Abstract

While neural language models can generate text with remarkable fluency and coherence, controlling for factual correctness in generation remains an open research question. This major discrepancy between the surface-level fluency and the content-level correctness of neural generation has motivated a new line of research that seeks automatic metrics for evaluating the factuality of machine text. In this paper, we introduce GO FIGURE, a *meta*-evaluation framework for evaluating factuality evaluation metrics. We propose five necessary conditions to evaluate factuality metrics on diagnostic factuality data across three different summarization tasks. Our benchmark analysis on ten factuality metrics reveals that our *meta*-evaluation framework provides a robust and efficient evaluation that is extensible to multiple types of factual consistency and standard generation metrics, including QA metrics. It also reveals that while QA metrics generally improve over standard metrics that measure factuality across domains, performance is highly dependent on the way in which questions are generated.

1 Introduction

The goal of text generation systems is to produce text that is fluent, coherent, relevant, as well as factually correct. Recent progress in neural approaches to building semantically constrained text generation systems has shown tremendous improvements in this direction (Liu and Lapata, 2019; Guo et al., 2018; Durmus et al., 2020; Wang et al., 2020). However, an important issue in text generation systems is that they can yield factually inconsistent text, caused by somewhat distorted or fabricated facts about the source text. Especially in document summarization tasks, models that abstract away salient aspects, have been shown to generate text with up to 30% factual inconsistencies (Kryscinski et al., 2019; Falke et al., 2019a; Zhu et al., 2020).

Commonly used metrics for measuring quality of generated text fail to capture structural aspects of language like negation and poorly correlate with human judgements (Hashimoto et al., 2019; Clark et al., 2019; Sellam et al., 2020), leading to a rapidly progressing search for factuality-driven summarization metrics.

In this work, we propose GO FIGURE[1], a meta-evaluation framework for assessing the effectiveness of factuality metrics across multiple domains - *extreme summarization*, *multi-sentence news summarization* and the understudied *dialogue summarization* domain. Our contributions are as follows: (*i*) a set of diagnostics for measuring sensitivity of metrics to factual inconsistency, (*ii*) a diagnostic evaluation dataset of context/summary pairs for measuring effectiveness of new factuality metrics in a controlled setting, and (*iii*) an evaluation dataset of summaries generated by transformer-based models (Raffel et al., 2019) annotated with types of factual errors.

2 Factuality Metric Meta Evaluation

Since reference summaries may be an incomplete representation of the salient facts in a source document or unavailable, we consider factuality in terms of how well candidate summaries are factually grounded with respect to the source document.

We define a set of five conditions for a factual consistency metric $M(D, S_i)$ to measure factuality of a summary S_i with respect to a source document D. These conditions are given in Table 1.

2.1 Testing Factuality Metric Validity

For the purposes of testing boundedness (Condition I), we define the **Lower Bound** for a metric M as

---

[*] Work done while first author was interning at MSR.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 478–487
August 1–6, 2021.

Condition	Definition	Motivation
Boundedness (I)	There exists S_r, S_f such that $M(D, S_r) \leq M(D, S_i) \leq M(S_f)$.	In general, the exact factuality level of S_i may be unclear. Metric bounds provide points of comparison.
Sensitivity (II)	The metric value for S_i should correlate with the level of factuality captured by S_i.	A bounded but insensitive factuality metric may assign higher values to mostly nonfactual or unrelated summaries over summaries that are close to the reference.
Robustness (III)	The metric should be *robust* across types of factual errors.	A metric that is sensitive only to a subset of errors might ignore a significant number of model-generated errors (Figure 1).
Generality (IV)	The metric should satisfy conditions I,II,III and V across domains.	Prior work such as Reiter and Belz (2009) highlight the risk of claiming validity without testing generality.
Human Correlation (V)	The metric should *correlate* with human judgements of factuality.	The scoring function $H(D, S_i)$ represented by human evaluation is a gold standard for assessment of generation quality (Chaganty et al., 2018), so $M(D, S_i)$ should be an approximation.

Table 1: Details of factuality metric conditions. Here M is a metric scoring function, D is a source document and S_i is a summary.

$M(D, S_r)$ where D is the source document and S_r is a randomly sampled summary from the corpus.[2] We define the **Upper Bound** for the metric as $M(D, S_f)$, where S_f is the reference ground-truth summary. Since our controlled experiments use transformed versions of the reference summary with injected errors, the original reference is guaranteed to be at least as factually consistent as a transformed summary.

To test sensitivity (Condition II), we measure the **correlation** (Pearson's r) between the factual inconsistency level[3] of the summaries (i.e. the number of injected errors) and the average metric score. Then we measure statistical significance using the ***p*-value** from a two-tailed hypothesis test. We check whether metrics satisfy robustness and generality (Conditions III and IV) by separately running this analysis over multiple domains and the factual error types shown in Figure 1. We measure how well metric values match human assessment of factuality by checking the correlation between factual consistency levels determined using manual annotation.

2.2 Theoretical Cases

For Condition I, we scope boundedness to only consider cases that are likely to arise in realistic summarization settings. However, there are hypothetical cases that may have ramifications for metric validity. For example, we expect that $M(D, D) \approx 1$ and $M(D, \varnothing) \approx 0$ for a metric M with values in the range $[0, 1]$, a document D, and an empty string summary $\varnothing$. For non-deterministic metrics, restrictions on variability between runs may also be desired.

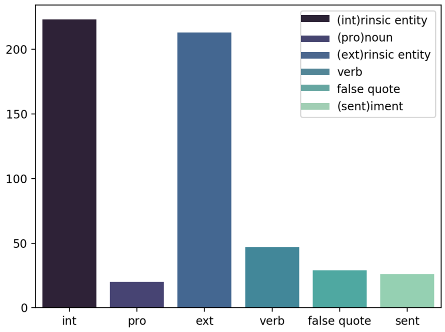

Figure 1: Distribution of common factual error types in sampled generated summaries (96.37% of all errors). We draw from the same error types for our controlled analysis to ensure we match the true distribution of errors. Here *extrinsic entity* refers to entities that did not previously appear in the source, while an *intrinsic entity* appeared in the source.

3 Evaluation Datasets

We evaluate metrics on three datasets: 1-sentence BBC news summaries from the XSUM extreme summarization dataset (Narayan et al., 2018), multi-sentence summaries from the

---

[2] While this may not be the strictest lower bound in theoretical terms, we consider it appropriate as an empirical lower bound since the content is irrelevant to the document. A single random summary is used.

[3] For our experiments, we inject up to a maximum of x errors with $x \in \{1, 2, 3\}$.

CNN/DailyMail dataset (Nallapati et al., 2016), and the recently released SAMSUM corpus (Gliwa et al., 2019) consisting of English language conversations written by linguists and aligned multi-sentence summaries.

3.1 Diagnostic Datasets

To test the ability of proposed metrics to fulfill our predefined conditions, we set up two diagnostic datasets consisting of (*i*) transformed reference summaries with simulated factuality errors that allow us to induce and measure factuality levels in a controlled setting and (*ii*) summaries generated by state-of-the-art transformer summarization models that allows us to measure the effectiveness of metrics in a real data setting. We sample 500 source / summary pairs for each domain.[4]

3.1.1 Model-Generated Datasets

In order to observe how metrics perform on machine-generated summaries, we generate summaries from fine-tuned T5 encoder-decoder summarization models (Raffel et al., 2019) that was pre-trained on news summarization data. We generate summary text using either beam search or sample-based decoding strategies. We then annotate the generated summaries for fine-grained factual errors using the types in Figure 1 to create a hand-curated factual consistency diagnostic dataset.

4 Factuality Metrics for Evaluation

We mainly focus on meta-evaluating most recently proposed factual consistency metrics which use two types of proxy natural language understanding (NLU) objectives aimed at implicitly capturing factuality in generated text: *question-answering* (QA) and a masked token prediction *cloze task*. For QA we evaluate using SummaQA (which uses QA pairs from the source, Scialom et al., 2019) and FEQA (which uses QA pairs from the summary, Durmus et al., 2020), while for the cloze task setting we use BLANC-Help and BLANC-Tune (Vasilyev et al., 2020, see the appendix for details of metrics). We also measure the *factual-awareness* of BERTScore (Zhang et al., 2020), a summarization metric that is aimed primarily at improving coherency rather than factual consistency, and standard summarization evaluation metrics (e.g. ROUGE (Lin, 2004)).

5 Meta-Analysis of Factuality Metrics

5.1 Controlled Data Experiments

We provide the results of the sensitivity analysis over our controlled data on the XSUM domain in Table 2, on CNNDM in Table 3 and on SAMSUM in Table 4. Our analysis reveals that QA metrics, ROUGE-(2/3) and BERTScore generally perform well at evaluating factuality. In contrast, ROUGE-(1/L) are frequently invalid as factuality metrics (Tables 2 and 3), and the performance of Cloze metrics varies across domains (BLANC-Tune is invalid on XSUM, but does fairly well on other domains). Also, performance of metrics tends to be much lower on news domains when we consider non-entity-based errors with the exception of QA-based metrics, ROUGE-(2/3) and BERTScore, indicating that while factuality and standard metrics are fairly attuned to changes in factual consistency that relate to entity-based errors, they are less robust to other types of factual errors.

5.2 Comparison with Human Evaluation of Model Generations

We find that metrics displaying invalid behavior on controlled data (for instance assigning higher metric values to more factually inconsistent summaries on XSUM in Table 2) also display this invalid behavior in model generations (Table 5). This indicates that meta-evaluation with controlled data is effective as a diagnostic tool for finding weak factuality metrics, and follows our intuition that non-entity errors, while frequently produced by abstractive summarization models, are difficult for standard summarization metrics to identify. When considering better-performing factuality metrics identified by the controlled error analysis, we find that the controlled data analysis is generally able to identify better-performing metrics (SummaQA, ROUGE-(2/3) and BERTScore) for XSUM with the exception of FEQA (FEQA metric performs well on XSUM controlled analysis (Table 2), but only approaches this performance on SAMSUM when we consider human eval). The strong overall performance of ROUGE-3 is consistent with the findings of (Fabbri et al., 2021) on CNNDM, our work confirms that this metric is more consistently correlated with factuality than other ROUGE variations across domains.

---

6 Related Work

Prior work concerning evaluation of automatic metrics and human evaluation for NLG systems has mainly focused on general analysis of output quality or coherence and fluency (Callison-Burch et al., 2007; Graham, 2015; Fabbri et al., 2021), rather than factuality. Recent efforts by NLP researchers have drawn attention to the issue of factual errors and hallucinations in the output of neural summarization models (Cao et al., 2018; Massarelli et al., 2019; Zhao et al., 2020; Falke et al., 2019b; Goodrich et al., 2019; Celikyilmaz et al., 2020). A number of works have highlighted the effectiveness of QA and cloze task objectives for evaluating or improving factuality on specific domains (Eyal et al., 2019; Huang et al., 2020). We aim to evaluate these metrics more broadly, and consider a wider range of domains (notably dialogue).

6.1 Discussion of Meta Evaluation and Conclusion

Our analyses show that in contrast to prior work on factual consistency that mostly concentrated on one specific domain and dataset, our GO FIGURE framework is effective at evaluating sensitivity and validity of factual consistency metrics with only reference summaries, rather than requiring computationally intensive testing across summarization model variants to identify metric strengths and shortcomings.

We highlight the following key points from experiments run using *meta*-evaluation:

Standard summarization metrics are not always valid measures of factuality. ROUGE-1 and ROUGE-L fail to accurately measure factual inconsistency across domains in our controlled analysis. The ROUGE-L results raise the question of context *relevance*. While ROUGE-L takes into account more context than other ROUGE variations, this context may not be relevant for assessing factuality. For example, swapping "decreased" for "increased" dramatically changes the meaning in the summary *"Scotland's renewable energy output increased by 45% in the first quarter of this year, compared with the same period last year."*, but ROUGE-L is not affected. Despite the frequent use of ROUGE-L as a more contextual measure, prior work has also noted that ROUGE-N outperforms ROUGE-L (Rankel et al., 2013; Fabbri et al., 2021).

Analysis on human annotated data is still necessary as an upper-bound on *meta*-evaluation quality. While BLANC-Help, FEQA metric and BERTScore values decrease with factual inconsistency on controlled data, the metrics may sometimes be positively correlated with factual inconsistency on generated data. This emphasizes the importance of a expert curated test set as part of the GO FIGURE meta evaluation for the most rigorous testing. **A question-answering objective is promising for measuring factual consistency across domains, but effectiveness depends on the question.** While QA metrics can perform well at measuring factual consistency of generated summaries, our *meta*-evaluation reveals this is dependent on the way in which questions are asked. While both QA metrics use SQuAD-based systems (Rajpurkar et al., 2016), asking questions from the source rather than the summary is most robust across domains. This opens the door to metrics based on more contextual QA like commonsense (Shwartz et al., 2020).

We will release our *meta*-evaluation framework and diagnostic datasets to aid in development of effective summarization factuality metrics. In future work, summary meta-metric results (e.g. correlation on simulated data) could be used as rewards for reinforcement learning driven approaches to training factuality metrics.

7 Ethics and Broader Impact Statement

Ethical considerations involving our *meta*-evaluation framework primarily revolve around human evaluation. News articles and dialogues may contain references to distressing events or abnormal social behavior. All our expert annotators voluntarily took part in the human evaluation with prior knowledge of the type of content being evaluated. Crowd-sourced human evaluation trials were conducted under an IRB exemption.

Our work outlines a simple and effective approach for evaluating factuality metrics in summarization. This can aid in development of more robust and sensitive factuality metrics to accurately evaluate the factual correctness of generative models. This is key as improvement in the coherency of models accelerates, potentially leading to generations that appear to be high quality while containing factual inaccuracies. Our framework could also evaluate factuality metrics for use in identifying human-written errors, mitigating potential spread of misinformation.

A Appendices

A.1 Additional Details of Datasets

We provide dataset statistics for each of our domains in Table 6.

A.2 Evaluation Metric Details

QA-Based Quality Score. Given a source or reference document D and candidate summary S_i, QA-based evaluation metrics assign a generation quality score to S_i to measure the ability of a QA system by accurately answering questions generated from D or S_i. We use the SummaQA (Scialom et al., 2019) and FEQA (Durmus et al., 2020) metrics. For the SummaQA metric, questions are generated from the source document D and the candidate summary S_i is used as input to the QA system. Alternatively, FEQA generates questions from S_i and uses D to answer these questions.

The generation quality score is typically the aggregated F_1 score measuring the similarity between ground-truth answers for questions generated from D and the answers predicted by the QA system. SummaQA also generally includes the aggregated model confidence probabilities for predictions.

Masked LM Prediction (Cloze Task) Score. Given a source document D and candidate summary S_i, Cloze-based evaluation metrics assign a generation quality score to S_i by measuring the ability of a NLU system to accurately predict masked tokens in the source document, given access to the information in S_i. We use two variants of BLANC (Vasilyev et al., 2020), BLANC-Help and BLANC-Tune. BLANC-Help uses both D and S_i as input to a pretrained masked token prediction model, while BLANC-Tune only uses D as input to a model that has been finetuned on the candidate summary. Both metrics are aimed at capturing fluency, informativeness and factual correctness of summaries.

Semantic Similarity. Semantic similarity metrics measure the overlap between contextual embeddings of a source or reference document D and candidate summary S_i. We use BERTScore (Zhang et al., 2020), which has been shown to correlate better with human judgements of coherency than standard summarization metrics and similarly to n-gram metrics on factual consistency of CNNDM summaries (Wang et al., 2020).

Lexical Overlap. Finally, we test ROUGE (Lin, 2004), which is the standard metric used for evaluating summarization. ROUGE measures the n-gram overlap between a source or reference document D and candidate summary S_i. We evaluate results using ROUGE-1 and ROUGE-2, as well as ROUGE-L, which measures longest common subsequence overlap. We follow prior work that considered ROUGE in factual consistency evaluations (Wang et al., 2020), though it has also been previously noted that ROUGE can underweight good summarization examples (Novikova et al., 2017).

A.3 Simulated Data Transformations

We inject errors into reference summaries by first using a part-of-speech tagging model and named entity recognition system (spaCy)[5] to extract entities, verbs, and adjectives from these summaries. For each named entity, we keep track of the label type (e.g. ORG, GPE, etc). All datasets are comprised of English language articles or dialogues and summaries, and we use the spaCy English NLP models.

Intrinsic entity errors. To inject intrinsic entity errors into a summary S, we construct a dictionary of all unique entities appearing in the source document for S **only**, organized by entity label type. We then swap a random entity in the reference summary for a different entity of the same label type in the constructed dictionary.

Extrinsic entity errors. For extrinsic entity errors, we use the same dictionary construction for all unique entities appearing in **all** the corpus source documents. To change a random adjective, we use WordNet (Miller, 1995) to obtain the synsets for that adjective and swap the adjective for its antonym.

Pronoun entity errors. Pronoun errors are introduced with a preset list of commonly used pronouns. We randomly extract a pronoun set (e.g. she/her) from the text using the preset list and swap it with another random pronoun set (e.g. he/him).

Verb Negation. We use a rule-based system for verb negation based on verb tense, and predict tense based on the suffix and preceding words.

---

Reference	**Type**	**Description**	**Example**
Irish Taoiseach (PM) Leo Varadkar has engaged in some "sock diplomacy" in his first meeting with Canadian Prime Minister Justin Trudeau in Dublin.	Intrinsic entity error (**int**)	An entity appearing in the source document is used incorrectly.	Canadian Taoiseach (PM) Leo Varadkar has engaged in some "sock diplomacy" in his first meeting with Irish Prime Minister Justin Trudeau in Dublin.
Irish Taoiseach (PM) Leo Varadkar has engaged in some "sock diplomacy" in his first meeting with Canadian Prime Minister Justin Trudeau in Dublin.	Extrinsic entity error (**ext**)	An entity appearing in the candidate summary does not appear in the source document.	French Taoiseach (PM) Leo Varadkar has engaged in some "sock diplomacy" in his first meeting with Canadian Prime Minister Justin Trudeau in Dublin.
Irish Taoiseach (PM) Leo Varadkar has engaged in some "sock diplomacy" in his first meeting with Canadian Prime Minister Justin Trudeau in Dublin.	Pronoun error (**pro**)	A pronoun in the candidate summary is used incorrectly. For example, (her/she instead of him/he).	Irish Taoiseach (PM) Leo Varadkar has engaged in some "sock diplomacy" in her first meeting with Canadian Prime Minister Justin Trudeau in Dublin.
Irish Taoiseach (PM) Leo Varadkar has engaged in some "sock diplomacy" in his first meeting with Canadian Prime Minister Justin Trudeau in Dublin.	Negation error (**verb**)	There are verb negations in the candidate summary that contradict the source document.	Irish Taoiseach (PM) Leo Varadkar has not engaged in some "sock diplomacy" in his first meeting with Canadian Prime Minister Justin Trudeau in Dublin.
People who have been prescribed powerful anxiety or pain relief drugs are being warned about a new drug-driving law.	Sentiment error (**sent**)	An adjective or adverb appearing in the candidate summary contradicts the source document.	People who have been prescribed weak anxiety or pain relief drugs are being warned about a new drug-driving law.

Table 7: Table of possible factual errors.

We note that injecting a certain level of error into a summary will have varying effects depending on the average length of summaries for a corpus. We use the same methodology for each corpus to maintain consistency, but future work may explore length-controlled error injection based on the objectives of the evaluation.

A.4 Metric Implementation Details

For all metrics, we use the publicly shared implementations. Due to BERT context size constraints, we limit the length of document input sentences to 400 tokens for BLANC variants. We use Roberta-large for BERTScore.

A.5 T5 Training

We fine-tune the T5-base model (220M parameters) trained on news summaries for each domain using the AdaFactor optimizer (Shazeer and Stern, 2018) with a learning rate of 0.001 and a batch size of 8. The learning rate was tuned using ROUGE score on a dev set, and we experimented with learning rates in the range of [0.01,0.0001]. All other hyperparameters follow from the original T5 paper. Best performing models were trained using one random seed on NVIDIA V100 GPUs.

A.5.1 Human Annotation Layout

For human annotation of factual consistency in summaries, we show the source document, reference summary and a candidate summary that should be assessed for factuality. We then ask a factuality question with three choices:

- Yes (i.e. the summary is factual)
- No (i.e. the summary contains factual inconsistencies)
- Not Sure (i.e. the summary is too incoherent to judge)

If a summary is judged to be factually incorrect, annotators are allowed to select the number and type of errors they observe using a predefined list of factual errors. A screenshot of the error types and examples shown in the annotation task is given in Figure 2. For less obvious cases of factual inconsistency (for example when summaries contain locations or political figures that require regional background knowledge), we check factuality using external knowledge bases to ensure correctness of annotation. We also adhere to a strict binary notion of factuality in deciding cases where summaries are imprecise but ambiguous in terms of correctness, opting to label these summaries as factually inaccurate. If summaries are completely incoherent, we treat these summaries as having the highest level of factual inconsistency.

We validated the effectiveness of the setup by computing inter-annotator agreement of in-house expert annotators for 30 XSUM summaries. We achieve "fair" agreement of Krippendorff's α = 0.32 with 3 annotators and "moderate" agreement of α = 0.44 with 2 annotators (Landis and Koch, 1977; Ageeva et al., 2015). The remaining annotations are done by one in-house expert annotator.

Type of Error	**Gold Summary**	**Summary with Error**
Intrinsic Entity Error	Exhibition of 25 pictures on display at **the un** headquarters in **new york** .	Exhibition of 25 pictures on display at the **new york** headquarters in **the un** .
Extrinsic Entity Error	**Eoin collins** , five , eats everything from stones and sponges to sand .	**Vera** , five , eats everything from stones and sponges to sand.
Pronoun Entity Error	Elizabeth Sullivan fell in love with the 23-flavored soft drink 40 years ago , when **she** was in **her** 60s .	Elizabeth Sullivan fell in love with the 23-flavored soft drink 40 years ago , when **he** was in **his** 60s .

Abstract

Recent work has shown that Aspect-Term Sentiment Analysis (ATSA) can be performed by Gradual Machine Learning (GML), which begins with some automatically labeled easy instances, and then gradually labels more challenging instances by iterative factor graph inference without manual intervention. As a non-i.i.d learning paradigm, GML leverages shared features between labeled and unlabeled instances for knowledge conveyance. However, the existing GML solution extracts sentiment features based on pre-specified lexicons, which are usually inaccurate and incomplete and thus lead to inadequate knowledge conveyance.

In this paper, we propose a Deep Neural Network (DNN) driven GML approach for ATSA, which exploits the power of DNN in feature representation for gradual learning. It first uses an unsupervised neural network to cluster the automatically extracted features by their sentiment orientation. Then, it models the clustered features as factors to enable implicit knowledge conveyance for gradual inference in a factor graph. To leverage labeled training data, we also present a hybrid solution that fulfills gradual learning by fusing the influence of supervised DNN predictions and implicit knowledge conveyance in a unified factor graph. Finally, we empirically evaluate the performance of the proposed approach on real benchmark data. Our extensive experiments have shown that the proposed approach consistently achieves the state-of-the-art performance across all the test datasets in both unsupervised and supervised settings and the improvement margins are considerable.

1 Introduction

r_i	s_{ij}	text
r_1	$s_{1.1}$	**service** was awful mostly because **staff** were overwhelmed.
	$s_{1.2}$	The **staff** should be a bit more friendly.
r_2	$s_{2.1}$	We ordered **lamb** which was perfectly cooked and tasted awesome.
	$s_{2.2}$	The **food** was well-prepared and presented.

Table 1: A running example: r_i denotes a review and $s_{i.j}$ denotes a sentence.

Aspect-Term Sentiment Analysis (ATSA) aims at inferring the sentiment polarity towards a particular aspect in a sentence (Hu and Liu, 2004; Pontiki et al., 2016). ATSA is important for many applications (e.g., e-commerce and social media), where the sentimental opinions in reviews can be leveraged to create value for businesses and customers. In ATSA, an aspect-term, also called target, is explicitly mentioned in a review. For instance, consider the running example shown in Table 1, r_1 evaluates the restaurant through two explicit aspects *service* and *staff*. The goal of ATSA is then to detect the respective sentiment polarities expressed towards these two aspects.

Up to now, the state-of-the-art solutions for ATSA have been built upon various DNN models. The earlier solutions were usually equipped with an attention mechanism (Tang et al., 2016b; Wang et al., 2016; Tang et al., 2016a; Ma et al., 2017; Chen et al., 2017; Li et al., 2018; Wang et al., 2018; Tang et al., 2019). They mostly attempted to learn aspect-related semantic representation of an input sentence. Recently, ATSA has experienced a considerable shift towards pre-trained language models (Sun et al., 2019; Tang et al., 2019; Karimi et al., 2020). Despite the effectiveness of these approaches, unfortunately their efficacy heavily relies on large quantities of accurately labeled data, which require intensive human labor.

To alleviate the burden of manual labeling, a solution based on the paradigm of Gradual Machine Learning (GML) has recently been proposed for

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 488–497
August 1–6, 2021.

ATSA (Wang et al., 2021). First proposed for entity resolution in (Hou et al., 2019, 2020), GML can enable effective machine labeling without the requirement for manual intervention. Given a classification task, GML begins with some easy instances, which can usually be automatically labeled by the machine with high accuracy, and then gradually reasons about the labels of its more challenging instances by factor graph inference. As a non-i.i.d (Independent and Identically Distributed) learning paradigm, GML leverages shared features between labeled and unlabeled instances for knowledge conveyance . However, the existing GML solution for ATSA relies on pre-specified lexicons to extract sentiment features. Its limitation is twofold: 1) sentiment lexicons may be inaccurate and incomplete; 2) a shared feature must explicitly appear in both instances. However, explicit features cannot capture the implicit similarity between instances and thus lead to inadequate knowledge conveyance. Consider the running example in Table 1. Unfortunately the word *well-prepared* is not included in most of the existing lexicons. It can also be observed that the instances $s_{2.1}$ and $s_{2.2}$ do not share any explicit feature, while *perfectly cooked* and *well-prepared* have very similar meanings and can thus serve as an implicit common feature.

Recently, DNN models have been proven to be very powerful in feature representation for many NLP tasks, where the features with the same semantic context are mapped to close points in the latent space (Devlin et al., 2018). For instance, the words *"cooked"* and *"well-prepared"* are usually represented by two points close to each other because they are semantically very close. Unfortunately, the existing embedding models are designed to map the features semantically, regardless of their sentiment orientation. Therefore, they may map two features with opposite polarities (e.g., *"good"* and *"bad"*) to two close points in the embedding space, which raises a challenge to be directly applied to feature extraction for ATSA.

In this paper, we propose a novel DNN-driven GML approach for ATSA. It essentially exploits DNN to sentimentally map the features of aspect-terms into different *polarity indicators*, and models them as shared factors in a factor inference graph to enable implicit knowledge conveyance. To this end, we first combine the sentiment lexicon and dependency parser-based relations, which are readily available, to generate aspect-opinion words. Secondly, we use an unsupervised neural network to filter the aspect-irrelevant and unsentimental words from an input sentence. Finally, the resulting weighted sentences, which can be considered to be purely sentimental, are used to learn polarity indicators. The model is trained to reconstruct the weighted sentence through a linear combination from polarity indicators. To leverage labeled training data, we also present a hybrid GML solution that fulfills gradual learning by fusing the influence of supervised DNN predictions and implicit knowledge conveyance in a unified factor graph.

Our main contributions can be summarized as follows:

1. We propose a DNN-driven GML approach for ATSA, which can effectively exploit the power of DNN in feature representation for GML;
2. We present an unsupervised attention-based neural network to cluster the features of aspect-terms by their sentimental orientation;
3. We present a hybrid GML solution for ATSA, which fulfills gradual learning by fusing the influence of supervised DNN predictions and implicit knowledge conveyance in a unified factor graph.
4. We empirically validate the efficacy of the proposed approach on benchmark data. Our extensive experiments have shown that the proposed approach consistently achieves the state-of-the-art performance across all the test datasets in both unsupervised and supervised settings and the improvement margins are considerable.

2 Related work

Aspect-Term Sentiment Analysis is a sub-task of aspect-based sentiment analysis, which aims to detect the sentiment polarity in response to a particular aspect in a sentence (Hu and Liu, 2004; Pontiki et al., 2016). Traditional machine learning techniques (Kiritchenko et al., 2014; Castellucci et al., 2014) proposed to learn SVM classifiers based on different features such as n-grams, non-contiguous n-grams and lexicon features. In comparison, the DNN-based models equipped with an attention mechanism have been shown to be more effective on ATSA (Tang et al., 2016b; Wang et al., 2016; Tang et al., 2016a). Following this trend, researchers have resorted to more sophisticated attention mechanisms to refine neural ATSA models (Ma et al., 2017; Chen et al., 2017; Li et al., 2018; Wang et al., 2018; Tang et al., 2019). To improve performance, they essentially attempted to explicitly capture the importance of each context word by learning aspect-related representation of an input sentence. SenHint (Wang et al., 2019) proposed to integrate DNN predictions and linguistic hints in a joint framework. Recently, ATSA has experienced a considerable shift towards pre-trained language models (Sun et al., 2019; Tang et al., 2019; Karimi et al., 2020). Unfortunately, the efficacy of these models heavily relies on labeled training data, which may not be readily available in real-scenario.

From unsupervised perspective, earlier solutions (Alvarez-López et al., 2016; Hutto and Gilbert, 2014) proposed to detect the polarities of aspect-terms based on lexicon rules. The authors of (Schouten et al., 2017) proposed a mechanism of spread activation for aspect-based polarity detection. More recently, the authors of (Wang et al., 2021) proposed an unsupervised solution based on GML for ATSA. However, the existing GML solution extracts features based on sentiment lexicons, which may not be accurate nor complete and thus lead to inadequate knowledge conveyance.

The idea of mapping features into different clusters has been investigated with different purposes. The authors of (Iyyer et al., 2016) proposed to learn a set of descriptors representing the fictional relationship between two characters changes over time, and (He et al., 2017) proposed to learn a set of aspect representatives from the corpora. Unfortunately, none of them investigated how to cluster implicit features by their polarity orientation.

3 Preliminaries

3.1 Task Definition

We formulate the task of aspect-term sentiment analysis as follows:

Definition 3.1 *[Aspect-Term Sentiment Analysis]. Let* $x = (r, s, t)$ *be a target unit, where* r *denotes a review,* s *a sentence in the review and* t *an aspect-term associated with the sentence. Given a set of target units,* X*, the goal of ATSA is to infer the sentiment polarity of each target unit in* X*.*

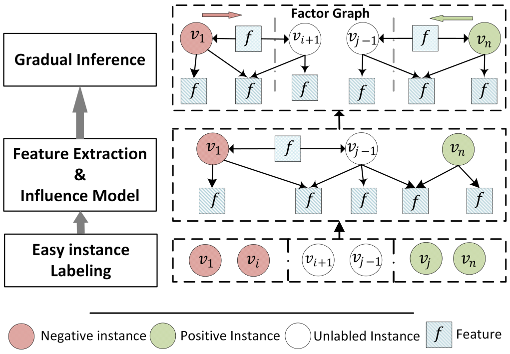

Figure 1: GML Paradigm Overview

3.2 GML Paradigm Overview

Our solution is built upon the non-i.i.d learning paradigm of GML (Hou et al., 2019, 2020). As shown in Figure 1, GML consists of the following three steps:

3.2.1 Easy Instance Labeling.

Given a classification task, it is usually very challenging to accurately label all the instances in the task without good-coverage training examples. However, the work can become much easier if we only need to automatically label some easy instances in the task. In real scenarios, easy instance labeling can be performed based on the simple user-specified rules or the existing unsupervised learning techniques. GML begins with the observations provided by the labels of easy instances. Therefore, high accuracy of automatic machine labeling on easy instances is critical for its ultimate performance on a given task.

For ATSA, this paper uses the unsupervised algorithm of spread activation (Schouten et al., 2017) to label easy instances. An instance is considered as easy if its resulting dominate label meets a pre-specified threshold.

3.2.2 Feature Extraction and Influence Modeling.

Feature serves as the medium for knowledge conveyance. This step extracts the common features shared by labeled and unlabeled instances. To facilitate effective knowledge conveyance, it is desirable that a wide variety of features are extracted to capture as much information as possible. For each extracted feature, this step also needs to model its influence over the labels of its relevant instances.

For ATSA, we extract two types of features: sentimental feature and relational feature. Relational feature, which has been well studied in (Wang et al., 2021), represents the explicit sentimental connection between sentences within the same review. In the running example, due to the absence of any shift word between s_{11} and s_{12}, their polarities can be supposed to be similar. In this paper, we focus on how to enable implicit knowledge conveyance by leveraging DNN for automatic extraction of sentimental features.

3.2.3 Gradual Inference.

This step gradually labels the instances with increasing hardness in a task. Since the scenario of gradual learning does not satisfy the i.i.d assumption, gradual learning is fulfilled from the perspective of evidential certainty. Gradual learning is conducted over a factor graph, which consists of the labeled and unlabeled instances and their common features, by iterative inference. At each iteration, it chooses to label the unlabeled instance with the highest degree of evidential certainty. The iteration is repeatedly invoked until all the instances in a task are labeled.

Given a factor graph, G, GML defines the probability distribution over its variables V as follows:

$$P_w(V) = \frac{1}{Z_w} \prod_{v \in V} \prod_{f \in F_v} \phi_f(v) \prod_{f' \in F'} \phi_{f'}(v_i, v_j), \tag{1}$$

where F_v denotes the set of sentimental features associated with the variable v, F' denotes the set of relational features, $\phi_f(v)$ denotes the factor associated with v and f, $\phi_{f'}(v_i, v_j)$ denotes the factor associated with the relational feature f', and Z is a partition function, i.e. normalization constant. To effectively learn the factor weights without access to the true labels of unlabeled variables, V_I, GML minimizes the negative log marginal likelihood given the observed labels of labeled variables, Λ, as follows:

$$\hat{w} = arg \min_{w} -log \sum_{V_I} P_w(\Lambda, V_I). \tag{2}$$

A scalable approach for gradual inference on ATSA has been presented in (Wang et al., 2021). First, the unlabeled variables are sorted according to their evidential support. Then, the top-m unlabeled variables are considered as the candidates for probability inference. To reduce the invocation frequency of factor graph inference, an efficient algorithm is used to approximate entropy estimation on m candidates and select the top-k most promising variables for factor graph inference. Finally, the probabilities of the selected k variables are inferred in the subgraphs of G. Since the inference process of the DNN-driven GML is very similar to what was presented in (Wang et al., 2021), its technical details are omitted here due to space limit.

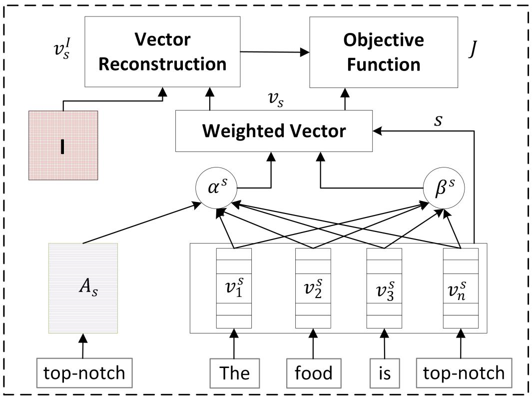

Figure 2: DNN for Implicit Feature Extraction.

4 DNN-driven GML

In this section, we first present an unsupervised neural network to extract implicit sentimental features. Then, we describe the unsupervised DNN-driven GML that integrates implicit features into the process of gradual inference. Finally, we describe the hybrid GML solution that fuses the influence of DNN predictions and implicit features for gradual learning.

4.1 Implicit Feature Extraction by DNN

The purpose of implicit feature extraction is to learn a set of polarity indicator embeddings I $\in \mathbb{R}^{k \times d}$, where k is the number of indicators, which can be leveraged to capture the similar features between instances. Each indicator represents a set of features that often occur in the contexts with the same polarity.

Specifically, for each input sentence s and its aspect term t, we first generate a set of aspect-opinion words, denoted by A_s. Then, we use A_s to construct a weighted vector $v_s \in \mathbb{R}^d$ that can be read as the sentimental representation of the input sentence given the target of t. To this end, we propose an attention-based unsupervised neural network to filter the sentence by down-weighting aspect-irrelevant and unsentimental information. The model is trained by reconstructing v_s as a linear combination of indicator embeddings from I. The architecture of the proposed DNN has been presented in Figure 2.

4.1.1 The Input

The input to our model is a couple of sentence s and its aspect-opinion words A_s. We use dependency-based parse tree to generate aspect-opinion words (*modifiers*) (Hu and Liu, 2004), then leverage the adjective words and those detected by the lexicon to construct A_s. Considering the running example in Table 1, the sentiment words of s_{11} are *awful* and *overwhelmed*. Suppose that we have a feature embedding matrix $\mathrm{L} \in \mathbb{R}^{c \times d}$, where c is the vocabulary size and d is the embedding dimension. Each word is then associated with a real-valued embedding $v_i \in \mathbb{R}^d$ from L representing its feature vector (Mikolov et al., 2013):

$$s = \{v_1^s, v_2^s, ..., v_n^s\}, \tag{3}$$

$$A_s = \{v_1^a, v_2^a, ..., v_m^a\}, \tag{4}$$

where $s \in \mathbb{R}^{n \times d}$ and n is the sentence length, while the input sentiment $A_s \in \mathbb{R}^{m \times d}$ and m is the number of aspect-opinion words.

4.1.2 Attention-based Sentimental Representation

For each input sentence s, we construct a weighted vector v_s to capture the sentimental information in response to the aspect t. To this end, we apply two attention mechanisms to filter away the irrelevant information. The first one attempts to down-weight non-sentimental words, while the second one is a self-attention to attend to aspect-relevant information (He et al., 2017).

Specifically, the first attention layer takes both the sentence s and its opinion words A_s as an input. Conceptually, we first compute the global sentiment vector v^a by averaging the word embeddings of A_s, and then use it to weight each word embedding v_i^s in s as follows:

$$v^a = \frac{1}{m} \sum_{v_i^a \in A_s} v_i^a, \tag{5}$$

$$o_i = v_i^{s\top} \cdot \mathrm{U} \cdot v^a, \tag{6}$$

where the symbol $\cdot$ stands for element-wise dot product, while $\mathrm{U} \in \mathbb{R}^{d \times d}$ is the transformation matrix (i.e., to be learned during training) between the global sentiment vector v^a and the input sentence s. Next, we apply a softmax layer to yield a non-negative weight for each word in s as follows:

$$\alpha_i^s = \frac{\exp(o_i)}{\sum_{j=1}^{n} \exp(o_j)}, \tag{7}$$

where the value of α_i^s can be read as the probability of each word in the sentence s being a sentiment word.

Although we have computed the sentimental importance for each word in s, but not all the sentiment words are contextually related to the aspect. Therefore, we apply another self-attention mechanism that takes only the sentence s as input. To compute each word's probability of being aspect-relevant information, namely β_i^s, we follow the same steps in the first attention layer. The only difference is that the global sentiment v^a in Equation 6 is replaced by the global context, which is simply computed by averaging the word embeddings of the input sentence s itself.

Finally, we sum both attention layer outputs, $\alpha^s \in \mathbb{R}^n$ and $\beta^s \in \mathbb{R}^n$, and use it to construct the weighted vector v_s as follows:

$$v_s = s^\top \cdot (\alpha^s + \beta^s), \tag{8}$$

in which the resulting weight vector v_s can be read as the aspect-relevant sentiment representation of the input sentence s.

4.1.3 Unsupervised Training

Now that we have obtained the aspect-relevant sentiment representation of an input sentence s, we explain how to learn its polarity indicators using a variant of dictionary learning. Considering the matrix of indicators I as a dictionary, we attempt to approximate v_s as a linear combination of items from I.

Formally, for each aspect-specific vector v_s, we compute a corresponding vector v_s^k over k polarity indicators by simply reducing v_s from d dimensions to k dimensions through a softmax layer as follows:

$$v_s^k = softmax(W \cdot v_s + b), \tag{9}$$

where $W \in \mathbb{R}^{k \times d}$ denotes a weight matrix and b denotes the bias, both of which are supposed to be learned during training. Note that v_s^k can be read as the probability that the input sentence s belongs to each indicator. Then, we reconstruct the representation vector by taking a weighted average over the polarity indicators as follows:

$$v_s^I = \mathrm{I}^\top \cdot v_s^k. \tag{10}$$

Since the objective is to make v_s^I similar to v_s, we apply the widely used contrastive max-margin

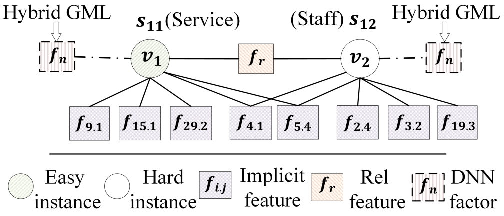

Figure 3: Factor graph of r_1 in the running example.

objective function (Iyyer et al., 2016; Ahmed et al., 2020). To that end, we randomly sample some sentences from the training data as negative samples, and compute the weighted vector v_s for each sample using Equation 8.

Specifically, the objective is a hinge loss that minimizes the inner product between the representation vector of v_s and the reconstructed vector v_s^I for the negative samples, while simultaneously maximizes their inner product for other samples in the training data. Formally, the hinge loss is defined as:

$$J(\theta) = \sum_{s \in D} \sum_{s^- \in D^-} max\{0, 1 - v_s^I \cdot v_s + v_s^I \cdot v_{s^-}\}, \tag{11}$$

where θ represents the model parameters, D represents the set of training data and D^- the subset of negative samples. Note that $\theta = \{I, U, W, b\}$.

To discourage the model from learning similar indicators, we add a regularization term to the objective function J that penalizes redundancy in the matrix of polarity indicators (Iyyer et al., 2016):

$$M(\theta) = ||\mathrm{I} \cdot \mathrm{I}^\top - \mathrm{Y}||, \tag{12}$$

where Y denotes the identity matrix. The final training objective L is then represented by the weighted sum of J and M as follows:

$$L(\theta) = J(\theta) + \lambda M(\theta), \tag{13}$$

where λ is a hyper-parameter that controls the magnitude of the regularization term.

4.2 Unsupervised GML Solution

Now that we have already learned a set of polarity indicators, we describe how they can serve as implicit features for gradual inference. Given a sentence, we first estimate its aspect-specific vector v_s using Equation 8, then compute the cosine similarity between v_s and each polarity indicator in I. It thus results in a list of scores in the form (*indicator index, similarity score*) representing how the aspect-term's features are close to each indicator. We sort the scores and use top-k corresponding indicators as representative features. We scale up the similarity score to 10 to augment the number of features and meanwhile avoid polarity conflict between features. As shown in Figure 3, $f_{5.4}$ represents an indicator feature with the index of 5 and the similarity scale of 4.

