic measures and human judgements. We also show that the accuracy of conversation summarization can be improved by augmenting a conversation summarization dataset with generated conversations.

1 Introduction

Automatic conversation systems require large quantities of data to learn task specific language patterns and underlying conversation policies. Such data either come from human-to-human conversation logs (Lowe et al., 2015; Hardalov et al., 2018) or is collected in crowd-sourced environments, where two or more crowd-workers play specific roles under some guidelines (Zhang et al., 2018; Budzianowski et al., 2018). Since real human-to-human conversation logs are scarce, many datasets have been created using the latter approach. However, crowd-sourced conversation data collection is time consuming, costly and presents multiple challenges to ensure data quality (Kang et al., 2018).

Conversation summarization is an emerging research area that has been ill-studied due to the lack of large-scale datasets. Most existing public datasets in this domain are small, for example, AMI meeting corpus (McCowan et al., 2005) contains 137 summary transcripts. CRD3 (Rameshkumar and Bailey, 2020) is a spoken conversation dataset that consists of 159 conversations and summaries. Samsum (Gliwa et al., 2019), the only large scale dataset for conversation summarization, contains over $16,000$ open-domain conversations and summaries created artificially by humans.

Large scale pre-trained language models (PLMs) (Lewis et al., 2020; Brown et al., 2020; Raffel et al., 2020) have been used in various text generation tasks (Budzianowski and Vulić, 2019; Min et al., 2020; Cachola et al., 2020). In recent studies, PLMs are used to generate training data for natural language processing (NLP) applications. For example, Anaby-Tavor et al. (2020); Yang et al. (2020) use PLMs to create paraphrases for intent classifiers in conversation systems, and show that, when the original datasets are augmented with the generated data, performance improves. More recently Mohapatra et al. (2020) generated entire conversations grounded on instructions that are provided to crowd-workers using a modular approach, where different PLMs are trained for different roles.

Our Contributions: We investigate how PLMs can be utilized to generate entire conversations that are grounded on a given summary. We explore three approaches: (1) Supervised Learning (SL) based conversation generation *(SL-Gen)*: where, a PLM is trained to generate an entire conversation, taking the summary of a conversation as input, (2) Reinforced Learning (RL) based conversation generation *(RL-Gen)*: where, we further improve the *SL-Gen* method using the quality of the generated conversations as a reward, and (3) Controlled turn-by-turn conversation generation *(CN-Gen)*: which allows us to generate conversations turn-by-turn, constrained on the summary and a set of pre-defined control parameters. We evaluate the quality of the generated conversations by conducting automatic and human evaluation. We

also show that once a conversation summarization dataset is augmented with the generated conversations, the performance of the downstream summarization task is improved.

2 Summary grounded conversation generation

In the conversation summarization task, a model takes a conversation as input, and learns to generate a summary. We study the inverse of that problem, where the input to our model is a summary, and the model generates a conversation. In this section, we propose three models for this task and the hyperparameters used in training the models are available in Section A of the appendix.

2.1 SL based generation (SL-Gen)

A seq2seq model can be trained for this task by providing a summary as the input and generating a conversation token-by-token. As PLMs have shown significant improvement over the traditional seq2seq architecture for text generation, we use a GPT-2 model and fine-tune it to generate a conversation given a summary as the input. Our input to the model follows the following format: *<bos>summary text <dialog>conversation text<eos>*. We also use different token-type-ids to indicate the summary and the conversation text. The model is trained to optimize Cross Entropy loss.

2.2 RL based generation (RL-Gen)

Many studies train text generation models with RL (Paulus et al., 2018; Li et al., 2016), where the generator network is optimized with a task specific reward. We investigate how the quality of the generated conversation can be used as a reward to improve the generation network. To this end, we train a summary generator network, which generates a summary, given a conversation. We measure the quality of the generated conversation by identifying the similarity between the summary of the generated conversation (generated, in turn, by the summary generator network) and the ground truth summary. The similarity score is used as a reward to train the conversation generation model. Our RL based generation framework is shown in Figure 1, and the critical components are described below.

Conversation Generator: A trained SL-Gen model is used as the conversation generator, which, given an summary can generate a conversation.

Summary Generator: We use a lightweight variant of BART (Lewis et al., 2019), named *DistilBART*, which is fine-tuned on the Extreme summarization task (Narayan et al., 2018). We further fine-tune this instance on the conversation summarization data by providing the conversations as the input and training the model to output summaries.

Reward Model: Once the Summary Generator generates an output summary for the generated conversation, the reward model compares it with the ground truth summary, which was used to ground the conversation generation. As Paulus et al. (2018) we use ROUGE-2 F1-score as the reward.

Policy training: We use proximal policy optimization (Schulman et al., 2017) as the optimizer for the policy training as it prevents the generator from deviating far away from the pretrained LM (Wu et al., 2020).

2.3 Controlled conversation generation

We propose another approach, *(CN-Gen)*, for conversation generation, which grants more control over the properties of the generated conversations. Here, we generate one utterance of the conversation at a time, as opposed to the *RL-Gen*, where we generate the whole conversation at once. The properties of the generated conversations is controlled by adding several components to the input sequence to the model. The following three variables were used as the control parameters, (1) Number of remaining turns to generate in the conversation (Num turns): During the generation of a turn, we indicate the remaining number of turns in the conversation. In generating a n turn conversation, this starts with n for the first turn and reduces by 1 after the generation of each turn, (2) The speaker of the next

Summary: person0 will be late. person1 will order pasta with salmon and basil for her.	
2 turn conversation: <Person0> I'll be late <Person1> I'll order some pasta with salmon and basil for you.	**3 turn conversation** <Person0> I'll be late. <Person1> I'll order some pasta with salmon and basil for you. <Person0> Thanks a lot!
6 turn conversation <Person0> Hello, I am going to be late. <Person1> Ok <Person1> I'll order some pasta with salmon and basil <Person0> Ok, sounds good! <Person0> Thank you! <Person1> No problem	**10 turn conversation** <Person0> I'll be late <Person1> ok <Person1> do you want me to order something for you? <Person1> pasta? <Person0> Yes <Person1> with salmon? <Person0> Yes <Person1> Ok <Person1> how about basil? <Person1> Yes please!

Table 1: Multiple conversations generated by the CN-Gen approach grounded on the same summary

Model	Ave. Turns	Ave. Tokens/Turn
Ground truth	11.55 ± 6.48	7.10 ± 6.29
SL-Conv-Gen	10.54 ± 6.80	5.69 ± 4.40
RL-Conv-Gen	8.40 ± 4.78	5.14 ± 3.64
CN-Conv-Gen	9.70 ± 5.67	5.62 ± 4.05

Table 2: Properties of the generated conversations.

turn (Speaker): This indicates to the model the speaker of the next turn, and (3) The length of the next turn (Turn length): We define, 3 categories of lengths: Short (≤ 3 tokens), Long (> 10 tokens) and Medium (otherwise).

We use the following input representation to fine-tune a GPT-2 model: *<bos> summary text <context> dialog context <turns_to_go> Num turns <speaker> speaker <turn_length> turn length <turn> utterance <eos>*. Changing these parameters allows us to generate different variants of conversations which are grounded on the same summary. During training, we obtain the values for the control parameters from the ground truth conversations, and at inference we randomly select the next speaker, number of turns of the conversation to be generated (in a range of 4-15 turns), and the next turn length. In Table 1 we show conversations of different lengths that were generated by the CN-Gen approach grounded on the same summary by changing the control parameters.

A summary and a conversation from the Samsum dataset (Gliwa et al., 2019), along with the conversations generated by the three aforementioned algorithms are shown in Figure 2. More examples are provided in the Section B of the Appendix.

3 Experiments

We experiment on the Samsum (Gliwa et al., 2019) dataset, which, to the best of our knowledge, is the only public large-scale conversation summarization dataset. We pre-process the dataset by replacing the personal names (ex: John) with unique tags (ex:<person_0 >). First, we evaluate of the quality of generated conversations using automatic measures and human judgments, and then assess the performance of the generated conversations in a downstream summarization task after augmentation.

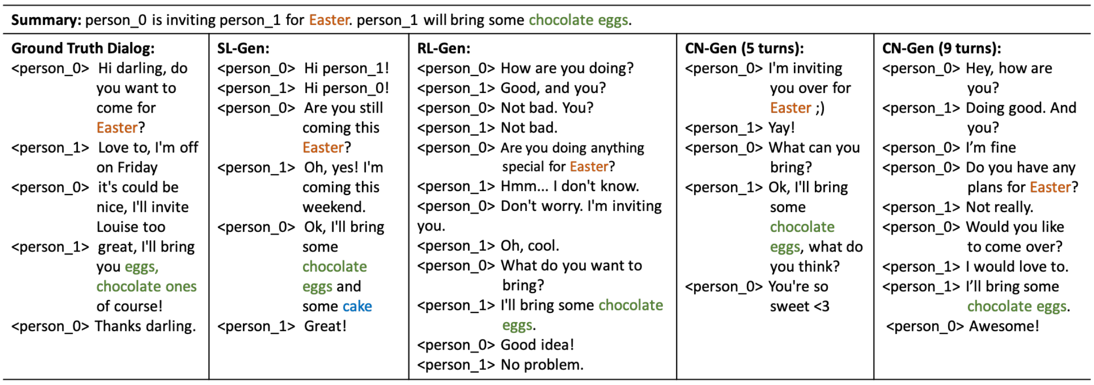
3.1 Quality of the generated conversations

We evaluate the quality of the conversations generated by the three approaches that were introduced in Section 2. In Table 2 we show the properties of generated conversations and the ground truth conversations in the test set of Samsum dataset.

Automatic Evaluation: We trained the conversation generation models on the Samsum training set and generated conversations on the test set. We compare the generated conversation with the ground truth conversations using the measures used by Sharma et al. (2017) to evaluate conversation system responses. The results shown in Table 3 suggest that CN-Gen outperform the SL-Gen and RL-Gen on all measures.

We also compare the summaries of generated conversations (generated by the Summary Generator) with the ground truth summaries, and the results are shown in Table 4. We believe that this is a semantic evaluation of the conversations, as the summaries capture the crux of the conversations. According to the results, CN-Gen outperforms the other two methods. This, along with the previous result suggest that the conversations produced by CN-Gen are the most similar to the ground truth conversations.

Human Evaluation: To evaluate the quality of generated conversations, we randomly selected 50 summaries from the Samsum test dataset and generated conversations using the three models. Three NLP experts were then asked to read the ground truth summary and rank the four conversations (3 generated and the ground truth conversation) using a [1-5] scale according to Grammaticality, Coherency, and Informativeness, with respect to the ground truth summary. Results are shown in table 5. As expected, the ground-truth conversations obtained the highest scores on all three aspects and can be considered as an upper bound for this task.



Summary: person_0 is inviting person_1 for Easter. person_1 will bring some chocolate eggs.				
Ground Truth Dialog:	**SL-Gen:**	**RL-Gen:**	**CN-Gen (5 turns):**	**CN-Gen (9 turns):**
<person_0> Hi darling, do you want to come for Easter? <person_1> Love to, I'm off on Friday <person_0> it's could be nice, I'll invite Louise too <person_1> great, I'll bring you eggs, chocolate ones of course! <person_0> Thanks darling.	<person_0> Hi person_1! <person_1> Hi person_0! <person_0> Are you still coming this Easter? <person_1> Oh, yes! I'm coming this weekend. <person_0> Ok, I'll bring some chocolate eggs and some cake <person_1> Great!	<person_0> How are you doing? <person_1> Good, and you? <person_0> Not bad. You? <person_1> Not bad. <person_0> Are you doing anything special for Easter? <person_1> Hmm... I don't know. <person_0> Don't worry. I'm inviting you. <person_1> Oh, cool. <person_0> What do you want to bring? <person_1> I'll bring some chocolate eggs. <person_0> Good idea! <person_1> No problem.	<person_0> I'm inviting you over for Easter ;) <person_1> Yay! <person_0> What can you bring? <person_1> Ok, I'll bring some chocolate eggs, what do you think? <person_0> You're so sweet <3	<person_0> Hey, how are you? <person_1> Doing good. And you? <person_0> I'm fine <person_0> Do you have any plans for Easter? <person_1> Not really. <person_0> Would you like to come over? <person_1> I would love to. <person_1> I'll bring some chocolate eggs. <person_0> Awesome!

RL-Gen	52.51	31.23	51.68
CN-Gen	**53.46**	**32.52**	**52.93**

Table 4: Rouge F1 evaluation of summaries of conversations against the ground truth summaries

RL-Gen and CN-Gen obtained higher scores than SL-Gen and relatively good scores compared to the Ground Truth conversations. This corroborates the assumption that our proposed models generate high quality conversations. The Welch Two Sample t-test (Welch, 1947) shows that both RL-Gen and CN-Gen models outperform the SL-Gen model statistically significantly with $p < 0.0001$. However, there is no statistical significance between the results obtained from RL-Gen and CN-Gen. We report in Table 6 the average quadratic Cohen's Kappa calculated over the three possible combinations of two judges (Toledo et al., 2019).

CN-Gen obtained the best scores during the automatic evaluation, while RL-Gen got the best scores from the human evaluation. The CN-Gen conversations are longer than the RL-Gen conversation by 1.3 turns on average (see Table 2), and hence would contain more word overlap with the ground truth. This results in better automatic evaluation scores for the CN-Gen, while the humans prefer short targeted conversations generated by RL-Gen.

3.2 Evaluation on the summarization task

To further evaluate the quality of the generate conversations, we augmented a conversation summarization dataset with generated conversations and evaluated the summarization model. We followed the following process: (1) We randomly selected x% of the summaries of the dataset and trained our conversation generation models, (2) The trained models were applied on the other (y=100-x%) of the summaries and generated conversations, (3) Those generated conversations along with the original summaries were added to the data. Using this approach, we can add extra y% (summary, conversation) pairs to the training data, (4) The conversation summarization model (discussed in Section 2 under 'Summary Generator') was trained on the augmented data. We compare the performance of the conversation summarization model on the original dataset and with augmentation.

Automatic Evaluation: We compare the three conversation generation methods at different augmentation percentages, and the results are shown in Table 7. At all augmentation levels, the summarization models trained with augmented data outperform the summarization model trained on the original dataset (without augmentation). CN-Gen based augmentation produces the best accuracy compared to other two methods. One prevalent pattern is that, when augmentation data increases, the accuracy seems to increase up to a certain point and then starts to decrease. The best accuracies were found around 30% data augmentation. We believe that more augmentation leads performance to drop due to the following reason. For augmenting with more data, we are left with less data to train the model for conversation generation (for 10% augmentation, the conversation generation models are trained on 90% of the data, while for 50% augmentation, the models are trained only on 50% of the

Model	Info	Gram	Cohe

	50%	52.36	31.75	44.85

Table 7: ROUGE F-1 evaluation on Samsum test set.

data). Therefore as the augmentation increases, the quality of generated conversations go down. This leads to overall smaller gains in the summarization task with increased augmentation after some point. To neutralize the effect of increasing the data points during augmentation, we experimented with a baseline which over-samples the original training data at different percentages to obtain same number of training instances as the augmented datasets. While the ROUGE-2 obtained with the original training data is 30.98, oversampling at 10%, 20%, 30%, 40% and 50%, only changes the ROUGE-2 to 30.55, 30.38, 30.74, 30.99 and 30.27 respectively. Hence, this suggests that oversampling hardly changes ROUGE scores obtained by training with the original dataset, while the augmentation according to our algorithms show significantly improved scores (as shown in Table 7).

Human Evaluation: We recruited 3 NLP experts to evaluate 50 instances of summaries generated with data augmentation (RL-Gen, CN-Gen), and respective summaries generated without augmentation (No-Aug). Here we consider two aspects with respect to a ground-truth summary: Coherency (whether the summary is easy to read) and Focus (whether the summary represents the ground-truth summary). Following (Amplayo and Lapata, 2020) we use the Best-Worst Scaling method. The score of each system is computed as the percentage of times it was chosen as the Best system minus times it was chosen as Worst. On the Coherency question, RL-Gen, CN-Gen and No-Aug obtained scores of 12.6, 6.6 and -4.0 respectively. On the Focus question RL-Gen, CN-Gen, and No-Aug obtained scores of 14.6, 6.0 and -2.6 respectively. These results confirm that the use of augmentation improves the quality of the summaries.

4 Conclusion

We investigated how the PLMs can be utilized to generate entire conversations that are grounded on a summary. We propose three approaches for conversation generation: SL-Gen, RL-Gen and CN-Gen and conducted multiple automatic and human evaluations to assess the quality of the generated conversations. Both automatic and human evaluations show that when compared to the ground truth conversations, RL-Gen and CN-Gen obtain high scores, suggesting that the proposed models generate high quality conversations. When a conversation summarization dataset is augmented with the generated conversations, the performance of conversation summarization is improved (over to 7% improvement in ROUGE-2 F-1), which also suggests that the proposed methods generate high quality conversations.

5 Ethics

We have used the publicly available Samsum dataset (`https://huggingface.co/datasets/samsum`). For the human evaluation of both conversations and summaries, we recruited 3 NLP researchers, who have graduate degree in NLP and Machine Learning. The annotation task itself was executed on Appen.com platform. Before the official annotation, we sampled 10 tasks to get an estimate of the duration of the task, and to make sure the instructions are clear enough.

A Model Training and Hyperparameter Details

A.1 Supervised Conversation Generation (SL-Conv-Gen)

We fine-tune a GPT-2 language model using the implementation available at HuggingFace (Wolf et al., 2019). The hyper-parameters used during training and inference are shown below. The model takes around 6 hours to train on 2 V100 GPUs (single machine).

```
model_name_or_path: gpt2
per_gpu_train_batch_size: 4
per_gpu_eval_batch_size: 4
gradient_accumulation_steps: 4
learning_rate: 6.25e-5
adam_epsilon: 1e-8
max_grad_norm: 1.0
num_train_epochs: 10
warmup_steps: 500
min_length: 20
max_length: 512
top_k: 0
top_p: 0.95
```

A.2 Summary Generator

We use DistilBART instance[1] fine-tuned on the extreme summarization (XSum) task, and we fine-tune this model further on the Samsum dataset. The model takes around 12 hours to train on 2 V100 GPUs (single machine).

The hyperparameters used for training the DistilBART model are as follows:

```
train_batch_size: 4
eval_batch_size: 4
num_train_epochs: 10
model_name_or_path: sshleifer/distilbart
-xsum-12-6
learning_rate: 3e-5
val_check_interval: 0.1
max_source_length: 512
max_target_length: 80
```

A.3 Reinforced Learning based conversation generation (RL-Conv-Gen)

To train the RL based conversation generation model, we adapted a publicly available Proximal Policy Optimization (PPO) implementation [2]. The model takes around 12 hours to train on 2 V100 GPUs (single machine). Following hyperparameters were used to train the model.

```
steps: 10000
batch_size: 16
forward_batch_size: 4
learning_rate: 1.41e-5
init_kl_coef:0.2
target: 6
horizon:10000
gamma:1
lam:0.95
cliprange: 0.2
cliprange_value: 0.2
vf_coef: 0.1
```

B Sample summaries with corresponding ground-truth

Figure 3 shows some samples of dialogs with their corresponding summaries - ground-truth and automatic generated ones.

Summary: Person0 closed some deals today. Person1 didn't manage to do it.

Ground Truth Dialog:	**SL-Gen:**	**RL-Gen:**	**CN-Gen:**
<Person0> It's been a long day. <Person1> Same here, Person0, good or bad? <Person0> Very busy. I closed some deals but I had a lot of stress also. <Person1> Lucky you. I couldn't close any deal. It annoys me. Some customers are negotiating for days, weeks. <Person0> Maybe they're just fishing. Want to compare offers. <Person1> That's what they do.	<Person0> Hi, are you still alive? <Person1> Hi, yes, still alive. <Person0> I closed some deals today. <Person1> Yeah, that's awesome. <Person0> Thanks.	<Person0> Hey, how are you? <Person1> Good, busy as usual. <Person0> I closed some deals today. <Person1> Too late, didn't manage to do it. <Person0> Sorry.	<Person0> Did you see this? ¡file_other¿ <Person1> Cool. What's up? <Person0> I closed some deals today and I feel good about it. <Person1> Great. I didn't manage to do it today. I'm sorry. I had no choice. <Person0> I'm sorry. <Person1> I didn't have the tools.

Summary: Person0 bought a table, six chairs, a vase and a pile of clothes and the second hand shop downtown. She paid 70 euros for everything.

Ground Truth Dialog:	**SL-Gen:**	**RL-Gen:**	**CN-Gen:**
<Person0> I went to the second hand shop downtown. <Person1> Cool Person0 What did you get? <Person0> Lots of stuff. A table, six chairs, a vase, a pile of clothes <Person1> That's really a lot of stuff Person0. Send us pictures <Person0> ¡photo_file¿ <Person1> Beautiful table.Is it wood? <Person0> Yes, oak. <Person1> Awesome! These are the clothes? I love the black dress. <Person0> It's absolutely beautiful. As soon as I saw it I knew it would be mine. I'm so happy with what I bought.	<Person0> I bought the second hand shop downtown. <Person1> So what happened? <Person0> I bought everything. <Person1> What do you mean? <Person0> I paid 70 euro for everything. <Person1> How much? <Person0> 6 chairs, six chairs, a vase and a pile of clothes. <Person1> Sounds like a bargain. <Person0> ou should be in business.	<Person0> Do you remember the second hand in downtown? <Person1> Yes, I do. What's inside? <Person0> A table, six chairs, a vase and a pile of clothes. <Person1> Is it expensive? <Person0> 70 euros.	<Person0> Look what I've bought! A table, six chairs, a vase. I bought a table, six chairs, a vase and a pile of clothes. <Person1> How much did you pay for everything? <Person0> I paid 70 euro for everything. And I thought it would cost me a fortune! I don't even know how much. <Person1> I am glad. <Person0> Me too. 70 euro for everything, including a vase!!!

Summary: Person1 is not at home. Person0 wants Person1 to keep her pasta in the microwave.

Ground Truth Dialog:	**SL-Gen:**	**RL-Gen:**	**CN-Gen:**
<Person0> U both at home? <Person1> No. I've just got ur msg. Why did u ask about it? <Person0> No reason. Keep my pasta in the microwave. <Person1> I haven't cooked anything.	<Person0> How are you doing? <Person1> I'm not at home <Person0> Why? <Person1> I wanted to keep some pasta in the microwave. <Person0> No need to. <Person1> In the microwave? <Person0> Yes.	<Person0> Are you at home? <Person1> No, I'm still at work. <Person0> Good, I should be home in about 15 minutes. <Person1> Can you put my pasta in the microwave? <Person0> Sure, I'll check it. <Person1> Thanks!	<Person0> Are you at home? <Person1> No, I'm busy at work. What do you want? <Person0> I want to put some pasta in microwave. <Person1> OK. I'll try.

Summary: Person0 needs Person1's help as he cannot get the application running.

Ground Truth Dialog:	**SL-Gen:**	**RL-Gen:**	**CN-Gen:**
<Person0> Person1, I need your help? <Person1> What's up, mate? <Person0> I can't get the application running. <Person1> Have you switched the computer on? <Person0> Very funny!!!!!!!!!!!!! <Person1> OK. Sorry. I can see it's serious. <Person0> Yeah, man. It is f**cking serious. <Person1> I'll be with you right now. <Person0> Thanks.	<Person0> Hey! I have a problem with the application. <Person1> Hello, Person0 <Person0> Could you please help me to get the application running? I cannot. <Person1> Why? <Person0> I have a problem with my laptop. The application is running on the USB port. I cannot access the computer. The computer is running. If I try to access the computer, the application will start. I hope that you can help me. <Person1> Okay. <Person0> Thank you, Person1.	<Person0> Person1, you there? <Person1> Yeah, what's up? <Person0> Do you need my help? <Person1> What's wrong? <Person0> I can't get the application running. <Person1> Did you try charging it first? <Person0> Yes, I tried that, but it doesn't work. <Person1> Try refreshing the database. <Person0> Damn, thanks!	<Person0> I cannot get the application running. <Person1> What's up? <Person0> Can you get the application running? <Person1> You sure you can't? Try and click on it. <Person0> You're so funny, Person1. <Person1> OK. I'm coming. <Person0> Thanks.

Summary: Person0 and Person1 will meet the new person in an hour.

Ground Truth Dialog:	**SL-Gen:**	**RL-Gen:**	**CN-Gen:**
<Person0> Can we meet with the new person soon? <Person1> Sure. In an hour okay? <Person0> Perfect.	<Person0> Hi, babe. <Person1> Hi. <Person0> We're meeting in an hour? <Person1> I'd prefer to be there in an hour. <Person0> Great!	<Person0> Did you get that message? <Person1> No, why? <Person0> I might have lost it. <Person1> Oh no, it's my mistake. I'm sorry. <Person0> Ok, don't worry. We can meet in an hour? <Person1> Ok!	<Person0> Wanna meet the new person? <Person1> Sure, I'll be there in an hour. <Person0> Perfect!

A Non-Autoregressive Edit-Based Approach
to Controllable Text Simplification

Sweta Agrawal, Weijia Xu, Marine Carpuat
Department of Computer Science
University of Maryland
{sweagraw, weijia, marine}@cs.umd.edu

Abstract

We introduce a new approach for the task of Controllable Text Simplification, where systems rewrite a complex English sentence so that it can be understood by readers at different grade levels in the US K-12 system. It uses a non-autoregressive model to iteratively edit an input sequence and incorporates lexical complexity information seamlessly into the refinement process to generate simplifications that better match the desired output complexity than strong autoregressive baselines. Analysis shows that our model's local edit operations are combined to achieve more complex simplification operations such as content deletion and paraphrasing, as well as sentence splitting.

1 Introduction

Text simplification (TS) aims to automatically rewrite text so that it is easier to read. What makes text simple depends on its target audience (Xu et al., 2015): replacing complex or specialized terms with simpler synonyms might be helpful for non-native speakers (Petersen and Ostendorf, 2007; Allen, 2009) whereas restructuring text into short sentences with simple words might better match the literacy skills of children (Watanabe et al., 2009). Studies of simplification tools for deaf or hard-of-hearing users also show that they prefer lexical simplification to be applied on-demand (Alonzo et al., 2020). Yet, research in TS has mostly focused on developing models that generate a generic simplified output for a given source text (Xu et al., 2015; Zhang and Lapata, 2017; Alva-Manchego et al., 2020). We contrast this Generic TS with Controllable TS which specifies desired output properties.

Prior work has addressed Controllable TS for either high-level properties, such as the target reading grade level for the entire text (Scarton and Specia, 2018; Nishihara et al., 2019), or low-level properties, such as the compression ratio or the nature of the simplification operation to use (Mallinson and Lapata, 2019; Martin et al., 2020; Maddela et al., 2020). Specifying the desired reading grade level might be more intuitive for lay users. However, it provides only weak control over the nature of simplification. As illustrated in Table 1, simplifying text to different grade levels results in diverse edits. To rewrite the grade 10 original for grade 5, the complex text is split into two sentences and paraphrased. When simplifying for grade 3, phrases are further simplified, and content is entirely deleted.

Grade	Text
10	Tesla is a maker of electric cars, which do not need gas and can be charged by being plugged into a wall socket.
5	Tesla cars can be charged by being plugged **in, like a phone. They** do not need any gas.
3	Tesla **builds** cars **that** do not need gas.

Table 1: Simplified text changes depending on the reading grade level of the target audience. The bold font highlights changes compared to the grade 10 version.

In this work, we adopt the intuitive framing for Controllable TS where the desired reading grade level is given as input, while providing fine-grained control on simplification by incorporating lexical complexity signals into our model. We adopt a non-autoregressive sequence-to-sequence model (Xu and Carpuat, 2020) that iteratively refines an input sequence to reach the desired degree of simplification and seamlessly integrate lexical complexity.

Unlike commonly used autoregressive (AR) models for simplification (Specia, 2010; Nisioi et al., 2017; Zhang and Lapata, 2017; Wubben et al., 2012; Scarton and Specia, 2018; Nishihara et al., 2019; Martin et al., 2020; Jiang et al., 2020, among others), our model relies on explicit edit

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3757–3769
August 1–6, 2021.

operations. It therefore has the potential of modeling the simplification process more directly than AR models which need to learn to copy operations implicitly. Unlike existing edit-based models for simplification which rely on pipelines of independently trained components (Alva-Manchego et al., 2017; Malmi et al., 2019; Mallinson et al., 2020), our model is trained end-to-end via imitation learning and thus learns to apply sequences of edits to transform the original source into the final simplified text. Furthermore, our approach does not require a custom architecture for simplification: it repurposes a non-autoregressive (NAR) model introduced for Machine Translation (MT) and can seamlessly incorporate lexical complexity information derived from data statistics in the initial sequence to be refined.

Based on extensive experiments on the Newsela English corpus, we show that our approach generates simplified outputs that match the target reading grade level better than strong AR baselines. Further analysis shows that the model learns complex editing operations such as sentence splitting, substitution and paraphrasing, and content deletion and applies these operations accordingly to match the complexity of the desired grade level.

2 An Edit-based approach for Controllable TS

Task We frame Controllable TS as follows: given a complex text c and a target grade level g_t, the task consists in generating a simplified output s that is appropriate for grade level g_t.

Approach Our approach, illustrated in Figure 1, is based on EDITOR (Xu and Carpuat, 2020), a NAR Transformer model where the decoder layer is used to apply a sequence of edits on an initial input sequence (possibly empty). The edits are of two types: (1) reposition and (2) insertion. The reposition layer predicts the new position of each token (including deletions). The insertion layer has two components: the first layer predicts the number of placeholders to be inserted and the fill-in layer generates the actual target tokens for each placeholder. At each iteration, the model applies a reposition operation followed by insertion to the current input. This is repeated until two consecutive iterations return the same output, or a preset maximum number of operations is reached. We tailor EDITOR for the task of Controllable TS as follows:

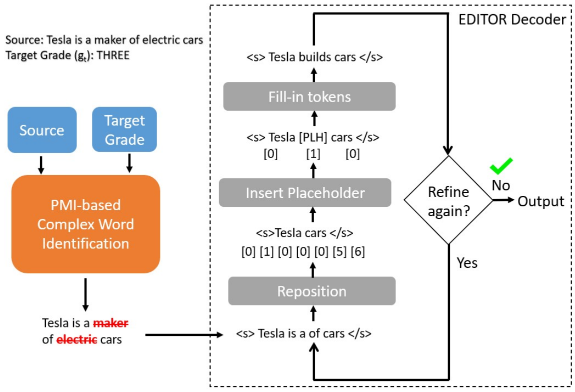

Figure 1: EDITOR iteratively refines a version of the input where words predicted to be too complex for 3rd grade readers have been deleted.

Control tokens The target complexity g_t is encoded as a special token added at the start of the input sequence. As in prior work with autoregressive models (Scarton and Specia, 2018; Nishihara et al., 2019), this token acts as a side-constraint, gets encoded in the encoder hidden states as any other vocabulary token, and informs hypothesis generation through the source-target attention mechanism.

Lexical complexity signals We automatically identify the source words that are too complex for the target grade and delete them from the initial sequence to be refined by EDITOR. This simple strategy provides finer-grained guidance to the simplification process than the sequence-level side-constraint, while leaving the EDITOR model the flexibility to rewrite the output without constraints. We quantify the relatedness between each vocabulary word (w) and grade-level (g) using their Pointwise Mutual Information (PMI) in the newsela corpus (Nishihara et al., 2019; Kajiwara, 2019):

$$PMI(w,g) = log\frac{p(w|g)}{p(w)} \qquad (1)$$

Here, $p(w|g)$ is the probability that word w appears in sentences of grade level g and $p(w)$ is the probability of word w in the entire training corpus.

While the desired grade level g_t is known in the task, we automatically predict the complexity g_s of each source sentence s_i using the Automatic Readability Index (ARI; Senter and Smith (1967)). The initial decoding sequence $\hat{s_i}$ takes the source sequence and deletes all words that are strongly related to the source grade level and unlikely to be found in text of the target grade level, with the exception of named entities:

$$\hat{s_i} = \{w|w \in s_i \wedge \quad \sim (PMI(w, g_s) > 0 \\ \wedge\, PMI(w, g_t) < 0 \wedge \; w \notin E_i)\} \tag{2}$$

where, E_i represents the set of entities in the source sequence s_i. Our approach contrasts with prior work where PMI has been used in the loss to reward the generation of target grade-specific words for Controllable TS (Nishihara et al., 2019) or to exclude complex words from the decoding vocabulary using hard constraints for Generic TS (Kajiwara, 2019). Our approach combines lexical complexity information from both the source and target grade level more flexibly. Starting from $\hat{s_i}$ as an initial sequence, EDITOR can still delete further content to match the target grade level, insert new words to fix fluency and preserve the original meaning, and has the flexibility to re-generate tokens that were incorrectly dropped from the initial sequence.

Training to generate & refine EDITOR uses imitation learning to learn an appropriate sequence of edit operations to generate the output sequence by efficiently exploring the large space of valid edit sequences that can reach a reference output. A roll-in policy is used to generate sequences to be refined and a roll-out policy is then used to estimate cost-to-go for all possible actions given the roll-in sequences. The model is trained to choose actions that minimizes the cost-to-go estimates from the roll-in sequences to the true reference by comparing the model actions to the oracle actions generated by the Levenshtein edit distance algorithm. The roll-in sequences are stochastic mixtures of the initial sequences and outputs of the insertion and reposition modules given an initial sequence. The initial sequence is generated by applying random word dropping (Gu et al., 2019) and random word shuffle (Lample et al., 2018) with a probability of 0.5 and maximum shuffle distance of 3 to either the target sequence for MT tasks (Xu and Carpuat, 2020) or to the source sequence for Automatic Post Editing (Gu et al., 2019). For Controllable TS, we combine both, training EDITOR to generate text based on the corrupted *target sequence* first, and then fine-tuning the model for refinement based on the corrupted *source sequence* next.

3 Experimental Settings

3.1 Data

The Newsela website provides high quality data to study text simplification (Xu et al., 2015). It consists of news articles rewritten by professional editors for students in different grade levels. We use English Newsela samples as extracted by Agrawal and Carpuat (2019) since their process preserves grade level information for each segment. We restrict the length of each segment to be between 5 and 80 resulting in 470k/2k/19k for training, development and test sets respectively. We pre-process the dataset using Moses tools for normalization, and truecasing. We refer to the resulting dataset as **newsela-grade**. We further segment tokens into subwords using a joint source-target byte pair encoding model with $32,000$ operations. We use spacy[1] to identify entities in the source sequence.

3.2 Model configurations

Architecture We adopt the base Transformer architecture (Vaswani et al., 2017) with d_{model} = 512, d_{hidden} = 2048, n_{heads} = 8, n_{layers} = 6, and $p_{dropout}$ = 0.1 for all our models. We add dropout to embeddings (0.1) and label smoothing (0.1). AR models are trained with the Adam optimizer with a batch size of 4096 tokens. Training stops after 8 checkpoints without improvement of validation perplexity. We decode with a beam size of 5 for the AR models. All NAR models are trained using Adam with initial learning rate of 0.0005 and a batch size of 16,000 tokens. We select the best checkpoint based on validation perplexity. Grade side-constraints are defined using a distinct special token for each grade level (from 2 to 12). All models are implemented using the Fairseq toolkit.

Preliminary We establish that our Transformer architecture choice is strong on the more standard Generic TS task, as it performs comparably to the state-of-the-art[2] (Jiang et al., 2020) on the Newsela-Auto corpus (Table 2).[3]

Experimental Conditions We compare our approach, i.e.,“NAR + PMI-based initialization”, described in Section 2 to three auto-regressive baselines for Controllable TS:

1. **AR** is a Transformer model which uses grade

---

[1] `https://spacy.io/`

[2] The Bert-initialized Transformer has parameters d_{model} = 768, d_{hidden} = 3072, n_{heads} = 12, n_{layers} = 12, and $p_{dropout}$ = 0.1. The encoder and decoder follow the BERT-base architecture. The encoder is initialized with a pre-trained checkpoint and the decoder is randomly initialized.

[3] This corpus contains complex-simple pairs extracted from 1,506 articles for training, 188 for validation and 188 for testing for Generic TS.

	SARI	add-F1	keep-F1	del-P
Results as reported in Jiang et al. (2020)				
EditNTS	35.8	2.4	29.4	**75.6**
Transformer-BERT	36.6	4.5	31.0	74.3
AR Transformer (ours)	36.1	3.8	**33.5**	71.1

Table 2: Generic TS Evaluation on Newsela-Auto: our Transformer baseline is comparable to SOTA models.

level tokens as side constraints (Scarton and Specia, 2018).

2. **AR + PMI-based constraints** is an AR Transformer model which incorporates lexical complexity information as hard constraints during decoding (Kajiwara, 2019): complex words are excluded from beam search using the dynamic beam allocation algorithm (Post and Vilar, 2018). While this approach was introduced for Generic TS, we adapt it to Controllable TS by defining hard constraints using the same criteria as for deleting words in initial sequences for EDITOR (Section 2).

3. **AR + PMI weighted loss** (Nishihara et al., 2019) is an AR Transformer model trained with a loss that weights words based on their PMI values with the desired target grade level.

3.3 Automatic Evaluation Metrics

We evaluate the output of the models using the following text simplification evaluation metrics:

SARI (Xu et al., 2016) measures lexical simplification based on the words that are added, deleted and kept by the systems by comparing system output against references and against the input sentence. It computes the F1 score for the n-grams that are added (add-F1). The model's deletion capability is measured by the F1 score for n-grams that are kept (keep-F1) and precision for the deleted n-grams (del-P) [4].

Pearson's correlation coefficient (PCC) measures the strength of the linear relationship between the complexity of our system outputs and the complexity of reference outputs. We estimate the reading grade level of the system outputs and reference text using the ARI score.

Adjacency ARI Accuracy represents the percentage of sentences where the system output grade level is within 1 grade of the reference text according to the ARI score (Heilman et al., 2008).

Mean Squared Error (MSE) between the predicted ARI grade level of the system output and the desired target grade level (Scarton and Specia, 2018; Nishihara et al., 2019).

4 Evaluation of Controllable TS

4.1 Automatic Evaluation

Table 3 summarizes the automatic evaluation of our approach on Controllable TS: `our approach`, "NAR + PMI-based initialization", improves all metrics—SARI, PCC, ARI-accuracy and MSE—compared to the AR baselines. It also outperforms the `AR + PMI-based constraints` baseline across all metrics except MSE which oversimplifies the source text by always deleting the complex tokens, as shown by a decrease in keep-F1 (-6.1) and improved del-P (+4.6). This results in lower MSE but worse PCC and ARI-Accuracy. By contrast, `our approach` uses lexical complexity information to provide an initial canvas and yields simplified sentences that match the desired target complexity better than the AR baselines. This is reflected in the higher SARI obtained by the `PMI-based initialization` baseline relative to the `Source`, which represents outputs generated by deleting complex tokens from the source text and hence by itself is not a well-formed. `AR + PMI weighted loss` performs comparably to the `AR` baseline across all the metrics except PCC, which could be due to PMI values being a relatively noisy signal at the token level during training, especially for the target grade levels where the data is scarce.[5]

We further compare `our approach` with the model that uses the `Oracle-keep` sequence, i.e., tokens from the source sequence that are present in the target sequence. As expected, the oracle significantly outperforms all models that do not have access to the reference, further confirming EDITOR's ability to make good use of the provided initial sequence. More interestingly, our method for identifying grade-specific complex tokens (Equation 2) achieves a recall of 91.3% and precision of

---

[5] We note that the improvement in SARI reported in prior work (Nishihara et al. (2019): +0.15) is within the confidence interval (+0.5) of the `AR` baseline (Table 3).

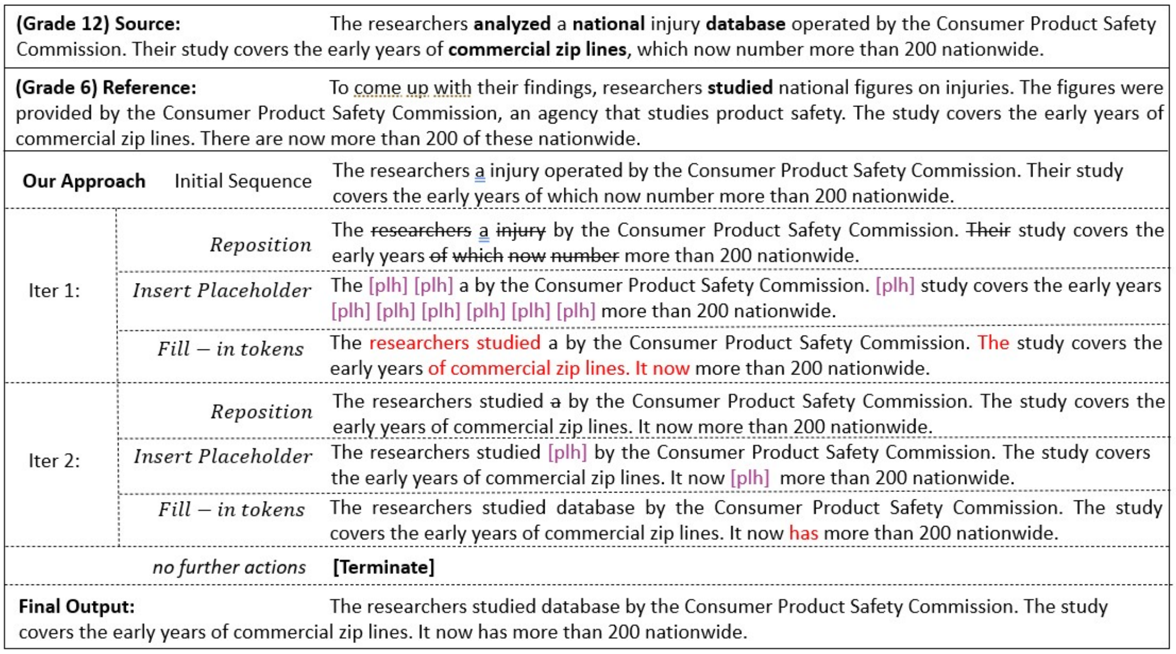
Table 3: Automatic evaluation results on Newsela-Grade test set: our approach outperforms AR baselines on SARI, PCC and ARI accuracy.



(Grade 12) Source: The researchers **analyzed** a **national** injury **database** operated by the Consumer Product Safety Commission. Their study covers the early years of **commercial zip lines**, which now number more than 200 nationwide.

(Grade 6) Reference: To come up with their findings, researchers **studied** national figures on injuries. The figures were provided by the Consumer Product Safety Commission, an agency that studies product safety. The study covers the early years of commercial zip lines. There are now more than 200 of these nationwide.

Our Approach Initial Sequence: The researchers a injury operated by the Consumer Product Safety Commission. Their study covers the early years of which now number more than 200 nationwide.

Iter 1:

Reposition: The ~~researchers~~ a ~~injury~~ by the Consumer Product Safety Commission. ~~Their~~ study covers the early years ~~of which now number~~ more than 200 nationwide.

Insert Placeholder: The [plh] [plh] a by the Consumer Product Safety Commission. [plh] study covers the early years [plh] [plh] [plh] [plh] [plh] [plh] more than 200 nationwide.

Fill – in tokens: The researchers studied a by the Consumer Product Safety Commission. The study covers the early years of commercial zip lines. It now more than 200 nationwide.

Iter 2:

Reposition: The researchers studied ~~a~~ by the Consumer Product Safety Commission. The study covers the early years of commercial zip lines. It now more than 200 nationwide.

Insert Placeholder: The researchers studied [plh] by the Consumer Product Safety Commission. The study covers the early years of commercial zip lines. It now [plh] more than 200 nationwide.

Fill – in tokens: The researchers studied database by the Consumer Product Safety Commission. The study covers the early years of commercial zip lines. It now has more than 200 nationwide.

no further actions **[Terminate]**

Final Output: The researchers studied database by the Consumer Product Safety Commission. The study covers the early years of commercial zip lines. It now has more than 200 nationwide.

Figure 2: Our approach substitutes "analyzed" correctly as well as splits the source sentence into two simple sentences to generate a simplified output that matches the lexical complexity of the desired grade-level 6. The tokens identified as complex using the proposed method in the source are bold.

76.4% with the oracle on the development set, indicating that the initial sequences contain appropriate vocabulary. Table 3 shows that `our approach` partially closes the gap in performance with the oracle by using this modified source sequence as opposed to the original source sequence (`NAR`).

Figure 2 illustrates the refinement process that generates the simplified output. Reposition and insertion operations are used in consecutive steps to perform complex editing operations (e.g., sentence splitting and lexical substitution) , which requires that the model learns to perform these operations sequentially. Furthermore, `our approach` recovers the tokens that were incorrectly identified as complex and thus deleted in the initial sequence, highlighting the benefits of the flexible refinement process.

4.2 Human evaluation

We randomly sample 60 source sentences from the Newsela-Grade dataset, among sources that are simplified toward four distinct grade levels (∼240 examples). For each of these target grades, we obtain ratings of system outputs and reference from

Model	SARI ↑	%PCC ↑	%ARI-Acc ↑	MSE ↓	Iteration	%Unchanged
our approach	40.2 ±0.0	73.9 ±0.3	36.1 ±0.2	3.73 ±0.03	2.32 ±0.04	17.6
−PMI-based Initialization	39.2 ±0.1	73.1 ±0.9	34.5 ±0.4	4.01 ±0.06	2.23 ±0.06	19.2
−Finetune	37.6 ±0.4	63.7 ±0.5	28.0 ±0.1	5.12 ±0.01	1.14 ±0.00	20.6
−Src Initialization	37.2 ±0.2	72.2 ±0.3	34.4 ±0.4	3.59 ±0.09	2.13 ±0.07	34.1
−Joint	39.7 ±0.1	68.1 ±1.7	31.6 ±0.2	4.70 ±0.05	1.00 ±0.00	11.0
Single Iteration	40.3 ±0.2	72.6 ±0.1	35.7 ±0.5	3.99 ±0.01	1.00 ±0.00	15.0
Gold Source Grade	40.2 ±0.1	74.1 ±0.5	36.5 ±0.3	3.71 ±0.04	2.33 ±0.03	17.3

Table 4: Ablation analysis on model design choices for our approach on Newsela-Grade development set.

	Meaning	Grammar	Simplicity		
	Mean	Mean	Mean	Abs. Diff ↓	Adj. Acc ↑
Reference	2.763	**3.193**	5.325	-	-
AR	**2.803**	3.171	5.157	2.035	0.533
our approach	2.647	3.081	5.310	**1.895**	**0.575**

Table 5: Human Evaluation Results: our approach generates output that match the reference judgements better than the AR baseline.

five Amazon Mechanical Turk workers. Following prior annotation protocols (Jiang et al., 2020), we ask workers to rate outputs on three dimensions: a) is the output grammatical? [0-4] b) to what extent is the meaning expressed in the original sentence preserved in the output? [0-4] and c) how simplified is the output with respect to the original source sentence? [0-10]. Different from prior work, we use a 10-point scale for evaluating simplicity to map the rating resolution to the gold grade differences. The detailed instructions provided to the workers are in the Appendix B.

We compute the absolute difference ("AbsDiff") in the simplicity ratings between the reference and the system output by the same annotator, and aggregate over all examples and all ratings. Table 5 shows that our outputs are closer to the reference according to the simplicity judgements than the AR system outputs. The "Mean" ratings indicate that the two models make different trade-offs: where the AR model under-simplifies the source sentence and preserves the meaning, our approach almost matches the mean simplicity of the reference at the cost of lower meaning preservation. Our outputs are also less grammatical than those of the AR model and the references, probably due to the independence assumptions made by the non-autoregressive model. The Adjacency Accuracy, representing the percentage of system outputs within a difference of one rating with the reference, is also higher for our approach relative to the AR model.

4.3 Ablation Experiments

Table 4 summarizes the impact of the design choices described in Section 2: Removing lexical information (`-PMI-based Initialization`) hurts both SARI and the grade specific metrics. Further, using the baseline EDITOR model that is trained only to generate, without `fine-tuning` for refinement, significantly hurts the performance across the board. In that setting, EDITOR never learns to delete tokens from the source, but only learns to delete tokens inserted by the model. Using EDITOR to generate the output from scratch instead (`-Src Initialization`) recovers the performance on SARI and grade specific metrics but fails to match the performance of our approach. This shows that fine-tuning for refinement and providing initial sequences informed by lexical complexity are both key to the performance of the EDITOR for Controllable TS.

We also compare our approach with the variant of the model that is trained to perform reposition independent of the insertion operation (`-Joint`), similar to Mallinson et al. (2020). Even though this variant is able to match SARI, the difference in grade-specific metrics is significant, showing the benefits of joint training of the insertion and reposition components.

Iterative refinement helps match the target grade better than single step refinement as suggested by ARI Accuracy, MSE and PCC. Figure 3 shows the number of iterations of refinement performed by our approach as the function of desired target grade level: simplifying to lower grade levels (2 or 3) requires on average 1 additional refinement step

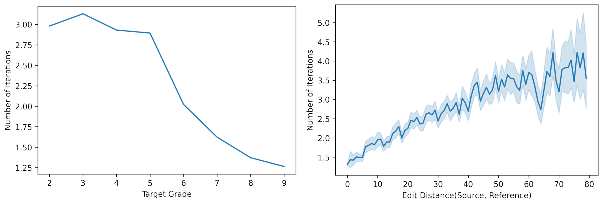


Figure 3: Our approach requires more number of iterations when simplifying to a lower grade level. The number of iterations performed by the model monotonically increases with the edit distance between source and reference.

than simplifiying to grade 8 or 9. This suggests that the iterative process helps simplification when the gap between source and target grades is wider.

Method	**Precision**	**Recall**
Target Only	76.4	80.2
Source (ARI) Only	**76.6**	78.2
Source (ARI) + Target	76.4	**91.3**

Table 6: Using both source and target grade to filter complex words yields maximum overlap with the set of tokens that are preserved from the source in the reference on the Newsela-Grade development set.

Finally, we verify that using ARI to estimate the complexity of the source is effective. Replacing the ARI predictions with the gold-standard grade-level improves the grade-specific metrics only marginally. Table 6 further shows the advantage of combining source and target grade information when identifying complex tokens (Equation 2) over using source or target grade only.