Considering the instance of s_{11} in Figur 3, s_{11}'s top-5 indicators and their similarity scores are (5, 0.44), (29, 0.2), (15, 0.16),(4, 0.13) and (9, 0.13). Then, its representative features are $F_{s_{11}} = \{f_{5.4}, f_{29.2}, f_{15.1}, f_{4.1}, f_{9.1}\}$. In gradual inference, we restrict two instances to share an implicit feature if and only if they are similar to the same indicator with the same score scale. For instance, in Figure 3, s_{11} and s_{12} share the indicators 4 and 5 with the same score scale of 1 and 4 respectively.

Given ATSA task, each aspect-term within the same review is represented by a variable. The evidence variables are assigned constant values 0 or 1 representing their polarity labeling, while the values of the inference ones are inferred based on G. The factor of an implicit feature f_e in Equation 1 is defined by:

$$\varphi_{f_e}(v_i) = \begin{cases} 1 & v_i = 0; \\ e^{w_{f_e}} & v_i = 1; \end{cases} \tag{14}$$

where v_i denotes a variable having the feature f_e, and w_{f_e} denotes the weight of f_e. Note that the weight w_{f_e} is initialized to zero, but needs to be learned in the process of gradual inference.

4.3 Hybrid GML Solution

In the hybrid solution, we model the influence of DNN outputs by DNN factors, denoted by f_n, as shown in Figure 3. In this paper, we have implemented the hybrid solution by the state-of-the-art BERT-based DNN of HP-SUM for ATSA (Karimi et al., 2020). However, other DNN models can be fused in the same way. Since supervised learning is usually more accurate than unsupervised learning, we also label easy instances by supervised DNN predictions. In other words, we consider the instances with the most extreme probabilities predicted by HP-SUM as easy ones to kick-start gradual inference.

In factor graph, the DNN factor f_n of a variable corresponding to the aspect-term unit, (r, s, t) is defined by:

$$\varphi_{f_n}(v_i) = \begin{cases} 1 & v_i = 0; \\ e^{w_{f_n}} & v_i = 1; \end{cases} \tag{15}$$

in which w_{f_n} denotes factor weight. The value of w_{f_n} is defined as

$$w_{f_n} = \ln(\frac{p}{1-p}), \tag{16}$$

where p is the probability output of DNN (i.e., estimated by HP-SUM) of a target t being positive in the sentence s. It can be observed that $W_{f_n} > 0$ if $p > 0.5$; otherwise, if $p < 0.5$, then $w_{f_n} < 0$.

5 Empirical Evaluation

We evaluate our solution on six benchmark datasets provided by the SemEval ABSA task across the years 2014, 2015 and 2016 for the Restaurant and Laptop domains (Pontiki et al., 2016). Note that the original datasets are three-way labels (i.e., positive, negative and neutral). Since this paper focuses on binary polarity classification, we only include the reviews with *positive* or *negative* labels in our experiments. Furthermore, we have trained the polarity indicators for the restaurant and laptop domains on unlabeled corpus collected from Citysearch and Amazon, which have also been widely used in previous work (Zhao et al., 2010; Ahmed et al., 2020).

For unsupervised training, we initialized word vectors by word2vec. We implemented GML inference using the Numbskull library [1], a Python NUMBA-based Gibbs sampler. Our GML implementation optimizes the parameters by Adam with the learning rate of 0.001. On all the test datasets, we set the number of polarity indicators k to 50, and the number of negative samples to 20. In the spread activation algorithm for easy instance labeling, the easiness threshold is set to 0.7 for all datasets. For the hybrid GML solution, the easy instances are the top-30% ones with most extreme probabilities as predicted by supervised DNN. For each instance, the associated implicit features are the top-5 polarity indicators' scores scaled to 10.

The compared unsupervised techniques include: (1) **LEX-SYN** (Alvarez-López et al., 2016). It infers polarity based on lexicon and syntactic dependency analysis; (2) **VADER** (Hutto and Gilbert, 2014). A rule-based approach; (3) **SPD-ACT** (Schouten et al., 2017). It infers polarity by spread activation; (4) **Lexicon-based GML** (Wang et al., 2021). The GML solution built upon sentiment lexicons.

The compared supervised DNN models include the latest BERT-based models as well as traditional attention-based models: (1) **ATAE-LSTM** (Wang et al., 2016). An attention-based LSTM; (2) **IAN** (Ma et al., 2017). An interactive attention model; (3) **RAM** (Chen et al., 2017). A deep memory model; (4) **TNet-LF** (Li et al., 2018). A target-specific transformation network; (5) **GCAE** (Xue and Li, 2018). A gated convolutional network; (6) **AEN** (Song et al., 2019). An attentional encoder network. AEN has two variants: AEN-Glove that uses Glove as feature embedding input, and

---

[1] https://github.com/HazyResearch/numbskull

AEN-BERT based on the pre-trained model BERT fine-tuning; (7) **BERT-SPC** (Song et al., 2019). A pseudo-sentence (i.e., sentence and aspect) BERT-based approach; (8) **HP-SUM** (Karimi et al., 2020). A BERT-based model equipped with parallel aggregation and hierarchical aggregation modules.

Note that among the listed DNN models, the last 3 models (i.e. AEN-BERT, BERT-SPC, and HP-SUM) were built upon the latest pre-trained BERT.

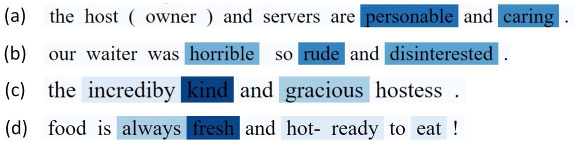
5.1 Main Results

We average the three runs' performances and report the detailed evaluation results in Table 2. We have the following observations: (1) **the unsupervised DNN-driven GML consistently gives the best accuracy compared to the unsupervised alternatives across all datasets.** The performance advantage of the DNN-driven GML over the lexicon-based GML suggests that a carefully-designed implicit feature mechanism can effectively perform better than lexicon-based explicit features for ATSA; (2) the unsupervised DNN-driven GML is even competitive with the traditional supervised attention-based models; (3) the supervised BERT-based approaches indeed achieve better performance than both traditional attention-based DNNs and unsupervised GML. However, their efficacy depends on the fine-tune phase that requires an access to the labeled training data, which are not available in the unsupervised setting; (4) **The hybrid GML solution consistently achieves the state-of-the-art performance across all datasets.** It improves the best performance by almost 2% on two datasets and 1%-2% on four out of six datasets. In light of the well recognized challenge of ATSA, these improvements are indeed considerable.

Illustrative Examples. To illustrate the effectiveness of implicit features, we present the features of the running example in Table 3. It can be observed that *overwhelmed*, *well-prepared*, and *presented* in r_{11} and r_{22} respectively are not captured by the lexicon, and r_{12} contains the context misunderstanding of *friendly*. Even though r_{11} and r_{12} do not share any explicit information, the negative context of *friendly* is very close to *overwhelmed*; they thus share the implicit features $f_{4.1}$ and $f_{5.4}$. Likewise, *well-prepared* in r_{22} is very close to *perfectly cooked* in r_{21}, and they share the implicit features $f_{7.4}$ and $f_{15.3}$.

r_{ij}	Features		GML Labeling	
	LEX	DDN-based	LEX	DNN
r_{11}	Awful	$\{f_{9.1}, f_{15.1}, f_{29.2}, f_{4.1}, f_{5.4}\}$	False	True
r_{12}	Friendly	$\{f_{2.4}, f_{3.2}, f_{4.1}, f_{5.4}, f_{19.3}\}$	False	True
r_{21}	Perfectly, Awesome	$\{f_{7.4}, f_{15.3}, f_{21.3}, f_{27.4}, f_{30.2}\}$	True	True
r_{22}	-	$\{f_{7.4}, f_{15.3}, f_{12.1}, f_{1.1}, f_{19.1}\}$	False	True

Table 3: Illustrative examples of implicit features.



(a) the host (owner) and servers are personable and caring .
(b) our waiter was horrible so rude and disinterested .
(c) the incrediby kind and gracious hostess .
(d) food is always fresh and hot- ready to eat !

Figure 4: Visualization of the attention weights.

5.2 Effectiveness of Sentiment Weighting

We illustrate the effectiveness of the designed attention mechanisms in terms of attending to aspect-relevant sentiment information, and understanding the context. We retrieve samples from the datasets and visualize their attention weights in Figure 4, in which the deeper the color, the more importance a word has. It can be observed that the aspect-opinion words are weighted among the others and the model effectively attends to the sentiment words that are not in the lexicon (e.g., personable, gracious in (a) and (c) respectively). Since the sentiment words dominate the sentence representation in Equation 8, this indeed encourages the model to sentimentally learn the representations of polarity indicators.

6 Conclusion

In this work, we propose a novel DNN-driven GML approach for ATSA that can effectively leverage common implicit features for knowledge conveyance. Our extensive experiments have shown that the proposed approach consistently achieves the state-of-the-art performance in both unsupervised and supervised setting. For future work, it is noteworthy that the DNN-driven GML approach is potentially applicable to other classification tasks; the technical solutions however need further investigation.

Abstract

Large-scale conversational assistants like Alexa, Siri, Cortana and Google Assistant process every utterance using multiple models for domain, intent and named entity recognition. Given the decoupled nature of model development and large traffic volumes, it is extremely difficult to identify utterances processed erroneously by such systems. We address this challenge to detect domain classification errors using offline Transformer models. We combine utterance encodings from a RoBERTa model with the N-best hypothesis produced by the production system. We then fine-tune end-to-end in a multi-task setting using a small dataset of human-annotated utterances with domain classification errors. We tested our approach for detecting misclassifications from one domain that accounts for <0.5% of the traffic in a large-scale conversational AI system. Our approach achieves an F1 score of 30% outperforming a bi-LSTM baseline by 16.9% and a standalone RoBERTa model by 4.8%. We improve this further by 2.2% to 32.2% by ensembling multiple models.

1 Introduction

Conversational assistants such as Cortana, Google Assistant, Alexa and Siri leverage multiple machine learning models and services like automatic speech recognition (ASR), natural language understanding (NLU), entity resolution (ER), utterance routing and text-to-speech (TTS). In particular, the NLU system is modularized into multiple domains such as Music, Movies, Weather etc. These domain teams then train one-vs-all domain, intent and named entity recognition models independently. At run time, a re-ranker is used to sort the output of these independent models and route the utterance to the right domain. This is a well-known design pattern used in large scale conversational assistants (Sarikaya, 2017; Su et al., 2018).

This modularized architecture allows scaling of NLU systems to support multiple domains catering to billions of diverse utterances. However, it is extremely challenging to isolate the source of error in utterances where the system fails, both due to the large traffic volume and the asynchronous nature of model development and updates by multiple independent teams. In particular, we focus on identifying utterances with domain classification errors, which we call false rejects (FR). Such errors can arise due to errors in individual domain classification models, re-ranker or routing algorithm and are extremely hard to isolate. To illustrate this challenge, consider a domain X that accounts for 0.5% of the traffic in a conversational assistant receiving Y utterances every week. Also assume that 20% of the utterances belonging to X are falsely routed to another domain. This implies that we have 0.1% of the total traffic that are FRs. Given a large traffic, manually sifting through the entire traffic to find such utterances is prohibitively expensive and infeasible.

Previous work in Feedback-Based Self-Learning in Large-Scale Conversational AI Agents (Ponnusamy et al., 2020) uses implicit user feedback as a signal to generate automated reformulations. However, for low traffic domains, the low frequency of occurrence for utterances at the tail end of the distribution does not allow for automated reformulations at scale. Finetuning of pretrained language representation models which leverage inductive transfer learning (Howard and Ruder, 2018) have shown marked performance improvement with very small training datasets. Language models with bidirectional encoding such as BERT (Devlin et al., 2019; Liu et al., 2019)

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 498–503
August 1–6, 2021.

which are pretrained using a masked language modeling task have shown further improvements on the finetuning task due to its deep bidirectional encoder-based language representation. Further, larger models with 100s of billions of parameters like GPT3 (Brown et al., 2020) have demonstrated significant performance improvements with increase in model size. However, leveraging such models in production systems is challenging due to latency constraints.

We address this challenge by leveraging the power of BERT based pretrained language representation models in an offline setting. We combine utterance encodings from RoBERTa with embeddings of the N-Best hypothesis for the same utterance from the production system and conduct end-to-end finetuning in a multitask learning setting (Caruana, 1997) with a small, manually curated training set containing FRs. Multitask learning enhances language representation by discovering synergies between various finetuning tasks. We then use this model to sift through all the traffic and identify other FRs.

We tested our approach for identifying FRs from one domain in a large-scale conversational assistant. Compared to the baseline F1 score of 13% using a bi-LSTM model, our approach achieves an F1 of 25% using RoBERTa encodings. We further improve performance to 28% using N-best output, 30% using multitask learning, and to 32.3% using an ensemble of multitask models.

The rest of the paper is organized as follows: first, we describe the production NLU system; next we present details of our FR detection system and finally we present experimental results and conclusion.

2 Architecture of Large-Scale NLU Systems

Large-scale NLU systems are typically modularized into domain-specific modules where a domain is typically something like Books, Music, Shopping etc. As illustrated in Figure 1, each domain consists of several sub-components that are served by models for Domain, Intent and Named Entity Recognition. Let's consider an example user utterance U: "play hello by adele". Assume there are M domains. This utterance is sent to all of them and each domain then processes the utterance by sending it through its sub-modules described below.

(1) A Domain Classifier is a one-vs-all classifier indicating if the utterance belongs to that domain. For the example utterance U, a good classifier should output a high score for the positive class in the "Music" domain and output a high score for the negative class in all the other domains.

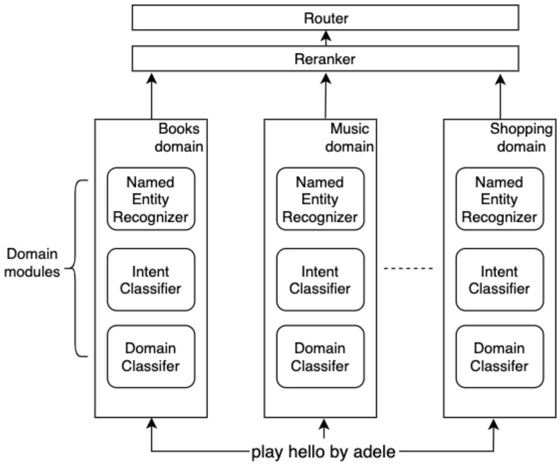

Figure 1: NLU System Architecture

(2) An Intent Classifier is a multi-class model that provides intent specific scores for each of the intents belonging to a target domain. For the example utterance U, a good intent classifier should produce a high score for the intent “PlayMusic” when run in the "Music" domain.

(3) A Named Entity Recognizer (NER) that identifies named entities present in an utterance. For the utterance U, a good classifier in the "Music" domain should select "hello" and "adele" tokens as probable named entities.

To minimize run-time latency constraints, most large-scale production systems use a combination of deterministic artifacts (like rules) and simple models like MaxEnt (Berger et al., 1996) for these tasks. Once the domains process the utterance, the outputs are fed into a predictive model called re-ranker to obtain a sorted list. This sorted output is then used by the Router to send the utterance to the right domain for processing.

Due to the high volumes of traffic and the modular architecture with several domains, detecting the presence of errors (for instance, a domain misclassification) and isolating their sources is very challenging. Errors can occur and accumulate through every step of the processing flow highlighted in Figure 1. We next present our approach to identify one such error called False Reject (FR) where an utterance does not get routed to the correct domain by the production system.

3 False Reject Detection

For a given domain D, the task of identifying false rejects (FR) involves analyzing all traffic routed to a domain other than D and identifying utterances that should instead have been routed to D. The key challenges are the availability of only a small number of annotated examples of such FR and the extreme imbalance in our test set between FRs and utterances that are routed correctly.

3.1 Baseline System

As a baseline model, we used a bi-LSTM (Schuster and Paliwal, 1997) model to classify whether an utterance belongs to a domain D or not. Utterances tokenized into words and characters are leveraged in the form of their pre-trained Glove embeddings (Sakketou and Ampazis, 2020) and passed to a bi-LSTM layer. The stateful output of the bi-LSTM layer is passed through a fully-connected layer which outputs the probability of an utterance belonging to domain D as per equation (1) where X_i represent the stateful output of the bi-LSTM layers, β the learned weights of the fully-connected layer and Y_i represents the classes.

$$\Pr(Y_i = 0) = \frac{e^{-\beta.X_i}}{1+e^{-\beta.X_i}} \tag{1}$$

$$\Pr(Y_i = 1) = 1 - \Pr(Y_i = 0) = \frac{1}{1 + e^{-\beta.X_i}}$$

The training data used for fine-tuning comes from a low-cost human annotation effort where a small set of utterances are marked as “False Reject” (FR) or not by expert annotators. The False Rejects (FRs) for a domain D are then identified by applying the bi-LSTM based model on a test set of utterances that match the production traffic distribution. The utterances that are assigned to a domain D by the bi-LSTM based model but are not assigned to a domain D by the production model are filtered as the final FR candidates.

3.2 Pre-trained transformer models

Pre-trained transformer models such as BERT, GPT, T5 have proven to be quite effective at multitude of NLU tasks. Specifically, they can be adapted to a downstream task by fine-tuning on a small-sized dataset.

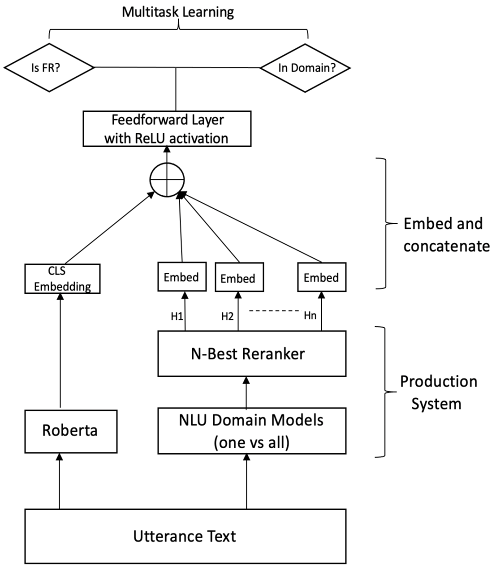

Figure 2: Transformer model leveraging N-Best from domain production models for FR detection

We leverage this strength for the task of FR detection. Specifically, we fine-tune a RoBERTa-based model for a binary classification problem in which given a domain D, we want the model to output the probability of an utterance belonging to that domain (represented as $\Pr(Y_i = 1)$ in equation (1). Instead of the bi-LSTM output, here X_i represents the weights from the pre-trained model passed through a fully-connected layer. The model is trained to optimize the cross-entropy loss using the same dataset as the baseline system. We use the Adam optimizer with bias correction (Kingma and Ba, 2017) and a learning rate of $2e^{-5}$ with a warmup for 1/10th of the total number of training steps.

3.3 Leveraging N-Best Embeddings

The NLU system described in Section 3 produces an N-best hypothesis that represents the top N domains a user utterance likely belongs to. We tested incorporating this information into the FR detection model using two steps.

Embed & Concatenate (N-best module): To leverage the N-best hypotheses, we choose top N hypotheses from the re-ranker, embed each of them into a 6-dimensional vector and concatenate them into a 6N-dimensional vector. This vector is further concatenated with the 1024 dimensional [CLS] token embedding from the pre-trained RoBERTa model. This (1024 + 6N) dimensional vector is then passed through a feed-forward layer to feed to the output layers.

Multi-task output: The model is trained to output predictions for two tasks. The first task is to determine if the utterance belongs to a domain or not. This is a generic task and is not specifically geared towards identifying if the production system falsely rejected an utterance. To this, we add a second classification task to specifically classify if the utterance is falsely rejected or not. These tasks could also share useful information across one another through their input hidden features.

The final model architecture that includes these components can be seen in Figure 2. A tokenized utterance is sent through the pre-trained RoBERTa model followed by the N-best module. The output from the N-best module is fed separately to two feed-forward layers to produce two outputs. The model is trained for 3 epochs using the same hyperparameters as the baseline transformer. The training took about 2 hours on a p3.dn24x large instance.

4 Results

We use a dataset with a FR to non-FR ratio of 1:15. This is not the true production distribution[1].

	Precision	**Recall**	**F1**
bi-LSTM	20.3	9.7	13.1
RoBERTa	50.1	16.3	25.2
RoBERTa + N-Best single task model	23.4	35.3	28.1
RoBERTa + N-Best multitask model	31.0	30.0	30.0
RoBERTa + N-Best multitask model (ensemble)	**37.4**	**28.3**	**32.2**

Table 1: Performance comparison of different FR detection techniques

However, it captures the imbalance and the low resource setting that we want to address in our framework. We hold out 15% of this dataset for validation. We have processed the data so that users are de-identified.

Table 1 compares the performance of different techniques we tested. We see a 12.1% absolute F1-score improvement from bi-LSTM to RoBERTa illustrating the value of pre-training for problems with extreme class imbalance and small training sets.

Incorporating the N-Best embeddings produces a further 3.1% improvement illustrating the value of using information from the production system itself to detect errors in its output. Using a multitask learning setting improves it further by 1.9% showing how similar tasks share learning representations. Ensembling produces an additional 2.2% improvement that is consistent with other machine learning results.

Figure 3 presents a comparison of the precision-recall curves for RoBERTa and RoBERTa+N-Best multitask models. While the performance is comparable at high precisions, at lower values, the latter significantly outperforms. This is because the standalone RoBERTa model identifies a small number of frequent FRs, while the RoBERTa+N-Best multitask model is able to identify a greater variety of FR patterns without compromising precision significantly. Thus, the latter model offers a better tradeoff in identifying FRs that can then be used as data to train the production domain classifiers.

4.1 Production model improvements

Our RoBERTa-large based model is not directly usable in production due to latency constraints. As a result, we use a human-in-the-loop system where we leverage our model by running it in an offline setting to identify false reject candidates. These false reject candidates are sent for human annotation and the resulting annotations are fed as training data to the production model. We've noticed that the annotation throughput of true false rejects is improved by 5x due to the curated candidates provided by the offline transformer model. Furthermore, because these annotations are used to further train the production model, the False Rejects are reduced by about 20%.

---

[1] For confidentiality reasons, we don't use the true production distribution.

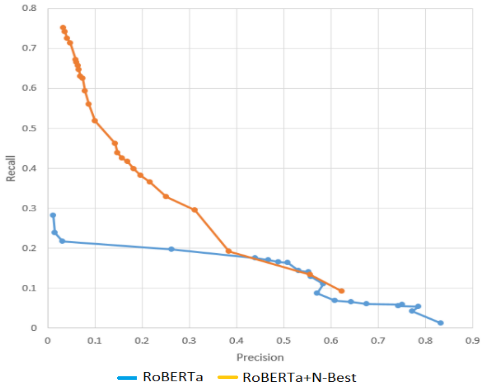

Figure 3: Precision-Recall Curve for RoBERTa and RoBERTa+N-Best embedding multitask

5 Conclusion

Our work presents a system for leveraging the power of computationally intensive, but accurate pre-trained language models to identify errors in a large-scale conversational assistant through offline analysis. Our results also demonstrate the effectiveness of such models in problems with large class imbalances. Specifically, we achieve an F1 score of 25.2% outperforming a bi-LSTM baseline by 12.1%. Further, we show that combining the output of the production system with pre-trained language models produce significant improvements (of 4.8 F1 points). As future work, we plan to leverage even larger models such as Megatron (Shoeybi et al., 2019) and T5 (Raffel et al., 2019) to achieve further improvements for the FR detection task.

Abstract

Out-of-domain (OOD) input detection is vital in a task-oriented dialogue system since the acceptance of unsupported inputs could lead to an incorrect response of the system. This paper proposes OutFlip, a method to generate out-of-domain samples using only in-domain training dataset automatically. A white-box natural language attack method HotFlip is revised to generate out-of-domain samples instead of adversarial examples. Our evaluation results showed that integrating OutFlip-generated out-of-domain samples into the training dataset could significantly improve an intent classification model's out-of-domain detection performance[1].

1 Introduction

Intent classification is crucial for task-oriented dialogue systems such as Google DialogFlow or Amazon Lex. It is vital for an intent classifier not only to map an input utterance into the correct label but also to detect *out-of-domain* (OOD) inputs. An accepted OOD input will lead the dialogue system to give erroneous responses.

Approaches for OOD detection in text classification could be classified into two major categories. Outlier detection approaches (Fei and Liu, 2016; Hendrycks and Gimpel, 2017; Shu et al., 2017; Lin and Xu, 2019; Yan et al., 2020; Xu et al., 2020) try to find out the boundaries of known classes in feature space. They need no labeled OOD dataset, but it is hard for them to deal with boundary cases. $(n+1)$-way classification approaches (Kim and Kim, 2018; Larson et al., 2019; Ryu et al., 2018; Zheng et al., 2020) train classifiers for OOD detection using (pseudo-)labeled OOD samples. In practice, it is difficult and expensive to collect a large number of labeled OOD samples with an open-world environment.

This paper proposes OutFlip, a method to generate OOD samples from in-domain training dataset automatically. For a given training dataset T and a reference intent classification model M which is trained with T, the OutFlip generates a set of OOD samples O. The generated OOD samples O could be used to train M iteratively to improve its OOD detection performance. Since the OutFlip does not require any modifications to the model architecture, it could be used with other OOD detection approaches to further improve the OOD detection performance.

The generated OOD samples should satisfy two conditions. First, they should be "hard-enough"; if the generated examples are too easy to distinguish from in-domain intents, they will be useless in training the OOD detector. Second, they should not belong to any in-domain intents. With a given reference model M and a set of in-domain labels I, this could be considered as finding a sentence $\mathbf{x}_o$ with truth label $y \notin I$ and model classification $y' \in I$. In this point of view, the OOD sample generation task could be considered as a variant of natural language attack on model M; the goal of natural language attack on M is to find a $\mathbf{x}_a$ with truth label $y \in I$ and model classification $y' \neq y$. We revised HotFlip (Ebrahimi et al., 2018), a natural language attack method, to generate such OOD samples.

Our evaluation results showed that the generated OOD samples could significantly improve the OOD detection performances of the reference models. We also showed that applying OutFlip with other OOD detection approaches could further improve the model's OOD detection performance. The evaluation results also suggest that the generated OOD samples could train the models other than the reference model to improve their OOD detection perfor-

mances.

Our contributions are summarized as follows:

- We proposed OutFlip, a simple and efficient OOD sample generation method using only in-domain training samples.
- We experimentally showed the effectiveness of our proposed approach using the intent classification benchmarks.
- We showed that the generated OOD samples could also improve the OOD detection performances of models other than the reference model.

2 Related Work

Previous OOD detection works could be classified into two major categories. Outlier detection approaches find boundaries of known classes in feature space. Fei and Liu (2016) computes a center for each class and transforms each document into a vector of similarities to the center. A binary classifier is built using the transformed data for each class. For deep learning-based systems, Hendrycks and Gimpel (2017) proposed the baseline of using softmax score as a threshold. Shu et al. (2017) trained the intent classifier using the sigmoid function and used the standard distribution to set each class's score threshold. Lin and Xu (2019) first trained the classifier using Large Margin Cosine Loss (LMCL) (Nalisnick et al., 2018), and applied Local Outlier Factor (Breunig et al., 2000) to detect the OOD inputs. Yan et al. (2020) proposed a semantic-enhanced Gaussian mixture model to gather vectors of the same classes closely. Xu et al. (2020) calculated the mean and covariance of training samples for each class and used Mahalanobis distance as a distance function.

$(n + 1)$-way classification approaches train the intent classifier with one additional class, where $(n + 1)$-th class represents the unseen intent. Kim and Kim (2018) proposed joint learning for in-domain and out-of-domain speeches. Larson et al. (2019) manually collected OOD samples to train intent classifiers. Ryu et al. (2018) generated OOD feature vectors using generative adversarial network (Goodfellow et al., 2014) to train an OOD detector. Since the approach proposed in Ryu et al. (2018) only works on continuous feature space, it highly depends on the feature encoder, which transforms inputs into feature vectors. Zheng et al. (2020) also generated OOD feature vectors, but they also used unlabeled examples to enhance classification performance further. Although the $(n + 1)$-way classification approaches are easy to adopt without modification in the classification model, it is incredibly costly and time-consuming to collect the appropriate OOD samples.

The proposed OutFlip automatically generates OOD samples using the only in-domain training set, significantly reducing the cost of manually collecting OOD samples. Also, the OutFlip does not depend on the feature encoder.

The goal of adversarial attack in text classification is to fool a given text classification model M, by generating an adversarial example $\mathbf{x}_a$ with truth label y and model classification $y' \neq y$. Many successful attacks first take a correctly classified example $\mathbf{x}$ and replace its important words or characters to get an adversarial sample $\mathbf{x}_a$. In a white-box scenario, the attacker has access to the target model's structure; thus, the important word or characters could be easily selected by inspecting the gradient of model M. HotFlip (Ebrahimi et al., 2018) estimates the best change of characters by maximizing the first-order approximation of the change in the loss.

In a black-box scenario, the attacker is not aware of the model or training data; the attacker is only capable of querying the target model with supplied inputs and obtaining the output predictions and their confidence scores. Alzantot et al. (2018) randomly selects a word from sentence $\mathbf{x}$ and selects a suitable replacement word that has a similar semantic meaning. Jin et al. (2020) proposed a word importance score, which is used to find the word to be replaced. Li et al. (2020) applied BERT (Devlin et al., 2018) pre-trained language model to find a replacement word.

The proposed OutFlip first extracts important words using the algorithm proposed in Jin et al. (2020), and applies a variant of HotFlip (Ebrahimi et al., 2018) to generate OOD samples which are hard to distinguish from the in-domain intents by the given reference model.

3 Proposed Approach

In this section, the proposed OOD sample generation approach OutFlip is described in more detail.

3.1 HotFlip

We first introduce the white-box adversarial example generation method HotFlip (Ebrahimi et al., 2018). Let M be a text classification model, V be the word vocabulary set, $\mathbf{x} = \{x_1; ...; x_n\}$ be a sentence with n words where $x_i \in \{0,1\}^{|V|}$ denotes one-hot vector representing the i-th word, and $L_M(\mathbf{x}, \mathbf{y})$ be the loss of M on input $\mathbf{x}$ with true output $\mathbf{y}$. For a given sentence $\mathbf{x}$, a flip of the i-th word from w_a to w_b is represented by the following vector:

$$\vec{v}_{ib} = (\vec{0}; ..; (0, .., -1, .., 1, 0, .., 0)_i; ..; \vec{0}) \quad (1)$$

where -1 and 1 are in the corresponding positions for words w_a and w_b in the word vocabulary, respectively. A first-order approximation of the change in loss $L_M(\mathbf{x}, \mathbf{y})$ can be obtained from a directional derivative along this vector:

$$\nabla_{\vec{v}_{ib}} L_M(\mathbf{x}, \mathbf{y}) = \nabla_x L_M(\mathbf{x}, \mathbf{y})^T \cdot \vec{v}_{ib} \quad (2)$$

Then, the HotFlip chooses the vector with the biggest increase in loss:

$$\begin{gathered} \max \nabla_x L_M(\mathbf{x}, \mathbf{y})^T \cdot \vec{v}_{ib} = \max_{ib} \frac{\partial L_M^{(b)}}{\partial x_i} - \frac{\partial L_M^{(a)}}{\partial x_i} \\ \text{subject to } sim(w_a, w_b) \geq T_{sim} \\ \text{and } POS(w_a) = POS(w_b) \end{gathered} \quad (3)$$

where T_{sim} is a similarity threshold between two words, and $POS(w_a)$ is the Part-of-Speech tagging of w_a. The two constraints are added to ensure that $\mathbf{x}_a$ is semantically similar to the original input $\mathbf{x}$. With equation 3, the HotFlip could determine the flip position i and the replacement word w_b.

3.2 OutFlip

For a given reference model M and an in-domain sample $\mathbf{x}$ with true output $\mathbf{y}$, the main idea of OutFlip is to flip the most important word of $\mathbf{x}$, $w_M(\mathbf{x})$, to a semantically different word, while *minimizing* the change of loss $L_M(\mathbf{x}, \mathbf{y})$. By doing so, the OutFlip expects to get a sample $\mathbf{x}_o$ whose truth label is different from the truth label of $\mathbf{x}$, while the model classifications of $\mathbf{x}_o$ and $\mathbf{x}$ are the same.

The word importance score proposed in Jin et al. (2020) is defined as follows:

$$I_{x_i}(M, \mathbf{x}) = o_y(M, \mathbf{x}) - o_y(M, \mathbf{x}_{\setminus x_i}) \quad (4)$$

Algorithm 1 OutFlip

```
Input In-domain training corpus $T = \{\mathbf{x}_1, ..., \mathbf{x}_t\}$,
      in-domain labels $Y$, vocabulary $V$, reference
      model $M$, similarity threshold $T_{sim}$
Output A set of OOD samples $O$
for $y \in Y$ do
    for $\mathbf{x}$ with truth label $y$ do
        Calculate $w_M(\mathbf{x})$
    end for
    $C_T(y) \leftarrow$ Top 5 most frequent $w_M(\mathbf{x})$
end for

for $\mathbf{x} \in T$ do
    $y \leftarrow$ truth label of $\mathbf{x}$
    if $w_M(\mathbf{x}) \in C_T(y)$ then
        $i \leftarrow$ the position of $w_M(\mathbf{x})$
        Sort $V$ in ascending order of $\frac{\partial L_M^{(b)}}{\partial x_i}$
        Candidate $\leftarrow$ Top 1% of $V$
        Remain only words whose similarity
          with $w_M(\mathbf{x})$ is less than $T_{sim}$
        Randomly select $w_b$ among candidates
        Replace $w_M(\mathbf{x})$ with $w_b$ to get $\mathbf{x}_o$
        if $M$ classifies $\mathbf{x}_o$ to $y$ then
            Add $\mathbf{x}_o$ to $O$
        end if
    end if
end for
```

where y is the truth label of $\mathbf{x}$, $o_y(M, \mathbf{x})$ is the logit output of the target model M for label y, and $\mathbf{x}_{\setminus x_i}$ is the sentence after masking x_i. The most important word $w_M(\mathbf{x})$ is defined as the word with the largest importance score in $\mathbf{x}$.

For each in-domain label y of the training dataset T, we define Core Class Token (CCT) $C_T(y)$ as the top 5 most frequent $w_M(\mathbf{x})$ among the training samples with truth label y. Since the importance score is calculated based on the reference model M, the OutFlip could select a wrong token as the most important token due to the model error. If the OutFlip flips such a word, the generated sentence's truth label will remain unchanged, leading to an erroneous OOD sample. To prevent such case, the OutFlip simply disregards $\mathbf{x}$ during OOD generation process if $w_M(\mathbf{x}) \notin C_T(y)$.

In summary, the OutFlip chooses the replace-

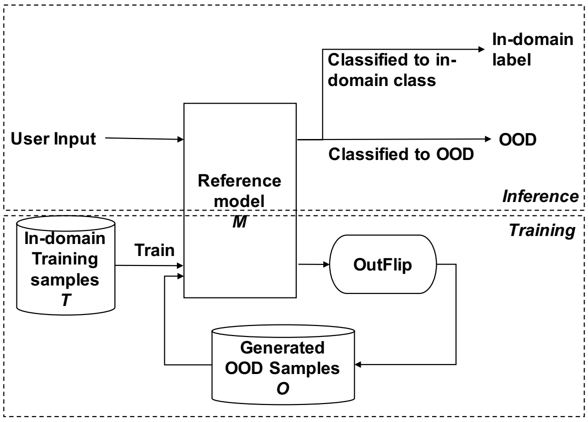

Figure 1: Applying the OutFlip to iteratively train the reference model M with newly generated OOD samples.

ment word w_b using the following equation:

$$\min \nabla_x L_M(\mathbf{x},\mathbf{y})^T \cdot \vec{v}_{ib} = \min_{ib} \frac{\partial L_M^{(b)}}{\partial x_i} - \frac{\partial L_M^{(a)}}{\partial x_i}$$
$$\text{subject to } sim(w_a, w_b) \leq T_{sim}$$
$$\text{and } w_a = w_M(\mathbf{x})$$
$$\text{and } w_a \in C_T(y) \qquad (5)$$

Since we do not need the generated OOD samples to be fluent, the part-of-speech condition is removed. The OutFlip randomly chooses w_b among the top 1% of the vocabulary in the ascending order of the loss change to generate more diverse samples. We used cosine similarity as the similarity measure.

The truth label of the generated sample $\mathbf{x}_o$ could be an in-domain label different from y by chance. The OutFlip checks the model classification result of $\mathbf{x}_o$ to see if it remains the same as $\mathbf{x}$. If the classification result changes, the OutFlip disregards $\mathbf{x}_o$. Algorithm 1 shows the pseudocode of the proposed OutFlip.

3.3 Iteratively Populating OOD samples

The reference model M could be iteratively trained with the generated OOD samples to improve its OOD detection performance. Figure 1 shows the overall framework. For each iteration, the set of generated OOD samples O is randomly split into training and dev set and used for the next train iteration.

Since the OutFlip does not require any change in model architecture, the OutFlip could be applied independently with other OOD detection algorithms that require modifications on model architecture or loss function, such as Shu et al. (2017) or Lin and Xu (2019). In such cases, those OOD detection algorithms are applied to the examples classified as in-domain to filter out the OOD samples further.

4 Experiments

In this section, experimental settings and evaluation results are shown.

4.1 Datasets

Experiments are conducted on 3 real task-oriented dialogue datasets, SNIPS (Coucke et al., 2018), ATIS (Hemphill et al., 1990) and Kakao dialogue corpus[2] (Choi et al., 2020). SNIPS and ATIS are well-known English benchmarks. Kakao dialogue corpus is a Korean intent classification benchmark. We evaluated the proposed OutFlip with the Kakao dataset to see if it could be applied to different languages. Table 1 summarizes the statistics of the datasets. The ATIS dataset is highly imbalanced; more than 70% samples belong to one class, while three classes have less than 10 samples. The SNIPS and Kakao datasets are relatively balanced.

Since the SNIPS dataset does not have a test set, we randomly selected 30% of the training set and used them as the test set.

4.2 Baselines

We implemented two sentence encoders to show the generality of the proposed approach. LSTM (Hochreiter and Schmidhuber, 1997)-based encoder applies one-layer BiLSTM with output dimension 128 on the word embeddings of the given input; a self-attention layer with attention dimension 10 is followed to get the feature vector. CNN-based model applies the algorithm proposed in Kim

---

[2] Since the Kakao dataset is not publicly available, we contacted the authors to get the Kakao dataset and Korean GloVe vectors.

Table 2: Comparisons of the OutFlip and previous OOD detection works. The top 2 results for each metric are marked in bold. T_{sim} is set to 0.3, and the OutFlip is applied for three iterations.

(2014). More precisely, one-dimensional convolutions with kernel sizes 2, 3, 4, 5 and filter size 32 are applied on top of the word embeddings. The results are max-pooled to get the feature vector. For both encoders, a dense layer is applied to the feature vector to get the logit of each class.

We also implemented three baseline OOD detection systems, as follows:

1. **Maximum Softmax Probability (MSP)** (Hendrycks and Gimpel, 2017) considers the maximum softmax probability of a sample as the rejection score. If the probability is below a certain threshold, the sample is classified as OOD. We used the threshold of 0.5, as the authors suggested.
2. **Deep Open Classification (DOC)** (Shu et al., 2017) replaces softmax with sigmoid activation as the final layer to calculate the score for each class separately. It also calculates the threshold for each class through a statistical approach.
3. **Large Margin Cosine Loss (LMCL)** (Lin and Xu, 2019) replaces the softmax loss with large margin cosine loss (Nalisnick et al., 2018), to force the model to maximize interclass variance and minimize intra-class variance. After training, it applies Local Outlier Factor (LOF) (Breunig et al., 2000) on training features vectors to detect outliers as OOD. We set the scaling factor $s = 30$ and cosign margin $m = 0.35$, following the authors.

By combining two feature encoders and three baseline OOD detection systems, we implemented eight baseline reference models, six with an OOD detection system and two without.

Pre-trained Embeddings	Accuracy
GloVe (Pennington et al., 2014)	83.17 %
Korean GloVe (Choi et al., 2020)	51.33 %

Table 3: Evaluation results of GloVe embeddings on the language-independent set of word analogy corpus.

4.3 Experimental Setup

Word embeddings are initialized with GloVe (Pennington et al., 2014) pre-trained word vectors. We downloaded the pre-trained embeddings containing 1.9M words trained on 42B tokens from the author's homepage. For Korean, Korean pre-trained GloVe embedding vectors proposed in Choi et al. (2020) are used. The dimensions of both pre-trained embeddings are 300.

We removed some classes from the train/dev set during training and integrated them back during testing, following the evaluation settings of Fei and Liu (2016); Shu et al. (2017); Lin and Xu (2019). We varied the number of known intents in the training dataset as 25%, 50%, and 75% of the intents, and used all intents for testing. We randomly select known intents by weighted random sampling without replacement in the training set. Note that the samples belonging to the unknown intents are removed during training and validation.

Following Fei and Liu (2016); Shu et al. (2017); Lin and Xu (2019), macro F1 score is used to evaluate the models. For each known intent selection, the F1 score for each class is calculated separately. Then the results are macro-averaged across all classes. We reported the average of 10 random known intent selections for each evaluation.

For each OutFlip iteration, 90% of the generated OOD samples are added to the training set, and

Table 4: Evaluation results of the baselines with the OutFlip applied. T_{sim} is set to 0.3, and the OutFlip is applied for three iterations. Small numbers below the macro F1 score represents the performance improvement compared to the same baseline without applying the OutFlip.

the remaining 10% are added to the dev set. The populated train/dev sets are used for the next train iteration.

Adam optimizer (Kingma and Ba, 2015) with an initial learning rate of 0.001 is used to train the model. The training batch size is set to 128. Exponential learning rate decay with a decay rate of 0.8 is applied for every two epochs. On each epoch, the trained classifier is evaluated against the dev set, and the training stops when the dev accuracy is not improved for five consequent epochs.