5 Analysis

Per Grade Analysis How does our model compare against the AR baselines for each target grade-levels? Figure 4a and 4b show the SARI and Adjacency Accuracy bucketed by target grade level. We observe that our approach achieves comparable or higher accuracy than the AR baselines for all grades except 2 and 3. Further analysis suggests that this is due to samples where the source grade level is 12, and where our approach deletes words too aggressively to simplify for the large grade gap (Figure 4c and 4d).

Model Edit operations We compare the number of edit operations performed by our model and the oracle Levenshtein Edit Distance (Section 2) when simplifying to different target grade levels. Figure 5 shows that the number of operations performed by our approach to generate its output track the number of oracle Levenshtein edits overall. The main differences are that our approach performs more than twice as many repositions than the oracle (5c) for grades 4 and above which suggest that the sequence of operations performed is suboptimal. Furthermore our approach overdeletes words for target grade levels lower than 4 (5b), and performs fewer insertions than the oracle (5a). We turn to manual analysis to shed more light on these results.

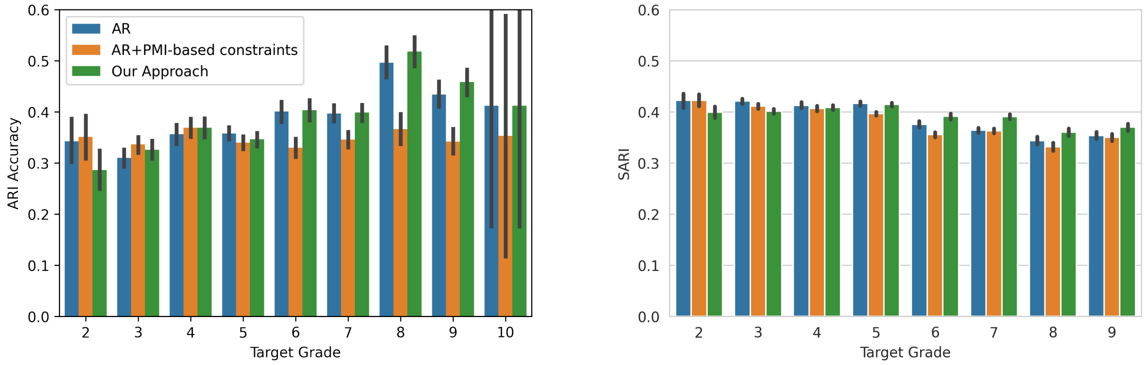
Simplification Operations Table 7 reports a manual annotation of the simplification operations observed for 50 randomly sampled segments, using an operation taxonomy from prior work (Xu et al., 2015; Jiang et al., 2020). Our approach performs content deletion in 7.5% more sentences than needed to generate the references. At the same time, it performs fewer insertions – in particular, our approach is unable to generate the elaborations and explanations found in the Newsela references (Srikanth and Li, 2020). This would require knowledge-based reasoning, which is beyond the capacity of the current model. However, our approach can model sentence splitting and substitution, which often require a sequence of insertion/deletion/reposition operations to be performed sequentially.

Type	% reference	% output
Lexical Substitution	25.0	17.5
Deletion	25.0	32.5
Reordering/Paraphrasing	35.0	20.0
Splitting	27.5	15.0
Content Elaboration	10.0	0.0
Unchanged	22.5	37.5

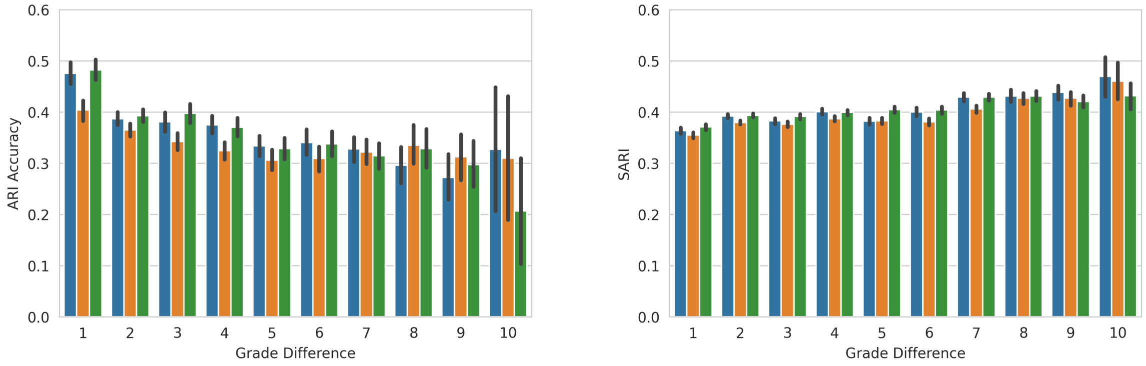
Table 7: Simplification Operations observed in the reference and output by our approach in 50 randomly sampled examples from the Newsela-Grade dataset.

6 Related Work

AR Models for TS Generic TS is often framed as machine translation where an autoregressive sequence-to-sequence model learns to model simplification operations implicitly from pairs of complex-simple training samples (Specia, 2010; Nisioi et al., 2017; Zhang and Lapata, 2017; Wubben et al., 2012; Scarton and Specia, 2018; Nishihara et al., 2019; Martin et al., 2020; Jiang

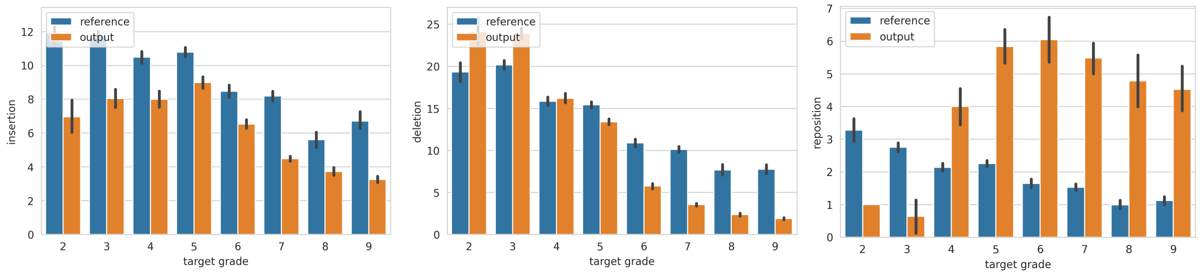


(a) ARI Accuracy (b) SARI



(c) ARI Accuracy (d) SARI

Figure 4: Analysis of automatic metrics for different target grade levels on the Newsela-Grade development set: our approach achieves higher or comparable SARI and ARI scores compared to the AR baselines for all grade levels except 2 or 3.



(a) Insertion (b) Deletion (c) Reposition

Figure 5: Edit operations accumulated over iterations for different target grade levels relative to the reference.

et al., 2020). There have been efforts at controlling a different aspect of the simplified output, such as controlling for a specific grade-level (Scarton and Specia, 2018; Nishihara et al., 2019) or employing lexical or syntactic constraints (Mallinson and Lapata, 2019; Martin et al., 2020), where the complexity of a word is either determined by its frequency or by manually tagging the tokens at inference time. We instead use the association of a word with the grade-level to define lexical constraints automatically. Furthermore, these models lack interpretability in terms of the type of operations performed, and need to generate the entire output sequence from scratch thus potentially wasting capacity in learning copying operations.

Edit-based Generic TS Recent work incorporates edit operations into neural text simplifications more directly. These approaches rely on custom multi-step architectures. They first learn to tag the source token representing the type of edit operations to be performed, and then use a secondary model for in-filling new tokens or executing the edit operation. The tagging and editing model are either trained independently (Alva-Manchego et al., 2017; Malmi et al., 2019; Kumar et al., 2020; Mallinson et al., 2020) or jointly (Dong et al., 2019). By contrast, we use a single model trained end-to-end to generate sequences of edit operations to transform the entire source sequence.

Lexical Complexity for TS Nishihara et al. (2019) introduced a training loss for Controllable TS that weights words that frequently appear in the sentences of a specific grade-level. By contrast, we use lexical complexity information to define the initial sequence for refinement, which does not require any change to the model architecture nor to the training process. For Generic TS, Kajiwara (2019) used complex words as negative constrained for decoding with an autoregressive model. By contrast our approach provides more flexibility to the model which results in better outputs in practice.

Non-autoregressive Seq2Seq Models They have primarily been used to speed up Machine Translation by allowing parallel edit operations on the output sequence (Lee et al., 2018; Gu et al., 2018; Ghazvininejad et al., 2019; Stern et al., 2019; Chan et al., 2020; Xu and Carpuat, 2020). Refinement approaches have been used to incorporate terminology constraints in machine translation, including as hard (Susanto et al., 2020) and soft constraints (Xu and Carpuat, 2020). They have also shown promise for Automatic Post Editing (APE) (Gu et al., 2019; Wan et al., 2020) , and grammatical error correction (Awasthi et al., 2019). In this work, we show that they are a good fit to incorporate lexical complexity information for Controllable TS.

7 Conclusion

We introduced an approach that repurposes a non-autoregressive sequence-to-sequence model to incorporate lexical complexity signals in Controllable TS. An extensive empirical study showed that our approach generates simplified outputs that better match the desired target-grade complexity than AR models. Analysis revealed promising directions for future work, such as improving grammaticality while encouraging tighter control on complexity by better aligning the model's atomic edit operations with more complex simplification operations.

A Appendix

A.1 Dataset Statistics

Table 8 provides the statistics of grade pair distribution in the Newsela-Grade dataset.

A.2 Implementation Details

We train all our models on two GeForce GTX 1080Ti GPUs. The average training time for a single seed of AR model is ∼8-9 hrs and for the EDITOR model is ∼20-22 hrs. Fine-tuning EDITOR takes additional 4-5 hrs.

B Human Annotation

Quality Control We set the location restriction to the United States to control for the quality of annotations. The correlation between the target grade levels and the simplicity ratings of the reference text is 0.582, which suggest that workers do rank simpler output higher than a relatively complex reference of the same source sentence.

Compensation We compensate the Amazon Mechanical Turk workers at a rate of $0.03 per HIT.

Instructions We provide the following instructions to the Amazon Mechanical Turk workers to evaluate generated simplified sentences.

Meaning You are given one sentence and 3 rewrites of the same sentence. Carefully read the instructions provided and then use the sliders to indicate the extent to which the meaning expressed in the original sentence is preserved in the rewrites (Agirre et al., 2016).

Score	Category
4	they convey the same key idea
3	they convey the same key idea but differ in some unimportant details
2	they share some ideas but differ in important details
1	they convey different ideas on the same topic
0	Completely different from the first sentence

Grammar You are given three sentences. Carefully read the instructions provided and then use the sliders to indicate the extent to which each of the sentence is grammatical (Heilman et al., 2014).

Score	Category
4	Perfect: The sentence is native-sounding.
3	Comprehensible: The sentence may contain one or more minor grammatical errors
2	Somewhat Comprehensible: The sentence may contain one or more serious grammatical errors,
1	Incomprehensible: The sentence contains so many errors that it would be difficult to correct
0	Other/Incomplete This sentence is incomplete

Simplicity You are given one sentence and 3 rewrites of the same sentence. Carefully read the instructions provided and use the sliders to indicate how simple is each of the rewrite as compared to the original sentence (0: not simplified at all, 10: most simplified). We provide the following examples for your reference.

Abstract

Multilingual transformers (XLM, mT5) have been shown to have remarkable transfer skills in zero-shot settings. Most transfer studies, however, rely on automatically translated resources (XNLI, XQuAD), making it hard to discern the particular linguistic knowledge that is being transferred, and the role of expert annotated monolingual datasets when developing task-specific models. We investigate the cross-lingual transfer abilities of XLM-R for Chinese and English natural language inference (NLI), with a focus on the recent large-scale Chinese dataset OCNLI. To better understand linguistic transfer, we created 4 categories of challenge and adversarial tasks (totaling 17 new datasets[1]) for Chinese that build on several well-known resources for English (e.g., *HANS*, NLI *stress-tests*). We find that cross-lingual models trained on English NLI do transfer well across our Chinese tasks (e.g., in 3/4 of our challenge categories, they perform as well/better than the best monolingual models, even on 3/5 uniquely Chinese linguistic phenomena such as *idioms, pro drop*). These results, however, come with important caveats: cross-lingual models often perform best when trained on a mixture of English and high-quality monolingual NLI data (OCNLI), and are often hindered by automatically translated resources (XNLI-zh). For many phenomena, all models continue to struggle, highlighting the need for our new diagnostics to help benchmark Chinese and cross-lingual models.

1 Introduction

Recent pre-trained multilingual transformer models, such as XLM(-R) (Conneau and Lample, 2019; Conneau et al., 2020), mT5 (Xue et al., 2020) and others (Liu et al., 2020; Lewis et al., 2020) have been shown to be successful in NLP tasks for several non-English languages (Khashabi et al., 2020; Choi et al., 2021), as well as in multilingual benchmarks (Devlin et al., 2019; Conneau et al., 2020; Xue et al., 2020; Artetxe et al., 2020). A particular appeal is that they can be used for *cross-lingual* and *zero-shot transfer*. That is, after pre-training on a raw, unaligned corpus consisting of text from many languages, models can be subsequently fine-tuned on a particular task in a resource-rich language (e.g., English) and directly applied to the same task in other languages without requiring any additional language-specific training.

Given this recent progress, a natural question arises: does it make sense to invest in large-scale task-specific dataset construction for low-resourced languages, or does cross-lingual transfer alone suffice for many languages and tasks? A closely related question is: how well do multilingual models transfer across specific linguistic and language-specific phenomena? While there has been much recent work on probing multilingual models (Wu and Dredze, 2019; Pires et al., 2019; Karthikeyan et al., 2019), *inter alia*, a particular limitation is that most studies rely on automatically translated resources such as XNLI (Conneau et al., 2018) and XQuAD (Artetxe et al., 2020), which makes it difficult to discern the particular linguistic knowledge that is being transferred and the role of large-scale, expert annotated monolingual datasets when building task- and language-specific models.

In this paper, we investigate the cross-lingual transfer abilities of XLM-R (Conneau et al., 2020) for Chinese natural language inference (NLI). Our focus on Chinese NLI is motivated by the recent release of the first large-scale, human-annotated Chinese NLI dataset OCNLI (**O***riginal* **C***hinese* **NLI**) (Hu et al., 2020)[2], which we use to directly in-

vestigate the role of high-quality task-specific data vs. English-based cross-lingual transfer. To better understand linguistic transfer, and help benchmark recent SOTA Chinese NLI models, we created 4 categories of challenge/adversarial tasks (totaling 17 new datasets) for Chinese that build on several well-established resources for English and the literature on model probing (see Poliak (2020)). Our new resources, which are summarized in Table 1, include: a new set of diagnostic tests in the style of the SuperGLUE (Wang et al., 2019) and CLUE (Xu et al., 2020) diagnostics; Chinese versions of the HANS dataset (McCoy et al., 2019) and NLI stress-tests (Naik et al., 2018), as well as a collection of the basic reasoning and logic *semantic probes* for Chinese based on Richardson et al. (2020).

Our results are largely positive: We find that cross-lingual models trained exclusively on English NLI do transfer relatively well across our new Chinese tasks (e.g., in 3/4 of the challenge categories shown in Table 1, they perform overall as well or better than the best monolingual Chinese models without additional specialized training on Chinese data, and have competitive performance on OCNLI). A particularly striking result is that such models even perform well on 3/5 uniquely Chinese linguistic phenomena such as *idioms, pro drop*, providing evidence that many language-specific phenomena do indeed transfer. These results, however, come with important caveats: on several phenomena we find that models continue to struggle and are far outpaced by conservative estimates of human performance (e.g., our best model on Chinese HANS remains ~19% behind human performance), highlighting the need for more language-specific diagnostics tests. Also, fine-tuning models on mixtures of English NLI data and high-quality monolingual data (OCNLI) consistently performs the best, whereas mixing with automatically translated datasets (XNLI-zh) can greatly hinder model performance. This last result shows that high-quality monolingual datasets still play an important role when building cross-lingual models, however, the particular type of monolingual dataset that is needed can vary and is best informed by targeted behavioral testing of the type we pursue here.

2 Related Work

There has been a lot of work on trying to understand multilingual transformers (Wu and Dredze, 2019; Pires et al., 2019), which has focused on either examining the representation of different layers in the transformer architecture or the lexical overlap between languages. Karthikeyan et al. (2019) investigate the role of network depth and number of attention heads, as well as syntactic/word-order similarity on the cross-lingual transfer performance. In addition to studies cited at the outset, positive results of cross-lingual transfer across a wide range of languages are reported in Wu and Dredze; Nozza et al. (2020), with a focus on transfer across specific tasks such as POS tagging, NER; in contrast, we focus on different categories of linguistic transfer, which has received less attention, as well as the role of monolingual data for transfer in NLI.

Studies into the linguistic abilities and robustness of current NLI models have proliferated in recent years, partly owing to the discovery of systematic biases, or *annotation artifacts* (Gururangan et al., 2018; Poliak et al., 2018), in benchmark NLI datasets such as SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018). This has been coupled with the development of new *adversarial tests* such as *HANS* (McCoy et al., 2019) and the NLI *stress-tests* (Naik et al., 2018), as well as several new linguistic *challenge datasets* (Glockner et al., 2018; Richardson et al., 2020; Geiger et al., 2020; Yanaka et al., 2019; Saha et al., 2020; Goodwin et al., 2020), *inter alia*, that focus on a wide range of linguistic and reasoning phenomena. All of this

---

English NLI dataset that was annotated in the style of English MNLI without any translation.

work focuses exclusively on English, whereas we focus on constructing analogous probing datasets tailored to Chinese to help advance research on Chinese NLI and cross-lingual transfer.

There has been a surge in the development of NLI resources for languages other than English. Such resources are often created in the following two ways: (1) from *scratch*, in the style of MNLI (Williams et al., 2018), where annotators are used to produce hypotheses and inference labels based on a provided set of premises, as pursued for Chinese OCNLI (Hu et al., 2020), or SciTail (Khot et al., 2018), where sentences are paired automatically and labeled by annotators (Amirkhani et al., 2020; Hayashibe, 2020). (2) Through *automatic* (Conneau et al., 2018; Budur et al., 2020; Real et al., 2020) or *manual* (Wijnholds and Moortgat, 2021) translation from existing English datasets. Studies on cross-lingual transfer for NLI have largely focused on XNLI (Conneau et al., 2018), which we show has limited utility for Chinese NLI transfer.

3 Dataset creation

In this section, we describe the details of the 4 types of challenge datasets we constructed for Chinese to study cross-lingual transfer (see details in Table 1). They fit into two general categories: **Adversarial datasets** (Section 3.1) built largely from patterns in OCNLI (Hu et al., 2020) and XNLI (Conneau et al., 2018) and **Probing/diagnostic datasets** (Section 3.2), which are built from scratch in a parallel fashion to existing datasets in English.

While we aim to mimic the annotation protocols pursued in the original English studies, we place the additional methodological constraint that each new dataset is vetted, either through human annotation using a disjoint set of Chinese linguists, or through internal mediation among local Chinese experts; details are provided below.

3.1 Adversarial dataset

Examples from the 7 adversarial tests we created are illustrated in Table 2.[3] Chinese HANS is built from patterns extracted in the large-scale Chinese NLI dataset OCNLI (Hu et al., 2020), whereas the **Distraction**, **Antonym**, **Synonym** and **Spelling** subsets are built from an equal mixture of OCNLI and XNLI-zh (Conneau et al., 2018) data; in the latter case, such a difference allows us to fairly compare the effect of training on expert-annotated (i.e., OCNLI) vs. automatically translated data (i.e., XNLI-zh) as detailed in Section 4.

Chinese HANS McCoy et al. (2019) discovered systematic biases/heuristics in the MNLI dataset, which they named "lexical/subsequence/constituent" overlap. "Lexical overlap" is defined to be the pairs where the vocabulary of the hypothesis is a subset of the vocabulary of the premise. For example, "*The boss is meeting the client.*" and "*The client is meeting the boss.*", which has an entailment relation. However, lexical overlap does not necessarily mean the premise will entail the hypothesis, e.g., "*The judge was paid by the actor.*" does not entail "*The actor was paid by the judge.*" (examples from McCoy et al. (2019)). Thus a model relying on the heuristic will fail catastrophically in the second case.

Inspired by the English HANS, we examine whether OCNLI also possesses such biases, as it has a similar annotation procedure as MNLI. We follow the design of the original HANS experiments, and adapt their scripts[4] to extract examples in OCNLI that satisfy the two heuristics. We find a heavy bias towards "entailment", where 79.5% of such examples are "entailment", similar to MNLI. To construct a Chinese HANS, we first look into syntactic structures of the examples having the two heuristics. Then we write 29 templates for the *lexical overlap* heuristic and 11 templates for *subsequence overlap*.[5] Using the templates and a vocabulary of 263 words, we generated 1,941 NLI pairs. See Table 2 for examples and Appendix A for details.

Distraction We add distractions to the premise or hypothesis, similar to the "length mismatch" and "word overlap" conditions in the NLI *stress tests* of Naik et al. (2018). The distractions are either tautologies ("true is not false") or a true statement from our world knowledge ("Finnland is not a permanent member of the UN security council"), which should not influence the inference label. We control whether the distraction contain a negation or not, and thus create four conditions: *premise-negation*, *premise-no-negation*, *hypothesis-negation*, and *hypothesis-no-negation*. See Table 2 for examples.

---

[3] A more detailed description of the data creation process can be found in Appendix A.

Table 2: Example NLI pairs in Chinese HANS and stress tests with translations.

Antonym We replace a word in the premise with its antonym to form a contradiction. To ensure the quality of the resulting NLI pairs, we manually examine the initially generated data and decided to only replace nouns and adjectives, as they are more likely to produce real contradictions.

Synonym We replace a word in the premise with its synonym to form an entailment.

Spelling We replace one random character in the hypotheses with its homonym (character with the same *pinyin* pronunciation ignoring tones) as this is one of the most common types of misspellings in Chinese.

Numerical reasoning We create a probing set for numerical reasoning, following simple heuristics such as the following. When the premise is *Mary types x words per minute*, the entailed hypothesis can be: *Mary types less than y words per minute*, where $x < y$. A contradictory hypothesis: *Mary types y words per minute*, where $x > y$ or $x < y$. Then a neutral pair can be produced by reversing the premise and hypothesis of the above entailment pair. 4 heuristic rules (with 6 words for quantification) are used and the seed sentences are extracted from Ape210k (Zhao et al., 2020), a dataset of Chinese elementary-school math problems. The resulting data contains 8,613 NLI pairs.

For **quality control** and to compute human performance, we randomly sampled 50 examples from all subsets and asked 5 Chinese speakers to verify. Our goal is to mimic the human annotation protocol from Nangia and Bowman (2019), which gives us a *conservative* estimate of human performance given that our annotators received very little instructions. Their majority vote agrees with the gold label 90.0% of the time, which suggests that our data is of high quality and allows us to later compare against model performance.[6]

3.2 Probing/diagnostic datasets

While the Chinese HANS and stress tests are designed to adversarially test the models, we also create probing or diagnostic datasets which are aimed at examining the models' linguistic and reasoning abilities.

Hand-crafted diagnostics We expanded the diagnostic dataset from the Chinese NLU Benchmark (CLUE) (Xu et al., 2020) in the following two ways:

First, 6 Chinese linguists (PhD students) created diagnostics for 4 Chinese-specific linguistic phenomena. Here are two of the phenomena:[7] (1) *pro-drop*: subjects or objects in Chinese can be dropped when they can be recovered from the context (Li et al., 1981). Thus the model needs to figure out the subject/object from the context. (2) *four-character idioms* (i.e., 成语 *Chengyu*). They are a special type of Chinese idioms that has exactly four characters, usually with a figurative meaning different from the literary meaning, e.g., 打草惊蛇 *hit hay startle snake* (behaving carelessly and causing your enemy to become vigilant). We construct examples to test whether models understand the figurative meaning in the idioms. Specifically, we first create a premise $\mathcal{P}$ which includes the idiom, where there is enough context so that a human is highly likely to

---

[6] Specifically: 98.0% on Chinese HANS, 86.0% on the stress tests. For comparison, different subsets of the English stress tests receives 85% to 98% agreement (Naik et al., 2018).

[7] For the other two, please refer to Appendix A.

interpret the idiom figuratively. Then we create an entailed hypothesis that is based on the figurative (correct) interpretation, and a neutral/contradictory hypothesis that uses the literal (incorrect) meaning (see Table 11 in the Appendix for an example). For each $\mathcal{P}$ we write 3 hypothesis, one for each inference relation. We also added diagnostics involving world knowledge.

Second, we double the number of diagnostic pairs for all 9 existing linguistic phenomena in CLUE with pairs whose premises are selected from a large news corpus[8] and hypotheses are handwritten by our linguists, to accompany the 514 artificially created data in CLUE. The resulting new diagnostics is 4 times as large as the original one, with a total of 2,122 NLI pairs. For quality control, each pair is double-checked by local Chinese linguists not involved in this study and the controversial cases were discarded after a discussion among the 6 linguists. See Table 11 in Appendix A for examples.

Semantic fragments Following Richardson et al. (2020) and Salvatore et al. (2019), we design synthesized fragments to examine models' understanding ability of six types of linguistic and logic inference: **boolean**, **comparative**, **conditional**, **counting**, **negation** and **quantifier**, where each category has 2-4 templates. See example templates and NLI pairs in Table 3.

The data is generated using context-free grammar rules and a vocabulary of 80,000 person names (Chinese and transliterated), 8659 city names and expanded predicates and comparative relations in Richardson et al. (2020) to make the data more challenging. As a result, we generated 1,000 examples for each fragment. For quality control, each template was checked by 3 linguists/logicians; also 20 examples from each category were checked for correctness by local experts.

4 Experimental setup

Our main goal is to test whether cross-lingual transfer are robust against the adversarial and probing data we created when evaluated without additional training. Thus we need to compare the best Chinese monolingual models with the best multilingual models trained either on English NLI data alone, or on combinations of Chinese and English data.[9]

Chinese monolingual models We experimented with two current state-of-the-art transformer models: RoBERTa-large (Liu et al., 2019) and Electra-large-discriminator (Clark et al., 2019). We use the Chinese models released from (Cui et al., 2020)[10] implemented the Huggingface Transformer library (Wolf et al., 2020).

Multilingual model We use XLM-RoBERTa-large (Conneau et al., 2020). We choose XLM-R over mT5 (Xue et al., 2020) because XLM-R generally performs better than mT5 under the same model size (see original paper for details). Also, XLM-R as a RoBERTa model is most related architecturally to existing Chinese pre-trained models.

Fine-tuning data for Chinese models & XLM-R (1) XNLI: the full Chinese training set in the machine-translated XNLI dataset, with 390k examples (Conneau et al., 2018). (2) XNLI-small: 50k examples from XNLI, the same size as the training data of OCNLI. (3) OCNLI: Original Chinese NLI dataset (Hu et al., 2020). It is a Chinese NLI dataset collected from scratch, following the MNLI procedure, with 50k training examples. We use this to measure the effect of the quality of training data; that is, whether it is better to use small, high-quality training data (OCNLI), or large, low-quality MT data (XNLI). (4) OCNLI + XNLI: a combination of the two training sets, 440k examples.

Fine-tuning data for XLM-R To examine cross-lingual transfer, we finetune XLM-R on English NLI data alone and English + Chinese NLI data: (1) MNLI: 390k examples from MNLI.train (Williams et al., 2018). (2) English all NLI: we combine MNLI (Williams et al., 2018), SNLI (Bowman et al., 2015), FeverNLI (Thorne et al., 2018; Nie et al., 2019) with ANLI (Nie et al., 2020), a total of 1,313k examples. (3) OCNLI + English all NLI. (4) XNLI + English all NLI. These two are set to examine whether combining Chinese and English fine-tuning data is helpful.

---

[8] We use the BCC corpus (Xun et al., 2016): http://bcc.blcu.edu.cn/.

[9] We also run the same experiments for Chinese-to-English transfer, i.e., fine-tuning XLM-R with OCNLI and evaluate on the four English counterpart datasets. We find that transferring from OCNLI to English does not perform as well as monolingual English models, likely due to the small size of OCNLI. Detailed results are reported in Appendix C.

[10] We use `hfl/chinese-roberta-wwm-ext-large` from https://github.com/ymcui/Chinese-BERT-wwm and `hfl/chinese-electra-large-discriminator` from https://github.com/ymcui/Chinese-ELECTRA.

XLM-R	mix: OCNLI + En-all-NLI	**82.18**	mixed
XLM-R	mix: XNLI + En-all-NLI	74.12	mixed

Table 4: Results on OCNLI dev. "**Scenario**" indicates whether the model is fine-tuned on Chinese *only* data (**monolingual**), English data (**zero-shot**) or **mixed** English and Chinese data; results in gray show best performance for each scenario. Best overall result in **bold**. Same below.

We fine-tune the models on OCNLI-dev. Acknowledging that different training runs can produce very different checkpoints for behavioral testing (D'Amour et al., 2020), we run 5 models on different seeds and report the mean accuracy of the models with the best hyper-parameter setting (for details see Appendix B).

5 Results and discussion

5.1 Results on OCNLI_dev

Results on the dev set of OCNLI are presented in Table 4. For monolingual RoBERTa, we see a similar performance as reported in the OCNLI paper (Hu et al., 2020), with 79.11% accuracy. The monolingual Electra achieves a very close accuracy of 79.02% (not shown in the Table). As we see the same trend in the following experiments, we will therefore only report results on RoBERTa.

For XLM-R, fine-tuning on MNLI or En-all-NLI gives us reasonable results of around 72% to 74%, which is better than models fine-tuned on XNLI, indicating that fine-tuning on an English data (MNLI) alone can outperform monolingual models fine-tuned on the same data but machine-translated into Chinese (XNLI).[11] This is consistent with previous results on Korean (Choi et al., 2021) and Persian (Khashabi et al., 2020) for other NLU tasks.

What is also interesting is that combining OCNLI and En-all-NLI gives us a boost of 2% to 82.18% (a result that is comparable to the current published SOTA), showing the power of mixing high-quality English and Chinese training data.

5.2 Chinese HANS

Table 5 shows results of the Chinese HANS data tested on the aforementioned monolingual models and cross-lingual model.

Cross-lingual transfer achieves strong results. We first notice that when XLM-R is fine-tuned solely on the English data (En-all-NLI), the performance (~69%) is only slightly worse than the best monolingual model (~71%). This suggests that cross-lingual transfer from English to Chinese is quite successful for an adversarial dataset like HANS. Second, adding OCNLI to En-all-NLI in the training data gives a big boost of about 9%, and achieves the overall best result. This is about 12% higher than combining XNLI and the English data, demonstrating the advantage of the expert-annotated OCNLI over machine translated XNLI, even though the latter is about 8 times the size of the former. Despite these results, however, we note that all models continue to perform below human performance, suggesting more room for improvement.

Our results also suggest that examples involving the *sub-sequence* heuristics are more difficult than

---

[11] For these experiments we also tested with another Chinese machine-translated MNLI (CMNLI), translated by a different MT system, which was released by CLUE (https://github.com/CLUEbenchmark/CLUE), and obtained similar results.

Model	Fine-tuned on	Overall	Lexical Overlap	Sub-sequence	Entailment	Non-Entailment	Δ

those targeting the *lexical overlap* heuristics for the transformers models we tested (see the "sub-sequence" and "lexical overlap" columns in Table 5). This is in line with the results reported in the English HANS paper (specifically Table 15 in McCoy et al. (2019) which also shows that the sub-sequence examples are more difficult for the English BERT model). Second, for the sub-sequence heuristics, results from monolingual model are 12% higher than those from XLM-R under the zero-shot transfer setting (61.48% versus 48.79% in "sub-sequence" column in Table 5). This stands in contrast with the lexical overlap heuristic, where the best monolingual model performs similarly to the best zero-shot cross-lingual transfer (75.39% versus 77.62%). This is one of the few cases where cross-lingual transfer under-performs the monolingual setting by a large margin, suggesting that in certain situations monolingual models may be preferred.

5.3 Stress tests

Table 6 presents the accuracies on all the stress tests. We first see that cross-lingual zero-shot transfer using all English NLI data performs even better than the best monolingual model (~74% vs. ~71%). This demonstrates the power of the cross-lingual transfer-learning. Adding OCNLI to all English NLI gives another increase of about 3 percentage points (to 77%), while adding XNLI hurts the performance, again showing the importance of having expert-annotated language-specific data.

Antonyms and Synonyms All models except those fine-tuned on OCNLI achieved almost perfect score on the synonym test. However, for antonyms, both monolingual and multilingual models fine-tuned with OCNLI perform better than XNLI. XLM-R fine-tuned with English NLI data only again outperforms the best of monolingual models (~80% vs. ~72%). Interestingly, adding XNLI to all English NLI data hurts the accuracy badly (a 14% drop), while adding OCNLI to the same English data improves the result slightly.

As antonyms are harder to learn (Glockner et al., 2018), we take our results to mean that either expert-annotated data for Chinese or a huge English NLI dataset is needed for a model to learn decent representations about antonyms, as indicated by the high performance of RoBERTa fine-tuned with OCNLI (71.81%), and XLM-R fine-tuned with En-all-NLI (80.36%), on antonyms. That is, using machine-translated XNLI will not work well for learning antonyms (~55% accuracy).

Distraction Results in Table 6 show that adding distractions to the hypotheses has a more negative negative impact on models' performance, compared with appending distractions to the premises. The difference is about 20% for all models (see "Distr H" columns and "Distr P" columns in Table 6), which has not been reported in previous studies, to the best of our knowledge. Including a negation in the hypothesis makes it even more challenging, as we see another one percent drop in the accuracy for all models. This is expected as previous literature has demonstrated the key role negation plays when hypotheses are produced by the annotators (Poliak et al., 2018).

Spelling This is another case where cross-lingual transfer with English data alone falls behind monolingual Chinese models (by about 4%). Also the best results are from fine-tuning XLM-R with OCNLI + XNLI, rather than a combination of English and Chinese data. Considering the data is created by swapping Chinese characters with others of the same pronunciation, we take it to suggest

Table 7: Accuracy on the expanded diagnostics. Uniquely Chinese linguistic features are prefixed with ⋆.

that monolingual models are still better at picking up the misspellings or learning the connections between characters at the phonological level.

Numerical Reasoning Results in the last column of Table 6 suggest a similar pattern: using all English NLI data for cross-lingual transfer outperforms the best monolingual model. However, fine-tuning a monolingual model with the small OCNLI (50k examples, accuracy: 54%) achieves better accuracy than using a much larger MNLI (390k examples, accuracy: 51%) for cross-lingual transfer, although both are worse than XLM-R fine-tuned with all English NLI which has more than 1,000k examples (accuracy: 83%). This suggests that there are cases where a monolingual setting (RoBERTa with OCNLI) is competitive against zero-shot transfer with a large English dataset (XLM-R with MNLI). However, that competitiveness may disappear when the English dataset grows to an order of magnitude larger in size or becomes more diverse (En-all-NLI contains 4 different English NLI datasets).

5.4 Hand-written diagnostics

Results on the expanded diagnostics are presented in Table 7. We first see that XLM-R fine-tuned with only English performs very well, at 70.2% and 71.9%, even slightly higher than the best monolingual Chinese model (69.3%).

Most surprisingly, **in 3/5 categories with uniquely Chinese linguistic features, zero-shot transfer outperforms monolingual models**. Only in "non-core arguments" and "time of event" do we see higher performance of OCNLI as the fine-tuning data. What is particularly striking is that for "idioms (*Chengyu*)", XLM-R fine-tuned only on English data achieves the best result, suggesting that the cross-lingual transfer is capable of learning meaning representation beyond the surface lexical information, at least for many of the idioms we tested. The overall results (accuracy of 74.3%) indicate that cross-lingual transfer is very successful in most cases. Manual inspection of the results shows that for many NLI pairs with idioms, XLM-R correctly predicts the figurative interpretation of the idiom as entailment, and the literal interpretation as non-entailment, as described in section 3.2. Looking at OCNLI and XNLI, we observe that they perform similarly when fine-tuned on monolingual RoBERTa. However, when fine-tuned with XLM-R, OCNLI has a clear advantage (68.0% versus 60.9%), suggesting that OCNLI may produce more

stable results than XNLI. Furthermore, when coupled with English data to be used with XLM-R, we see again that OCNLI + En-all-NLI results in an accuracy 3 percent higher than XNLI + En-all-NLI.

5.5 Semantic fragments

Results on the semantic probing datasets (shown in Table 8) are more mixed. First, the results are in general much worse than the other evaluation data, but overall, XLM-R fine-tuned with OCNLI and all English data still performs the best. The overall lower performance is likely due to the longer length of premises and hypotheses in the semantic probing datasets, compared with the other three evaluation sets. Second, zero-shot transfer is better or on par with monolingual Chinese RoBERTa in 4/6 semantic fragments (except Boolean and quantifier). Third, for Boolean and comparative, XLM-R fine-tuned with OCNLI has a much better result than all other monolingual models or XLM-R fine-tuned with mixed data. We also observe that all models have highest performance on the "counting" fragment. Note that none of the models have seen any data from the "counting" fragment during fine-tuning. That is, all the knowledge come from the pre-training and fine-tuning on general NLI datasets. The surprisingly good performance of XLM-R model (w/ En-all-NLI, 92.34%) suggests that it may have already acquired a mapping from counting the words/names to numbers, and this knowledge can be transferred cross-linguistically.

6 Conclusion and Future Work

In this paper, we examine the cross-lingual transfer ability of XLM-R in the context of Chinese NLI through four new sets of aversarial/probing tasks and a total of 17 new high quality and linguistically motivated challenge datasets. We find that multilingual transfer via fine-tuning solely on benchmark English data generally yields impressive performance. In 3/4 on our task categories, such *zero-shot transfer* outperforms our best monolingual models trained on benchmark Chinese NLI data, including 3/5 of our hand-crafted challenge tasks that test uniquely Chinese linguistic phenomena. These results suggest that multilingual models are indeed capable of considerable cross-lingual linguistic transfer and that zero-shot NLI may serve as a serious alternative to large-scale dataset development for new languages.

These results come with several important caveats. Model performance is still outperformed by conservative estimates of human performance and our best models still have considerable room for improvement; we hope that our new resources will be useful for continuing to benchmark progress on Chinese NLI. We also find that high-quality Chinese NLI data (e.g., OCNLI) *can* help improve results further, which suggests an important role for certain types of expertly annotated monolingual data in a training pipeline. In virtue of our study being limited to *behavioral testing*, the exact reason for *why* cross-lingual zero-shot transfer generally performs well, especially on some Chinese-specific phenomena, is an open question that requires further investigation. In particular, we believe that techniques that couple behavioral testing with *intervention* techniques (Geiger et al., 2020; Vig et al., 2020) and other analysis methods (Giulianelli et al., 2018; Belinkov and Glass, 2019) might provide insight, and that our new Chinese resources can play an important role in such future work.

Total	541	840	560

Table 10: Distributional statistics of our synthesized Chinese HANS dataset.

A Details for dataset creation

In this section, we list example NLI pairs and their translations. For examples of the Chinese HANS and stress tests, see Table 2. For the expanded diagnostics, see Table 11. For the semantic/logic probing dataset, see Table 3.

Chinese HANS Table 9 lists the number of examples in OCNLI for each inference label that satisfy the two heuristics we are examining. We observe that *entailment* examples take the majority for both heuristics. Therefore, we hypothesize that if the heuristics are learned, the *entailment* examples are likely to be correctly predicted while *non-entailment* (contradiction and neutral) examples are prone to receive wrong prediction.

To guarantee the generated sentences are syntactically and semantically sound, we add features for our vocabulary so that subject- predicate and verb-object constraints are satisfied, e.g., some verbs can only take animate subjects and objects. We then generate 50 premise-hypothesis pairs for each template described in our Github repository.[12] Excluding duplicated examples, our generated dataset has 1,941 pairs and the distribution of the three labels is shown in Table 10.

Antonym After looking at the quality of initially generated data, we decided to replace only the nouns and adjectives with their antonyms since such replacements are most likely result in grammatical and contradictory hypotheses.[13]

Synonym After inspecting the initially generated data, we decided to perform replacements only to verbs and adjectives. To ensure the quality of synonyms, we rank the synonyms from a commonly used synonym dictionary by their vector similarity to the original word, and pick the top ranking synonym.[14]

Distraction We created the distraction data similar to the stress test setting (Naik et al., 2018) but experimented with variations as to where "distractor statement"—either a tautology or a true statement—was added: the premise or the hypothesis. The distractor statement also varied w.r.t. whether it contains a negation:

- **Premise-no-negation**: A distractor statement is added to the end of the premise and it contains no negation.
- **Premise-negation**: A distractor statement containing a negation is added to the premise.
- **Hypothesis-no-negation**: A distractor statement is added to the end of the hypothesis.
- **Hypothesis-negation**: Same as the previous condition except that the distractor contains a negation.

Only two tautologies are used in Naik et al. (2018). In this paper, to thoroughly examine the influence of different true statements, we designed 50 tautology/statements varied in three factors: length, out-of-vocabulary, and negation word. There are 25 statements pairs in total (1 tautology and 24 true statements); each pair includes a true statement and its corresponding true statement with negation form. All the statements range from 5 to 16 characters. For the true statements in negation form, two common Chinese negation words 不 and 没 are used for negation. For the 24 true statement pairs, half of them contains at least one Out-of-Vocabulary word in OCNLI.

Experiments show that length, Out-of-Vocabulary words, and the choice of negator have little effects on the results.

Spelling We generate a set of data containing "spelling errors" by replacing one random character in the hypotheses with its homonym, which is defined as a character with the same *pinyin* pronunciation ignoring tones. We also limit the frequency

---

[12] https://github.com/huhailinguist/ChineseVariousNLI

[13] We use the LTP toolkit (https://github.com/HIT-SCIR/ltp) to annotate the POS tags and our antonym list is from https://github.com/liuhuanyong/ChineseAntiword.

[14] We use the synonym list from https://github.com/Keson96/SynoCN and the similarity score from the Python package Synonyms at https://github.com/chatopera/Synonyms.

of the homonym as within the range of 100 to 6000 so that the character is neither too rare nor too frequent.

Numerical reasoning We extracted sentences from Ape210k (Zhao et al., 2020), a large-scale math word problem dataset containing 210K Chinese elementary school-level problems[15]. We generate entailed, contradictory and neutral hypotheses for each premise, with the rules below:

1. **Entailment:** Randomly choose a number x and change it to y from the hypothesis. If the y > x, prefix it with one phrase that translate to “less than”; if y < x, prefix it with one phrase that translate to “more than”.
   Premise: *Mary types 110 words per minute.* Hypothesis: *Mary types less than 510 words per minute.*
2. **Contradiction:** Perform either 1) randomly choose a number x from the hypothesis and change it; 2) randomly choose a number from the hypothesis and prefix it with one phrase that translate to “less than” or “more than”.
   Premise: *Mary types 110 words per minute.* Hypothesis: *Mary types 710 words per minute.*
3. **Neutral:** Reverse the corresponding entailed premise-hypothesis pairs.
   Premise: *Mary types less than 510 words per minute.* Hypothesis: *Mary types 110 words per minute.*

The result contains 2,871 unique premise sentences and 8,613 NLI pairs.

Diagnostics The diagnstics for *classifiers* (or measure word) and *non-core arguments* are explained in detail below (see examples in Table 11).

1. *classifiers* (or measure word): in Chinese, when modified by a numeral, a noun must be preceeded by a category of words called classifier. They can be semantically vacuous but sometimes also carry semantic content: 一匹狼 *one pi wolf* (one wolf); 一群狼 *one qun wolf* (one pack of wolves). Our examples require the model to understand the semantic content of the classifiers.
2. *non-core arguments*: in Chinese syntax, sometimes a noun phrase at the argument position (e.g., object) is not serving as an object: 今天吃筷子，不吃叉子。*today eat chopsticks, not eat fork* (We eat **with** chopsticks today, not with fork). Sun (2009) shows that this structure is very productive in Chinese and we take example sentences from her dissertation.

Additionally, for the *pro-drop* examples, they are constructed such that the models return the correct inference relation only when they successfully identify what the dropped *pro* refers to. That is, our constructed premises involve several entities the dropped *pro* could potentially refer to, and the entailed hypothesis identifies the correct referent while the neutral/contradictory hypothesis does not (see Table 11 for an example).

B Hyperparameters for experiments

Table 12 presents the hyperparameters used for the models. The learning-rate search space for RoBERTa is: 1e-5, 2e-5, 3e-5, 4e-5 and 5e-5, for XLM-R: 5e-6, 7e-6, 9e-6, 2e-5 and 5e-5.

C Chinese-to-English transfer

We present Chinese-to-English transfer results in this section. As mentioned in the main text, for most of the cases, zero-shot transfer learning does not work well mostly likely due to the small size of OCNLI. However, for 3 out of the 4 datasets, XLM-R fine-tuned with the mix data outperforms the monolingual setting, suggesting that even OCNLI is only 1/20 of En-all-NLI, XLM-R can still acquire some useful information from OCNLI, in addition to what is present in En-all-NLI.

Specifically, (1) for English HANS, XLM-R fine-tuned with OCNLI is about 13 percentage points below the best English monolingual model, shown in Table 13. (2) For stress tests shown in Table 14, the gap is about 5 percent (XLM-R with OCNLI = 74%; RoBERTa with En-all-NLI = 79%). Interestingly, XLM-R with OCNLI performs the best for Negation and Word overlap. It even outperforms RoBERTa w/ MNLI on the Antonym, which seems to be consistent with the high performance of OCNLI-trained models on the Chinese Antonym in our constructed stress tests. (3) For semantic probing data, as shown in Table 15, XLM-R with OCNLI is 5 percent behind monolingual model fine-tuned with all English NLI, but performs better than the monolingual RoBERTa fine-tuned with

---

[15] We split all problems into individual sentences and filter out sentences without numbers. Then we remove sentences without any named entities (“PERSON”, “LOCATION” and “ORGANIZATION”) using the NER tool provided by LTP toolkit (Che et al., 2020).

Table 12: Hyper-parameters used for fine-tuning the models. All models are fine-tuned for 3 epochs with maximum length of 128.

MNLI (53.6% vs. 51.3%). This is quite surprising since the size of OCNLI is only 1/8 of MNLI. (4) For the English diagnostics as shown in Table 16 and Table 17, XLM-R with OCNLI is 7 percent behind RoBERTa fine-tuned with MNLI.

We leave it for future work to thoroughly examine transfer learning from a “low-resource” language such as Chinese to the high-resource one such as English.

Using surprisal and fMRI to map the neural bases of broad and local contextual prediction during natural language comprehension

Abstract

Context guides comprehenders' expectations during language processing, and information-theoretic surprisal is commonly used as an index of cognitive processing effort. However, prior work using surprisal has considered only within-sentence context, using n-grams, neural language models, or syntactic structure as conditioning context. In this paper, we extend the surprisal approach to use broader topical context, investigating the influence of local and topical context on processing via an analysis of fMRI time courses collected during naturalistic listening. Lexical surprisal calculated from ngram and LSTM language models is used to capture effects of local context; to capture the effects of broader context a new metric based on topic models, topical surprisal, is introduced. We identify distinct patterns of neural activation for lexical surprisal and topical surprisal. These differing neuro-anatomical correlates suggest that local and broad contextual cues during sentence processing recruit different brain regions and that those regions of the language network functionally contribute to processing different dimensions of contextual information during comprehension. More generally, our approach adds to a growing literature using methods from computational linguistics to operationalize and test hypotheses about neuro-cognitive mechanisms in sentence processing.

1 Introduction

Narratives unfold over time and comprehenders incrementally process words and sentences. In order to understand the current word and sentence, we have to integrate current input with the information from the previous context.

In characterizing this process, the notion of *surprisal* from information theory has been prevalent in psycholinguistic modeling, following the work of Hale (2001) and Levy (2008). Surprisal operationalizes how unexpected a word is as its pointwise information content given prior context, $-\log \mathrm{P}(w_i|w_1...w_{i-1})$. Generally the theory of surprisal, as applied in the study of human language comprehension, proposes that probabilistic predictions made by comprehenders yield variability in word-by-word processing difficulty: when surprisal is high, the current word is unexpected and cognitive processing effort increases accordingly. This linking has been validated in prior work connecting surprisal with measurable reflexes of cognitive effort, using probabilities conditioned on lexical (sequential) and syntactic contexts (e.g. Brennan et al., 2016; Lopopolo et al., 2017; Brennan and Hale, 2019; Shain et al., 2020).

In this paper, we extend the surprisal paradigm beyond prior work looking only at local context, to investigate the influence of broader contextual information during incremental sentence processing. As an illustration, consider examples (a) and (b), which illustrate that, while a word might be extremely difficult to predict given the immediate local context, it might be less unexpected/more predictable given the broader topic under discussion. The actual word to be predicted here is *China*, which is not at all predictable given the immediate context, but more likely in a longer discourse about traveling (*airplanes*, *places*, *world*, *geography*, etc).

(a) I could recognize at first glance _____

(b) *So I had to choose another profession, and I learned to fly airplanes. I flew a little in many places around the world. And geography it's true has served me well.* I could recognize at first glance _____

Following prior studies, we use measures of lexical surprisal to capture the influence of local context, and we introduce a new measure, *topical*

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3786–3798
August 1–6, 2021.

surprisal, to operationalize the predictive role of broader context. We use both kinds of predictors to investigate how processing based on different contextual cues differs in their mapping in the brain. Specifically, our research questions are:

- How does the previous topical context affect our expectations about the next word?
- How do local vs. broad contextual prediction influence our incremental language processing? Do they have distinct neural correlates?

We apply computational modeling to investigate these questions in a way that would not be feasible in a more traditional, trial-based experimental paradigm by taking advantage of data collected using fMRI brain imaging during continuous, naturalistic listening (Hamilton and Huth, 2020). This data collection method has emerged as a new testing ground for linking processing hypotheses with neurobiological architectures in the brain (Maguire, 2012; Willems, 2015; Kandylaki and Bornkessel-Schlesewsky, 2019). Using lexical surprisal and our new measure of topical surprisal as computational predictors of cognitive activity, we demonstrate that processing of local and broad context recruits different brain regions, suggesting that those regions of the language network functionally contribute to processing different dimensions of contextual prediction during human language comprehension.