4.4 Evaluation Results

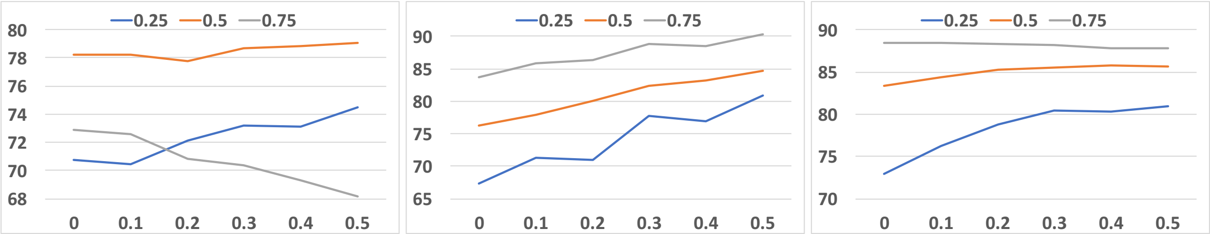
Table 2 shows the evaluation results of the proposed OutFlip and other baseline systems. As can be observed from the table, the proposed OutFlip outperforms other baselines when the number of known intents is small. The small number of known intents is the most similar case to real-world applications, since in the open-world environment, the number of unknown intents is much larger than the number of known intents. The OutFlip also gives comparable results for ATIS and SNIPS corpus with the larger number of known intents.

For the Kakao corpus, the OutFlip performance is lower compared to the other baselines. To figure out the reason, the qualities of English GloVe embeddings and Korean GloVe embeddings are compared. We used 4 out of 14 categories in the word analogy corpus (Mikolov et al., 2013) for fair comparison; `capital-common-countries`, `capital-world`, `currency` and a subset of `family`. We removed all the syntactic questions since they cannot be translated into Korean words one-to-one. Part of `family` category is removed for the same reason. We also removed categories that give an advantage on English pre-trained embeddings; for example, the `city-in-state` category is removed because it contains relationships between US cities and US states. The remaining 6,168 questions are manually translated into Korean.

Table 3 shows the evaluation results of the English and Korean GloVe vectors on our subset of the word analogy corpus. As can be observed, the accuracy of Korean GloVe is much lower compared to the English GloVe vectors. Since the OutFlip relies on the cosine similarities between pre-trained embedding vectors to generate the OOD samples, the quality of embedding vectors is critical to the OOD generation performance.

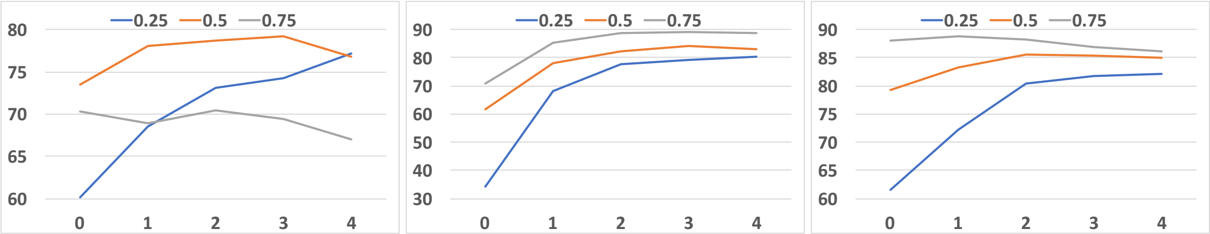
Next, we applied the proposed OutFlip to other OOD detection baselines to see if the OutFlip could further improve their performance. Table 4 shows the evaluation results. In most cases applying the OutFlip to other OOD detection approaches resulted in performance improvement. The performance improvement was significant when the dataset is balanced, and the number of known intents is small.

We conducted a set of experiments to find out the best OutFlip iteration number and T_{sim} value. Figure 2 and Figure 3 shows the OutFlip performances on the benchmark datasets with changing



(a) ATIS dataset (b) SNIPS dataset (c) Kakao dataset

Figure 2: Evaluation results of **OutFlip**$_{cnn}$ with changing T_{sim}. We fixed the number of OutFlip iteration to 2.



(a) ATIS dataset (b) SNIPS dataset (c) Kakao dataset

Figure 3: Evaluation results of **OutFlip**$_{cnn}$ with changing OutFlip iteration number. We fixed T_{sim} to 0.3.

T_{sim} values and OutFlip iteration numbers, respectively. Increasing T_{sim} value would cause the OutFlip to generate more challenging examples, but the chance of developing wrong OOD samples would also increase.

Figure 2 suggests that the balanced dataset like SNIPS could easily recover the errors introduced from large T_{sim} values. In contrast, the ATIS dataset's macro F1 score decreases with the increased T_{sim} values when many intents are known. Since 3 out of 18 ATIS intents have less than ten sentences, one or two erroneous OOD samples could lead to a performance drop. The macro F1 score of the balanced Kakao dataset does not increase with the T_{sim} values larger than 0.3. Since the quality of Korean GloVe is relatively low, large T_{sim} values introduce more errors compared to the English datasets.

As can be observed from Figure 3, in most cases, the macro F1 score converges with two to three OutFlip iterations. Additional OutFlip iterations give small or no performance improvements for balanced datasets and decrease macro F1 score for unbalanced dataset ATIS by introducing more errors.

One advantage of the OutFlip is that the generated OOD samples could be used to train and improve the OOD detection performance of the models other than the reference model without applying additional OutFlip iterations. We trained the BERT-base and BERT-large models (Devlin et al., 2018) with the ATIS and SNIPS benchmarks. As the same as previous experiments, the unknown intents are removed during training and integrated back during testing. Besides, we added OOD samples generated using reference models **OutFlip**$_{cnn}$ and **OutFlip**$_{lstm}$ with three OutFlip iterations and T_{sim} value 0.3, while training the BERT models.

Table 5 shows the evaluation results of the BERT models trained with the OutFlip-generated OOD samples. As can be observed from the table, the OutFlip-generated OOD samples significantly improved the OOD detection performances of BERT models, regardless of the reference models used to generate the OOD samples.

4.5 Error Analysis

We randomly selected 200 samples from the OOD examples generated by **OutFlip**$_{cnn}$ with three iterations and $T_{sim} = 0.3$ for the ATIS dataset, when 75% of the intents are known. The number of newly generated OOD samples for each iteration is shown in Table 6. We manually analyzed the selected examples for errors.

Among the 200 examples, 186 of them were correctly generated OOD sentences. Out of 14 error cases, 12 were due to the wrongfully extracted Core Class Tokens. Some ATIS intents have too few examples to extract Core Class Tokens; for example, intent `atis_restriction` has only six samples. Also, an entity which shows up too frequently could also lead to wrong Core Class Token

Model	Reference model for OutFlip	ATIS			SNIPS		
		25%	50%	75%	25%	50%	75%
BERT-base	*None*	62.14	74.73	72.61	34.66	60.76	70.49
	OutFlip$_{cnn}$	70.60	76.08	72.45	**74.51**	**81.09**	**86.92**
	OutFlip$_{lstm}$	**71.58**	**78.22**	**72.68**	73.02	81.04	86.50
BERT-large	*None*	62.17	74.01	73.32	34.56	61.07	70.51
	OutFlip$_{cnn}$	**76.02**	80.68	**79.54**	70.95	**80.53**	**87.06**
	OutFlip$_{lstm}$	74.55	**81.46**	75.38	**73.15**	80.31	86.60

Table 5: Results of applying OutFlip-generated samples to train models other than the reference model. Reference model *None* means no OutFlip-generated OOD samples are added during training.

Iteration	1	2	3	4
ATIS	2003	1648.5	755.5	336.6
SNIPS	4923.5	4644.2	3221.5	1956.2

Table 6: The number of generated OOD samples for each OutFlip iteration with reference model **OutFlip**$_{cnn}$, $T_{sim} = 0.3$. 75% of the intents are known. Numbers are the average of 10 known intent selections.

extraction result. For intent `atis_flight`, 797 out of 4,334 samples contain the entity "Denver".

For one case, the OutFlip-generated sentence accidentally belongs to the other in-domain intent. However, due to the reference model's error, the OutFlip fails to remove the generated sentence. A training instance "Can you list the cheapest round trip **fare** from Orlando to Kansas City" (truth label `atis_airfare`) is converted to a sentence "Can you list the cheapest round trip **airplane** from Orlando to Kansas City" (truth label `atis_flight`), but the reference model classifies the converted sentence to `atis_airfare`. Since the classification result remains the same, the OutFlip considers the generated sentence as "hard-enough" OOD sample.

The ATIS dataset allows an instance to have multiple labels; two or more labels are assigned to 23 ATIS training instances. The OutFlip failed to properly handle those instances. The remaining one error case is generated from a training instance with two assigned labels.

5 Conclusion

In this paper, we proposed OutFlip, a method to generate OOD samples using only in-domain training dataset. Our evaluation results showed that the proposed OutFlip could significantly improve the OOD detection performance of an intent classification model by iteratively generating difficult OOD samples. Since OutFlip does not require any modifications to model architecture, it could be used with other OOD detection approaches to improve OOD detection performance further. We also showed that the generated OOD samples could be used to train and improve the OOD detection performance of models other than the reference model, without applying additional OutFlip iterations.

Currently, we only focused on generating difficult OOD samples, which can fool the reference model. However, generating meaningful OOD samples could also be beneficial, since then the dialogue engine developer could check the generated OOD samples to find new intents. As our future work, we will focus on generating meaningful, fluent OOD samples.

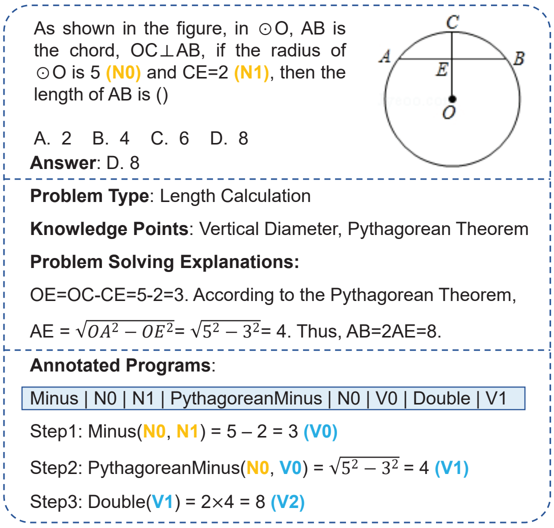
Abstract

Automatic math problem solving has recently attracted increasing attention as a long-standing AI benchmark. In this paper, we focus on solving geometric problems, which requires a comprehensive understanding of textual descriptions, visual diagrams, and theorem knowledge. However, the existing methods were highly dependent on handcraft rules and were merely evaluated on small-scale datasets. Therefore, we propose a **Geo**metric **Q**uestion **A**nswering dataset **GeoQA**, containing 5,010 geometric problems with corresponding annotated programs, which illustrate the solving process of the given problems. Compared with another publicly available dataset GeoS, GeoQA is 25 times larger, in which the program annotations can provide a practical testbed for future research on explicit and explainable numerical reasoning. Moreover, we introduce a Neural Geometric Solver (NGS) to address geometric problems by comprehensively parsing multimodal information and generating interpretable programs. We further add multiple self-supervised auxiliary tasks on NGS to enhance cross-modal semantic representation. Extensive experiments on GeoQA validate the effectiveness of our proposed NGS and auxiliary tasks. However, the results are still significantly lower than human performance, which leaves large room for future research. Our benchmark and code are released at https://github.com/chen-judge/GeoQA.



As shown in the figure, in ⊙O, AB is the chord, OC⊥AB, if the radius of ⊙O is 5 (N0) and CE=2 (N1), then the length of AB is ()

A. 2 B. 4 C. 6 D. 8

Answer: D. 8

Problem Type: Length Calculation

Knowledge Points: Vertical Diameter, Pythagorean Theorem

Problem Solving Explanations:

OE=OC-CE=5-2=3. According to the Pythagorean Theorem,

AE = $\sqrt{OA^2 - OE^2}$= $\sqrt{5^2 - 3^2}$= 4. Thus, AB=2AE=8.

Annotated Programs:

Minus | N0 | N1 | PythagoreanMinus | N0 | V0 | Double | V1

Step1: Minus(N0, N1) = 5 – 2 = 3 (V0)

Step2: PythagoreanMinus(N0, V0) = $\sqrt{5^2 - 3^2}$ = 4 (V1)

Step3: Double(V1) = 2×4 = 8 (V2)

Figure 1: Illustration of a typical geometry problem with the annotated programs in our GeoQA dataset.

1 Introduction

In recent years, developing machine learning systems to solve math word problems (MWPs) automatically has attracted increasing attention due to its high academic value and the great application potential in smart education (Bajaj and Sharma, 2018; Lin et al., 2018). Most of the existing methods focus on solving arithmetic and algebraic problems, including traditional machine learning approaches (Kushman et al., 2014; Zhou et al., 2015; Huang et al., 2016) and network-based models (Wang et al., 2017, 2018; Xie and Sun, 2019), while solving geometric problems has been rarely investigated (Seo et al., 2014, 2015a; Sachan et al., 2017). As a classic math problem, geometry dominates a large portion of secondary education. Due to its challenges and data characteristics, geometry problem can also serve as a multimodal numerical reasoning benchmark requiring joint reasoning over diagram and text.

As shown in Figure 1, a typical geometric question mainly consists of textual descriptions and geometric diagrams. Compared with math word problems, which only involve problem texts, geometric questions have posed the following new challenges. **First**, the additional problem diagrams provide essential information absent from the problem text,

such as the relative location of lines and points; thus, the solver should have the capability to parse the diagram. **Second**, to solve a geometry problem, we need to understand and align the semantics of text and diagram simultaneously. However, the problem text often includes some ambiguous references and implicit relations to diagram elements, which increases the difficulty of joint reasoning over text and diagram. **Third**, many geometric problems require extra theorem knowledge in the problem solving process. For example, in Figure 1, the Pythagorean Theorem is used to calculate the length of line AE.

Though some previous methods (Seo et al., 2014, 2015a; Sachan et al., 2017, 2020; Sachan, 2020) attempt to resolve the mentioned issues, the performance of their geometric problem solving systems is far away from satisfactory. They highly depended on limited handcraft rules and were only validated on small-scale datasets, making it hard to generalize to more complex and real-world cases. Besides, the solving process is sophisticated, which means it is difficult for a human to understand and examine its reliability.

To refresh the research on geometric problem solving and promote further study on multimodal numerical reasoning, we propose a large-scale real-world geometric question answering dataset called GeoQA, which contains 5,010 multiple-choice geometric problems collected from real math exams in Chinese middle school. Inspired by Amini et al. (2019), we additionally introduce a new domain-specific language to model precise operation programs corresponding to the geometry problem. These executable programs represent the numerical reasoning steps of geometry problems. Compared with the existing dataset GeoS and GeoS++ (Seo et al., 2015a; Sachan et al., 2017), our GeoQA is larger, more diverse, provides additional program annotation, thus serves as a promising benchmark to improve both generalization and interpretability of the multimodal numerical reasoning approaches.

Moreover, we propose the first deep learning-based approach for geometry problem solving, named as Neural Geometric Solver (NGS). It applies a co-attention mechanism to fuse the representation of text and diagram, and predicts the explainable programs based on the cross-modal representation. These sequential programs can be executed to obtain a final answer. Benefiting from the structured and explainable program prediction, our NGS has both merits in superior performance by learning-based models compared to previous rule-based methods, as well as generating explainable numerical reasoning steps via the program sequence in favor of the model diagnosis. We further design three highly-relevant pretext tasks to enhance text-diagram semantic representation, including diagram jigsaw location prediction, diagram geometric element prediction, and knowledge point prediction. Extensive experiments are conducted on GeoQA benchmark, and the quantitative comparisons show the superiority of the proposed NGS and auxiliary tasks over other multimodal baselines.

In summary, our contributions are three-fold:

- We construct a large-scale dataset for geometric problem solving, which contains 5,010 Chinese geometric multiple-choice questions with rich domain-specific program annotations.
- A novel Neural Geometric Solver is proposed to solve geometric problems by generating symbolic programs based on the joint understanding of textual descriptions and diagrams.
- Multiple specialized auxiliary tasks are employed to effectively improve the semantic representation of text and diagrams. Experiments show the superiority of our NGS equipped with these auxiliary tasks.

2 Related Work

Geometry Problems Solving Developing automated systems to solve geometry problems has a long history in AI (Gelernter et al., 1960; Wen-Tsun, 1986; Chou et al., 1996; Ye et al., 2008). For example, Seo et al. (2014, 2015a) built the first automated system, GeoS, to solve SAT style geometry problems. GeoS used NLP and computer vision techniques (e.g., OCR) to parse a geometry problem's text and diagram jointly as logic forms. However, this system highly depended on the manually designed logic forms and was only examined in a small dataset with 185 problems. Besides, the limited logic forms are hard to cover various geometry problems, leading to low generalization. To improve GeoS, Sachan et al. (2017); Sachan and Xing (2017) replaced these handcraft constraints with geometry axiomatic knowledge in the form of horn-clause rules, but their dataset and code are not released. To boost the generalization and interpretability of existing works, we propose a large-scale GeoQA benchmark, which is 25 times larger than the only public dataset Seo et al. (2015a), and provides program annotation.

Multimodal Reasoning Visual question answering is a representative multimodal task that requires the model to have reasoning ability (Goyal et al., 2017; Yu et al., 2019). Johnson et al. (2017) built a new diagnostic VQA dataset (called CLEVR) with annotated functional programs. Based on this benchmark, some methods proposed an implicit reasoning framework to jointly encode multimodal information (Perez et al., 2017; Santoro et al., 2017). Moreover, several works (Yi et al., 2018; Mao et al., 2019) utilize domain-specific languages to perform explicit symbolic reasoning. However, these program languages only consider elementary operations, such as counting objects. They are not directly applicable to geometric problems, which require multiple steps of numerical calculation and involve theorem knowledge.

Self-supervised Auxiliary Task Self-supervised pretraining has gradually emerged (Doersch and Zisserman, 2017; Newell and Deng, 2020) as a effective technique to deal with label scarcity and improve model performance. To enhance visual features, most of these methods construct pseudo labels automatically and train on auxiliary tasks, including image jigsaw (Noroozi and Favaro, 2016; Ahsan et al., 2019), inpainting (Pathak et al., 2016), super resolution (Ledig et al., 2017), etc. Inspired by these works, we design two self-supervised auxiliary tasks and a supervised auxiliary task to enhance the reasoning ability of our NGS.

3 GeoQA Dataset

Due to the limited data scale and problem types, the existing geometric problem reasoning dataset (Seo et al., 2015a) can neither comprehensively reflect model's reasoning ability, nor support the training of neural models. To propose a better benchmark for the evaluation of multimodal numerical reasoning and inspire applications in smart education, we collect a new dataset GeoQA. It contains 5,010 diverse real-world geometric problems in Chinese middle school exams, and each problem is additionally annotated by specific programs that describe the problem solving process. Besides, we also provide human performance on GeoQA, as shown in Table 3.

	Total	Train	Val	Test
Number	5010	3509	746	755
Angle	2745	1939	388	418
Length	1873	1303	287	283
Other	392	267	71	54
#Avg DS	108×140	108×140	107×141	107×140
#Avg QL	52.5	52.4	52.4	57.7
#Avg KP	2.10	2.10	2.07	2.14
#Avg ET	1.11	1.13	1.08	1.09
#Avg OP	1.98	1.99	1.92	1.98
#Avg PL	5.35	5.39	5.17	5.36

Table 1: Statistics of our GeoQA dataset. It contains three types of problems, including angle, length, and other problems. Besides, DS, QL, KP, and ET represent diagram size, question length, knowledge points, and element types, respectively. OP and PL represent operation number and program length.

3.1 Data Description

Generally, a geometry multiple-choice problem can be represented as a tuple (t, d, c, i) where t is the problem text in natural language, d is the problem diagram, $\mathbf{c} = (c_1, c_2, c_3, c_4)$ represents the 4 numerical options for the problem, i is the answer index. Given the text t and diagram d, an algorithm is required to predict the correct answer $c_i \in \mathbf{c}$. To collect as much useful information as possible, we also provide the natural language-based problem solving explanations e, problem type t, the related knowledge points k, and our annotated programs p for each problem. Therefore, a geometry problem can be represented as (t, d, c, i, e, t, k, p). Fig. 1 shows an example of geometric problems.

Moreover, there are three problem types in our GeoQA, i.e., angle calculation, length calculation, and others which contain various types of problems such as area calculation. We adopt the corpus diversity metric proposed by Miao et al. (2020) to evaluate the diversity of GeoQA. The result is 0.47, which is relatively high compared with other math problem datasets, indicating that our dataset is diverse. The source data already contains manually tagged knowledge points in each problem, we design rule-based regular expressions to normalize the original knowledge points to 50 categories. We split our GeoQA into three subsets – train set, valid set, and test set, in a ratio of 7.0: 1.5: 1.5. The data statistics of our GeoQA are shown in Table 1.

3.2 Program Representation

The neural network has proved to be a powerful tool to address complex multimodal reasoning tasks. However, it still faces challenges when

Types	Programs
Basic	Equal, Double, Half
Arithmetic	Add, Minus, Multiply, Divide
Trigonometric	Sin, Cos, Tan, Arc-Sin, Arc-Cos
Theorem & Formula	Pythagorean Add/Minus, Proportion, Circle Area, Circle Perimeter, Cone Area
Constant	30, 60, 90, 180, 360, π, 0.618

Table 2: An overview of 18 operations of four different types and 7 constants in the defined program set.

conducting numerical calculation and providing explicit problem solving process, which are actually two crucial points in the task of geometric problem solving. To make better use of neural networks in the geometric problems solving process, inspired by Amini et al. (2019), we introduce a new domain-specific language to model the geometric problem solving process based on the GeoQA dataset. This program language can be directly executed to calculate the numerical answer based on the predefined operations and their arguments.

The program types contain operations OP, constants $Const$, problem variables N, and process variables V. As shown in Table 2, operations are divided into multiple categories, including Basic, Arithmetic, Trigonometric, Theorem, and Formula operations. Each operator involves $n(=1,2,3)$ elements selected from constants and variables. Constants are predefined numbers that are frequently used in geometric problems, such as π and the degree of a Right Angle (90). The problem variables refer to all the number that appears in the current problem, and process variables are obtained during the execution process.

In addition to the common math operations, our programs also contain some operations representing the knowledge of theorems and formulas that is helpful to address geometric problems, such as the Pythagorean theorem and the area calculation formula of a circle. It is worth noting that many simple geometric formulas do not require additional definitions. For example, given a square with side length a, its area can be directly computed by Multiply(a, a).

The interpretability of our program is reflected on the sequential process of the operations, the selected constants and variables, and the application of theorems and formulas. As shown in Figure 1, we can have a general understanding of the entire problem solving process after reading the program.

3.3 Collection and Annotation

We collect GeoQA from two online education websites[1]. These problems are oriented grades 6-12, containing various types of problems with corresponding knowledge points and solving explanations. we organize more than ten well-trained college students with a relevant major to specifically annotate our programs by referring to the solving explanations. To ensure label quality and consistency, they are required to read the guideline of annotation standards and examples in advance. Each annotated program is double-checked by one of the authors, and the annotator with low accuracy would be disqualified. The annotated operations required to solve the problem are limited to a maximum of 4 steps, thus a small number of complex and hard problems are filtered.

4 Neural Geometric Solver

We propose Neural Geometric Solver (NGS) to address geometric problems by jointly understanding text, diagram, and then generating explainable programs. Moreover, we utilize some novel auxiliary tasks to enhance the understanding ability of our NGS. The overall architecture of our NGS is shown in Fig. 2.

4.1 The Architecture of NGS

4.1.1 Problem Encoder

Text Encoder Given a problem text $P = \{x_i\}_{i=1}^{n}$, each token x_i is first embedded into a word vector $\mathbf{x}_i$. A single-layer unidirectional LSTM (Hochreiter and Schmidhuber, 1997) is then applied to encode each word embedding $\mathbf{x}_i$ into a hidden state $\mathbf{h}_i$. The sequence of the hidden state in LSTM are used to represent problem text P as $H_P = [\mathbf{h}_0; ...; \mathbf{h}_n]$.

Diagram Encoder For representing a problem diagram, we apply the first three stages of a ResNet-101 (He et al., 2016) to extract it as the diagram feature, which can be formalized as a feature matrix $H_D \in \mathbb{R}^{m \times d}$. Moreover, we also apply multiple auxiliary tasks for pretraining the diagram encoder. Note that the parameters of the diagram encoder are fixed when training the overall NGS.

4.1.2 Joint Reasoning Module

Given the text feature H_P and the diagram feature H_D, it is crucial for solving geometric prob-

---

[1] http://www.zxxk.com/ and http://www.jyeoo.com/

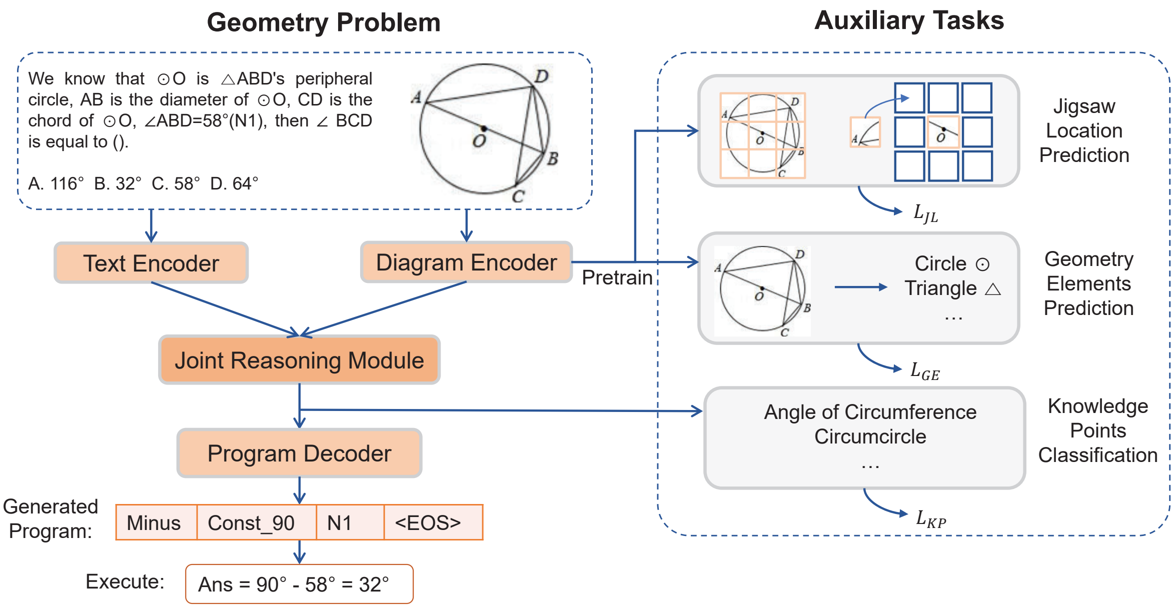

Figure 2: The overall architecture of our Neural Geometric Solver (left) in conjunction with auxiliary tasks (right). The problem text and diagram is encoded separately, then fed into a joint reasoning module together to obtain cross-modal fusion of text and diagram features. A decoder utilizes fused multimodal features to generate the interpretable programs. In addition, we propose three auxiliary tasks to enhance feature representation and facilitate multimodal reasoning.

lems to jointly fuse and align the cross-modal information. To this end, inspired by Yu et al. (2019), we adopt a co-attention module to conduct cross-modal joint reasoning with attention mechanism. The co-attention module consists of 12 self-attention (SA) units and 6 guided-attention (GA) units, which fully fuse and align the text representation H_P and the diagram representation H_D. H_P is first encoded by 6 self-attention units (i.e., original Transformer), and the final hidden state processed by the 6-th self-attention unit is used as guiding information. Then, the guiding information is fed into another stacked 6 self-attention units and 6 guided-attention units to achieve cross-modal semantic fusion and alignment. Finally, the co-attention module outputs a cross-modal representation $F_D = [f_1^D; ...; f_n^D]$, which contains rich information over the problem text and diagram.

In this work, we find that text information is more fundamental than diagram information. Therefore, we further enhance the cross-modal representation with the help of textual information. Specifically, we concatenate H_P and F_D to acquire an enhanced reasoning module output F_R for decoding programs.

Besides, an attentional reduction network with a two-layer MLP is applied to aggregate feature F_D into $\tilde{F}_D$. Similarly, we concatenate $\tilde{F}_D$ and the last encoder state of the text encoder $\boldsymbol{h}_n$, obtaining $\tilde{F}_R$ as the final gathered multimodal feature vector.

4.1.3 Program Decoder

The program decoder module generates the programs sequentially under the guidance of multimodal information. Concretely, we use a LSTM decoder (Hochreiter and Schmidhuber, 1997) with attention (Bahdanau et al., 2014) over the reasoning module output F_R . Let $\{y_t\}(1 \leq t \leq T)$ be the target program to be generated and $\boldsymbol{s}_t$ be the hidden state of LSTM at time step t. $\tilde{F}_R$ is fed into a linear layer to obtain the initial state $\boldsymbol{s}_0$. $\boldsymbol{s}_t$ is concatenated with the attention result and fed to a linear layer with the softmax function to predict the distribution of the next program token P_t.

During training, the generation loss L_g is the negative log-likelihood (NLL) of the target program:

$$\mathcal{L}_g(\boldsymbol{\theta}) = \frac{1}{T}\sum_{t=1}^{T} \log P_t(y_t|\boldsymbol{x}, y_1, ..., y_{t-1}; \boldsymbol{\theta}),$$

where $\boldsymbol{\theta}$ are the parameters of the entire NGS architecture except for the diagram encoder, $\boldsymbol{x}$ is the input of both problem text and the extracted diagram feature. When testing, the decoder only observes the input text and diagram feature along with the program parts that have been generated.

4.1.4 Program Executor

After a beam of top N program sequences $\{g_1, ..., g_n\}$ are generated from the program decoder, the executor computes them step by step. When executing the program, the token sequence is first divided into several parts based on the position of operators in the program. Once a complete operation program has been decoded, each operator in the program is executed sequentially to obtain a numerical result. The execution process fails if g_i has a grammar error (e.g., the number of augments does not match the current operator), or the executed value does not match any options in the current problem. NGS adopts the first successfully executed program as the predicted solution and chooses the corresponding operation. If all N program sequences fail, the executor will report "no result" directly instead of guessing an option. Fig. 1 shows the detailed step-by-step execution of a final predicted program sequence.

4.2 Auxiliary Tasks

4.2.1 Self-supervised Diagram Auxiliary Task

Although our NGS can jointly fuse text feature and diagram feature with a co-attention mechanism, a powerful diagram encoder is needed to improve the problem understanding and answer accuracy. To obtain a high-quality diagram feature, we investigate two self-supervised auxiliary tasks, named as **Jigsaw Location Prediction** and **Geometry Elements Prediction**, to pretrain diagram encoder.

Jigsaw Location Prediction In the Jigsaw location prediction task that enforces pixel-level perception, we first split a diagram as $m \times m$ blocks and select the center block as the target. Then, we shuffle other blocks randomly and train the diagram encoder to predict the correct relative location between these shuffled blocks and the target using a cross-entropy loss.

Geometry Elements Prediction For object-level understanding, we design a geometry elements prediction task that aims at training the diagram encoder to predict the geometry elements appearing in the diagram. A diagram usually contains multiple geometry elements which are also mentioned in the problem text and the solving explanation. We extract these geometry elements from text as the label and deploy an N-way classifier with binary cross-entropy (BCE) as the loss function to train the diagram encoder, where N is the number of the possible geometry elements on the training set.

4.2.2 Knowledge Points Prediction

In addition to self-supervised diagram training, we also propose another auxiliary learning task called knowledge points prediction to enhance a problem's overall representation by providing an extra training signal. We summarize about 50 knowledge points for our GeoQA, and label each problem with one or more knowledge points. We predict the knowledge points for each problem based on the gathered feature vector $\tilde{F}_R$ outputted from the joint reasoning module. Different from the diagram training, the knowledge points prediction task is trained with NGS simultaneously. We also deploy a K-way classifier with binary cross-entropy (BCE) as the loss function to train the knowledge points prediction multi-label task, where K is the total number of the possible knowledge points on the training set.

5 Experiments

5.1 Experimental Setup and Training Details

We conduct experiments on GeoQA dataset, and adopt answer accuracy as the evaluation metric. Although there is another available geometric problem dataset (Seo et al., 2015a), the limited data scale (with only 67 training samples) makes it impossible to support neural network training. On the other hand, previous geometry problem solving systems require additional inputs (e.g., OCR and dependency parsing results) of the problem (Ye et al., 2008; Seo et al., 2015b) or not release their codes (Sachan and Xing, 2017; Sachan, 2020). Therefore, they are not comparable on our GeoQA dataset.

Implementation Details: In this work, we implement the proposed method with Pytorch (Paszke et al., 2017). The learning rate is $1e^{-3}$ and the batch size is set to 32. All models are trained around 100 epochs and optimized by Adam optimizer (Kingma and Ba, 2014). The beam size is typically set to 10. When pretraining the diagram encoder, we first fill the diagram with a white background to make it equal in length and width, and resize it to 224×224. Then, we utilize the diagram feature extracted by the encoder to predict jigsaw location and geometry elements simultaneously and optimize the diagram encoder to obtain an informative diagram feature with a learning rate

Method		Total (%)	Angle (%)	Length (%)	Other (%)
Human	Text-Only	63.0	58.1	71.7	55.6
	Text-Diagram	92.3	94.3	90.5	87.0
W/O Program	FiLM (Perez et al., 2017)	31.7	34.0	29.7	24.1
	RN (Santoro et al., 2017)	38.0	42.8	32.5	29.6
	MCAN (Yu et al., 2019)	39.7	45.0	34.6	25.9

	NGS-Auxiliary (Ours)	**60.7**	**72.0**	**47.0**	**44.4**

Table 3: The answer accuracy comparison on different test subsets of GeoQA dataset. "Human", "W/O Program", "Text-Only", and "Text-Diagram" refer to the performance of human, not using the program, using text modal only, and conducting multimodal numerical reasoning on both text-diagram modals, respectively.

Method	BS	Acc(%)	NR(%)
Seq2Prog + Diagram	1	31.7	58.3
	10	52.6	20.4
	100	58.3	5.86
NGS-Auxiliary	1	45.6	42.6
	10	60.7	14.6
	100	64.5	2.95

Table 4: Performance comparison under different beam size settings. BS, Acc, and NR represent beam size, accuracy, and no result, respectively.

of $1e^{-5}$. Finally, the loss weight of the knowledge points classification task is set to 1, to promote the overall understanding of problems.

5.2 Experimental Results

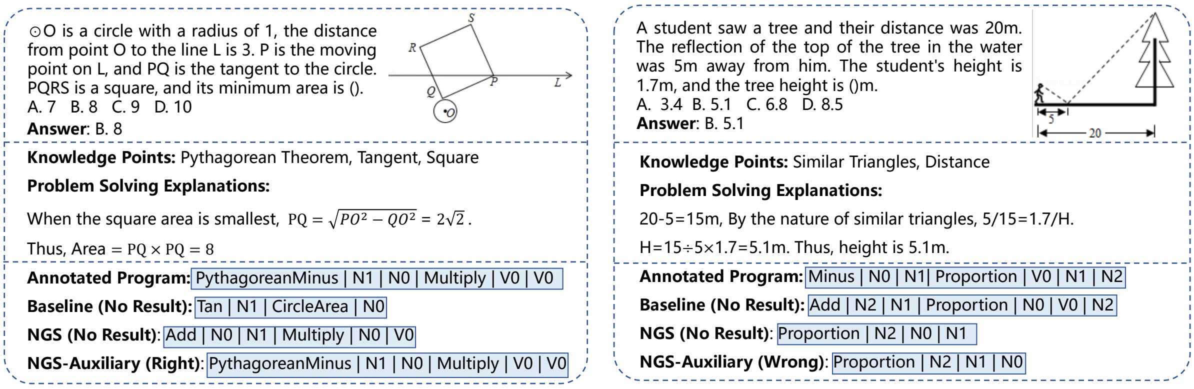
We introduce three types of models here and test them on our GeoQA. The performance comparison with various methods on the different subset types of GeoQA is reported in Table 3.

Human Performance. We invite 10 students with a high score (top 1%) in the national university entry exam to answer these geometric problems. For each question, they first try to solve the problem with the text only and draw a diagram by themselves. Then, the actual diagram is given to answer the complete question. The total time for each question is limited to two minutes. When using text and diagram simultaneously, the human performance is improved from 63.2% to 92.3%, which indicates that humans are not good at solving problems using only text, but handling multimodal information successfully. The result shows that there is still a huge gap between the existing models and human experts, leaving large room for future research.

The effectiveness of program. "W/O Program" refers to not using programs and regarding GeoQA as a classification problem similar to VQA. Therefore, we conduct experiments on three models with multimodal reasoning capabilities, including FiLM, RN, and MCAN. However, their performance results show that these methods fail to reason about such complex geometric problems, achieving poor performance on GeoQA. These results prove the effectiveness and importance of our designed interpretable programs.

The necessity of multi-modality. "Text-Only" means that models only use text to generate program sequences since humans can also understand the intent of the question, draw diagram based on the text, and solve the problem. Motivated by Amini et al. (2019), we design a Sequence-to-Program (Seq2Prog) model using GRU encoder with an attention mechanism. Moreover, we replace the encoder with BERT and get a stronger BERT2Prog. By predicting our tailor-designed programs, these two methods are effective, while the performance is not satisfactory enough. These results show that multimodal reasoning ability is indispensable when solving geometric problems.

Multimodal numerical reasoning baselines. "Text-Diagram" refers to using text and diagram simultaneously. We concatenate the text embedding with the diagram feature extracted by ResNet (He et al., 2016) as the baseline methods, such as Seq2Prog + Diagram and BERT2Prog + Diagram. These feature fusion methods do not have the strong reasoning ability and fail to improve the program decoding. For instance, by adding diagram, the performance of BERT2Prog + Diagram declines from 54.7% to 50.3%, which may result



⊙O is a circle with a radius of 1, the distance from point O to the line L is 3. P is the moving point on L, and PQ is the tangent to the circle. PQRS is a square, and its minimum area is ().
A. 7 B. 8 C. 9 D. 10
Answer: B. 8

Knowledge Points: Pythagorean Theorem, Tangent, Square

Problem Solving Explanations:

When the square area is smallest, $PQ = \sqrt{PO^2 - QO^2} = 2\sqrt{2}$.

Thus, Area $= PQ \times PQ = 8$

Annotated Program: PythagoreanMinus | N1 | N0 | Multiply | V0 | V0
Baseline (No Result): Tan | N1 | CircleArea | N0
NGS (No Result): Add | N0 | N1 | Multiply | N0 | V0
NGS-Auxiliary (Right): PythagoreanMinus | N1 | N0 | Multiply | V0 | V0

A student saw a tree and their distance was 20m. The reflection of the top of the tree in the water was 5m away from him. The student's height is 1.7m, and the tree height is ()m.
A. 3.4 B. 5.1 C. 6.8 D. 8.5
Answer: B. 5.1

Knowledge Points: Similar Triangles, Distance

Problem Solving Explanations:

20-5=15m, By the nature of similar triangles, 5/15=1.7/H.

H=15÷5×1.7=5.1m. Thus, height is 5.1m.

Annotated Program: Minus | N0 | N1| Proportion | V0 | N1 | N2
Baseline (No Result): Add | N2 | N1 | Proportion | N0 | V0 | N2
NGS (No Result): Proportion | N2 | N0 | N1
NGS-Auxiliary (Wrong): Proportion | N2 | N1 | N0

Figure 3: Typical cases. No Result represents the answer executed by the programs is not in the options, and Wrong represents getting a wrong option. Baseline is a "Seq2Prog + Diagram" model. In the case on the left, NGS-Auxiliary successfully predicts the knowledge of the Pythagorean theorem through auxiliary tasks and get the right answer. For the case on the right, the problem is quite hard that current model cannot solve it.

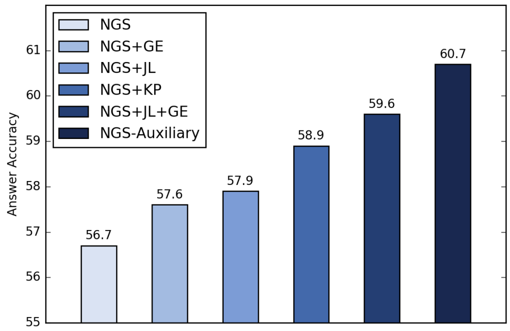


Figure 4: Ablation study on different auxiliary components. '+' represents we add the auxiliary component. NGS-Auxiliary means that adding all three auxiliary tasks together.

from the extra diagram that disturbs the text pretraining model. Note that multimodal pretraining models (Lu et al., 2019; Li et al., 2020) cannot be applied to geometric problems, since these models are based on Faster-RCNN to extract object-level features from natural images.

The effectiveness of our methods. Our proposed NGS shows a relatively-good performance compared to the various models mentioned above. When adding all three auxiliary tasks together to enhance NGS solver, our NGS-Auxiliary with multimodal reasoning ability becomes the existing best-performing method (60.7%) on GeoQA dataset. It also achieves the highest accuracy on all types of problems. For example, compared with Seq2Prog+Diagram, NGS-Auxiliary obtains an 8.4% performance improvement on the angle type problems. Compared with other "Text-Diagram" baselines, our model is effective when reasoning on multimodal information.

The effect of different beam size. In general, we set the beam size to 10 for testing. In this section, we explore the influence of different beam size. After the searched sequence program is executed, there will be three situations: right answer, wrong answer, and no result. As shown in Table. 4, as the beam size is larger, we get higher accuracy and a lower proportion of no result. When beam size equals 1, the NGS-Auxiliary outperforms baselines significantly. Our model can achieve the highest accuracy of 64.5% when beam size is 100.

5.3 Ablation Study

As shown in Fig. 4, we conduct experiments to evaluate the contribution of different auxiliary tasks. We consider six different combinations: 1) only the NGS; 2) NGS + Geometry Elements (NGS+GE); 3) NGS + Jigsaw Location (NGS+JL); 4) NGS + Knowledge Points (NGS+KP); 5) NGS + diagram-based pretraining (NGS+JL+GE); 6) NGS with all three auxiliary tasks (NGS-Auxiliary). We can see that all three auxiliary tasks can promote the performance of NGS. The accuracy gains of GE, JL, KP, JL + GE, and combining all three tasks are 0.9%, 1.2%, 2.2%, 2.9%, 4.0%, respectively. These results show that all our self-supervised and auxiliary tasks can enhance the comprehensive understanding and multimodal reasoning ability of NGS.