2 Background and Related Work

2.1 Surprisal as a cognitive measure

Prior neurolinguistic work has used surprisal as an index of cognitive processing effort. Behavioral measurements like self-paced reading are one way to infer how much effort is involved while processing some piece of linguistic input (e.g., Futrell et al., 2021); other methods more directly measure activity in the brain, including functional magnetic resonance imaging (fMRI), which we will focus on in this paper, as well as magnetoencephalography (MEG) (e.g., Brodbeck et al., 2018) and electroencephalography (EEG) (e.g., Ettinger et al., 2016; Brennan and Hale, 2019; Michaelov and Bergen, 2020).

In such work, the logic is generally as follows. First, as noted in §1 we assume that when a word is less expected given the context, processing it during comprehension will require more work in the brain. Then, we computationally estimate a model of surprisal using a corpus:

$$\text{surprisal}_M(w_i) = -\log \text{P}_M(w_i | w_1 ... w_{i-1}) \quad (1)$$

Two common instantiations for M include ngram models and models conditioned on prior syntactic context (Hale, 2001).

By the first assumption, the value of Eq (1) is taken to be a predictor of processing effort at word w_i. Therefore, the key final step is to analyze the relationship between that estimated effort, as predicted by the model, and observed activity measured in the brain. In the case of fMRI, neural activity is measured by detecting changes associated with blood flow (see §4). When there are significant correlations between the predicted effort, surprisal$_M$, and activity in some region of the brain, this constitutes evidence for that region being involved in processing of the information that M has used in its predictions. For example, if the brain activity in a region is correlated with an estimate of surprisal that uses syntactic predictions, that provides evidence for that region being a locus for human syntactic processing.

In prior work following this logic, using the surprisal paradigm with fMRI to localize processing associated with lexical and syntactic context, the findings implicate a range of core regions of the language network. Across different languages, lexical surprisal recruits a mostly left-lateralized network, predominantly consisting of Inferior Frontal Gyrus, Interior Temporal Sulcus, Middle Frontal Gyrus, Posterior Temporal regions, extending to some bilateral regions, namely Anterior Temporal Lobe and Superior Temporal Gyrus (Brennan, 2016; Willems et al., 2016; Lopopolo et al., 2017; Shain et al., 2020). Syntactic surprisal has also mapped onto a left-lateralized network consisting of the Inferior Parietal Lobule, Inferior Frontal Gyrus, Middle Temporal Gyrus, along with some evidence for bilateral processing in the Anterior Temporal Lobe (Brennan et al., 2016; Henderson et al., 2016; Lopopolo et al., 2017; Shain et al., 2020).

2.2 Neural language models in cognitive neuroscience

There has been a growing trend of using neural language models in cognitive neuroscience research, often using neural data collected from individuals during naturalistic listening.[1] As one salient example, Wehbe et al. (2014) investigated how well vector representations predicted brain activity for subjects reading fiction, in their case material from *Harry Potter and the Sorcerer's Stone*, based on within-sentence context. Also working within the sentence using naturalistic listening, Toneva et al. (2020) derived composed representations of "supra-word meaning" using contextualized word representations (ELMo, Peters et al., 2018) to capture the compositional meaning of multi-word expressions and event/argument structure. Jain and Huth (2018) make predictions of neural activity using LSTM representations from up to the previous 20 words of context (which would be on the order of 8-10 seconds of speech on average).

Work of this kind has a number of dimensions of variation. One is the nature of the neural measurement, e.g. fMRI versus MEG, which relates crucially to the cognitive questions being asked, since some questions involve temporal locality, a strength of MEG, and others involve spatial locality, a strength of fMRI. Another dimension is the nature of the training data for the computational modeling, e.g. material from the experimental dataset (*Harry Potter*, as in Wehbe et al. (2014)) versus a broader coverage corpus such as a large collection of Reddit comments as used by Jain and Huth (2018)). Finally, there is the nature of the model itself; for example, how much context it takes into account and whether it involves, for example, non-contextual word embeddings, sequentially derived embeddings, or something else.

In this work, we use broad coverage corpora such as COCA (Davies, 2008) or Wikipedia to train our models. In addition to using ngram and LSTM models to capture within-sentence context, we introduce topical surprisal (§3.5), based on topic modeling, as a way to look at functional localization of correlates of broader, non-sequential contextual processing using fMRI.

3 fMRI Study

3.1 Method

We follow Brennan et al. (2012) in using a spoken narrative as a stimulus. Participants hear a story over headphones while they are in the MRI scanner. As we describe in greater detail in §4, the sequence of neuroimages collected during their session becomes the dependent variable in a regression against word-by-word predictors that have been derived from the text of the story.

3.2 Stimuli

The English audio stimulus was Antoine de Saint-Exupéry's *The Little Prince*, translated by David Wilkinson and read by Karen Savage. It constitutes a fairly lengthy exposure to naturalistic language, comprising 19,171 tokens; 15,388 words and 1,388 sentences, and lasting over an hour and a half. *The Little Prince* has been used in a number of previous fMRI studies of language processing, e.g. Li et al. (2018); Bhattasali et al. (2019); Zhang (2020); Stanojević et al. (2021)

3.3 Participants

56 participants were scanned and 5 of them were excluded since they had incomplete scanning sessions. Participants included were fifty-one volunteers (32 women and 19 men, 18-37 years old) with no history of psychiatric, neurological, or other medical illness or history of drug or alcohol abuse that might compromise cognitive functions. All strictly qualified as right-handed on the Edinburgh handedness inventory (Oldfield, 1971). All self-identified as native English speakers and gave their written informed consent prior to participation, in accordance with Cornell University's IRB guidelines. Participants were compensated for their time, consistent with typical practice for studies of this kind. They were paid $65 at the end of the session.

3.4 Presentation

After giving their informed consent, participants were familiarized with the MRI facility and assumed a supine position on the scanner gurney. The presentation script was written in PsychoPy (Peirce, 2007). Auditory stimuli were delivered through MRI-safe, high-fidelity headphones (Confon HP-VS01, MR Confon, Magdeburg, Germany) inside the head coil. The headphones were secured against the plastic frame of the coil using foam blocks. Using a spoken recitation of the US Constitution, an experimenter increased the volume until participants reported that they could hear clearly. Participants then listened passively to the audio storybook for 1 hour 38 minutes. The story had nine chapters and at the end of each chapter the

---

[1] Although not directly relevant to the scientific strategy we discuss here, we note that there is also a body of work that goes in the other direction, using methods from psycholinguistics and neuroscience to improve our understanding and use of neural language models, e.g. Toneva and Wehbe (2019); Ettinger (2020); Misra et al. (2020).

participants were presented with a multiple-choice questionnaire with four questions (36 questions in total), concerning events and situations described in the story. These questions served to confirm participants' comprehension. They were viewed via a mirror attached to the head coil and answered through a button box. The entire session lasted around 2.5 hours.[2]

3.5 Deriving the predictors

Recall that surprisal measures how unexpected each word w_i is given the preceding context (Eq 1), and we use measures of surprisal as the linking hypotheses in our study between the contextual predictions of our model and neural activity. The three different surprisal predictors we use are described below, along with how they were calculated. Fig. 2 shows a visual comparison of the word-by-word predictors on a single sentence from the text.[3]

Ngram surprisal. The ngram surprisal values are based on a 5gram language model and were calculated using the `kenlm` library (Heafield et al.) with Modified Kneser-Ney Smoothing. The 5gram language model was trained on the Corpus of Contemporary American English (COCA, Davies, 2008), which is a large, genre-balanced corpus of American English and consists of over one billion words of text sampled across spoken, fiction, popular magazines, newspapers, and academic texts.

LSTM surprisal. These surprisal values are based on a long short-term memory (LSTM) language model (Hochreiter and Schmidhuber, 1997) trained on 90 million words of English Wikipedia by Gulordava et al. (2018). It had two LSTM layers with 650 hidden units each, 650 dimensional word embeddings, a learning rate of 20, a dropout rate of 0.2 and a batch size 128, and was trained for 40 epochs (with early stopping). Like the majority of previous work computing LSTM-surprisal, our input is a single sentence and we make predictions only based on context within the sentence (Brennan and Hale (2019); van Schijndel and Linzen (2018), though cf. Jain and Huth (2018)). The surprisal values were calculated using the Neural Complexity toolkit with the baseline non-adaptive model (van Schijndel and Linzen, 2018).

Topical surprisal. We introduce a new predictor based on topic models, adapting surprisal to operationalize the influence of context beyond the sentence level. Topical surprisal for a word is defined as the weighted average of the word's probability given topic, where weights are the (posterior) probability for the topic in that context.

$$\text{surprisal}(w_i \text{ in context c}) = -\log \sum_{t \in \text{Topics}} P(w_i|t)P(t|c) \tag{2}$$

Fig. 1 illustrates how topical surprisal is computed using a sample excerpt from the text.

Topics are defined and probabilities estimated using an LDA topic model (Blei et al., 2003). Using the wrapper for Mallet LDA (McCallum) in the Gensim toolkit (Řehůřek and Sojka), we estimated a 100-topic model with the default hyperparameters using 219,380 documents from COCA, yielding P$(w|t)$ for all word-topic pairs and making it possible to compute the posterior topic probabilities P$(t|c)$ for any new document c. We compute topical surprisal for all the non-function words in the audio sample using the content in the 30-second window prior to the word to define the LDA "document" c.

4 Data Analysis

fMRI data is acquired with physical, biological constraints and we followed a standard preprocessing pipeline for fMRI imaging data that allowed us to make adjustments to improve the signal to noise ratio.[4]

The research questions presented above in §1 motivate two statistical analyses looking at correlations between model-based predictions and observed brain activity. In Analysis 1, we use ngram surprisal (from a 5gram language model) to instantiate local context and compare it against topical surprisal, which captures the influence of broader, topical context. As a follow-up, in Analysis 2, we use surprisal from a state-of-the-art LSTM language model to instantiate local context while still using topical surprisal for broader context, in order to illuminate potential differences between the neural correlates of ngram and LSTM models.

Measurements of neural activity using fMRI are based on an increase in blood flow to regions of the brain, which reflects increased cerebral activity. Because blood flow is slow relative to neural activity, this introduces a temporal lag and presents a

---

[2] Further details about the fMRI data collection can be found in the Appendix.

[3] A correlation matrix for the predictors is included in the Appendix.

[4] See the Appendix for further preprocessing details.

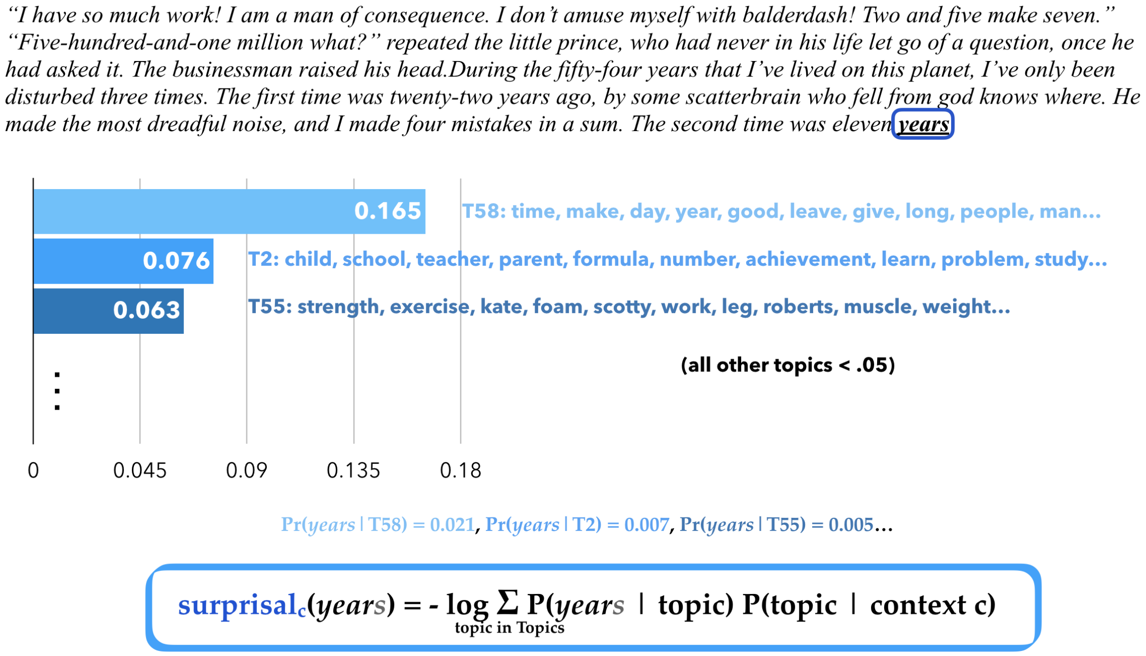

Figure 1: Real example illustrating the computation of topical surprisal. We calculate the probability of the word *years* conditioned on its topical context by using the previous 30 seconds of of the story to define a "document" c and computing its posterior topic distribution based on an LDA model for a large, diverse collection of English text. In the figure each topic is represented by its highest probability words.

challenge for modeling the time course of processing. To address this issue, predictors are convolved using a canonical hemodynamic response function (HRF) to model the observed time-course of the brain's hemodynamic response (BOLD - Blood Oxygenation Level Dependent) in each voxel.[5] Brennan (2016) provides a detailed description of how word-by-word predictors are convolved to estimate the fMRI BOLD signal in studies like the present one.

In order to look at correlations between predictors and brain activity, our analyses employ the General Linear Model (GLM; carried out using SPM12, Friston et al., 2007).[6] GLM is a hierarchical model with two levels that is typically used in fMRI data analysis (Poldrack et al., 2011), and its use within neuro-computational models of language processing for continuous, naturalistic fMRI studies is well-established (Brennan et al., 2012; Brennan, 2016; Willems et al., 2016; Bhattasali et al., 2018; Li et al., 2018; Bhattasali et al., 2019). At the first level of the GLM model, the data for each subject is modeled separately to calculate subject-specific parameter estimates and within-subject variance such that for each subject, a regression model is estimated for each voxel against the fMRI time series. The second-level model takes subject-specific parameter estimates as input and uses the between-subject variance to make statistical inferences about the larger population. The end result is a time series linear regression between the estimated fMRI BOLD signal and observed BOLD signals across the whole brain. Correlations between time series can then be computed with determinations of statistical significance, with suitable corrections for multiple comparisons.

4.1 Analysis 1: ngram surprisal vs. Topical surprisal

We regressed the word-by-word predictors against fMRI timecourses recorded during passive story-listening in a whole-brain analysis. The regressors were time-locked at the offset of each word in the audiobook. For each of the 15,388 words in the story, their timestamps were estimated using Praat TextGrids (Boersma and Weenink). Each word was annotated with its 5gram surprisal and the 6,243 non-function words were annotated with its topical surprisal values, as described in §3.5.

Additionally, we entered four regressors of non-interest into the GLM analysis: word-offset, word

---

[5] For more details about the hemodynamic response, see chapter 2 of Kemmerer (2014).

[6] Processing time on a Mac OS 10.13 takes 1.5 hours per subject and increases linearly with additional subjects.

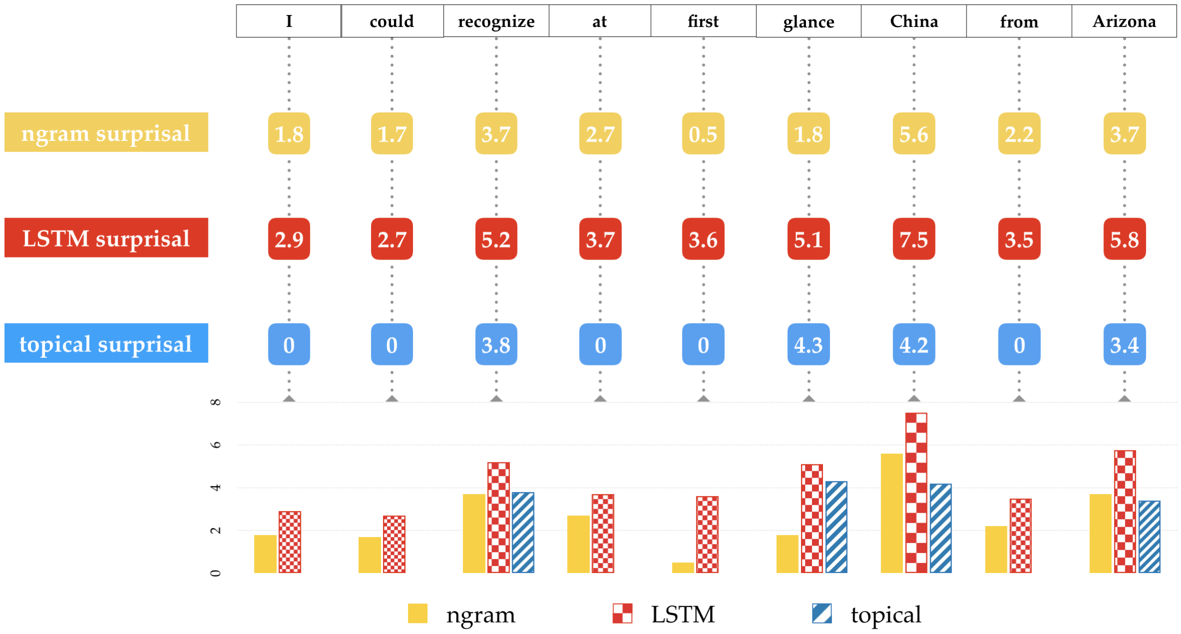

Figure 2: Comparing the word-by-word predictors on a single sentence: ngram surprisal (in yellow), neural surprisal (in red), topical surprisal (in blue). Values scaled for visualization purposes.

frequency, pitch, and intensity, which serve to improve the sensitivity, specificity and validity of activation maps (Bullmore et al., 1999; Lund et al., 2006). These were added to ensure that conclusions about lexical surprisal and topical surprisal would be specific to the cognitive processes they were taken to instantiate, as opposed to more general aspects of speech perception. These regressors were not orthogonalized.

4.2 Analysis 2: LSTM surprisal vs. Topical surprisal

Analysis 2 uses the same predictors as in Analysis 1, except that we use an LSTM language model to calculate lexical surprisal. Each word is annotated with its corresponding LSTM surprisal value (as described in §3.5), instead of 5gram surprisal, along with topical surprisal value given to the non-function words. These regressors were also not orthogonalized.

4.3 Group-level Analysis

In the second-level group analysis, each contrast was analyzed separately at the group-level. An 8 mm FWHM Gaussian smoothing kernel was applied on the contrast images from the first-level analysis to counteract inter-subject anatomical variation.

5 Results and Discussion

To begin with necessary details, behavioural results in the comprehension task confirmed that subjects were listening attentively to the auditory story presentation: across 51 participants, average accurate responses to the comprehension questions was 90% (SD = 3.7%). All whole-brain effects reported below survived a $p < 0.05$ Family-Wise-Error voxel correction for multiple comparisons which resulted in T-scores > 5.3. All brain region labels are from the Harvard-Oxford Cortical Structure Atlas.

Turning to the results of our analyses, functional localization identified using fMRI — via significant correlation with surprisal models — is interpreted to show which brain regions are recruited in processing the different types of contextual information captured by those models. To summarize, we observe a functionally distinct network that shows the difference between the influence of broad contextual cues and local contextual cues during sentence processing.

5.1 Analysis 1: Group-level results for ngram surprisal vs. topical surprisal

Whole-brain contrasts show that broad contextual cues and local contextual cues implicate different brain regions with no overlap (see Fig. 3). We observe a right-lateralized pattern of activation for topical surprisal (instantiating broad context) with

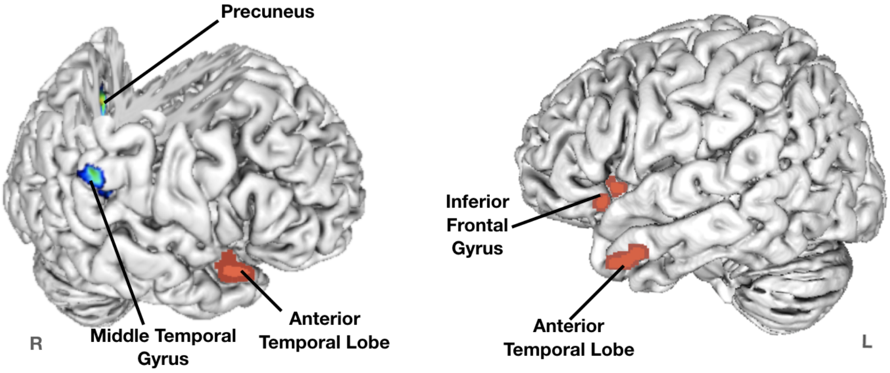

Figure 3: Whole brain contrast image with significant clusters for 5gram surprisal (in orange) and topical surprisal (in blue) after FWE voxel correction with p < 0.05. Table with significant clusters of peak activation included in Supplementary Materials.

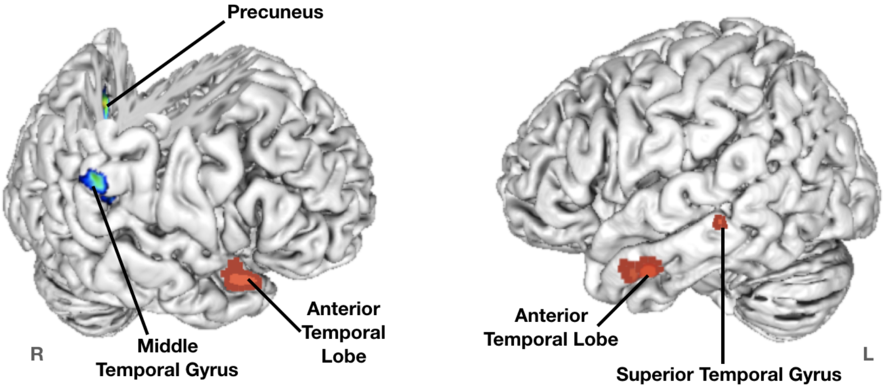

Figure 4: Whole brain contrast image with significant clusters for LSTM surprisal (in orange) and topical surprisal (in blue) after FWE voxel correction with p < 0.05. Table with significant clusters of peak activation are included in Supplementary Materials.

neural activation in the Precuneus and Middle Temporal Gyrus. For 5gram surprisal, the significant clusters are in the bilateral Anterior Temporal Lobe and left Inferior Frontal Gyrus.

5.2 Analysis 2: Group level results for LSTM surprisal vs. topical surprisal

Regression analyses localized the activation patterns for local and broad context to different areas (see Fig. 4). The peak activation for LSTM surprisal (instantiating local context) was observed in bilateral Anterior Temporal Lobe, along with a small cluster in left Superior Temporal Gyrus. Significant clusters for topical surprisal (instantiating broad context) were seen in the right Precuneus and right Middle Temporal Gyrus.

5.3 Discussion

In terms of Marr's (1982) levels, studies of the kind described here involve a linkage between proposals at the algorithmic-representational level and processing at the implementation level. Specifically, the logic of surprisal-based studies in computational cognitive neuroscience is based on the idea that when a word is less expected, it gives rise to increased brain activity due to increased cognitive load. Different instantiations of surprisal are used to model aspects of processing taking place during language comprehension, and correlations of surprisal with increased brain activity provide evidence about those aspects of the human comprehension process. Surprisal defined using ngrams embodies the use of sequential contextual representations during sentence processing. Syntactic surprisal embodies the use of hierarchical syntactic representations.

The present neuroimaging study introduces a new model, topical surprisal, which concerns the use of broader contextual information during processing — the topical probability of a word as defined in Eq (2) can be interpreted as an expected value of the word's probability given the topic being discussed, under the posterior topic distribution for the context. Our goal in this paper was to contrast context within a sentence with broader topical context. This can be viewed as a natural step in a progression from narrow ngram surprisal to sentential (syntactic and LSTM) surprisal to broader context that comprehenders might be taking into account.

The results in §5 based on our new model show that the patterns of activation for topical surprisal differ from those of lexical surprisal and syntactic surprisal, notably involving the right hemisphere. The centrality of the right Middle Temporal Gyrus and right Precuneus is consistent with previous studies demonstrating the role of those regions in broader contextual prediction during language comprehension: studies on narrative shifts (Whitney et al., 2009), contrasting sentences and narratives (Xu et al., 2005), contrasting coherent and incoherent narratives (Maguire et al., 1999), and sentences with and without preceding context (Raposo and Marques, 2013) that have found these same brain regions are involved in processing broader context and discourse-level information. The converging evidence confirms that our formalization of topical surprisal represents a cognitively plausible metric. Moreover, the neural correlates for topical surprisal corroborate previous work on lexical access and semantic integration (Binder et al., 2009; Graves et al., 2010; Hickok and Poeppel, 2007; Hagoort and Indefrey, 2014), suggesting that this broader contextual prediction is involved in these psycholinguistic processes beyond the sentence level.

Our novel approach to investigating contextual fit beyond the sentence level is also broadly consistent with prior results demonstrating how cortical hierarchy overlaps with language regions by using increasingly larger temporal receptive windows Lerner et al. (2011). Our results can be taken to support the argument that smaller versus larger temporal receptive windows implicate regions associated with lower-level and higher-level tasks respectively, a connection we plan to explore further.

Looking just at the ngram and LSTM models of lexical surprisal, our results provide additional corroboration for previous findings in the cognitive neuroscience literature involving sequential and syntactic processing (Willems et al., 2016; Brennan, 2016; Lopopolo et al., 2017; Shain et al., 2020). They also constitute an addition to the literature on understanding the linguistic properties captured by deep learning architectures. Numerous authors have shown that LSTM models capture not only sequential but also longer-distance structural dependencies (Linzen et al., 2016; Gulordava et al., 2018; van Schijndel and Linzen, 2018; Kuncoro et al., 2018; Futrell et al., 2019). In our study, we find that, while overlapping in the bilateral Anterior Temporal Lobe, the ngram and syntactic surprisal models also give rise to differently localized brain activity: the ngram model implicates the left Inferior Frontal Gyrus (IFG), while the LSTM surprisal model implicates the left Superior Temporal Gyrus (STG). The key observation here is that left-lateralized STG activity is uncontroversially correlated with syntactic processing (Pallier et al., 2011; Thompson and Meltzer-Asscher, 2014; Bhattasali et al., 2019; Shain et al., 2020). In contrast, the functional role of left IFG has variously been interpreted as involving combinatorial, sequential, or syntactic processes (Sahin et al., 2009; Snijders et al., 2009; Pallier et al., 2011; Brennan et al., 2016). The patterns of activity in this study therefore provide support from the implementation level for the idea that LSTMs are capturing aspects of syntactic representation that ngram models do not. Narrowing down the nature of those differences (e.g., sequential versus structural, or short- versus long-distance syntactic dependencies) remains a subject for future work.

6 Conclusion

The present study posed the questions of how broader topical context influences expectations in human sentence comprehension, and how local versus broader contexts might be processed differently in the brain. To address those questions we have introduced topical surprisal, a straightforward and intuitive extension to the highly productive surprisal-based paradigm in computational psycho- and neurolinguistics that employs topic modeling to estimate word probabilities conditioned on contexts beyond the sentence level.

Using analysis of fMRI brain imaging during naturalistic listening, we showed that the processing of broader topical context gives rise to neural activity in different brain regions than local contextual prediction as modeled using ngrams or an LSTM. The brain regions we identified turn out to be consistent with prior studies looking at neural correlates for processing of narratives and discourse.

In addition, we explored the neuro-anatomical

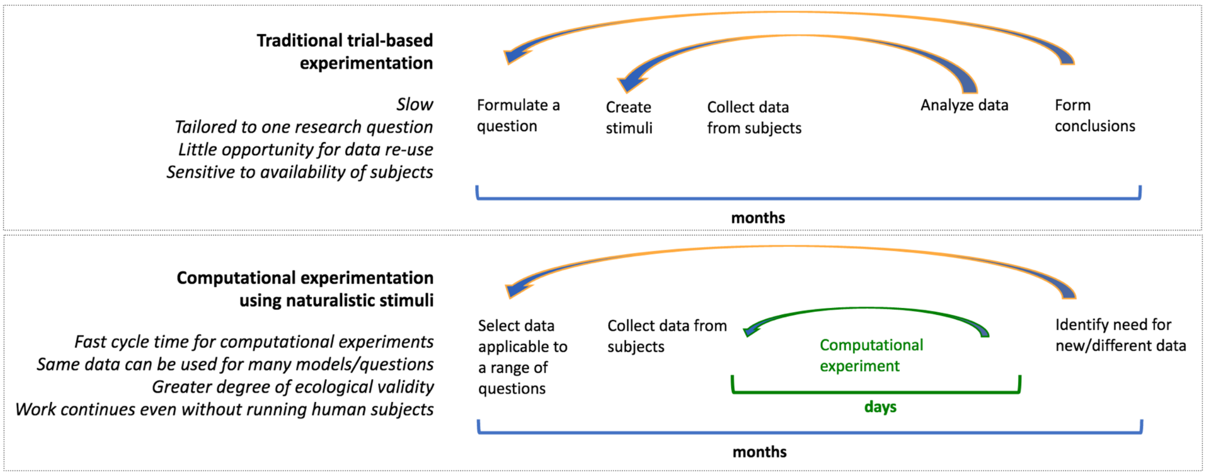

Figure 5: Visual comparison between two different experimental paradigms for cognitive neuroscience research

correlates of ngram and LSTM processing and obtained results that are consistent with claims in the deep learning literature regarding the sensitivity of LSTMs to long-distance syntactic structure.

More generally, this paper adds another data point demonstrating the relevance of tools from computational linguistics in cognitive neuroscience research (Brennan and Hale, 2019; Jain and Huth, 2018; Toneva et al., 2020) and the value of naturalistic stimuli in contextually situated and ecologically valid research (Maguire, 2012; Brennan, 2016; Hamilton and Huth, 2020).

Finally, we note that the paradigm we have employed here — computational modeling with previously collected natural-listening data — promotes reusability of datasets and replicability of results, and safeguards against unexpected delays in data collection such as a pandemic. Even more important, it offers a rapid experimental cycle dramatically better suited to computational research than traditional, trial-based methods in psycholinguistic and neurolinguistic research (Figure 5). As such, computational experimentation with naturalistic stimuli presents an invitation to computational linguists to collaborate with cognitive neuroscientists and apply their skills in operationalizing and testing hypotheses about neurocognitive mechanisms in sentence processing.

Ethical Considerations

This scientific study was reviewed and approved by the Cornell University Institutional Review Board, and human subject participation was conducted according to standard practices for research of this kind, including compensation of $65 for participants who completed the study. No personally identifiable data are stored. As is frequently the case for academic human subjects studies, our sample is drawn from a university population and may not be representative of the population at large. In addition, safety protocols required excluding participants with metal in their body (e.g. surgical implants, fresh tattoos), and following standard practice we included only participants with no history of psychiatric, neurological, or other medical illness or history of drug or alcohol abuse that might compromise cognitive functions, nor anyone taking antidepressant or psychoactive medications. Although the study was conducted in English, it included international and bilingual participants.

Acknowledgments

We would like to thank John Hale for his help in designing the study. We would also like to thank the audiences at AMLaP 2020, SNL 2020, the UMD Cognitive Neuroscience of Language group, and the MIT Computational Psycholinguistics group for their feedback on earlier stages of this study. We are also grateful to the reviewers for their thoughtful comments.

Appendix for Using surprisal and fMRI to map the neural bases of broad and local contextual prediction during natural language comprehension

1 Data Collection

Imaging was performed using a 3T MRI scanner (Discovery MR750, GE Healthcare, Milwaukee, WI) with a 32-channel head coil at the Cornell MRI Facility. Blood Oxygen Level Dependent (BOLD) signals were collected using a T2 -weighted echo planar imaging (EPI) sequence (repetition time: 2000 ms, echo time: 27 ms, flip angle: 77deg, image acceleration: 2X, field of view: 216 x 216 mm, matrix size 72 x 72, and 44 oblique slices, yielding 3 mm isotropic voxels). Anatomical images were collected with a high resolution T1-weighted (1 x 1 x 1 mm^3 voxel) with a Magnetization-Prepared RApid Gradient-Echo (MP-RAGE) pulse sequence.

2 Preprocessing

Primary preprocessing steps were carried out in AFNI version 16 (Cox, 1996) and include motion correction, coregistration, and normalization to standard MNI space. After the previous steps were completed, ME-ICA (Kundu et al., 2012) was used to further preprocess the data. ME-ICA is a denoising method which uses Independent Components Analysis to split the T2*-signal into BOLD and non-BOLD components. Removing the non-BOLD components mitigates noise due to motion, physiology, and scanner artifacts (Kundu et al., 2017).

3 Correlation Matrix for Predictors

Fig. 1 shows the correlation matrix for the three surprisal predictors.

4 Group-level results

Table 1 shows the significant clusters of activation for topical surprisal using brain region labels from the Harvard-Oxford Cortical Structure Atlas.

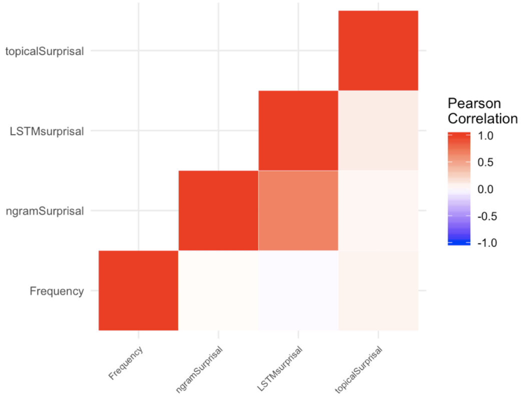

Figure 1: Correlation matrix (Pearson's r) of the convolved regressors included in the GLM models reported in Analysis 1 and Analysis 2.

Regions	Cluster size (in voxels)	MNI Coordinates x	y	z	p-value (corrected)	T-score (peak-level)
R Middle Temporal Gyrus	497	50	-50	18	0.000	8.46
R Precuenus	253	10	-62	30	0.011	5.83

Table 1: Significant clusters for topical surprisal after FWE voxel correction with $p < 0.05$. Peak activation is given in MNI coordinates and p-values are reported at peak-level after voxel correction.

Abstract

Multilingual Transformer-based language models, usually pretrained on more than 100 languages, have been shown to achieve outstanding results in a wide range of cross-lingual transfer tasks. However, it remains unknown whether the optimization for different languages conditions the capacity of the models to generalize over syntactic structures, and how languages with syntactic phenomena of different complexity are affected. In this work, we explore the syntactic generalization capabilities of the monolingual and multilingual versions of BERT and RoBERTa. More specifically, we evaluate the syntactic generalization potential of the models on English and Spanish tests, comparing the syntactic abilities of monolingual and multilingual models on the same language (English), and of multilingual models on two different languages (English and Spanish). For English, we use the available SyntaxGym test suite; for Spanish, we introduce SyntaxGymES, a novel ensemble of targeted syntactic tests in Spanish, designed to evaluate the syntactic generalization capabilities of language models through the SyntaxGym online platform.

1 Introduction

Transformer-based neural models such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b), DistilBERT (Sanh et al., 2019), XLNet (Yang et al., 2019), etc. are excellent learners. They have been shown to capture a range of different types of linguistic information, from morphological (Edmiston, 2020) over syntactic (Hewitt and Manning, 2019) to lexico-semantic (Joshi et al., 2020). A particularly significant number of works study the degree to which these models capture and generalize over (i.e., learn to instantiate correctly in different contexts) syntactic phenomena, including, e.g., subject-verb agreement, long distance dependencies, garden path constructions, etc. (Linzen et al., 2016; Marvin and Linzen, 2018; Futrell et al., 2019; Wilcox et al., 2019a). However, most of these works focus on monolingual models, and, if the coverage of syntactic phenomena is considered systematically and in detail, it is mainly for English, as, e.g., (Hu et al., 2020a). This paper aims to shift the attention from monolingual to multilingual models and to emphasize the importance to also consider the syntactic phenomena of languages other than English when assessing the generalization potential of a model. More specifically, it systematically assesses how well multilingual models are capable to generalize over certain syntactic phenomena, compared to monolingual models, and how well they can do it not only for English, but also for Spanish.

Multilingual models such as mBERT (multilingual BERT, (Devlin et al., 2019)), XLM (Lample and Conneau, 2019) and XLM-R (Conneau et al., 2020) proved to achieve outstanding performance on cross-lingual language understanding tasks, including on low-resource languages for which only little training data is available. However, these models face the risk of running into what Conneau et al. (2020) refer to as "curse of multilinguality": adding languages to the model increases the performance on low-resource languages up to a point, after which the overall performance on monolingual and cross-lingual benchmarks degrades. The question is thus whether, and if yes to what degree, this degradation affects the syntactic generalization potential of multilingual models across languages.

The reason to extend the evaluation to other languages (in our case, Spanish) is that many existing syntactic phenomena such as determiner and adjective agreement within the noun phrase, subject pro-drop, or flexible word order – to name only a few – are not prominent or do not exist in English, while in Spanish all of them do.

Our evaluation methodology is similar to that by

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3799–3812
August 1–6, 2021.

Hu et al. (2020a), who test 20 model type combinations and data sizes on 34 English syntactic test suites, and find substantial differences in the syntactic generalization performance across different models. We draw upon their tests to test the syntactic generalization potential of monolingual and multilingual transformer-based models for English, and upon the Spanish SyntaxGym introduced in this paper for Spanish. Tu run the tests, we use the SyntaxGym toolkit (Gauthier et al., 2020).

Our results show that, indeed, there is a substantial difference between the syntactic generalization potential of monolingual and multilingual models. But this difference depends on the language: While for English monolingual models (BERT and RoBERTa) offer a higher syntactic generalization than multilingual models (mBERT and XLM-R), this is not the case for Spanish, for which multilingual models (XLM-R) generalize better. Furthermore, multilingual models do not generalize equally well across languages, with mBERT generalizing, in general, better in English and XLM-R better in Spanish. Our experiments also show that it depends on the language how well a multilingual model captures a specific syntactic phenomenon such as, e.g., Agreement, Center-embedding or Garden Path.

The remainder of the paper is structured as follows. Section 2 introduces the work that is related to ours in terms of the evaluation methodology and, in particular, in terms of the assessment of multilingual language models. Section 3 describes the English test suites, and presents the novel Spanish SyntaxGym test suites. Section 4 details the models that we tested and outlines how we use them to evaluate the probability of a text sequence. Section 5 offers a detailed analysis of the syntactic generalization abilities of the monolingual and multilingual versions of BERT and RoBERTa, and Section 6 summarizes the implications that our work has for the use of multilingual language models.

2 Related Work

Our work on the evaluation of the capability of monolingual and multilingual transformer-based LMs to capture syntactic information is in line with a number of previous works, including, e.g., those that are based on psycholinguistic experiments, focusing on highly specific measures of language modeling performance and allowing to distinguish models with human-like representations of syntactic structure (Linzen et al., 2016; Lau et al., 2017; Gulordava et al., 2018; Marvin and Linzen, 2018; Futrell et al., 2019). Supervised probing models have been used to test for the presence of a wide range of linguistic phenomena (Conneau et al., 2018; Hewitt and Manning, 2019; Liu et al., 2019a; Tenney et al., 2019; Voita and Titov, 2020; Elazar et al., 2020). Warstadt et al. (2020) isolate specific phenomena in syntax, morphology, and semantics, finding that state-of-the-art models struggle with some subtle semantic and syntactic phenomena, such as negative polarity items and extraction islands.

Recently, a number of works also address the cross-language assessment of models. Hu et al. (2020b) introduces XTREME, a multi-task benchmark for evaluating the cross-lingual generalization capabilities of multilingual representations across 40 languages and 9 tasks. They show that while XLM-R reduces the difference between the performance on the English test set and all other languages compared to mBERT for tasks such as XQuAD and MLQA, it does not have the same impact on structured prediction tasks such as PoS and NER. Mueller et al. (2020) introduces a set of subject-verb agreement tests, showing that mBERT performs better than English BERT on Sentential Complements, Short VP Coordination, and Across a Prepositional Phrase, but worse on Within-an-Object Relative Clause, Across-an-Object Relative Clause and in Reflexive Anaphora Across a Relative Clause, and offers high syntactic accuracy on English, but noticeable deficiencies on other languages, most notably on those that do not use Latin script, as also noted by Hu et al. (2020b). On the same line, Rönnqvist et al. (2019) concludes that mBERT is not able to substitute a well-trained monolingual model in challenging tasks.

As already mentioned in Section 1, Hu et al. (2020a) assembled a set of English syntactic tests in order to assess the syntactic generalization potential of a number of different neural LMs (LSTM, ON-LSTM, RNNG and GPT-2). The tests are accessible through the SyntaxGym toolkit (Gauthier et al., 2020); cf. also Section 3.1. Our methodology is analogous, although our objective is different. Rather than comparing the performance of several monolingual models, we contrast the performance of monolingual and multilingual transformer-based models. Furthermore, while their only test suite source is the English SyntaxGym, we create and use also a Spanish SyntaxGym; cf. Section 3.2.

3 Test Suites

For the English test suites, we used SyntaxGym,[1] an online platform that compiles a variety of linguistic tests used by Hu et al. (2020a) to assess the syntactic coverage of language models. It contains 34 suites, grouped into 6 different so-called *circuits*, a classification based on what is required from the models to process the targeted constructions. For the Spanish test suites, we created SyntaxGymEs, adapting 11 of the existing suites for English and building 15 new ones, including a whole new circuit. In what follows, we first introduce the original English SyntaxGym and then present in detail the novel SyntaxGymEs.

3.1 SyntaxGym for English

The tests in the SyntaxGym designed by Hu et al. (2020a) (henceforth also referred to as "English SyntaxGym") are based on the notion of *surprisal*. A sequence of words is given to a language model, which assigns a probability to each of the following candidate words. Given the syntactic properties of the considered language, some candidate words are less surprising than others, and so should be predicted by a language model. For instance, after the sequence *The cat*, the inflected word *sleeps* should be less surprising than *sleep*.

Each test consists of a list of ITEMS that vary in a controlled way according to a set of CONDITIONS determined by the experimental design. The other main component is a series of PREDICTIONS comparing surprisal values in specific regions of the items across conditions. If the relevant syntactic generalization has been learned by the model, the predictions should hold.

Moreover, some tests have versions with MODIFIERS, in which additional clauses or phrases have been embedded inside each item. These modifiers increase the linear distance between two co-varying items, making the task harder. Sometimes they also include a distractor word in the middle of a syntactic dependency, which can lead the models to misinterpret the dependency.

The test suites are arranged in terms of the following *circuits*:

• **Agreement**: Morphosyntactic phenomena that occur when the features of an item constrain another item to adopt a specific form. This is a marginal phenomenon in English, so the original circuit only includes 3 test suites on *Subject-verb number agreement*, all of them with modifiers (Marvin and Linzen, 2018).

• **Licensing**: A construction's need for the presence of a *licensor* to allow its occurrence in a sentence. The circuit consists of 4 suites on *Negative polarity items* (2 of them with modifiers) and 6 on *Reflexive pronouns* (all of them with modifiers), also from Marvin and Linzen (2018).

• **Center embedding**: Subordinate clauses that sit in the middle of their superordinate clause, creating nested dependencies. This circuit contains 2 test suites: *Center embedding* and *Center embedding with modifier*, from Wilcox et al. (2019a).

• **Long-distance dependencies (LDDs)**: LDDs occur when two constituents that are syntactically related do not appear adjacent to one another, but at a longer distance from one another. The circuit includes 6 suites on *Filler-gap dependencies* (2 with modifiers and 4 addressing extraction and hierarchy) from Wilcox et al. (2018) and Wilcox et al. (2019b), and 2 suites on *Cleft structure* that were first introduced in (Hu et al., 2020a).

• **Gross syntactic expectation**: Expectation for a large syntactic structure usually induced by subordinating adverbs or conjunctions. 4 test suites on *Subordination* (from Futrell et al. (2018), 3 of them with modifiers) constitute the circuit.

• **Garden path effects**: Effects that emerge when an incorrect but locally likely parse needs to be abandoned in favor of the correct one, once a specific word appears in the sentence. Two such effects are considered in this circuit: *Main verb/reduced relative clause (MVRR)* and *NP/Z garden paths*, with respectively 2 and 4 suites, all from Futrell et al. (2018).

3.2 SyntaxGymES: SyntaxGym for Spanish

For Spanish, we expand the tests in (Hu et al., 2020a) so as to cover language-specific phenomena. In this section, we detail which of the original tests we retained, which ones we modified, and which ones we added within each original circuit. A whole new circuit regarding the linear order of a sentence's basic constituents was also added, since flexibility in this respect is a characteristic that distinguishes Spanish (and other Romance languages) from English. For a more detailed description with examples and predictions, see the Supplementary Material; upon acceptance of the paper, Syntax-

---

[1] `http://syntaxgym.org/`

GymES will be published in the SyntaxGym platform http://syntaxgym.org/.

3.2.1 Notation

We follow the usual notations in linguistic literature. An asterisk '*' preceding an example signals that the sentence is ungrammatical, it violates some principle or constraint. A question mark '?' is used to indicate a marginal sentence, i.e., a sentence that is grammatical but very uncommon or that requires a non-straightforward interpretation. The exclamation mark '!' indicates a highly difficult sentence to process for the human mind.

3.2.2 Agreement

Unlike English, Spanish is a morphologically rich language, and as such it presents many morphosyntactic phenomena related to agreement. For this reason, out of the six original circuits, **Agreement** was the one that underwent the most changes.

Regarding verbal agreement (constraints imposed on the verb by the subject), we adapted two existing test suites, **Subject-Verb Agreement with Object Relative Clause** and **Subject-Verb Agreement with Subject Relative Clause**, and created a new one, **Basic Subject-Verb Agreement**, in which both person and number features were taken into consideration.

(1) Tú cocinas
you.2SG cook.2SG

(2) * Tú cocinais/cocino/cocinan
you.2SG cook.2PL/1SG/3PL

As for nominal agreement (constraints that a noun's gender and number features can impose on the form of other words in the sentence), we also created several new test suites: **Determinant-Noun Agreement** simply pairs a noun with the four possible forms of the definite article (*el*, *la*, *los*, *las*), while **Adjective-Noun Agreement** pairs a noun with the four possible forms of an adjective that modifies it (we excluded articles to avoid providing extra information).

(3) La tienda vende discos usados
the store sells disc.M.PL used.M.PL

(4) * La tienda vende discos
the store sells disc.M.PL
usados/usado/usadas/usada
used.M.PL/M.SG/F.PL/F.SG

In addition to these two suites, we built similar ones for **Attribute Agreement** in copulative constructions, to which we added two versions with object or subject relative clauses as modifiers, and also for **Predicative Agreement** in constructions with subject or object predicative complement. The only difference here is that the two words that must agree are not adjacent anymore. In terms of predictions, the verb/noun with matching features should have a lower surprisal than the others, and the verb/noun that matches only one feature should have a lower surprisal that the one that doesn't match any.

3.2.3 Center Embedding

For this circuit, we adapted to Spanish the two existing test suites in English, creating **Center Embedding** and **Center Embedding with PP modifier**. In the basic suite, a relative clause is center embedded after the subject of the main clause. Verb transitivity and subject-verb plausibility are used to test if the models are capable of retaining the relevant information and predicting the verbs in the correct order.

3.2.4 Gross Syntactic Expectation

From the four original suites in this circuit, we adapted three of them: **Subordination**, and two of its versions with modifiers, **Subordination with Object Relative Clause** and **Subordination with Subject Relative Clause**. Given a sentence that starts with a typically subordinating adverb or conjunction, these suites test the models' ability to maintain the expectation for the onset of a matrix clause for as long as the subordinate one lasts.

3.2.5 Long-distance Dependencies

Filler-gap dependencies are an example of LDDs. They occur when a phrase (the filler) is realized somewhere in the sentence, but is semantically interpreted at some other point (the gap). For this circuit, we created a **Basic Filler-Gap Dependencies** test and adapted from the original English circuit a version that includes modifiers, **Filler-Gap Dependencies with Three Sentencial Embeddings**. Embedding three sentences between filler and gap makes the task more challenging. We also adapted to Spanish the novel **Pseudo-Cleft Structures** suite introduced in (Hu et al., 2020a).

3.2.6 Garden Path Effects

The Garden Path effect can be created by several syntactic ambiguities that differ cross-linguistically. The Main Verb/Reduced Relative garden path effect was the subject of two suites in the original

English circuit, but it does not translate to Spanish, so those suites were not included in Spanish SyntaxGym.

On the other hand, the ambiguity responsible for NP/Z also holds for Spanish. Here, an NP is initially interpreted as the object in a subordinate clause when it actually is the subject of the main clause (the subordinate clause having a Zero/null object). The ambiguity can be prevented with a comma, but also by placing an overt object in the subordinate clause, as is done in **NP/Z Garden Path Effect (with Overt Object)**, or by substituting its verb with a pure intransitive verb, as is done in **NP/Z Garden Path Effect (with Intransitive Verb)**. Both suites correspond to Spanish adaptations of the two original suites regarding this effect.

(5) !Mientras ella leía sus manuscritos se volaron por la ventana.

!'While she read her manuscripts went out the window.'

(6) Mientras ella [dormía]/[leía un libro]/[leía,] sus manuscritos se volaron por la ventana.

'While she [slept]/[read a book]/[read,] her manuscripts went out the window.'

3.2.7 Licensing

Negative polarity items (NPIs), like *any* or *ever* in English, are examples of words that need to be licensed by negation. Since Spanish NPIs do not function exactly in the same way, we took the original NPI Licensing test as inspiration and created two new suites: **Negative Polarity Items** and **NPIs and Polarity Agreement**.

Constructions with verbs in subjunctive mood also require the presence of a licensor. In Spanish, a verb expressing feelings (e.g. of joy, surprise, pleasantness) in the main clause, creates the expectation for subjunctive mood in the subordinate clause. This was the basis for a new test suite: **Subjunctive Mood and Verbs that Express Feeling**.

(7) Espero que mañana llueva/*lloverá.
(I)hope that tomorrow rain.SUB/will.rainIND

'I hope it [rains]/[will rain] tomorrow.'

The other new suite in this circuit, **Subjunctive Mood, Negation and Belief Verbs**, relies on the fact that belief verbs can also license subjunctive mood, but only when combined with negation:

(8) No creo que mañana
NEG (I)believe that tomorrow
llueva/*lloverá.
rain.SUB/will.rain.IND

'I don't think it [rain]/[will rain] tomorrow.'

(9) Creo que mañana no
(I)believe that tomorrow NEG
lloverá/*llueva.
will.rain.IND/rain.SUB

'I think it [won't]/[don't] rain tomorrow.'

3.2.8 Linearization

One of the main syntactic distinctions between languages is constituent order within the sentence. But, in addition to the canonical order in which these elements appear, languages also differ in their flexibility to alter that order. Spanish allows some flexibility, which was the basis for three new test suites.

For **Subject–Auxiliary Verb–Main Verb Linearization**, the possibility to postpone the subject is compared with the rigidity of the relation between main and auxiliary verb, which must be adjacent and do not allow inversion:

(10) Juan [ha comido]/*[comido ha].

'John [has eaten]/[eaten has].'

(11) Ha [comido Juan]/*[Juan comido].

*'Has [eaten John]/[John eaten].'

In the **Subject–Verb–Object Linearization** test, we compare the phenomenon in affirmative versus interrogative sentences. In Spanish, word order flexibility holds for affirmative sentences, but not for interrogative ones, where subject-verb inversion is compulsory:

(12) Ana compró un libro. / Compró un libro Ana.

'Ann bought a book. / Bought a book Ann.'

(13) ¿Qué compró Ana? / *¿Qué Ana compró?

'What did Ann buy? / *What Ana did buy?'

Word order variations also appear within the NP, as captured by the **Noun-Adjective and Noun-PP Linearization** test. Contrary to English, Spanish adjectives usually come after the noun. But again, the language allows for some flexibility and they can be swapped. This possibility, however, does not apply to other noun modifiers like prepositional phrases:

(14) Construyó una [mesa robusta]/[robusta mesa].

'He built a [sturdy table]/[table sturdy].'

(15) Construyó una [mesa de madera]/*[de madera mesa].

'He built a [wooden table]/*[table wooden].'

4 Experiments

We test the base cased versions of BERT and mBERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b) and XLM-R (Conneau et al., 2020) on the English SyntaxGym and BETO (Canete et al., 2020), mBERT and XLM-R on the Spanish SyntaxGym. To run the experiments, we use the SyntaxGym toolkit (Gauthier et al., 2020).

4.1 Experimental Setup

The SyntaxGym test suites are designed from the perspective of sentence generation, i.e., with the hypothesis that if a model has correctly learned some relevant syntactic generalization, it should assign higher probability to grammatical and natural continuations of sentences. This requires asking the models to predict the next token given a context of previous tokens, in a left-to-right generative fashion. However, BERT-based and RoBERTa-based families of models (in our case, BERT and mBERT on the one side, and RoBERTa and XLM-R on the other side) are bidirectional, they are trained with a masked language modeling objective to predict a word given its left and right context. In this work, we follow Wang and Cho (2019)'s sequential sampling procedure to evaluate the probability of a text sequence, encoding unidirectional context in the forward direction. To compute the probability distribution for a sentence with N tokens, we start with a sequence of $N+2$ tokens: a *begin_of_sentence* token plus $N+1$ *mask* tokens, where the last *mask* corresponds to the *end_of_sentence* token. For each token position i in $[1, N]$, we compute the probability distribution over the vocabulary given the left context of the original sequence, and select the probability assigned by the model to the original word.

For example, in an agreement test with the sentence '*The girls run fast.*', a model that has properly learned agreement should assign a higher probability to *run* than to *runs* for the third word. In order to test it, we feed the tokens sequence *[[bos] [The] [girls] [mask] [mask] [mask] [mask]]* to the model, and compare the probabilities assigned by the model to *run* and *runs* for position 4.

	Average SG performance	
Model	**English**	**Spanish**
BERT	77.80	—
RoBERTa	82.04	—
mBERT	77.55	72.31
XLM-R	71.84	78.50
BETO	—	67.92

4.2 Results of the experiments

This section summarizes the results of our experiments that aim to: (i) contrast the performance of monolingual and multilingual models on English and Spanish and (ii) provide insights on the performance of the multilingual models across languages.

Table 1 shows the average SyntaxGym (SG) performance of the evaluated monolingual and multilingual models on the English and Spanish SyntaxGyms. Figures 1 and 2 zoom in on the performance of the tested models with respect to specific circuits for English and Spanish respectively.

Six of the English test suites (Center Embedding, Cleft structure, MVRR, NPZ-Verb, NPZ-Object, Subordination) and five of the Spanish test suites (Attribute Agreement, Basic Subject-Verb Agreement, Subordination, Center Embedding, Basic Filler-Gap Dependencies) include tests with and without modifiers, i.e,. intervening content inserted before the critical region. Figures 3 and 4 show the models' average scores in these test suites, without modifiers (dark bars) and with modifiers (light bars), evaluating how robust each model is with

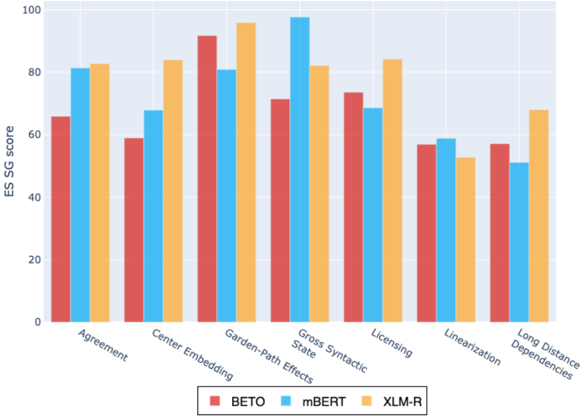

Figure 2: Performance accuracy across Spanish circuits

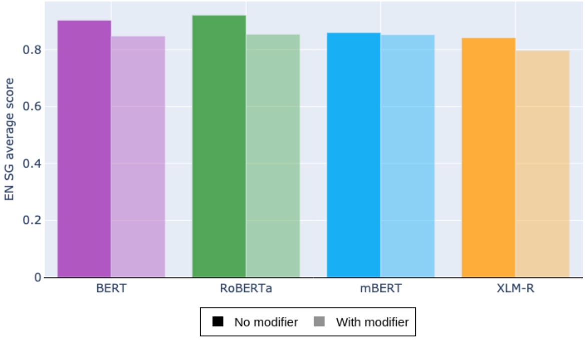

Figure 3: Models average English SG score in Center Embedding, Cleft structure, MVRR, NPZ-Verb, NPZ-Object and Subordination, with and without modifiers.

respect to the corresponding content.

5 Discussion

Let us assess in detail the results of the experiments from above. In what follows, we compare the performance of monolingual with the performance of multilingual models and analyze the cross-language performance of multilingual models, as well as the stability of the individual models with respect to modifiers.

5.1 Monolingual vs multilingual models

RoBERTa shows an overall higher performance than the other models for English (Table 1). This is not surprising since it is trained on 10 times more data than BERT, and it has been shown to improve over BERT in many NLU tasks. However, while mBERT does not seem to lose performance compared to BERT, XLM-R loses around 10 points compared to RoBERTa. As XLM-R is specifically designed to offer a more balanced performance across languages, with a special focus on low-resource languages, it appears natural that it loses some performance on high-resource languages such as English. For Spanish, the multilingual models clearly outperform the monolingual model. This is likely due to the fact that while BETO and mBERT are of comparable size and are trained with the same amount of data (16GB), BETO is only trained with a Masked Language Modeling (MLM) objective, and mBERT is trained on MLM and Next Sentence Prediction (NSP). On the other hand, XLM-R is also only trained on MLM, but it is trained on more than 2TB of data, 53 GB corresponding to Spanish data.

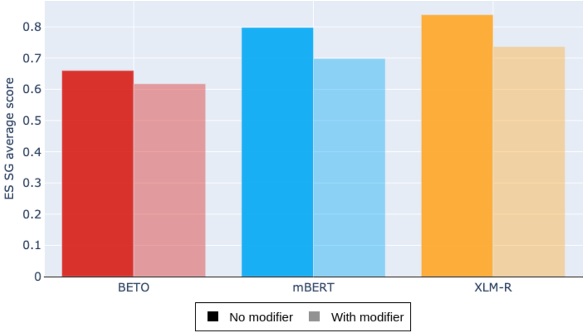

Figure 4: Models average Spanish SG score in Attribute Agreement, Subject-Verb Agreement, Subordination, Center Embedding and Filler-Gap Dependencies, with and without modifiers.

RoBERTa outperforms all other models in all the English circuits (cf. Figure 1), except in Gross Syntactic State, in which BERT-based models clearly outperform RoBERTa-based models, and the multilingual model outperforms the monolingual one in both families. Intuitively, we believe that the NSP training objective of BERT-based models helps them to better understand the relation between two sentences, and this knowledge can also be applied to the relation between two clauses (which is the basis of the Gross Syntactic State circuit). Comparing the BERT and RoBERTa model families, it is interesting to notice that while RoBERTa outperforms XLM-R in all circuits except Gross Syntactic State, BERT only outperforms mBERT in 3 of them.

Interestingly, all models seem to struggle with Agreement in English. This observation is aligned with Mueller et al. (2020)'s hypothesis that language models learn better hierarchical syntactic generalizations in morphologically complex languages (such as, e.g., Spanish), which frequently provide overt cues to syntactic structure, than in morphologically simpler languages (such as, e.g., English). Indeed, the fact that XLM-R offers the lowest performance may be related to the fact that the model has been more exposed to more complex languages than the others. For Long Distance Dependencies, BERT-based models show a low performance compared to RoBERTa-based models. This might be due to the different training procedures adopted in both model families (i.e., that RoBERTa does not include the Next Sentence Prediction task (as BERT does) and introduces dynamic masking).

On the other hand, in specific circuits for Spanish (cf. Figure 2) XLM-R outperforms the other two models in 5 out of 7 circuits. As observed for English, the BERT-based models struggle with the Long Distance Dependencies tests, and mBERT offers an outstanding performance in Gross Syntactic State. The monolingual model, BETO, is outperformed by mBERT in 4 out of 7 tests, and by XLM-R in all 6 out of 7 tests. As mentioned before, these differences may be related to the fact that, unlike BERT, BETO is not trained with the NSP objective; but also to the difference in training data size: 16GB for BETO vs. more than 2TB (of which 53GB of Spanish data) for XLM-R.

All models offer a low performance in the new Linearization test for Spanish. A more in-depth investigation is necessary to explain this. The test has been designed with literary Peninsular Spanish in mind, and it is possible that the training data may not contain enough samples that show the targeted word order varieties, or may contain data from American Spanish sources, which may show differences in canonical word order with respect to Peninsular Spanish.

5.2 Cross-language multilingual models performance

As shown in Table 1, multilingual models do not syntactically generalize equally well in both languages. While mBERT offers a better generalization in English, outperforming XLM-R by almost 6 points, XLM-R generalizes better in Spanish, outperforming mBERT by 6 points. This observation corroborates our intuition that XLM-R sacrifices performance in high-resource languages (e.g., English, with 300GB of training data) to be able to offer a more balanced performance across languages (e.g., Spanish, with 53GB of training data).

Comparing Figures 1 and 2, we observe improvements in the Spanish tests for XLM-R in 4 out of 6 circuits, particularly noticeable in Agreement and Center Embedding, while it loses around 10 points in Long Distance Dependencies. On the other hand, mBERT also shows a big improvement in the Spanish tests in Agreement, while it loses performance in Garden Path Effects, Licensing and Long Distance Dependencies.

5.3 Model stability with respect to modifiers

Since modifiers increase the linear distance between the elements in a dependency structure, thus making the task more demanding, stability in this respect indicates that models have robustly learnt the appropriate syntactic generalization and do not depend that much on adjacency. Figures 3 and 4 show the models' average scores in those test suites that have two versions: without modifiers (dark bars) and with modifiers (light bars). As was intuitively expected, all the models offer a higher performance in the tests without modifiers. While for English the multilingual models are the less affected, for Spanish BETO seems to be more robust than the multilingual models, even though it offers a lower performance.

6 Conclusions

In this paper, we assessed the syntactic generalization potential of selected transformer-based language models on English and Spanish. We have shown that multilingual models do not generalize equally well across languages: mBERT generalizes better for phenomena in English, while XLM-R does it better for phenomena in Spanish. We have also shown that the answer to the question whether monolingual or multilingual models generalize better is equally language-specific: the monolingual RoBERTa generalizes better on English, while the multilingual XLM-R generalizes better on Spanish. While it is possible that the multilingual abstractions captured by XLM-R become useful for morphologically rich languages such as Spanish, this difference may also be related to the difference in the amount of training data used to train BETO and XLM-R, and therefore it is possible that a monolingual model trained with a comparable amount of data could outperform the multilingual models.

The performance of all models is affected by the presence of modifiers, which shows that the complexity of the syntactic structure is still a challenge. In general, each syntactic phenomenon deserves attention. For instance, Agreement in English is hard to learn, given the scarcity of cues (especially if compared to a morphologically rich language), and so is Linearization in Spanish.

As far as the nature of the training procedures of the models is concerned, the lack of Next Sentence Prediction (NSP) objective in the RoBERTa model family seems to harm BETO, but not XLM-R; this suggests that the performance of BETO may be improved with (much) more training data. It also seems to harm in the case of the Gross Syntactic State circuit, suggesting that RoBERTa-based models may also benefit from complementary training objectives in their pretraining procedure.

Overall, our experiments have also shown the importance of testing models on a wider range of languages, in particular, morphologically rich ones. As part of our future work, we plan to expand further SyntaxGymES and develop SyntaxGyms for a number of other selected languages. Also, careful examination of a wider range of material is necessary to ensure that important phenomena are not left out, so as to assess the actual coverage of the test suites.

A Spanish SyntaxGym: Description of Test Suites

This appendix lists and describes all the test suites compiled for Spanish SyntaxGym. Each test consists of a list of ITEMS that vary in a controlled way according to a set of CONDITIONS determined by the experimental design. A series of PREDICTIONS compare surprisal values at specific regions of the items across conditions. Some tests have versions with MODIFIERS that increase the linear distance between two co-varying items, making the task more demanding.

The test suites are arranged in terms of *circuits* of related syntactic phenomena. Each of the following sections corresponds to one of these circuits.

Notation. An asterisk * signals an ungrammatical sentence, a question mark ? indicates a marginal sentence (grammatical but very uncommon or requiring a difficult interpretation), an exclamation point ! denotes high processing difficulty.

A.1 Agreement

Agreement is a morpho-syntactic phenomenon that occurs when the features of an item constrain another item to adopt a specific form.

- **Basic Subject-Verb Agreement**. New suite. Spanish finite verbs in any tense/mood have six inflected forms according to person and number features. The verb's features the subject's, otherwise the result is ungrammatical.

(16) Tú cocinas
you.2SG cook.2SG

(17) * Tú cocinais/cocino/cocinan
you.2SG cook.2PL/1SG/3PL

Predictions: The surprisal at the verb region is expected to be lower when it matches the subject than in any other condition. It is also expected to be lower when at least one of the features (person or number) agrees than when both disagree.

- **Subject-Verb Agreement with Subject Relative Clause**. Adapted from English. This test focuses on number agreement. The subject relative clause includes a *distractor* NP differing in number with the subject.

(18) El fontanero que ayudó a los
the.SG plumber that helped.3SG to thePL
albañiles trabaja/*trabajan los sábados.
bricklayers work.3SG/3PL the saturdays.
'The plumber who helped the bricklayers works/*work on saturdays.'

(19) Los fontaneros que ayudaron al
the.PL plumbers that helped.3SG to.thePL
albañil *trabaja/trabajan los sábados.
bricklayer work.3PL/3SG the saturdays.
'The plumbers who helped the bricklayer *works/work on saturdays.'

Predictions: A successful model should place higher probability to the verb agreeing with the subject (instead of the distractor) both in singular and in plural.

- **Subject-Verb Agreement with Object Relative Clause**. Adapted from English. Equal to the previous one, but with an object relative clause.

Nominal agreement was the basis for the following 6 new test suites. All of them share the same predictions: the surprisals should be lower when both gender and number features in the second word of the agreement relation match those in the first word. They should also be lower when only one of the features agrees than when both disagree.

- **Determiner-Noun Agreement**. New suite. The four possible forms of the definite article are paired with different nouns.

(20) El/*La/*Los/*Las gato
the.M.SG/*F.SG/*M.PL/*F.PL cat

- **Adjective-Noun Agreement**. New suite. The test pairs a noun with the four possible forms of an adjective that modifies it (we used constructions without determiner to avoid providing the models with extra information).

(21) La tienda vende discos
the store sells discs
usados/*usado/*usadas/*usada
used.M.PL/M.SG/F.PL/F.SG
'The store sells second-hand discs.'

- **Attribute Agreement**. New suite. Here, a noun is paired with and adjective through a copulative construction. This suite has 2 versions with object or subject relative clauses as modifiers.

(22) El piso está vacío/*vacía/*vacíos/*vacías
the flat is empty.M.SG/*F.SG/*M.PL/*F.PL

- **Predicative Agreement**. New suite. The subject or the object is paired with an adjective functioning as a predicative complement.

(23) Los niños llegaron
the children arrived
cansados/*cansado/*cansadas/*cansada
tired.M.PL/*M.SG/*F.PL/*F.SG
'The children arrived tired.'

A.2 Center Embedding

A center embedded clause is a subordinate clause that sits in the middle of its superordinate clause, creating nested dependencies that may be challenging for the models.

- **Center Embedding**. Adapted from English. A relative clause is center embedded after the subject of the main clause. Verb transitivity and subject-verb plausibility are used to test if the models are capable of retaining the relevant information and predicting the verbs in the correct order.

(24) La tormenta que el capitán [capeó amainó]/?[amainó capeó].
'The storm the captain [weathered abated]/?[abated weathered].'

Prediction: The surprisal of the combination of verbs should be smaller when their relative order creates a plausible sentence than when it creates an implausible one.

- **Center Embedding with modifier**. In the version with modifier, a prepositional phrase is inserted after the subject of the subordinate clause.

A.3 Gross Syntactic State

Expectation for a large syntactic structure at some point within the sentence.

- **Subordination**. Adapted from English. A sentence starting with a subordinate clause creates the expectation for the onset of a matrix clause for as long as the subordinate one lasts.

(25) ?(Mientras) ella miraba los resultados, el doctor entró en la habitación.
'While she looked at the results, the doctor entered the room.'

(26) (*Mientras) ella miraba los resultados.
'(*While) she looked at the results.'

Predictions: The surprisal for the lack of a second clause should be higher when there is a subordinating conjunction or adverb than where there is not. But having two clauses joined by a conjunction/adverb should be less surprising than their juxtaposition.

- **Subordination with Object Relative Clause** and **Subordination with Subject Relative Clause**. Adapted from English. Versions of the previous suite but with a modifier.

A.4 Long-distance Dependencies

LDDs occur when two syntactically related groups do not appear adjacent to one another but at a longer distance from one another.

- **Basic Filler-Gap Dependencies**. New suite, a simplified version of the existing FGD tests for English. FGDs occur when a phrase (the filler) is realized somewhere in the sentence but is semantically interpreted at some other point (the gap).

(27) Yo sé [lo que]/*que tu amigo tiró _ al suelo.
'I know what/*that your friend threw _.'

(28) Yo sé *[lo que]/que tu amigo tiró una colilla al suelo.
'I know *what/that your friend threw a cigarette butt.'

Predictions: The overt object should be more surprising when there is a filler when there is not. We also expect lower surprisal when the sentence has a filler later followed by gap than when it has a conjunction instead but the gap remains.

- **Filler-Gap Dependencies with Three Sentencial Embeddings**. Adapted from English. It is a version of the previous test that includes a modifier (three sentential embeddings) between filler and gap. This makes the task more challenging. The predictions, though, remain the same.

- **Pseudo-Cleft Structures** Adapted from English. A pseudo-cleft or wh-cleft is formed by a wh-element extracting content from a relative clause joined by a copula to a constituent that provides the content requested by the wh-element. The extracted constituent can be a NP or a VP. In the VP case, the verb in the relative clause must be an inflected form of 'hacer' ('to do').

(29) Lo que tú difundiste/?hiciste fue un rumor.
'What you spread/*did was a rumor.'

(30) Lo que tú *difundiste/hiciste fue confirmar un rumor.
'What you *spread/did was confirm a rumor.'

Predictions: The surprisal should be lower for the extracted VP when the verb in the relative clause is a light verb (*hacer* – 'to do') than when it is not, but it should be higher for the extracted NP when the verb is light than when it is semantically heavier and matches the NP. In addition, the difference in the first case should be more important than in the second one. This happens because the light verb admits a wider range of objects, whereas in the first case, one of the options is syntactically incorrect.

A.5 Garden Path Effects

Garden-path effects emerge when an incorrect but locally likely parse needs to be abandoned in favor of the correct one. In the NP/Z garden path, an NP is initially interpreted as the object in a subordinate clause, but when the main verb appears, this NP should be reinterpreted as its subject. The effect can be prevented by adding a comma, but also by placing an overt object in the subordinate clause, or by substituting its verb with a purely intransitive one. These are the basis for the next two suites.

- **NP/Z Garden Path Effect (Overt Object)**.
- **NP/Z Garden Path Effect (Intransitive Verb)**. Both adapted from English.

(31) !Mientras ella leía sus manuscritos se volaron por la ventana.
!'While she read her manuscripts went out the window.'

(32) Mientras ella [dormía]/[leía un libro]/[leía,] sus manuscritos se volaron por la ventana.
'While she [slept]/[read a book]/[read,] her manuscripts went out the window.'

Predictions: The main verb should be more surprising in the garden path condition than when the effect has been prevented either by the comma or by interfering with the verb. Moreover, the difference in surprisal should be bigger when the comma is essential to solve the garden path effect than when it is not.

A.6 Licensing

In natural language, some words or constructions need the presence of a licensor to allow their occurrence in a sentence. This happens with NPIs (Negative polarity items) and subjunctive mood, for instance.

- **Negative Polarity Items and Polarity Agreement**. New suite. In Spanish, NPIs that follow the verb (such as *nunca* 'never', *nadie* 'nobody', and *nada* 'nothing') need to be licensed by negation. This 'double negative' does not result in an affirmative, it is a sort of polarity agreement.

(33) Yo no bebo nunca/?siempre.
I NEG drink never/always
'I never drink./I don't drink always.'

(34) Yo bebo *nunca/siempre.
'I *ever/always drink.'

Predictions: We expect the surprisals in both agreeing conditions (negative-NPI, positive-PPI) to be lower than in any of the non-agreeing conditions (negative-PPI, positive-NPI).

- **Negative Polarity Items**. New suite. NPIs also need to be in the scope of the negation to be licensed by it. This suite compares between a negative particle that "commands" the NPI and one that doesn't.

(35) Tú, como no mirabas por la ventana,
You, as NEG looked by the window,
*(no) has visto a nadie.
NEG have seen at nobody
'As you weren't looking through the window, you have *(not) seen anybody.'

(36) Tú, como mirabas por la ventana, *(no)
You, as looked by the window, NEG
has visto a nadie.
have seen at nobody
'As you were looking through the window, you have *(not) seen anybody.'

Predictions: The NPI should be more surprising when there isn't a negative particle that commands it, independently of the presence of another one that does not command it.

- **Subjunctive Mood and Verbs that Express Feeling**. New suite. Feeling verbs that introduce a subordinate clause serve as licensors for subjunctive mood, whereas other type of verbs do not.

(37) Espero que mañana llueva/*lloverá.
(I)hope that tomorrow rain.SUB/will.rain.IND
'I hope it rains/*[will rain] tomorrow.'

(38) Sé que mañana
(I)know that tomorrow
*llueva/lloverá.
rain.SUB/will.rain.IND
'I know it [will rain]/rains tomorrow.'

Predictions: Subjunctive mood should be less surprising than indicative mood when the verb in the main clause expresses feelings. But when it doesn't, subjunctive should be more surprising than indicative mood. Moreover, subjunctive mood should also be more surprising with a feeling verb than with a non-feeling verb.

- **Subjunctive Mood, Negation and Belief Verbs**. New suite. Belief verbs can also license subjunctive mood, but only when combined with negation.

(39) No creo que mañana
NEG believe that tomorrow
llueva/*lloverá.
rain.SUB/will.rain.IND
'I don't think it rains/[will rain] tomorrow.'

(40) Creo que mañana no
(I)believe that tomorrow NEG
*llueva/lloverá.
rain.SUB/will.rain.IND
'I think it rains/[won't rain] tomorrow.'

Predictions: The subordinate verb should be less surprising in subjunctive than in indicative mood when the main clause is negated. However, the contrary should hold when the subordinate clause is negated but the main one is not. In addition, subjunctive mood should be less surprising when the negation is in the main clause than when it is in the subordinate clause.

A.7 Linearization

Constituent order is commonly used in linguistics as a way to classify languages. But, in addition to the canonical order in which elements appear, languages also differ in their flexibility to alter that order.

- **Subject – Auxiliary Verb – Main Verb Linearization**. New suite. Subject-verb order admits inversion in Spanish but main and auxiliary verb do not and they must be adjacent.

(41) Juan ha comido. / Ha comido Juan
'John has eaten. / Has eaten John.'

(42) *Juan comido ha. / *Ha Juan comido.
'John eaten has. / Has John eaten.'

Predictions: The postposed subject should be less surprising than any of the alterations involving auxiliary and main verb. The canonical SV order, however, should be less surprising than postposing the subject, and the difference in this case should be less important than the differences in the first two cases.

- **Subject – Verb – Object Linearization**. New test. In Spanish, word order flexibility holds for affirmative sentences but not for interrogative ones, where subject-verb inversion is compulsory.

(43) Ana compró un libro/Compró un libro Ana.
'Ann bought a book. / Bought a book Ann.'

(44) ¿Qué compró Ana? / ¿Qué Ana compró?
'What did Ana buy? / 'What Ana did buy?'

Predictions: A postposed subject in an affirmative sentence should be less surprising than lack of SV inversion in an interrogative one. The canonical SV order in the affirmative sentence, however, should be less surprising than postposing the subject, and the difference in this case should be less important than the difference in the first one.

- **Noun-Adjective and Noun-PP Linearization**. New suite. Spanish adjectives usually come after the noun, but this order can be inverted. Other noun modifiers like prepositional phrases cannot.

(45) Construyó una [mesa robusta]/[robusta mesa].
'He built a [sturdy table]/[table sturdy].'

(46) Construyó una [mesa de madera]/*[de madera mesa].
'He built a [wooden table]/*[table wooden].'

Predictions: A PP preceding the noun should be more surprising than one following it. An adjective preceding the noun should also be more surprising than one following it, but the difference in this case should be less important than in the first one.

Are Larger Pretrained Language Models Uniformly Better? Comparing Performance at the Instance Level

Ruiqi Zhong **Dhruba Ghosh** **Dan Klein** **Jacob Steinhardt**
Computer Science Division, University of California, Berkeley
{ruiqi-zhong, djghosh13, klein, jsteinhardt}@berkeley.edu

Abstract

Larger language models have higher accuracy on average, but are they better on every single instance (datapoint)? Some work suggests larger models have higher out-of-distribution robustness, while other work suggests they have lower accuracy on rare subgroups. To understand these differences, we investigate these models at the level of individual instances. However, one major challenge is that individual predictions are highly sensitive to noise in the randomness in training. We develop statistically rigorous methods to address this, and after accounting for pretraining and finetuning noise, we find that our BERT-LARGE is worse than BERT-MINI on at least $1-4\%$ of instances across MNLI, SST-2, and QQP, compared to the overall accuracy improvement of $2-10\%$. We also find that finetuning noise increases with model size, and that instance-level accuracy has momentum: improvement from BERT-MINI to BERT-MEDIUM correlates with improvement from BERT-MEDIUM to BERT-LARGE . Our findings suggest that instance-level predictions provide a rich source of information; we therefore recommend that researchers supplement model weights with model predictions.

1 Introduction

Historically, large deep learning models (Peters et al., 2018; Devlin et al., 2019; Lewis et al., 2020; Raffel et al., 2019) have improved the state of the art on a wide range of tasks and leaderboards (Schwartz et al., 2014; Rajpurkar et al., 2016; Wang et al., 2018), and empirical scaling laws predict that larger models will continue to increase performance (Kaplan et al., 2020). However, little is understood about such improvement at the instance (datapoint) level. Are larger models uniformly better? In other words, are larger pretrained models better at every instance, or are they better at some instances, but worse at others?

Prior works hint at differing answers. Hendrycks et al. (2020) and Desai and Durrett (2020) find that larger pretrained models consistently improve out-of-distribution performance, which implies that they might be uniformly better at a finer level. Henighan et al. (2020) claim that larger pretrained image models have lower downstream classification loss for the majority of instances, and they predict this trend to be true for other data modalities (e.g. text). On the other hand, Sagawa et al. (2020) find that larger non-pretrained models perform worse on rare subgroups; if this result generalizes to pretrained language models, larger models will not be uniformly better. Despite all the indirect evidence, it is still inconclusive how many instances larger pretrained models perform worse on.

A naïve solution is to finetune a larger model, compare it to a smaller one, and find instances where the larger model is worse. However, this approach is flawed, since model predictions are **noisy at the instance level**. On MNLI in-domain development set, even the same architecture with different finetuning seeds leads to different predictions on $\sim$8% of the instances. This is due to under-specification (D'Amour et al., 2020), where there are multiple different solutions that can minimize the training loss. Since the accuracy improvement from our BERT-BASE[1] to BERT-LARGE is 2%, most signals across different model sizes will be dominated by noise due to random seeds.

To account for the noise in pretraining and finetuning, we define *instance accuracy* as "how often a model correctly predicts an instance" (Figure 1 left) in expectation across pretraining and finetuning seeds. We estimate this quantity by pretraining 10 models with different seeds, finetuning 5 times for each pretrained models (Figure 1 middle), and

	Seed 1	Seed 2	Seed 3	Instance Accuracy
Instance 1	X	✓	✓	**66%**
Instance 2	X	X	X	**0%**
Instance 3	✓	X	X	**33%**
Instance 4	✓	✓	✓	**100%**

Figure 1: **Left**: Each column represents the same architecture trained with a different seed. We calculate accuracy for each instance (row) by averaging across seeds (column), while it is usually calculated for each model by averaging across instances. **Middle**: A visual layout of the model predictions we obtain, which is a binary-valued tensor with 4 axes: model size s, instance i, pretraining seeds P and finetuning seeds F. **Right**: for each instance, we calculate the accuracy gain from MINI to LARGE and plot the histogram in blue, along with a random baseline in red. Since the blue distribution has a bigger left tail, smaller models are better at some instances.

averaging across them.

However, this estimate is still inexact, and we might falsely observe smaller models to be better at some instances by chance. Hence, we propose a random baseline to estimate the fraction of *false discoveries* (Section 3, Figure 1 right) and formally upper-bound the false discoveries in Section 4. Our method provides a better upper bound than the classical Benjamini-Hochberg procedure with Fisher's exact test.

Using the 50 models for each size and our improved statistical tool, we find that, on the MNLI in-domain development set, the accuracy "decays" from BERT-LARGE to BERT-MINI on at least ∼4% of the instances, which is significant given that the improvement in overall accuracy is 10%. These decaying instances contain more controversial or wrong labels, but also correct ones (Section 4.2). Therefore, larger pretrained language models are not uniformly better.

We make other interesting discoveries at the instance level. Section 5 finds that instance-level accuracy has momentum: improvement from MINI to MEDIUM correlates with improvement from MEDIUM to LARGE . Additionally, Section 6 attributes variance of model predictions to pretraining and finetuning random seeds, and finds that finetuning seeds cause more variance for larger models. Our findings suggest that instance-level predictions provide a rich source of information; we therefore recommend that researchers supplement model weights with model predictions. In this spirit, we release all the pretrained models, model predictions, and code here: `https://github.com/ruiqi-zhong/acl2021-instance-level`.

2 Data, Models, and Predictions

To investigate model behavior, we considered different sizes of the BERT architecture and finetuned them on Quora Question Pairs (QQP[2]), Multi-Genre Natural Language Inference (MNLI; Williams et al. (2020)), and the Stanford Sentiment Treebank (SST-2; Socher et al. (2013)). To account for pretraining and finetuning noise, we averaged over multiple random initializations and training data order, and thus needed to pretrain our own models rather than downloading off the internet. Following Turc et al. (2019) we trained 5 architectures of increasing size: MINI (L4/H256, 4 Layers with hidden dimension 256), SMALL (L4/H512), MEDIUM (L8/H512), BASE (L12/H768), and LARGE (L24/H1024). For each architecture we pre-trained models with 10 different random seeds and fine-tuned each of them 5 times (50 total) on each task; see Figure 1 middle. Since pretraining is computationally expensive, we reduced the context size during pretraining from 512 to 128 and compensated by increasing training steps from 1M to 2M. Appendix A includes more details about pretraining and finetuning and their computational cost, and Appendix B verifies that our cost-saving changes do not affect accuracy qualitatively.

Notation. We use i to index an instance in the evaluation set, s for model sizes, P for pretraining seeds and F for finetuning seeds. c is a random variable of value 0 or 1 to indicate whether the prediction is correct. Given the pretraining seed P and the finetuning seed F, $c_i^s = 1$ if the model of

	$\mathrm{Diff}_{\mathrm{FTune}}$	$\mathrm{Diff}_{\mathrm{PTrain}}$	$\mathrm{Std}_{\mathrm{all}}$
MINI	7.2%	10.7%	0.2%
SMALL	7.2%	10.7%	0.3%
MEDIUM	8.0%	10.7%	0.3%
BASE	8.5%	10.6%	0.2%
LARGE	8.6%	10.1%	0.2%

Table 1: Larger model sizes are at the bottom rows. $\mathrm{Diff}_{\mathrm{FTune}}$: how much do the predictions differ, if two models have the same pretraining seed but different finetuning seeds F? $\mathrm{Diff}_{\mathrm{PTrain}}$: the difference if the pretraining seeds P are different. $\mathrm{Std}_{\mathrm{all}}$: the standard deviation of overall accuracy, around 40 times smaller than $\mathrm{Diff}_{\mathrm{FTune}}$.

size s is correct on instance i, 0 otherwise. To keep the notation uncluttered, we sometimes omit these superscripts or subscripts if they can be inferred from context.

Unless otherwise noted, we present results on the MNLI in-domain development set in the main paper.

3 Comparing Instance Accuracy

To find the instances where larger models are worse, a naïve approach is to finetune a larger pretrained model, compare it to a smaller one, and find instances where the larger is incorrect but the smaller is correct. Under this approach, BERT-LARGE is worse than BERT-BASE on 4.5% of the instances and better on 7%, giving an overall accuracy improvement of 2.5%.

However, this result is misleading: even if we compare two BERT-BASE model with different finetuning seeds, their predictions differ on 8% of the instances, while their accuracies differ only by 0.1%; Table 1 reports this baseline randomness across model sizes. Changing the pretraining seed also changes around 2% additional predictions beyond finetuning.

Table 1 also reports the standard deviation of overall accuracy, which is about 40 times smaller. Such stability starkly contrasts with the noisiness at the instance level, which poses a unique challenge.

Instance-Level Metrics To reflect this noisiness, we define the *instance accuracy* Acc_i^s to be how often models of size s predict instance i correctly,

$$\mathrm{Acc}_i^s := \mathbb{E}_{P,F}[c_i^s]. \tag{1}$$

The expectation is taken with respect to the pretraining and finetuning randomness P and F. We estimate Acc_i^s via the empirical average $\hat{\mathrm{Acc}}_i^s$ accross 10 pretraining $\times$ 5 finetuning runs.

We histogram $\hat{\mathrm{Acc}}_i^s$ in Figure 2 (a). On most instances the model always predicts correctly or incorrectly ($\hat{\mathrm{Acc}} = 0$ or 1), but a sizable fraction of accuracies lie between the two extremes.

Recall that our goal is to find instances where larger models are less accurate, which we refer to as *decaying* instances. We therefore study the *instance difference* between two model sizes s_1 and s_2, defined as

$$^{s_1}_{s_2}\Delta\mathrm{Acc}_i := \mathrm{Acc}_i^{s_2} - \mathrm{Acc}_i^{s_1}, \tag{2}$$

which is estimated by the difference between the accuracy estimates $\hat{\mathrm{Acc}}_i^s$, i.e.

$$^{s_1}_{s_2}\Delta\hat{\mathrm{Acc}}_i := \hat{\mathrm{Acc}}_i^{s_2} - \hat{\mathrm{Acc}}_i^{s_1}. \tag{3}$$

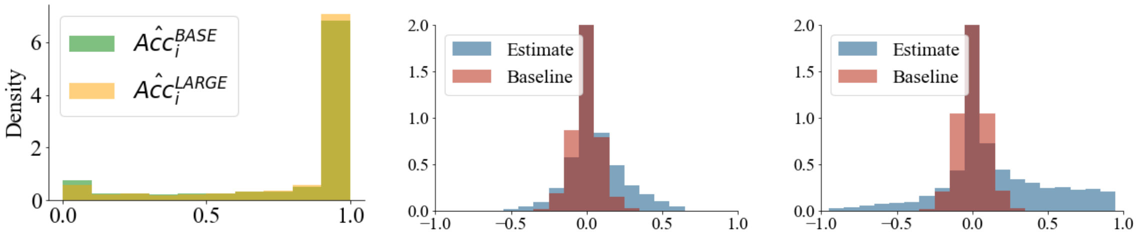
We histogram $^{\mathrm{BASE}}_{\mathrm{LARGE}}\Delta\hat{\mathrm{Acc}}_i$ in Figure 2 (b). We observe a unimodal distribution centered near 0, with tails on both sides. Therefore, the estimated differences for some instances are negative.

However, due to estimation noise, we might falsely observe this accuracy decay by chance. Therefore, we introduce a random baseline $^{s_1}_{s_2}\Delta\mathrm{Acc}'$ to control for these false discoveries. Recall that we have 10 smaller pretrained models and 10 larger ones. Our baseline splits these into a group A of 5 smaller + 5 larger, and another group B of the remaining $5 + 5$. Then the empirical accuracies $\hat{\mathrm{Acc}}^A$ and $\hat{\mathrm{Acc}}^B$ are identically distributed, so we take our baseline $^{s_1}_{s_2}\Delta\mathrm{Acc}'$ to be the difference $\hat{\mathrm{Acc}}^A - \hat{\mathrm{Acc}}^B$. We visualize and compare how to calculate $^{s_1}_{s_2}\Delta\hat{\mathrm{Acc}}$ and $^{s_1}_{s_2}\Delta\mathrm{Acc}'$ in Figure 3.

We histogram this baseline $^{\mathrm{BASE}}_{\mathrm{LARGE}}\Delta\mathrm{Acc}'$ in Figure 2 (b), and find that our noisy estimate $^{\mathrm{BASE}}_{\mathrm{LARGE}}\Delta\hat{\mathrm{Acc}}$ has a larger left tail than the baseline. This suggests that decaying instances exist. We similarly compare MINI to LARGE in Figure 2 (c) and find an even larger left tail.

4 Quantifying the Decaying Instances

The left tail of $\Delta\hat{\mathrm{Acc}}$ noisily estimates the fraction of decaying instances, and the left tail of the random baseline $\Delta\mathrm{Acc}'$ counts the false discovery fraction due to the noise. Intuitively, the true fraction of decaying instances can be captured by the difference of these left tails, and we formally quantify this below.



(a) BASE vs. LARGE , Acc (b) BASE vs. LARGE , ΔAcc (c) MINI vs. LARGE , ΔAcc

Figure 2: (a) The distribution of instance accuracy $\hat{\mathrm{Acc}}_i$. (b, c) Histogram of instance difference estimate (x-axis), $\Delta\hat{\mathrm{Acc}}$ (blue) and its baseline $\Delta\mathrm{Acc}'$ (red) compares BASE and LARGE . To better visualize, we truncated the density (y-axis) above 2. Since the blue histogram has a larger left tail than the red one, there are indeed instances where larger models are worse.

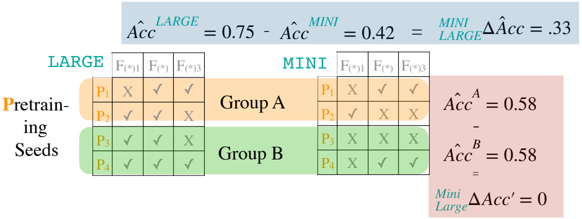


Figure 3: The tables are model predictions with visual notations established in Figure 1 middle. $\Delta\hat{\mathrm{Acc}}$ (blue) is the mean difference between the left and the right table, each corresponding to a model size. The random baseline $\Delta\mathrm{Acc}'$ (red) is the mean difference between group A (orange) cells and group B (green), which are identically and independently distributed.

Suppose instance i is drawn from the empirical evaluation distribution. Then we can define the true decaying fraction Decay as

$$\mathrm{Decay} := \mathbb{P}_i[\Delta\mathrm{Acc}_i < 0]. \tag{4}$$

Since $\Delta\mathrm{Acc}_i$ is not directly observable and $\Delta\hat{\mathrm{Acc}}_i$ is noisy, we add a buffer and only consider instances with $\Delta\hat{\mathrm{Acc}}_i \leq t$, which makes it more likely (but still uncertain) that the true $\Delta\mathrm{Acc}_i < 0$. We denote this "discovery fraction" $\widehat{\mathrm{Decay}}(t)$ as

$$\widehat{\mathrm{Decay}}(t) := \mathbb{P}_i[\Delta\hat{\mathrm{Acc}}_i \leq t]. \tag{5}$$

Similarly, we define a baseline control (false discovery fraction) $\mathrm{Decay}'(t) := \mathbb{P}_i[\Delta\mathrm{Acc}'_i \leq t]$. Hence, $\widehat{\mathrm{Decay}}$ and Decay' are the cumulative distribution function of $\Delta\hat{\mathrm{Acc}}$ and $\Delta\mathrm{Acc}'$ (Figure 4).

We have the following theorem, which we formally state and prove in Appendix D:

Theorem 1 *(Informal) If all the random seeds are independent, then for all thresholds t,*

$$\mathrm{Decay} \geq \mathbb{E}[\widehat{\mathrm{Decay}}(t) - \mathrm{Decay}'(t)] \tag{6}$$

Proof Sketch Suppose we observe $c^{s_1}_{R_{1\ldots 2k}}$ and $c^{s_2}_{R_{2k+1\ldots 4k}}$, where there are $2k$ different random seeds for each model size [3]. Then

$$\Delta\hat{\mathrm{Acc}}_i := \frac{1}{2k}\Big(\sum_{j=1}^{2k} c^{s_1}_{R_j,i} - \sum_{j=2k+1}^{4k} c^{s_2}_{R_j,i}\Big), \tag{7}$$

and hence the discovery rate $\widehat{\mathrm{Decay}}(t)$ is defined as

$$\widehat{\mathrm{Decay}}(t) := \frac{1}{|\mathcal{T}|}\sum_{i=1}^{|\mathcal{T}|} \mathbf{1}[\Delta\hat{\mathrm{Acc}} \leq t]. \tag{8}$$

For the random baseline estimator, we have

$$\begin{aligned}\Delta\mathrm{Acc}'_i := \frac{1}{2k}\Big(&\sum_{j=1}^{k} c^{s_1}_{R_j,i} + \sum_{j=2k+1}^{3k} c^{s_2}_{R_j,i} \\ &- \sum_{j=k+1}^{2k} c^{s_1}_{R_j,i} - \sum_{j=3k+1}^{4k} c^{s_2}_{R_j,i}\Big),\end{aligned} \tag{9}$$

and the false discovery control Decay' is defined as

$$\mathrm{Decay}'(t) := \frac{1}{|\mathcal{T}|}\sum_{i=1}^{|\mathcal{T}|} \mathbf{1}[\Delta\mathrm{Acc}'_i \leq t]. \tag{10}$$

Formally, the theorem states that

$$\mathrm{Decay} \geq \mathbb{E}_{R_1\ldots R_{4k}}[\widehat{\mathrm{Decay}}(t) - \mathrm{Decay}'(t)], \tag{11}$$

which is equivalent to

$$\begin{aligned}\sum_{i=1}^{|\mathcal{T}|}(\mathbf{1}[\Delta\mathrm{Acc}_i < 0] - \mathbb{P}[\Delta\hat{\mathrm{Acc}}_i \leq t] \\ + \mathbb{P}[\Delta\mathrm{Acc}'_i \leq t]) \geq 0\end{aligned} \tag{12}$$

---

[3] We assumed even number of random seeds since we will mix half of the models from each size to compute the random baseline

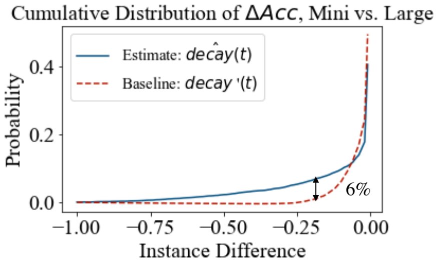

Figure 4: The cumulative distribution function of the histogram in Figure 2 (c); only the negative x-axis is shown because it corresponds to decays. The maximum difference between the two curves (6%) is a lower bound of the true decaying fraction.

Hence, we can declare victory if we can prove that for all i, if $\Delta\text{Acc}_i \geq 0$,

$$\mathbb{P}[\Delta\text{Acc}'_i \leq t] \geq \mathbb{P}[\Delta\hat{\text{A}}\text{cc}_i \leq t].$$

This is easy to see, since $\Delta\text{Acc}'_i$ and $\Delta\hat{\text{A}}\text{cc}_i$ are both binomial distributions with the same n, but the first has a larger rate. [4] □

Roughly speaking, the true decaying fraction is at least the difference between $\widehat{\text{Decay}}(t)$ and $\text{Decay}'(t)$ at every threshold t. Therefore, we take the maximum difference between $\widehat{\text{Decay}}(t)$ and $\text{Decay}'(t)$ to lower-bound the fraction of decaying instances.[5] For example, Figure 4 estimates the true decaying fraction between MINI and LARGE to be at least 6%.

We compute this lower bound for other pairs of model sizes in Table 2, and the full results across other tasks and model size pairs are in Appendix C. In all of these settings we find a non-zero fraction of decaying instances, and larger model size differences usually lead to more decaying instances.

Unfortunately, applying Theorem 1 as above is not fully rigorous, since some finetuning runs share the same pretraining seeds and hence are dependent.[6] To obtain a statistically rigorous lower bound, we slightly modify our target of interest. Instead of examining individual finetuning runs, we ensemble our model across 5 different finetuning runs for each pretraining seed; these predictions are essentially the same as individual finetuning runs, except that the finetuning randomness is averaged out. Hence we obtain 10 independent sets of model predictions with different random seeds, which allows us to apply Theorem 1.

$s_1 \setminus s_2$	MINI	SMALL	BASE	LARGE
MINI	N/A	9%	18%	21%
SMALL	3%	N/A	14%	18%
BASE	6%	5%	N/A	10%
LARGE	6%	5%	2%	N/A

Table 2: We lower-bound the fraction of instances that improve when model size changes from s_1 (row) to s_2 (column). For example, when model size decreases from LARGE to MINI , 6% of instances improve (i.e. decays).

Threshold	$\widehat{\text{Decay}}$	Decay'	Diff
$t = -0.4$	4.22%	3.49e−3	3.87%
…	…	…	…
$t = -0.9$	0.91%	1.44e−7	0.91%
$t = -1.0$	0.48%	2.06e−8	0.48%

Table 3: Comparing MINI vs. LARGE by calculating the discovery fraction $\widehat{\text{Decay}}$, the false discovery control Decay', and their difference (Diff) under different thresholds t. LARGE is worse on at least ~4% (maximum Diff) of instances.

We compare MINI to LARGE using these ensembles and report the discovery $\widehat{\text{Decay}}$ and the baseline Decay' in Table 3. Taking the maximum difference across thresholds, we estimate at least ~4% of decaying instances. This estimate is lower than the previous 6% estimate, which used the full set of 50 models' predictions assuming they were independent. However, this is still a meaningful amount, given that the overall accuracy improvement from MINI to LARGE is 10%.

4.1 Fisher's Test + Benjamini-Hochberg

Here is a more classical approach to lower-bound the decaying fraction. For each instance, we compute a significance level α under the null hypothesis that the larger model is better, using Fisher's exact test. We sort the significance levels ascendingly, and call the p^{th} percentile α_p. Then we pick a false discovery rate q (say, 25%), find the largest p s.t. $\alpha_p < pq$, and estimate the decaying fraction to be at least $p(1-q)$. This calculation is known as the Benjamini-Hochberg procedure (Benjamini and Hochberg, 1995).

To compare our method with this classical approach, we estimate the lower bound of the decaying fraction for different pairs of model sizes with different numbers of pretrained models available.

---

[4] More details are in Appendix D.

[5] Adaptively picking the best threshold t depending on the data may incur a slight upward bias. Appendix E estimates that the relative bias is at most 10% using a bootstrap method.

[6] Although we anticipate such dependencies do not cause a substantial difference, as discussed in Appendix D.1.

s1	s2		2	6	10
MINI	LARGE	ours	1.9%	3.1%	4.0%
MINI	LARGE	BH	0.0%	0.9%	1.9%
BASE	LARGE	ours	0.4%	0.9%	1.2%
BASE	LARGE	BH	0.0%	0.0%	0.0%

Table 4: We compare our method to the Fisher's exact test + Benjamin-Hochberg (BH) procedure described in Section 4. For all different model size pairs and number of pretrained models available, ours always provides a higher (better) lower bound of the decaying fraction.

To make sure our choice of the false discovery rate q does not bias against the classical approach, we adaptively choose q to maximize its performance. Appendix F includes the full results and Table 4 is a representative subset.