5.4 Case Analysis

As shown in Fig. 3, we select two typical cases to demonstrate the programs generated by different models and some representative errors.

In the left case, the knowledge of the

Pythagorean theorem, tangent, and square are required for solving the problem. Baseline method and our NGS fail to generate the correct operations and get no result. However, our NGS-Auxiliary successfully predicts the use of knowledge in the proposed auxiliary task. And more importantly, the correct ”PythagoreanMinus” program is generated, and the right answer is obtained.

The right one is a typical error case, in which model needs to understand a complex scene. Although NGS-Auxiliary has predicted the knowledge points of Proportion program correctly, all three models fail to predict the correct answer. A better multimodal method is required to handle this hard high-level reasoning task in the future.

6 Conclusion

In this work, we focus on the geometric problem and propose the first large-scale geometric question answering dataset “GeoQA”, containing 5,010 problems with program annotation. Besides, we propose a deep neural baseline, named as Neural Geometric Solver (NGS), to solve a geometric problem by jointly reasoning over multimodal data and generating interpretable programs. We further propose multiple novel auxiliary tasks to enhance the semantic representation of text and diagram. Extensive experimental results and analyses show that our GeoQA is challenging, and our NGS-Auxiliary outperforms other methods on GeoQA.

7 Ethical Impact

We collected GeoQA from two online education websites, which is only used for academic research, and the copyright belongs to the original websites. This work may inspire research in the field of multimodal numerical reasoning.

Abstract

Document-level relation extraction has attracted much attention in recent years. It is usually formulated as a classification problem that predicts relations for all entity pairs in the document. However, previous works indiscriminately represent intra- and inter-sentential relations in the same way, confounding the different patterns for predicting them. Besides, they create a document graph and use paths between entities on the graph as clues for logical reasoning. However, not all entity pairs can be connected with a path and have the correct logical reasoning paths in their graph. Thus many cases of logical reasoning cannot be covered. This paper proposes an effective architecture, SIRE, to represent intra- and inter-sentential relations in different ways. We design a new and straightforward form of logical reasoning module that can cover more logical reasoning chains. Experiments on the public datasets show SIRE outperforms the previous state-of-the-art methods. Further analysis shows that our predictions are reliable and explainable. Our code is available at `https://github.com/PKUnlp-icler/SIRE`.

1 Introduction

Relation Extraction (RE) is an important way of obtaining knowledge facts from natural language text. Many recent advancements (Sahu et al., 2019; Christopoulou et al., 2019; Yao et al., 2019b; Nan et al., 2020; Zeng et al., 2020; Wang et al., 2020) manage to tackle the document-level relation extraction (doc-level RE) that extracts semantic relations among entities across multiple sentences. Due to its strong correlation with real-world scenarios, doc-level RE has attracted much attention in the field of information extraction.

The doc-level RE task is usually formulated as a classification problem that predicts possible relations for all entity pairs, using the information from the entire document. It has two different kinds of relations: intra-sentential relation and inter-sentential relation. We show examples of these two kinds of relations in Figure 1. When two entities have mentions co-occurred in the same sentence, they may express intra-sentential relations. Otherwise, they may express inter-sentential relations.

Previous methods do not explicitly distinguish these two kinds of relations in the design of the model and use the same method to represent them. However, from the perspective of linguistics, intra-sentential relations and inter-sentential relations are expressed in different patterns. For two intra-sentential entities, their relations are usually expressed from local patterns within their co-occurred

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 524–534
August 1–6, 2021.

sentences. As shown in the first example in Figure 1, *(Polar Music, country of origin, Swedish)* and *(Wembley Arena, located in, London)* can be inferred based solely on the sentence they reside in, i.e., sentences 1 and 6 respectively. Unlike intra-sentential relations, inter-sentential relations tend to be expressed from the global interactions across multiple related sentences, also called supporting evidence. Moreover, cross-sentence relations usually require complex reasoning skills, e.g., logical reasoning. As shown in the second example in Figure 1, (*São Paulo*, continent, *South America*) can be inferred from the other two relation facts expressed in the document: (*São Paulo*, country, *Brazil*) and (*Brazil*, continent, *South America*). So the different patterns between intra- and inter-sentential relations show that it would be better for a model to treat intra- and inter-sentential relations differently. However, previous works usually use the information from the whole document to represent all relations, e.g., 13 sentences for predicting *(Polar Music, country of origin, Swedish)* in the first example in Figure 1. We argue that this will bring useless noises from unrelated sentences that misguide the learning of relational patterns.

Besides, previous methods (Christopoulou et al., 2019; Zeng et al., 2020) treat logical reasoning as a representation learning problem. They construct a document graph from the input document using entities as nodes. And the paths between two entities on their graphs, usually passing through other entities, could be regarded as clues for logical reasoning. However, since not all entity pairs can be connected with a path and have the correct logical reasoning paths available on the graph, many cases of logical reasoning cannot be covered. So their methods are somehow limited, and we should consider a new form of logical reasoning to better model and cover all possible reasoning chains.

In this paper, we propose a novel architecture called **S**eparate **I**ntra- and inter-sentential **RE**asoning (**SIRE**) for doc-level RE. Unlike previous works in this task, we introduce two different methods to represent intra- and inter-sentential relations respectively. For an intra-sentential relation, we utilize a sentence-level encoder to represent it in every co-occurred sentence. Then we get the final representation by aggregating the relational representations from all co-occurred sentences. This will encourage intra-sentential entity pairs to focus on the local patterns in their co-occurred sentences. For an inter-sentential relation, we utilize a document-level encoder and a mention-level graph proposed by Zeng et al. (2020) to capture the document information and interactions among entity mentions, document, and local context. Then, we apply an evidence selector to encourage inter-sentential entity pairs to selectively focus on the sentences that may signal their cross-sentence relations, i.e., finding supporting evidence. Finally, we develop a new form of logical reasoning module where one relation instance can be modeled by attentively fusing the representations of other relation instances in all possible logical chains. This form of logical reasoning could cover all possible cases of logical reasoning in the document.

Our contributions can be summarized as follows:

- We propose an effective architecture called SIRE that utilizes two different methods to represent intra-sentential and inter-sentential relations for doc-level RE.
- We come up with a new and straightforward form of logical reasoning module to cover all cases of logical reasoning chains.

We evaluate our SIRE on three public doc-level RE datasets. Experiments show SIRE outperforms the previous state-of-the-art models. Further analysis shows SIRE could produce more reliable and explainable predictions which further proves the significance of the separate encoding.

2 Separate Intra- and Inter-sentential Reasoning (SIRE) Model

SIRE mainly consists of three modules: intra- and inter-sentential relation representation module (Sec. 2.1), logical reasoning module (Sec. 2.2), classification module (Sec. 2.3), as is shown in Figure 2. Assume we have a document $\mathcal{D}$ containing l sentences $\{\mathcal{S}_i\}_{i=1}^{l}$.

2.1 Intra- and Inter-sentential Relation Representation Module

As is discussed in Sec. 1, for two intra-sentential entities, their relations are usually determined by the local patterns from their co-occurred sentences, while for two inter-sentential entities, their relations are usually expressed across multiple related sentences that can be regarded as the supporting evidence for their relations. So in this module, we utilize two different methods to represent intra-sentential and inter-sentential relations separately.

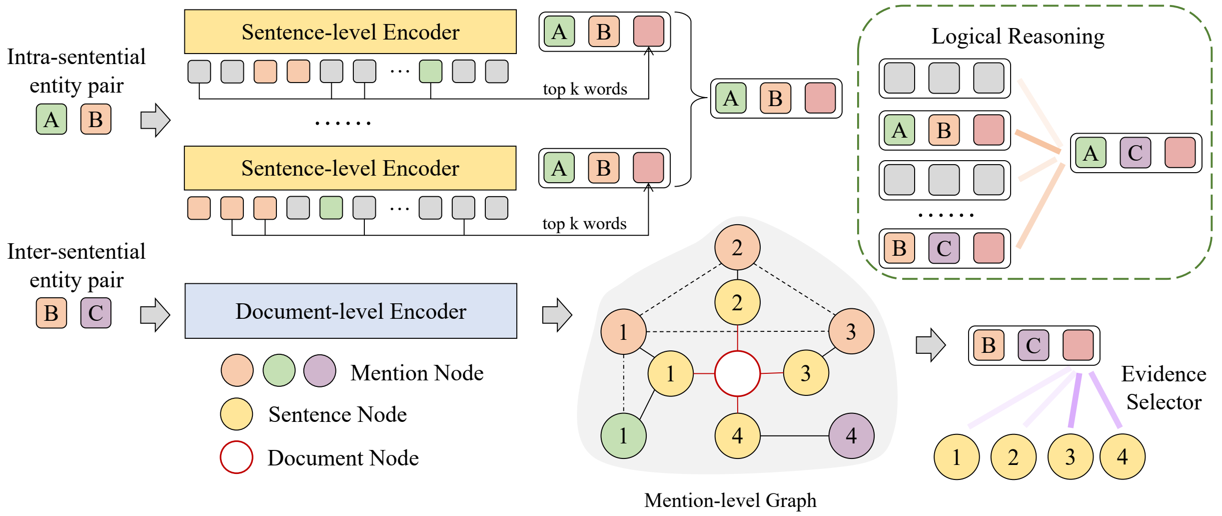

Figure 2: The architecture of SIRE. In the mention-level graph, the number in each circle is its sentence number. Mention nodes with the same color belong to the same entity. Different types of edges are in different styles of line. Our model uses different methods to represent intra- and inter-sentential relations and the self-attention mechanism to model the logical reasoning process. We use the logical reasoning chain:$e_A \rightarrow e_B \rightarrow e_C$ for illustration.

Our methods encourage intra-sentential entity pairs to focus on their co-occurred sentences as much as possible and encourage inter-sentential entity pairs to selectively focus on the sentences that may express their cross-sentence relations. We use three parts to represent the relation between two entities: head entity representation, tail entity representation and context representation.

2.1.1 Intra-sentential Relation Representation Module

Encoding. We use a sentence-level encoder to capture the context information for intra-sentential relations and produce contextualized word embedding for each word. Formally, we convert the i-th sentence $\mathcal{S}_i$ containing n_i words $\left\{w_j^{\mathcal{S}_i}\right\}_{j=1}^{n_i}$ into a sequence of vectors $\left\{\mathbf{g}_j^{\mathcal{S}_i}\right\}_{j=1}^{n_i}$.

For each word w in $\mathcal{S}_i$, we first concatenate its word embedding with entity type embedding and co-reference embedding[1]:

$$\mathbf{x} = [E_w(w); E_t(t); E_c(c)] \qquad (1)$$

where $E_w(\cdot)$, $E_t(\cdot)$ and $E_c(\cdot)$ denote the word embedding layer, entity type embedding layer and co-reference embedding layer, respectively. t and c are named entity type and entity id.[2]

Then the vectorized word representations are fed into the sentence-level encoder to obtain the sentence-level context-sensitive representation for each word:

$$[\mathbf{g}_1^{\mathcal{S}_i}, \dots, \mathbf{g}_{n_i}^{\mathcal{S}_i}] = f_{enc}^{\mathcal{S}}([\mathbf{x}_1^{\mathcal{S}_i}, \dots, \mathbf{x}_{n_i}^{\mathcal{S}_i}]) \qquad (2)$$

where the $f_{enc}^{\mathcal{S}}$ denotes sentence-level encoder, which can be any sequential encoder. We will also get the sentence representation $\mathbf{s}^{\mathcal{S}_i}$ for sentence $\mathcal{S}_i$ from this encoder. For LSTM, $\mathbf{s}^{\mathcal{S}_i}$ is the hidden state of the last time step; for BERT, $\mathbf{s}^{\mathcal{S}_i}$ is the output representation of the special marker [CLS].

Representing. For i-th entity pair $(e_{i,h}, e_{i,t})$ which expresses intra-sentential relations, where $e_{i,h}$ is the head entity and $e_{i,t}$ is the tail entity, their mentions co-occur in C sentences $S_{co-occur} = \{\mathcal{S}_{i_1}, \mathcal{S}_{i_2}, \dots, \mathcal{S}_{i_C}\}$ once or many times. In j-th co-occurred sentence $\mathcal{S}_{i_j}$, we use the entity mentions in $\mathcal{S}_{i_j}$ to represent head and tail entity. And we define that the context representation of this relation instance in $\mathcal{S}_{i_j}$ is the top K words correlated with the relations of these two mentions.

Specifically, head entity mention ranging from s-th to t-th word is represented as the average of the words it contains: $\mathbf{e}_{i,h}^{\mathcal{S}_{i_j}} = \frac{1}{t-s+1}\sum_{k=s}^{t}\mathbf{g}_k^{\mathcal{S}_{i_j}}$, so is the tail entity mention $\mathbf{e}_{i,t}^{\mathcal{S}_{i_j}}$. Then, we concatenate

---

[1] The existing doc-level RE datasets annotate which mentions belong to the same entity. So for each word in the document, it may belong to the i-th entity or non-entity in the document. We embed this co-reference information between entity mention (surface words) and entity (an abstract concept) into the initialized representation of a word.

[2] For those words not belonging to any entity, we introduce *None* entity type and id.

the representations of head and tail entity mentions and use it as a query to attend all words in $\mathcal{S}_{i_j}$ and compute relatedness score for each word in $\mathcal{S}_{i_j}$:

$$s_{i,k} = \sigma((W_{intra} \cdot [\mathbf{e}_{i,h}^{\mathcal{S}_{i_j}}; \mathbf{e}_{i,t}^{\mathcal{S}_{i_j}}])^T \cdot \mathbf{g}_k^{\mathcal{S}_{i_j}}) \tag{3}$$

$$\alpha_{i,k} = Softmax(s_{i,k}) \tag{4}$$

where $[\cdot;\cdot]$ is a concatenation operation. $W_{intra} \in \mathbb{R}^{d\times 2d}$ is a parameter matrix. σ is an activation function (e.g., ReLU).

Then, we average the representations of top K related words to represents the context information $\mathbf{c}_i$ for intra-sentential entity pair $(e_{i,h}, e_{i,t})$ in $\mathcal{S}_{i_j}$. In order to make W_{intra} trainable during computing gradient, we also add an item which is the weighted average representation of all words:

$$\mathbf{c}_i^{\mathcal{S}_{i_j}} = \beta\cdot\frac{1}{K}\sum_{k\in topK(\alpha_{i,*})}\mathbf{g}_k^{\mathcal{S}_{i_j}} + (1-\beta)\cdot\sum_t^{n_{i_j}}\alpha_{i,t}\mathbf{g}_t^{\mathcal{S}_{i_j}} \tag{5}$$

where β is a hyperparameter and we use 0.9 here to force model to focus on the top K words but still consider the subtle influence from other words.

Next, we concatenate the three parts obtained above to form the relational representation of intra-sentential entity pair $(e_{i,h}, e_{i,t})$ in $\mathcal{S}_{i_j}$ and further average the representations in all co-occured sentences $\mathcal{S}_{co-occur}$ to get our final relation representation $\mathbf{r}_i$ for intra-sentential entity pair $(e_{i,h}, e_{i,t})$ [3]:

$$\mathbf{r}_i = \frac{1}{C}\sum_{\mathcal{S}_{i_j}\in\mathcal{S}_{co-occur}}[\mathbf{e}_{i,h}^{\mathcal{S}_{i_j}}; \mathbf{e}_{i,t}^{\mathcal{S}_{i_j}}; \mathbf{c}_i^{\mathcal{S}_{i_j}}] \tag{6}$$

This way, we could force the intra-sentential entity pairs to focus on the semantic information from their co-occurred sentences and ignore the noise information from other sentences.

2.1.2 Inter-sentential Relation Representation Module

Encoding. According to the nature of inter-sentetential relation, we use a document-level encoder to capture the global interactions for inter-sentential relations and produce contextualized word embedding for each word. Formally, we convert a document $\mathcal{D}$ containing m words $\{w_i^{\mathcal{D}}\}_{i=1}^m$ into a sequence of vectors $\left\{\mathbf{g}_j^{\mathcal{D}}\right\}_{j=1}^m$.

Same as the embedding for intra-sentential relations, we use Equation 1 to embed each word in the document. Then the vectorized word representations are fed into the document-level encoder to obtain document-level context-sensitive representation for each word:

$$[\mathbf{g}_1^{\mathcal{D}}, \ldots, \mathbf{g}_m^{\mathcal{D}}] = f_{enc}^{\mathcal{D}}([\mathbf{x}_1^{\mathcal{D}}, \ldots, \mathbf{x}_m^{\mathcal{D}}]) \tag{7}$$

where $f_{enc}^{\mathcal{D}}$ denotes the document-level encoder. And we will also get the document representation $\mathbf{d}^{\mathcal{D}}$ from this encoder.

To further enhance the document interactions, we utilize the mention-level graph (MG) proposed by Zeng et al. (2020). MG in Zeng et al. (2020) contains two different nodes: mention node and document node. Each mention node denotes one particular mention of an entity. Furthermore, MG also has one document node that aims to model the document information. We argue that this graph only contains nodes concerning prediction, i.e., the mentions of the entities and document information. However, it does not contain the local context information, which is crucial for the interaction among entity mentions and the document. So we introduce a new type of node: sentence node and its corresponding new edges to infuse the local context information into MG.

So there are four types of edges[4] in MG:

Intra-Entity Edge: Mentions referring to the same entity are fully connected. This models the interactions among mentions of the same entity.

Inter-Entity Edge: Mentions co-occurring in the same sentence are fully connected. This models the interactions among different entities via co-occurrences of their mentions.

Sentence-Mention Edge: Each sentence node connects with all entity mentions it contains. This models the interactions between mentions and their local context information.

Sentence-Document Edge: All sentence nodes are connected to the document node. This models the interactions between local context information and document information, acting as a bridge between mentions and document.

Next, we apply Relational Graph Convolutional Network (R-GCN, Schlichtkrull et al., 2017) on MG to aggregate the features from neighbors for each node. Given node u at the l-th layer, the graph

---

[3] If a head entity mentioned N times in a sentence, we will get N intra-sentential relational representations for each of the other tail entities in this sentence.

[4] Note that we remove the mention-document edges of original MG in (Zeng et al., 2020) and substitute them by introducing mention-sentence and sentence-document edges.

convolutional operation can be defined as:

$$\mathbf{h}_u^{(l+1)} = ReLU\left(\sum_{t\in\mathcal{T}}\sum_{v\in\mathcal{N}_u^t\bigcup\{u\}}\frac{1}{c_{u,t}}W_t^{(l)}\mathbf{h}_v^{(l)}\right) \tag{8}$$

where $\mathcal{T}$ is a set of different types of edges, $W_t^{(l)} \in \mathbb{R}^{d\times d}$ is a trainable parameter matrix. $\mathcal{N}_u^t$ denotes a set of neighbors for node u connected with t-th type edge. $c_{u,t} = |\mathcal{N}_u^t|$ is a normalization constant.

We then aggregate the outputs of all R-GCN layers to form the final representation of node u:

$$\mathbf{m}_u = ReLU(W_u \cdot [\mathbf{h}_u^{(0)}; \mathbf{h}_u^{(1)}; \ldots; \mathbf{h}_u^{(N)}]) \tag{9}$$

where $W_u \in \mathbb{R}^{d\times Nd}$ is a trainable parameter matrix. $h_u^{(0)}$ is the initial representation of node u. For a mention ranging from the s-th word to the t-th word in the document, $\mathbf{h}_u^{(0)} = \frac{1}{t-s+1}\sum_{j=s}^{t}\mathbf{g}_j^{\mathcal{D}}$; for i-th sentence node, it is initialized with $\mathbf{s}^{\mathcal{S}_i}$ from sentence-level encoder; for the document node, it is initialized with $\mathbf{d}^{\mathcal{D}}$ from document-level encoder.

Representing. We argue that inter-sentential relations can be inferred from the following information sources: 1) the head and tail entities themselves; 2) the related sentences that signal their cross-sentence relations, namely supporting evidences; 3) reasoning information such as logical reasoning, co-reference reasoning, world knowledge, etc. We here only consider the first two information and leave the last in Sec. 2.2.

Different from intra-sentential relations, inter-sentential relations tend to be expressed from the global interactions. So for the i-th entity pair $(e_{i,h}, e_{i,t})$ which expresses inter-sentential relation, the head entity representation $\mathbf{e}_{i,h}$ and the tail entity representation and $\mathbf{e}_{i,t}$ are defined as the average of their entity mentions from MG:

$$\mathbf{e}_i = \frac{1}{N}\sum_{j\in M(e_i)}\mathbf{m}_j \tag{10}$$

where the $M(e_i)$ is the mention set of e_i.

And we apply an evidence selector with attention mechanism (Bahdanau et al., 2015) to encourage the inter-sentential entity pair to selectively focus on the sentences that express their cross-sentence relations. This process could be regarded as finding supporting evidence for their relations. So the context representation $\mathbf{c}_i$ for inter-sentential entity pair $(e_{i,h}, e_{i,t})$ is the weighted average of the sentence representations from MG:

$$P(\mathcal{S}_k|e_{i,h}, e_{i,t}) = \sigma(W_k \cdot [\mathbf{e}_{i,h}; \mathbf{e}_{i,t}; \mathbf{m}_{\mathcal{S}_k}]) \tag{11}$$

$$\alpha_{i,k} = \frac{P(\mathcal{S}_k|e_{i,h}, e_{i,t})}{\sum_l P(\mathcal{S}_l|e_{i,h}, e_{i,t})} \tag{12}$$

$$\mathbf{c}_i = \sum_k^l \alpha_{i,k}\cdot\mathbf{m}_{\mathcal{S}_k} \tag{13}$$

where $W_k \in \mathbb{R}^{1\times 2d}$ is a trainable parameter matrix. σ is a *sigmoid* function.

Next, the final relation representation for inter-sentential entity pair $(e_{i,h}, e_{i,t})$ should be:

$$\mathbf{r}_i = [\mathbf{e}_{i,h}; \mathbf{e}_{i,t}; \mathbf{c}_i] \tag{14}$$

2.2 Logical Reasoning Module

In this module, we focus on logical reasoning modeling. As mentioned in Sec. 1, previous works usually use the paths between each entity pair as the clues for logical reasoning. Furthermore, they concatenate the path representations with entity pair representations to predict relations. However, since not all entity pairs are connected with a path and have the correct logical reasoning paths in their graph, many cases of logical reasoning cannot be covered. So their methods are somehow limited.

In this paper, we utilize self-attention mechanism (Vaswani et al., 2017) to model logical reasoning. Specifically, we can get the relational representations for all entity pairs from the above sections. For i-th entity pair (e_h, e_t), we can assume there is a two-hop logical reasoning chains: $e_h \rightarrow e_k \rightarrow e_t$ in the document, where e_k can be any other entities in the document except e_h and e_t. So (e_h, e_t) can attend to all the relational representations of other entity pairs including (e_h, e_k) and (e_k, e_t), termed as $\mathcal{R}_{att}$. Finally, the weighted sum of $\mathcal{R}_{att}$ can be treated as a new relational representation for (e_h, e_t), which considers all possible two-hop logical reasoning chains in the document.[5]

$$\mathbf{r}_i^{new} = \sum_{\mathbf{r}_k\in\mathcal{R}_{att}\cup\{\mathbf{r}_i\}}\gamma_k\cdot\mathbf{r}_k \tag{15}$$

$$\gamma_k = Softmax((W_{att}\cdot\mathbf{r}_i)^T\cdot\mathbf{r}_k) \tag{16}$$

where $W_{att} \in \mathbb{R}^{3d\times 3d}$ is a parameter matrix.

In this way, the path in the previous works could be converted into the individual attention on every entity pair in the logical reasoning chains. We argue that this form of logical reasoning is simpler

---

[5] This can be scaled to muti-hop logical reasoning by increasing the self-attention layers. We only consider two-hop logical reasoning in this paper following Zeng et al. (2020).

and more scalable because it will consider all possible logical reasoning chains without connectivity constraints in the graph structure.

2.3 Classification Module

We formulate the doc-level RE task as a multi-label classification task:

$$P(r|e_{i,h}, e_{i,t}) = sigmoid\left(W_1\sigma(W_2\mathbf{r}_i + b_1) + b_2\right) \tag{17}$$

where W_1, W_2, b_1, b_2 are trainable parameters, σ is an activation function (e.g., ReLU). We use binary cross entropy as objective to train our SIRE:

$$\begin{aligned}\mathcal{L}_{rel} = -\sum_{\mathcal{D}\in\mathcal{C}}\sum_{h\neq t}\sum_{r_i\in\mathcal{R}} \mathbb{I}\left(r_i = 1\right)\log P\left(r_i|e_{i,h}, e_{i,t}\right) \\ + \mathbb{I}\left(r_i = 0\right)\log\left(1 - P\left(r_i|e_{i,h}, e_{i,t}\right)\right)\end{aligned} \tag{18}$$

where $\mathcal{C}$ denotes the whole corpus, $\mathcal{R}$ denotes relation type set and $\mathbb{I}\left(\cdot\right)$ refers to indicator function.

3 Experiments

3.1 Dataset

We evaluate our proposed model on three document-level RE datasets:

DocRED: The largest human-annotated document-level relation extraction dataset was proposed by Yao et al. (2019b). It is constructed from Wikipedia and Wikidata and contains 96 types of relations, $132,275$ entities, and $56,354$ relational facts in total. Documents in DocRED have about 8 sentences on average. More than 40.7% relation facts can only be extracted from multiple sentences. 61.1% relation instances require various reasoning skills such as logical reasoning. 93.4% intra-sentential relations can be inferred based solely on their co-occurred sentences. We show two examples from DocRED in Figure 1. We follow the standard split of the dataset, $3,053$ documents for training, $1,000$ for development, and $1,000$ for testing.

CDR (BioCreative V): The Chemical-Disease Reactions dataset was created by Li et al. (2016) manually. It contains one type of relation: *Chemical-Induced-Disease* between chemical and disease entities. We follow the standard split of the dataset, 500 documents for training, 500 for development, and 500 for testing.

GDA (DisGeNet): The Gene-Disease-Associations dataset was introduced by Wu et al. (2019). It contains one type of relation: *Gene-Induced-Disease* between gene and disease entities. We use standard split of the dataset, $23,353$ documents for training, $5,839$ for development, and $1,000$ for testing.

3.2 Experimental Settings

In our SIRE implementation, we use 3 layers of GCN, use ReLU as our activation function, and set the dropout rate to 0.3, learning rate to 0.001. We train SIRE using AdamW (Loshchilov and Hutter, 2019) as optimizer with weight decay 0.0001 and implement SIRE under PyTorch (Paszke et al., 2017) and DGL (Wang et al., 2019b) frameworks.

We implement two settings for our SIRE. **SIRE-GloVe** uses GloVe (100d, Pennington et al., 2014) and BiLSTM (512d, Schuster and Paliwal, 1997) as word embedding and encoder, respectively. **SIRE-BERT** use BERT-base (Devlin et al., 2019) as encoder on DocRED, cased BioBERT-Base v1.1 as the encoder on CDR/GDA, and the learning rate for BERT parameters is set to $1e^{-5}$ and learning rate for other parameters remains $1e^{-3}$. Detailed hyperparameter settings are in Appendix.

3.3 Baselines and Evaluation Metrics

We use the following models as our baselines:

Yao et al. (2019b) propose the **BiLSTM** (Schuster and Paliwal, 1997) as the encoder on DocRED and use the output from the encoder to represent all entity pairs to predict relations.

Wang et al. (2019a) propose **BERT** to replace the BiLSTM as the encoder on DocRED. Moreover, they also propose **BERT-Two-Step**, which first predicts whether two entities have a relation and then predicts the specific target relation.

Tang et al. (2020) propose the hierarchical inference networks **HIN-GloVe** and **HIN-BERT**, which make full use of multi-granularity inference information including entity level, sentence level, and document level to infer relations.

Similar to Wang et al. (2019a), Ye et al. (2020) propose a language representation model called **CorefBERT** as encoder on DocRED that can capture the coreferential relations in context.

Nan et al. (2020) propose the **LSR-GloVe** and **LSR-BERT** to dynamically induce the latent dependency tree structure to better model the document interactions for prediction.

Wang et al. (2020) propose a global-to-local network **GLRE**, which encodes the document information in terms of entity global and local representations as well as context relation representations.

Zeng et al. (2020) propose the graph aggregation-and-inference networks **GAIN-GloVe** and **GAIN-**

Model	Dev				Test	
	Ign F1	F1	Intra-F1	Inter-F1	Ign F1	F1

BERT which utilize two levels of graph structures: mention-level graph and entity-level graph to capture document interactions and conduct path logical reasoning mechanism, respectively.

Verga et al. (2018) propose a self-attention encoder **BRAN** to consider interactions across mentions and relations across sentence boundaries.

Following the previous works (Yao et al., 2019b; Zeng et al., 2020), we use the F1 and Ign F1 as the evaluation metrics to evaluate the overall performance of a model. The Ign F1 metric calculates F1 excluding the common relation facts in the training and dev/test sets. We also use the intra-F1 and inter-F1 metrics to evaluate a model's performance on intra-sentential relations and inter-sentential relations on the dev set.

3.4 Results

The performances of SIRE and baseline models on the DocRED dataset are shown in Table 1. Among the model not using BERT encoding, SIRE outperforms the previous state-of-the-art model by 0.88/1.38 F1/Ign F1 on the test set. Among the model using BERT encoding, SIRE outperforms the previous state-of-the-art models by 1.18/0.81 F1/Ign F1 on the test set. The improvement on Ign F1 is larger than that on F1. This shows SIRE has a stronger generalization ability on the unseen relation instances. On intra-F1 and inter-F1, we can observe that SIRE is better than the previous models that indiscriminately represent the intra- and inter-sentential relations in the same way. This demonstrates that representing intra- and inter-sentential relations in different methods is better than representing them in the same way. The improvement on intra-F1 is greater than the improvement on inter-F1. This shows that SIRE mainly improves the performance of intra-sentential relations. The performances of SIRE and baseline models on the CDR/GDA dataset are shown in Table 2, which are consistent with the improvement on DocRED.

3.5 Ablation Study

To further analyze SIRE, we also conduct ablation studies to illustrate the effectiveness of different modules in SIRE. We show the results in Table 1.
1) **the importance of the logical reasoning module**: When we discard the logical reasoning module, the performance of SIRE-GloVe decreases by 0.41 F1 on the DocRED test set. This shows the effectiveness of our logical reasoning module, which can better model the reasoning information in the document. Moreover, it drops significantly on inter-F1 and drops fewer points on intra-F1. This shows our logical reasoning module mainly improves the performance of the inter-sentential relations that usually require reasoning skills.
2) **Ablation on context representations in Eq. 6**

Type	Examples
Intra-sentential relation instances	"***Your Disco Needs You***" is a song performed by Australian recording artist and songwriter ***Kylie Minogue***, taken from her seventh studio album *Light Years* (2000). **Relation:** performer
	Lark Force was an *Australian Army* formation established in ***March 1941*** during *World War II* for service in *New Britain* and *New Ireland*. **Relation:** inception
	Lake Hiawatha is one of the few lakes through which *Minnehaha Creek* flows , and the last one before it reaches ***Minnehaha Falls*** and then the ***Mississippi River***. **Relation:** mouth of the watercourse
Inter-sentential relation instances	[1] (0.87) *IBM Research–Brazil* is one of twelve research laboratories comprising *IBM Research*, its first in ***South America***. [2] (0.66) It was established in *June 2010*, with locations in ***São Paulo*** and *Rio de Janeiro*. Figure 3: Cases for illustrating the reliable and explainable predictions of our SIRE. Head entities, tail entities, and sentence numbers along with the scores from evidence selector are colored in blue, red, green, respectively. In intra-sentential relations, words with pink background color are the top 4 words from Equation 5.

and Eq. 14: When we remove the context representations in intra- and inter-sentential relational representations, the performance of SIRE-GloVe on the DocRED test set drops by 1.81 F1. This shows context information (top K words for intra, evidence sentences for inter) is important for both intra- and inter-sentential relation representation.
3) **Using the inter-sentential module also for intra-sentential entity pairs**: In this experiment, we do not distinguish these two types of relations, using the encoding method for inter-sentential to encode all entity pairs, and remain the logical reasoning module unchanged. The performance of SIRE-GloVe drops by 2.66/2.13 F1/intra-F1 on the DocRED test set. This confirms the motivation that we cannot use global information to learn the local patterns for intra-sentential relations.

3.6 Reasoning Performance

Furthermore, we evaluate the reasoning ability of our model on the development set in Table 3. We use infer-F1 as the metric that considers only two-hop positive relation instances in the dev set. So it will naturally exclude many cases that do not belong to the two-hop logical reasoning process to strengthen the evaluation of reasoning performance. As Table 3 shows, SIRE is superior to previous models in handling the two-hop logical reasoning process. Moreover, after removing the logical reasoning module, out SIRE drops significantly on infer-F1. This shows that our logical reasoning module plays a crucial role in modeling the logical reasoning process.

Model	Infer-F1	P	R
BiLSTM	38.73	31.60	50.01
GAIN-GloVe	40.82	32.76	54.14
SIRE-GloVe	**42.72**	**34.83**	**55.22**
- *LR Module*	39.18	31.97	50.59

Table 3: Infer-F1 results on dev set of DocRED. P: Precision, R: Recall.

3.7 Case Study

Figure 3 shows the prediction cases of our SIRE. In intra-sentential relations, the top 4 words related to the relations of three entity pairs conform with our intuition. Our model correctly find the words by using Eq.5 that trigger the relations of these entity pairs. In inter-sentential relations, the supporting evidence that the model finds, i.e., sentences 1 and 2, indeed expresses the relations between São Paul and South America. We also conduct logical reasoning in terms of the logical reasoning chains: São Paul→ other-entity → South America. Our SIRE could focus on the correct logical reasoning chains: São Paul→ Brazil → South America. These cases show the predictions of SIRE are explainable.

4 Related Work

Document-level relation extraction. Many recent efforts (Quirk and Poon, 2017; Peng et al., 2017; Gupta et al., 2019; Song et al., 2018; Jia et al., 2019; Yao et al., 2019b; Wang et al., 2019a; Tang et al., 2020; Nan et al., 2020; Zeng et al., 2020; Wang et al., 2020; Dai et al., 2020) manage to tackle the document-level relation extraction. Most of them use graph-based models, such as Graph Convolutional Networks (GCNs, Kipf and Welling, 2017; Schlichtkrull et al., 2017) that has been used in many natural language processing tasks (Marcheggiani and Titov, 2017; Yao et al., 2019a; Liu et al., 2020). They construct a graph structure from the input document. This graph uses the word, mentions or entities as nodes and uses heuristic rules and semantic dependencies as edges. They use this graph to model document information and interactions and to predict possible relations for all entity pairs. Nan et al. (2020) proposed a latent structure induction to induce the dependency tree in the document dynamically. Zeng et al. (2020) proposed a double graph-based graph aggregation-and-inference network that constructs two graphs: mention-level graph and entity-level graph. They use the former to capture the document information and interactions among entity mentions and document and use the latter to conduct path-based logical reasoning. However, these works do not explicitly distinguish the intra- and inter-sentential relation instances in the design of the model and use the same way to encode them. So the most significant difference between our model and previous models is that we treat intra-sentential and inter-sentential relations differently to conform with the relational patterns for their prediction.

Reasoning in relation extraction. Reasoning problem has been extensively studied in the field of question answering (Dhingra et al., 2018). However, few works manage to tackle this problem in the document-level relation extraction task. Zeng et al. (2020) is the first to propose the explicit way of relational reasoning on doc-level RE, which mainly focuses on logical reasoning. They use the paths on their entity-level graph to provide clues for logical reasoning. However, since not all entity pairs are connected with a path and have the correct logical reasoning paths in their graph, their methods are somehow limited. In this work, we design a new form of logical reasoning to cover more cases of logical reasoning.

5 Conclusion

Intra- and inter-sentential relations are two types of relations in doc-level RE. We propose a novel architecture, SIRE, to represent these two relations in different ways separately in this work. We introduce a new form of logical reasoning module that models logical reasoning as a self-attention among representations of all entity pairs. Experiments show that our SIRE outperforms the previous state-of-the-art methods. The detailed analysis demonstrates that our predictions are explainable. We hope this work will have a positive effect on future research regarding new encoding schema, a more generalizable and explainable model.

A Hyperparameter settings

We use the development set to manually tune the optimal hyperparameters for SIRE, based on the Ign F1 score. Experiments are run on NVIDIA-RTX-3090-24GB GPU. Hyperparameter settings for SIRE-GloVe, SIRE-BERT on DocRED are listed in Table 4, 5, respectively. The values of hyperparameters we finally adopted are in bold. Note that we do not tune all the hyperparameters.

Hyperparameter	Value
Batch Size	16, **32**

Abstract

We present a novel method for relation extraction (RE) from a single sentence, mapping the sentence and two given entities to a canonical fact in a knowledge graph (KG). Especially in this presumed sentential RE setting, the context of a single sentence is often sparse. This paper introduces the *KGPool* method to address this sparsity, dynamically expanding the context with additional facts from the KG. It learns the representation of these facts (entity alias, entity descriptions, etc.) using neural methods, supplementing the sentential context. Unlike existing methods that statically use all expanded facts, *KGPool* conditions this expansion on the sentence. We study the efficacy of *KGPool* by evaluating it with different neural models and KGs (Wikidata and NYT Freebase). Our experimental evaluation on standard datasets shows that by feeding the *KGPool* representation into a Graph Neural Network, the overall method is significantly more accurate than state-of-the-art methods.

1 Introduction

Knowledge graphs (KGs) are the foundation for many downstream applications and are growing ever larger. However, due to the sheer volume of knowledge and the world's dynamic nature where new entities emerge and unknown facts about them are learned, KGs need to be continuously updated. Distantly supervised Relation Extraction (RE) is an important KG completion task aiming at finding a semantic relationship between two entities annotated on the unstructured text with respect to an underlying knowledge graph (Ye and Ling, 2019). In the literature, researchers mainly studied two variants in the RE: 1) multi-instance RE and 2) sentential RE. The multi-instance RE assumes that in a given bag of sentences, if two entities participate in a relation, there exists at least one sentence with these two entities, which may contain the target relation (Riedel et al., 2010; Vashishth et al., 2018). In this setting, researchers aim to incorporate contextual signals from the previous occurrences of an entity pair into the neural models to support relation extraction (Ye and Ling, 2019; Xu and Barbosa, 2019; Wu et al., 2019). In contrast, sentential RE restricts the scope of document context only to the input sentence (disregards other occurrences of entity pairs) while predicting the KG relation (Sorokin and Gurevych, 2017). Hence, sentential RE makes the multi-instance setting more difficult by limiting the available context.

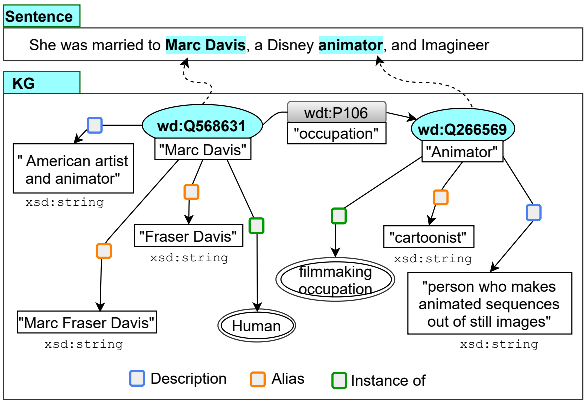

Figure 1: Illustration of Knowledge Graph Context associated with the annotated entities in a sentence. Here, entity aliases do not play any role in the understanding of the sentence for finding the KG relation. [a]

Recent approaches for RE not only base KGs for relation inventory but also consider it for extending contextual knowledge for further improvement of RE task (Vashishth et al., 2018; Bastos et al., 2021). A few multi-instance RE methods rely on entity attributes (properties) such as descriptions, aliases, and types (as additional context) along with entity pair occurrences from previous sentences to improve the overall extraction quality (Ji et al., 2017; Vashishth et al., 2018). For

the sentential RE, the RECON approach (Bastos et al., 2021) aims to effectively encode KG context derived from the entity attributes and entity neighborhood triples. RECON employs a Graph Neural Network (GNN) as a context aggregator for combining sentential context (annotated entities and sentence) and structured KG representation. Although the additional KG context has a positive effect on the overall relation extraction in multi-instance and sentential RE settings, not all KG context forms are necessary for every input sentence. Consider Figure 1, where the task is to infer a semantic relation 'occupation' between two entities *wd:Q568631 (Marc Davis)*[1] and *wd:Q266569 (animator)*. Wikidata (Vrandecic, 2012) KG provides semantic information such as description, instance-of, and aliases about entities. Here, the entity alias (Marc Fraser Davis, Fraser Davis for *wd:Q568631*; and cartoonist for *wd:Q266569*) has no impact on understanding the sentence because the entities are explicitly mentioned in the sentence. Furthermore, there is empirical evidence in the literature that for several sentences, statically adding all KG context offered minimal or negative impact (Bastos et al., 2021). Hence, there are open research questions as to how an RE approach can dynamically utilize the sufficient context from KG and whether or not the selected KG context positively impacts the overall performance?

This paper studies these concerning questions proposing the *KGPool* approach. *KGPool* utilizes a self-attention mechanism in a Graph Convolution Network (GCN) (Kipf and Welling, 2017) for selecting a sub-graph from the KG to extend the sentential context. The concept of dynamically mapping the structural representation of a KG to a latent representation of a sentence has not been widely studied in prior literature. In RE, *KGPool* is the initial attempt. The existing approaches (Bastos et al., 2021; Xu and Barbosa, 2019; Wu et al., 2019; Vashishth et al., 2018) feed all the available context (either derived from a bag of sentences or a KG or both) into a neural model and relied on the model to figure out the consequences, resulting in limited performance in many cases (Bastos et al., 2021). Conversely, we study the efficacy of *KGPool* in dynamically choosing KG context for the sentential RE task using two standard community datasets (NYT Freebase (Riedel et al., 2010), and Wikidata (Sorokin and Gurevych, 2017)). Our work makes the following key contributions:

- The *KGPool* approach dynamically selects structural knowledge and transform it into a representation suitable to supplement the latent representation of sentential context learned using a neural model. We deduce that *KGPool* is the first approach that works independently of the underlying context aggregators used in the literature (Graph Neural Network (Zhu et al., 2019) or LSTM-based (Sorokin and Gurevych, 2017)).
- We are the first to map the task of KG Context Selection to a Graph Pooling Problem. Therefore, our proposed approach legitimizes the application of graph pooling algorithms for choosing the relevant context.
- *KGPool*, paired with a GNN as context aggregator, significantly outperforms the existing baselines on both datasets, in one experiment increasing the precision by 12 points over to baseline (P@30 on NYT Freebase). Furthermore, our empirical results (cf., Table 3) conclude that an LSTM model paired with *KGPool* is able to notably outperform a GNN-based approach (Zhu et al., 2019) and nearly all multi-instance baselines (Ye and Ling, 2019; Wu et al., 2019; Vashishth et al., 2018) published in the recent years.