We find that our approach is more powerful, particularly when the true decaying fraction is likely to be small and only a few models are available, which is usually the regime of interest. For example, across all pairs of model sizes, our approach only needs 2 random seeds (i.e. pretrained models) to provide a non-zero lower bound on the decaying fraction, while the classical approach sometimes fails to do this even with 10 seeds. Intuitively, when fewer seeds are available, the smallest possible significance level for each instance is larger than the decaying fraction, hence hurting the classical approach.

4.2 Understanding the Decaying Instances

We next manually examine the decaying instances to see whether we can find any interpretable patterns. One hypothesis is that all the decaying fractions are in fact mislabeled, and hence larger models are not in fact worse on any instances.

To investigate this hypothesis, we examined the group of instances where $^{\text{MINI}}_{\text{LARGE}}\Delta\hat{\text{Acc}}_i \leq -0.9$. MINI is almost always correct on these instances, while LARGE is almost always wrong, and the false discovery fraction is tiny. For each instance, we manually categorize it as either: 1) Correct, if the label is correct, 2) Fine, if the label might be controversial but we could see a reason why this label is reasonable, 3) Wrong, if the label is wrong, or 4) Unsure, if we are unsure about how to label this instance. Each time we annotate, with 50% probability we randomly sample either a decaying instance or an instance from the remaining dataset as a control. We are blind to which group it comes from.

	Correct	Fine	Wrong	Unsure
MNLI^D	66%	17%	9%	5%
MNLI^C	86%	5%	5%	1%
SST-2^D	55%	8%	10%	25%
SST-2^C	88%	4%	0%	6%
QQP^D	60%	26%	10%	2%
QQP^C	87%	10%	1%	0%

Table 5: MINI vs. LARGE . We examine whether there are mislabels for the **D**ecaying fractions (superscript ^{D}) and the rest of the dataset (**C**ontrol group ^{C}). The decaying fraction contains more mislabels, but includes correct labels as well.

For each task of MNLI, QQP, and SST-2, the first author annotated 100 instances (decay + control group) (Table 5). We present all the annotated decaying instances in Appendix J.

Conclusion We find that the decaying fraction has more wrong or controversial labels, compared to the remaining instances. However, even after we adjust for the fraction of incorrect labels, the Decay fraction still exceeds the false discovery control. This implies that MINI models are better than LARGE models on some correctly labeled instances. The second author followed the same procedure and reproduced the same qualitative results.

However, we cannot find an interpretable pattern for these correctly labeled decaying instances by simply eyeballing. We discuss future directions to discover interpretable categories in Section 7.

5 Correlation of Instance Difference

We next investigate whether there is a momentum of instance accuracy increase: for example, if the instance accuracy improves from MINI(s_1) to MEDIUM(s_2), is it more likely to improve from MEDIUM(s_2) to LARGE(s_3)?

The naïve approach is to calculate the Pearson correlation coefficient between $^{\text{MINI}}_{\text{MEDIUM}}\Delta\hat{\text{Acc}}$ and $^{\text{MEDIUM}}_{\text{LARGE}}\Delta\hat{\text{Acc}}$, and we find the correlation to be zero. However, this is partly an artifact of accuracies being bounded in $[0, 1]$. If MEDIUM drastically improves over MINI from 0 to 1, there is no room for LARGE to improve over MEDIUM. To remove this inherent negative correlation, we calculate the correlation conditioned on the accuracy of the middle-sized model, $\hat{\text{Acc}}^{\text{MEDIUM}}$.

Therefore, we bucket instances by their estimated MEDIUM accuracy into intervals of size 0.1,

$(s_1, s_2, s_3)\downarrow$ Buckets$\rightarrow$	0.10	0.20	0.30	0.40	0.50	0.60	0.70	0.80	0.90	1.00
SMALL, MEDIUM, BASE	0.07	0.22	0.29	0.40	0.35	0.33	0.38	0.27	0.24	0.13
MINI, MEDIUM, LARGE	0.03	0.15	0.18	0.33	0.17	0.16	0.22	0.20	0.19	0.09

Table 6: Each row corresponds to a triplet of model sizes. Each column t represents a bucket that contains instances with $\hat{\mathrm{Acc}}^{s_2} \in [t - 0.1, t]$. Within each bucket, we calculate the Pearson correlation coefficient between the estimated accuracy improvements: ${}^{s_1}_{s_2}\Delta\hat{\mathrm{Acc}}$ and ${}^{s_2}_{s_3}\Delta\hat{\mathrm{Acc}}$. These correlations are positive and become higher when model size differences are small.

and we find the correlation to be positive within each bucket (Table 6, row 2). This fixes the problem with the naïve approach by getting rid of the negative correlation, which could have misled us to believe that improvements by larger models are uncorrelated.

We additionally find that the correlations between improvements become stronger when model size differences are smaller. Table 6 row 1 reports results for another model size triplet with smaller size difference, i.e. (s_1, s_2, s_3) = (SMALL, MEDIUM, BASE), and the correlation is larger for all buckets. Results for more tasks and size triplets are in Appendix G and the same conclusions hold qualitatively.

6 Variance at the Instance Level

Section 3 found that the overall accuracy has relatively low variance, but model predictions are noisy. This section formally analyzes variance at the instance level. For each instance, we decompose its loss into three components: Bias^2, variance due to pretraining randomness, and variance due to finetuning randomness. Formally, we consider the $0/1$ loss:

$$\mathcal{L}_i := 1 - c_i = (1 - c_i)^2, \tag{13}$$

where c_i is a random variable 0/1 indicating whether the prediction is correct or incorrect, with respect to randomness in pretraining and finetuning. Therefore, by bias-variance decomposition and total variance decomposition, we have

$$\mathcal{L}_i = \mathrm{Bias}^2{}_i + \mathrm{PretVar}_i + \mathrm{FineVar}_i, \tag{14}$$

where, by using P and F as pretraining and finetuning random seeds:

$$\begin{aligned} \mathrm{Bias}^2{}_i &:= (1 - \mathbb{E}_{P,F}[c_i])^2, \\ \mathrm{PretVar}_i &:= \mathrm{Var}_P[\mathbb{E}_F[c_i]], \\ \mathrm{FineVar}_i &:= \mathbb{E}_P[\mathrm{Var}_F[c_i]], \end{aligned} \tag{15}$$

capturing “how wrong is the average prediction”, variance due to pretraining, and variance due to finetuning seeds, respectively.

	Bias^2	$\mathrm{PretVar}$	$\mathrm{FineVar}$
MINI	0.203	0.017	0.036
SMALL	0.179	0.017	0.036
MEDIUM	0.157	0.014	0.040
BASE	0.134	0.010	0.043
LARGE	0.111	0.007	0.043

Table 7: The bias, pretraining variance, and finetuning variance for each model size, averaged across all test instances. Finetuning variance is much larger than pretraining variance; larger models have larger finetuning variance.

We can directly estimate $\mathrm{FineVar}$ by first calculating the sample variance across finetuning runs for each pretraining seed, and then averaging the variances across the pretraining seeds. Estimating $\mathrm{PretVar}$ is more complicated. A naïve approach is to calculate the empirical variance, across pretraining seeds, of the average accuracy across finetuning seeds. However, the estimated average accuracy for each pretraining seed is noisy itself, which causes an upward bias on the $\mathrm{PretVar}$ estimate. We correct this bias by estimating the variance of the estimated average accuracy and subtracting it from the naïve estimate; see Appendix H for details, as well as a generalization to more than two sources of randomness. Finally, we estimate Bias^2 by subtracting the two variance estimates from the estimated loss.

For each of these three quantities, Bias^2, $\mathrm{PretVar}$ and $\mathrm{FineVar}$, we estimate it for each instance, average it across all instances in the evaluation set, and report it in Table 7. The variances at the instance level are much larger than the variance of overall accuracy, by a factor of 1000.

We may conclude from Table 7 that larger models have larger finetuning variance and smaller pretraining variance. However, lower bias also inherently implies lower variance. To see this, suppose a model has perfect accuracy and hence zero bias; then it always predicts the same label (the correct one) and hence has zero variance. This might favor larger models and “underestimate” their variance,

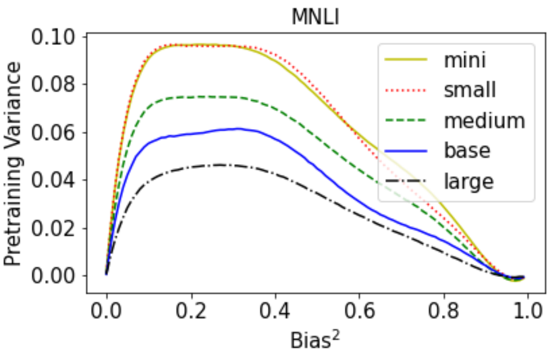

Figure 5: The pretraining variance conditioned on Bias^2 (the level of correctness). Each curve represents a model size. Larger models have lower pretraining variance across all levels of bias.

since they have lower bias. Therefore, we calculate and compare the variances conditioned on the bias, i.e. $\mathrm{PretVar}(b^2) := \mathbb{E}_i[\mathrm{PretVar}_i|\mathrm{Bias}^2{}_i = b^2]$.

We estimate $\mathrm{PretVar}^s(b^2)$ using Gaussian process regression and plot it against b^2 in Figure 5. We find that larger models still have lower pretraining variance across all levels of bias on the specific task of MNLI under the 0/1 loss. To further check whether our conclusions are general, we tested them on other tasks and under the squared loss $\mathcal{L}_i := (1 - p_i)^2$, where p_i is the probability assigned to the correct class. Below are the conclusions that generally hold across different tasks and loss functions.

Conclusion We find that 1) larger models have larger finetuning variance, 2) LARGE has smaller pretraining variance than BASE ; however, the ordering between other sizes varies across tasks and losses, and 3) finetuning variance is $2-8$ times as large as pretraining variance, and the ratio is bigger for larger models.

7 Discussion and Future Directions

To investigate model behaviors at the instance level, we produced massive amounts of model predictions in Section 2 and treated them as raw data. To extract insights from them, we developed better metrics and statistical tools, including a new method to control the false discoveries, an unbiased estimator for the decomposed variances, and metrics that compute variance and correlation of improvements conditioned on instance accuracy. We find that larger pretrained models are indeed worse on a non-trivial fraction of instances and have higher variance due to finetuning seeds; additionally, instance accuracy improvements from MINI to MEDIUM correlate with improvements from MEDIUM to LARGE .

Overall, we treated model prediction data as the central object and built analysis tools around them to obtain a finer understanding of model performance. We therefore refer to this paradigm as "**instance level understanding as data mining**". We discuss three key factors for this paradigm to thrive: 1) scalability and the cost of obtaining prediction data, 2) other information to collect for each instance, and 3) better statistical tools. We analyze each of these aspects below.

Scalability and Cost of Data Data mining is more powerful with more data. How easy is it to obtain more model predictions? In our paper, the main bottleneck is pretraining. However, once the pretrained models are released, individual researchers can download them and only need to repeat the cheaper finetuning procedure.

Furthermore, model prediction data are under-shared: while many recent research papers share their code or even model weights to help reproduce the results, it is not yet a standard practice to share all the model predictions. Since many researches follow almost the same recipe of pretraining and finetuning (McCoy et al., 2020; Desai and Durrett, 2020; Dodge et al., 2020), much computation can be saved if model predictions are shared. On the other hand, as the state of the art model size is increasing at a staggering speed[7], most researchers will not be able to run inference on a single instance. The trend that models are becoming larger and more similar necessitate more prediction sharing.

Meta-Labels and Other Predictions Data mining is more powerful with more types of information. One way to add information to each instance is to assign "meta-labels". In the HANS (McCoy et al., 2019) dataset, the authors tag each instance with a heuristic [8] that holds for the training distribution but fails on this instance. Naik et al. (2018a) and Ribeiro et al. (2020) associate each instance with a particular stress test type or subgroup, for example, whether the instance requires the model to reason numerically or handle negations. Nie et al.

---

[7] e.g. BERT (Devlin et al., 2019) has 340M parameters, while Switch-Transformer has over 1 trillion parameters (Fedus et al., 2021).

[8] For example, "the label [entailment] is likely if the premise and the hypothesis have significant lexical overlap".

(2020) collects multiple human responses to estimate human disagreement for each instance. This meta-information can potentially help us identify interpretable patterns for the disagreeing instances where one model is better than the other. On the flip side, identifying disagreeing instances between two models can also help us generate hypothesis and decide what subgroup information to annotate.

We can also add performance information on other tasks to each instance. For example, Pruksachatkun et al. (2020) studied the correlation between syntactic probing accuracy (Hewitt and Liang, 2019) and downstream task performance. Turc et al. (2019) and Kaplan et al. (2020) studied the correlation between language modelling loss and the downstream task performance. However, they did not analyze correlations at the instance level. We may investigate whether their results hold on the instance level: if an instance is easier to tag by a probe or easier to predict by a larger language model, is the accuracy likely to be higher?

Statistical Tools Data mining is more powerful with better statistical tools. Initially we used the Benjamini-Hochberg procedure with Fisher's exact test, which required us to pretrain 10 models to formally verify that the decaying instances exist. However, we later realized that 2 is in fact enough by using our approach introduced in Section 4. We could have saved 80% of the computation for pretraining if this approach was known before we started.

Future work can explore more complicated metrics and settings. We compared at most 3 different model sizes at a time, and higher order comparisons require novel metrics. We studied two sources of randomness, pretraining and finetuning, but other sources of variation can be interesting as well, e.g. differences in pretraining corpus, different model checkpoints, etc. To deal with more sophisticated metrics, handle different sources and hierarchies of randomness, and reach conclusions that are robust to noises at the instance level, researchers need to develop new inference procedures.

To conclude, for better instance level understanding, we need to produce and share more prediction data, annotate more diverse linguistic properties, and develop better statistical tools to infer under noises. We hope our work can inform researchers about the core challenges underlying instance level understanding and inspire future work.

Summary

In this 4-page appendix, we include 1) details on model training and the datasets we used 2) high-level ideas underlying the theoretical results, and 3) relatively more important discussions. We also have a longer version of this appendix on our github, which contains the full proofs, discussions, plots, and tables.

A Pretraining and Finetuning Details

To obtain model predictions under the "pretraining and finetuning" framework (Devlin et al., 2019), we need to decide a model **size**, perform **pretraining**, finetune on a **training set** with a choice of **hyper-parameters**, and test the model on an **evaluation set**. We discuss each bolded aspects below.

Size Similar to Turc et al. (2019), we experimented with the following five model sizes, listed in increasing order: MINI (L4/H256) [9] , SMALL (L4/H512), MEDIUM (L8/H512), BASE (L12/H768), and LARGE (L24/H1024).

Pretraining We used the pretraining code from Devlin et al. (2019) and the pre-training corpus from Li et al. (2020). Compared to the original BERT release, we used context size 128 instead of 512, since computation cost grows quadratically with respect to context size; we also pretrained for 2M steps instead of 1M.

Training Set We consider 3 datasets: Quora Question Pairs (QQP) [10], Multi-Genre Natural Language Inference (MNLI; Williams et al. (2020)), and the Stanford Sentiment Treebank (SST-2; (Socher et al., 2013)). For QQP we used the official training split. For MNLI we used 350K out of 400K instances from the original training split, and added the remaining 50K to the evaluation set, since the original in-domain development set only contains 10K examples. For SST-2, we mix the training and development set of the original split, split the instances into 5 folds, train on four of them, and evaluate on the remaining fold.

Hyperparameters As in Turc et al. (2019), we finetune 4 epochs for each dataset. For each task and model size, we tune hyperparameters in the following way: we first randomly split our new training set into 80% and 20%; then we finetune on the 80% split with all 9 combination of batch size [16, 32, 64] and learning rate [1e-4, 5e-5, 3e-5], and choose the combination that leads to the best average accuracy on the remaining 20%.

Evaluation Set After finetuning our pretrained models, we evaluate them on a range of in-domain, out-of-domain, or challenging datasets to obtain model predictions. Models trained on MNLI are also evaluated on Stanford Natural Language Inference (SNLI; (Bowman et al., 2015)), Heuristic Analysis for NLI Systems (HANS; (McCoy et al., 2019)), and stress test evaluations (STRESS; (Naik et al., 2018b)). Models trained on QQP are also evaluated on Twitter Paraphrase Database (TwitterPPDB; (Lan et al., 2017)).

Since pretraining introduces randomness, for each model size s, we pretrain 10 times with different random seed P; since finetuning also introduces noise, for each pretrained model we pretrain 5 times with different random seed F; besides, we also evaluate the model at the checkpoints after E epochs, where $E \in [3, 3\frac{1}{3}, 3\frac{2}{3}, 4]$.

Pretraining 10 models for all 5 model sizes altogether takes around 3840 hours on TPU v3 with 8 cores. Finetuning all of them 5 times for all three tasks in our paper requires around 1200 hours.

B Compare Our Models to the Original

Since we decreased the pre-training context length to save computation, these models are not exactly the same as the original BERT release by Devlin et al. (2019) and Turc et al. (2019). We need to benchmark our model against theirs to ensure that the performance of our model is still reasonable and the qualitative trend still holds. For each each size and task, we finetune the original model 5 times and calculate the average of overall accuracy.

The comparison can be seen in Table 8. We find that our model does not substantially differ from the original ones on QQP and SST-2. On MNLI, the performance of our BERT-BASE and BERT-LARGE is $2\sim3\%$ below the original release, but the qualitative trend that larger models have better accuracy still holds robustly.

C More Instance Difference Results

Similar to Figure 4, for all 10 pairs of model sizes and all in-distribution instances of MNLI, SST-2, and QQP, we plot the cumulative density of $\Delta\hat{\mathrm{Acc}}$ and $\Delta\mathrm{Acc}'$, or say, $\widehat{\mathrm{Decay}}(t)$ and $\mathrm{Decay}'(t)$. See the long appendix for the figures.

	QQP	MNLI	SST-2
MINI $^{\text{orig}}$	88.2%	74.6%	92.8%
MINI $^{\text{ours}}$	87.3%	74.3%	92.8%
SMALL $^{\text{orig}}$	89.1%	77.3%	93.9%
SMALL $^{\text{ours}}$	88.7%	76.7%	93.9%
MEDIUM $^{\text{orig}}$	89.8%	79.6%	94.2%
MEDIUM $^{\text{ours}}$	89.5%	78.9%	94.2%
BASE $^{\text{orig}}$	90.8%	83.8%	95.0%
BASE $^{\text{ours}}$	90.6%	81.2%	94.6%
LARGE $^{\text{orig}}$	91.3%	86.8%	95.2%
LARGE $^{\text{ours}}$	91.0%	83.8%	94.8%

Table 8: Comparing our pretrained model (superscript ^{orig}) to the original release by Devlin et al. (2019) and Turc et al. (2019) (superscript ^{ours}). All pretrained models are finetuned with the training set and tested on the in-distribution evaluation set described in Appendix A.

Additionally, for each pair of model sizes s_1 and s_2, we estimate "how much instances are getting better/worse accuracy?" by taking the maximum difference between the red curve and the blue curve. We report these results for MNLI, SST-2, and QQP in Table 9. We find that larger model size gaps lead to larger decaying fraction, but also larger improving fraction as well.

D Proof of Theorem 1

Formal Setup Suppose each instance is indexed by i, the set of all instances is $\mathcal{T}$, and the random seed is R; then $c_R^s \in \{0, 1\}^{|\mathcal{T}|}$ is a random $|\mathcal{T}|$ dimensional vector, where $c_{R,i}^s = 1$ if the model of size s correctly predicts instance i under the random seed R. We are comparing model size s_1 and s_2, where s_2 is larger; to keep notation uncluttered, we omit these indexes whenever possible.

Suppose we observe $c_{R_{1\dots 2k}}^{s_1}$ and $c_{R_{2k+1\dots 4k}}^{s_2}$, where there are $2k$ different random seeds for each model size [11]. Then

$$\Delta\hat{\text{Acc}}_i := \frac{1}{2k}\Big(\sum_{j=1}^{2k} c_{R_j,i}^{s_1} - \sum_{j=2k+1}^{4k} c_{R_j,i}^{s_2}\Big), \quad (16)$$

and hence the discovery rate $\widehat{\text{Decay}}(t)$ is defined as

$$\widehat{\text{Decay}}(t) := \frac{1}{|\mathcal{T}|}\sum_{i=1}^{|\mathcal{T}|} \mathbf{1}[\Delta\hat{\text{Acc}} \leq t]. \quad (17)$$

For the random baseline estimator, we have

$$\begin{aligned}\Delta\text{Acc}'_i := \frac{1}{2k}\Big(&\sum_{j=1}^{k} c_{R_j,i}^{s_1} + \sum_{j=2k+1}^{3k} c_{R_j,i}^{s_2} \quad (18)\\ &- \sum_{j=k+1}^{2k} c_{R_j,i}^{s_1} - \sum_{j=3k+1}^{4k} c_{R_j,i}^{s_2}\Big),\end{aligned}$$

and the false discovery control Decay' is defined as

$$\text{Decay}'(t) := \frac{1}{|\mathcal{T}|}\sum_{i=1}^{|\mathcal{T}|} \mathbf{1}[\Delta\text{Acc}'_i \leq t]. \quad (19)$$

Formally, theorem states that

$$\text{Decay} \geq \mathbb{E}_{R_1\dots R_{4k}}[\widehat{\text{Decay}}(t) - \text{Decay}'(t)] \quad (20)$$

Proof By re-arranging terms and linearity of expectation, Equation 20 is equivalent to the following

$$\begin{aligned}\sum_{i=1}^{|\mathcal{T}|}\big(&\mathbf{1}[\Delta\text{Acc}_i < 0] - \mathbb{P}[\Delta\hat{\text{Acc}}_i \leq t] \quad (21)\\ &+ \mathbb{P}[\Delta\text{Acc}'_i \leq t]\big) \geq 0\end{aligned}$$

Hence, we can declare victory if we can prove that for all i,

$$\begin{aligned}\mathbf{1}[\Delta\text{Acc}_i < 0] - \mathbb{P}[\Delta\hat{\text{Acc}}_i \leq t] \quad (22)\\ + \mathbb{P}[\Delta\text{Acc}'_i \leq t] \geq 0\end{aligned}$$

To prove Equation 22, we observe that if $\text{Acc}_i < 0$, since the probabilities are bounded by 0 and 1, its left-hand side must be positive. Therefore, we only need to prove that

$$\begin{aligned}&\Delta\text{Acc}_i \geq 0 \quad (23)\\ &\Rightarrow \mathbb{P}[\Delta\text{Acc}'_i \leq t] \geq \mathbb{P}[\Delta\hat{\text{Acc}}_i \leq t],\end{aligned}$$

which will be proved in Lemma 1.□

Lemma 1

$$\begin{aligned}&\Delta\text{Acc}_i \geq 0 \quad (24)\\ &\Rightarrow \mathbb{P}[\Delta\text{Acc}'_i \leq t] \geq \mathbb{P}[\Delta\hat{\text{Acc}}_i \leq t],\end{aligned}$$

For $m = 1, 2$, define

$$p_i^{s_m} := \mathbb{E}_R[c_i^{s_m}], \quad (25)$$

then

$$p_i^{s_1} \leq p_i^{s_2} \quad (26)$$

---

[11] We assumed even number of random seeds since we will mix half of the models from each size to compute the random baseline

MNLI $s_1 \setminus s_2$	MINI	SMALL	MEDIUM	BASE	LARGE

LARGE	0.020	0.017	0.015	0.008	0.000

Table 9: On QQP, MNLI in domain development set and SST-2 we lowerbound the fraction of instances that improves when model size changes from s_1 (row) to s_2 (column).

Since $c_i^{s_1}$ and $c_i^{s_2}$ are both Bernoulli random variables with rate $p_i^{s_1}$ and $p_i^{s_2}$ respectively, we can write down the probability distribution of $\Delta\hat{\text{Acc}}_i$ and $\Delta\text{Acc}'_i$ as the sum/difference of several binomial variables, i.e.

$$\Delta\hat{\text{Acc}}_i \sim (\text{Binom}(k, p_i^{s_2}) + \text{Binom}(k, p_i^{s_2}) - \text{Binom}(k, p_i^{s_1}) - \text{Binom}(k, p_i^{s_1}))/2k, \tag{27}$$

and

$$\Delta\text{Acc}'^{i} \sim (\text{Binom}(k, p^{s_2,i}) + \text{Binom}(k, p^{s_1,i}) - \text{Binom}(k, p^{s_1,i}) - \text{Binom}(k, p^{s_2,i}))/2k \tag{28}$$

$p_i^{s_1} \leq p_i^{s_2}$, Binom$(k, p^{s_2,i})$) first order stochastically dominates Binom$(k, p^{s_1,i})$. Therefore, $\Delta\text{Acc}'^{i}$ dominates $\Delta\hat{\text{Acc}}_i$, hence completing the proof. □

D.1 Independent Seed Assumption

See the long appendix for discussion.

E Upward Bias of Adaptive Thresholds

In section 3 we picked the best threshold that can maximize the lowerbound, which can incur a slight upward bias. Here we estimate that the bias is at most 10% relative to the unbiased lowerbound with a bootstrapping method.

We use the empirical distribution of 10 pretrained models as the ground truth distribution for bootstrapping. We first compute a best threshold with 10 sampled smaller and larger pretrained models, and then compute the lowerbound L with this threshold on another sample of 10 smaller and larger models. Intuitively, we use one bootstrap sample (which contains 10 smaller pretrained models and 10 larger pretrained models) as the development set to "tune the threshold", and then use this threshold on a fresh bootstrap sample to compute the lowerbound. We refer to the lowerbound that uses the best threshold as L^*, and compute the relative error $\mathbb{E}[(L^* - L)]/\mathbb{E}[L)]$, where the expectation is taken with respect to bootstrap samples.

See the long appendix for more detailed results. In general, we find that the upward bias is negligible, which is at most around 10%.

F Comparison with Significance Testing

See the long appendix for the Table that compares our procedure with the classical method that uses the Fisher's exact test and Benjamini-Hochberg procedure for other tasks and model size pairs.

In general, we find that our method always provide a tighter (higher) lowerbound than the classical method, and 2 models are sufficient to verify the existence (i.e. lowerbound > 0) of the decaying fraction; in contrast, the classical method sometimes fails to do this even with 10 models, e.g., when comparing BASE to LARGE .

Intuitively, our approach provides a better lower-bound because it better makes use of the information that on most instances, both the smaller and the larger models agree and predict completely correctly or incorrectly[12]. For an extreme example, suppose we only observe 2 smaller models and 2 larger models, and infinite number of datapoints, whose predictions are independent. On 99.98% datapoints, both models have instance accuracy 1; on 0.01% datapoints, smaller model is completely correct while bigger completely wrong, while on the rest 0.01% smaller completely wrong but bigger completely correct. Setting threshold to be 2, our decay estimate $\hat{\mathrm{Decay}}$ is 0.01%, while $\mathrm{Decay}' = 0$: since the models either completely predict correct or wrongly, there is never a false discovery. Therefore, our method can provide the tightest lowerbound 0.01% in this case. On the other hand, since we only have 4 models in total, the lowest significance-level given by the fisher exact test is $17\% \gg 0.1\%$, hence the discovery made by the Benjamin-Hochberg procedure is 0.

G More Results on Momentum

See the long appendix for correlations with other model size triplets on other tasks.

H Loss Decomposition and Estimation

The core of the $\mathrm{PretVar}$ estimator builds on the following theorem:

Theorem 2 *Suppose* $\mathcal{D}_k, k \in [\mathcal{F}]$ *are independently sampled from the same distribution* Ξ*, which is a distribution of distributions;* $\hat{\mu}_k$ *is an unbiased estimator of* $\mathbb{E}_{X\in\mathcal{D}_k}[X]$*, and* $\hat{\phi}_k$ *to be an unbiased estimator of the variance of* $\hat{\mu}_k$*, then*

$$\hat{Var}_F = \frac{1}{\mathcal{F}-1}\sum_{k\in[\mathcal{F}]}(\hat{\mu}_k - \hat{\mu})^2 - \frac{1}{\mathcal{F}}\sum_{k\in[\mathcal{F}]}\hat{\phi}_k \qquad (29)$$

is an unbiased estimator for

$$V = Var_{\mathcal{D}\sim\Xi}[\mathbb{E}_{X\sim\mathcal{D}}[X]], \qquad (30)$$

where

$$\hat{\mu} := \frac{1}{\mathcal{F}}\sum_{k\in[\mathcal{F}]}\hat{\mu}_k \qquad (31)$$

In this estimator, the first term "pretends" that $\hat{\mu}.$ are perfect estimator for the population mean and calculate the variance, while the second term corrects for the fact that the empirical mean estimation is not perfect. Notice the theorem only requires that $\hat{\mu}$ and $\hat{\phi}$ are unbiased, and is agnostic to the actual computation procedure by these estimators.

To estimate $\mathrm{PretVar}$, we need $\hat{\mu}_k$ and $\hat{\phi}_k$. The first term is the empirical accuracy for each pretraining seed; the second is an unbiased estimator of the variance of empirical accuracy for each pretraining seed, which can be estimated by the sample variance of finetuning divided by the number of finetuning runs.

See the long Appendix for a more detailed proof, and also how to generalize this estimator to estimate arbitrary level of variance decomposition.

I Variance Conditioned on Bias

See the long appendix for more figures.

J Example Decaying Instances

Here we present some random annotated decaying instances on MNLI.

Premise : and that you're very much right but the jury may or may not see it that way so you get a little anticipate you know anxious there and go well you know
Hypothesis : Jury's operate without the benefit of an education in law.
Label : Neutral, **Category** : Correct

Premise : In fiscal year 2000, it reported estimated improper Medicare Fee-for-Service payments of $11.
Hypothesis : The payments were improper.
Label : Entailment, **Category** : Fine

Premise : INTEREST RATE - The price charged per unit of money borrowed per year, or other unit of time, usually expressed as a percentage.
Hypothesis : Interest rate is defined as the total amount of money borrowed.
Label : Entailment, **Category** : Wrong

---

[12] This is for intuition, though, and we do not need any assumption on the prior of instance accuracy, which requires a Bayes interpretation.

Named Entity Recognition through Deep Representation Learning and Weak Supervision

Abstract

Weakly supervised methods estimate the labels for a dataset using the predictions of several noisy supervision sources. Many machine learning practitioners have begun using weak supervision to more quickly and cheaply annotate data compared to traditional manual labeling. In this paper, we focus on the specific problem of weakly supervised named entity recognition (NER) and propose an end-to-end model to learn optimal assignments of latent NER tags using observed tokens and weak labels provided by labeling functions. To capture the sequential dependencies between the latent and observed variables, we propose a sequential graphical model where the components are approximated using neural networks. State-of-the-art contextual embeddings are used to further discriminate the quality of noisy weak labels in various contexts. Results of experiments on four public weakly supervised named entity recognition datasets show a significant improvement in F1 score over recent approaches.

1 Introduction

Many industries and organizations have collected large amounts of unlabeled text data that they want to make use of for various Natural Language Processing (NLP) applications. However, in many of these applications (named-entity recognition, question answering, text summarization, relation extraction), obtaining a large number of labels can be prohibitively expensive, error-prone, or otherwise infeasible. Furthermore, domain adaptation (Han and Eisenstein, 2019), which is commonly used in scarce label settings, can often struggle in new emerging / specific domains that don't have any closely related labeled datasets.

Under the absence of a closely related labeled dataset, *weakly supervised learning* is often used as a cheaper, less time-consuming alternative to obtaining gold standard labels. The main idea of weak supervision is to approximate the true labels by integrating multiple sets of noisy training labels. Each set of noisy labels (commonly referred to as "weak labels") is provided by a weak labeling function which often comes in the form of a knowledge base, heuristic, or pre-trained model. Weak supervision has obtained a lot of success in several NLP tasks containing approximately *i.i.d.* data such as topic classification (Bach et al., 2019), sentiment analysis, and social media content tagging (Fu et al., 2020).

Weak supervision on sequential data labeling problems such as NER is an emerging topic. Most current methods require either the time-consuming creation of additional heuristics such as 'linking rules'(Safranchik et al., 2020) or 'entity boundary detectors'(Fries et al., 2017), or assume that the accuracy of a weak labeler only depends on the true latent class (Safranchik et al., 2020; Lison et al., 2020; Fries et al., 2017). The latter is likely suboptimal since we would expect the accuracy to vary even within instances of the same class depending on the context given by surrounding tokens. One exception to this is the Fuzzy-LSTM-CRF(Shang et al., 2018). However, it ignores which weak labeler each prediction came from as well as the number of predictions for each class. This could be an issue when the weak labelers have differing accuracies, since the model may learn from a majority of wrong labels.

To address these foregoing issues, one of our main contributions is the proposal of an end-to-end method called **D**eep **W**eak Supervision on **S**equential Data (DWS), that learns context-dependent proficiency representations for weak labelers, enhanced further through contextual embeddings from pre-trained language models. In addition, instead of following the traditional approach that treats named entity (NE) tags as multi-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3828–3839
August 1–6, 2021.

nomial samples, we directly model the conditional dependency of tags on tokens as interactions of two representations: tag representation and contextual token representation.

Advantages of adopting representation learning are two-fold: First, learning context-aware proficiency of labeling functions enables the weak supervision procedure to denoise unreliable labels at tokens where labeling functions have many disagreements. Second, because embedding methods have demonstrated great potential in capturing semantic meanings, the proposed model allows flexible transfer of existing NER pipelines to new domains through leveraging pre-trained domain-specific embeddings.

DWS relies on a graphical model to capture statistical dependencies among tokens, weak labels and true latent NE tags. However, latent variable estimation is challenging and the techniques are often both sample and computationally complex. For example, Ratner et al. (2017) required a Gibbs-based algorithm, and Ratner et al. (2019) required estimating the full inverse covariance matrix among the labelers. In video analysis, Varma et al. (2019b) required the use of multiple iterations of stochastic gradient descent (SGD) to learn accuracy parameters, but the dependencies are limited to weak labels and true labels. When context of the sequential inputs are directly involved in the model, optimizing or even formulating the analytical solution becomes much more difficult.

Our solution is motivated by the advantages of using neural networks to model the transition and output distributions (Bengio and Frasconi, 1996; Li and Shum, 2006). Instead of deriving analytical formulations to learn the parameters for the given structure, we use deep neural networks to approximate conditional dependencies and sequential transitions. Furthermore, the marginal likelihood of the proposed model is optimized via hard EM (Min et al., 2019) to find the most probable sequence of latent tags. Such a hybrid process allows us to easily integrate distributed representations in our model and also enables us to explore complex model structures.

We benchmarked the proposed DWS model on several NER datasets and compared it with some recent weak supervision approaches. Experimental results show DWS's advantage on tagging tasks where there are a lot of conflicting weak labels. Furthermore, we conduct detailed analysis to evaluate the complexity of these NER datasets in terms of the number of NE tags and labeling functions and also the amount of inconsistency among the weak labels.

We conclude that some datasets used in past works are useful to evaluate the robustness of weak supervision models, whereas others contain weak labels that are trivial to denoise and result in all algorithms looking equivalent. Therefore, directly comparing results on weakly labeled datasets without accounting for the difficulty of denoising their labels can drive misleading conclusions. To more rigorously test how the performance of the algorithms scale with the difficulty of the weak supervision problem, we introduce a new method which stratifies a dataset into tokens containing varying levels of weak labeler disagreement, quantified by the entropy of the weak label predictions, and compares how the performance of each algorithm scales with the difficulty of the denoising task. Results show that the performance advantage of our algorithm over the current methods grows quickly with respect to the disagreement among the weak labelers.

2 Related Work

Snorkel (Ratner et al., 2017) is a well-known tool that learns a generative model to estimate the accuracies and correlations between weak labelers on *i.i.d.* data. SwellShark (Fries et al., 2017) treats weakly supervised NER as an *i.i.d.* task but requires creating additional heuristics (sometimes called entity span generators) to find the entity boundaries. In recent years, various new algorithms have been introduced to extend the weak supervision idea to tasks involving sequential data such as NER. BOND (Liang et al., 2020) and AutoNER (Shang et al., 2018) respectively denoise predictions of a single weak labeler and a set of dictionaries. Several generative approaches such as Hidden Markov Model (Lison et al., 2020; Safranchik et al., 2020) and a discriminative method Fuzzy-LSTM-CRF (Shang et al., 2018) have been proposed to model the dependencies between NE tags; thus, entity span generators are no longer needed. There have also been several relevant approaches on other weak supervision tasks. ReHession (Liu et al., 2017) was developed for weakly supervised relation extraction and tries to learn the contexts where each weak labeler is proficient, then uses that knowledge to infer the true labels. Varma et al.

(2019a) proposes a robust PCA-based algorithm to learn dependency structures for image classification. In the application of video analysis, Fu et al. (2020) applies a general binary Ising model to factorize likelihood expectations over cliques so an analytical solution is found to speed up the model parameter learning.

In this paper, we systematically compare most of the recent approaches proposed for NER except for BOND, AutoNER, and Swellshark which are not directly applicable to our experimental settings.

3 Problem Definition

We assume a sequential labeling problem formulation where we are given a sequence of tokens $\mathcal{X} = \{x_1, ..., x_N\}$ which map to a sequence of latent class variables $\mathcal{Y} = \{y_1, .., y_N\}$. In a fully supervised scenario, $\mathcal{Y}$ is usually partially annotated thus $\mathcal{Y} = \mathcal{Y}_{\text{train}} \cup \mathcal{Y}_{\text{test}}$, so model parameters are estimated from $(\mathcal{X}_{\text{train}}, \mathcal{Y}_{\text{train}})$. Because $\mathcal{Y}_{\text{train}}$ is usually expensive to obtain, our primary goal is to estimate $\mathcal{Y}_{\text{train}}$ with the help of multiple, potentially noisy labeling sources. Suppose we have a set of weak labels $\mathcal{L}_{\text{train}}$ available for $\mathcal{X}_{\text{train}}$, where each token is assigned a set of weak labels provided by m different labeling sources $\lambda_1, ..\lambda_m$ (labelers can choose to make no prediction by voting 'Abstain'). For simplicity, we drop the notion of training and test data, and simply use $\mathcal{X}, \mathcal{Y}, \mathcal{L}$ to represent all tokens, latent tags, and weak labels in our problem. Additionally, we define the vote of weak labeler λ_j on token x_i as $l_{i,j}$.

In a supervised setting where $\mathcal{Y}$ are given, we learn model parameters Θ by maximizing the log-likelihood of $\mathcal{Y}$ given the input $\mathcal{X}$ with respect to Θ:

$$J_{sup}(\Theta|\mathcal{X}, \mathcal{Y}) = \max \log P(\mathcal{Y}|\mathcal{X}; \Theta) \tag{1}$$

whereas in our weak supervision scenario, $\mathcal{Y}$ are hidden and $\mathcal{L}$ are fully observable, so the learning objective can instead be to maximize the marginal likelihood of the weak labels. Letting $\mathcal{E}$ be the set of K entity classes which includes 'No Entity', we have:

$$P(\mathcal{L}|\mathcal{X}; \Theta) = \sum_{Y_c \in \mathcal{E}^N} P(\mathcal{L}, Y_c|\mathcal{X}; \Theta) \tag{2}$$

which can be used to compute the objective as follows:

$$J_{weak}(\Theta|\mathcal{X}, \mathcal{L}) = \max \log P(\mathcal{L}|\mathcal{X}; \Theta) \tag{3}$$

4 Model Overview

4.1 Model Structure and Likelihood

To incorporate the dependencies among tokens, weak labels, and true labels, we define a graphical structure illustrated as Figure 1. The proposed graphical model is partially directed and its analytical solutions and exact inference are available through segmentations of the input sequence but are usually complex to derive. In our approach, the likelihood $P(\mathcal{L}, \mathcal{Y}|\mathcal{X})$ defined in (2) is factorized as $P(\mathcal{L}|\mathcal{X}, \mathcal{Y})$ and $P(\mathcal{Y}|\mathcal{X})$, where each is approximated via a neural network. These networks are described in Sections 4.2 and 4.3, respectively. The parameters are learned through maximizing an approximation to the marginal likelihood $P(\mathcal{L}|\mathcal{X})$ using a hard EM algorithm. Following is an in depth description of the model formulation.

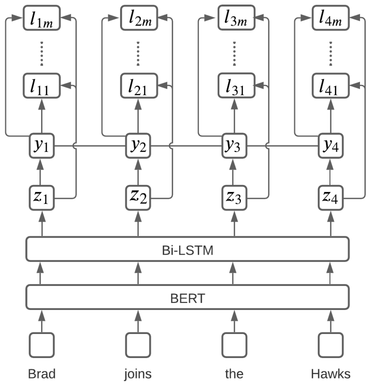

Figure 1: The DWS model where z_i denotes the contextual embedding for the token at index i.

According to (3) and (2) we have:

$$\begin{aligned} P(\mathcal{L}|\mathcal{X}) &= \sum_{Y_c \in \mathcal{E}^N} P(\mathcal{L}, Y_c|\mathcal{X}) \\ &= \sum_{Y_c \in \mathcal{E}^N} P(\mathcal{L}|\mathcal{X}, Y_c) P(Y_c|\mathcal{X}) \end{aligned}$$

We now assume different labeling functions are independent of each other given the input text and true labels. Additionally, we assume the weak labels at token x_i are conditionally independent of the true labels at any index $k \neq i$ when given the input text and true label at index i (d-separation details are in Appendix A.2). Therefore, we have:

$$P(\mathcal{L}|\mathcal{X}, Y_c) = \prod_i \prod_j P(l_{i,j}|\mathcal{X}, Y_c) \tag{4}$$

$$= \prod_i \prod_j P(l_{i,j}|\mathcal{X}, y_{c,i}) \tag{5}$$

where $y_{c,i}$ denotes the label at index i of Y_c. This means:

$$\log P(\mathcal{L}|\mathcal{X}) = \log \sum_{Y_c \in \mathcal{E}^N} P(Y_c|\mathcal{X}) \prod_i \prod_j P(l_{i,j}|\mathcal{X}, y_{c,i}) \tag{6}$$

In it's current form, the conditional log likelihood is difficult to optimize because of the sum-product inside the logarithm. As an alternative, we maximize J_{HardEM} which is an approximation to the conditional log-likelihood where the summation over entity labels is replaced with a maximum.

$$\begin{aligned} J_{HardEM} &= \log \Big[\max_{Y_c \in \mathcal{E}^N} P(Y_c|\mathcal{X}) \prod_i \prod_j P(l_{i,j}|\mathcal{X}, y_{c,i}) \Big] \\ &= \max_{Y_c \in \mathcal{E}^N} \Big[\log P(Y_c|\mathcal{X}) + \sum_i \sum_j \log P(l_{i,j}|\mathcal{X}, y_{c,i}) \Big] \\ &= \max_{Y_c \in \mathcal{E}^N} \log P(\mathcal{L}, Y_c|\mathcal{X}) \end{aligned} \tag{7}$$

This new optimization problem attempts to find accurate modes of $P(\mathcal{L}, \mathcal{Y}|\mathcal{X})$. All that remains is to formulate $P(Y_c|\mathcal{X})$ and $P(l_{i,j}|\mathcal{X}, y_{c,i})$ for some pair (i, j).

4.2 Modeling Weak Labeler Representations

In practice, a weak labeler is usually derived from a specific rule or a controlled vocabulary. Thus, it is reasonable to assume its accuracy depends on the context of the token it is making a prediction on. Inspired by Liu et al. (2017), we model labeling function λ_j providing the correct label to x_i as a discrete event following a *Bernoulli* distribution, given by:

$$P(l_{i,j}|\mathcal{X}, y_{c,i}) = \begin{cases} \alpha_{ij} & \text{if } l_{i,j} = y_{c,i} \\ 1 - \alpha_{ij} & \text{if } l_{i,j} \neq y_{c,i} \end{cases} \tag{8}$$

Here, $\alpha_{ij} = \sigma(\frac{z_i^T \theta_j}{\sqrt{d}})$, σ is the sigmoid function, θ_j is a learnable embedding specific to λ_j, and $z_i (z_i \in \mathbb{R}^d)$ is the contextual embedding of the token x_i. This formulation improves the modeling capacity over many past methods such as Snorkel (Ratner et al., 2017) or the HMM (Safranchik et al., 2020; Lison et al., 2020) which have purely class-conditioned accuracies. In addition, it allows the utilization of external knowledge from large pretrained language models by making z_i a function of their contextual embeddings. When a weak labeler abstains, there is no concept of accuracy. We chose to set the probability of the 'Abstain' votes to 1, but in the future could instead model the probability of abstaining.

4.3 Modeling Class Representations and Transition Scores

We model $P(Y_c|\mathcal{X})$ as a function of the contextual embeddings z. The model uses a linear-chain conditional random field (CRF) output layer which is often utilized to model dependencies between labels (Huang et al., 2015; Lample et al., 2016; Akbik et al., 2018). The distribution $P(Y_c|\mathcal{X})$ is given by

$$P(Y_c|\mathcal{X})) = \frac{e^{C(\mathcal{X}, Y_c)}}{\sum_{Y' \in \mathcal{E}^N} e^{C(\mathcal{X}, Y')}} \tag{9}$$

$$\text{where} \quad C(\mathcal{X}, Y) = \sum_{j=1}^{N} s_{j,y_j} + \sum_{j=1}^{N-1} T[y_j, y_{j+1}] \tag{10}$$

$$\text{and} \qquad s_{j,y_j} = \frac{z_j^T t_{y_j}}{\sqrt{d}} \tag{11}$$

where T is a learnable matrix defining the transition scores between any two entity classes and t_{y_i} is the learnable embedding for class y_i. We have scaled the dot products in both the formula for α_{ij} and (11), by the square root of the embedding size d to significantly increase the stability of training as was shown to be useful in Vaswani et al. (2017).

4.4 Algorithm for Optimization

To maximize the objective J_{HardEM}, we repeat the following two steps:

1. Calculate $Y' = \arg\max_{Y_c \in \mathcal{E}^N} \Big(\log P(\mathcal{L}, Y_c|\mathcal{X}) \Big)$
2. Maximize $\log P(\mathcal{L}, Y'|\mathcal{X})$ for one gradient ascent step.

This approach is often termed *hard EM* and has been successful in other areas such as weakly supervised relation extraction (Liu et al., 2017) and question answering (Min et al., 2019). Step 1 can be computed as follows:

$$Y' = \arg\max_{Y_c \in \mathcal{E}^N} \Big(\log P(\mathcal{L}, Y_c|\mathcal{X}) \Big) \tag{12}$$

$$= \arg\max_{Y_c \in \mathcal{E}^N} \Big(\sum_{i=1}^{N} s'_{i,y_{c,i}} + \sum_{k=1}^{N-1} T[y_{c,k}, y_{c,k+1}] \Big) \tag{13}$$

$$\text{where} \quad s'_{i,y_{c,i}} = s_{i,y_{c,i}} + \sum_{j=1}^{m} \log P(l_{i,j}|\mathcal{X}, y_{c,i}) \tag{14}$$

The details of the derivation are in Appendix A.1. Equation (13) can be solved efficiently with the same Viterbi decoding algorithm used in Huang et al. (2015). In practice, we constrain each y'_i to be in the set of classes voted on among weak labelers on the token x_i by setting $s'_{i,y_{c,i}} = -\infty$ for any $y_{c,i}$ that does not satisfy the constraint. Additionally, we found it useful to penalize choosing sequences Y' containing illegal class transitions. This was done by adding a hyperparameter τ to the transition matrix T from (13) in all locations that correspond to illegal transitions. For example, transitioning from the middle to the beginning of a 'Person' entity (i.e, I-Per → B-Per) would be penalized as it does not make sense.

4.5 Training Details

The contextual token embeddings z used to calculate (8) and (11) are obtained from a trainable single layer bidirectional LSTM that uses contextual word embeddings from pre-trained BERT models as described in Section 5.2. We choose to freeze the parameters of the pre-trained models to allow fast and inexpensive training.

To obtain a better starting point for the EM algorithm, the models are given a warm start by training for one epoch where the token labels Y' in step 2 of the optimization algorithm in Section 4.4 are set to be the majority vote labels.

Lastly, we choose the model parameters to be those that give the best entity F1 score on a held out validation set over 10 random restarts of 5 epochs each. Further details of the training procedure and architectures used are described in Appendix A.3 and A.4.

5 Experiments and Results

Experiments are conducted on four public weakly supervised NER datasets (Lison et al., 2020; Safranchik et al., 2020) as summarized in Table 1. We use the same weak labeling functions as reported in these approaches. Each dataset is split into train, validation, and test set using the same splits as Safranchik et al. (2020) suggests for NCBI-Disease, BC5CDR, and LaptopReview, and Liang et al. (2020) for CoNLL2003[1].

5.1 Weakly Labeled Dataset Difficulty

We first conduct a study to establish the difficulty of denoising the weak labels in each dataset. As we will demonstrate, this allows a detailed analysis of the strengths and weaknesses of each model. Both the amount and types of disagreement among the weak labelers differ drastically between weakly supervised NER datasets. Knowledge about the types of difficulties in each dataset is necessary to understand the contexts where each model is most useful as well as how to gauge which results are the most important. We categorize disagreements into three types: **Token Position** (i.e., $\{B, I, L, U, O\}$), **Positioned Class** (i.e., $\{B\text{-}Per, I\text{-}Per, L\text{-}Per\}$), and **Unpositioned Class** (i.e., $\{Per, Loc, Org, Misc\}$).

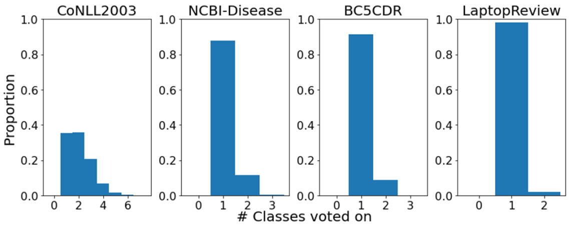

Figure 2: The tokens in each dataset containing weak labels were bucketed based on the number of classes voted on among weak labelers. This figure shows the proportion of tokens in each bucket.

To understand the prominent types of disagreement in each weakly labeled dataset, we calculated the number of tokens which contain each type of disagreement. The results are displayed in the last three columns of Table 1, and show that weak labelers on NCBI-Disease, BC5CDR, and LaptopReview disagree on a token's positioning within an entity much more often than on the unpositioned entity class. This indicates that the main difficulty on those weakly labeled datasets is resolving disagreements on where each entity begins and ends. To the contrary, CoNLL2003 contains many disagreements on both the token position and unpositioned class predictions.

We also include Figure 2 to emphasize the difficulty of the weakly labeled CoNLL2003 dataset compared to the others. On average there are a much higher number of classes being disagreed upon per token, a heuristic for the difficulty of the weakly labeled dataset.

5.2 Results

Our experiments focus on the following topics:
(1) Comparison of the proposed method's performance with existing methods on benchmark datasets. (2) Stratified analysis and benchmarking of various models w.r.t. the difficulty of the NER task. (3) Systematic study to establish the importance of various design decisions of our proposed method.

The proposed DWS model is compared to sev-

---

[1] Lison et al. (2020) did not define a validation set or test set split. Instead, their results were on the full dataset.

Dataset	Document Type	#WL's	#Tokens	#Entities	Entity Types	#Unpositioned	#Positioned	#Position
CoNLL2003	News	46	301,649	35,089	Per,Loc,Org,Misc	7439	9236	6203
LaptopReview	Online reviews	12	63,379	3,005	Laptop Aspect	23	43	40
NCBI-Disease	PubMed Articles	12	183,330	6,873	Disease	310	923	904
BC5CDR	PubMed Articles	26	351,508	28,687	Chemical,Disease	216	1058	1001

Table 1: Summary statistics of the four datasets where WL refers to 'Weak Labelers'. The weak labels for CoNLL2003 are defined by Lison et al. (2020) and the weak labels for NCBI-Disease, LaptopReview, and BC5CDR are defined by Safranchik et al. (2020). The last three columns are defined as: **'#Unpositioned'**: is the number of tokens with more than one unpositioned class voted on. **'#Positioned'**: is the number of tokens with more than one positioned class voted on. **'#Position'**: is the number of tokens with more than one position (i.e, B,I,L,U) voted on. On CoNLL2003, the weak labelers were created such that their votes are in the set of the 19 OntoNotes5.0 classes. The weak supervision model is trained using this full set of classes and then at inference time, it's predictions are mapped to the set of CoNLL2003 classes or 'No Entity' for types such as Date or Ordinal.

eral recently introduced models which are trained on the benchmark datasets. Those include **Snorkel** (Ratner et al., 2017) where each token is considered as an independent example, **Fuzzy-LSTM-CRF** (Shang et al., 2018), **HMM** (Lison et al., 2020), the HMM formulation from Safranchik et al. (2020) which does not use 'linking rules', **Majority Vote**, and **Unweighted Vote** (Safranchik et al., 2020) which creates probabilistic training labels using the empirical distribution of the weak labels on each token. To make a fair comparison with DWS, the Fuzzy-LSTM-CRF uses the same model architecture as its discriminative component $P(\mathcal{Y}|\mathcal{X})$. To enhance performance, we use contextual token embeddings from RoBERTa (Liu et al., 2019) on CoNLL2003, uncased BERT (Devlin et al., 2019) on Laptop Review, and BioBERT (Lee et al., 2019) on NCBI-Disease and BC5CDR as inputs to our model and the Fuzzy-LSTM-CRF.

Our weak supervision pipeline has two steps: **Step 1)** First it learns the latent labels of the training data using weak labels and tokens, so the learned data can be used as annotated training data to train NER classifiers. We measure model performance in this step through evaluating the micro-entity precision, recall, and F1 scores of the learned latent labels against the ground truth labels. Table 2 (upper) displays these results and shows that the proposed DWS method creates training labels with an F1 score of 1.65% higher than the nearest comparing model on CoNLL2003 and F1 scores within 0.1% and 0.03% of the best comparative approach on BC5CDR and NCBI-Disease, respectively. Additionally, DWS is outperformed by an F1 score of 0.58% on LaptopReview but this is expected since the dataset only contains 43 tokens where the weak labelers disagree. This is likely far too little for DWS to learn robust deep representations for the accuracies of each weak labeler.

Step 2) Using the learned labels as training labels, we train classifiers and apply the trained classifiers on test data. We train the same classifier mentioned in Safranchik et al. (2020) on the weakly labeled training data obtained by each algorithm on all benchmark datasets. We also keep the test data identical per each dataset and report the obtained performance on test data using micro-entity precision, recall, and F1 score. According to the results displayed in Table 2 (lower), the proposed DWS outperforms the next best model by an F1 score of 3.95% on CoNLL2003, which is arguably the hardest dataset given the analysis in Section 5.1. Additionally, DWS outperforms the closest competitor on NCBI-Disease by an F1 score of 0.83%, and achieves the second best performance on both BC5CDR and LaptopReview.

The purpose of reporting performance separately in two steps is to clearly demonstrate the improvement of performance obtained by weak supervision alone, which only compares the quality of learned annotations with true labels in Step 1. To our understandings, this is important because in practice, model selection and quality control of weak supervision should also focus on the quality of learned annotations. The second step, after the training data is automatically annotated, focuses on the bias-variance problem in a supervised scenario and the main goal is to select the best classifier to generalize well on unseen data.

5.3 Performance vs Entropy of Weak Labels

As previously discussed, comparing F1 scores alone across weak supervision approaches without knowing the difficulties of the problem could drive misleading conclusions. For example, if the weak labels provided for a dataset are highly correlated, it becomes a trivial problem to denoise them - meaning algorithms will have indistinguish-

Step 1

DWS (ours)	**76.96**	**75.32**	**76.13**	**84.15**	81.88	82.99	78.60	74.01	**76.22**	69.08	58.75	63.44

Table 2: **Step 1:** Training set results of the training labels produced by the weak supervision models. **Step 2:** Test set results of discriminators trained on the label predictions of the weakly supervised NER algorithms. All of the results in both tables are the average scores over 5 runs of each model using different random seeds.
* HMM1 is from Lison et al. (2020) and HMM2 is the Hidden Markov Model from Safranchik et al. (2020) without 'linking' rules. Note that we attempted to train HMM2 on CoNLL2003 but ran out of memory when using 64GB of RAM.
** We use our own implementation for the Fuzzy-LSTM-CRF. The results differ from Shang et al. (2018) since different weak labelers are used.

able F1 scores. To more clearly differentiate the performance of algorithms, we can calculate how their performance scales with the difficulty of the denoising task. Intuitively, we expect that better algorithms should be more robust to challenging denoising tasks. To demonstrate this, we first bucket tokens in the weakly labeled CoNLL2003 training dataset based on the level of disagreement among their weak labels, which can be thought of as the difficulty of denoising them, and then plot the differences in average token F1 scores between DWS and the comparative models in each bucket. To quantify the 'disagreement' of the weak labelers on a token, we use the entropy of the distribution of their non-abstained votes. To gain further insight into the strengths and weaknesses of each model, we group entropy and F1 calculations by 3 different class types: **Token Position**, **Positioned Class**, **Unpositioned Class**. These are described in Section 5.1. The results are plotted in Figure 3.

Figure 3 shows the improvement in F1 score obtained by DWS over other comparing methods at several different levels of entropy. The left figure shows that as entropy increases, generally the improvement of performance on unpositioned classes also increases. The middle figure shows that our model does not have much of an advantage in resolving disagreements over the position each token has within an entity (ie B,I,L,U), and that Fuzzy-LSTM-CRF is actually significantly better at high entropy levels. Most importantly though, when both types of disagreement are combined in Figure 3 (right), the advantage of DWS becomes very significant as the gaps in performance between itself and others are steadily increasing functions.

5.4 Ablation Studies

To better understand the importance of each component in DWS, we study how the performance of DWS on CoNLL2003 is affected by removing some design functions in DWS. Specifics of the experiments are as follows:

No Penalty: Sets the penalty given to illegal class transitions (defined in Section 4.4) to 0. Without this illegal class transition penalty, validation and test F1 scores drop by 1.27% and 2.34% respectively.

No Penalty No CRF: In addition to removing the penalty for illegal tag transitions as explained above, we treat the true tags as conditionally independent by replacing the CRF in $P(Y|X)$ with a token-wise softmax. Such changes result in lowering the test F1 score by 8.77%. This experiment helps to highlight the importance of modeling sequential dependencies since without it, the performance is lower than even majority voting.

No Warm Start: Warm starting by initializing the hard EM procedure with majority votes is helpful

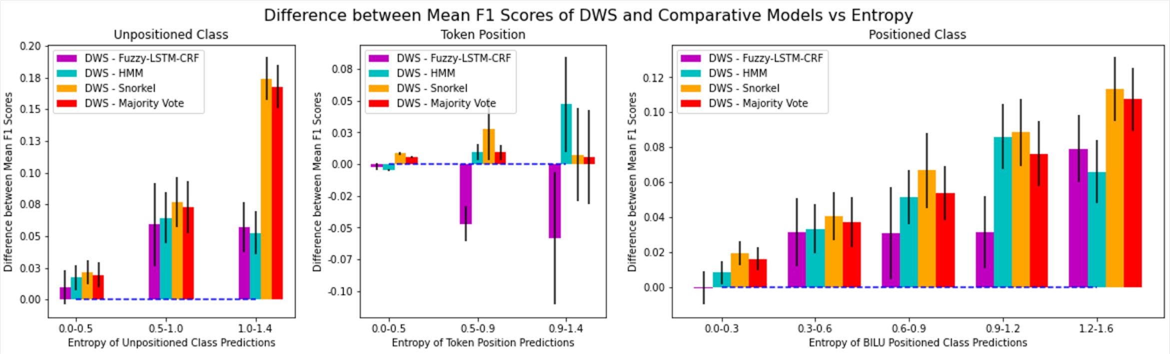

Figure 3: Each plot contains 95% confidence intervals on the difference in mean token F1 scores between DWS and comparing models in each bucket. These were calculated using the results from 5 randomized runs for each model. When the entropy is large, there is a lot of disagreement; when it's zero, the weak labelers all agree on the same class.

Model	CoNLL2003					
	Dev Precision	**Dev Recall**	**Dev F1**	**Test Precision**	**Test Recall**	**Test F1**
DWS	79.13	77.36	78.23	76.96	75.32	76.13
DWS (No Penalty)	77.92	76.02	76.96	74.35	73.25	73.79
DWS (No Penalty or Crf)	72.88	69.54	71.16	69.56	65.30	67.36
DWS (No Warm Start)	77.39	76.77	77.07	73.43	73.40	73.41

Table 3: Validation and test set results of a discriminator trained on the label predictions of each model listed in the table. The micro-entity precision, recall, and F1 scores are averaged over 5 random seeds.

to achieve better performance compared to random initialization. After iterating hard EM for the same epochs, warm start boosts validation and test F1 scores by 1.16% and 2.72% respectively, compared to random initialization. The results of each ablation are reported in Table 3.

6 Discussion

In Section 5.1 we showed that the amount of disagreement between the weak labelers varied substantially between datasets. This insight is important when interpreting the effectiveness of a weak supervision model because on datasets containing very little disagreement, we wouldn't expect to be able to learn anything much different than majority voting. As the number of contradictions between the weak labeler votes increases, for the most part so does the amount of information to help gauge the accuracies of the weak labelers and surpass majority voting. This means that we would roughly expect a good algorithm to have its greatest performance advantage on CoNLL2003 followed by NCBI-Disease and BC5CDR, and lastly LaptopReview which did not contain many weak labeler disagreements. The results in Section 5.2 show that as we would hope, our method has the largest performance advantage on CoNLL2003 and retains strong results on the remaining datasets which have fewer disagreements.

In Section 5.3 ('Performance vs Entropy'), we more concretely show that the F1 score advantage of DWS over the other models when using positioned labels increases with respect to the amount of contradiction information. These advantages may be attributable to the learned proficiency representations of weak labelers that help discriminate noisy labels provided by labeling functions with low proficiencies.

Experiments in Section 5.3 also show that DWS is very effective at resolving disagreements on unpositioned classes but is more mediocre at denoising disagreements on the entity positioning. These results suggest that the ideal model to use in a practical scenario likely depends on the amount of each type of disagreement in the given weakly labeled dataset.

7 Conclusion

In this paper we introduced a novel method (DWS) for weakly supervised NER which learns context-dependent proficiency for labeling sources while also modeling sequential dependencies among weak labels, inputs, and true labels. The proposed approach integrates representation learning and graphical models within the weak supervision setting, and obtains better performance on public benchmark datasets than recently introduced approaches. The proposed method is quite generic and can be applied to other sequential learning tasks in NLP or other modalities such as image analysis/computer vision by adopting various pre-trained domain-specific models to embed the input sequence.

A Appendix

A.1 Derivations

The details for efficiently computing Y' in step 1 of the hard EM algorithm as mentioned in Section 4.4 are as follows:

$$
\begin{aligned}
Y' &= \arg\max_{Y_c \in \mathcal{E}^N} \Big(\log(P(\mathcal{L}, Y_c|\mathcal{X})) \Big) && (15) \\
&= \arg\max_{Y_c \in \mathcal{E}^N} \Big(\log(P(Y_c|\mathcal{X})) + && (16) \\
&\qquad \sum_{i=1}^{N} \sum_{j=1}^{m} \log(P(l_{i,j}|\mathcal{X}, y_{c,i})) \Big) \\
&= \arg\max_{Y_c \in \mathcal{E}^N} \Big(\log(\frac{e^{C(X,Y_c)}}{K}) + && (17) \\
&\qquad \sum_{i=1}^{N} \sum_{j=1}^{m} \log\left(P(l_{i,j}|\mathcal{X}, y_{c,i})\right) \Big) \\
&= \arg\max_{Y_c \in \mathcal{E}^N} \Big(\sum_{i=1}^{N} s_{i,y_{c,i}} + \sum_{k=1}^{N-1} T[y_{c,k}, y_{c,k+1}] + \\
&\qquad \sum_{i=1}^{N} \sum_{j=1}^{m} \log(P(l_{i,j}|X, y_{c,i})) \Big) \\
&= \arg\max_{Y_c \in \mathcal{E}^N} \Big(\sum_{i=1}^{N} s'_{i,y_{c,i}} + \sum_{k=1}^{N-1} T[y_{c,k}, y_{c,k+1}] \Big) && (18) \\
&\text{where} \quad s'_{i,y_{c,i}} = s_{i,y_{c,i}} + \sum_{j=1}^{m} \log\left(P(l_{i,j}|X, y_{c,i})\right)
\end{aligned}
$$

where K is a normalizing constant and C is the function defined in equation 10.

A.2 Graphical Model of DWS

We illustrate the exact graphical model of DWS in Figure 4, where the structure is similar to the Input/Output HMM(IOHMM) proposed by (Bengio and Frasconi, 1996). In IOHMM, transitions from latent variables y_{i-1} to y_i are directional, and analytical solutions are available based on factorizations of the sequence marginal likelihood. Here in our approach, similar analytical solutions could be derived as a partially directed model (e.g., CRF) without the need of parameterized distributions of input embeddings z_i. However, hybrid approaches that integrate neural networks with graphical models to enable efficient and scalable model training are preferred (Bourlard and Wellekens, 1990; Bengio et al., 1992; Bengio and Frasconi, 1996; Li and Shum, 2006).

A.3 Weak Supervision Model Architecture / Training Details

Weak Supervision Model Architectures: DWS and the Fuzzy-LSTM-CRF used a one layer

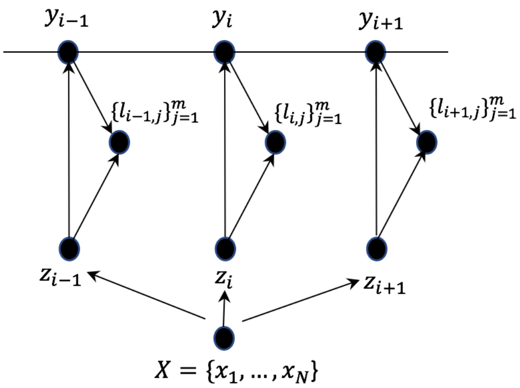

Figure 4: The input sequence $X = \{x_1, ..., x_N\}$ is transformed to a series of contextual embeddings $\{z_1, ..., z_N\}$ using a pre-trained BERT model followed by a BiLSTM. The conditional dependencies between input token embeddings z_i, latent NE tags y_i, and weak labels $\{l_{i,j}{}_{j=1}^{m}\}$ are modeled as functions of linear products between labeler representation θ_j and token embeddings z_i as formulated in equation 8. The dependencies between latent tags y_{i-1}, y_i are represented as an undirected graph through a CRF.

bidirectional LSTM with hidden size 768 to obtain the contextual token embeddings with dimension 768. The inputs to the BiLSTM were contextual word embeddings from RoBERTa (Liu et al., 2019) on CoNLL2003, uncased BERT on Laptop Review, and BioBERT (Lee et al., 2019) on NCBI-Disease and BC5CDR. These variants of BERT (Devlin et al., 2019) were not fine-tuned during training. Additionally, the class embeddings have dimension 768.

Training Details DWS: The optimizer used was RMSProp with learning rate 0.001. The model parameters were chosen to be those that gave the best micro-entity F1 score on the validation set over 10 random restarts of 5 epochs each. The batch sizes used were 32 for LaptopReview, 128 for NCBI-Disease, 256 for CoNLL2003, and 512 for BC5CDR. We defined the batch size by the number of tokens with at least 1 weak vote. Additionally, the illegal transition penalty was -2 for LaptopReview and -10 for the remaining datasets. Lastly, we used 1 warm-up epoch on majority vote labels and a dropout probability of 0.1 in the BiLSTM. These hyperparameters were chosen through manual tuning on the validation set.

Training Details Fuzzy-LSTM-CRF: The optimizer used was RMSProp with learning rate 0.01. The model parameters were chosen to be those that gave the best micro-entity F1 score on the validation set over 5 random restarts of 10 epochs each since it converged more slowly than DWS and had less variance among the random restarts. The best batch sizes were found to be the same as DWS. Lastly, the dropout probability in the BiLSTM was 0.1. The learning rate was chosen from $\{0.0001, 0.0005, 0.001, 0.01, 0.02\}$, the batch size was chosen from $\{32, 64, 128, 256, 512, 1024\}$, and the dropout was chosen from $\{0, 0.1, 0.2, 0.4\}$.

Training Details of Other Comparing Models: We used the same priors for the HMM1 model as were used in Lison et al. (2020) on CoNLL2003. For the remaining datasets the priors were tuned the on the validation sets. Additionally, we tried running the HMM from Safranchik et al. (2020) on CoNLL2003 but ran out of memory when using 64GB of RAM even when reducing the batch size to 1 and using unpositioned classes rather than BILU positioned classes (reduces number of classes by a factor of 4).

To improve the performance of *majority vote* and *unweighted vote* on CoNLL2003, which has many very noisy labels, we predicted 'No Entity' with probability 1 when there were less than T votes which was a tuned hyperparameter. The best value of T was found to be 5 for both methods and was chosen from $\{1, 5, 10\}$.

A.4 Discriminator Model Architecture / Training Details

The architecture of the discriminator was the same as used in Safranchik et al. (2020) which consisted of a 2 layer BiLSTM with 200 dimensional embeddings along with a CRF as the output layer. The model used both word embeddings from a variant of BERT and character embeddings from a CNN as input. Additionally, we used their noise aware loss function.

Explaining NLP Models via Minimal Contrastive Editing (MICE)

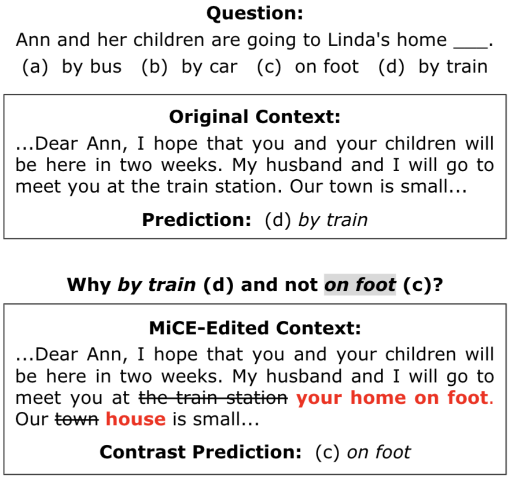
Abstract

Humans have been shown to give contrastive explanations, which explain why an observed event happened *rather than* some other counterfactual event (the *contrast case*). Despite the influential role that contrastivity plays in how humans explain, this property is largely missing from current methods for explaining NLP models. We present MINIMAL CONTRASTIVE EDITING (MICE), a method for producing contrastive explanations of model predictions in the form of edits to inputs that change model outputs to the contrast case. Our experiments across three tasks—binary sentiment classification, topic classification, and multiple-choice question answering—show that MICE is able to produce edits that are not only contrastive, but also *minimal* and *fluent*, consistent with human contrastive edits. We demonstrate how MICE edits can be used for two use cases in NLP system development—debugging incorrect model outputs and uncovering dataset artifacts—and thereby illustrate that producing contrastive explanations is a promising research direction for model interpretability.



Question:
Ann and her children are going to Linda's home ___.
(a) by bus (b) by car (c) on foot (d) by train

Original Context:
...Dear Ann, I hope that you and your children will be here in two weeks. My husband and I will go to meet you at the train station. Our town is small...
Prediction: (d) *by train*

Why *by train* (d) and not *on foot* (c)?

MiCE-Edited Context:
...Dear Ann, I hope that you and your children will be here in two weeks. My husband and I will go to meet you at ~~the train station~~ **your home on foot**. Our ~~town~~ **house** is small...
Contrast Prediction: (c) *on foot*

Figure 1: An example MICE edit for a multiple-choice question from the RACE dataset. MICE generates contrastive explanations in the form of edits to inputs that change model predictions to target (contrast) predictions. The edit (bolded in red) is minimal and fluent, and it changes the model's prediction from "by train" to the contrast prediction "on foot" (highlighted in gray).

1 Introduction

Cognitive science and philosophy research has shown that human explanations are **contrastive** (Miller, 2019): People explain why an observed event happened rather than some counterfactual event called the *contrast case*. This contrast case plays a key role in modulating what explanations are given. Consider Figure 1. When we seek an explanation of the model's prediction "by train," we seek it not in absolute terms, but in contrast to another possible prediction (i.e. "on foot"). Additionally, we tailor our explanation to this contrast case. For instance, we might explain why the prediction is "by train" and not "on foot" by saying that the writer discusses meeting Ann at the train station instead of at Ann's home on foot; such information is captured by the edit (bolded red) that results in the new model prediction "on foot." For a different contrast prediction, such as "by car," we would provide a different explanation. In this work, we propose to give contrastive explanations of model predictions in the form of targeted minimal edits, as shown in Figure 1, that cause the model to change its original prediction to the contrast prediction.

Given the key role that contrastivity plays in human explanations, making model explanations contrastive could make them more user-centered and thus more useful for their intended purposes, such as debugging and exposing dataset biases (Ribera and Lapedriza, 2019)—purposes which require that *humans* work with explanations (Alvarez-Melis et al., 2019). However, many currently popular instance-based explanation methods produce

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 3840–3852
August 1–6, 2021.

highlights—segments of input that support a prediction (Zaidan et al., 2007; Lei et al., 2016; Chang et al., 2019; Bastings et al., 2019; Yu et al., 2019; DeYoung et al., 2020; Jain et al., 2020; Belinkov and Glass, 2019) that can be derived through gradients (Simonyan et al., 2014; Smilkov et al., 2017; Sundararajan et al., 2017), approximations with simpler models (Ribeiro et al., 2016), or attention (Wiegreffe and Pinter, 2019; Sun and Marasović, 2021). These methods are not contrastive, as they leave the contrast case undetermined; they do not tell us what would have to be different for a model to have predicted a particular contrast label.[1]

As an alternative approach to NLP model explanation, we introduce **MINIMAL CONTRASTIVE EDITING (MICE)**—a two-stage approach to generating contrastive explanations in the form of targeted minimal edits (as shown in Figure 1). Given an input, a fixed PREDICTOR model, and a contrast prediction, MICE generates edits to the input that change the PREDICTOR's output from the original prediction to the contrast prediction. We formally define our edits and describe our approach in §2.

We design MICE to produce edits with properties motivated by human contrastive explanations. First, we desire edits to be **minimal**, altering only small portions of input, a property which has been argued to make explanations more intelligible (Alvarez-Melis et al., 2019; Miller, 2019). Second, MICE edits should be **fluent**, resulting in text natural for the domain and ensuring that any changes in model predictions are not driven by inputs falling out of distribution of naturally occurring text. Our experiments (§3) on three English-language datasets, IMDB, NEWSGROUPS, and RACE, validate that MICE edits are indeed contrastive, minimal, and fluent.

We also analyze the quality of MICE edits (§4) and show how they may be used for two use cases in NLP system development. First, we show that MICE edits are comparable in size and fluency to human edits on the IMDB dataset. Next, we illustrate how MICE edits can facilitate debugging individual model predictions. Finally, we show how MICE edits can be used to uncover dataset artifacts learned by a powerful PREDICTOR model.[2]

2 MICE: Minimal Contrastive Editing

This section describes our proposed method, MINIMAL CONTRASTIVE EDITING, or MICE, for explaining NLP models with contrastive edits.

2.1 MICE Edits as Contrastive Explanations

Contrastive explanations are answers to questions of the form *Why p and not q?* They explain why the observed event p happened instead of another event q, called the *contrast case*.[3] A long line of research in the cognitive sciences and philosophy has found that human explanations are contrastive (Van Fraassen, 1980; Lipton, 1990; Miller, 2019). Human contrastive explanations have several hallmark characteristics. First, they cite *contrastive features*: features that result in the contrast case when they are changed in a particular way (Chin-Parker and Cantelon, 2017). Second, they are minimal in the sense that they rarely cite the entire causal chain of a particular event, but select just a few relevant causes (Hilton, 2017). In this work, we argue that a minimal edit to a model input that causes the model output to change to the contrast case has both these properties and can function as an effective contrastive explanation. We first give an illustration of contrastive explanations humans might give and then show how minimal contrastive edits offer analogous contrastive information.

As an example, suppose we want to explain why the answer to the question "*Q*: Where can you find a clean pillow case that is not in use?" is "*A*: the drawer."[4] If someone asks why the answer is not "*C1*: on the bed," we might explain: "*E1*: Because only the drawer stores pillow cases that are not in use." However, *E1* would *not* be an explanation of why the answer is not "*C2*: in the laundry hamper," since both drawers and laundry hampers store pillow cases that are not in use. For contrast case *C2*, we might instead explain: "*E2*: Because only laundry hampers store pillow cases that are not clean." We cite different parts of the original question depending on the contrast case.

In this work, we propose to offer contrastive explanations in the form of minimal edits that result in the contrast case as model output. Such edits are effective contrastive explanations because, by construction, they highlight contrastive features. For

---

[1] Free-text rationales (Narang et al., 2020) can be contrastive if human justifications are collected by asking "why... instead of..." which is not the case with current benchmarks (Camburu et al., 2018; Rajani et al., 2019; Zellers et al., 2019).

[2] Our code and trained EDITOR models are publicly available at `https://github.com/allenai/mice`.

[3] Related work also calls it the *foil* (Miller, 2019).

[4] Inspired by an example in Talmor et al. (2019): Question: "Where would you store a pillow case that is not in use?" Choices: "drawer, kitchen cupboard, bedding store, england."

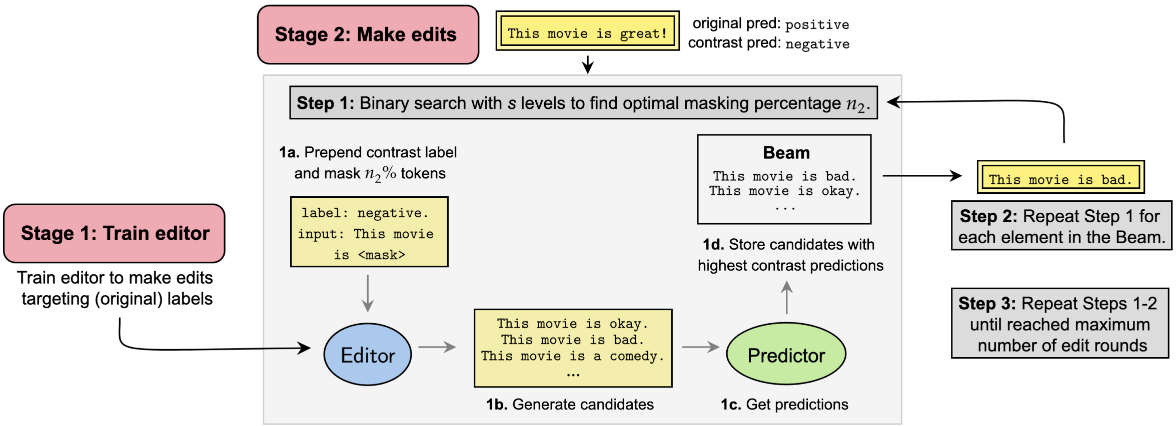


Figure 2: An overview of MiCE, our two-stage approach to generating edits. In Stage 1 (§2.3), we train the Editor to make edits targeting specific predictions from the Predictor. In Stage 2 (§2.4), we make contrastive edits with the Editor model from Stage 1 such that the Predictor changes its output to the contrast prediction.

example, a contrastive edit of the original question for contrast case *C1* would be: “Where can you find a clean pillow case that is ~~**not**~~ in use?”; the information provided by this edit—that it is whether or not the pillow case is in use that determines whether the answer is “the drawer” or “on the bed”—is analogous to the information provided by *E1*. Similarly, a contrastive edit for contrast case *C2* that changed the question to “Where can you find a ~~**clean**~~ **dirty** pillow case that is not in use?” provides analogous information to *E2*.

2.2 Overview of MiCE

We define a contrastive edit to be a modification of an input instance that causes a Predictor model (whose behavior is being explained) to change its output from its original prediction for the unedited input to a given target (contrast) prediction. Formally, for textual inputs, given a fixed Predictor f, input $\boldsymbol{x} = (x_1, x_2, ..., x_N)$ of N tokens, original prediction $f(\boldsymbol{x}) = y_p$ and contrast prediction $y_c \neq y_p$, a contrastive edit is a mapping $e : (x_1, ..., x_N) \rightarrow (x'_1, ..., x'_M)$ such that $f(e(\boldsymbol{x})) = y_c$.

We propose MiCE, a two-stage approach to generating contrastive edits, illustrated in Figure 2. In Stage 1, we prepare a highly-contextualized Editor model to associate edits with given end-task labels (i.e., labels for the task of the Predictor) such that the contrast label y_c is not ignored in MiCE’s second stage. Intuitively, we do this by masking the spans of text that are “important” for the given target label (as measured by the Predictor’s gradients) and training our Editor to reconstruct these spans of text given the masked text and target label as input. In Stage 2 of MiCE, we generate contrastive edits $e(\boldsymbol{x})$ using the Editor model from Stage 1. Specifically, we generate candidate edits $e(\boldsymbol{x})$ by masking different percentages of $\boldsymbol{x}$ and giving masked inputs with prepended contrast label y_c to the Editor; we use binary search to find optimal masking percentages and beam search to keep track of candidate edits that result in the highest probability of the contrast labels $p(y_c|e(\boldsymbol{x}))$ given by the Predictor.

2.3 Stage 1: Fine-tuning the Editor

In Stage 1 of MiCE, we fine-tune the Editor to infill masked *spans* of text in a targeted manner. Specifically, we fine-tune a pretrained model to infill masked spans given masked text and a target end-task label as input. In this work, we use the Text-to-Text Transfer Transformer (T5) model (Raffel et al., 2020) as our pretrained Editor, but any model suitable for span infilling can in principle be the Editor in MiCE. The addition of the target label allows the highly-contextualized Editor to condition its predictions on both the masked context and the given target label such that the contrast label is not ignored in Stage 2. What to use as target labels during Stage 1 depends on who the end-users of MiCE are. The end-user could be: (1) a model developer who has access to the labeled data used to train the predictor, or (2) lay-users, domain experts, or other developers without access to the labeled data. In the former case, we could use the gold label as targets, and in the latter case, we could use the labels predicted by Predictor. Therefore, during fine-tuning, we experiment with using both gold labels and original predictions

y_p of our PREDICTOR model as target labels. To provide target labels, we prepend them to inputs to the EDITOR. For more information about how these inputs are formatted, see Appendix B. Results in Table 2 show that fine-tuning with target labels results in better edits than fine-tuning without them.

The above procedure allows our EDITOR to condition its infilled spans on both the context and the target label. But this still leaves open the question of where to mask our text. Intuitively, we want to mask the tokens that contribute most to the PREDICTOR's predictions, since these are the tokens that are most strongly associated with the target label. We propose to use gradient attribution (Simonyan et al., 2014) to choose tokens to mask. For each instance, we take the gradient of the predicted logit for the target label with respect to the embedding layers of f and take the ℓ_1 norm across the embedding dimension. We then mask the $n_1\%$ of tokens with the highest gradient norms. We replace consecutive tokens (i.e., spans) with sentinel tokens, following Raffel et al. (2020). Results in Table 1 show that gradient-based masking outperforms random masking.

2.4 Stage 2: Making Edits with the EDITOR

In the second stage of our approach, we use our fine-tuned EDITOR to make edits using beam search (Reddy, 1977). In each round of edits, we mask consecutive spans of $n_2\%$ of tokens in the original input, prepend the contrast prediction to the masked input, and feed the resulting masked instance to the EDITOR; the EDITOR then generates m edits. The masking procedure during this stage is gradient-based as in Stage 1.

In one round of edits, we conduct a binary search with s levels over values of n_2 between values $n_2 = 0\%$ to $n_2 = 55\%$ to efficiently find a value of n_2 that is large enough to result in the contrast prediction while also modifying only minimal parts of the input. After each round of edits, we get f's predictions on the edited inputs, order them by contrast prediction probabilities, and update the beam to store the top b edited instances. As soon as an edit $e^* = e(\boldsymbol{t})$ is found that results in the contrast prediction, i.e., $f(e^*) = y_c$, we stop the search procedure and return this edit. For generation, we use a combination of top-*k* (Fan et al., 2018) and top-*p* (nucleus) sampling (Holtzman et al., 2020).[5]

3 Evaluation

This section presents empirical findings that MICE produces minimal and fluent contrastive edits.

3.1 Experimental Setup

Tasks We evaluate MICE on three English-language datasets: IMDB, a binary sentiment classification task (Maas et al., 2011), a 6-class version of the 20 NEWSGROUPS topic classification task (Lang, 1995), and RACE, a multiple choice question-answering task (Lai et al., 2017).[6]

PREDICTORS MICE can be used to make contrastive edits for any differentiable PREDICTOR model, i.e., any end-to-end neural model. In this paper, for each task, we train a PREDICTOR model f built on ROBERTA-LARGE (Liu et al., 2019), and fix it during evaluation. The test accuracies of our PREDICTORS are 95.9%, 85.3% and 84% for IMDB, NEWSGROUPS, and RACE, respectively. For training details, see Appendix A.1.

EDITORS Our EDITORS build on the base version of T5. For fine-tuning our EDITORS (Stage 1), we use the original training data used to train PREDICTORS. We randomly split the data, 75%/25% for fine-tuning/validation and fine-tune until the validation loss stops decreasing (for a max of 10 epochs) with $n_1\%$ of tokens masked, where n_1 is a randomly chosen value in $[20, 55]$. For more details, see Appendix A.2. In Stage 2, for each instance, we set the label with the second highest predicted probability as the contrast prediction. We set beam width $b = 3$, consider $s = 4$ search levels during binary search over n_2 in each edit round, and run our search for a max of 3 edit rounds. For each n_2, we sample $m = 15$ generations from our fine-tuned EDITORS with $p = 0.95$, $k = 30$.[7]

Metrics We evaluate MICE on the test sets of the three datasets. The RACE and NEWSGROUPS test sets contain 4,934 and 7,307 instances, respectively.[8] For IMDB, we randomly sample 5K of the

---

[5] We use this combination because we observed in preliminary experiments that it led to good results.

[6] We create this 6-class version by mapping the 20 existing subcategories to their respective larger categories—i.e. "talk.politics.guns" and "talk.religion.misc" → "talk." We do this in order to make the label space smaller. The resulting classes are: alt, comp, misc, rec, sci, and talk.

[7] We tune these hyperparameters on a 50-instance subset of the IMDB validation set prior to evaluation. We note that for larger values of n_2, the generations produced by the T5 EDITORS sometimes degenerate; see Appendix C for details.

[8] For the NEWSGROUPS test set, there are 7,307 instances remaining after filtering out empty strings.

MICE VARIANT	IMDB			NEWSGROUPS			RACE

Table 1: Efficacy of the MICE procedure. We evaluate MICE edits on three metrics (described in §3.1): flip rate, minimality, and fluency. We report mean values for minimality and fluency. * marks full MICE variants; others explore ablations. For each property (i.e., column), the best value across MICE variants is bolded. We experiment with PREDICTOR's predictions (PRED) and gold labels (GOLD) as target labels during Stage 1. Across datasets, our GRAD MICE procedure achieves a high flip rate with small and fluent edits.

25K instances in the test set for evaluation because of the computational demands of evaluation.[9]

For each dataset, we measure the following three properties: (1) **flip rate:** the proportion of instances for which an edit results in the contrast label; (2) **minimality:** the "size" of the edit as measured by the word-level Levenshtein distance between the original and edited input, which is the minimum number of deletions, insertions, or substitutions required to transform one into the other. We report a normalized version of this metric with a range from 0 to 1—the Levenshtein distance divided by the number of words in the original input; (3) **fluency:** a measure of how similarly distributed the edited output is to the original data. We evaluate fluency by comparing masked language modeling loss on both the original and edited inputs using a pretrained model. Specifically, given the original N-length sequence, we create N copies, each with a different token replaced by a mask token, following Salazar et al. (2020). We then take a pretrained T5-BASE model and compute the average loss across these N copies. We compute this loss value for both the original input and edited input and report their *ratio*—i.e., edited / original. We aim for a value of 1.0, which indicates equivalent losses for the original and edited texts. When MICE finds multiple edits, we report metrics for the edit with the smallest value for minimality.

3.2 Results

Results are shown in Table 1. Our proposed GRAD MICE procedure (upper part of Table 1) achieves a high flip rate across all three tasks. This is the outcome regardless of whether predicted target labels (first row, 91.5–100% flip rate) or gold target labels (second row, 94.5–100% flip rate) are used for fine-tuning in Stage 1. We observe a slight improvement from using the gold labels for the RACE PREDICTOR, which may be explained by the fact that it is less accurate (with a training accuracy of 89.9%) than the IMDB and NEWSGROUPS classifiers.

MICE achieves a high flip-rate while its edits remain small and result in fluent text. In particular, MICE on average changes 17.3–33.1% of the original tokens when predicted labels are used in Stage 1 and 18.5–33.5% with gold labels. Fluency is close to 1.0 indicating no notable change in mask language modeling loss after the edit—i.e., edits fall in distribution of the original data. We achieve the best results across metrics on the IMDB dataset, as expected since IMDB is a binary classification task with a small label space. These results demonstrate that MICE presents a promising research direction for the generation of contrastive explanations; however, there is still room for improvement, especially for more challenging tasks such as RACE.

In the rest of this section, we provide results from several ablation experiments.

Fine-tuning vs. No Fine-tuning We investigate the effect of fine-tuning (Stage 1) with a baseline that skips Stage 1 altogether. For this NO-FINETUNE baseline variant of MICE, we use the vanilla pretrained T5-BASE as our EDITOR. As shown in Table 1, the NO-FINETUNE variant underperforms all other (two-stage) variants of MICE for the IMDB and NEWSGROUPS datasets.[10] Fine-

---

[9] A single contrastive edit is expensive and takes an average of ≈ 15 seconds per IMDB instance (≈ 230 tokens). Calculating the fluency metric adds an additional average of ≈ 16.5 seconds per IMDB instance. For more details, see Section 5.

[10] We leave RACE out from our evaluation with the NO-FINETUNE baseline because we observe that the pretrained

IMDB Condition Stage 1	Stage 2	↑ Flip Rate	↓ Minim.	≈ 1 Fluen.
No Label	No Label	0.994	0.369	0.966
No Label	Label	0.997	0.362	0.967
Label	No Label	0.999	0.327	0.968
Label	Label	**1.000**	**0.173**	**0.981**

Table 2: Effect of using target end-task labels during the two stages of PRED+GRAD MICE on the IMDB dataset. When end-task labels are provided, they are original PREDICTOR labels during Stage 1 and contrast labels during Stage 2. The best values for each property (column) are bolded. Using end-task labels during both Stage 1 (EDITOR fine-tuning) and Stage 2 (making edits) of MICE outperforms all other conditions.

tuning particularly improves the minimality of edits, while leaving the flip rate high. We hypothesize that this effect is due to the effectiveness of Stage 2 of MICE at finding contrastive edits: Because we iteratively generate many candidate edits using beam search, we are likely to find a prediction-flipping edit. Fine-tuning allows us to find such an edit at a lower masking percentage.

Gradient vs. Random Masking We study the impact of using gradient-based masking in Stage 1 of the MICE procedure with a RAND variant, which masks spans of randomly chosen tokens. As shown in the middle part of Table 1, gradient-based masking outperforms random masking when using both predicted and gold labels across all three tasks and metrics, suggesting that the gradient-based attribution used to mask text during Stage 1 of MICE is an important part of the procedure. The differences are especially notable for RACE, which is the most challenging task according to our metrics.

Targeted vs. Un-targeted Infilling We investigate the effect of using target labels in both stages of MICE by experimenting with removing target labels during Stage 1 (EDITOR fine-tuning) and Stage 2 (making edits). As shown in Table 2, we observe that giving target labels to our EDITORS during both stages of MICE improves edit quality. Fine-tuning EDITORS without labels in Stage 1 ("No Label") leads to worse flip rate, minimality, and fluency than does fine-tuning EDITORS with labels ("Label"). Minimality is particularly affected, and we hypothesize that using target end-task labels in both stages provides signal that allows the EDITOR in Stage 2 to generate prediction-flipping edits at lower masking percentages.

4 Analysis of Edits

In this section, we compare MICE edits with human contrastive edits. Then, we turn to a key motivation for this work: the potential for contrastive explanations to assist in NLP system development. We show how MICE edits can be used to debug incorrect predictions and uncover dataset artifacts.

4.1 Comparison with Human Edits

We ask whether the contrastive edits produced by MICE are minimal and fluent in a meaningful sense. In particular, we compare these two metrics for MICE edits and human contrastive edits. We work with the IMDB contrast set created by Gardner et al. (2020), which consists of original test inputs and human-edited inputs that cause a change in *true* label. We report metrics on the subset of this contrast set for which the human-edited inputs result in a change in model prediction for our IMDB PREDICTOR; this subset consists of 76 instances. The flip rate of MICE edits on this subset is 100%. The mean minimality values of human and MICE edits are $\mathbf{0.149}$ (human) and $\mathbf{0.179}$ (MICE), and the mean fluency values are $\mathbf{1.01}$ (human) and $\mathbf{0.949}$ (MICE). The similarity of these values suggests that MICE edits are comparable to human contrastive edits along these dimensions.

We also ask to what extent human edits overlap with MICE edits. For each input, we compute the overlap between the original tokens changed by humans and the original tokens edited by MICE. The mean number of overlapping tokens, normalized by the number of original tokens edited by humans, is $\mathbf{0.298}$. Thus, while there is some overlap between MICE and human contrastive edits, they generally change different parts of text.[11] This analysis suggests that there may exist multiple informative contrastive edits for a single input. Future work can investigate and compare the different kinds of insight that can be obtained through human and model-driven contrastive edits.

4.2 Use Case 1: Debugging Incorrect Outputs

Here, we illustrate how MICE edits can be used to debug incorrect model outputs. Consider the RACE

T5 model does not generate text formatted as span infills; we hypothesize that this model has not been trained to generate infills for masked inputs formatted as multiple choice inputs.

[11] MICE edits explain PREDICTORS' behavior and therefore need not be similar to human edits, which are designed to change gold labels.

IMDB	**Original pred** y_p = positive **Contrast pred** y_c = negative An interesting pairing of stories, this little flick manages to bring together seemingly different characters and story lines all in the backdrop of WWII and succeeds in tying them together without losing the audience. I was impressed by the depth portrayed by the different characters and also by how much I really felt I understood them and their motivations, even though the time spent on the development of each character was very limited. The outstanding acting abilities of the individuals involved with this picture are easily noted. A fun, stylized movie with a slew of comic moments and a bunch more head shaking events. ~~7/10~~ **4/10**
RACE	**Question:** Mark went up in George's plane ____________. (a) twice (b) only once (c) several times (d) once or twice. **Original pred** $y_p = (a)$ twice **Contrast pred** $y_c = (b)$ only once When George was thirty-five, he bought a small plane and learned to fly it. He soon became very good and made his plane do all kinds of tricks. George had a friend, whose name was Mark. One day George offered to take Mark up in his plane. Mark thought, "I've traveled in a big plane several times, but I've never been in a small one, so I'll go." They went up, and George flew around for half an hour and did all kinds of tricks in the air. When they came down again, Mark was glad to be back safely, and he said to his friend in a shaking voice, "Well, George, thank you very much for those two ~~trips~~ **tricks** in your plane." George was very surprised and said, "Two ~~trips?~~ **tricks."** ~~Yes,~~ **That's** my first ~~and my last~~ **time, George**." ~~answered~~ **said** Mark.

Table 3: Examples of edits produced by MiCE. Insertions are bolded in red. Deletions are struck through. y_p is the PREDICTOR's original prediction, and y_c the contrast prediction. True labels for original inputs are underlined.

input in Table 3, for which the RACE PREDICTOR gives an incorrect prediction. In this case, a model developer may want to understand why the model got the answer wrong. This setting naturally brings rise to a contrastive question, i.e., *Why did the model predict the wrong choice ("twice") instead of the correct one ("only once")?*

The MiCE edit shown offers insight into this question: Firstly, it highlights which part of the paragraph has an influence on the model prediction—the last few sentences. Secondly, it reveals that a source of confusion is Mark's joke about having traveled in George's plane twice, as changing Mark's dialogue from talking about a "first and...last" trip to a single trip results in a correct model prediction.

MiCE edits can also be used to debug model *capabilities* by offering hypotheses about "bugs" present in models: For instance, the edit in Table 3 might prompt a developer to investigate whether this PREDICTOR lacks non-literal language understanding capabilities. In the next section, we show how insight from individual MiCE edits can be used to uncover a bug in the form of a dataset-level artifact learned by a model. In Appendix D, we further analyze the debugging utility of MiCE edits with a PREDICTOR *designed* to contain a bug.

4.3 Use Case 2: Uncovering Dataset Artifacts

Manual inspection of some edits for IMDB suggests that the IMDB PREDICTOR has learned to rely heavily on numerical ratings. For instance, in the IMDB example in Table 3, the MiCE edit results in a negative prediction from the PREDICTOR even though the edited text is overwhelmingly positive. We test this hypothesis by investigating whether numerical tokens are more likely to be edited by MiCE.

y_c = ***positive***		y_c = ***negative***	
Removed	**Inserted**	**Removed**	**Inserted**
4/10	excellent	10/10	awful
ridiculous	enjoy	8/10	disappointed
horrible	amazing	7/10	1
4	entertaining	9	4
predictable	10	enjoyable	annoying

Table 4: Top 5 IMDB tokens edited by MiCE at a higher rate than expected given their original frequency (§4.3). Results are separated by contrast predictions.

We analyze the edits produced by MiCE (GOLD + GRAD) described in §3.1. We limit our analysis to a subset of the 5K instances for which the edit produced by MiCE has a minimality value of ≤0.05, as we are interested in finding simple artifacts driving the predictions of the IMDB PREDICTOR; this subset has 902 instances. We compute three metrics for each unique token, i.e., type t:

$$\begin{aligned} p(t) &= \#\_\text{occurrences}(t) / \#\_\text{all\_tokens}, \\ p_r(t) &= \#\_\text{removals}(t) / \#\_\text{all\_removals}, \\ p_i(t) &= \#\_\text{insertions}(t) / \#\_\text{all\_insertions}, \end{aligned}$$

and report the tokens with the highest values for the ratios $p_r(t)/p(t)$ and $p_i(t)/p(t)$. Intuitively, these tokens are removed/inserted at a higher rate than expected given the frequency with which they appear in the original IMDB inputs. We exclude tokens that occur $<$10 times from our analysis.

Results from this analysis are shown in Table 4. In line with our hypothesis, we observe a bias towards removing low numerical ratings and inserting high ratings when the contrast prediction y_c is positive, and vice versa when y_c is negative. In other words, in the presence of a numerical score, the PREDICTOR may ignore the content of the review and base its prediction solely on the score (as in the IMDB example in Table 3).

5 Discussion

In this section, we reflect on MICE's shortcomings. Foremost, MICE is computationally expensive. Stage 1 requires fine-tuning a large pretrained generation model as the EDITOR. More significantly, Stage 2 requires multiple rounds of forward and backward passes to find a minimal edit: Each edit round in Stage 2 requires $b \times s \times m$ decoded sequences with the EDITOR, as well as $b \times s \times m$ forward passes and b backward passes with the PREDICTOR (with $b = 1$ the first edit round), where b is the beam width, s is the number of search levels in binary search over the masking percentages, and m is the number of generations sampled for each masking percentage. Our experiments required 180 forward passes, 180 decoded sequences, and 3 backward passes for edit rounds after the first.

While efficient search for targeted edits is an open challenge in other fields of machine learning (Russell, 2019; Dandl et al., 2020), this problem is even more challenging for language data, as the space of possible perturbations is much larger than for tabular data. An important future direction is to develop more efficient methods of finding edits.

This shortcoming prevents us from finding edits that are minimal in a precise sense. In particular, we may be interested in a constrained notion of minimality that defines an edit $e(\boldsymbol{x})$ as minimal if there exists no subset of $e(\boldsymbol{x})$ that results in the contrast prediction. Future work might consider creating methods to produce edits with this property.