This paper is structured as follows: Section 2 reviews the related work. Section 3 formalizes the problem and the proposed approach is described in Section 4. Section 5 describes the experimental setup. The results are in Section 6. We conclude in Section 7.

2 Related Work

Multi-instance RE: a few multi-instance RE approaches use convolution neural network (dos Santos et al., 2015), attention CNN (Wang et al., 2016) and attention-based recurrent neural models for relation extraction (Zhou et al., 2016). Other approaches such as (Ji et al., 2017; Vashishth et al., 2018) incorporate entity descriptions, entity and relation aliases from KG to supplement context from the previous sentences. Work in (Vashishth et al., 2018) employs a graph convolution network to encode entity and relation aliases derived from Wikidata. HRERE (Xu and Barbosa, 2019) proposes an approach for jointly

---

[1] wd: binds to `https://www.wikidata.org/wiki/`

learning sentence and KG representation using cross-entropy loss function. To effectively capture the available entity context in the documents, Ye and Ling (2019) suggest an approach incorporating intra-bag and inter-bag attentions. For a detailed survey, we point readers to (Smirnova and Cudré-Mauroux, 2018).

Sentential RE: researchers (Sorokin and Gurevych, 2017) utilized additional relations present in the sentence to assist the process of extracting the target relation using an LSTM-based model. GP-GNN (Zhu et al., 2019) generates parameters of GNN based on the input sentence, which enables GNNs to process-relational reasoning on unstructured text inputs. RECON (Bastos et al., 2021) is an approach that uses the entity attributes (aliases, labels, descriptions, instance-of) and KG triples to signal an underlying GNN model for sentential RE. Authors conclude that the multi-instance requirement can be relaxed provided a good representation of KG context to enrich the sentential RE model. However, RECON and multi-instance approaches (Xu and Barbosa, 2019; Vashishth et al., 2018) utilize statically derived context from the KG, i.e., KG context does not vary depending the sentence.

Graph Pooling and Dynamic Context Selection: researchers proposed several models for the graph classification aka. graph pooling task (Cangea et al., 2018; Ying et al., 2018; Gao and Ji, 2019). These models employ various approaches such as graph topology-based (Rhee et al., 2018), and by learning the hierarchical graph-structure (Ying et al., 2018). Another graph pooling model relies on node features and topological information using self-attention (Lee et al., 2019) in which a specific number of nodes are always eliminated. In *KGPool*, the elimination of nodes depends on a context coefficient and node importance (Section 4). For context selection, a recent work focuses on dynamically selecting the KG context to optimize a Pre-Trained Language Model (PLM) for entity typing and relation classification (Su et al., 2020). *KGPool* has the following fundamental differences compared to (Su et al., 2020): *KGPool* inspires its self-attention mechanism from (Lee et al., 2019; Vaswani et al., 2017) to learn a representation of the KG context. Hence, *KGPool* works agnostic of the underlying model used for the context aggregation (unlike Su et al. (2020), which is tightly coupled with PLM). Approaches such as (Liu et al., 2017; Zhang et al., 2018; Kang et al., 2020) also perform dynamic context selection for respective tasks. However, these approaches are not focused on knowledge graph context selection.

3 Problem Statement

We define the KG as a tuple given by $KG = (\mathcal{E}, \mathcal{R}, \mathcal{T}^+)$ where $\mathcal{E}$ denotes the set of all vertices in the graph representing entities, $\mathcal{R}$ is the set of edges representing relations, and $\mathcal{T}^+ \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ is a set of all KG triples. The *RE Task* predicts the target relation $r^c \in \mathcal{R}$ between a given pair of entities $\langle e_i, e_j \rangle$ from the sentence $\mathcal{W} = (w_1, w_2, ..., w_l)$. If no relation is inferred, it returns 'NA' label. We aim for the sentential RE task which put a constraint that the sentence within which a given pair of entities occurs is the only visible sentence from the bag of sentences. We view RE as a classification task similar to (Sorokin and Gurevych, 2017). In a KG triple $\tau = (e_h, r, e_t) \in \mathcal{T}^+$, the relation $r \in \mathcal{R}$, e_h is the head entity (relation origin) while e_t is the tail entity. For each entity, associated semantic properties such as entity label, description, instance-of, and aliases are known as entity attribute (At^e) (cf., graph construction step of Figure 2). We aim to model KG contextual information to improve the classification. This is achieved by learning the effective representations of the sets At^e, e_h, e_t, and $\mathcal{W}$ (cf. section 4).

4 KGPool Approach

KGPool consists of three components illustrated in Figure 2: 1) *Graph Construction* aggregates the sentence, entities and its attributes as a Heterogeneous Information Graph (HIG) for input representation. 2) *Context Pooling* step utilizes a self-attention mechanism in a graph convolution to calculate attention scores for entity attributes using node features and graph topology. The pooling process allows *KGPool* to construct a Context Graph (CG), which is a contextualized representation of HIG with lesser number of nodes. 3) *Context Aggregator* takes as input the sentence, entities, contextual representations of HIG, and classifies the target relation between the entities. We detail the approach in the following.

4.1 Graph Construction

As first step, we extract entity attributes (At^e) from public dumps of Freebase (Bollacker et al.,

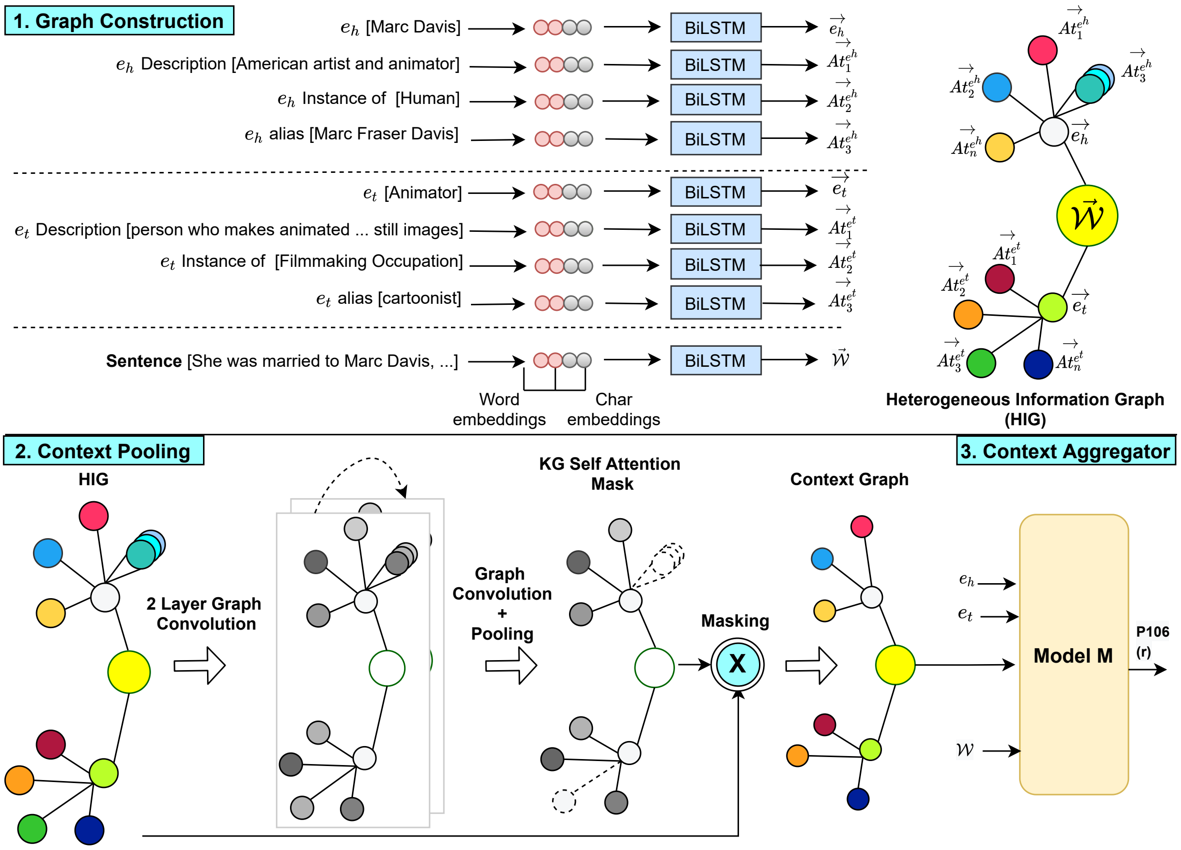

Figure 2: *KGPool* approach has three components to supplement sentential context with necessary KG context.

2007) and Wikidata (Vrandecic, 2012) KGs depending on the dataset. For the KG context, we rely on the most commonly available properties of the entities as suggested by (Bastos et al., 2021): aliases, description, instance-of, and label. An example of various entity attributes is given in Figure 2 at the Graph Construction step. Then, the sentence $\mathcal{W}$ is transformed to another representation using Bi-LSTM (Schuster and Paliwal, 1997) by concatenating its word and character embeddings:

$$\vec{\mathcal{W}} = BiLSTM(\mathcal{W}) \tag{1}$$

Similar representation is created for each entity e_i where $i = (h, t)$:

$$\vec{e_i} = BiLSTM(e_i) \tag{2}$$

For entity e_i, its KG contexts (entity attributes) $At_j^{e_i}$ (where $j = [0...N]$) are independently converted into associated embedding representations:

$$\vec{At_j}^{e_i} = BiLSTM(At_j^{e_i}) \tag{3}$$

For a knowledge representation of the KG context concerning the sentential context (sentence and annotated entities), we introduce the special graph $HIG = (A, F)$, a Heterogeneous Information Graph, represented in the adjacency matrix $A \in \{0,1\}^{n \times n}$, where n is the maximum number of neighboring nodes for an entity e_i. Here, $F \in \mathbb{R}^{n \times f}$ is the node feature matrix assuming each node has f features learned from the Bi-LSTM in the equations 1, 2, and 3. In these equations, BERT (Devlin et al., 2019), or any other recent Transformer-based model can be used. Due to hardware limitations, we are bound to Bi-LSTM using Glove embeddings (Pennington et al., 2014).

4.2 Context Pooling

Context pooling is built upon three layers of Graph Convolutional Networks (GCN) and a readout layer associated with each of them. Moreover, the last layer of GCN is coupled with a pooling layer (cf., ablation studies for architectural design choice experiments).

4.2.1 Graph Convolution

Since *KGPool* is expected to select the sufficient context, the Context Graph CG is a reduction of HIG using the mapping $\Psi : HIG \longrightarrow CG$. The challenge here is the no natural notion of spatial locality, i.e., it is not viable to pool together all context nodes in an "m × m" patch on HIG because the complex topological structure of graphs prevents any straightforward, deterministic definition of a "patch". Furthermore, entities nodes have a varying number of neighboring nodes, making the graph pooling challenging (similar to other graph classification problems (Ying et al., 2018)). In HIG, entity nodes do not contain information of their neighbors. Hence, we aim to enrich each entity node with the adjacent node's contextual information. Therefore, we employ a GNN variant to utilize its message-passing architecture to learn node embeddings from a message propagation function. The message propagation function depends on the adjacency matrix A, trainable parameters θ, and the node embeddings F (Ying et al., 2018). We rely on a GCN model by Kipf and Welling (2017). The GCN layer is defined as:

$$F^{(k)} = \text{ReLU}\left(\tilde{D}^{-\frac{1}{2}}\tilde{A}\tilde{D}^{-\frac{1}{2}}F^{(k-1)}\theta^{(k-1)}\right) \quad (4)$$

where $\tilde{A} = A + I$, $\tilde{D} = \sum_j \tilde{A_{i,j}}$ and $\theta^{(k)}$ is the trainable matrix. The GCN module might run k iteration and normally is in the range of two to six (Ying et al., 2018). A few graph representation learning approaches propose to use readout layer that aggregates node features to learn a fixed size representation (Xu et al., 2018; Cangea et al., 2018). We perform this summarizing after each block of the network (Equation 4), and aggregate all of the intermediate representation together by taking their sum. We define readout layer R as:

$$R^{(k)} = \frac{1}{N}\sum_{i=1}^{N} F_i^{(k)} \| \max_{i=1}^{N} F_i^{(k)} \quad (5)$$

where N is the number of nodes in the graph and F is the node feature embedding.

4.2.2 KG Self-Attention Mask

Until Equation 5, *KGPool* focuses on learning node features. Next, *KGPool* learns the importance of each entity attribute node using self-attention. Please note, in HIG, pooling happens only for entity attribute nodes ($\vec{At_j}^{e^i}$ from Equation 3). The sentence $\vec{\mathcal{W}}$ and entities $\vec{e_h}, \vec{e_t}$ remain intact. Hence, each entity representation $\vec{e_h}$ and $\vec{e_t}$ is enriched by the useful attribute context (KG context). The entity attribute nodes which do not provide relevant context are excluded from the graph. To choose the relevant entity attribute nodes, we use a self-attention score Z (Lee et al., 2019) calculated as follows:

$$Z = \tanh\left(\tilde{D}^{-\frac{1}{2}}\tilde{A}\tilde{D}^{-\frac{1}{2}}F^{(k)}\Theta_{att}\right) \quad (6)$$

where $\Theta_{att} \in \mathbb{R}^{F\times 1}$ is the only parameter of the pooling layer. For ranking, we take the attention score and pass it through a softmax layer where Z_{score} is the normalized self attention score.

$$Z_{score} = \exp(Z_i) / \sum_i \exp(Z_i) \quad (7)$$

After Equation 7, we compute the scores for each entity attribute node. Next, we propose a node selection method in which nodes are selected on the basis of **Context Coefficient** α which is a hyper parameter. The top nodes are selected as:

$$idx = \max(Z_{score}) - \alpha * \sigma(Z_{score}) \quad (8)$$

where $\sigma(Z_{score})$ is the standard deviation of Z_{score}, idx represents the node selection result, and Z_{mask} is the corresponding attention mask. Equation 8 acts as a soft constraint in selecting the context nodes for each HIG which depends on the value of α. Learning α during training may cause over-fitting. Hence, we decided to consider α as a trade-off parameter similar to λ in regularization (Bühlmann and Van De Geer, 2011). Next, the Context Graph (CG) is formed by pooling out the less essential entity attribute nodes as:

$$F' = F^{(k)}_{\text{idx},:}, F_{out} = F' \odot Z_{mask}, A_{out} = A_{\text{idx},\text{idx}} \quad (9)$$

In addition to the dynamically selected nodes, we also inherit the intermediate node and graph representations of $k-1$ layers similar to ResNET (He et al., 2016). The intermediate representations ($k-1$) and the CG (k^{th} layer) is given as follows:

$$\begin{aligned} \vec{e_h}' &= F^{(1)}_{e_h} \oplus F^{(2)}_{e_h} \oplus ....F^{(k)}_{e_h} \\ \vec{e_t}' &= F^{(1)}_{e_t} \oplus F^{(2)}_{e_t} \oplus ....F^{(k)}_{e_t} \\ \vec{\mathcal{W}}' &= F^{(1)}_{\mathcal{W}} \oplus F^{(2)}_{\mathcal{W}} \oplus ....F^{(k)}_{\mathcal{W}} \\ \vec{R}' &= R^{(1)} \oplus R^{(2)} \oplus ....R^{(k)} \end{aligned} \quad (10)$$

where in the i^{th} layer: $F^{(i)}_{e_l}$ is the node embedding of e_l, $l = (h, t)$, $F^{(i)}_{\mathcal{W}}$ is the node embedding of sentence $\mathcal{W}$, and $R^{(i)}$ is the readout. In the k^{th} layer, $F^{(k)}$ is the F_{out} from Equation 9. The $\oplus$ is the concatenation among the vectors.

4.3 Context Aggregator

Finally, *KGPool* combines the latent representation (sentential context) with the structured representation learned in Equation 10. As such, we employ a model M which learns latent relation vector $\vec{r'}$. In the state-of-the-art approaches that use KG context, the representation of $\vec{r'}$ is learned using sentential and all static KG context (Vashishth et al., 2018; Bastos et al., 2021). However, in *KGPool*, relation r is realized based on the sentential context and dynamically chosen KG context. Hence, we employ context aggregators similar to the baselines (section 5.3) for jointly learning the enriched KG context in the form of CG and sentential context. The final relation is:

$$P(r \mid e_h, e_t, W) = softmax(MLP(\vec{r'} \oplus \vec{e_h}' \oplus \vec{e_t}' \oplus \vec{W}' \oplus \vec{R}')) \quad (11)$$

5 Experimental Setup

5.1 Datasets

We consider two standard datasets (English version): Wikidata dataset (Sorokin and Gurevych, 2017) and NYT Freebase (Riedel et al., 2010). Both datasets were annotated using distant supervision (associated stats are in Table 1). Datasets include 'NA' as one of the target relations.

Dataset	#Train Sentences	#Test sentences	#Relations
Wikidata	372,059	360,334	353
NYT	455,771	172,448	53

Table 1: Statistics of the Datasets

5.2 KGPool Configurations

KGPool is configured with two context aggregator modules. We inherit context aggregators from existing sentential RE baselines. Our experimental aim is to assess as how *KGPool* performs along with the state-of-the-art context aggregators (comparative study). Our two settings are:

1. $KGPool_{+lstm}$: *KGPool* is coupled with a context aware LSTM model from (Sorokin and Gurevych, 2017) as context aggregator.

2. $KGPool_{+gnn}$: this implementation has *KGPool* plugged-in with a variant of GNN module used by (Zhu et al., 2019; Bastos et al., 2021).

5.3 Baseline Models

We consider the recent sentential RE approaches for our empirical study:

RECON (Bastos et al., 2021): induces KG context (entity attributes and 1&2 hop entity triples) along with the sentence in a GNN.

RECON-EAC (Bastos et al., 2021): a variant of RECON contains entity attributes as only KG context (same context as *KGPool*).

GP-GNN (Zhu et al., 2019): performs multi-hop reasoning using a GNN.

Context-LSTM (Sorokin and Gurevych, 2017): uses context from other sentential relations.

Sorokin-LSTM (Sorokin and Gurevych, 2017): the NYT dataset contains one relation per sentence, but Context-LSTM requires at least two relations in a sentence. Thus, the other setting is an LSTM model without a sentential relation context, is used as a baseline on the NYT dataset.

Multi-instance RE Approaches: Please note, the Wikidata dataset does not have multiple instances for an entity pair. Hence multi-instance baselines do not have values on it. We inherit the recent multi-instance baselines and all empirical values from (Bastos et al., 2021): (i) **HRERE** (Xu and Barbosa, 2019) (ii) **Wu-2019** (Wu et al., 2019), (iii) **Yi-Ling-2019** (Ye and Ling, 2019), (iii) **RESIDE** (Vashishth et al., 2018).

5.4 Metrics and Hyper-parameters

Graph Construction step (section 4.1) use a Bi-LSTM with one hidden layer of size 50 (Bastos et al., 2021). The word embedding dimension is 50 initialized by Glove embeddings (Pennington et al., 2014). The context pooling parameters are from (Lee et al., 2019). For model M, we used the default parameters provided by the authors (Zhu et al., 2019; Sorokin and Gurevych, 2017). For brevity, details are in the appendix.

Metric and Optimization: Our experiment settings are borrowed from (Bastos et al., 2021). Hence, on Wikidata dataset, we use (micro) precision (P), recall (R), and F-score (F1). On the NYT Freebase dataset, (micro) P@10 and P@30 is reported. P@K here represents precision at K percent recall. We also study the effect of Context Coefficient (α) for both *KGPool* configurations (trained end-to-end). We ignore the probability predicted for the NA relation during testing. We employ the Adam optimizer (Kingma and Ba, 2015) with categorical cross entropy loss where each model is run three times on the whole training set. For the P/R curves (with best α values of *KGPool* variants), the result from the first run of each model is selected. For ablation, we use the McNemar's test for statistical significance to find if the reduction in error in the *KGPool* configura-

tions are significant. The differences in the models is statistically significant if the $p - value < 0.05$ (Dietterich, 1998). We release all experiment code and data on a public GitHub[2].

6 Results

We conduct our experiments and analysis in response to the question **RQ**: "What is the efficacy of *KGPool* in dynamically selecting the KG context for the sentential RE task?" As such, we also compare *KGPool* against approaches that do not dynamically treat the context.

Model	P	R	F1
Context-LSTM	72.09	72.06	72.07
GP-GNN	82.30	82.28	82.29
RECON-EAC	85.44	85.41	85.42
RECON	87.24	87.23	87.23
$KGPool_{+lstm}$ (α=1)	84.20	82.19	84.20
$KGPool_{+lstm}$ (α=2)	84.12	84.13	84.12
$KGPool_{+lstm}$ (α=3)	84.00	83.97	83.98
$KGPool_{+lstm}$ (α=4)	83.81	83.79	83.80
$KGPool_{+gnn}$ (α=1)	**88.60**	**88.59**	**88.60**
$KGPool_{+gnn}$ (α=2)	88.57	88.56	88.57
$KGPool_{+gnn}$ (α=3)	88.54	88.55	88.54
$KGPool_{+gnn}$ (α=4)	88.52	88.50	88.51

Table 2: Comparison of *KGPool* configurations with sentential RE models on Wikidata dataset. Best score in bold.

Performance on Wikidata Dataset: Table 2 summarizes the performance of *KGPool* variants against the sentential RE models. Agnostic of the underlying aggregator (LSTM or GNN), *KGPool* effectively captures the KG context complimenting the sentential context. The $KGPool_{+gnn}$ (α=1) configuration outperforms other *KGPool* variants along with all sentential RE baselines. We can observe that even when the available context is limited to entity attributes, the $KGPool_{+gnn}$ variant surpasses RECON that also contains context from 1&2 hop triples besides the entity attributes. RECON-EAC and $KGPool_{+gnn}$ rely on entity attributes as KG context with the same context aggregator. When $KGPool_{+gnn}$ variants choose KG context dynamically, they perform better than RECON-EAC. It is interesting to notice that when an LSTM model is fed with the dynamically chosen context, the performance gain is more than ten absolute points ($KGPool_{+lstm}$ Vs Context-LSTM), even outperforming GP-GNN.

Model	P@10	P@30
HRERE	86.1	76.6
Wu-2019	81.7	61.8
RESIDE	73.6	59.5
Ye-Ling-2019	78.9	62.4
Sorokin-LSTM	75.4	58.7
GP-GNN	81.3	63.1
RECON-EAC	83.5	73.4
RECON	87.5	74.1
$KGPool_{+lstm}$ (α=1)	83.7	72.7
$KGPool_{+lstm}$ (α=2)	83.5	71.6
$KGPool_{+lstm}$ (α=3)	84.1	70.6
$KGPool_{+lstm}$ (α=4)	83.1	72.1
$KGPool_{+gnn}$ (α=1)	90.1	**86.7**
$KGPool_{+gnn}$ (α=2)	91.0	85.0
$KGPool_{+gnn}$ (α=3)	**92.3**	85.4
$KGPool_{+gnn}$ (α=4)	90.6	84.4

Table 3: Comparison of *KGPool* with sentential and multi-instance RE models on NYT Freebase dataset. Best score in bold.

Performance on NYT Freebase Dataset: Similar to the Wikidata dataset, the $KGPool_{+gnn}$ variants significantly outperform all baselines (cf. Table 3). The P@30 is comparatively high for $KGPool_{+gnn}$ against baselines. The behavior could be interpreted as follows: dynamically adding context from the KG for the entity pairs

---

[2] `https://github.com/nadgeri14/KGPool`

Compared Models	Contingency table		Statistic	p-value	Significance	Dataset
$KGPool_{+gnn}$ (α=3) vs RECON	160916 3169	4702 3613	298.18	$8.18 * 10^{-67}$	Statistically Significant	NYT- Freebase
$KGPool_{+gnn}$ (α=1) vs RECON	617266 29255	38652 55593	1300.08	$1.08 * 10^{-284}$	Statistically Significant	Wikidata

Table 4: The McNemar's test for statistical significance for KGPool's best configuration Vs previous baseline.

keeps the precision higher over a more extended recall range. For both datasets, *KGPool* configurations ($KGPool_{+gnn}$ and $KGPool_{+lstm}$) have the best-reported performance varying as per the α. This validates our choice to introduce a soft constraint in selecting the context nodes (cf., Equation 8). The P/R curves in Figure 3 show that *KGPool* performs better than baselines over the entire recall range. We conclude that the effective dynamic context selection by *KGPool* has a positive impact on the sentential RE task (which successfully answers our research question).

Models	DEG (HIG)	DEG (CG)	Dataset
$KGPool_{+gnn}$ (α=1)	5.33	1.15	Wikidata
$KGPool_{+gnn}$ (α=2)	5.33	1.52	
$KGPool_{+gnn}$ (α=3)	5.33	2.87	
$KGPool_{+gnn}$ (α=4)	5.33	4.71	
$KGPool_{+gnn}$ (α=1)	6.34	1.67	NYT Freebase
$KGPool_{+gnn}$ (α=2)	6.34	1.91	
$KGPool_{+gnn}$ (α=3)	6.34	2.73	
$KGPool_{+gnn}$ (α=4)	6.34	5.16	

Table 5: Effect of Context Pooling. 'DEG' denotes average degree of an entity node (e_i). 'DEG' of entity nodes in CG is drastically reduced wrt the HIG.

6.1 Ablation Studies

We conducted two ablation studies to understand the behavior of *KGPool* configurations:

Significance of Dynamic Context Selection: we perform McNemar's test for the best *KGPool* configuration against the previous sentential state-of-the-art (i.e. RECON). The results in Table 4 are statistically significant on both datasets, illustrating *KGPool*'s robustness. Although $KGPool_{+gnn}$ variants achieve statistically significant results against RECON, there exist several sentences for which our approach is unable to select supplementary KG context ((RW) values in the contingency table). It requires further investigation, and we plan it for our future work.

Effect on the Degree of Nodes for Entities: for studying the effect of context pooling (Section 4.2), we also conducted a study to understand the impact of *KGPool* on the reduction of the average degree of entity nodes (e_i) in the HIG. Table 5 summarizes the effect of Context Coefficient on the average degree of entity nodes. Irrespective of α, *KGPool* notably reduces the degree of e_i by removing less relevant nodes.

Architectural Choice Experiment: In *KGPool*, we chose to introduce pooling in the last layer of a three-layered architecture (three blocks). To support our choice, we performed several additional experiments by introducing pooling in various layers. We employ the Wikidata dataset for our experiments. We use best configuration of our model ($KGPool_{+gnn}$ (α=1)) and created several variants of it. For instance, $KGPool_{+gnn}$ (P=all) comprises the configuration where we introduce pooling in all three GCN blocks. The configuration $KGPool_{+gnn}$ (¶=2&3) has no pooling in the first layer but has a pooling layer in the remaining two GCN blocks. $KGPool_{+gnn}$ is the best configuration of *KGPool* where pooling is just in the final layer. In Table 6, we observe that $KGPool_{+gnn}$ with pooling only in the last GCN block has the superior performance compared to other two variants. Here, the first two layers are used to learn the node features, which are then employed with self-attention for node selection. Our experiments justify the architectural choice decision. However, with a newer graph pooling technique, such decisions will solely depend on the performance of the approach, and we can not generalize the results of these experiments.

Model	F1
$KGPool_{+gnn}$ (¶=all)	84.19
$KGPool_{+gnn}$ (¶=2&3)	86.87
$KGPool_{+gnn}$ (¶=3) (best)	**88.60**

Table 6: When we introduce pooling in all three layers or in two layers, the performance of *KGPool*'s variants drop. Hence, it justify our choice to add pooling only in the third layer that gives the best performance (values in bold). We use best configuration of our model ($KGPool_{+gnn}$ (α=1)).

Case-Studies: To understand the *KGPool*'s performance gain, we report a few top relations in Table 7. It can be observed from this table that in a few cases, with lesser context, *KGPool* can perform significantly better. In the next case study, to understand the *KGPool*'s performance while adding additional context (more noise), we induce extra context in the form of 1&2-hop triples along with entity attributes. For the same, we considered *KGPool*'s best configurations on the Wikidata dataset. The configurations $KGPool_{+gnn}$ $(+T)$ and $KGPool_{+lstm}$ $(+T)$ represent *KGPool* fed with additional triple context. For both configurations agnostic of underlying aggregator, we observe a slight increase in performance (Table 8). There are several triples which are the irrelevant source of information not needed for a given sentence. *KGPool* can remove that information and does not suffer the performance drop due to added noise in the context. Details on error analysis, performance for worst performing individual relations, and on a human-annotated dataset are provided in the appendix.

Relation	*KGPool*	RECON	GP-GNN
vocal specialization	**1.00**	0.00	0.00
list of works	**1.00**	0.00	0.00
track gauge	**1.00**	0.92	0.00
position played	**0.99**	**0.99**	0.92
sport	**0.99**	**0.99**	0.97
record label	**0.95**	0.90	0.64
list of episodes	**0.95**	0.00	0.49
wing configuration	**0.94**	0.57	0.00
numeric value	**0.93**	0.27	0.46
vessel class	**0.87**	0.00	0.00

Table 7: Micro F-score of Top performing Relations for $KGPool_{gnn}$ (α=1) (on Wikidata dataset). Dynamically chosen context significantly improves performance for many relations.

Model	F1
$KGPool_{+gnn}$ $(+T)$	**88.85**
$KGPool_{+lstm}$ $(+T)$	84.42
$KGPool_{+gnn}$	88.60
$KGPool_{+lstm}$	84.12

Table 8: To scale the sources of the contexts, we induce additional triple context in the *KGPool* shown as $(+T)$ configurations. We use best configurations of our model ($KGPool_{+gnn}$ (α=1) and $KGPool_{+lstm}$ (α=1)). We observe a slight jump in the performance, however, *KGPool* is still able to pool irrelevant context.

7 Discussion and Conclusion

Although KGs are often employed for providing background context in the RE tasks (cf. Section 2), yet there is limited research about defining relevant context. In this work, we proposed *KGPool* and provide a set of experiments proving: 1) Given the limited context that is in individual sentences, dynamically bringing context from KG significantly improves the RE performance. 2) We introduced Context Coefficient (α), which acts as a soft constraint in determining the relevant entity context nodes. 3) Our approach *KGPool* is invariant of the context aggregator and enables us to learn effective knowledge representation of the required KG context for a given sentential context. Our evaluation concerns several key questions:

- **Data quality impact on an effective knowledge representation:** in spite *KGPool*'s significant performance, there exist several sentences for which our model finds a limitation compared to the baseline (cf. Table 4). One potential interpretation could be about the noise injected due to the data quality of the KG context (Weichselbraun et al., 2018). Hence, how does the quality of contextual data impact the performance of context selection approaches is an open direction.

- **Impact of additional sources of KG context:** In ablation, we provide a study by adding 1 & 2-hop triples in addition to entity attributes. There is no significant increase in the performance, although *KGPool* is able to remove irrelevant context for a given sentence. Furthermore, we did not consider edge features in HIG although *KGPool* can be extended to support edge features using techniques such as (Simonovsky and Komodakis, 2017). Additional experiments are needed to verify that our empirical observations hold in this setting, and we leave it for future work.

Overall, *KGPool* provides an effective knowledge representation for set-ups where sentence context is sparse. It is interesting to observe that effective knowledge representation learned using *KGPool* paired with an LSTM model outperforms GP-GNN (Zhu et al., 2019), and nearly all multi-instance baselines. Our conclusive results open a new research direction: *is it possible to apply effective context selection techniques coupled with deep learning models to other downstream NLP tasks?* For example, our results can encourage researchers to extend *KGPool* or develop novel context selection methods for the tasks where KGs have been extensively used as additional background knowledge, such as in entity linking (Mulang' et al., 2020; Mulang et al., 2020), KG completion (Wang et al., 2020; Shi et al., 2017), and recommendation system (Yang et al., 2020).

8 Ethics/ Impact Statement:

In this work, we present significant progress in solving sentential RE task. Harvesting knowledge is an essential goal that human beings seek along with the advancement of technology. This research and many RE approaches rely on additional signals from the public KGs to design systems that extract structured knowledge from unstructured contents. When it comes to who may be disadvantaged from this research, we do not think it is applicable since our study of addressing the KG context capabilities is still at an early stage. Having said so, we are fully supporting the development of ethical and responsible AI. The potential bias in the standard public datasets that may lead to wrong knowledge needs to be cleaned or corrected with validation mechanisms.

A Appendix

Due to page limit, we could not put several empirical results in the main paper. This section describes the remaining empirical studies.

A.1 Error Analysis

To understand the failure cases of *KGPool*, we conducted exhaustive error analysis. We calculated (micro) F1-Score of each relation in Sorokin dataset (Sorokin and Gurevych, 2017). Table 10 illustrates performance of ten relations on which *KGPool* performs the worst (ascending order of Micro-F1 score). To put the study in the right perspective, we also report all sentential RE baselines' performance on these relations. While analyzing the errors, we observe three patterns. First, all models fail in the relations for which number of instances are sparse. For example, the relation *mother* has only 190 instances (occurances) and the relation *killed by* has 48 instances. The scarcity in training data has made all models to fail on certain relations. Secondly, our model fails in very closed relations. For example, instead of predicting the relation *drafted by*[3], our model predicts *member of sport team*[4]. Similarly, in case of *unmarried partner*, our model predicts *spouse*. We believe that introducing logical reasoning in the model can help these borderline cases. The third observed pattern for errors is the quality of context. It is worthwhile to mention that in GP-GNN and Context-LSTM, there is only a sentential context. RECON and *KGPool* use KG context. Still, performance is limited for many relations such as *use* and *different from* as reported in the table 10. The lack of quality context in the KG possibly a reason for limited performance for KG-context-induced models in erroneous cases. Detailed exploration is needed to understand the impact of data quality on *KGPool* performance, and we leave it for the future work.

A.2 Effect of Context Pooling

Models	**DEG (HIG)**	**DEG (CG)**	**Dataset**
$KGPool_{+lstm}$ (α=1)	5.33	1.06	Wikidata
$KGPool_{+lstm}$ (α=2)	5.33	2.12	
$KGPool_{+lstm}$ (α=3)	5.33	4.32	
$KGPool_{+lstm}$ (α=4)	5.33	4.81	
$KGPool_{+lstm}$ (α=1)	6.34	1.23	NYT Freebase
$KGPool_{+lstm}$ (α=2)	6.34	1.74	
$KGPool_{+lstm}$ (α=3)	6.34	3.05	
$KGPool_{+lstm}$ (α=4)	6.34	6.30	

Table 9: Effect of Context Pooling. 'DEG' denotes average degree of an entity node (e_i). We observe a reduction in the degree of entity nodes in CG compared to the HIG.

In the main paper, we presented the effect of context pooling on *KGPool*'s best configuration ($KGPool_{+gnn}$). Table 9 describes the reduction in the average degree of nodes for $KGPool_{+lstm}$ configuration for various context coefficient (α). On both datasets, there is a significant reduction in the degree of nodes. On Wikidata dataset (Sorokin and Gurevych, 2017), $KGPool_{+lstm}$ with (α=1) reports the highest value among its other configurations. For the same, the average degree of nodes is reduced from 5.33 to 1.06. Please note, the degree of nodes in HIG remains the same. However, for CG, the degree of nodes differs based on the context aggregator. We train the model end to end, and due to back-propagation, context weights adjust as per the context aggregator.

A.3 Results on a Human Annotated Dataset

The employed datasets Wikidata (Sorokin and Gurevych, 2017) and NYT Freebase (Riedel et al., 2010) are created using distant supervision techniques. Considering distant supervision techniques inherit a noise, to provide a comprehensive ablation study, (Zhu et al., 2019) provided a human evaluation setting. Following the same setting, RECON provided human-annotated data

A.4 Datasets and Hyper-parameters

We augmented two datasets Wikidata dataset and Riedel Freebase dataset with our proposed KG context. The Wikidata dataset has 353 unique relations, 372,059 sentences in training, 123824 sentences in validation and 360,334 for testing. The number of sentences in the training and test set are 455,771 and 172,448 respectively in the Riedel dataset. No explicit validation set has been provided for Riedel dataset. For augmenting entity attribute context, we relied on public dumps of Wikidata and Freebase. From these dumps, we automatically extracted entities and its properties: labels, aliases, instance of, descriptions. For Wikidata, we used public API[5] using a SPARQL query and for Freebase, we took original depreciated dump[6].

We use the nltk english tokenizer for splitting the sentence into its corresponding tokens in the Riedel dataset. We do not do any further data preprocessing. We used 1 GPU NVIDIA TITAN X Pascal with 12GB of GPU storage to run our experiments. We train the models upto a maximum of 14 epochs and select the best performing model based on the micro F1 scores of the validation set. The tables 14, 15 and 12 detail the hyper-parameter settings used in our experiments. We do not do any further hyper-parameter tuning.

Abstract

Structural syntax knowledge has been proven effective for semantic role labeling (SRL), while existing works mostly use only one singleton syntax, such as either syntactic dependency or constituency tree. In this paper, we explore the integration of heterogeneous syntactic representations for SRL. We first consider a TreeLSTM-based integration, collaboratively learning the phrasal boundaries from the constituency and the semantic relations from dependency. We further introduce a label-aware GCN solution for simultaneously modeling the syntactic edges and labels. Experimental results demonstrate that by effectively combining the heterogeneous syntactic representations, our methods yield task improvements on both span-based and dependency-based SRL. Also our system achieves new state-of-the-art SRL performances, meanwhile bringing explainable task improvements.

1 Introduction

Semantic role labeling (SRL) aims to disclose the predicate-argument structure of a given sentence. Such shallow semantic structures have been shown highly useful for a wide range of downstream tasks in natural language processing (NLP), such as information extraction (Fader et al., 2011; Bastianelli et al., 2013), machine translation (Xiong et al., 2012; Shi et al., 2016) and question answering (Maqsud et al., 2014; Xu et al., 2020). Based on whether to recognize the constituent phrasal span or the syntactic dependency head token of an argument, prior works categorize SRL into two types: the span-based SRL popularized in CoNLL05/12 shared tasks (Carreras and Màrquez, 2005; Pradhan et al., 2013), and the dependency-based SRL introduced in CoNLL08/09 shared tasks (Surdeanu et al., 2008; Hajič et al., 2009). By adopting various neural network methods, two types of SRL have achieved significant performances in recent years (FitzGerald et al., 2015; He et al., 2017; Fei et al., 2021a)

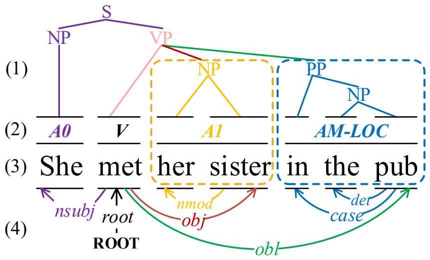

Figure 1: The mutual benefit to integrate both the (1) syntactic constituency and (4) dependency structures for (2) SRL, based on (3) an example sentence.

Syntactic features have been extensively verified to be highly effective for SRL (Pradhan et al., 2005; Punyakanok et al., 2008; Marcheggiani and Titov, 2017; Strubell et al., 2018; Zhang et al., 2019). In particular, syntactic dependency features have gained a majority of attention, especially for the dependency-based SRL, considering their close relevance with the dependency structure (Roth and Lapata, 2016; He et al., 2018; Xia et al., 2019; Fei et al., 2021b). Most existing works focus on designing various methods for modeling the dependency representations into the SRL learning, such as TreeLSTM (Li et al., 2018; Xia et al., 2019) and graph convolutional networks (GCN) (Marcheggiani and Titov, 2017; Li et al., 2018). On the other hand, some efforts try to encode the constituency representations for facilitating the span-based SRL (Wang et al., 2019; Marcheggiani and Titov, 2020).

Yet almost all the syntax-based SRL methods use one standalone syntactic tree, i.e., either dependency or constituency tree. Constituent and dependency syntax actually depict the syntactic structure from different perspectives, and integrat-

ing these two heterogeneous representations can intuitively bring complementary advantages (Farkas et al., 2011; Yoshikawa et al., 2017; Zhou and Zhao, 2019). As exemplified in Figure 1, the dependency edges represent the inter-relations between arguments and predicates, while the constituency structure[1] locates more about phrase boundaries of argument spans, and then directs the paths to the predicate globally. Interacting these two structures can better guide the system to focus on the most proper granularity of phrasal spans (as circled by the dotted box), while also ensuring the route consistency between predicate-argument pairs. Unfortunately, we find that there are very limited explorations of the heterogeneous syntax integration in SRL. For instance, Li et al. (2010) manually craft two types of discrete syntax features for statistical model, and recently Fei et al. (2020a) implicitly distill two heterogeneous syntactic representations into one unified neural model.

In this paper, we present two innovative neural methods for explicitly integrating two kinds of syntactic features for SRL. As shown in Figure 2, in our framework, the syntactic constituent and dependency encoders are built jointly as a unified block (i.e., Heterogeneous Syntax Fuser, namely `HeSyFu`), and work closely with each other. In the first architecture of `HeSyFu` (cf. Figure 3), we take two separate TreeLSTMs as the structure encoders for two syntactic trees. Based on our framework, we try to answer the following questions:

► **Q1**. *Whether the combination of constituent and dependency syntax can really improve SRL*?

► **Q2**. If yes, *how much will such improvements be for the dependency- and span-based SRL*?

We further propose *Const* GCN and *Dep* GCN encoders to enhance the syntax encoding in `HeSyFu`, where the *syntactic labels* (i.e., dependent arc types and constituency node types) are modeled in a unified manner within the label-aware GCN, as illustrated in Figure 4. With this, we can dig deeper:

► **Q3**. *How different will the results be by employing the TreeLSTM or GCN encoder*?

► **Q4**. *Can SRL be further improved by leveraging syntactic labels?*

► **Q5**. *What kind of associations can be discovered between SRL structures and these heterogeneous syntactic structures*?