6 Related Work

The problem of generating minimal contrastive edits, also called counterfactual explanations (Wachter et al., 2017),[12] has previously been explored for tabular data (Karimi et al., 2020) and images (Hendricks et al., 2018; Goyal et al., 2019; Looveren and Klaise, 2019) but less for language. Recent work explores the use of minimal edits changing true labels for evaluation (Gardner et al., 2020) and data augmentation (Kaushik et al., 2020; Teney et al., 2020), whereas we focus on minimal edits changing model predictions for *explanation*.

Contrastive Explanations within NLP There exist limited methods for automatically generating contrastive explanations of NLP models. Jacovi and Goldberg (2020) define contrastive highlights, which are determined by the inclusion of contrastive features; in contrast, our contrastive edits specify *how* to edit (vs. whether to include) features and can insert new text.[13] Li et al. (2020a) generate counterfactuals using linguistically-informed transformations (LIT), and Yang et al. (2020) generate counterfactuals for binary financial text classification using grammatically plausible single-word edits (REP-SCD). Because both methods rely on manually curated, task-specific rules, they cannot be easily extended to tasks without predefined label spaces, such as RACE.[14] Most recently, Jacovi et al. (2021) propose a method for producing contrastive explanations in the form of latent representations; in contrast, MICE edits are made at the textual level and are therefore more interpretable.

This work also has ties to the literature on causal explanation (Pearl, 2009). Recent work within NLP derives causal explanations of models through counterfactual interventions (Feder et al., 2021; Vig et al., 2020). The focus of our work is the largely unexplored task of creating targeted interventions for language data; however, the question of how to derive causal relationships from such interventions remains an interesting direction for future work.

Counterfactuals Beyond Explanations Concurrent work by Madaan et al. (2021) applies con-

---

[12] Formally, methods for producing targeted counterfactual explanations solve the same task as MICE. However, not all contrastive explanations are counterfactual explanations; contrastive explanations can take forms beyond contrastive edits, such as free-text rationales (Liang et al., 2020) or highlights (Jacovi and Goldberg, 2020). In this paper, we choose to refer to MICE edits as "contrastive" rather than "counterfactual" because we seek to argue for the utility of *contrastive explanations* of model predictions more broadly; we present MICE as one method for producing contrastive explanations of a particular form and hope future work will explore different forms of contrastive explanations.

[13] See Appendix D for a longer discussion about the advantage of inserting new text in explanations, which MICE edits can do but methods that attribute feature importance (i.e. highlights) cannot.

[14] LIT relies on hand-crafted transformation for NLI tasks based on linguistic knowledge, and REP-SCD makes antonym-based edits using manually curated, domain-specific lexicons for each label.

trolled text generation methods to generate targeted counterfactuals and explores their use as test cases and augmented examples in the context of classification. Another concurrent work by Wu et al. (2021) presents POLYJUICE, a general-purpose, untargeted counterfactual generator. Very recent work by Sha et al. (2021), introduced after the submission of MICE, proposes a method for targeted contrastive editing for Q&A that selects answer-related tokens, masks them, and generates new tokens. Our work differs from these works in our novel framework for efficiently finding *minimal* edits (MICE Stage 2) and our use of edits as explanations.

Connection to Adversarial Examples Adversarial examples are minimally edited inputs that cause models to incorrectly change their predictions despite no change in true label (Jia and Liang, 2017; Ebrahimi et al., 2018; Pal and Tople, 2020). Recent methods for generating adversarial examples also preserve fluency (Zhang et al., 2019; Li et al., 2020b; Song et al., 2020)[15]; however, adversarial examples are designed to find *erroneous* change in model outputs; contrastive edits place no such constraint on model correctness. Thus, current approaches to generating adversarial examples, which can exploit semantics-preserving operations (Ribeiro et al., 2018) such as paraphrasing (Iyyer et al., 2018) or word replacement (Alzantot et al., 2018; Ren et al., 2019; Garg and Ramakrishnan, 2020), cannot be used to generate contrastive edits.

Connection to Style Transfer The goal of style transfer is to generate minimal edits to inputs to result in a target style (sentiment, formality, etc.) (Fu et al., 2018; Li et al., 2018; Goyal et al., 2020). Most existing approaches train an encoder to learn style-agnostic latent representation of inputs and train attribute-specific decoders to generate text reflecting the content of inputs but exhibiting a different target attribute (Fu et al., 2018; Li et al., 2018; Goyal et al., 2020). Recent works by Wu et al. (2019) and Malmi et al. (2020) adopt two-stage approaches that first identify where to make edits and then make them using pretrained language models. Such approaches can only be applied to generate contrastive edits for classification tasks with well-defined "styles," which exclude more complex tasks such as question answering.

7 Conclusion

We argue that contrastive edits, which change the output of a PREDICTOR to a given contrast prediction, are effective explanations of neural NLP models. We propose MINIMAL CONTRASTIVE EDITING (MICE), a method for generating such edits. We introduce evaluation criteria for contrastive edits that are motivated by human contrastive explanations—minimality and fluency—and show that MICE edits for the IMDB, NEWSGROUPS, and RACE datasets are contrastive, fluent, and minimal. Through qualitative analysis of MICE edits, we show that they have utility for robust and reliable NLP system development.

8 Broader Impact Statement

MICE is intended to aid the interpretation of NLP models. As a model-agnostic explanation method, it has the potential to impact NLP system development across a wide range of models and tasks. In particular, MICE edits can benefit NLP model developers in facilitating debugging and exposing dataset artifacts, as discussed in §4. As a consequence, they can also benefit downstream users of NLP models by facilitating access to less biased and more robust systems.

While the focus of our work is on interpreting NLP models, there are potential misuses of MICE that involve other applications. Firstly, malicious actors might employ MICE to generate adversarial examples; for instance, they may aim to generate hate speech that is minimally edited such that it fools a toxic language classifier. Secondly, naively applying MICE for data augmentation could plausibly lead to less robust and more biased models: Because MICE edits are intended to expose issues in models, straightforwardly using them as additional training examples could reinforce existing artifacts and biases present in data. To mitigate this risk, we encourage researchers exploring data augmentation to carefully think about how to select and label edited instances.

We also encourage researchers to develop more efficient methods of generating minimal contrastive edits. As discussed in §5, a limitation of MICE is its computational demand. Therefore, we recommend that future work focus on creating methods that require less compute.

---

[15] Song et al. (2020) propose a method to produce fluent *semantic collisions*, which they call the "inverse" of adversarial examples.

Abstract

Texts convey sophisticated knowledge. However, texts also convey sensitive information. Despite the success of general-purpose language models and domain-specific mechanisms with differential privacy (DP), existing text sanitization mechanisms still provide low utility, as cursed by the high-dimensional text representation. The companion issue of utilizing sanitized texts for downstream analytics is also under-explored. This paper takes a direct approach to text sanitization. Our insight is to consider both sensitivity and similarity via our new local DP notion. The sanitized texts also contribute to our sanitization-aware pretraining and fine-tuning, enabling privacy-preserving natural language processing over the BERT language model with promising utility. Surprisingly, the high utility does not boost up the success rate of inference attacks.

1 Introduction

Natural language processing (NLP) requires a lot of training data, which can be sensitive. Naïve redaction approaches (*e.g.*, removing common personally identifiable information) is known to fail (Sweeney, 2015): innocuous-looking fields can be linked to other information sources for reidentification. The recent success of many language models (LMs) has motivated security researchers to devise advanced privacy attacks. Carlini et al. (2020b) recover texts from (a single document of) the *training data* via querying to an LM pretrained from it. Pan et al. (2020) and Song and Raghunathan (2020) target the text embedding, *e.g.*, revealing from an encoded *query* to an NLP service.

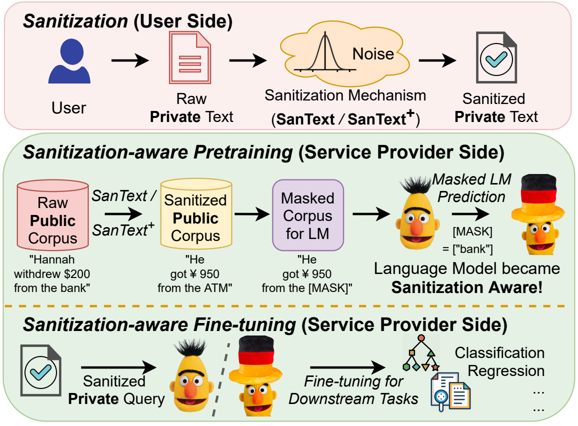

Figure 1: Workflow of our PPNLP pipeline, including the user-side sanitization and the service provider-side NLP modeling with pretraining/fine-tuning

Emerging NLP works focus on only specific document-level (statistical) features (Weggenmann and Kerschbaum, 2018) or producing private text representations (Xie et al., 2017; Coavoux et al., 2018; Elazar and Goldberg, 2018; Li et al., 2018) as initial solutions to the first issue above on training-data privacy. However, the learned representations are *not* human-readable, which makes *transparency* (*e.g.*, required by GDPR) questionable: an average user may not have the technical know-how to verify whether sensitive attributes have been removed or not. Moreover, consider the whole NLP pipeline, the learned representations often entail extra modeling or non-trivial changes to existing NLP models, which take dedicated engineering efforts.

1.1 Sanitizing Sensitive Texts, Naturally

With this state-of-affairs of the security and the NLP research, we deem it better to address privacy from the root, *i.e.*, directly producing sanitized text documents. Being the most native format, they

incur minimal changes to existing NLP pipelines. Being human-readable, they provide transparency (to privacy-concerning training-data contributors) and explainability (*e.g.*, to linguists who might find the need for investigating how the training data contribute to a certain result). Moreover, it naturally extends the privacy protection to the inference phase. Users can apply our sanitization mechanism before sending queries (*e.g.*, medical history) to the NLP service provider (*e.g.*, diagnosis services).

Conceptually, we take a natural approach – we sanitize text documents into also (sanitized) text documents. This is in great contrast to the typical "post-processing" for injecting noises either to gradients in training (a deep neural network) (McMahan et al., 2018) or the "cursed" *high-dimensional* text representations (Lyu et al., 2020a,b; Feyisetan et al., 2020). It also leads to our $O(1)$ efficiency, freeing us from re-synthesizing the document word-by-word via nearest neighbor searches over the entire vocabulary space $\mathcal{V}$ (Feyisetan et al., 2020).

Technically, we aim for the *de facto* standard of local differential privacy (LDP) (Duchi et al., 2013) to sanitize the user data *locally*, based on which the service provider can build NLP models without touching any raw data. DP has been successful in many contexts, *e.g.*, location privacy and survey statistics (Andrés et al., 2013; Murakami and Kawamoto, 2019). However, DP text analytics appears to be a difficult pursuit (as discussed, also see Section 2), which probably explains why there are only a few works in DP-based text sanitization. In high-level terms, text is rich in semantics, differentiating it from other more structured data.

Our challenge here is to develop *efficient* and effective mechanisms that *preserve the utility* of the text data with *provable and quantifiable* privacy guarantees. Our insight is the formulation of a new LDP notion named *Utility-optimized Metric LDP (UMLDP)*. We attribute our success to the focus of UMLDP on protecting what matters (sensitive words) via "sacrificing" the privacy of non-sensitive (common) words. To achieve UMLDP, our mechanism directly samples noises on tokens.

Our result in this regard is already better than the state-of-the-art LDP solution producing sanitized documents (Feyisetan et al., 2020) – we got 28% gain in accuracy on the SST-2 dataset (Wang et al., 2019) on average at the same privacy level (*i.e.*, the same LDP parameter) while being much more efficient ($\sim$60× faster, precomputation included).

1.2 Privacy-Preserving NLP, Holistically

Text sanitization is essential but just one piece of the whole privacy-preserving NLP (PPNLP) pipeline. While most prior works in text privacy are motivated by producing useful data for some downstream tasks, the actual text analytics are hardly explored, not to say in the context of many recent general-purpose language models. As simple as it might seem, we start to see design choices that can be influential. Specifically, our challenge here is to adapt the currently dominating pretraining-fine-tuning paradigm (*e.g.*, BERT (Devlin et al., 2019)) over sanitized texts for building the model.

Our design is to build in privacy at the root again, in contrast to the afterthought approach. We found it beneficial to sanitize even the public data before feeding them to training. It is not for protecting the public data per se. The intuition here is that it "prepares" the model to work with sanitized queries, which explains our eventual (slight) increase in accuracy while *additionally ensuring privacy*.

Specifically, we propose a sanitization-aware pretraining procedure (Figure 1). We first use our mechanisms to sanitize the public texts, mask the sanitized texts (as in BERT), and train the LM by predicting a `MASK` position as its *original unsanitized token*. LMs preptrained with our sanitization-aware procedure are expected to be more robust to noises in the sanitized texts and achieve better utility when fine-tuning on downstream tasks.

We conduct experiments on three representative NLP tasks to empirically confirm that our proposed PPNLP pipeline preserves both utility and privacy. It turns out that our sanitization-based pretraining (using only $1/6$ of data used in the original BERT pretraining) can even improve the utility of NLP tasks while maintaining privacy comparable to the original BERT. Note that there is an inherent tension between utility and privacy, and privacy attack is also inference in nature. To empirically demonstrate the privacy aspect of our pipeline, *i.e.*, it does not make our model a more powerful tool helping the attacker, we also conduct the "mask token inference" attack on private texts, which infers the masked token given its context based on BERT. As a highlight, our base solution SANTEXT improves the defense rate by 20% with only a 4% utility loss on the SST-2 dataset. We attribute our surprising result of mostly helping only good guys to our natural approach: to avoid the model memorizing sensitive texts "too well," we fed it with sanitized text.

2 Related Work

Privacy risks in NLP. A taxonomy of attacks that recover sensitive attributes or partial raw text from text embeddings output by popular LMs has been proposed (Song and Raghunathan, 2020), without any assumptions on the structures or patterns in input text. Carlini et al. (2020b) also show a powerful black-box attack on GPT-2 (Radford et al., 2019) that extracts verbatim texts of training data. Defense with rigorous guarantees (DP) is thus vital.

Differential privacy and its application in NLP. DP (Dwork, 2006) has emerged as the *de facto* standard for statistical analytics (Wang et al., 2017, 2018; Cormode et al., 2018). A few efforts inject high-dimensional DP noise into text representations (Feyisetan et al., 2019, 2020; Lyu et al., 2020a,b). The noisy representations are not human-readable and not directly usable by existing NLP pipelines, *i.e.*, they consider a different problem not directly comparable to ours. More importantly, they fail to strike a nice privacy-utility balance due to "the curse of dimensionality," *i.e.*, the magnitude of the noise is too large for high-dimensional token embedding, and thus it becomes exponentially less likely to find a noisy embedding close to a real one on every dimension. This may also explain why an earlier work focuses on document-level statistics only, *e.g.*, term-frequency vectors (Weggenmann and Kerschbaum, 2018).

Our approaches produce natively usable sanitized texts via directly sampling a substitution for each token from a precomputed distribution (to be detailed in Section 4), circumventing the dimension curse and striking a privacy-utility tradeoff while being much more efficient. A concurrent work (Qu et al., 2021) also considers the whole NLP pipeline, but it still builds on the token-projection approach (Feyisetan et al., 2020).

Privacy-preserving text representations. Learning private text representations via adversarial training is also an active area (Xie et al., 2017; Coavoux et al., 2018; Elazar and Goldberg, 2018; Li et al., 2018). An adversary is trained to infer sensitive information jointly with the main model, while the main model is trained to maximize the adversary's loss and minimize the primary learning objective. While we share the same general goal, our aim is not such representations (similar to those with DP) but to release sanitized text for general purposes.

3 Defining (Local) Differential Privacy

Suppose each user holds a document $D = \langle x_i \rangle_{i=1}^{L}$ of L tokens (which can be a character, a subword, a word, or an n-gram), where x_i is from a vocabulary $\mathcal{V}$ of size $|\mathcal{V}|$. For privacy, each user derives a sanitized version $\hat{D}$ by running a common text sanitization mechanism $\mathcal{M}$ over D on local devices. Specifically, $\mathcal{M}$ works by replacing every token x_i in D with a substitution $y_i \in \mathcal{V}$, assuming that x_i itself is unnecessary for NLP tasks while its semantics should be preserved for high utility. The output $\hat{D}$ is then shared with an NLP service provider.

We consider a typical threat model in which each user does not trust any other party and views them as an attacker with access to $\hat{D}$ in conjunction with any auxiliary information (including $\mathcal{M}$).

3.1 (Variants of) Local Differential Privacy

Let $\mathcal{X}$ and $\mathcal{Y}$ be the input and output spaces. A randomized mechanism $\mathcal{M} : \mathcal{X} \to \mathcal{Y}$ is a probabilistic function that assigns a random output $y \in \mathcal{Y}$ to an input $x \in \mathcal{X}$. Every y induces a probability distribution on the underlying space. For sanitizing text, we set both $\mathcal{X}$ and $\mathcal{Y}$ as the vocabulary $\mathcal{V}$.

Definition 1 (ϵ-LDP (Duchi et al., 2013))**.** *Given a privacy parameter* $\epsilon \geq 0$, $\mathcal{M}$ *satisfies* ϵ*-local differential privacy (*ϵ*-LDP) if, for any* $x, x', y \in \mathcal{V}$,

$$\Pr[\mathcal{M}(x) = y] \leq e^{\epsilon} \cdot \Pr[\mathcal{M}(x') = y].$$

Given an observed output y, from the attacker's view, the likelihoods y is derived from x and x' are similar. A smaller ϵ means better privacy due to a higher indistinguishability level of output distributions, yet the outputs retain less utility.

ϵ-LDP is a very strong privacy notion for its homogeneous protection over all input pairs. However, this is also detrimental to the utility: no matter how unrelated x and x' are, their output distributions must be similar. As a result, a sanitized token y may not (approximately) capture the semantics of its input x, degrading the downstream tasks.

LDP over metric spaces. To capture semantics, we borrow the relaxed notion of Metric-LDP (MLDP) (Alvim et al., 2018) originally proposed for location privacy (Andrés et al., 2013) with the distance metric $d(\cdot, \cdot)$ between two locations (*e.g.*, Manhattan distance (Chatzikokolakis et al., 2013)).

Definition 2 (MLDP)**.** *Given* $\epsilon \geq 0$ *and a distance metric* $d : \mathcal{V} \times \mathcal{V} \to \mathbb{R}_{\geq 0}$ *over* $\mathcal{V}$, $\mathcal{M}$ *satisfies*

MLDP or $\epsilon \cdot d(x, x')$*-LDP if, for any* $x, x', y \in \mathcal{V}$,

$$\Pr[\mathcal{M}(x) = y] \le e^{\epsilon \cdot d(x,x')} \cdot \Pr[\mathcal{M}(x') = y].$$

When $d(x, x') = 1 \; \forall x \neq x'$, MLDP becomes LDP. For MLDP, the indistinguishability of output distributions is further scaled by the distance between the respective inputs. Roughly, the effect of ϵ becomes "adaptive." To apply MLDP, one needs to carefully define the metric d (see Section 4.2).

Incorporating ULDP to further improve utility. Utility-optimized LDP (Murakami and Kawamoto, 2019) (ULDP) also relaxes LDP, which was originally proposed for aggregating ordinal responses. It exploits the fact that different inputs have different sensitivity levels to achieve higher utility. By assuming that the input space is split into *sensitive* and *non-sensitive* parts, ULDP achieves a privacy guarantee equivalent to LDP for *sensitive* inputs.

In our context, more formally speaking, let $\mathcal{V}_S \subseteq \mathcal{V}$ be the set of sensitive tokens common to all users, and $\mathcal{V}_N = \mathcal{V} \setminus \mathcal{V}_S$ be the set of remaining tokens. The output space $\mathcal{V}$ is split into the *protected* part $\mathcal{V}_P \subseteq \mathcal{V}$ and the *unprotected* part $\mathcal{V}_U = \mathcal{V} \setminus \mathcal{V}_P$.

The image of $\mathcal{V}_S$ is restricted to $\mathcal{V}_P$, *i.e.*, a sensitive $x \in \mathcal{V}_S$ can only be mapped to a protected $y \in \mathcal{V}_P$. For text, we can set $\mathcal{V}_S = \mathcal{V}_P$ for simplicity. While a non-sensitive $x \in V_N$ can be mapped to $\mathcal{V}_P$, every $y \in \mathcal{V}_U$ must be mapped from $\mathcal{V}_N$, which helps to improve the utility.

3.2 Our New Utility-optimized MLDP Notion

Among many variants of (L)DP notions, we found the above two variants (*i.e.*, ULDP and MLDP) provide useful insight in quantifying semantics and privacy of text data. We thus formulate the new privacy notion of utility-optimized MLDP (UMLDP).

Definition 3 (UMLDP)**.** *Given* $\mathcal{V}_S \cup \mathcal{V}_N = \mathcal{V}$*, two privacy parameters* $\epsilon, \epsilon_0 \geq 0$*, and a distance metric* $d : \mathcal{V} \times \mathcal{V} \to \mathbb{R}_{\geq 0}$*,* $\mathcal{M}$ *satisfies* $(\mathcal{V}_S, \mathcal{V}_P, \epsilon, \epsilon_0)$*-UMLDP, if*
i) for any $x, x' \in \mathcal{V}$ *and any* $y \in \mathcal{V}_P$*, we have*

$$\Pr[\mathcal{M}(x) = y] \le e^{\epsilon d(x,x') + \epsilon_0} \Pr[\mathcal{M}(x') = y];$$

ii) for any $y \in \mathcal{V}_U$*, i.e., from an unprotected set* $\mathcal{V}_U$ *where* $\mathcal{V}_U \cap \mathcal{V}_P = \emptyset$*, there is an* $x \in \mathcal{V}_N$ *such that*

$$\Pr[\mathcal{M}(x) = y] > 0,$$
$$\Pr[\mathcal{M}(x') = y] = 0 \; \forall x' \in \mathcal{V} \setminus \{x\}.$$

Figure 2 summarizes the treatment of UMLDP. It exhibits "invertibility," *i.e.*, $y \in \mathcal{V}_U$ must be "noise-free" and mapped deterministically. Apart from generalizing ϵ in the ULDP definition (recalled in Appendix A.1) into $\epsilon d(x, x')$, we incorporate an additive bound ϵ_0 due to the invertibility, which makes the derivation of ϵ easier. Looking ahead, ϵ_0 would appear naturally in the analysis of our UMLDP mechanism for the invertible case.

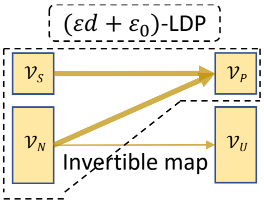

Figure 2: Overview of our new UMLDP notion

UMLDP (and MLDP), as an LDP notion, satisfies the *composability* and *free post-processing*. The former means that the sequential execution of ϵ_1-LDP and ϵ_2-LDP mechanisms satisfies $(\epsilon_1 + \epsilon_2)$-LDP, *i.e.*, ϵ can be viewed as the privacy "budget" of a sophisticated task comprising multiple subroutines, each consumes a part of ϵ such that their sum equals ϵ. The latter means further processing the mechanism outputs incurs no extra privacy loss.

4 Our Privacy-Preserving NLP Pipeline

4.1 Overview

We propose two token-wise sanitization methods with (U)MLDP: SANTEXT and SANTEXT$^+$, which build atop a variant of the exponential mechanism (EM) (McSherry and Talwar, 2007) over the "native" text tokens as both input and output spaces to avoid going to the "cursed dimensions" of token embeddings. EM samples a replacement y for an input x based on an exponential distribution, with more "suitable" y's sampled with higher probability (detailed below). It is well-suited for (U)MLDP by considering the "suitability" as how well the semantics of x is preserved for the downstream tasks (run over the sanitized text y) to remain accurate.

To quantify this, we utilize an embedding model mapping tokens into a real-valued vector space. The semantic similarity among tokens can then be measured via the Euclidean distance between their corresponding vectors. Our base design SANTEXT outputs y with probability inverse proportional to the distance between x and y: the shorter the distance, the more semantically similar they are. SANTEXT$^+$ considers some tokens $\mathcal{V}_N$ in $\mathcal{V}$ are non-sensitive, and runs SANTEXT over the sensitive part $\mathcal{V}_S = V \setminus \mathcal{V}_N$ (*i.e.*, it degenerates to SANTEXT if $\mathcal{V}_S = \mathcal{V}$). For $\mathcal{V}_N$, we tailor a probability distribution to provide UMLDP as a whole.

Algorithm 1: Base Mechanism SanText

```
Input: A private document $D = \langle x_i \rangle_{i=1}^{L}$,
       and a privacy parameter $\epsilon \geq 0$
Output: Sanitized document $\hat{D}$
Derive token vectors $\phi(x_i)$ for $i \in [1, L]$;
for $i = 1, \ldots, L$ do
    Run $\mathcal{M}(x_i)$ to sample a sanitized token
      $y_i$ with probability defined in Eq. (1);
end
Output sanitized $\hat{D}$ as $\langle y_i \rangle_{i=1}^{L}$;
```

With SanText or SanText$^+$, each user sanitizes D into $\hat{D}$ and uploads it to the service provider for performing any NLP task built atop a pretrained LM, *e.g.*, BERT. Typically, the task pipeline consists of an embedding layer, an encoder module, and task-specific layers, *e.g.*, for classification.

Without the raw text, the utility can degrade; we thus propose two approaches for improving it. The first one is to pretrain only the encoder on the sanitized public corpus to adapt to the noise. It is optional if pretraining is deemed costly. The second is to fine-tune the full pipeline on $\hat{D}$'s, which updates both the encoder and task layers.

4.2 Base Sanitization Mechanism: SanText

In NLP, a common step is to employ an embedding model[1] mapping semantically similar tokens to close vectors in a Euclidean space. Concretely, an embedding model is an injective mapping $\phi : \mathcal{V} \to \mathbb{R}^m$, for dimensionality m. The distance between any two tokens x and x' can be measured by the Euclidean distance of their embeddings: $d(x, x') = d_{\text{euc}}(\phi(x), \phi(x'))$. As ϕ is injective, d satisfies the axioms of a distance metric.

Algorithm 1 lists the pseudo-code of SanText for sanitizing a private document D at the user side. The first step is to use ϕ to derive token embeddings of each token[2] x in D. Then, for each x, we run $\mathcal{M}(x)$ to sample a sanitized y with probability

$$\Pr[\mathcal{M}(x) = y] = C_x \cdot e^{-\frac{1}{2}\epsilon \cdot d_{\text{euc}}(\phi(x), \phi(y))} \quad (1)$$

where $C_x = (\sum_{y' \in \mathcal{V}} e^{-\frac{1}{2}\epsilon \cdot d_{\text{euc}}(\phi(x), \phi(y'))})^{-1}$.

The smaller $d_{\text{euc}}(\phi(x), \phi(y))$, the more likely y is to replace x. To boost the sanitizing efficiency, we can precompute a $|\mathcal{V}| \times |\mathcal{V}|$ probability matrix, where each entry (i, j) denotes the probability of outputting y_j on input x_i, upon obtaining $\phi(x)$ for $\forall x \in \mathcal{V}$. Lastly, the sanitized $\hat{D} = \langle y_i \rangle_{i=1}^{L}$ can be released to the service provider for NLP tasks.

Algorithm 2: Enhanced SanText$^+$

```
Input: A private document $D = \langle x_i \rangle_{i=1}^{L}$, a
       privacy parameter $\epsilon \geq 0$, probability
       $p$ for a biased coin, and sensitive $\mathcal{V}_S$
Output: Sanitized document $\hat{D}$
Derive token vectors $\phi(x_i)$ for $i \in [1, L]$;
for $i = 1, \ldots, L$ do
    if $x_i \in \mathcal{V}_S$ then
        Sample a substitution $y_i \in \mathcal{V}_P = \mathcal{V}_S$
          with probability given in Eq. (1) ▷
          Run SanText over $\mathcal{V}_S$ and $\mathcal{V}_P$;
    else
        Output $y_i = x_i$ with prob. $(1 - p)$;
          or $y_i \in \mathcal{V}_P$ with prob. in Eq. (2);
    end
end
Output sanitized $\hat{D}$ as $\langle y_i \rangle_{i=1}^{L}$;
```

4.3 Enhanced Mechanism: SanText$^+$

In SanText, all tokens in $\mathcal{V}$ are treated as sensitive, which leads to excessive protection and utility loss. Following the less-is-more principle, we divide $\mathcal{V}$ into $\mathcal{V}_S$ and $\mathcal{V}_N$, and focus on protecting $\mathcal{V}_S$.

Observing that most frequently used tokens (*e.g.*, a/an/the) are non-sensitive to virtually all users, we use token frequencies for division. A simple strategy, which is also used in our experiments, is to mark the top w of low-frequency tokens (according to a certain corpus) as $\mathcal{V}_S$, where w is a tunable parameter. Looking ahead, this "basic" method already showed promising results. (Further discussion can be found in Section 4.5).

Algorithm 2 lists the pseudo-code of SanText$^+$ with $\mathcal{V}_S = \mathcal{V}_P$ and $\mathcal{V}_N = \mathcal{V}_U$ shared by all users. The first step, as in SanText, is to derive the token embeddings in D. Then, for each token x, if it is in $\mathcal{V}_S$, we sample its substitution y from $\mathcal{V}_P$ with probability given in Eq. (1). (This is equivalent to running SanText over $\mathcal{V}_S$ and $\mathcal{V}_P$.) For $x \in \mathcal{V}_N$, we toss a biased coin. With probability $(1 - p)$, we output y as x (*i.e.*, the "invertibility"). Otherwise, we sample $y \in \mathcal{V}_P$ with probability

$$\Pr[\mathcal{M}(x) = y] = p \cdot C_x \cdot e^{-\frac{1}{2}\epsilon \cdot d_{\text{euc}}(\phi(x), \phi(y))} \quad (2)$$

where $C_x = (\sum_{y' \in \mathcal{V}_P} e^{-\frac{1}{2}\epsilon \cdot d_{\text{euc}}(\phi(x), \phi(y'))})^{-1}$.

As in SanText, we can also precompute two $|\mathcal{V}_S| \times |\mathcal{V}_P|$ and $|\mathcal{V}_N| \times |\mathcal{V}_P|$ probability matrices, which correspond to Eq. (1) and (2), for optimizing

---

[1] We assume that it has been trained on a large public corpus and shared by all users.

[2] For easy presentation, we omit the subscript i later.

the sanitizing efficiency. Lastly, the sanitized $\hat{D}$ of $\langle y \rangle_{i=1}^{L}$ can be released to the service provider.

Theorem 1. *Given* $\epsilon \geq 0$ *and* d_{euc} *over the embedding space* ϕ *of* $\mathcal{V}$*,* SANTEXT *satisfies MLDP.*

Theorem 2. *Given* $(\mathcal{V}_S = \mathcal{V}_P) \subseteq \mathcal{V}$*,* $\epsilon \geq 0$*,* $\epsilon_0 = \ln \frac{1}{p} \geq 0$*, and* d_{euc} *over the embedding space* ϕ *of* $\mathcal{V}$*,* SANTEXT$^+$ *satisfies* $(\mathcal{V}_S, \mathcal{V}_P, \epsilon, \epsilon_0)$*-UMLDP.*

Their proofs are in Appendix A.2.

4.4 NLP over Sanitized Text

With $\hat{D}$'s (shared by the users), the service provider can perform any NLP task. In this work, we focus on those built on a pretrained LM, and in particular, we study BERT as an example due to its wide adoption and superior performance. The full NLP pipeline is deployed at the service provider.

Given a piece of (sanitized) text, the embedding layer maps it to a sequence of token embeddings. The encoder computes a sequence representation from the token embeddings, allowing task-specific layers to make predictions. For example, the task layer could be a feed-forward neural network for multi-label classification of a diagnosis system.

The injected noise deteriorates the performance of downstream tasks as the service provider cannot access the raw texts $\{D\}$. To mitigate this, we propose two approaches – pretraining the encoder and fine-tuning the full pipeline, which allow the tasks to be "adaptive" to the noise to some extent.

Pretraining BERT over sanitized public corpus. Besides $\hat{D}$'s, the service provider can also obtain a massive amount of text that is publicly available (say, the English Wikipedia). It also has access to the sanitization mechanisms, and it can produce the sanitized public text (as how users produce $\hat{D}$'s).

Our key idea is to let the service provider pretrain the encoder (*i.e.*, BERT) over the sanitized public text, making it more "robust" in handling $\hat{D}$'s. We thus initialize the encoder with the original BERT checkpoint and conduct further pretraining with an adapted masked language model (MLM) loss. In more detail, the adapted MLM objective is to predict the *original masked tokens* given the sanitized context instead of the one from the raw public text. We note that this is beneficial for improving the task utility, yet may breach the user privacy as the objective learns to "recover" the original tokens or semantics. In Section 5.4, our results will show that such pretrained BERT indeed improves accuracy, with comparable privacy as in original BERT.

Fine-tuning the full NLP pipeline. After pretraining BERT using sanitized public text, the service provider can further improve the efficacy of downstream tasks by fine-tuning the full pipeline. We assume that the ground-truth labels are available to the service provider, say, inferring from $\hat{D}$'s when they can preserve similar semantics to the raw text. Then, the sanitized text-label pairs are used for training/fine-tuning downstream task models, with gradients back-propagated to update the parameters of both the encoder and task layer. We leave more realistic/complex labeling processes based on sanitized texts as future work.

4.5 Definition of "Sensitivity"

Simply treating the top w of least frequent tokens (*e.g.*, according to a public reference corpus) as the sensitive token set already led to promising results (see Section 5.2). By this definition, stop words are mostly non-sensitive (*e.g.*, for $w = 0.9$ over the sentiment classification dataset we used, $\sim$98% of the stop words are deemed non-sensitive). For context-specific corpus, this strategy is better than merely using stop words, *e.g.*, breast cancer becomes non-sensitive among breast-cancer patients.

Sophisticated machine-learning approaches or other heuristics could also be considered, *e.g.*, training over context-specific reference corpus or identifying tokens with personal (and hence sensitive) information (*e.g.*, names). We leave as future work.

Moreover, the definition of sensitivity may vary across users. Some may consider a token deemed non-sensitive by most other users sensitive. The original ULDP work (Murakami and Kawamoto, 2019) has discussed a personalized mechanism that preprocesses such tokens by mapping them to a set of semantic tags, which are the same for all users. These tags will be treated as sensitive tokens for the ULDP mechanism. Apparently, this approach is application-specific and may not be needed in some applications; hence we omit it in this work.

5 Experiments

5.1 Experimental Setup

We consider three representative downstream NLP tasks (datasets) with privacy implications.

Sentiment Classification (SST-2). When people write online reviews, especially the negative ones, they may worry about having their identity traced via writing too much that may provide hints of authorship or linkage to other online writings. For

Mechanisms	**SST-2**			**MedSTS**			**QNLI**		
	$\epsilon = 1$	$\epsilon = 2$	$\epsilon = 3$	$\epsilon = 1$	$\epsilon = 2$	$\epsilon = 3$	$\epsilon = 1$	$\epsilon = 2$	$\epsilon = 3$
Random	0.4986	0.4986	0.4986	0.0196	0.0196	0.0196	0.5152	0.5152	0.5152
Feyisetan et al. (2020)	0.5099	0.5143	0.5345	0.0201	0.0361	0.0452	0.5162	0.5256	0.5333
SanText	0.5101	0.5838	0.8374	0.0351	0.5392	0.8159	0.5372	0.5598	0.8116
SanText$^+$	**0.7796**	**0.7943**	**0.8516**	**0.4965**	**0.7082**	**0.8162**	**0.7699**	**0.7760**	**0.8131**
Unsanitized	0.9251			0.8527			0.9090		

Table 1: Utilities comparison of sanitization mechanisms under similar privacy levels using the GloVe embedding

this task, we use the preprocessed version in GLUE benchmark (Wang et al., 2019) of (binary) Stanford Sentiment Treebank (SST-2) dataset (Socher et al., 2013). *Accuracy* (w.r.t. the ground truth included in the dataset) is used as the evaluation metric.

Medical Semantic Textual Similarity (MedSTS). Automated processing of patient records is a significant research direction, and one such task is computing the semantic similarity between clinical text snippets for the benefit of reducing the cognitive burden. We choose a very recent MedSTS dataset (Wang et al., 2020) for this task, which assigns a numerical score to each pair of sentences, indicating the degree of similarity. We report the *Pearson correlation coefficient* (between predicted similarities and human judgments) for this task.

Question Natural Language Inference (QNLI). Question-answering (QA) aims to automatically answer user questions based on documents. We consider a simplified setting of QA, namely QNLI, which predicts whether a given document contains the answer to the question. We use the QNLI dataset from GLUE benchmark (Wang et al., 2019).

We implement our sanitized mechanisms using Python and the sanitization-aware training using the Transformers library (Wolf et al., 2020). We use sanitized data to train and test prediction models for all three tasks. We either build vocabularies for the tasks using GloVe embeddings (Pennington et al., 2014) or adopt the same BERT vocabulary (Devlin et al., 2019). Table 2 shows their sizes. Our sanitization-aware pretraining uses WikiCorpus (English version, a 2006 dump, 600M words) (Reese et al., 2010). We start from the `bert-base-uncased` (instead of randomly initialized) model to accelerate the pretraining.

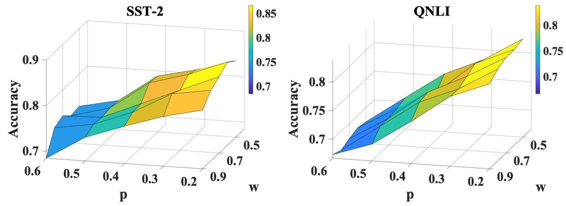

Figure 3: Performance of SanText$^+$ over (w, p) when fixing $\epsilon = 2$ based on the GloVe embedding

We set the maximum sequence length to 512, training epoch to 1, batch size to 6, learning rate to 5e-5, warmup steps to 2000, and MLM probability to 0.15. Our sanitization-aware fine-tuning uses the `bert-base-uncased` model for SST-2/QNLI, and `ClinicalBERT` (Alsentzer et al., 2019) for MedSTS. We set the maximum sequence length to 128, training epochs to 3, batch size to 64 for SST-2/QNLI or 8 for MedSTS, and learning rate to 2e-5 for SST-2/QNLI or 5e-5 for MedSTS. Other hyperparameters are kept default. Our hyperparameters followed the transformer library (Wolf et al., 2020) and popular setups in the original dataset literature (Wang et al., 2019, 2020).

5.2 Comparison of Sanitization Mechanisms

We first compare our SanText and SanText$^+$ with random sanitization and the state-of-the-art of Feyisetan et al. (FBDD). Here, we use the GloVe embedding as in FBDD for a fair comparison. Random sanitization picks a token from the vocabulary uniformly. We set the UMLDP parameters $p = 0.3, w = 0.9$ for SanText$^+$ (while Figure 3 plots the impacts of p and w when fixing $\epsilon = 2$).

Table 1 shows the utility of the four mechanisms for the three selected tasks at different privacy levels. FBDD has a higher utility than random replacements. While both FBDD and SanText are based on word embeddings, SanText does not suffer from the "curse-of-dimensionality" and achieves better utility at the same privacy level. SanText$^+$ achieves the best utilities in all cases since it allows the non-sensitive tokens to be noise-free, lowering the noise and improving the utility.

In terms of efficiency, our SanText and SanText$^+$ are very efficient (*e.g.*, ∼2min for the SST-2 dataset) compared with FBDD (∼117min) when they all run on a 24 core CPU machine. This is because our mechanisms only need to compute the sampling probability once and use the same probability matrix for sampling each time, while FBDD needs to recalculate the additive noise and re-search the nearest neighbor each time.

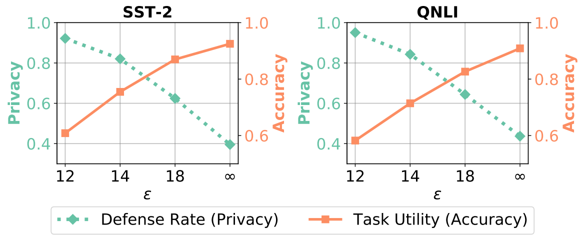

Figure 4: Privacy and Utility Tradeoffs of SANTEXT in terms of Defense Rate (of the Mask Token Inference Attack) versus Accuracy ($\epsilon = \infty$ means "unsanitized.")

Datasets	GloVe embeddings		BERT embeddings	
	$\mathcal{V}$	$\mathcal{V}_S$	$\mathcal{V}$	$\mathcal{V}_S$
SST-2	14,730	13,258	30,522	27,469
MedSTS	3,320	2,989		
QNLI	88,159	79,343		

Table 2: Sizes of vocabularies ($w = 0.9$ for $\mathcal{V}_S$)

5.3 Mask Token Inference Attack

From now on, we adopt the BERT embedding for its superiority. As (U)MLDP is distance-metric dependent, we need to use different ϵ's (*e.g.*, Figure 5) to ensure a similar privacy level, specifically, $\epsilon \cdot d$.

Our sanitization mechanisms provide broad protection for seen/unseen attacks at a fundamental level (by sampling noise to directly replace original tokens) with formally-proven DP, *e.g.*, two guesses of the original token with different styles are nearly probable in an attempt of authorship attribution (Weggenmann and Kerschbaum, 2018) or other "indirect" attacks. Here, we consider a *mask token inference attack* as a representative study to "confirm the theory" by empirically measuring the "concrete" privacy level of sanitized texts.

To infer or recover original tokens given the sanitized text, one can let a pretrained BERT model infer the `MASK` token given its contexts. After all, BERT models are trained via masked language modeling. For each sanitized text of the downstream (private) corpus, we replace each token sequentially by the special token `[MASK]` and input the masked text to the pretrained BERT model to obtain the prediction of the `[MASK]` position. Then, we compare the predicted token to the original token in the raw text. Figure 4 reports the defense rate (the proportion of unmatched tokens to total tokens) and task utility of sanitized texts (by SANTEXT) as well as unsanitized texts on SST-2 and QNLI. We see a privacy-utility trade-off: the more restrictive the privacy guarantee (smaller ϵ), the lower the utility score. Notably, we improve the defense rate substantially with only a small amount of privacy loss (*e.g.*, when $\epsilon = 16$, SANTEXT improves the defense rate by 20% with only 4% task utility loss over the SST-2 dataset in Figure 4).

Datasets	ϵ	**Utility**		Δ_{privacy}
		Original	**+Pretrain**	
SST-2	12	0.6084	**0.6208**	0.0089
	14	0.7548	**0.7731**	0.0101
	16	0.8698	**0.8830**	-0.0046
QNLI	12	0.5822	**0.6037**	0.0076
	14	0.7143	**0.7309**	-0.0047
	16	0.8265	**0.8369**	-0.0039

Table 3: Sanitization-aware pretraining via SANTEXT

5.4 Effectiveness of Pretraining

We then show how the sanitization-aware pretraining further improves the utility but does not hurt the original privacy. Specifically, Table 3 compares the accuracy of sanitization-aware fine-tuning based on the publicly-available `bert-base-uncased` model and our sanitization-aware pretrained one at different privacy levels on SST-2 and QNLI. Our sanitization-aware pretrained BERT models can obtain a 2% absolute gain on average. We conjecture that it can be improved since our pretraining only uses $1/6$ of the data used in the original BERT pretraining and 1 training epoch as an illustration.

To demonstrate that such utility improvement is not obtained by sacrificing privacy, we record the change of defense rate (Δ_{privacy}) in launching mask token inference attacks on the original BERT models and our sanitization-aware pretrained BERT models. As Table 3 confirmed, the privacy level of our sanitization-aware pretrained model is nearly the same as the original (sometimes even better).

5.5 Influence of Privacy Parameter ϵ

We aim at striking a nice balance between privacy and utility by tuning ϵ. To empirically show the influence of ϵ, we report the utility and privacy scores over the SST-2 dataset based on SANTEXT. The utility score is the accuracy over the test set. We define three metrics to "quantify" privacy. Firstly, $N_x = \Pr[\mathcal{M}(x) = x]$, which we estimate by the frequency of seeing no replacement by $\mathcal{M}()$. The output distribution of x has full support over $\mathcal{V}$, *i.e.*, $\Pr[\mathcal{M}(x) = y] > 0$ for any $y \in \mathcal{V}$. Yet, we are interested in the effective support $\mathcal{S}$, a set of y's with cumulative probability larger than a threshold, and then define S_x as its size. S_x can be estimated by the number of distinct tokens mapped from x. Both N_x and S_x can be related to two extremes of the Rényi entropy (Rényi, 1961), defined as

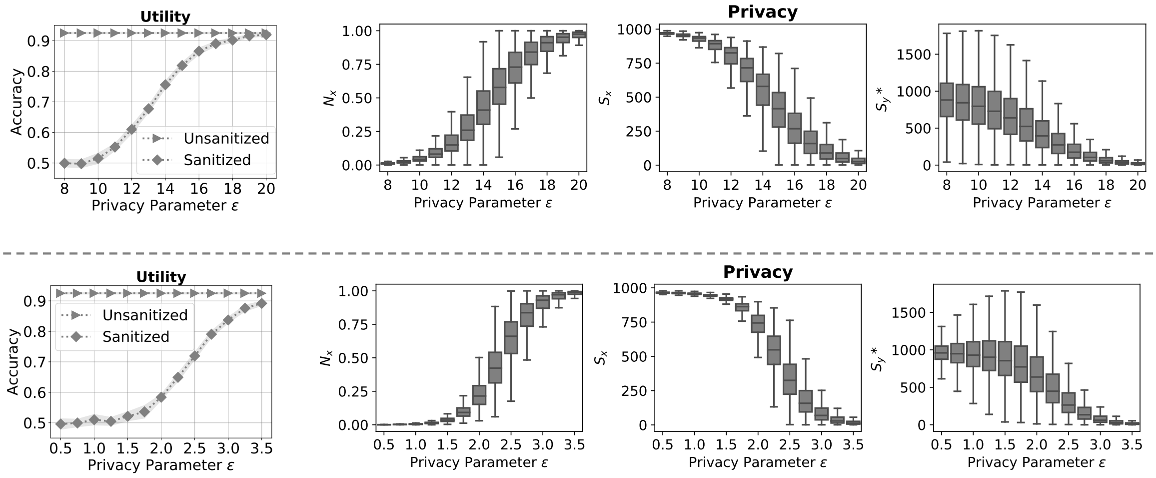

Figure 5: Influence of privacy parameter ϵ of SanText on the utility and privacy (N_x, S_x, S_y^*) based on the SST-2 dataset: The top panel is based on BERT embeddings, and the bottom panel is based on GloVe embeddings.

$H_\alpha(\mathcal{M}(x)) = \frac{1}{1-\alpha}\log(\sum_{y\in\mathcal{V}}\Pr[\mathcal{M}(x) = y]^\alpha)$, with an order $\alpha \geq 0$ and $\alpha \neq 1$. The two extremes are obtained by setting $\alpha = 0$ and $= \infty$, resulting in the Hartley entropy H_0 and the min-entropy H_∞. This implies that we can also approximate H_0 and H_∞ by $\log S_x$ and $-\log N_x$, respectively. Making them large increases the entropy of the distribution.

Another important notion is *plausible deniability* (Bindschaedler et al., 2017), *i.e.*, a set of x's could have led to an output y with a similar probability. We define S_y^* as the set size, estimated by the number of distinct tokens mapped to y.

We run SanText $1,000$ times for the whole SST-2 dataset vocabulary. As Figure 5 shows, when ϵ increases, the utility boosts and N_x increases while S_x, S_y^*, and the privacy level of the mechanism decrease, which gives some intuition in picking ϵ, *e.g.*, for ~40% probability of replacing each token to a different one based on the BERT embeddings (top panel), we could set $\epsilon = 15$ since the median of N_x is ~60% and the accuracy is ~81%.

6 Conclusion

Great predictive power comes with great privacy risks. The success of language models enables inference attacks. There are only a few works in differentially private (DP) text sanitization, probably due to its intrinsic difficulty. A new approach addressing the (inherent) limitation (*e.g.*, in generality) of existing works is thus needed.

Theoretically, we formulate a new LDP notion, UMLDP, which considers both sensitivity and similarity. While it is motivated by text analytics, it remains interesting in its own right. UMLDP enables our natural sanitization mechanisms without the curse of dimensionality faced by existing works.

Practically, we consider the whole PPNLP pipeline and build in privacy at the root with our sanitization-aware pretraining and fine-tuning. With our simple and clear definition of sensitivity, our work already achieved promising performance. Future research in sophisticated sensitivity measures will further strengthen our approach.

Surprisingly, our PPNLP solution is discerning like a cryptographic solution: it is kind (maintains high utility) to the good but not as helpful to the bad (not boosting up inference attacks). We hope our results with different metrics for quantifying privacy can provide more insights in privacy-preserving NLP and make it accessible to a broad audience.