To find the answers, we conduct extensive experiments on both span- and dependency-based SRL benchmarks (i.e., CoNLL05/12 and CoNLL09). The results and analyses show that,

►**A1**. *combining two types of syntax information is more helpful than just using either one of them*;

►**A2**. *the improvement for span-based SRL is more obvious than dependency-based one*;

►**A3**. *GCN performs better than TreeLSTM*;

►**A4**. *syntactic labels are quite helpful for SRL*;

►**A5**. *SRL and both kinds of syntactic structures have strong associations and should be exploited for mutual benefits*.

In our experiments, our SRL framework with two proposed `HeSyFu` encoders achieves better results than current best-performing systems, and yield more explainable task improvements.

2 Related Work

The SRL task, uncovering the shallow semantic structure (i.e. '*who did what to whom where and when*') is pioneered by Gildea and Jurafsky (2000), and popularized from PropBank (Palmer et al., 2005) and FrameNet (Baker et al., 1998). SRL is typically divided into the span-based one and dependency-based one on the basis of the granularity of arguments (e.g., phrasal spans or dependency heads). Earlier efforts focus on designing hand-crafted features with machine learning methods (Pradhan et al., 2005; Punyakanok et al., 2008; Zhao et al., 2009b,a). Later, SRL works mostly employ neural networks with distributed features for the task improvements (FitzGerald et al., 2015; Roth and Lapata, 2016; Marcheggiani and Titov, 2017; Strubell et al., 2018). Most high-performing systems model the task as a sequence labeling problem with *BIO* tagging scheme for both two types of SRL (He et al., 2017; Ouchi et al., 2018; Fei et al., 2020c,b).

On the other hand, syntactic features are a highly effective SRL performance enhancer, according to numbers of empirical verification in prior works (Marcheggiani et al., 2017; He et al., 2018; Swayamdipta et al., 2018; Zhang et al., 2019), as intuitively SRL shares much underlying structure with syntax. Basically, the syntactic dependent feature is more preferred to be injected into the dependency-based SRL (Roth and Lapata, 2016; Marcheggiani and Titov, 2017; He et al., 2018; Kasai et al., 2019), while other consider the constituent syntax for the span-based SRL (Wang

---

[1] Following Marcheggiani and Titov (2020), we strip off the nodes of POS tags from the constituency tree for brevity.

et al., 2019; Marcheggiani and Titov, 2020).

Actually, the constituent and dependency syntax depict the structural features from different angles, while they can share close linguistic relevance. Related works have revealed the mutual benefits on integrating these two heterogeneous syntactic representations for various NLP tasks (Collins, 1997; Charniak, 2000; Charniak and Johnson, 2005; Farkas et al., 2011; Yoshikawa et al., 2017; Zhou and Zhao, 2019; Strzyz et al., 2019; Kato and Matsubara, 2019). Unfortunately, there are very limited explorations for SRL. For example, Li et al. (2010) construct discrete heterogeneous syntactic features for SRL. More recent work in Fei et al. (2020a) leverage knowledge distillation method to inject the heterogeneous syntax representations from various tree encoders into one model for enhancing the span-based SRL. In this work, we consider an explicit integration of these two syntactic structures via two neural solutions. To our knowledge, we are the first attempt performing thorough investigations on the impacts of the heterogeneous syntax combination to the SRL task.

Various neural models have been proposed for encoding the syntactic structures, such as attention mechanism (Strubell et al., 2018; Zhang et al., 2019), TreeLSTM (Li et al., 2018; Xia et al., 2019), GCN (Marcheggiani and Titov, 2017; Li et al., 2018; Marcheggiani and Titov, 2020), etc. In this work, we take the advantages of the TreeLSTM and GCN models for encoding the constituent and dependency trees, as two solutions of our `HeSyFu` encoders. It is worth noticing that prior works using GCN to encode dependency (Marcheggiani and Titov, 2017) and constituent (Marcheggiani and Titov, 2020), where however the syntactic labels are not managed in a unified manner. We thus consider enhancing the syntax GCN by simultaneously modeling the syntactic labels within the structure.

3 SRL Model

3.1 Task Modeling

Following prior works (Tan et al., 2018; Marcheggiani and Titov, 2020), our system aims to identify and classify the arguments of a predicate into semantic roles, such as *A0*, *A1*, *AM-LOC*, etc. We denote the complete role set as $\mathcal{R}$. We adopt the *BIO* tagging scheme. And given a sentence s=$\{w_1,\cdots,w_n\}$ and a predicate w_p, the model assigns each word w_i a label $\hat{y} \in \mathcal{Y}$, where $\mathcal{Y}$=$(\{B,I\}\times\mathcal{R}) \cup \{O\}$.[2] Note that each semantic argument corresponds to a word span of $\{w_j,\cdots,w_k\}$ $(1\leq j\leq k\leq n)$.[3]

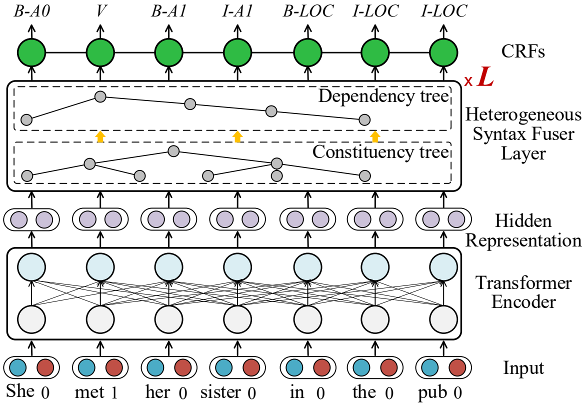

Figure 2: Overview of our SRL framework.

3.2 Framework

As illustrated in Figure 2, our SRL framework consists of four components, including input representations, Transformer encoder, heterogeneous syntax fuser layer and CRFs decoding layer.

Given an input sentence s and a predicate word w_p (p is the position), the input representations $\boldsymbol{x}_i$ are the concatenation ($\oplus$) of word embeddings $\boldsymbol{x}_{w_i}$ and predicate binary embeddings $\boldsymbol{x}_{(i==p)}$ indicating the presence or absence of w_p:

$$\boldsymbol{x}_i = \boldsymbol{x}_{w_i} \oplus \boldsymbol{x}_{(i==p)} . \tag{1}$$

Afterwards, we adopt Transformer (Vaswani et al., 2017) as our base encoder for yielding contextualized word representations. Transformer (*Trm*) works with multi-head self-attention mechanism:

$$\text{Softmax}(\frac{\boldsymbol{Q}\cdot\boldsymbol{K}^{\text{T}}}{\sqrt{d_k}})\cdot\boldsymbol{V} , \tag{2}$$

where $\boldsymbol{Q}$, $\boldsymbol{K}$ and $\boldsymbol{V}$ are the linear projections from the input representation $\boldsymbol{x}_i$. We simplify the flow:

$$\{\boldsymbol{r}_1,\cdots,\boldsymbol{r}_n\} = \text{Trm}(\{\boldsymbol{x}_1,\cdots,\boldsymbol{x}_n\}) . \tag{3}$$

Next, based on the hidden representation $\boldsymbol{r}_i$, our heterogeneous syntax fuser (`HeSyFu`) layer, which will be elaborated in Section §4, integrates the constituency and dependency syntax, and yields the syntax-aware hidden representation:

$$\{\boldsymbol{s}_1,\cdots,\boldsymbol{s}_n\} = \text{HeSyFu}(\{\boldsymbol{r}_1,\cdots,\boldsymbol{r}_n\}) . \tag{4}$$

---

[2] This work focuses on the pipeline-style SRL which is under the assumption that predicates are pre-identified.

[3] When $j=k$, the span-based SRL model shifts into the dependency-based one.

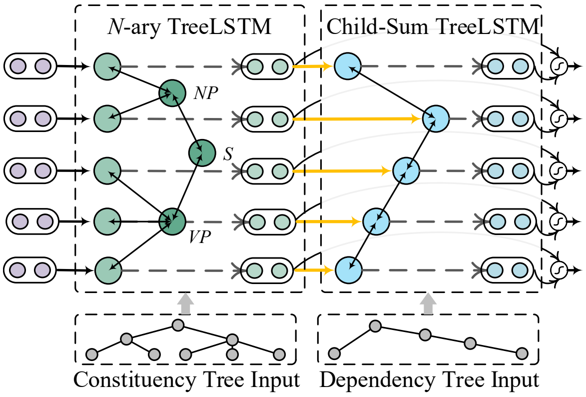

Figure 3: TreeLSTM-based `HeSyFu` layer.

Based on the syntax-aware hidden representation $\boldsymbol{s}_i$, we use CRFs (Lafferty et al., 2001) to compute the probability of each candidate output $\boldsymbol{y} = \{y_1, \cdots, y_n\}$:

$$p(y|s) = \frac{\exp\{\sum_i (\boldsymbol{W}\boldsymbol{s}_n + \boldsymbol{T}_{y_{i-1},y_i})\}}{Z}, \quad (5)$$

where $\boldsymbol{W}$ and $\boldsymbol{T}$ are the parameters and Z is a normalization factor. The Viterbi algorithm is used to search for the highest-scoring tag sequence $\hat{\boldsymbol{y}}$.

4 Integration of Syntactic Constituency and Dependency Structure

We present two neural heterogeneous syntax fusers (a.k.a., `HeSyFu`), including a TreeLSTM-based `HeSyFu` (cf. Figure 3), and a label-aware GCN-based `HeSyFu` (cf. Figure 4). `HeSyFu` is stacked with total L layers for a full syntax interaction. We design the architecture with the constituency (denoted as *const.*) encoding in front of the dependency (denoted as *dep.*) encoding, based on the intuition that the boundary recognition helped by *const.* syntax should go before the semantic relation determination aided by *dep.* syntax.

4.1 TreeLSTM Heterogeneous Syntax Fuser

Our TreeLSTM-based `HeSyFu` (Tr-`HeSyFu`) is comprised of the N-ary TreeLSTM for *const.* trees and the Child-Sum TreeLSTM for *dep.* trees motivated by Tai et al. (2015).

Constituency tree encoding The flow in TreeLSTM is bidirectional, i.e., bottom-up and top-down, for a full information interaction. For each node u in the tree, we denote the hidden state and memory cell of its v-th ($v \in [1, M]$) branching child as $\boldsymbol{h}_{uv}^{\uparrow}$ and $\boldsymbol{c}_{uv}$. The bottom-up one computes the representation $\boldsymbol{h}_u^{\uparrow}$ from its children hierarchically:

$$\begin{aligned}
\boldsymbol{i}_u &= \sigma(\boldsymbol{W}^{(i)}\boldsymbol{r}_u + \textstyle\sum_{v=1}^{M}\boldsymbol{U}_v^{(i)}\boldsymbol{h}_{uv}^{\uparrow} + \boldsymbol{b}^{(i)}),\\
\boldsymbol{f}_{uk} &= \sigma(\boldsymbol{W}^{(f)}\boldsymbol{r}_u + \textstyle\sum_{v=1}^{M}\boldsymbol{U}_{kv}^{(f)}\boldsymbol{h}_{uv}^{\uparrow} + \boldsymbol{b}^{(f)}),\\
\boldsymbol{o}_u &= \sigma(\boldsymbol{W}^{(o)}\boldsymbol{r}_u + \textstyle\sum_{v=1}^{M}\boldsymbol{U}_v^{(o)}\boldsymbol{h}_{uv}^{\uparrow} + \boldsymbol{b}^{(o)}),\\
\boldsymbol{u}_u &= \mathrm{Tanh}(\boldsymbol{W}^{(u)}\boldsymbol{r}_u + \textstyle\sum_{v=1}^{M}\boldsymbol{U}_v^{(u)}\boldsymbol{h}_{uv}^{\uparrow} + \boldsymbol{b}^{(u)}),\\
\boldsymbol{c}_u &= \boldsymbol{i}_u \odot \boldsymbol{u}_u + \textstyle\sum_{k=1}^{M}\boldsymbol{f}_{uk} \odot \boldsymbol{c}_{uk},\\
\boldsymbol{h}_u^{\uparrow} &= \boldsymbol{o}_u \odot \tanh(\boldsymbol{c}_u),
\end{aligned} \quad (6)$$

where $\boldsymbol{W}$, $\boldsymbol{U}$ and $\boldsymbol{b}$ are parameters. $\boldsymbol{r}_u, \boldsymbol{i}_u$, $\boldsymbol{o}_u$ and $\boldsymbol{f}_{uv}$ are the input token representation, input gate, output gate and forget gate. Analogously, the top-down N-ary TreeLSTM calculates the representation $\boldsymbol{h}_u^{\downarrow}$ the same way. We concatenate the representations of two directions: $\boldsymbol{h}_u^{const} = \boldsymbol{h}_u^{\uparrow} \oplus \boldsymbol{h}_u^{\downarrow}$. Note that the constituent tree nodes include terminal word nodes and non-terminal constituent nodes, and we only take the representations (i.e., $\boldsymbol{h}_i^{const}$) corresponding to the word node w_i for any usage.

Dependency tree encoding Slightly different from N-ary TreeLSTM for *const.* tree, the non-terminal nodes in *dep.* tree encoded by Child-Sum TreeLSTM are all the word nodes. We also consider the bidirectional calculation here. The bottom-up TreeLSTM obtains $\boldsymbol{h}_i^{\uparrow}$ of the word w_i via:

$$\begin{aligned}
\overline{\boldsymbol{h}}_i^{\uparrow} &= \textstyle\sum_{j\in C(i)}\boldsymbol{h}_j^{\uparrow},\\
\boldsymbol{i}_i &= \sigma(\boldsymbol{W}^{(i)}\boldsymbol{r}_i^{'} + \boldsymbol{U}^{(i)}\overline{\boldsymbol{h}}_i^{\uparrow} + b^{(i)}),\\
\boldsymbol{f}_{ij} &= \sigma(\boldsymbol{W}^{(f)}\boldsymbol{r}_i^{'} + \boldsymbol{U}^{(f)}\overline{\boldsymbol{h}}_j^{\uparrow} + b^{(f)}),\\
\boldsymbol{o}_i &= \sigma(\boldsymbol{W}^{(o)}\boldsymbol{r}_i^{'} + \boldsymbol{U}^{(o)}\overline{\boldsymbol{h}}_i^{\uparrow} + b^{(o)}),\\
\boldsymbol{u}_i &= \mathrm{Tanh}(\boldsymbol{W}^{(u)}\boldsymbol{r}_i^{'} + \boldsymbol{U}^{(u)}\overline{\boldsymbol{h}}_i^{\uparrow} + b^{(u)}),\\
\boldsymbol{c}_i &= \boldsymbol{i}_i \odot \boldsymbol{u}_i + \textstyle\sum_{j\in C(i)}\boldsymbol{f}_{ij} \odot \boldsymbol{c}_j,\\
\boldsymbol{h}_i^{\uparrow} &= \boldsymbol{o}_i \odot \tanh(\boldsymbol{c}_i),
\end{aligned} \quad (7)$$

where $C(i)$ is the set of child nodes of w_i. $\boldsymbol{r}_i^{'}$ is the input token representation consulting the foregoing constituent output representation: $\boldsymbol{r}_i^{'} = \boldsymbol{r}_i + \boldsymbol{h}_i^{const}$. The top-down one yields $\boldsymbol{h}_i^{\downarrow}$, which is concatenated with the bottom-up one: $\boldsymbol{h}_i^{dep} = \boldsymbol{h}_i^{\uparrow} \oplus \boldsymbol{h}_i^{\downarrow}$.

Integration To fully make use of the heterogeneous syntactic knowledge, we fuse these two resulting syntactic representations. We apply a fusion gate to flexibly coordinate their contributions:

$$\begin{aligned}
\boldsymbol{g}_i &= \sigma(\boldsymbol{W}^{(g_1)}\boldsymbol{h}_i^{const} + \boldsymbol{W}^{(g_2)}\boldsymbol{h}_i^{dep} + b^{(g)}),\\
\boldsymbol{s}_i &= \boldsymbol{g}_i \odot \boldsymbol{h}_i^{const} + (1 - \boldsymbol{g}_i) \odot \boldsymbol{h}_i^{dep}.
\end{aligned} \quad (8)$$

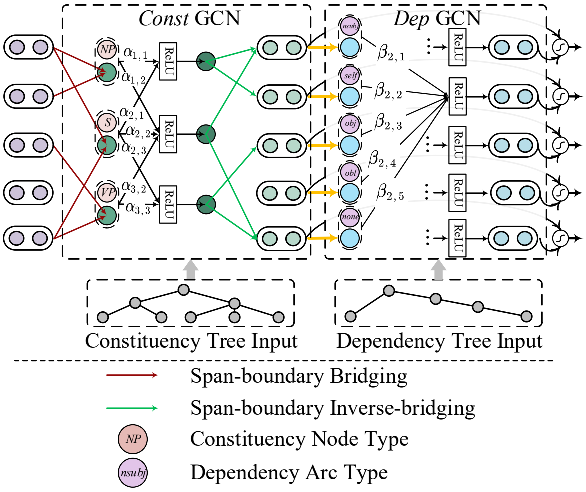

Figure 4: Label-aware GCN-based `HeSyFu` layer.

4.2 Label-aware GCN-based Heterogeneous Syntax Fuser

Compared with TreeLSTM, GCN is more computationally efficient on performing the structural propagation among nodes, i.e., with O(1) complexity. On the other hand, it is also crucial to leverage the syntactic labels (i.e., dependent arc types, and constituent phrasal types) into the SRL learning. For example, within the dependency tree, the information from the neighboring nodes under distinct types of arcs can contribute in different degrees. However we note that current popular syntax GCNs (Marcheggiani and Titov, 2017, 2020) do not encode the dependent or constituent labels with the nodes in a unified manner, which could be inaccurate to describe the syntactic connecting attributes between the neighbor nodes. Based on their syntax GCNs, we newly propose label-aware constituency and dependency GCNs which are able to explicitly formalize the structure edges with syntactic labels simultaneously, and normalize them unitedly.[4] As illustrated in Figure 4, our label-aware GCN-based `HeSyFu` (denoted as LG-`HeSyFu`) has a similar assembling architecture to TreeLSTM-based `HeSyFu`, and will finally be navigated via the gate mechanism as in Eq. (8).

Constituency tree encoding The constituent tree is modeled as a graph $G^{(c)}$=$(U^{(c)}, E^{(c)})$, where $U^{(c)}$ is the node set and $E^{(c)}$ is the edge set. We denote $e^{(c)}_{uv}$=1 if there is an edge between node u and node v, and e_{uv}=0 vice versa. We enable the edges to be bidirectional. μ_u represents the constituent label of node u, such as *S*, *NP* and *VP*, etc. We take the vectorial embedding $\boldsymbol{v}^{(c)}_u$ for the node label μ_u. Our constituent GCN (denoted as *Const* GCN) yields the node representations $\boldsymbol{h}^{(c)}_u$:

$$\boldsymbol{h}^{(c)}_u = \text{ReLU}\{\textstyle\sum_{v=1}^{M}\alpha_{uv}(\boldsymbol{W}^{(c_1)}\cdot\boldsymbol{r}^b_v+\boldsymbol{W}^{(c_2)}\cdot\boldsymbol{v}^{(c)}_v+b^{(c)})\}\,, \tag{9}$$

where $\boldsymbol{r}^b_v$ is the initial node representation of the node v via **span-boundary bridging operation**, i.e., adding the start and end token representation of the phrasal span, $\boldsymbol{r}^b_v = \boldsymbol{r}_{start} + \boldsymbol{r}_{end}$. And α_{uv} is the constituent connecting distribution:

$$\alpha_{uv} = \frac{e^{(c)}_{uv}\cdot\exp\{(\boldsymbol{z}^{(c)}_u)^T\cdot\boldsymbol{z}^{(c)}_v\}}{\sum_{v'=1}^{M} e^{(c)}_{uv'}\cdot\exp\{(\boldsymbol{z}^{(c)}_u)^T\cdot\boldsymbol{z}^{(c)}_{v'}\}}\,, \tag{10}$$

where $\boldsymbol{z}^{(c)}_u = \boldsymbol{v}_u + \boldsymbol{v}^{(c)}_u$. This distribution α_{uv} encodes both the syntactic edge and label information, and thus comprehensively reflects the connecting strengths between neighbors. We then perform **span-boundary inverse-bridging** to restore the token node representation $\boldsymbol{h}^{const}_i$ for each word w_i, i.e., $\boldsymbol{h}^{const}_i = \boldsymbol{h}^{(c)}_{u'} + \boldsymbol{h}^{(c)}_{v'}$.

Dependency tree encoding Likewise, the dependent tree is modeled as a graph $G^{(d)}$=$(U^{(d)}, E^{(d)})$. $e^{(d)}_{ij}$=1/0 denotes the dependency arc existence. $\pi^{\leftrightarrow}_{ij}$ represents the edge label between w_i and w_j, which is also bidirectional. Besides of the pre-defined dependency labels, we additionally add a '*self*' label as the self-loop edge $\pi^{\leftrightarrow}_{ii}$, and a '*none*' label representing no edge between w_i and w_j. We use the embedding form $\boldsymbol{v}^{(d)}_{ij}$ for $\pi^{\leftrightarrow}_{ij}$. The update in dependent GCN (denoted as *Dep* GCN) is written as:

$$\boldsymbol{h}^{(d)}_i = \text{ReLU}(\textstyle\sum_{j=1}^{n}\beta_{ij}(\boldsymbol{W}^{(d_1)}\cdot\boldsymbol{r}^{'}_j+\boldsymbol{W}^{(d_2)}\cdot\boldsymbol{v}^{(d)}_{ij}+b^{(d)}))\,, \tag{11}$$

where $\boldsymbol{r}^{'}_j = \boldsymbol{r}_j + \boldsymbol{h}^{const}_i$. β_{ij} is the neighbor connecting-strength distribution:

$$\beta_{ij} = \frac{e^{(d)}_{ij}\cdot\exp\{(\boldsymbol{z}^{(d)}_i)^T\cdot\boldsymbol{z}^{(d)}_j\}}{\sum_{j'=1}^{n} e^{(d)}_{ij'}\cdot\exp\{(\boldsymbol{z}^{(d)}_i)^T\cdot\boldsymbol{z}^{(d)}_{j'}\}}\,, \tag{12}$$

where $\boldsymbol{z}^{(d)}_i = \boldsymbol{r}^{'}_i + \boldsymbol{v}^{(d)}_{ij}$. Here $\boldsymbol{h}^{(d)}_i$ also can be denoted as $\boldsymbol{h}^{dep}_i$, which navigates the dependent arc and label information in a more unified way.

5 Experiments

5.1 Setups

We conduct experiments on the span-based SRL datasets (CoNLL05 & CoNLL12), and

dependency-based SRL dataset (CoNLL09). Each dataset has its own training, development, and test sets. We convert the constituency syntax annotations in CoNLL05&12 into dependency annotations by following the standard of Stanford Typed Dependency (v3.3.0).[5] We obtain the constituency annotations for CoNLL09 from the PTB data. We adopt the CoNLL05 evaluation scripts[6] to evaluate the performances, with precision (P), recall (R) and F1 score as the metrics. We conduct significance tests via Dan Bikel's evaluation comparer.[7] The Transformer hidden size is 768. The hidden sizes in TreeLSTM and GCN encoders are in [250,300,350]. We adopt the Adam optimizer with an initial learning rate of 2e-5. We train the model[8] by mini-batch size in [16,24,32] with early-stop strategy. We also load the pre-trained parameters[9] from the RoBERTa language model (Liu et al., 2019) to our Transformer encoder for boosting the performance. The environment is with Intel i9 CPU and NVIDIA RTX 3090Ti GPU.

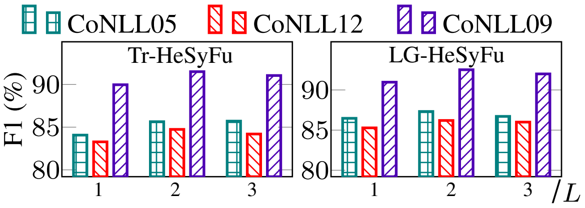

Figure 5: `HeSyFu` with different layers.

5.2 Development Experiments

We first perform preliminary experiments based on the development sets.

Layer of syntax encoder From Figure 5 we see that either too larger or fewer layers of `HeSyFu` does no benefits to the overall performances. When L=2 for Tr-/LG-`HeSyFu`, the performances be-

come universally the best.

Order of the heterogeneous syntax encoding We design the architecture with constituency encoding before dependency encoding, as described earlier. If we exchange this encoding order, we see from Table 2 that the drops come out. Also the drops are more severe on the span-based SRL data. This verifies the correctness of our model design.

5.3 Main Results

Our aim is to answer the research questions as listed in Section §1, based on the main experimental results in Table 1 and Table 3. **[★ Answer to Q1]** Our first observation is that leveraging syntax knowledge, e.g. either the dependency or constituency, benefits both the span-based and dependency-based SRL, while the integration of two heterogeneous syntax contributes the most, more than any one of the standalone syntax.

However we see that the improvements from this syntax integration is slightly different between span-based and dependency-based SRL. **[★ Answer to Q2]** In particular, the improvements for span-based SRL are more notable than dependency-based SRL, which can be learned by the comparisons between 'Trm+RoBERTa' and 'LG-HeSyFu+RoBERTa' on two tables. Our conjecture is that the the constituent structure knowledge will additionally help the span boundary detection of span-based SRL, compared with dependency-based SRL. Also we find that using only constituency syntax contributes more span-based SRL, while the dependency-based SRL benefits more from dependency syntax.

Looking into the specific results, within the scope of heterogeneous syntax integration methods, our systems (both Tr-HeSyFu and LG-HeSyFu) outperform Fei et al. (2020a), demonstrating the advances of our heterogeneous syntax integrating methods. Overall, our LG-HeSyFu model wins the new state-of-the-art performances on the used datasets, and with the help of the RoBERTa language model, the superiority is still maintained.

Table 3: Results on dependency-based SRL CoNLL09 dataset.

[★ Answer to Q3] Also we show that our LG-HeSyFu based system consistently outperforms Tr-HeSyFu based one. Even LG-HeSyFu without using the syntax label features can still keep better. It is also clear that the GCN based encoders show consistently higher scores than the TreeLSTM based ones, verifying the effectiveness of leveraging GCN encoding syntax (Marcheggiani and Titov, 2017; Li et al., 2018). **[★ Answer to Q4]** Meanwhile, the ablation of syntax label information reveals the importance of its leverage for the SRL learning.

5.4 Analysis and Discussion

Correlations between SRL and syntax structures We explore the correlations between the SRL structure and the two syntax structures. We reach this by analyzing the SRL prediction with the neighbor connecting weights, i.e., α_{uv} of *Const* GCN and β_{ij} of *Dep* GCN. We visualize the results (on CoNLL05) in Figure 6. **[★ Answer to Q5]** We learn that our framework indeed has captured the underlying inter-dependency between the SRL structures and the syntactic structure from the diversified visualizations. By accurately modeling

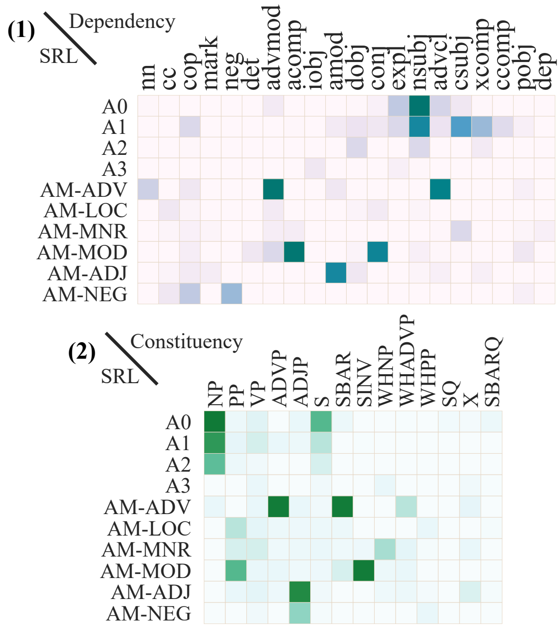

Figure 6: Discovered correlations of (1) SRL vs. dependent structure, (2) SRL vs. constituent structure.

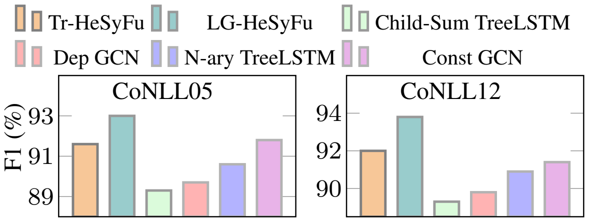

Figure 7: F1 scores for span boundary detection.

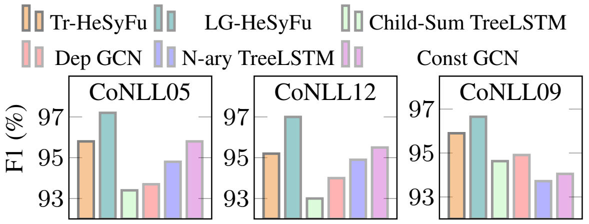

Figure 8: Results on the argument role label prediction.

such correlations, our LG-`HeSyFu` system naturally yields prominent meanwhile explainable SRL performances. Also some interesting patterns can be observed. Actually, not all the syntactic elements contribute the SRL learning. For example, the semantic roles `A0`, `A1` and `A2` relates more to the dependent edge *nsubj* and *csubj*, and more to the constituent phrase *NP*. We believe this can lay a crucial foundation for the direction of unsupervised semantic role labeling that relies on the syntactic structures.

Span boundary detection We now investigate the influences of the heterogeneous syntax integration to the span boundary match[10] on span-based SRL, i.e., on CoNLL05/12 data. From Figure 7 we learn that the heterogeneous syntax integration can improve the boundary detection over any standalone syntax leverage, while actually the constituency syntax contributes more significantly than dependency feature. And our LG-`HeSyFu` shows the best helpfulness than Tr-`HeSyFu`.

Label prediction We next evaluate the role label prediction. We only measure the correctly extracted arguments on whether its label further matches the gold annotation. We show the F1 score in Figure 8. Similar to the span boundary identification, the heterogeneous syntax integration can contribute the most than that with any single syntax usage. Interestingly, the standalone dependency syntax shows more improvements on the dependency-based SRL, while the phrasal constituency features benefit more the span-based SRL.

Error breakdown To analyze which error types different syntax-aided SRL models tend to make, we follow prior works (He et al., 2017; Strubell et al., 2018), manually fixing the errors by applying oracle transformations incrementally based on CoNLL05.[11] The analysis is shown in Figure 9. Specifically, constituency syntax methods perform better than dependency-aided methods, w.r.t. the span boundary errors (‘Merge Spans’, ‘Split Spans’ and ‘Fix Span Boundary’). Most importantly, it is quite clear that our heterogeneous syntax integrated systems (Tr-`HeSyFu` and LG-`HeSyFu`) makes fewer errors than baseline standalone syntax-aware methods, demonstrating the necessity to combine both two types of syntax.

Syntax distribution By observing the gate values $\boldsymbol{g}_i$ (in Eq. 8) we can analyze the distributions of dependency and constituency features required by span-based and dependency-based SRL. From Figure 10 we see that span-SRL relies more on constituency feature, while dependency-SRL needs more dependency-aware feature. Such finding quite coincides with the foregoing quantitative analysis, as well as our intuition.

---

[10] A correct match means both the start and end boundary of an argument span is correct, regardless of its label.

[11] The bigger the correction error improves, the more the model makes on it.

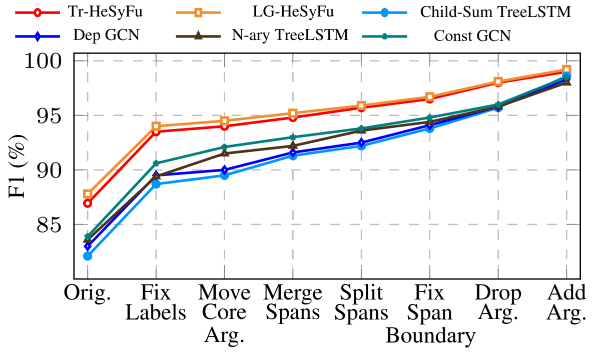

Figure 9: Performances after error corrections.

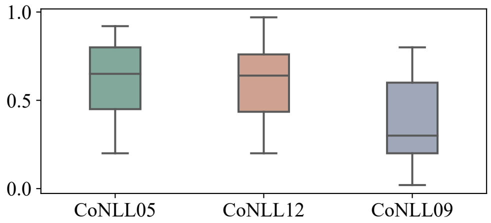

Figure 10: Heterogeneous syntax distribution. Level ≥0.5 means more reliance upon constituent syntax, otherwise for dependency

6 Conclusion and Future Work

We investigated the integration of constituency and dependency syntax for the SRL task. We first introduced TreeLSTM-based heterogeneous syntax fusing encoders, and further proposed innovative label-aware syntax GCN encoders for the integration. Experimental results showed that combining the heterogeneous syntax brought better results on both span-based and dependency-based SRL, than any one standalone syntax knowledge. As future work, we investigate other kinds of structural knowledge integration besides syntax, such as Semantic Dependency Structure, Abstract Meaning Representation (AMR), and explore the possibility of extending our model to incorporating such structured information. Besides, integrating the heterogeneous syntax knowledge into pre-training language models will be a promising direction.

Abstract

Paraphrase generation is an important and challenging NLG problem. In this work, we propose a new Identification-then-Aggregation (IA) framework to tackle this task. In the identification step, the input tokens are sorted into two groups by a novel Primary/Secondary Identification (PSI) algorithm. In the aggregation step, these groups are separately encoded, before being aggregated by a custom designed decoder, which autoregressively generates the paraphrased sentence. In extensive experiments on two benchmark datasets, we demonstrate that our model outperforms previous studies by a notable margin. We also show that the proposed approach can generate paraphrases in an interpretable and controllable way.

1 Introduction

Paraphrases refer to text (often sentences) that share the same meaning but use different choices of words and their ordering. Automatic generation of paraphrases is a longstanding problem that is important to many downstream NLP applications such as question answering (Dong et al., 2017; Buck et al., 2018), machine translation (Cho et al., 2014), and semantic parsing (Su and Yan, 2017). Most early research adopts the sequence-to-sequence model (Prakash et al., 2016; Cao et al., 2017; Li et al., 2018) to map the input text to its paraphrase by processing and generating each word in a uniform way. Rather than processing each word uniformly, some recent studies tackles this task in a decomposable manner. For instance, Li et al. (2019) adopt an external word aligner to extract paraphrasing patterns at different levels of granularity and then perform generation. Fu et al. (2019) first use source words to predict their neighbors and then organize the predicted neighbors into a complete sentence.

How are baby elephants called?

A yellow stove and refrigerator and a building.

Figure 1: Examples of paraphrase pair sampled from Quora and MSCOCO datasets in which the words in red refer to the primary content and the rest of the words make up the secondary content.

In this work, we investigate decomposable paraphrase generation from a different perspective. Specifically, we consider using a non-parametric approach to label each token in an input sentence as either (i) primary, or (ii) secondary. Intuitively, the primary content of a sentence refers to the factual information that defines the shared meaning of the paraphrase pair. All other content is deemed as secondary, and typically controls the structure of the sentence. In practice, this distinction is determined by an algorithm that decides whether tokens are primary or secondary, as described in §3. To better illustrate our idea, in Figure 1, we show some examples sampled from Quora and MSCOCO (Lin et al., 2014) datasets. We see that, for many cases, the paraphrase pairs maintain the similar primary content (e.g., the phrases "*baby elephants*" and "*baby elephant*" in the first example) while the secondary content can be rephrased in several different ways.

Based on the above observation, we propose an Identification-then-Aggregation (IA) framework to address the paraphrase generation task. Given an input sentence, generating a paraphrase follows a two-stage process. First, the primary and secondary content of the input sentence is identified via a novel Primary/Secondary Identification (PSI) algo-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 560–569
August 1–6, 2021.

rithm which is based on a common non-parametric rank coefficient. Second, a new neural paraphrase generation model aggregates the identified information and generates the result. Specifically, the proposed model consists of (1) two encoders which separately process the identified primary and secondary content; and (2) an aggregation decoder which integrates the processed results and generates the paraphrased sentence.

We test the proposed approach on two benchmark datasets with automatic and human evaluation. The results show that our approach outperforms previous studies and can generate paraphrases in an interpretable and controllable way.

2 Related Work

The automatic generation of paraphrases is important for many downstream NLP applications and it has attracted a number of different approaches. Early researches included rule-based approaches (McKeown, 1979; Meteer and Shaked, 1988) and data-driven methods (Madnani and Dorr, 2010). With the advances of neural networks, recent approaches tackle this problem by treating it as a sequence-to-sequence language generation task. Prakash et al. (2016) proposed to modify the networks structure to improve the generation quality. Cao et al. (2017), Wang et al. (2019), and Kazemnejad et al. (2020) proposed to improve the model performance by leveraging external resources, including phrase dictionary, semantic annotations, and an off-the-shelf pre-trained neural retriever. Other works proposed to adopt techniques like reinforcement learning (Li et al., 2018) and unsupervised learning (Roy and Grangier, 2019) for this task.

While achieving satisfactory results, these above methods do not offer users the way to control the generation process in a fine-grained way. To incorporate controllability into the generation model, different approaches have been proposed. Iyyer et al. (2018) trained the model to produce the paraphrased sentence with a given syntax. Li et al. (2019) proposed to adopt an external word aligner to train the model to generate paraphrases from different levels. In Fu et al. (2019)'s work, the model generates paraphrases by planning the neighbour of words and realizing the complete sentence.

3 Primary/Secondary Identification

Given an input sentence, our goal is to identify the primary content that are likely to appear in the paraphrased sentence. To this end, we propose a Primary/Secondary Identification (PSI) approach which dynamically evaluates the importance of different parts of the input sentence. The parts with high importance are deemed the primary content, while the rest parts are deemed secondary content.

Token Importance Formally, given a paraphrase pair $\mathbf{X}$ and $\mathbf{Y}$, we define their pairwise similarity as $\mathcal{F}(\mathbf{X},\mathbf{Y})$. To determine the importance of the i-th token x_i of $\mathbf{X}$ in relation to $\mathbf{Y}$, we first compute the pairwise similarity between $\mathbf{X}' = \mathbf{X} \ominus x_i$ and $\mathbf{Y}$ as $\mathcal{F}(\mathbf{X}',\mathbf{Y})$, where the $\ominus$ operator removes the token x_i from $\mathbf{X}$. We assume that if the token x_i belongs to the primary content that is maintained in both $\mathbf{X}$ and $\mathbf{Y}$, then removing it from $\mathbf{X}$ will cause a significant drop in the pairwise similarity between $\mathbf{X}$ and $\mathbf{Y}$. Based on this assumption, we measure the importance of x_i as the ratio of change in the pairwise similarity score as

$$\mathcal{G}(x_i;\mathbf{X},\mathbf{Y}) = \frac{\mathcal{F}(\mathbf{X},\mathbf{Y}) - \mathcal{F}(\mathbf{X}',\mathbf{Y})}{\mathcal{F}(\mathbf{X},\mathbf{Y})}. \qquad (1)$$

Intuitively, a higher $\mathcal{G}(x_i;\mathbf{X},\mathbf{Y})$ means a larger decrease in the pairwise similarity, indicating a higher importance of the token x_i and vice versa.

Similarity Measurement We now describe the details of the function $\mathcal{F}(\cdot,\cdot)$. Inspired by Zhelezniak et al. (2019), we measure the pairwise similarity between $\mathbf{X}$ and $\mathbf{Y}$ based on a non-parametric rank correlation coefficient. Specifically, given $\mathbf{X}$ and $\mathbf{Y}$, we first transform them into the representation matrices $\mathcal{M}(\mathbf{X}) \in \mathbb{R}^{|\mathbf{X}|\times D}$ and $\mathcal{M}(\mathbf{Y}) \in \mathbb{R}^{|\mathbf{Y}|\times D}$ via a D-dimensional pretrained embeddings. Then, the matrices are mapped into fixed size context vectors $\hat{x} \in \mathbb{R}^{1\times D}$ and $\hat{y} \in \mathbb{R}^{1\times D}$ via an element-wise max-pooling operation. Finally, the pairwise similarity $\mathcal{F}(\mathbf{X},\mathbf{Y})$ is measured using Spearman's correlation coefficient $\hat{\rho}$ of the context vectors $\hat{x}$ and $\hat{y}$ as

$$\mathcal{F}(\mathbf{X},\mathbf{Y}) = 1 - \frac{6 \times \sum_{j=1}^{D}(r[\hat{x}_j] - r[\hat{y}_j])^2}{D \times (D^2 - 1)} \qquad (2)$$

where $r[\hat{x}_j]$ denotes the integer rank of $\hat{x}_j$ in the context vector $\hat{x}$ (similarly $r[\hat{y}_j]$).

For a better illustration, in Table 1, we show sentence sampled from Quora and MSCOCO datasets along with their pairwise similarities. We see that the numerical results are highly correlated with human judgement which empirically demonstrate the effectiveness of our measurement method.

Sentence 1	Sentence 2	Pairwise Similarity
What are the best games you can play with just paper?	Which games can you play on paper in your free time with your friends?	0.745
	What can I do to become a professional chess player?	0.438
	Should animals be used for testing medicines and drugs?	0.140
Three bears walking on dried grass toward the green wooded area.	Two brown bears walking through a green, grassy area.	0.743
	A simple plain clear vase with a dead twig and water inside.	0.439
	A man using a phone next to a motorcycle.	0.128

Table 1: Examples of different sentence pairs $(\mathbf{X}, \mathbf{Y})$ and their corresponding pairwise similarity scores $\mathcal{F}(\mathbf{X}, \mathbf{Y})$.

Algorithm 1: Primary/Secondary Identification

```
Input : Input sentence $\mathbf{X} = (x_1, ..., x_{|\mathbf{X}|})$;
        Paraphrased sentence $\mathbf{Y} = (y_1, ..., y_{|\mathbf{Y}|})$;
        Primary content threshold $\alpha_p$;
        Importance measurement function $\mathcal{G}(\cdot, \cdot, \cdot)$.
$\mathbf{X}_p \leftarrow \{\}$; $\mathbf{X}_s \leftarrow \{\}$;
for $i = 1$ to $N$ do
    $\mathbf{X}' \leftarrow \mathbf{X} \ominus x_i$;
    if $\mathcal{G}(x_i; \mathbf{X}, \mathbf{Y}) > \alpha_p$ then
        $\mathbf{X}_p \leftarrow x_i$ and $\mathbf{X}_s \leftarrow$ [MASK];
    else
        $\mathbf{X}_p \leftarrow$ [MASK] and $\mathbf{X}_s \leftarrow x_i$;
    end
end
$\mathbf{X}_p \leftarrow$ joinmask($\mathbf{X}_p$); $\mathbf{X}_s \leftarrow$ joinmask($\mathbf{X}_s$).;
Output : Primary Content $\mathbf{X}_p$;
         Secondary Content $\mathbf{X}_s$.
```

Putting this together, the detailed description for splitting the input sentence $\mathbf{X}$ into the primary content $\mathbf{X}_p$ and secondary content $\mathbf{X}_s$ is given in Algorithm 1, where the token `[MASK]` is used as a special placeholder and the threshold α_p is tuned based on the performance on the validation set[1]. The joinmask$(\cdot)$ operation joins consecutive `[MASK]` tokens into a single `[MASK]` token. We note that the incorporation of the `[MASK]` token is crucial. Because, in this way, the generation model could have access to the original source sentence structure by simply overlapping the primary and secondary content. In the experiments, we found that removing `[MASK]` from the identified content causes a significant drop in model performance as the model can no longer have access to the original sentence structure.

In Figure 2, we show the computed results from PSI of an example presented in Figure 1. We can see that the primary content is effectively identified.

Inference During inference, given an input sentence, the primary and secondary content could not be directly identified as $\mathbf{X}_p, \mathbf{X}_s = \text{PSI}(\mathbf{X}, \mathbf{Y})$ since we do not have access to the target sentence $\mathbf{Y}$. To this end, we propose two alternative approaches. For the first one, we simply identify the primary and secondary content using the input sentence $\mathbf{X}$ as $\mathbf{X}'_p, \mathbf{X}'_s = \text{PSI}(\mathbf{X}, \mathbf{X})$. For the second one, we train a neural sequence tagger $\mathcal{S}$ based on the labels provided by PSI$(\mathbf{X}, \mathbf{Y})$. Then we extract the content using the input $\mathbf{X}$ as $\mathbf{X}'_p, \mathbf{X}'_s = \mathcal{S}(\mathbf{X})$. In the experiment section, we provide more detailed comparisons between these approaches.

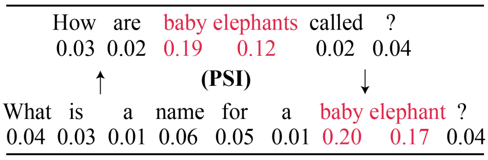

Figure 2: For each token, the score from the PSI algorithm is presented. The words in red is the identified primary content and the rest words make up the secondary content.

4 Neural Paraphrase Generator

Overview Given the input sentence $\mathbf{X}$, it is first partitioned into the primary and secondary content using the PSI algorithm. Then the identified content is independently processed by the primary encoder and the secondary encoder. Finally, an aggregation decoder integrates the outputs from both encoders and generates the result. In Figure 3, we provide an illustration of the proposed framework.

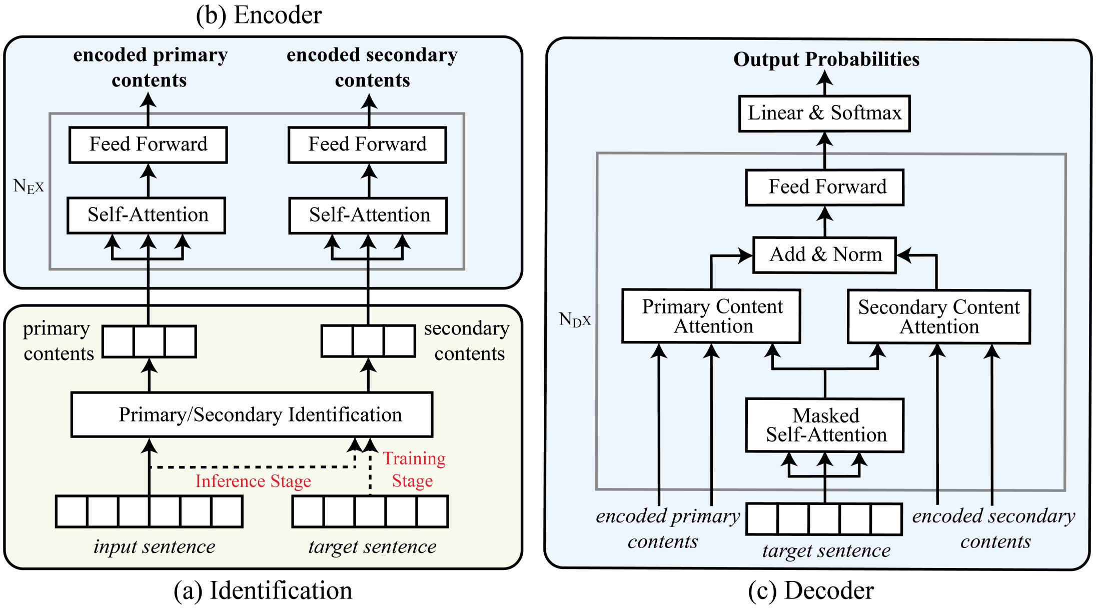
Encoder Stacks In this work, we use the transformer architecture (Vaswani et al., 2017) to construct the primary and secondary encoders. Formally, the Multi-Head Attention is defined as MultiHead$(\mathbf{Q}, \mathbf{K}, \mathbf{V})$, where $\mathbf{Q}$, $\mathbf{K}$, $\mathbf{V}$ are query, key and value. Each encoder has N_E layers. Given the input $\mathbf{X}$, the first layer operates as

$$\mathbf{V}_{\mathbf{X}}^{(1)} = \text{MultiHead}(E(\mathbf{X}), E(\mathbf{X}), E(\mathbf{X})), \quad (3)$$

$$\mathbf{O}_{\mathbf{X}}^{(1)} = \text{FFN}(\mathbf{V}_{\mathbf{X}}^{(1)}), \quad (4)$$

---

[1] In this work, we set α_p as 0.1 for all experiments based on the model performance on the validation set.



(b) Encoder

(a) Identification

(c) Decoder

Figure 3: Overview of the proposed framework: *Italic* and **Boldface** denote the inputs and outputs at each stage. For a better illustration, we separately draw the encoder and decoder of the paraphrase generator. **(a)** During training, the primary and secondary content of the input sentence are identified by the PSI algorithm using the input and target sentence. During inference, the content is identified solely based on the input sentence. **(b)** The identified results are then encoded by separate encoders. **(c)** The aggregation decoder takes the encoded primary and secondary content as input and produces the probability of the target sentence. It should be noted that, during the training stage, the encoder and decoder are jointly trained in an end-to-end fashion.

where $E(\mathbf{X})$ is the input sequence embedding and FFN$(\cdot)$ is a feed-forward layer. For other layers:

$$\mathbf{V}_{\mathbf{X}}^{(n)} = \text{MultiHead}(\mathbf{O}_{\mathbf{X}}^{(n-1)}, \mathbf{O}_{\mathbf{X}}^{(n-1)}, \mathbf{O}_{\mathbf{X}}^{(n-1)}), \tag{5}$$

$$\mathbf{O}_{\mathbf{X}}^{(n)} = \text{FFN}(\mathbf{V}_{\mathbf{X}}^{(n)}), \tag{6}$$

where $n = 2, ..., N_E$.

Given the primary content $\mathbf{X}_p$ and secondary content $\mathbf{X}_s$ of the input sequence, their representations $\mathbf{O}_{\mathbf{X}_p}^{(N_E)} \in \mathbb{R}^{|\mathbf{X}_p| \times d}$ and $\mathbf{O}_{\mathbf{X}_s}^{(N_E)} \in \mathbb{R}^{|\mathbf{X}_s| \times d}$ are computed by the primary and secondary encoder respectively and d is the model size.

Decoder Stacks We design an aggregation decoder to integrate information coming from both encoders. Given the target sentence $\mathbf{Y}$, it is first encoded via a masked multi-head attention as

$$\mathbf{V}_{\mathbf{Y}_m}^{(1)} = \text{Mask-MultiHead}(E(\mathbf{Y}), E(\mathbf{Y}), E(\mathbf{Y})). \tag{7}$$

Then, the primary content attention module takes the encoded primary content $\mathbf{O}_{\mathbf{X}_p}^{(N_E)}$ and $\mathbf{V}_{\mathbf{Y}_m}^{(1)}$ as input and produces the intermediate result $\mathbf{V}_{\mathbf{Y}_m^p}^{(1)}$ as

$$\mathbf{V}_{\mathbf{Y}_m^p}^{(1)} = \text{MultiHead}(\mathbf{V}_{\mathbf{Y}_m}^{(1)}, \mathbf{O}_{\mathbf{X}_p}^{(N_E)}, \mathbf{O}_{\mathbf{X}_p}^{(N_E)}). \tag{8}$$

Similarly, the result $\mathbf{V}_{\mathbf{Y}_m^s}^{(1)}$ from the encoded secondary content $\mathbf{O}_{\mathbf{X}_s}^{(N_E)}$ is computed as

$$\mathbf{V}_{\mathbf{Y}_m^s}^{(1)} = \text{MultiHead}(\mathbf{V}_{\mathbf{Y}_m}^{(1)}, \mathbf{O}_{\mathbf{X}_s}^{(N_E)}, \mathbf{O}_{\mathbf{X}_s}^{(N_E)}). \tag{9}$$

The first layer output $\mathbf{O}_{\mathbf{Y}}^{(1)}$ is then acquired as

$$\mathbf{V}_{\mathbf{Y}_i}^{(1)} = \text{LayerNorm}(\mathbf{V}_{\mathbf{Y}_m^p}^{(1)} + \mathbf{V}_{\mathbf{Y}_m^s}^{(1)}), \tag{10}$$

$$\mathbf{O}_{\mathbf{Y}}^{(1)} = \text{FFN}(\mathbf{V}_{\mathbf{Y}_i}^{(1)}). \tag{11}$$

The final output $\mathbf{O}_{\mathbf{Y}}^{(N_D)} \in \mathbb{R}^{|\mathbf{Y}| \times d}$ is computed via a stack of N_D layers. The final probability of $\mathbf{Y}$ is produced by a linear softmax operation.

Learning Finally, given the input primary content $\mathbf{X}_p$, secondary content $\mathbf{X}_s$ and the target sequence $\mathbf{Y}$, the learning objective is defined as

$$\mathcal{L} = \sum_{t=1}^{|\mathbf{Y}|} \log p(\mathbf{Y}_t | \mathbf{Y}_{<t}, \mathbf{X}_p, \mathbf{X}_s). \tag{12}$$

5 Datasets

We test our approach on two benchmark paraphrase generation datasets: (1) Quora dataset[2] and (2) MSCOCO dataset (Lin et al., 2014).

---

[2] https://www.kaggle.com/c/quora-question-pairs

The Quora dataset was developed for the task of duplicated question detection. Each data instance consists of one source sentence and one target sentence. In the experiment, we randomly select one sentence as the source and the other as the target.

The MSCOCO dataset was originally developed for the image captioning task. In this dataset, each image is associated with five human-written captions. Although there is no guarantee that these captions must be paraphrases as they could describe different objects in the image, most of these captions are generally close to each, therefore the overall quality of this dataset is favorable and it is widely used for the paraphrase generation task.

Following Li et al. (2019) and Fu et al. (2019), for the Quora dataset, we split the size of training, validation and test sets as 100k, 4k and 20k. The MSCOCO dataset is split into 93k, 4k and 20k. The maximum sentence length for these two datasets is set as 16. The vocabulary size of the Quora and MSCOCO datasest are set to be 8k and 11k.

6 Experiments

6.1 Model Comparisons

We compare the proposed model with several representative baselines, including Residual-LSTM (Prakash et al., 2016), β-VAE (Higgins et al., 2017), Transformer (Vaswani et al., 2017), DNPG (Li et al., 2019), LBOW-Topk and LBOW-Gumbel (Fu et al., 2019)[3]. To compare different inference approaches, three variants of our model are used.

IANet+X: Given the input sentence $\mathbf{X}$, this model extracts the primary and secondary content using the approximated PSI$(\mathbf{X}, \mathbf{X})$ algorithm. Then, the paraphrase generator produces the paraphrased sentence using the identified content.

IANet+$\mathcal{S}$: In this case, a neural sequence tagger $\mathcal{S}$ is first trained based on the labels provided by PSI$(\mathbf{X}, \mathbf{Y})$. During inference, the model extracts the primary and secondary content of the input as $\mathbf{X}'_p, \mathbf{X}'_s = \mathcal{S}(\mathbf{X})$ and then perform generation.

IANet+ref: In contrast to previous variants, this model obtains the primary and secondary content using the exact PSI$(\mathbf{X}, \mathbf{Y})$ algorithm against the reference $\mathbf{Y}$. The reason to include this model is that, besides our proposed alternatives, there are other options that we can use. We will explore these options in the future work. But by evaluating IANet+ref we can show an upper bound on how much could be improved in this way.

6.2 Implementation Details

We implement our model with PyTorch (Paszke et al., 2017). For the primary and secondary encoders, we use a 3-layer transformer with model size of 256 and heads of 8. Since the decoder has to integrate the information from both encoders, we build it with a larger capacity. The number of layers is set to 4. The model size and the attention heads are set to be 512 and 8. For the sequence tagger $\mathcal{S}$ that is used in the IANet+$\mathcal{S}$ model, we use a 2-layer LSTM with hidden size of 512.

In the experiments, we adopt pretrained 300-dimensional FastText Embeddings (Bojanowski et al., 2017) to perform the PSI algorithm. During training , we use Adam (Kingma and Ba, 2015) to optimize our model with a learning rate of 1e-4. In all experiments, we set α_p in Algorithm 1 as 0.1 based on the performance on the validation set.

6.3 Evaluation Metrics

Following previous studies (Prakash et al., 2016; Fu et al., 2019; Li et al., 2019), we report results on several automatic metrics, including BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004). All lower n-gram metrics (1-4 grams in BLEU and 1-2 grams in ROUGE) are reported. In addition, we include iBLEU (i-B) (Sun and Zhou, 2012) as another evaluation metric, which penalizes repeating the source sentence in its paraphrase.

6.4 Main Results

Table 2 lists the results on both datasets. We see that the transformer baseline already achieves pretty strong results. This is because the capacity of transformer model is large enough to fit the datasets quite well. Nonetheless, in most of the evaluation metrics, our model outperforms previous studies by a notable margin, demonstrating the effectiveness of the proposed approach.

By comparing different variants of our model, we see that IANet-ref achieves the best results on all metrics. This is expected as it uses the reference sentence in determining the primary and secondary content. It is worth emphasising that the IANet+ref model, like everything else, does not receive the target sentence, it just gets inputs $\mathbf{X}$ and has their primary and secondary content more accurately

---

[3] The hyperparameter setups and optimization in all baseline models are the same as their original works. For methods that do not release their code, we directly use the results in their original papers.

identified. This suggests that the deomposition of our approach is beneficial, and further work can be focused more on the identification step. On the other hand, without using the target sentence, both IANet+$\mathbf{X}$ and IANet+$\mathcal{S}$ must use an approximated approach at the inference time, which inevitably introduces noise in the identified content. As a result, the performance is lower than IANet+ref. We will provide more analysis in the analysis section.

6.5 Human Evaluation

We also conduct a human evaluation to assess our model, using graders proficient in English from an internal grading platform. We randomly select 150 examples from the Quora test set and compare our model with three representative baselines[4]. Three annotators are asked to rate the generated results from different models on a 3-point Likert scale (0, 1, or 2) with respect to the following features[5]:

- **Fluency**: Whether the generated paraphrase is grammatically correct and easily understood.

	Fluency	**Accuracy**	**Diversity**
Agreement	0.582	0.543	0.498
Residual-LSTM	1.57	1.41	1.29
Transformer	1.63	1.50	1.40
LBOW-Topk	1.61	1.49	1.43
IANet+$\mathcal{S}$	**1.71**	**1.57**	**1.61**
Reference	1.85	1.78	1.68

Table 3: Human Evaluation Results

- **Accuracy**: Whether the content in the generated paraphrase is consistent with the content in the original sentence.
- **Diversity**: Whether the generated sentence structure differs from the reference sentence.

To measure the agreement between the annotators, we use the Fleiss$'$ kappa coefficient (Fleiss et al., 1971). The agreement results are shown in the first row of Table 3, indicating moderate agreement between annotators on all metrics.

From Table 3, we see that our model achieves the best result on all metrics, which demonstrates the effectiveness of the proposed approach. Especially, on the diversity metric, our model significantly outperforms other baselines (Sign Test, with p-value < 0.05) and performs comparably with the

---

[4] Because the authors of DNPG (Li et al., 2019) did not release their code, thus we are not able to reproduce their results and are not able to include this model in the human evaluation.

[5] More details of the human evaluation guideline can be found in the supplementary material.

	Rec.(%)	Prec.(%)	F1(%)	B-4	R-L
PSI($\mathbf{X}, \mathbf{X}$)	71.2	88.5	78.9	26.52	57.13
Tagger $\mathcal{S}$	78.1	90.1	83.7	27.09	58.01
PSI($\mathbf{X}, \mathbf{Y}$)	**87.4**	**91.3**	**89.3**	**28.71**	**59.43**

Table 4: Comparisons between the identification performances of different algorithms on Quora dataset

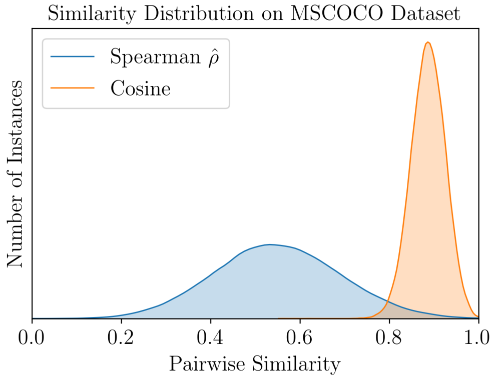

Figure 4: Comparison of similarity distribution

reference sentence (p-value = 0.23). The improvement in the diversity metric mainly comes from the two-step nature of our generation framework. By first determining which parts of the sentence to keep (primary) or to change (secondary), our model could then focus on maintaining the primary content while rewriting the secondary content, resulting in a more accurate and diverse paraphrase.

6.6 Further Analysis

In this section, we present further discussions and empirical analysis of the proposed approach.

6.6.1 Inference Algorithms Comparison

As shown in Table 2, IANet-ref outperforms IANet-$\mathbf{X}$ and IANet-$\mathcal{S}$ on both datasets. Our analysis is that IANet-ref could more accurately identify the primary content from the source comparing with the other variants. To provide more analysis, we separately use PSI($\mathbf{X}, \mathbf{X}$), the sequence tagger $\mathcal{S}$, and PSI($\mathbf{X}, \mathbf{Y}$) to identify the words that both appear in the source and target sentences in the Quora dataset. The results are shown in Table 4. We see that all three methods perform comparably on the precision (prec.) metric. However, PSI($\mathbf{X}, \mathbf{Y}$) significantly outperforms other methods on the recall (rec.) metric, showing that it can accurately extract more primary content from the source. From Table 4, we also observe that better identification results lead to better generation performances. Therefore, to improve the model performance, future work could be focused more on the identification step.

Metric	B-2	B-4	R-2	R-L
Cosine	50.34	24.91	14.78	37.62
Spearman $\hat{\rho}$	**53.09**	**26.90**	**17.13**	**40.58**

Table 5: Result comparison between the cosine similarity and the Spearman's $\hat{\rho}$ on the MSCOCO dataset.

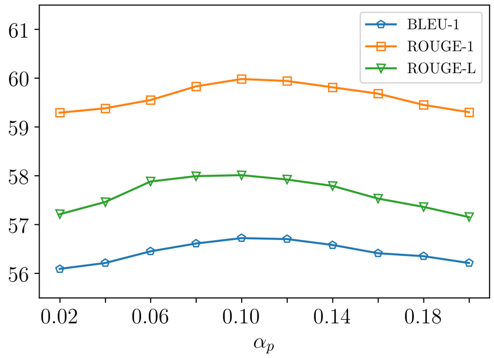

Figure 5: Effect of α_p on the model performance

6.6.2 Similarity Measurement Comparison

In this part, we analyze the differences between different similarity measurements. As described in Eq. (1) and Algorithm 1, the pairwise similarity measurement $\mathcal{F}(\mathbf{X}, \mathbf{Y})$ is the basis of the PSI algorithm. To see how different similarity measurements affect the system performance, we compare the adopted Spearman's $\hat{\rho}$ with the cosine similarity which is commonly used for measuring text similarity. We use both metrics to measure the training pair similarity of the MSCOCO dataset and the results are shown in Figure 4. As it can be seen that the distribution of cosine similarity is condensed in a much smaller interval comparing with the one from Spearman's $\hat{\rho}$, showing that the Spearman's $\hat{\rho}$ is more discriminative and can detect more subtle differences between the sentence pairs. Therefore, it can better identify the primary content, leading to better model performance. For further analysis, we run experiments on the MSCOCO dataset using cosine similarity as the measurement approach. The results of IANet+$\mathcal{S}$ using both metrics are shown in Table 5 which also demonstrate the fact that a more discriminative measurement approach leads to a better model performance.

6.6.3 Effect of α_p in PSI

As described in Algorithm 1, the proposed PSI algorithm relies on a predefined threshold α_p to perform the extraction of primary and secondary content. In this part, we examine the effect of different α_p on the model performance. We vary the value of α_p and measure the results of IANet+$\mathcal{S}$

Table 6: **Paraphrase Generation Samples from Quora dataset**: To compare different inference algorithms, we present the results of different model variants for the sampled instance. To examine the generation controllability of the proposed model, we generate sentences by manually decomposing the input sentence. Specifically, we choose different parts of the input sentence as the primary content (highlighted in blue) and the rest as the secondary content. The results on the right side are the corresponding generated paraphrases.

model on the Quora dataset. The results of three metrics (B-1, R-1, and R-L) are depicted in Figure 5. We see that the optimal value of α_p is 0.1 and by further decreasing or increasing α_p, the model performance drops. Our analysis is that, when α_p is too small, the words that only cause small variation in the pairwise similarity (Eq. (1)) will be misclassified as primary. Therefore, extra noise might be introduced to the model input which in turns decreases the model performance. On the other hand, when α_p is too large, some important words that should be classified as primary content might be excluded by the PSI algorithm, which also leads to the decrease of model performance.

6.6.4 Case Study

As described in section §6.6.1, the reason why IANet+ref outperforms IANet+$\mathbf{X}$ and IANet+$\mathcal{S}$ is that it can more accurately identify the primary content in order to generate a paraphrase that is similar to the reference sentence. On the other hand, both IANet+$\mathbf{X}$ and IANet+$\mathcal{S}$ adopt an approximated algorithm which would inevitably introduce extra noise in the identified content.

For a better illustration, we sample one test case from Quora dataset and present the results generated by our different model variants in Table 6. We can see that, given the input sentence, all model variants can generate a sentence that is similar to the reference paraphrase. By further comparing the primary content (words in blue), we can see that only the IANet+ref successfully identifies all the primary content that are also contained in the reference sentence. On the other hand, IANet+$\mathbf{S}$ misses the word *best* and IANet+$\mathbf{X}$ ignores the words *young* and *adult*. As a result, IANet+ref can generate paraphrase that is closer to the reference sentence, leading to higher performances in different evaluation metrics as shown in Table 2.

6.6.5 Controllable Paraphrase Generation

Since the identification of the primary and secondary content of the input are separated from the neural generator, we therefore have the flexibility to manually choose these content. In this way, we can more precisely control the generation process.

To examine the controllability of the proposed approach, we manually select the primary and secondary content of the sampled instance and use the IANet+$\mathcal{S}$ model to generate paraphrases accordingly. The results based on different selections are presented in Table 6. As demonstrated by the examples, our model is flexible to generate different paraphrases given different combinations of the primary and secondary content. We can observe in the generated paraphrases that the selected primary content is largely maintained while the secondary content is properly rephrased.

This controllable attribute could make our model useful for other tasks such as task-oriented dialogue generation. Suppose we want to generate more utterances with the same meaning of the user utterance "*book a great* restaurant *in* London *tonight*". The slot values can be fixed as the primary content and our model could produce more utterances with the same intent, e.g. "*make a reservation at the best* London restaurant *for this evening*". This remains to be rigorously tested in future work.

7 Conclusion

In this work, we propose a novel IA framework to tackle the paraphrase generation task. Additionally, we design a new neural paraphrase generator which works coherently under the proposed framework. We conduct extensive experiments on two benchmark datasets. The results of quantitative experiments and human evaluation demonstrate that our approach improves upon previous studies. The qualitative experiments show that the generation of the proposed model is interpretable and controllable. In the future, we would like to investigate a better inference algorithm to further bridge the gap between the IANet+$\mathcal{S}$ and IANet+ref models.

Acknowledgments

The authors wish to thank Jialu Xu, Deng Cai, and Sihui Wang for their insightful discussions and support. Many thanks to our anonymous reviewers for their suggestions and comments.

Ethical Statement

We honor and support the ACL Code of Ethics. Paraphrase generation aims at automatically generating paraphrased sentence given the source sentence. The generation process does not involve any bias towards the users. All datasets used in this work are from previously published works, and in our view, do not have any attached privacy or ethical issues.

Contrastive Fine-tuning Improves Robustness for Neural Rankers

Abstract

The performance of state-of-the-art neural rankers can deteriorate substantially when exposed to noisy inputs or applied to a new domain. In this paper, we present a novel method for fine-tuning neural rankers that can significantly improve their robustness to out-of-domain data and query perturbations. Specifically, a contrastive loss that compares data points in the representation space is combined with the standard ranking loss during fine-tuning. We use relevance labels to denote similar/dissimilar pairs, which allows the model to learn the underlying matching semantics across different query-document pairs and leads to improved robustness. In experiments with four passage ranking datasets, the proposed contrastive fine-tuning method obtains improvements on robustness to query reformulations, noise perturbations, and zero-shot transfer for both BERT and BART-based rankers. Additionally, our experiments show that contrastive fine-tuning outperforms data augmentation for robustifying neural rankers.

1 Introduction

Recent advances in neural language modeling have shifted the paradigm of natural language processing (NLP) towards a two-stage process: pre-training on a large amount of data with self-supervised tasks followed by fine-tuning on the target datasets with task-specific loss functions. Current state-of-the-art neural rankers for information retrieval fine-tune pre-trained language models using ranking losses on datasets containing examples of positive and negative query-document pairs. While usually achieving good performance on in-domain test sets, neural rankers trained on large datasets can still exhibit poor transferability when tested in new domains, and suffer from robustness problems when exposed to various types of perturbations. For example, a neural ranker trained on a dataset with mostly natural language queries can perform badly when tested on keyword queries which are very common in information retrieval (Bhatia et al., 2020).

A considerable number of previous works have focused on domain adaptation to improve model 's overall transferability. While domain adaptation approaches can help to address the out-of-domain robustness problem (Pan and Yang, 2010; Zhang et al., 2019; Ma et al., 2019), they rely on the availability of either labeled data or at least a target corpus which is usually not available at training time for a neural ranking model deployed in the wild.

The vulnerability of deep NLP models to various forms of adversarial attacks such as word-importance-based replacement (Jin et al., 2020), human-curated minimal perturbations (Khashabi et al., 2020), misspelling (Sun et al., 2020), grammatical errors (Yin et al., 2020), rule-based perturbations (Si et al., 2020; Ribeiro et al., 2018) is well-documented in the literature (Emma Zhang et al., 2019). While various methods have been proposed to remediate model robustness issues in NLP, most of them are either task-specific (Shah et al., 2019; Zhou et al., 2020; Gan and Ng, 2020; Wang and Bansal, 2018), requiring auxiliary tasks (Zhou et al.), or relying on data augmentation (Min et al., 2020; Kaushik et al., 2019; Cheng et al., 2020; Wei and Zou, 2019) which highly depends on the quality and diversity of the perturbed data.

An alternative strategy for optimizing machine learning models that has the potential to improve both out-of-domain generalization and robustness is contrastive learning. Representations obtained under contrastive self-supervised settings have demonstrated improved robustness to out-of-domain distributions and image corruptions in computer vision tasks (Hendrycks et al., 2019; Radford et al., 2021). In contrastive learning, representa-

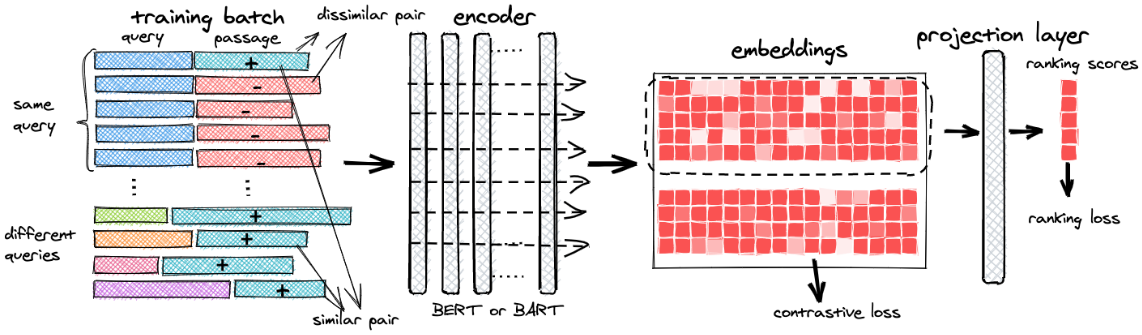

Figure 1: Contrastive fine-tuning for neural rankers. During fine-tuning, a batch of positive and negative samples from different queries is fed into a neural encoder. The embeddings of query-document pairs from the same query are used to generate ranking scores, which are employed to compute the ranking loss. In parallel, the embeddings of all pairs are used to compute the contrastive loss.

tions are learned by comparing among similar and dissimilar samples (Le-Khac et al., 2020; Khosla et al., 2020; Van Den Oord et al., 2018; Hjelm et al., 2018). This is different from discriminative learning, where models learn a mapping of input samples to labels, and generative learning, where models reconstruct input samples. While several works have investigated contrastive learning for sentence classification (Gunel et al., 2020), sentence representation learning (Wu et al., 2020), and multi-modal representation learning (Radford et al., 2021) under either self-supervised or supervised settings, their potential for improving the robustness of neural rankers has not been explored yet.

In this paper, we propose a novel contrastive learning approach to fine-tune neural rankers and investigate its benefits for improving model robustness. We focus on rankers that use single-tower architectures and are normally trained by optimizing a ranking loss that compares scores of positive and negative query-document pairs involving the same query. We propose to additionally use a contrastive loss that compares the distance between the representation of positive and negative pairs involving distinct queries (i.e, representations of positive pairs should be close in the latent space and distant to the representation of negative pairs, and vice-versa). The goal of using this contrastive loss in addition to the ranking loss is to stimulate the model to learn the underlying matching semantics across different query-document pairs, which can potentially lead to improved robustness.

Our main contributions are as follows:

- We propose to combine contrastive loss with ranking loss during fine-tuning of neural ranking models and investigate its impact in improving model robustness and generalization.
- Our experimental results using two language model-based neural rankers (BERT and BART) on four different datasets indicate that our proposed method improves upon standard ranking loss in zero-shot transfer across domains, leading to an increase of up to 9 absolute points in Mean Average Precision (MAP).
- We develop new datasets for evaluating the robustness of neural rankers. The datasets are based on WikiQA test set (Yang et al., 2015) and were created semi-automatically. We plan to release these datasets upon acceptance of the paper.
- We show that contrastive fine-tuned rankers are robust to 1) different types of query reformulations commonly seen in information retrieval (headline, paraphrase, and change of voice); and 2) query perturbations such as adding/removing punctuations, typos, and contractions/expansions.

2 Contrastive Representation Learning for Neural Ranking

In neural ranking models, given an input query q and a set of candidate documents $\{d_0, d_1, ..., d_n\}$, a neural network h is used to create vector representations $\{h(q, d_1), ..., h(q, d_n)\}$, which are given to a function $s : \overrightarrow{x} \rightarrow \mathbb{R}$, that computes a score for each query-document pair, $\{s(h(q, d_1)), ..., s(h(q, d_n))\}$. Normally s performs a simple linear projection of the input embedding, and the training of neural ranking models consists in optimizing a ranking loss that tries to enforce $s(h(q,d^+)) > s(h(q,d^-))$ for each training query q, where d^+ is a positive document for q while d^- is a negative one (See top part of Fig. 1).

We propose to augment the training of neural rankers with the use of contrastive representation learning. While ranking-based methods compute the loss with respect to the predicted scores, contrastive losses measure the distance/similarity between similar and dissimilar samples in the representation space. In our case, the key idea consists in using a loss that compares the distance between the representation of query-document pairs, and enforces that positive pairs are close together in the latent space while being far apart from negative pairs, i.e., $D(h(q,d^+), h(q',d'^+)) < D(h(q,d^+), h(q,d^-))$, where q' is either a variation of q or a completely different query, and d'^+ is a positive document for q'. Figure 1 illustrates our proposed approach, which is detailed in the remainder of this section.

2.1 Ranking Loss

Popular ranking losses include 1) the *pairwise ranking loss*, in which the relevance information is given in the form of preferences between pairs of candidates, and 2) the *listwise ranking loss* which directly optimizes a rank-based metric. In this work, we experiment with two pairwise ranking losses. The first one is the *standard hinge loss* (SHL) defined on a triplet (q, d^+, d^-) as follows:

$$\mathcal{L}_{SHL}(q,d^+,d^-;\theta) = \max\{0, \lambda - s(h(q,d^+);\theta) + s(h(q,d^-);\theta)\} \quad (1)$$

The other is a *modified hinge loss* (MHL) function defined as:

$$\mathcal{L}_{MHL}(q,d^+,\{d_i^-\};\theta) = \max\{0, \lambda - s(h(q,d^+);\theta) + \max_i\{s(h(q,d_i^-);\theta)\}\} \quad (2)$$

where q is a query, λ is the margin of the hinge loss, d^+ refer to the positive document. d^- and $\{d_i^-\}$ refer to a negative document and the list of negative documents of the query q within the same batch, respectively. θ includes the set of parameters of the network h and the projection layer in s. Based on preliminary experiments, our modified ranking hinge loss generally performs better than the standard pairwise ranking hinge loss. Note that MHL loss has been used in previous work on passage ranking (dos Santos et al., 2016).

2.2 Contrastive Loss

For contrastive learning of representations, we employ the conceptually simple but widely adopted *triplet margin loss* (**TML**) (Weinberger et al.; Chechik et al., 2010), which has the following form:

$$\mathcal{L}_{TML}(a,k^+,k^-;\theta) = \max\{0, m + D(a,k^+;\theta) - D(a,k^-;\theta)\} \quad (3)$$

where a is the anchor point, k^+ and k^- are the similar and dissimilar samples with respect to the anchor point a. m is the margin of the TML loss. In our neural ranking setting, an anchor point is the representation of a query-document pair. We use Euclidean or L2 distance D in our experiment. The contrastive loss can be applied to the representations from a variety of encoders $h(\cdot) \in R^d$. In this work, we explore contrastive fine-tuning for both BERT (Devlin et al., 2018) and BART (Lewis et al.) models.

The key to effective contrastive learning is to design the *notion of similarity* such that positive pairs may be very different in the input space yet semantically related. In this work, we leverage the relevance label in the training data and consider as similar positive pairs (q_i, d_i^+) and (q_j, d_j^+) from different queries i and j in the same batch (as illustrated in Fig. 1). Our intuition is that, by enforcing that positive pairs are close together in the embedding space and distant from negative pairs, we make the scoring task easier. Additionally, it allows the model to learn the underlying matching semantics across different query-document pairs, which leads to improved robustness. We additionally conduct a brief experiment in Sec. 5.4 where we use paraphrases of the original query to generate similar pairs.

2.3 Combined Loss

Our final loss is a weighted average of the ranking loss $\mathcal{L}_{ranking}$ and the contrastive loss $\mathcal{L}_{contrastive}$:

$$\mathcal{L} = w_1 \cdot \mathcal{L}_{ranking} + w_2 \cdot \mathcal{L}_{contrastive} \quad (4)$$

The weights w_1 and w_2 are hyper-parameters that need to be determined. Our main experiments use a simple but effective combination method which consists in given equal weights to the ranking loss and contrastive loss.

3 Related Work

Our work is related to the recent body of works that demonstrate contrastive and self-supervised approaches can improve model robustness and generalization. Hendrycks et al. (2019) have shown that self-supervision increases image classifier's robustness to adversarial examples, label corruption, and common input corruptions. Radford et al. (2021) have demonstrated that multi-modal contrastive learning can significantly improve the robustness of image classifiers to distribution shift.

In the NLP space, some recent works on sentence-level contrastive representation learning have shown its potential to improve robustness for classification (Gunel et al., 2020) and semantic text similarity tasks (Wu et al., 2020). There are two main distinctions between our work and these two papers: 1) they focus on classification and text similarity tasks, while we focus on ranking; and 2) while they rely on data augmentation approaches to define the notion of similarity, our approach mainly relies on document relevance information which is already present in the training data.

Our work is also related to recent work on neural retrieval that focus on hard negative mining to improve model performance (Gillick et al., 2019; Xiong et al., 2020; Karpukhin et al., 2020; Lu et al., 2020). The main differences between our work and this line of research are: 1) while we leverage relevance information across different queries to create a notion of similarity, the focus on those papers are on finding hard negatives for each individual query in order to improve training efficiency. Hard negative mining can actually be used together with our method, as we show in Sec. 6.2. 2) we focus in reranking models, which use single-tower model that create a single representation for a query-document pair. In contrast, neural retrieval models create separate representations for query and document.

4 Experimental Setup

In this section, we describe the details of our experimental setup.

4.1 Passage Ranking Datasets

We test our method on four publicly available passage ranking/answer selection datasets that vary in size and domain. Passage ranking is an important task in information retrieval. It is often used to retrieve relevant content for open-domain question-answering systems (Wang et al., 2020).

WikiQA (Yang et al., 2015) is a dataset of question and sentence pairs, collected and annotated for research on open-domain question answering. The questions are factoid and selected from Bing query logs. The answers are in the summary section of a linked Wikipedia page. The candidates are retrieved using Bing.

WikiPassageQA (Cohen et al., 2018) is a benchmark collection for the research on non-factoid answer passage retrieval. The queries are created from Amazon Mechanical Turk over the top 863 Wikipedia documents from the Open Wikipedia Ranking.

InsuranceQA (Feng et al., 2016) The question and answer pairs from this dataset are collected from the internet in the insurance domain. Each question has an answer pool of 500 candidates retrieved using SOLR.

YahooQA (Tay et al., 2017) contains questions and answers from Yahoo! Answers website. The dataset is a subset of the Yahoo! Answers corpus from a 10/25/2007 dump. The questions are selected for their linguistic properties. For example, they all start with how $\{to \mid do \mid did \mid does \mid can \mid would \mid could \mid should\}$.

The statistics of the datasets are presented in Table 1. All four datasets provide validation sets, which have size similar to the respective test sets.

Dataset	Domain	Train: #Q (#P/Q)	Test: #Q (#P/Q)
WikiQA	Wikipedia	873 (9)	243 (9)
WikipassageQA	Wikipedia	3,332 (58.3)	416 (57.6)
InsuranceQA	insurance	12,889 (500)	2,000 (500)
YahooQA	community	50,112 (5)	6,283 (5)

Table 1: Dataset statistics. #Q stands for *number of questions* and #P/Q is the *average number of passages per question*

4.2 Datasets for Robustness Assessment

In order to assess the robustness of our models to different types of query reformulations and query perturbations, we built robustness test datasets based on the original WikiQA test set.

We assessed query perturbations by leveraging CheckList (Ribeiro et al., 2020) to construct three types of popular perturbations: *adding/removing punctuation*, *introducing typos* and *changing of contraction form*. For each query in WikiQA test set, we produce three new versions of the query, one for each perturbation type.

We assessed robustness to three types of query reformulations: *paraphrase*, *headline* and *change of voice*. We semi-automatically created the datasets for query reformulations in two steps: (1) a pretrained T5-base model (Raffel et al., 2019) is fine-tuned on a combination of large public paraphrase datasets (Quora [1] and PAWS (Zhang et al., 2019)) and human-curated query reformulations. The human-curated reformulations are based on the queries from the SQuAD 1.1 official dev set [2]. For each query in SQuAD 1.1 dev set, the annotators are asked to generate three new versions of the query (one for each reformulation type). During fine-tuning and inference, we use control codes to instruct T5 on the type of reformulation to be generated. Note that this T5 model can be also used for the purpose of data augmentation, as shown in Sec. 5.4. (2) each query in WikiQA test set is processed by the fine-tuned T5 and three reformulations of the query are generated. All generated queries are post-processed in order to ensure it is grammatically correct and semantically equivalent to the original query. To ensure reliable evaluation, we did a round of human annotations to filter out low-quality generations. Examples of query reformulations are presented in Table 2.

We evaluate the lexical diversity of generated query reformulations by computing the BLEU scores between the original query and the reformulated query. The results of comparing four different generation methods are presented in Figure 2. Our T5 generated queries overall exhibit higher diversity than human generated and back translation generated paraphrases. Note that the lower the BLEU score the higher the diversity.

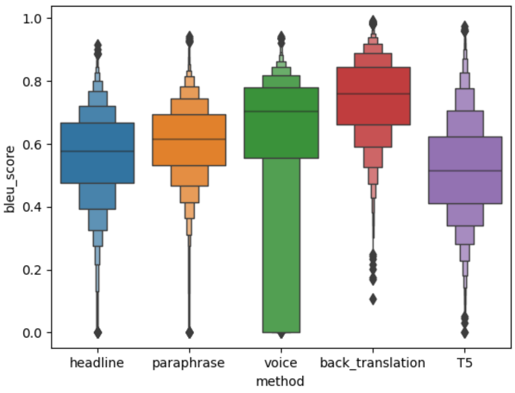

Figure 2: Comparison of BLEU scores between original query and reformulations generated by human annotation, back translation and fine-tuned T5 model.