A Supplementary Formalism Details

A.1 Definition of ULDP

Definition 4 (($\mathcal{V}_S, \mathcal{V}_P, \epsilon$)-ULDP (Murakami and Kawamoto, 2019)). *Given* ($\mathcal{V}_S = \mathcal{V}_P$) $\subseteq \mathcal{V}$*, a privacy parameter* $\epsilon \geq 0$*,* $\mathcal{M}$ *satisfies* ($\mathcal{V}_S, \mathcal{V}_P, \epsilon$)*-ULDP if it satisfies the properties:*
i) for any $x, x' \in \mathcal{V}$ *and any* $y \in \mathcal{V}_P$*, we have*

$$\Pr[\mathcal{M}(x) = y] \leq e^{\epsilon} \Pr[\mathcal{M}(x') = y];$$

ii) for any $y \in \mathcal{V}_U$*, there is an* $x \in \mathcal{V}_N$ *such that*

$$\Pr[\mathcal{M}(x) = y] > 0; \Pr[\mathcal{M}(x') = y] = 0 \textit{ for } x \neq x'.$$

A.2 Differential Privacy Guarantee

Proof of Theorem 1. Consider $L = 1$, *i.e.*, $D = \langle x \rangle$. For another document D' with $x' \in \mathcal{V} \setminus \{x\}$ and a possible output $y \in \mathcal{V}$:

$$\begin{aligned}
&\frac{\Pr[\mathcal{M}(x) = y]}{\Pr[\mathcal{M}(x') = y]} \\
=&\frac{C_x \cdot e^{-\frac{1}{2}\epsilon \cdot d_{\text{euc}}(\phi(x),\phi(y))}}{C_{x'} \cdot e^{-\frac{1}{2}\epsilon \cdot d_{\text{euc}}(\phi(x'),\phi(y))}} \\
=&\frac{C_x}{C_{x'}} \cdot e^{\frac{1}{2}\epsilon \cdot [d(x',y) - d(x,y)]} \\
\leq&\frac{C_x}{C_{x'}} \cdot e^{\frac{1}{2}\epsilon \cdot d(x,x')} \\
=&\frac{\sum_{y' \in \mathcal{V}} e^{-\frac{1}{2}\epsilon \cdot d(x',y')}}{\sum_{y' \in \mathcal{V}} e^{-\frac{1}{2}\epsilon \cdot d(x,y')}} \cdot e^{\frac{1}{2}\epsilon \cdot d(x,x')} \\
\leq& e^{\frac{1}{2}\epsilon \cdot d(x,x')} \cdot e^{\frac{1}{2}\epsilon \cdot d(x,x')} = e^{\epsilon \cdot d(x,x')}
\end{aligned}$$

The proof, showing SanText ensures $\epsilon \cdot d(x, x')$-LDP, mainly relies on the triangle inequality of d. To generalize to the case of $L > 1$, we sanitize every token x_i in D independently, and thus:

$$\Pr[\mathcal{M}(D) = \hat{D}] = \prod_{i=1}^{L} \Pr[\mathcal{M}(x_i) = y_i].$$

Then, for any D, D', the privacy bound is given as

$$\frac{\Pr[\mathcal{M}(D) = \hat{D}]}{\Pr[\mathcal{M}(D') = \hat{D}]} \leq e^{\epsilon \cdot \sum_{i=1}^{L} d(x_i, x'_i)},$$

which follows from the composability. □

Proof of Theorem 2. Consider the case $L = 1$ with $D = x$ and $D' = x'$. For $x, x' \in \mathcal{V}_S$, the output y is restricted to $\mathcal{V}_P$, with the proof identical to the above theorem (as SanText is run over $\mathcal{V}_S, \mathcal{V}_P$).

For $x, x' \in \mathcal{V}_N$ and $y \in \mathcal{V}_P$, we have

$$\begin{aligned}
\frac{\Pr[\mathcal{M}(x) = y]}{\Pr[\mathcal{M}(x') = y]} &= \frac{p \cdot C_x \cdot e^{-\frac{1}{2}\epsilon \cdot d_{\text{euc}}(\phi(x),\phi(y))}}{p \cdot C_{x'} \cdot e^{-\frac{1}{2}\epsilon \cdot d_{\text{euc}}(\phi(x'),\phi(y))}} \\
&\leq e^{\epsilon \cdot d(x,x')}.
\end{aligned}$$

For $x \in \mathcal{V}_S$, $x' \in \mathcal{V}_N$, and $y \in \mathcal{V}_P$, we have

$$\begin{aligned}
\frac{\Pr[\mathcal{M}(x) = y]}{\Pr[\mathcal{M}(x') = y]} &= \frac{C_x \cdot e^{-\frac{1}{2}\epsilon \cdot d_{\text{euc}}(\phi(x),\phi(y))}}{p \cdot C_{x'} \cdot e^{-\frac{1}{2}\epsilon \cdot d_{\text{euc}}(\phi(x'),\phi(y))}} \\
&\leq \frac{1}{p} \cdot e^{\epsilon \cdot d(x,x')} = e^{\epsilon \cdot d(x,x') + \epsilon_0}.
\end{aligned}$$

The probability for $x \in \mathcal{V}_N$ is $(1-p)$. The above inequalities thus show that SanText^{+} ensures the properties of UMLDP. Similarly, we use the composability to generalize for $L > 1$. □

A.3 Qualitative Observations

Below, we focus on SanText sanitizing a single token x. We first make two extreme cases explicit.
(1) When $\epsilon = 0$, the distribution in Eq. (1) becomes $\Pr[\mathcal{M}(x) = y] = \frac{1}{|\mathcal{V}|}, \forall y \in \mathcal{V}$. SanText is perfectly private since y is uniformly sampled at random, independent of x. Yet, such a y does not preserve any information of x.
(2) When $\epsilon \to \infty$, we have $\Pr[\mathcal{M}(x) = x] \gg \Pr[\mathcal{M}(x) = y], y \in \mathcal{V} \setminus \{x\}$. $\Pr[\mathcal{M}(x) = x]$ dominates others since $d(x, x) = 0$ and $d(x, y) > 0$. This loses no utility as x almost stays unchanged, yet provides no privacy either.

For a general $\epsilon \in (0, \infty)$, the distribution has full support over $\mathcal{V}$, *i.e.*, we have a non-zero probability for any possible $y \in \mathcal{V}$ such that $\mathcal{M}(x) = y$. Also, given $y, y' \in \mathcal{V}$ with $d(x, y) < d(x, y')$, we have $\Pr[\mathcal{M}(x) = y] > \Pr[\mathcal{M}(x) = y']$. As ϵ increases, $\Pr[\mathcal{M}(x) = y]$ for the y's with large $d(x, y)$ goes smaller (and even approaches 0). This means that the output distribution becomes "skewed," *i.e.*, the outputs concentrate on those y's with small $d(x, y)$. This is good for utility, which stems from the semantics preservation of every token. On the contrary, too much concentration weakens the privacy.

For SanText^{+}, the above results directly apply to the case $x \in V_S$ (as SanText is run over $\mathcal{V}_S$ and $\mathcal{V}_P$). There is an extra p determining whether a $x \in \mathcal{V}_N$ is mapped to a $y \in \mathcal{V}_P$. If so, the results are similar except with an extra multiplicative p. A larger p leads to stronger privacy as the probability $(1 - p)$ of x being unchanged becomes smaller.

C Supplementary Related Works

Privacy is a practically relevant topic that also poses research challenges of diverse flavors. Below, we discuss some "less-directly" relevant works, showcasing some latest advances in AI privacy.

Cryptographic Protection of (Text) Analytics. There has been a flurry of results improving privacy-preserving machine-learning frameworks (*e.g.*, (Lou et al., 2020)), which make use of cryptographic tools such as homomorphic encryption and secure multi-party computation (SMC) for general machine/deep learning. These cryptographic designs can be adapted for many NLP tasks in principle. Nevertheless, they will slow down computations by orders of magnitude since cryptographic tools, especially fully homomorphic encryption, are generally more heavyweight than the DP approaches. One might be tempted to replace cryptography with *ad hoc* heuristics. Unfortunately, it is known to be error-prone (*e.g.*, a recently proposed attack (Wong et al., 2020) can recover model parameters during "oblivious" inference).

A recent trend (*e.g.*, (Wagh et al., 2021)) relies on multiple non-colluding servers to perform SMC for secure training. However, SMC needs multiple rounds of communication. It is thus more desirable to have a dedicated connection among the servers.

Albeit with better utility (than DP-based designs), cryptographic approaches mostly consider immunity against membership inference (Shokri et al., 2017) to be out of their protection scope since DP mechanisms could be applied over the training data before the cryptographic processing.

There is a growing interest in privacy-preserving analytics in the NLP community too. Very recently, TextHide (Huang et al., 2020) devises an "encryption" layer for the hidden representations. Unfortunately, it is shown to be insecure by cryptographers and privacy researchers Carlini et al. (2020a).

Hardware-Aided Approaches. GPU can compute linear operations in a batch much faster than CPU. Nevertheless, we still need a protection mechanism in using GPU, another protection mechanism for the non-linear operations, and their secure integration. In general, utilizing GPU for privacy-preserving machine-learning computations is non-trivial (*e.g.*, see (Ng and Chow, 2021) for an extended discussion).

To exploit the parallelism of GPU while minimizing the use of cryptography, one can resort to a trusted processor (*e.g.*, Intel SGX) for performing non-linear operations within its trusted execution environment (TEE) Note that one still needs to use cryptographic protocols to outsource the linear computation to (untrusted) GPU. Slalom (Tramèr and Boneh, 2019) is such a solution that supports privacy-preserving inference. Training is a more challenging task that was left as an open challenge. Recently, it is solved by Goten (Ng et al., 2021). Notably, both works are from cryptographers but also get recognized by the AI community.

Finally, we remark that the use of TEE is not a must in GPU-enabled solutions. For example, GForce (Ng and Chow, 2021) is one of the pioneering works that proposes GPU-friendly protocols for non-linear layers with other contributions.

Synthesizing Adversarial Negative Responses for Robust Response Ranking and Evaluation

Abstract

Open-domain neural dialogue models have achieved high performance in response ranking and evaluation tasks. These tasks are formulated as a binary classification of responses given in a dialogue context, and models generally learn to make predictions based on context-response content similarity. However, over-reliance on content similarity makes the models less sensitive to the presence of inconsistencies, incorrect time expressions and other factors important for response appropriateness and coherence. We propose approaches for automatically creating adversarial negative training data to help ranking and evaluation models learn features beyond content similarity. We propose mask-and-fill and keyword-guided approaches that generate negative examples for training more robust dialogue systems. These generated adversarial responses have high content similarity with the contexts but are either incoherent, inappropriate or not fluent. Our approaches are fully data-driven and can be easily incorporated in existing models and datasets. Experiments on classification, ranking and evaluation tasks across multiple datasets demonstrate that our approaches outperform strong baselines in providing informative negative examples for training dialogue systems.[1]

1 Introduction

Due to growing availability of dialogue corpora (Li et al., 2017; Zhang et al., 2018; Smith et al., 2020) and the advancement of neural architectures (Radford et al., 2019; Brown et al., 2020; Devlin et al., 2019), dialogue systems have achieved considerable success. As typically formulated, dialogue models generate one or more candidate responses to a provided context, consisting of past dialogue turns. Dialogue ranking (Zhou et al., 2018; Wu et al., 2019) and evaluation models (Tao et al., 2018; Yi et al., 2019; Sato et al., 2020), in turn, are deployed to select and score candidate responses according to coherence and appropriateness.

Ranking and evaluation models are generally trained using true positive responses and randomly selected negative responses, which raises two issues. First, random negative candidates often have low content similarity with the context, and thus models learn to associate response coherence and appropriateness with content similarity (Yuan et al., 2019; Whang et al., 2021; Sai et al., 2020). In real systems, generated response candidates tend to be more similar in terms of content, and so other factors (e.g., time expressions, dialogue acts, inconsistencies) tend to be more important. Second, randomly selecting candidates as negative examples in an open domain context can result in false negatives, leading to misclassification of appropriate responses.

To make dialogue models more robust to the spurious pattern of content similarity, prior work proposed to leverage adversarial and counterfactual examples (Kaushik et al., 2020; Srivastava et al., 2020). A reliable method for creating counterfactual data is to collect human-written adversarial negative responses (Sai et al., 2020), but it is expensive, time-consuming, and difficult to scale. Our goal is to create reliable automatic methods for *synthesizing* adversarial negative responses.

The most common approach to generating natural language adversarial examples is to paraphrase or insert typos, synonyms, or words relevant to the context in the inputs (Iyyer et al., 2018; Ebrahimi et al., 2018; Alzantot et al., 2018; Zhang et al., 2019). In open domain conversations, however, a context can have a wide range of possible responses with varied forms and semantics. Small lexical

	Error category	Description	Sample responses
C-ent	Incorrect entities or actors (R,G)	Incorrect subject or object of verbs or presence of one or more incorrect entities or coreference.	*Context:* I am so happy that you are doing okay. *Response:* My friend is always happy.
C-time	Incorrect Time expressions (R)	Use of incorrect time expressions or tense of verbs.	*Context:* What are you going to do on Monday? *Response:* Yesterday, I celebrated my daughter's wedding anniversary.
C-cont	Contradictory or extraneous details (R,G)	Presence of details which make the response inconsistent within itself or contradict the context	*Context:* A: I don't know why I bothered to come here. B: Did you enjoy your stay? *Response:* I enjoyed the concert a lot.
C-speaker	Incorrect speaker turn (R)	The response is relevant to the conversation but from the wrong speaker.	*Context:* What starting salary would you expect here? *Response:* If you work overtime, I will pay you extra salary.
C-follow	Does not directly address the context (R,G)	The response does not follow immediately from the context.	*Context:* What would you like for main course sir? *Response:* I know very well how to make noodles, and I taught one of my friends.
C-strat	Incorrect strategies (R,G)	Use of incorrect dialogue act, emotion, persona or style	*Context:* I can't find the paper clips. *Response:* Ok, great work.
C-lang	Poor language (G)	Presence of poor grammar, incorrect sentence structures or repetitions	*Context:* Do you have mixed drinks available here? *Response:* Yes. This order is divided by 16 divided for main main ones of order.

Table 1: Error categories prevalent in inappropriate responses with high context-response semantic relatedness. We present 7 categories with their descriptions and sample context and response pairs. For each category we also indicate whether it is frequently observed in Retrieval (R) or Generation (G) models. Models which simply learn to associate response coherence with content similarity often ignore these errors. Our approaches create adversarial negative data for training dialogue models by introducing such errors in context relevant utterances.

variations via substitutions and paraphrasing do not provide adequate coverage over the possible space of adversarial responses, and they can also lead to generation of false negatives due to the open-ended nature of dialogues. Creating adversarial dialogue responses is thus different, and can be more challenging than in other natural language domains.

We propose two approaches for adversarial response creation: 1) a mask-and-fill approach that corrupts gold responses related to the context but retains content similarity, and 2) a keyword-guided generative approach that uses concepts from the context to generate topically relevant but incoherent responses. These approaches do not require additional annotations, are black-box (do not need access to model parameters), and are easily adapted to new datasets and domains.

The main contributions of this paper are: 1) We identify and discuss error patterns present in retrieval and generation model outputs, which are difficult to detect due to high content similarity; 2) To the best of our knowledge, we are the first to propose automatic approaches for creating adversarial responses for dialogue model training in a black-box setting; and, 3) We demonstrate that our proposed approaches achieve better performance compared to strong baselines on two datasets on dialogue classification, ranking and evaluation tasks.

2 Properties of Adversarial Responses

Models trained using randomly sampled negative examples tend to assign high scores to responses with high content similarity with the context, and often ignore other important factors necessary for response appropriateness and coherence. Therefore, we aim to generate adversarial negative responses which have high content similarity with the context, but which still possess factors rendering the responses inappropriate to the context. We present the categorization of such factors or error types which can make a response inappropriate in Table 1. For each category, we provide its description and sample context-response pairs. To create this categorization, we manually analyzed responses present in outputs of generative models, candidates of retrieval sets, and human written adversarial dialogue responses (Sai et al., 2020). Categories C-ent, C-time and C-cont are errors related to various inconsistencies and logical flaws in the responses and indicate poor response *appropriateness*. Categories C-speaker, C-follow and C-strat are error types specific to the dialogue setting and indicate poor response *coherence*. Category C-lang indicates poor response *fluency*. Our categorization of errors is inspired by the categorization suggested by Pagnoni et al. (2021) for factuality of summarization, and Higashinaka et al. (2019); Ko et al.

(2019) and Sato et al. (2020) for dialogue. These categories inform our approaches as well as error analysis.

3 Methodology

For a given dialogue context C and its gold response R_g, our goal is to generate an adversarial response R_a such that while achieving high scores from dialogue ranking or evaluation models, it should not be a valid response to the context C. Dialogue ranking and evaluation models trained with such hard synthetic negative responses should learn to associate response relevance with features beyond content similarity, and hence become robust against spurious features.

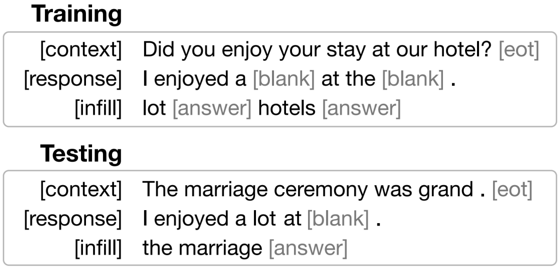
The adversarial responses should satisfy the following criteria: 1) have high content similarity with input contexts; 2) have one or more errors (Table 1) which make the response inappropriate to the context; 3) be hard training examples, that is, they should likely be misclassified by current models as correct; and 4) sufficiently cover errors which occur naturally in model generated responses and retrieval candidates, and therefore they should be plausible and diverse. We propose two approaches for synthesizing adversarial negative examples - a mask-and-fill approach and a keyword-guided generation approach which we discuss next.

3.1 Mask-and-fill Approach

This approach modifies and corrupts original utterances related to a context as shown in Figure 1. It consists of two steps: 1) masking, where one or more tokens of an original utterance are masked out; and 2) infilling, where the masked out tokens are substituted with new tokens. For a context C, the set of original utterances consists of:

- Set of ground truth responses of the context - R_g.
- Set of utterances from the context - U_c.
- Set of retrieved responses based on context - R_e.

Masking: We use the hierarchical masking function from Donahue et al. (2020) which selectively masks spans at the granularities of words, n-grams, and sentences. We apply the masking function to each utterance multiple times to get up to 3 masked versions per utterance. Each utterance is constrained to have at least two masked spans. The spans are selected randomly for masking following Donahue et al. (2020).



Training

[context] Did you enjoy your stay at our hotel? [eot]
[response] I enjoyed a [blank] at the [blank] .
[infill] lot [answer] hotels [answer]

Testing

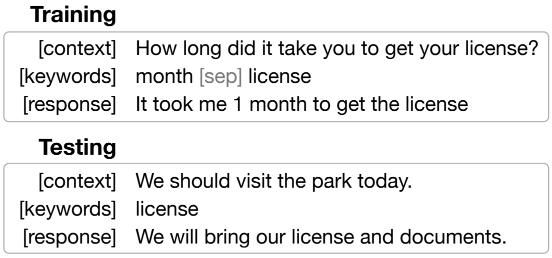
[context] The marriage ceremony was grand . [eot]
[response] I enjoyed a lot at [blank] .
[infill] the marriage [answer]

Figure 1: *Mask-and-fill* approach using ILM model. ILM is trained to infill n-grams in place of blanks in a response. Tokens after [infill] replace the [blank] tokens. During training, *Mask-and-fill* learns to infill responses conditioned on the correct context. During testing, it infills the response conditioned on a random context which introduces errors in the response.

Infilling: We extend the Infilling Language Model (ILM) from Donahue et al. (2020) for dialogue response infilling (Figure 1). The ILM model is a GPT-2 (Radford et al., 2019) based language model. For any piece of text t with some spans masked with [blank] tokens, it is trained to predict the blanked spans in t as a sequence generation problem. Each blank is infilled with an n-gram which can consist of one or more tokens. For generating adversarial responses, infilling is done by conditioning on random contexts C_{rand} instead of the original context C to introduce various categories of errors (Table 1). For example in Figure 1, conditioning on a random context leads to the infilling of “the marriage” in the response, introducing error of type C-ent. For the context “Did you stay your stay at our hotel?” it generates a response “I enjoyed at lot at the marriage”. By corrupting the three types of utterances R_g, U_c and R_e, this approach is able to introduce errors covering the 7 categories in Table 1.

Preventing false negatives: Accidentally incorporating false negatives during training can lead to the model learning to misclassify appropriate responses. However due to the open-ended nature of dialogue responses, preventing generation of false negatives is not trivial. In addition to conditioning on random contexts, we incorporate the following mechanisms during infilling to further reduce false negative generation:

- *Semantics of substitution*: We only select token substitutions which were not present in the tokens which were blanked. We also lower the generation probability of the blanked tokens’ top 10 related words based on GloVe embedding (Pennington et al., 2014) similarity by a factor of 100. This ensures that the blanks are not infilled by the originally blanked tokens or any related words.
- *Degree of substitution* - To ensure that the gen-



Training

[context]	How long did it take you to get your license?
[keywords]	month [sep] license
[response]	It took me 1 month to get the license

Testing

[context]	We should visit the park today.
[keywords]	license
[response]	We will bring our license and documents.

Figure 2: Keyword-guided approach for adversarial response generation. During training, the model learns to generate a response conditioned on its keywords and the correct context. During testing, it generates the response conditioned on a random context and keywords extracted from the correct context. The generated response thus shares content with the test context but does not directly address the context.

erated negative response is sufficiently different from the original utterance, we filter out the original utterance if the number of words in the utterance after stop-word removal is less than 2. We also filter a generated response if the difference in count of non stop-words between the original and generated response is less than 2.

Improving fluency: The ILM model often generates responses with poor grammar or structure. To improve the fluency of the adversarial response sets, we first generate up to 4 different infilled variations of the masked original utterances, then score them using a GPT-2 based scorer named lm-scorer[2]. We then select the desired number of responses from this larger set.

3.2 Keyword-guided Approach

This approach generates adversarial responses using keywords from the context as guidance, as shown in Figure 2. The base generative architecture is a GPT-2 based dialogue model and it is trained to generate responses conditioned on the context and the response keywords. For adversarial response generation, the generation is conditioned on a random context C_{rand} and keywords from the test context C. In Figure 2, for the context "How long did it take you to get your license?" it generates a response "We will bring our license and documents." To create the keyword set K for a response, the model selects n number of keywords randomly from the set of all keywords extracted from the context C, where n is chosen randomly between 1 to 3 for every context. Keyword extraction is performed using Rake (Rose et al., 2010). We call this model *Key-context*. Since the generation is conditioned on keywords from context C, the generated response shares some content and semantics with the test context. However, since it is also conditioned on a random context C_{rand}, the generated response also incorporates entities, time expressions, speaker role, dialogue act, and other details based on C_{rand}. Since the generation model is not perfect, it also introduces errors related to fluency. Hence, the model is able to introduce errors covering the 7 categories in Table 1.

Key-context only uses keywords from the context to induce content similarity with the context. However, responses can have high content similarity due to the presence of similar concepts rather than just keywords. To introduce content similarity at concept level, we expand the keyword set K with their top 10 most related words based on their GloVe embeddings. We use the gensim library[3] to find the most related words. For example, the related words for the keyword "christmas" are "holidays" and "easter". We replace a keyword in keyword set K with one of its related words with a probability of 0.5. We call this variant *Key-sem*.

3.3 Classification Model

Our classification model architecture is based on the Speaker-Aware Bert (SA-Bert) model (Gu et al., 2020). Given a dialogue context $C = \{C_1, C_2, \ldots, C_h\}$ with C_k denoting k_{th} utterance in the context, a response r and a label $y \in \{0, 1\}$, the goal of the dialogue model M is to learn a score $s(C, r)$ by minimizing cross-entropy loss function for the binary classification task. To calculate $s(C, r)$, C and r are concatenated, with a prepended [CLS] token. The output vector $\mathbf{E}_{[CLS]} \in \mathbb{R}^H$ for the [CLS] token is used as the aggregated representation for the context-response pair classification. The final prediction is made as $\hat{y} = softmax(\mathbf{W}\mathbf{E}_{[CLS]})$, where $\mathbf{W} \in \mathbb{R}^{2 \times H}$. SA-Bert model incorporates speaker information in two ways. First, an additional speaker embedding is added to the token representations which indicates the speaker's identity for each utterance. Second, a [EOT] token is added at the end of each speaker turn. Before fine-tuning Bert model on the classification task, we first adapt Bert to the dataset by using the standard masked language model objective (Devlin et al., 2019).

4 Experiments

We test our approaches and baselines on dialogue classification, ranking and evaluation tasks.

4.1 Training Details

We use the base-uncased checkpoints for BERT (Devlin et al., 2019) and ELECTRA (Clark et al., 2020) from the Hugging Face transformers library (Wolf et al., 2020). We trained the models with maximum sequence length of 128, maximum number of training epochs set to 3, Adam optimizer with initial learning rate of 5e-5 with linear decay, batch size of 60 per GPU on machines with 4 Nvidia 2080Ti GPUs. For generation, we use temperature of 0.9, nucleus sampling with p equal to 0.9 and minimum length of 5. We repeat each experiment three times (five times for BERT-based models) with different random seeds, use the validation split to select the best model, and report the mean metric values. Validation was done every 200 batches.

4.2 Experimental Setup

4.2.1 Datasets

We use two open-domain dialogue datasets: *DailyDialog++* (Sai et al., 2020) and PersonaChat (Zhang et al., 2018). DailyDialog++ consists of 16900 dialogue contexts in train set, 1028 in validation set and 1142 in the test set. Each context contains 5 positive responses and 5 random negative responses. It also contains 5 adversarial responses per context collected through crowdsourcing where annotators were instructed to create negative responses with high content similarity with the context. A subset of 9259 out of the 16900 training contexts have 5 human-written adversarial negative responses. It has two test sets, adversarial test set and random test set, based on the type of the negative response. *PersonaChat* dataset (Zhang et al., 2018) is a corpus of human-human persona-conditioned conversations consisting of 8938 dialogues in the train set. We sample 2 random context-response pairs from each dialogue with a total of 17876 contexts for training. We prepend the persona utterances to the dialogue contexts in our experiments. Since there is no human-created adversarial test set available for PersonaChat dataset, we construct an artificial adversarial dataset by randomly selecting an utterance from the dialog context and inserting it in the set of candidate responses following Jia and Liang (2017) and Whang et al. (2021). The adversarial test set for each context consists of the ground truth response, one utterance selected from the dialog context, and 8 random negative responses. The random test set consists of 9 random negative responses.

4.2.2 Metrics

For classification task, we report the accuracy following (Sai et al., 2020). For ranking task, we report standard ranking metrics - Recall $R_n@k$ and mean reciprocal rank (MRR). For DailyDialog++, n is 6 in Recall as candidates consist of one positive response with 5 negative responses. For PersonaChat, n is 10. For both classification and ranking tasks, we report results separately for the adversarial and the random test sets.

The dialogue evaluation task comprises of scoring or rating a response for its quality. For this task, we report the correlation of model scores with human provided ratings. We leverage the human ratings released by the following sources: 1) 600 ratings for response "sensibility" from (Zhao and Kawahara, 2020) with inter-rater agreement > 0.6 (Krippendorff's α (Krippendorff, 2018)). The responses consist of outputs from hierarchical recurrent encoder decoder (HRED) model with Attention (Serban et al., 2016) and Variational HRED model with attention (Serban et al., 2017); 2) 700 ratings for response quality from (Zhao et al., 2020). The responses are from 6 different generative models - Seq-2-Seq (Sutskever et al., 2014), attentional Seq-2-Seq, HRED, VHRED, GPT2-small, and GPT2-medium (Wolf et al., 2019) with greedy decoding, ancestral sampling, and nucleus sampling based decoding (Holtzman et al., 2020). The inter-rater agreement is 0.815 (Krippendorff's α), and 3) Since the first two sources do not cover retrieval model outputs, we additionally collect quality ratings for 100 responses from a retrieval model's (Poly-Encoder (Humeau et al., 2020)) selected responses and 100 human written responses with moderate inter-annotator agreement (Cohen's Kappa 0.45 (Cohen, 1968)). All data points belong to the Dailydialog dataset and ratings are scaled between 0–1. By combining these sources we have a total of 1500 ratings for different context-response pairs.

4.2.3 Baselines

We compare the following approaches of creating adversarial negative response sets.

Model	Approach	Adversarial test set			Random test set		
		Accuracy	R@1	MRR	Accuracy	R@1	MRR
Poly-encoder	Random	-	0.684	0.806	-	**0.849**	**0.914**
	Mask-and-fill (Ours)	-	0.758	0.856	-	0.821	0.897
	Key-sem (Ours)	-	**0.788**	**0.877**	-	0.828	0.902
	Human	-	0.847	0.913	-	0.831	0.902
Electra	Random	77.74	0.915	0.748	89.58	0.957	**0.927**
	Mask-and-fill (Ours)	**87.24**	0.945	**0.893**	**89.61**	**0.959**	**0.927**
	Key-sem (Ours)	86.24	**0.951**	0.881	89.47	0.957	0.924
	Human	91.94	0.984	0.967	87.95	0.944	0.911
Bert	Random	77.82	0.906	0.742	**89.34**	**0.959**	**0.923**
	Semi-hard (Li et al., 2019)	79.05	0.913	0.756	89.32	0.956	**0.923**
	Token-subs (Kryscinski et al., 2020)	77.23	0.901	0.783	88.60	0.950	0.906
	BM25 (Karpukhin et al., 2020)	84.42	0.936	0.872	87.68	0.948	0.902
	Mask-and-fill (Ours)	**87.45**	**0.946**	**0.904**	88.32	0.951	0.918
	Key-context (Ours)	86.23	0.939	0.891	88.16	0.953	0.922
	Key-sem (Ours)	87.02	0.944	0.897	89.31	0.954	0.916
	Human (Sai et al., 2020)	91.22	0.987	0.973	88.04	0.943	0.901

Table 2: Performance on classification and ranking tasks on DailyDialog++ test sets. Mask-and-fill and Key-sem approaches consistently perform the best across all model architectures compared to baselines on the Adversarial test set, just short of models trained with human created adversarial data. Poly-encoder's accuracy is not available as it ranks candidates relative to each other.

Human (Sai et al., 2020) Human written adversarial responses.

Random Responses sampled from random contexts.

Semi-hard (Li et al., 2019) Sampling scheme which selects samples from a batch based on their similarity scores with a margin of α from the positive response score. We perform static sampling and use Sentence-Bert (Reimers and Gurevych, 2019) for semantic similarity calculation with α set to the recommended value of 0.07.

Token-subs (Kryscinski et al., 2020) Training data is generated by applying a series of rule-based transformations on the positive responses. Transformations include pronoun, entity and number swapping, sentence negation and noise injection.

BM25 Top responses returned by BM25 (Robertson and Zaragoza, 2009) based on similarity with the context. Any ground truth response is removed from this response set if present by chance. This baseline is inspired from Karpukhin et al. (2020) and Lin et al. (2020) and has shown strong performance in passage and response retrieval.

Mask-and-fill Our approach that infills utterances conditioned on random contexts.

Key-context Our approach that generates responses conditioned on test context keywords and random context history.

Key-sem Our approach similar to Key-context which additionally conditions on words semantically related to the keywords in the context.

For each context, adversarial train sets are created by adding 5 random negative responses to the set of 5 negative responses created from the above approaches. If an approach create more than 5 responses, we randomly select 5 from them.

For dialogue evaluation, we compare the above approaches with BLEU, METEOR (Banerjee and Lavie, 2005), embedding based metrics SkipThought (Kiros et al., 2015), Vec Extrema (Forgues et al., 2014), and RUBER (Tao et al., 2018) and BERTScore (Zhang et al., 2020a).

4.2.4 Models

We experiment with following architectures for ranking and evaluation models in our experiments: 1) Bert (Devlin et al., 2019). We use the SA-Bert model (Gu et al., 2020), 2) Electra (Clark et al., 2020), pre-trained with a replaced token detection objective and employs a generator-discriminator framework, and 3) Poly-encoders (Humeau et al., 2020), allows for fast real-time inference by precomputing each candidate response representation once, and then ranking candidate responses for retrieval by attending to the context.

4.3 Results and Discussion

In this section, we compare the performance of our approaches with the baselines on dialogue classification, ranking and evaluation tasks.

Performance on classification Our proposed approaches Mask-and-fill and Key-sem achieve the highest classification accuracy on the adversarial test set (Table 2), a few percentage short of the Human baseline. The closest baseline is BM25 which has a gap of 3% in accuracy compared to our

Approach	Adversarial test set		Random test set	
	R@1	MRR	R@1	MRR
Random	0.905	0.820	0.963	**0.914**
Semi-hard	0.906	0.820	**0.964**	0.913
Token-subs	0.895	0.825	0.958	0.901
BM25	0.925	0.859	0.940	0.874
Mask-and-fill (Ours)	**0.933**	**0.871**	0.952	0.890
Key-sem (Ours)	0.920	0.856	0.947	0.884

Table 3: Performance on ranking task on PersonaChat dataset with Bert architecture. Our approaches perform better than all baselines on the adversarial test set.

Approach	Pearson	Spearman
BLEU-2	0.046	0.004
METEOR (Banerjee and Lavie, 2005)	0.081	0.007
SkipThought (Kiros et al., 2015)	0.059	0.069
Vec Extrema (Forgues et al., 2014)	0.157	0.150
BERTScore (Zhang et al., 2020a)	0.208	0.198
RUBER (Tao et al., 2018)	0.253	0.282
Random	0.296	0.313
Semi-hard (Li et al., 2019)	0.299	0.315
BM25 (Karpukhin et al., 2020)	0.310	0.350
Token-subs (Kryscinski et al., 2020)	0.324	0.388
Mask-and-fill (Ours)	0.338	0.361
Key-sem (Ours)	**0.382**	**0.401**
Human (Sai et al., 2020)	0.348	0.371

Table 4: Comparison of approaches on dialogue evaluation. Trainable metrics are based on Bert architecture. For all entries except for the ones underlined, t-test *p-value* < 0.05. Mask-and-fill and Key-sem perform better than all baselines including the Human baseline.

approaches. Token-subs, which applies transformations on positive responses to corrupt them, does not fair well on this task. This indicates that simple transformations do not provide good coverage of semantic variations present in the adversarial test responses. Our approaches achieve similar performance across different model architectures, demonstrating their generalizability. Unsurprisingly, the Human baseline performs strongly as the training and test data were created in the same manner and have similar distributions. On the random test set, the performance of all approaches is either very close or lower than the Random baseline. Since the similarity between correct responses and the context is generally a lot higher than between random responses and the context in the random test set, Random baseline performs better since it associates coherence mostly with semantic similarity. Finally, our analysis shows that all baselines tend to assign low scores to valid responses which do not address a context directly. For example, for the context "Will you join us for the concert?", if the response is "It is supposed to rain this week.", models assign it a low score. Such scenarios require understanding of social and commonsense related factors. We leave addressing this limitation to future work.

Performance on ranking On the DailyDialog adversarial test set, Mask-and-fill and Key-sem approaches achieve the best Recall and MRR, closely followed by BM25 baselines (Table 2). The trends of the ranking metrics are similar to those observed for accuracy metrics. Our approaches perform better than the Human baseline on the random test set. On PersonaChat dataset, Mask-and-fill and Key-sem perform better than the baselines (Table 3), especially on the adversarial test set. This demonstrates the extensibility of our approach across datasets. Mask-and-fill performs better than Key-sem as the keyword sets contain a lot of keywords from the persona because of which responses have high content similarity with the persona rather than with the context. The poor performance of the Random baseline provides evidence that training models using random negative candidates does not make the models robust against hard test cases during testing. BM25 is a strong baseline for both datasets since retrieved responses also provide coverage over errors of various categories. However, retrieved response quality and diversity depends on the size of the retrieval pool. Furthermore, a stronger retrieval mechanism can lead to higher false negatives. While the variation in BM25 response sets is constraint by the size of the dataset, and they provide lesser coverage over categories C-cont, C-strat and C-lang (Table 1), our approaches have no such constraints.

Performance on dialogue evaluation To study the performance of various approaches on real systems, we compare them on the task of Dialogue evaluation or scoring. We measure the correlation between the scores predicted by the approaches in Table 4 with human provided ratings. Reference based metrics like BLEU-2, METEOR, SkipThought and Vec Extrema achieve very low correlations, similar to findings reported in prior art (Liu et al., 2016; Gupta et al., 2019). BERTScore and RUBER achieve moderate correlation. Our approach Key-sem achieves the best correlations, followed by Mask-and-fill. BM25's performance is lower than that of our approaches, but it is higher than the Random and Semi-hard approaches. Although Token-subs did not achieve high performance on the classification and ranking tasks, it performs well on this task. This is likely because real model outputs contains more of

Context	A: Julia, will you be my wife? B: I'm sorry, Steven. C: Please, Julia, I have made proposal to you five times . I really want to share the rest of my life with you.
Random	(1) Yes of course it's a promise. (2) It's better to go somewhere else. (3) Let me first look at your work, how you have done it. (4) Being in love is a deep experience while having a crush is shallow. (5) Sometimes I don't understand, what is your problem?
Mask-and-fill	(1) You can't force me for to do that. They are designed for people of all ages and religions. (2) There you are. I'll have to make my own lunch! (3) I majored in economics. I really want i hope i can get some practical experience in life with you. (4) We will go to, and to meet some of the children who are visiting at school. (5) It takes time to learn. Bless you, baby!
Key-sem	(1) And what about the potatoes? Steven, i don't know. (2) Sorry, there is no problem. (3) Your wife didn't like it. Please don't tell me she is really interested in gardening. (4) I really want to go inside. It's really cold outside. (5) Really? I really want to pay a visit. I really want to spend the rest of my time enjoying this meal.
Human	(1) I want to finish my home work by five and then I am going to take rest. (2) Follow these five tips, and you'll write a winning project proposal every time. (3) I met my wife a three to four times before the marriage. (4) Its difficult to live a life in a Dorze tribal area. (5) I shared a large number of ideas with the wedding planner.

Table 5: Sample adversarial responses from various approaches. Random responses are sampled from random dialogues. Human written responses are from the DailyDialog++ dataset. Mask-and-fill and Key-sem approaches create responses which are semantically related and yet inappropriate responses to the context.

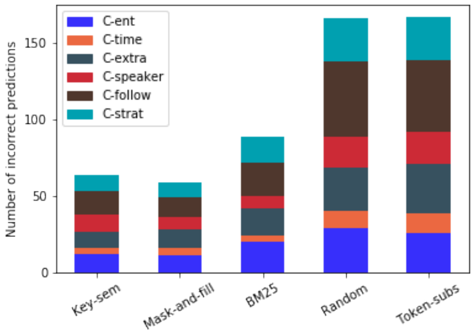

Figure 3: Analysis of error types for different approaches on DailyDialog++ predictions. C-lang error type is not present in DailyDialog++. Mask-and-fill and Key-sem achieve a more uniform distribution over error categories compared to other approaches.

the factual inconsistencies and contradictions that this approach captures, than what the adversarial test sets contain. Key-sem performs better than Mask-and-fill on evaluation since while Mask-and-fill only modifies utterances related to the context, Key-sem can freely generate more diverse adversarial responses for training. Also, Key-sem achieves higher correlation than Human baseline. This may be because it is difficult for humans to create erroneous responses with distributions similar to the ones in model generated or selected responses, especially error types like C-speaker, C-strat and C-lang. In contrast, our approaches provide good coverage over all error types.

Analysis of errors types We analyze the classification outputs of various approaches on the DailyDialog++ adversarial test set and report the types of misclassifications by each approach in Figure 3. We first select a subset of test data where at least one of the approaches misclassifies the adversarial response as positive. We then manually categorize the types of errors presented in Table 1 for 200 randomly selected contexts from this subset. Each response can have multiple error types. C-follow and C-extra are the dominant error types which are misclassified by baselines Random, BM25 and Token-subs. Key-sem and Mask-and-fill approaches achieve improvement in all error types compared to baselines and have a more uniform error distribution. While Key-sem performs better on C-extra, Mask-and-fill is better on C-follow and C-speaker.

Adversarial response examples We present sample responses from our approaches along with Random and Human baseline responses in Table 5. Random approach generates responses which are easily distinguishable from ground truth responses. Mask-and-fill approach modifies either the ground truth response, utterances from the context or BM25 retrieved responses. It modifies these utterances to introduce corruptions such as non-contextual tokens, extraneous entities, incorrect time expressions, affective words or contradictions which makes the response either inappropriate or incoherent to the context, but it remains topically similar to the context. In Key-sem the dialogue acts, some entities and other tokens of the generated response depend on a random context the response is conditioned on, which also makes the response inappropriate or incoherent to the context.

5 Related Work

Dialogue response ranking and evaluation are important tasks in dialogue domain because even the recent large pretrained-language model based architectures (Zhang et al., 2020b; Humeau et al., 2020; Adiwardana et al., 2020; Roller et al., 2021; Gupta et al., 2021) have been shown to be susceptible to creating inconsistent, ungrammatical and incoherent responses (Roller et al., 2021). Traditional word-overlap based metrics like BLEU have been shown to be ineffective for dialogue response scoring (Liu et al., 2016; Gupta et al., 2019). Recently trainable metrics such as ADEM (Lowe et al., 2017), RUBER (Ghazarian et al., 2019) and USR (Mehri and Eskenazi, 2020) have been proposed for these tasks. However, since they are trained using negative samples obtained from random contexts, they are also prone to the spurious pattern of content similarity.

Adversarial or counterfactual data creation techniques have been proposed for applications such as evaluation (Gardner et al., 2020; Madaan et al., 2020), attacks (Ebrahimi et al., 2018; Wallace et al., 2019; Jin et al., 2020), explanations (Goodwin et al., 2020; Ross et al., 2020) or training models to be robust against spurious patterns and biases (Garg et al., 2019; Huang et al., 2020). Adversarial examples are crafted through operations such as adding noisy characters (Ebrahimi et al., 2018; Pruthi et al., 2019), paraphrasing (Iyyer et al., 2018), replacing with synonyms (Alzantot et al., 2018; Jin et al., 2020), rule based token-level transformations (Kryscinski et al., 2020), or inserting words relevant to the context (Zhang et al., 2019). While these approaches are optimized to change the predictions of a target model by perturbing the inputs, our approaches are more general and are not optimized towards any target model. Polyjuice (Wu et al., 2021) and FactCC (Kryscinski et al., 2020) proposed approaches for model-agnostic general-purpose counterfactual generation. These approaches change the model's prediction by creating small edits through substitutions and insertions to the inputs. They are not applicable to our setting where we aim to flip the gold label, that is, convert a valid response to an adversarial response, while the model prediction should ideally remain the same to create hard training examples. Furthermore small perturbations do not provide good coverage over the adversarial response space and can create false negative responses. Adversarial semantic collisions (Song et al., 2020) aims to generate texts that are semantically unrelated but judged as similar by NLP models to expose model vulnerabilities. However, the outputs which are unrelated to the context are not useful for adversarial training as they are easy to classify.

Finally, negative sampling strategies have also been studied for creating hard negative samples in context of visual embeddings (Faghri et al., 2018; Guo et al., 2018), knowledge graphs (Kotnis and Nastase, 2017), document retrieval (Saeidi et al., 2017; Karpukhin et al., 2020) and response retrieval (Li et al., 2019; Lin et al., 2020). In this work we compare and build upon past work and are the first to propose generative approaches for adversarial negative response creation in dialogue.

6 Conclusion

This paper introduces approaches for synthesizing adversarial negative responses for training more robust dialogue response ranking and evaluation models. To synthesize a rich and comprehensive set of responses, we present and analyze categories of errors which affect the models. Our proposed approaches do not require any manual annotation and achieve high performance in dialogue classification, ranking and evaluation tasks across two datasets. These results demonstrate the promise of synthetic negative examples for improving open domain dialogue. Future work, we will explore synthesizing adversarial test sets and methods for finer grained, controlled adversarial response generation.

A Quality of negative candidates

We perform a human evaluation experiment to test the number of false negative responses created by the different approaches. Three in-house annotators were asked to go through the set of 5 adversarial negative responses from 5 different approaches for 100 randomly selected contexts. They were instructed to report the number of responses which are appropriate responses for the context, which in this case is the number of false negatives. After annotating separately, annotators finally discussed the responses marked as appropriate and aggregated the results. We observe that Human baselines responses had 2, Random baseline had 5, Mask-and-fill had 3, Key-sem had 4 and BM25 had 10 false negative responses in the set of 500 responses (100 contexts, with 5 adversarial responses each). This shows that our approaches do not generate high number of false negatives. BM25 on the other hand leads to a relatively higher number of false negatives which can impede the learning process of the models.

B Experiments with Masking

We experiment with two procedures for masking in the Mask-and-fill approach: 1) Random masking, which masks contiguous chunks of tokens some probability p. We leverage the masking function from (Donahue et al., 2020) which can selectively mask spans at the granularities of words, n-grams, and sentences. 2) Importance masking, which keeps the most important tokens in a response relevant to the context and masks the rest. For Importance masking, we leverage the matching model from (Cai et al., 2019) which is trained to estimate the sequence-level quality $s(q, r)$ of a response r for a given query q. They decompose the sequence level matching score between a context and a response into a set of token-level scores as follows:

$$
\begin{aligned}
s(q, r) &= \mathbf{x}_q^T W^s \mathbf{x}_r \\
&= \mathbf{x}_q^T W^s \sum_{k=1}^{m} \omega_k \left(\mathbf{r}_k + \mathbf{e}_{r_k}\right) \\
&= \sum_{k=1}^{m} \omega_k \mathbf{x}_q^T W^s \left(\mathbf{r}_k + \mathbf{e}_{r_k}\right) \quad = \sum_{k=1}^{m} \omega_k s_k
\end{aligned}
$$

where $s_k = \mathbf{x}_q^T W^s \left(\mathbf{r}_k + \mathbf{e}_{r_k}\right)$, and x_r is the weighted sum of a Bert Transformer encoder outputs r_k as well as their initial vector representations e_k. The importance of each response token k to the context is estimated by s_k. We mask out any token with importance weight ω_k less than the average ω and only retain tokens highly relevant to the context following Cai et al. (2019). In our initial experiments we found that the Importance masking procedure lead to worse performance than Random masking. The adversarial test set accuracy on DailyDialog adversarial test set was 85.43% compared to the 87.45% accuracy using Random masking. Our analyses showed that Importance masking masked out about 50% of the response tokens, and the infills generated by the ILM model were mostly poor in fluency as the number of masked tokens was high. We therefore finally used Random masking for Mask-and-fill.

C Sample Model Generated Responses

In continuation of sample responses presented in Table 5 of the main paper, we present some more sample responses from different approaches along with Random and Human baseline responses in Table 6.

D Additional Implementation Details

For BM25 approach, we use the open source implementation from transformer rankers[4]. The DailyDialog++ dataset contains 16900 dialogue contexts but only 9259 of those have adversarial negative responses for the Human baseline. For the results reported in Table 4, all approaches from Random and below use the Bert architecture and trained using DailyDialog domain data. Additionally, RUBER is also trained on the DailyDialog++ dataset. The approaches above Random in the table do not require training. Each approach predicts a score for the set of 1500 responses created using a set of generative and retrieval models as detailed in section 4.2.2. Sentence-Bert used in Semi-hard sampling scheme is fine-tuned on the datasets used in this paper.

For the Mask-and-fill approach, the model takes in the following sequence of inputs: {[context] C_1 [eot],.., [eot] C_h [response] r-with-blanks [infill] B_1 [answer],.., B_l [answer]}, where $C_{c=1}^{h}$ represents a context with h utterances, r the response and $B_{b=1}^{l}$ are the tokens blanked in the response. [eot] is used to indicate end of turn. To generate a set of 5 adversarial responses in the Mask-and-fill approach, we first create 4 masked versions

Context or Model	Utterances
Context	A: OK . Now I'll put the dishes in the sink. B: Thank you . I'll wash them. C: OK . Then I will clean the table.
Random	(1) May I have your name and number, Sir? (2) Then I hope to get the other documents by end of the day. (3) She is very experienced in that area, including all the years in college (4) I am in Computer Science department. (5) Sure, you can talk to him.
Mask-and-fill	(1) Ok. Thank you. But, what are you going to do with him? (2) Uh, it's time to wake up. I will clean it up and then go to bed. (3) Oh, thank you. You have helped a lot. (4) Don't, thank you very much for saying it like that. Only in your opinion do you have to wear proper clothes. (5) Yes, thank you! But, i am not satisfied with the work you've done.
Key-sem	(1) Sorry, he didn't put the dishes on the table. (2) Ok. We'll clean up the room now. I can walk you through the process. (3) Don't forget to wash the dishes and put away the clothes. (4) In my field, i put on quite a few weight -bearing exercise in order to improve my lung capacity. (5) Thank you for your understanding. What are your recipes for tableware?
Human	(1) I just now saw the news that the boat was sinking due to heavy goods. (2) I want to thank my friend because he helped me to wash my dress at school camp. (3) Nowadays, table fans are getting very cheap online. (4) I know that using a facial scrub can make your skin look beautiful, clean and soft. (5) I gifted a sink to my friend for his house warming ceremony.
Context	A: Can you tell me what's my responsibility in this position? B: Yes, of course . You would be responsible for the development of software products. C: I see . This is my advantage.
Random	(1) Okay! That sounds great to me. (2) Well! How much will it cost per kg? (3) Well! You can pay it on monthly or yearly basis, it is upto you. (4) I usually spend those days with my family and it is quite fun you see. (5) What type of games do you like to play?
Mask-and-fill	(1) Yes. Maybe he is just looking for some publicity. You are responsible, too. (2) I see. Then we will all get on our own. (3) That's nice. And i would be willing to take them for that. (4) You also have to work on the meetings to be more focused. I need to add some training. (5) What kind of software do they use now?
Key-sem	(1) Let me see, in your brochure, what kind of promotion you're promising? (2) Tell me about it. What do you think? Will you marry her? (3) Of course. Of course there are many things online. Tell me about it. (4) Yes, i appreciate your cooperation. The development of the l / c is our utmost priority. (5) Thank you. I do want to get him a diamond ring. He's responsible for development of the etv.
Human	(1) Of course, the museum is in the closing stage because of financial issues. (2) I was searching on some websites for the junior engineer position to develop my knowledge in the hardware field. (3) I see, is there any terms and condition that I have to sign for this position in your company? (4) Of course, you must provide me the full details about our company's financial position by today evening. (5) Of course, My friend is very much interested to work in a software company. Can you give him a chance in your company?

Table 6: Outputs from different approaches for negative response set creation. Random responses are unrelated to the contexts. Mask-and-fill and Key-sem approaches create responses which are highly similar to the content of the contexts, and hence the model needs to learn factors important for response coherence and appropriateness such as presence of correct entities, time expressions, strategies and others.

of every utterance related to the context (R_g, U_c and R_e). ILM model then generates 4 infills per masked utterance. Thus each utterance gets 16 different modified versions. All these modified utterances are then ranked using the lm-scorer library and we select the top 5. BM25 similarity is used to create the retrieved response set.

For the Keyword-guided approaches, the model is given as input the context C, keywords from the ground truth response K, and the ground truth response r as shown in Figure 2. Specifically, the model takes in the following sequence of inputs - $\{$[context] C_1 [eot],.., [eot] C_h [keywords] K_1 [sep],..,[sep] K_n [response] $r\}$. For both approaches during training, positive responses and negative responses are interleaved, i.e. each positive response is followed by one random and one adversarial response.