4.3 Neural Ranker Training

We train neural rankers by fine-tuning two pretrained language models: BERT and BART. For fine-tuning BERT, we use BERT-base model (12 layers, 110M parameters) from Huggingface's transformer codebase (Wolf et al., 2019). Similar to the setup of sentence pair classification task in (Devlin et al., 2018), we concatenate the query sentence and the candidate passage together as a single input to the BERT encoder. We compute both the contrastive loss and ranking scores based on the [CLS] token embedding of the final hidden layer. For BART model fine-tuning, we use a BART-base model (6 layers encoder, 6 layer decoder, 139M parameters). We adopt the setting of BART for classification task in (**?**). The concatenation of query text and passage text is fed into both the encoder and decoder and the last layer's hidden state of the end decoder token is fed into a linear scorer. Similar to the [CLS] token in BERT, the embedding of the end token from the decoder is used as the representation of the complete input. For training with SHL, we sample triplets (q, d^+, d^-) from different queries to form a single batch. For MHL training, a single batch consists of a positive passage d^+ and a list of negative passages $\{d_i^-\}$ from the same query q. We leverage the toolkit developed by Musgrave et al. (2020) for contrastive loss calculation, and fine-tune the models for a maximum of 10 epochs and adopt early stopping using the validation sets of each dataset. The hyper-parameters for fine-tuning neural rankers are listed in Appendix A.

5 Results and Discussion

5.1 In-Domain Fine-tuning

The results of in-domain fine-tuning of BERT and BART-based neural rankers on four passage ranking datasets are presented in table 3. To ensure a fair comparison, all the hyper-parameters between the ranking and the contrastive settings are kept the same and equal weights between ranking loss and

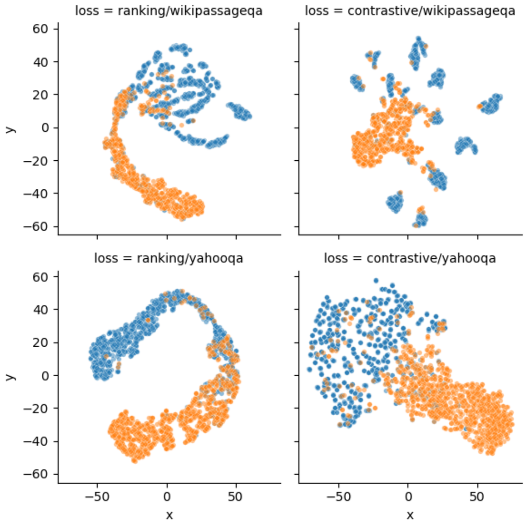

Figure 3: t-SNE plot of representations from BERT-based rankers trained with either ranking or combined ranking and contrastive loss for samples from WikiPassageQA (top) and YahooQA (bottom) test sets. Positive samples are represented by orange color.

contrastive loss are used. Our rankers produce state-of-the-art results when training with either of the two ranking-based losses **MHL** and **SHL**. Adding contrastive loss (**TML**) slightly improves the in-domain performance for BERT-based rankers, and performs similarly as ranking loss for BART-based rankers. Since our modified hinge loss (MHL) generally performs better than standard hinge loss (SHL), most of the results presented in the following sections are based on MHL, which corresponds to the setting illustrated in Figure 1.

To illustrate the effect of the contrastive loss on the representation space, we present the t-SNE plot of sample representations from the test set of two datasets WikiPassageQA and YahooQA in Figure 3. The color in the figures represents the positive and negative labels of query-passage pairs. As we can see from the plots, adding contrastive loss enables further separation of the positive samples from the negative samples.

5.2 Zero-Shot Transfer

The zero-shot transfer performance of neural rankers reflects their robustness to out-of-domain distributions, which is a key property of neural rankers since they are usually deployed in the wild. In Table 4, we show the results of applying the models trained in each one of the four datasets (source) and applied to the other three datasets (targets). Overall, we see significant improvements in the zero-shot transferability of the model across all datasets when the neural ranker is trained using the combination of ranking and contrastive losses. The biggest improvement is from YahooQA → WikiPassageQA where we observe absolute 9 points, 10.6 points, and 11.8 points improvement in MAP, MRR, and P@1, respectively. As expected, the transfer between datasets from similar domains tends to be better (e.g. WikiQA ↔ WikiPassageQA) than that between dissimilar domains. Our intuition regarding the benefit of contrastive learning of representations to improve zero-shot transfer consists on the fact that, by using information from different queries and enforcing that positive pairs are close together in the embedding space and distant from negative pairs, the model ends up learning representations that are more general and therefore easier to transfer to new domains.

5.3 Robustness to Query Perturbations

In this section, we evaluate the model robustness to various types of reformulations and noisy transformations of the input queries. The test sets used in the experiments are the 6 variations of the WikiQA test set described in Sec. 4.2. We compare the results of using ranking loss (MHL) and the combination of ranking and contrastive loss (MHL+TML). The robustness evaluation is are presented in Table 5. As shown in Table 5, adding contrastive loss improves model robustness against all types of perturbations we tested. We also conduct experiments by fine-tuning neural rankers on combined SHL loss and TML loss. The robustness evaluation of BERT-based rankers trained on SHL loss or combined SHL loss and TML loss are presented in Table 6. Similar to the MHL case, the combined loss achieves a significant improvement in robustness than SHL loss only. More results on model robustness can be found in Appendix B.

5.4 Comparison with Data Augmentation

One of the traditional approaches for improving the robustness of machine learning models is to augment the training data with noisy data. In this section, we compare our contrastive fine-tuning method with a data augmentation approach in which automatically generated query reformulations are added to the training data. For each query in the training set, we use our fine-tuned T5 model to generate 5 new queries of each reformulation type (headline, paraphrase, change of voice). Effec-

Table 7: Comparison with data argumentation.

tively, we increase the training set and the number of training steps by a factor of 5 for each reformulation type. Since our proposed training approach is general and can be used with any dataset, we also experiment with data augmentation combined with contrastive fine-tuning. When performing contrastive fine-tuning, we use the 5 reformulations of each query to create similar pairs (the notion of similarity == query formulation) in each batch, which essentially keeps the number of training steps the same as when training with the original dataset. The results on data augmentation for BERT-based neural rankers are presented in Table 7. For rows with MHL loss, we argument the training data with paraphrased queries and train the model on a combined dataset using MHL loss only. Note this is the standard way to do data argumentation training. For rows using MHL+TML loss, we pair each query in the batch with its paraphrased query for contrastive loss calculation. The model is trained on combined MHL+TML loss. For both methods, we expose the model with the same amount of paraphrased training samples. As we can see from the table, augmenting the training data with a similar type of query reformulation can improve the robustness of the model against that particular type of reformulation. However, it is not as effective in improving the robustness against other reformulation types. On the other hand, contrastive fine-tuning, even trained with a single type of query reformulation can generally improve the model robustness against the other two types. Furthermore, contrastive fine-tuning achieves this with significantly less (4× less) training time even after considering the additional computation of the contrastive loss calculation. Essentially, the experimental results indicate that using paraphrased training samples to perform contrastive learning is both effective (produces more robust rankers) as well as efficient (faster to train since augmented data is used in parallel, i.e. same batch as original data) than using regular data augmentation.

5.5 Comparison with Ranking Loss using same Batch Size

When training with MHL plus contrastive loss we effectively increase the batch size because we need to augment the training batch with additional positive samples from different queries. To check if the improvements achieved by our approach are due to the increase of training batch size only, we perform an ablation study where we compare the performance of models trained with a ranking loss but with the same batch size as the contrastive fine-tuning setting. The comparison results are presented in Table 8. As we can see in the table, for WikiQA datase, increasing the batch size helps the performance of in-domain and some of the robustness test sets. The contrastive setting still outperforms the ranking setting in all the test categories. Increasing the batch size of MHL is not always beneficial. We see big degradation on the WikiPassageQA dataset. On the other hand, we observed consistent improvement when the model is trained with contrastive loss.

6 Ablation Study

We present ablation experiments that check the impact of the number of positive samples per batch and the use of hard negative mining. Additionally, in Appendix C, we also present a preliminary experiment on formulating our combined loss (Equation 4) as a multi-objective optimization (MOO).

6.1 Effect of Number of Positive Samples Per Batch

The number of positive samples within a single batch determines the total number of potential triples constructed. In this section, we vary the number of positive samples within a batch and evaluate its effect on the model performance. The results are presented in Table 9. As expected, the model performance benefits by increasing the number of positives in a batch. As shown in Table 9, although not strictly monotonically, both the in-domain performance and zero-shot transfer performance improve with the number of positive pairs.

6.2 Effect of Hard Negative Mining

In a batch of N samples, there are $O(N^3)$ possible triplets, many of which are not very helpful to model convergence (e.g triplets where $D(a, k^+) >> D(a, k^-)$). It's important to construct only the most important triplets. Many works have discussed the benefit of hard negative mining techniques that produce useful gradients and help the models converge quickly. In this section, we explore the effect of three hard negative mining methods that are compatible with TML: Angular miner (Wang et al., 2017) (output triplets that form an angle greater than a threshold), BatchHard (Hermans et al., 2017) (produce a single triplet for each

anchor point consisting of the hardest positive and hardest negative samples), and TripletMargin (only output a triplet when the difference between the anchor-positive distance and the anchor-negative distance is smaller than a margin). The results of hard negative mining on models trained on WikiQA dataset are presented in Table 10, in which we evaluate both the in-domain and zero-shot performance of the rankers. As we can see from the results, hard negative mining can further improve the transferability of of both BERT-based ranker and BART-based ranker. In particular, BatchHard outperforms other mining methods and improve the overall performance significantly for BERT-based rankers while TripletMargin is more effective for BART-based rankers. We believe there is still a margin for improvement if the hyper-parameters of the miners are properly tuned.

7 Conclusion

In this paper, we propose a novel method for fine-tuning neural rankers by combining contrastive loss with ranking loss. Using a semi-automatic approach, we created 6 new versions of WikiQA test set to assess the robustness of our models to query reformulations and perturbations. Our experimental results show that the proposed method improves ranker's robustness to out-of-domain distributions, query reformulations, and perturbations. Comprehensive experiments and ablation studies were conducted to investigate the impact of some design choices as well as to confirm that the gains do not originate only from larger batch sizes. Contrastive fine-tuning with generated data is more effective than data augmentation. As future work, we plan to evaluate the performance of other state-of-the-art contrastive loss functions and novel methods of aggregating multiple losses.

A Details of Neural Ranker Fine-tuning

The fine-tuning of neural rankers is conducted on an AWS EC2 P3 machine. Important hyperparameters of fine-tuning for each model-dataset combination are listed in Table 11.

B More Results of Robustness Against Query Perturbations

In this section, we present more results of model robustness evaluation for neural rankers trained on InsuranceQA and YahooQA datasets. The results are shown in Table 12.

C Fine-tuning as Multi-objective Optimization

We performed a preliminary experiment on formulating equation 4 as a multi-objective optimization (MOO) problem in which optimizing both $\mathcal{L}_{ranking}$ and $\mathcal{L}_{contrastive}$ are two objectives of the task. We adopt a *dynamic weighted aggregation* (DWA) method (Jin et al., 2001, 2004) which is both effective and computationally efficient. In DWA, the weights of the two loss terms are changed gradually according to the following equations:

$$w_1(t) = |\sin 2\pi t/\ F| \tag{5}$$
$$w_2(t) = 1 - w_1(t) \tag{6}$$

where t is the iteration number. It is noticed that $w_1(t)$ changes from 0 to 1 periodically. The change frequency can be adjusted by F.

Figure 4 shows the evolution of the contrastive loss during fine-tuning of the BART-based ranker on the WikiQA dataset. As can be seen from the plot, adopting the MOO method improves the model convergence. A lower contrastive loss is achieved using dynamic weighting which translates to an average improvement of 0.7 points over the equal weighting setting in zero-shot transfer performance (see Table 13).

Cross-Lingual Transfer in Zero-Shot Cross-Language Entity Linking

Elliot Schumacher **James Mayfield** **Mark Dredze**
Johns Hopkins University
`eschumac@cs.jhu.edu` `mayfield@jhu.edu` `mdredze@cs.jhu.edu`

Abstract

Cross-language entity linking grounds mentions written in several languages to a monolingual knowledge base. We use a simple neural ranking architecture for this task that uses multilingual BERT representations of both the mention and the context as input, so as to explore the ability of a transformer model to perform well on this task. We find that the multilingual ability of BERT leads to good performance in monolingual and multilingual settings. Furthermore, we explore zero-shot language transfer and find surprisingly robust performance. We conduct several analyses to identify the sources of performance degradation in the zero-shot setting. Results indicate that while multilingual transformer models transfer well between languages, issues remain in disambiguating similar entities unseen in training.

1 Introduction

Entity linking grounds named entities mentioned in text, such as *Chancellor*, to a reference knowledge base (KB) or ontology entry, such as *Angela Merkel*. Historically, entity linking work focused on English documents and knowledge bases, but subsequent work expanded the task to consider multiple languages (McNamee et al., 2011). In cross-language entity linking, entities in a set of multilingual documents is linked to a KB in a single language. The TAC KBP shared task (Ji et al., 2015), for example, links mentions in Chinese and Spanish documents with an English KB. Success in building cross-language linking systems can be helpful in tasks such as discovering all documents relevant to an entity, regardless of language.

Successfully linking a mention across languages requires adapting several common entity linking components to the cross-language setting. Consider the example in Figure 1, which contains the Spanish mention *Oficina de la Presidencia*, a reference to the entity *President of Mexico* in an English KB. To link the mention to the relevant entity we must compare the mention text and its surrounding textual context in Spanish to the English entity name and entity description, as well as compare the mention and entity type. Previous work has focused on transliteration or translation approaches for name and context (McNamee et al., 2011; Pan et al., 2015), or leveraging large amounts of cross-language information (Tsai and Roth, 2016) and multilingual embeddings (Upadhyay et al., 2018).

Since this work emerged, there have been major advances in multilingual NLP (Wu and Dredze, 2019; Pires et al., 2019). Mainstream approaches to multilingual learning now use multilingual encoders, trained on raw text from multiple languages (Devlin et al., 2019). These models, such as multilingual BERT or XMLR (Conneau et al., 2019), have achieved impressive results on a range of multilingual NLP tasks, including part of speech tagging (Tsai et al., 2019), parsing (Wang et al., 2019; Kondratyuk and Straka, 2019), and semantic similarity (Lo and Simard, 2019; Reimers and Gurevych, 2019).

We propose to leverage text representations with multilingual BERT (Devlin et al., 2019) for cross-language entity linking to handle the mention text, entity name, mention context and entity description[1]. We use a neural ranking objective and a deep learning model to combine these representations, along with a one-hot embedding for the entity and mention type, to produce a cross-language linker. We use this ranking architecture to highlight the ability of mBERT to perform on this task without a more complex architecture. Although previous work tends to use multilingual encoders for one language at a time, *e.g.,* train a Spanish NER system

August 1–6, 2021. ©2021 Association for Computational Linguistics

with mBERT, we ask: can our model effectively link entities *across* languages? We find that, somewhat surprisingly, our approach does exceedingly well; scores are comparable to previously reported best results that are trained on data not available to our model (they have access to non-English names). Next, we consider a multilingual setting, in which a single system is simultaneously trained to link mentions in multiple languages to an English KB. Previous work (Upadhyay et al., 2018) has shown that multilingual models can perform robustly on cross-language entity linking. Again, we find that, surprisingly, a model trained on multiple languages at once does about as well, or in some cases better, than the same model trained separately on every language.

These encouraging results lead us to explore the challenging task of zero-shot training, in which we train a model to link single language documents (*e.g.,* English) to an English KB, but apply it to unseen languages (*e.g.,* Chinese) documents. While the resulting model certainly does worse on a language that is unobserved, the reduction in performance is remarkably small. This result leads us to ask: 1) Why do zero-shot entity linking models do so well? 2) What information is needed to allow zero-shot models to perform as well as multilingually trained models? Using a series of ablation experiments we find that correctly comparing the mention text and entity name is the most important component of an entity linking model. Therefore, we propose an auxiliary pre-training objective to improve zero-shot performance. However, we find that this text-focused approach does not improve performance significantly. Rather, we find that much of the remaining loss comes not from the language transfer, but from mismatches of entities mentioned across the datasets. This suggests that future work on the remaining challenges in zero-shot entity linking should focus on topic adaptation, instead of improvements in cross-lingual representations.

In summary, this paper uses a simple ranker to explore effective cross-language entity linking with multiple languages. We demonstrate its effectiveness at zero-shot linking, evaluate a pre-training objective to improve zero-shot transfer, and lay out guidelines to inform future research on zero-shot linking.

2 Cross-Language Entity Linking

A long line of work on entity linking has developed standard models to link textual mentions to entities in a KB (Dredze et al., 2010; Durrett and Klein, 2014; Gupta et al., 2017). The models in this area have served as the basis for developing multilingual and cross-language entity linking systems, and they inform our own model development. We define **multilingual** to mean a model that can operate on mentions from more than one language at the same time (link both English and Chinese mentions to an ontology) and **cross-language** to refer to linking mentions in one language (*e.g.,* Spanish) to an ontology in another (*e.g.,* English).

A common approach to cross-language entity linking is to use transliteration data to transform non-English mentions into English strings. Early transliteration work (McNamee et al., 2011) uses a transliteration corpus to train a support vector machine ranker, which uses common entity linking features such as name and context matching, co-occurring entities, and an indicator for NIL (no matching candidate.) Pan et al. (2017) uses transliteration data for a set of 282 languages to generate all possible combinations of mentions. A related approach is to use machine translation to translate a document into English, and then use an English entity linker. However, an MT system may not be available, and it further needs a specialized name module to properly translate entity names. Several systems from the TAC 2015 KBP Entity Discovery and Linking task (Ji et al., 2015) translate non-English documents into English, then use standard Entity Linking systems.

Cross-language Wikification is a closely related task, which uses links within Wikipedia, combined with equivalent pages in other languages to train an entity linker with Wikipedia as the KB. This approach typically uses English Wikipedia as the KB, though it could use a KB in other languages. Tsai and Roth (2016) use a two-step linking approach, first using an IR-based triage system (which we also use). Second, they use a candidate ranking step based on a linear ranking SVM model with several features, including contextual, document, and coreference.

The most closely related work to our own is that of Upadhyay et al. (2018), who use multilingual embeddings as the basis for their representations, and Wikipedia as training data. They use FastText (Bojanowski et al., 2017; Smith et al., 2017)

... el jefe de la **Oficina de la Presidencia** *(m.01p1k, ORG)*, Aurelio Nuño y ...

name	*President of Mexico* (m.01p1k)
desc.	*The President of the United ...*
type	government_office

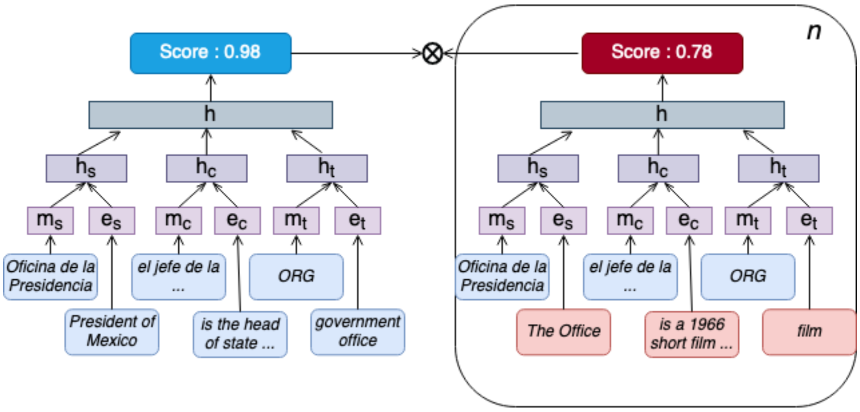

Figure 1: Example Spanish mention *Oficina de la Presidencia*, which is a link to entity *President of Mexico*, and the architecture for our neural ranker, using that example and a negatively-sampled entity *The Office*.

to align embeddings across languages, and a small dictionary to identify alignments. They pass these representations through a convolutional neural network to create a mention representation. They in turn use the other mention representations in the document to create a contextual representation, and also use a separate type vector. They train their network on hyperlinks from multiple languages in Wikipedia. Before the ranking step, they use a triage system similar to that of Tsai and Roth (2016). They evaluate on several entity linking datasets, including **TAC**. As their system only uses English Wikipedia as the KB, they set all mentions that link to a entity outside of Wikipedia to NIL; this results in a different evaluation setup than we need for our work. Their results show that training on all languages, instead of monolingual or bilingual training, generally performs best. For zero-shot entity linking, they train on English language Wikipedia. They find that their performance is heavily dependent on a prior probability derived from the triage system – otherwise, there is a large drop in performance.

Rijhwani et al. (2019) investigate zero-shot entity linking on low-resource languages. They propose a model consisting of a similarity model using encoders separately trained on high-resource language mentions, related to the low-resource language, and English entities. They then use the high-resource language as a pivot language for low resource language mentions, allowing them to score mentions in an unseen language. Raiman and Raiman (2018) consider multilingual entity linking, in which they use a KB in the same language as the mention, but exploit multilingual transfer for the model's type system. They formulate a type system as a mixed integer problem, which they use to learn a type system from knowledge graph relations.

3 Entity Linking Model

We propose a cross-language entity linker based on a pointwise neural ranker that scores a mention m and entity e pair, adapting from an architecture discussed in Dehghani et al. (2017). Unlike a classification architecture, a ranking architecture is able to score previously unseen entities. As is standard, we use a two stage system: triage followed by ranking; this reduces the number of entities that must be ranked, and results in better performance. Our system is shown in Figure 1. We select this architecture so as to focus on the ability of multilingual transformers to handle this task.

The ranker takes as input information about the mention and entity: 1) the mention string and entity name; 2) the context of the mention and entity description; and 3) the types of the mention and entity. We represent the mention string, entity name, mention context and entity description using a pre-trained multilingual deep transformer encoder (Devlin et al., 2019), while the mention and entity type are represented as one-hot embeddings. We describe the multilingual representation, model architecture and training procedure.

3.1 Multilingual Representations

We use multilingual BERT (mBERT) (Devlin et al., 2019)[2], which has been shown to create effective multilingual representations for downstream NLP tasks (Wu and Dredze, 2019). Consider the Spanish example in Figure 1. First, we create a represen-

tation of the mention text m_s, *Oficina de la Presidencia*, by creating an mBERT representation of the entire sentence, selecting the lowest layer representations of each of the mention's sub-words,[3] and form a single representation using max pooling. We create a representation of the entity name e_s, *President of Mexico* in the same way, although there is no surrounding context as in a sentence.

For the mention context m_c we select the surrounding sentences up to BERT's 512 sub-word limit, positioning the mention in the middle, and pass the text to BERT, using the resulting top layer of the `[CLS]` token. We create a similar representation for the entity context e_c from the definition or other text in the KB, using the first 512 subword tokens from that description. For the mention type m_t and entity type e_t we create one-hot embeddings, omitting ones that do not occur more than 100 times in the training set.

3.2 Architecture

We feed the representations of the name (m_s and e_s), context (m_c, e_c) and type (m_t, e_t) into a neural ranker. Each of these three pairs is passed into distinct multilayer perceptrons (MLPs), which each produce an embedding that captures the similarity between each type of information. For example, we input m_s and e_s into a text-specific hidden layer, which produces a combined representation r_s. The same is done for the context and type representations, producing representations r_c and r_t, respectively. These three representations are then fed into a final MLP, which produces a final score ($[-1, 1]$.) The entire network is jointly trained with the ADAM optimizer and a ranking objective. We apply dropout at every layer, use ReLu as the intermediate activation function, and Tanh for the final layer. While additional features such as entity salience are likely useful for this task, we chose to restrict our model as much as possible to use only text features. This focuses on mBERT's multilingual ability, and allows for easier adaptation to new KBs than with KB-specific features.

3.3 Model Training

We learn the parameters θ of our scoring function S using a pairwise approach; this allows us to train our model without annotated scores. Our ranker scores a mention m and positive entity e_+ pair, and separately scores the same mention paired with n sampled negative entities e_-. We apply the hinge loss between our correct entity and the highest scoring negative entity,

$$L(\theta) = \mathbf{max}\{0, \epsilon - (S(\{m, e_+\}; \theta) - \\ \mathbf{max}\{S(\{m, e_{0-}\}; \theta) \ldots S(\{m, c_{n-}\}; \theta)\}\}$$

We jointly train all components of the network, including the positive and negative portions of the network. The major benefit of this pairwise approach is that it does not rely on annotated scores, but instead uses negative sampling to train the ranker. We

---

[3] We experimented with several BERT layers and found this to be the best performing on the **TAC** development set.

tested random combinations of hidden layer sizes and dropout rates to find the best configuration (see Appendix A for parameter selection details).

4 Datasets

We conduct our evaluation on two cross-language entity linking datasets. We predict NILs by applying a threshold; mentions where all entities are below a given threshold are marked as NIL. We evaluate all models using the evaluation script provided by Ji et al. (2015), which reports Precision, Recall, F_1, and Micro-averaged precision. For implementation details, please see the appendix.

TAC. The 2015 TAC KBP Entity Linking dataset (Ji et al., 2015) consists of newswire and discussion form posts in English, Spanish, and Mandarin Chinese linked to an English KB. We use their evaluation set, and provide a comparison to the numbers noted in Ji et al. (2015). The referenced systems had access to non-English language KB text which we exclude, and thus are a goal rather than a baseline. Later papers, such as Upadhyay et al. (2018), also use this dataset but only for evaluation, instead training on Wikipedia and treating mentions that are linked to TAC entities without Wikipedia links as NIL. Therefore, we cannot compare our evaluation to this work.

Wiki. We created a cross-language entity linking dataset from Wikipedia links (Pan et al., 2017) that includes Korean, Farsi, Arabic, and Russian. A preprocessed version of Wikipedia has links in non-English Wikipedia pages to other non-English pages annotated with that link and an English page link if a corresponding page was available. From these annotations we created a dataset consisting of non-English mentions linked to English-language entities (Wikipedia page) using English Wikipedia as the KB. We consider this to be silver-standard data because–unlike the **TAC** dataset–the annotations have not been reviewed by annotators. Since we do not have a separate development set for this dataset, we apply the hyperparameters selected on **TAC** development data to this dataset.

Triage. We assume gold-standard mention boundaries in our analysis. We use the triage system of Upadhyay et al. (2018), which is largely based on work in Tsai and Roth (2016). This allows us to score a smaller set of entities for each mention as opposed to the entire KB. For a give mention m, a triage system will provide a set of k candidate entities $e_1 \ldots e_k$. The system uses Wikipedia cross-links to generate a prior probability $\mathtt{P}_{\mathtt{prior}}(e_i|m)$ by estimating counts from those mentions. This prior is used to provide the top k English Wikipedia page titles for each mention ($k = 10$ for **TAC** and $k = 100$ for **Wiki**).

5 Model Evaluation

We consider several different training and evaluation settings to explore the multilingual ability of transformers on this task. Recent studies suggest that multilingual models can achieve similar or even better performance on cross-language entity linking (Upadhyay et al., 2018). Other work (Mueller et al., 2020) has shown that this is not always the case. Therefore, we begin by asking: does our linker do better when trained on all languages (multilingual cross-language) or trained separately on each individual language (monolingual cross-language)?

We train our model on each of the 7 individual languages in the two datasets (noted as **Mono**). Next, we train a single model for each dataset (3 languages in **TAC**, 4 in **Wiki**, each noted as **Multi**). **Mono** and **Multi** share the exact same architecture - there are no multilingual adjustments made, and the model contains no language-specific features. As **Multi** uses data available in all languages and thus has more training data than **Mono**, we include a model that is trained on a randomly-sampled subset of the multilingual training data that set to match the training size of **Mono** (**MultiDS**) . For **TAC Multi** models, we also report results using a candidate oracle instead of triage (**Multi+Or**), where the correct entity is always added to the candidate list. For all **Mono** and **Multi**-based models we report the average of three runs. The metric-specific standard deviations were all small, with all but one at or below 0.017. We note the best performing architecture from (Ji et al., 2015) as **Tri**, again noting that those systems have access to non-English text. We also evaluate a simple nearest neighbor model (noted as **NN**). This model scores each mention-entity pair using the cosine similarity between the mention name representation m_s and the entity representation e_s, and selects the highest-scoring pair.

Table 1 shows that for **TAC** there is a small difference between the **Mono** and **Multi** models. For **Wiki** the difference is often larger. **Multi** often does better than **Mono**, suggesting that additional training data is helpful specifically for languages (*e.g.,* Farsi) with smaller amounts of data. Table 4: Change in performance for monolingually-trained models using monolingually-trained BERT models, compared to monolingually-trained models using mBERT.

all, these results are encouraging as they suggest that a single trained model for our system can be used for cross-language linking for multiple languages. This can reduce the complexity associated with developing, deploying and maintaining multiple models in a multilingual environment. For some models, the **Multi** improvement may be due to additional data available, as shown in the difference in performance between **Multi** and **MultiDS** (*e.g.,* Spanish F_1 **Multi** is +.026 over **MultiDS**). However, the small difference in performance shows that even by providing additional out-of-language training data, reasonable performance can be achieved even with reduced in-language training.

6 Zero-shot Language Transfer

Encouraged by the results on multilingual training, we explore performance in a zero-shot setting. How does a model trained on a single language perform when applied to an unseen language? We consider all pairs of languages, *i.e.,* train on each language and evaluate on all others in the same dataset[4].

Table 2 shows the change in F_1 for monolingually-trained models compared to multilingual models. While zero-shot performance does worse than a model with access to within-language training data, the degradation is surprisingly small: often less than 0.1 F_1. For example, a model trained on all 3 **TAC** languages achieves an F_1 of 0.79 on Chinese, but if only trained on English, achieves an F_1 of 0.76. This pattern is consistent across both models trained on related languages (Arabic → Farsi, loss of 0.08 F_1), and on unrelated languages (Russian → Korean, loss of 0.13 F_1).

Analysis. Why does zero-shot language transfer do so well for cross-language entity linking? What challenges remain to eliminate the degradation in performance from zero-shot transfer?

We answer these questions by exploring the importance of each component of our cross-language ranking system: mention string, context, and type. We conduct ablation experiments investigating the performance loss from removing these information sources. We then evaluate each model in an English-trained zero-shot setting. First, we train a zero shot model using only the mention text and entity name. We then compare the performance change that results from adding the context, the type, and both context and type (all features).

Table 3 shows that comparing the name and men-

---

[4] Work in Cross-language entity linking (Upadhyay et al., 2018; Tsai and Roth, 2016) has done similar evaluations, but focus on using external large data sources (Wikipedia) to train their models.

tion text alone accounts for most of the model's performance, a sensible result given that most of the task involves matching entity names. We find that context accounts for most of the remaining performance, with type information having a marginal effect. This highlights the importance of the multilingual encoder, since both name and context rely on effective multilingual representations.

Separately, how does using a multilingual transformer model, such as mBERT, affect the performance of our ranker? First, it is possible that using a monolingual linker with a BERT model trained only on the target language would improve performance, since such a model does not need to represent several languages as the same time. As shown in Table 4, model performance for these settings is largely worse for English-only and Arabic-only (Safaya et al., 2020) models when compared to using mBERT, with the exception that precision increases significantly for English. Second, perhaps a monolingual linker with a BERT model trained only on a related language – *e.g.,* English BERT for Spanish, Arabic BERT for Farsi – would produce acceptable results. Again, as shown in Table 4, the performance is most often worse, illustrating that mBERT is an important aspect of the linker's performance.

7 Improving Zero-shot Transfer

7.1 Name Matching Objective

Given the importance of matching the mention string with the entity name, will improving this component enhance zero-shot transfer? While obtaining within-language entity linking data isn't possible in a zero-shot setting, we can use pairs of translated names, which are often more easily available (Irvine et al., 2010; Peng et al., 2015). Since Chinese performance suffers the most zero-shot performance reduction when compared to the multilingual setting, we use Chinese English name pair data (Huang, 2005) to support an auxiliary training objective. An example name pair: "巴尔的摩－俄亥俄铁路公司" and *Baltimore & Ohio Railroad.*

We augment model training as follows. For each update in a mini-batch, we first calculate the loss of the subset of the model that scores the mention string and entity name on a randomly selected pair $k = 25,000$ of the Chinese/English name pair corpus. We score the Chinese name z and the correctly matched English name e_+ pair, and separately score the same Chinese name paired with n negatively sampled English names e_-. We create representations for both z and e using the method described for names in §3.1 which are passed to the name-only hidden layer. We add a matching-specific hidden layer, which produces a score. We apply the hinge loss between positive and negative examples,

$$N(\theta) = \mathbf{max}\{0, \epsilon - (S(\{z, e_+\}; \theta) - \mathbf{max}\{S(\{z, e_{0-}\}; \theta) \ldots S(\{z, e_{n-}\}; \theta)\}\}$$

The name pair loss is then multiplied by a scalar $\lambda = 0.5$ and added to the loss described in §3.3. The resulting loss $L_{joint}(\theta) = (\lambda * N(\theta)) + L(\theta)$ is jointly minimized. After training, we discard the layer used to produce a score for name matches. This procedure still only uses source language entity linking training data, but makes use of auxiliary resources to improve the name matching component, the most important aspect of the model.

We analyze the resulting performance by considering modifications to our English-only training setting, which are designed to replicate scenarios where there is little training data available. To show the effect of a smaller training corpus, we select a random 50% of mentions, partitioned by document (**Rand**). To show the importance of training on frequently occurring entities, we select 50% of mentions that are linked to the least frequent entities in the English dataset (**Tail**).

Table 5 shows the results on each of the three development **TAC** languages compared to the **Multi** model. For the **Rand** training set, we see a large improvement in Chinese micro-average and a small one in F_1, but otherwise see small reductions in performance. In the **Tail** training setting, a similar pattern occurs, with the exception that Chinese is less improved than in **Rand**. Overall, performance loss remains from zero-shot transfer which suggests that improvements need to be explored beyond just name matching.

7.2 Entities

Another possible source of zero-shot degradation is the lack of information on specific entities mentioned in the target language. For entity linking, knowledge of the distribution over the ontology can be very helpful in making linking decisions. While zero-shot models have access to general domain text, *i.e.,* news, they often lack text discussing the same entities. For example, some entities that only occur in Chinese (231 unique entities in **Dev**),

en		zh		es				en		zh		es	
avg	F_1	avg	F_1	avg	F_1			avg	F_1	avg	F_1	avg	F_1

N-1	+.01	+.02	−.04	−.02	−.08	−.03
N-1U	−.24	-.14	−.49	−.22	−.38	−.19
Tail	−.16	-.08	−.31	−.15	−.26	−.12

Table 6: For each of the English-only training data subsets described in §7.2, ΔMicro-average and ΔF_1 compared to the full **Multi** model. Models that see even a single example of an entity (*e.g.,* **N-1**) outperform models that see a portion (*e.g.,* **Tail**) or none (*e.g.,* **N-1U**).

such as the frequently occurring entity *Hong Kong*, have a number of similar entities and thus are more challenging to disambiguate.

We measure this effect through several diagnostic experiments where we evaluate on the development set for all languages, but train on a reduced amount of English training data in the following ways: In addition to the **Rand** and **Tail** settings, we sample a single example mention for each entity (**N-1**), resulting in a much smaller training as compared to those datasets. We also take **N-1** and remove all evaluation set entities (**N-1U**), leaving all evaluation entities unseen at train time.

Table 6 reports results on these reduced training sets. All languages use a -1 NIL threshold. Compared to the multilingual baseline (**Multi**) trained on all languages, there is a decrease in performance in all settings. Several patterns emerge. First, the models trained on a subset of the English training data containing more example entities - *e.g.,* **N-1** - have much higher performance than the models that do not. This is true even in non-English languages. Unobserved entities do poorly at test time, suggesting that observing entities in the training data is important.

However, a mention training example can improve the performance of a mention in another language if linked to the same entity, which suggests that this provides the model with data-specific entity information. Therefore, the remaining zero-shot performance degradation can be largely attributed not to a change in language, but to a change in topic, *i.e.,* what entities are commonly linked to in the data. This may also explain why although the name matching component is so important in zero-shot transfer, our auxiliary training objective was unable to fully mitigate the problem. The model may be overfitting to observed entities, forcing the name component to memorize specific names of popular entities seen in the training data. This means we are faced with a topic adaptation rather than a language adaptation problem.

We validate this hypothesis by experimenting with information about entity popularity. Will including information about which entities are popular improve zero-shot transfer? We answer this question by re-ranking the entity linker's top ten predicted entities using popularity information, selecting the most most popular entity from the list. Adding this feature into the model and re-training did not lead to a significant performance gain. We define the popularity of an entity to be the number of times it occurred in the training data. We report results for two popularity measures–one using the popularity of the English subset of the data used for training, and one using all of the training data (including for Spanish and Chinese).

Table 5 shows that both strategies improve F_1, meaning that a missing component of zero-shot transfer is information about which entities are favored in a specific dataset. The gain from using popularity estimated from the training data only is smaller than using the popularity data drawn from all of **TAC**. With more accurate popularity information, we can better mitigate loss.

Several patterns emerge from most common corrections made with the Population reranking for **Tail**, included in Table 8. Many errors arise from selecting related entities that are closely related to the correct entity – for example, *United States Congress* instead of the *United States of America*. Additionally, people with similar names are often confused (e.g. *Edmund Hillary* instead of *Hillary Clinton*). Finally, many appear to be annotation decisions – often both the original prediction (e.g. *Islamic State*) and the corrected popular prediction (e.g. *Islamic State of Iraq and Syria*) appear reasonable choices. While most corrections were in Chinese (632), some occurred in both English (419) and Spanish (187). These errors – especially those in English – illustrate that much of the remaining error is in failing to adapt to unseen entities.

8 Conclusion

We demonstrate that a basic neural ranking architecture for cross-language entity linking can leverage the power of multilingual transformer representations to perform well on cross-lingual entity linking. Further, this enables a multilingual entity linker to achieve good performance, eliminating the need for language-specific models. Additionally, we find that this model does surprisingly well at zero-shot language transfer. We find that the zero-shot transfer loss can be partly mitigated by an auxiliary training objective to improve the name matching components. However, we find that the remaining error is *not* due to language transfer, but to topic transfer. Future work that improves zero-shot transfer should focus on better ways to adapt to entity popularity in target datasets, instead of relying on further improvements in multilingual representations. Focusing on adapting to the topic and entities present in a given document is critical. This could be accomplished by adding a document-level representation or by leveraging other mentions in the document. English-focused work on rare entity performance (Orr et al., 2020; Jin et al., 2014) may provide additional direction.

Table 6: To select parameters for the ranker, we tried 10 random combinations of the above parameters, and selected the configuration that performed best on the TAC development set. The selected parameter is in bold. We report results after training for 500 epochs for TAC and 800 for Wiki. The full TAC multilingual model takes approximately 1 day to train on a single NVIDIA GeForce Titan RTX GPU, including candidate generation, representation caching, and prediction on the full evaluation dataset.

B Dataset Details

The NIL threshold is selected based on the development**TAC** dataset. Unless noted, we use -0.8 for English and -1 otherwise.

TAC: The training set consists of 30,834 mentions (6,857 NIL) across 447 documents. We reserved a randomly selected 20% of these documents as our development set, and will release development splits. The evaluation set consists of 32,459 mentions (8,756 NIL) across 502 documents. A mention is linked to NIL if there is no relevant entity in the KB, and the KB is derived from a version of BaseKB.

TAC Triage: We use the system discussed in for both the **TAC** and **Wiki** datasets. However, while the triage system provides candidates in the same KB as the **Wiki** data, not all entities in the **TAC** KB have Wikipedia page titles. Therefore, the **TAC** triage step requires an intermediate step - using the Wikipedia titles generated by triage ($k = 10$), we query a Lucene database of BaseKB for relevant entities. For each title, we query BaseKB proportional to the prior provided by the triage system, meaning that we retrieve more BaseKB entities for titles that have a higher triage score, resulting in $l = 200$ entities. First, entities with Wikipedia titles are queried, followed by the entity name itself. If none are found, we query the mention string - this provides a small increase in triage recall. This necessary intermediate step results in a lower recall rate for the **TAC** dataset (85.1% for the evaluation set) than the **Wiki** dataset, which was 96.3% for the evaluation set .

Wiki: Some BaseKB entities used in the **TAC** dataset have Wikipedia links provided; we used those links as seed entities for retrieving mentions, retrieving mentions in proportion to their presence in the **TAC** dataset, and to sample a roughly equivalent number of non-TAC entities. We mark 20% of the remaining mentions as NIL. In total, we train and evaluate on 5,923 and 1,859 Arabic, 3,927 and 1,033 Farsi, 5,978 and 1,694 Korean, and 5,337 and 1,337 Russian mentions, respectively.

Abstract

Answering questions about why characters perform certain actions is central to understanding and reasoning about narratives. Despite recent progress in QA, it is not clear if existing models have the ability to answer "why" questions that may require commonsense knowledge external to the input narrative. In this work, we introduce **TellMeWhy**, a new crowd-sourced dataset that consists of more than 30k questions and free-form answers concerning why characters in short narratives perform the actions described. For a third of this dataset, the answers are not present within the narrative. Given the limitations of automated evaluation for this task, we also present a systematized human evaluation interface for this dataset. Our evaluation of state-of-the-art models show that they are far below human performance on answering such questions. They are especially worse on questions whose answers are external to the narrative, thus providing a challenge for future QA and narrative understanding research.

1 Introduction

The actions people perform are steps of plans to achieve their desired goals. When interpreting language, humans naturally understand the reasons behind described actions, even when the reasons are left unstated (Schank and Abelson, 1975). For NLP systems, answering questions about *why* people perform actions in a narrative can test this ability. Answering such questions often requires filling the implicit gaps in the story itself.

Consider this narrative from ROCStories (Mostafazadeh et al., 2016b):

> Rudy was convinced that bottled waters all tasted the same. He went to the store and bought several popular brands. He went back home and set them all on a table. He spent several hours tasting them one by one. He came to the conclusion that they actually did taste different.

Now try to answer the question, *"Why did he go to the store and buy several popular brands?"* The answer *"he wanted to taste test"* is not explicit in the narrative and requires us to read between the lines to fill in the gaps (Norvig, 1987). While humans can visualise and process the events in a story to hypothesize why they might have occurred (Kintsch and Dijk, 1978), current NLP systems fall well short of exhibiting similar capabilities. They are unable to adequately formulate the reasons behind actions in specific contexts.

How can we get NLP models to reason about why actions are performed? One way is to consider theories like script learning (Schank and Abelson, 1975; Pichotta and Mooney, 2014) or learning from co-occurrence (Chambers and Jurafsky, 2009). But they only partially capture this type of knowledge – much like other forms of commonsense knowledge, the reasons for why actions are performed are often left implicit in text. Even though there are many large scale QA datasets, they rarely contain questions about *why* people perform actions.

Therefore, we introduce the TellMeWhy dataset, a collection of 30,519 such why-questions, each with 3 "gold standard" human answers. Each record in TellMeWhy contains a short story, an associated question, and its 3 possible answers.

Further, we focus on enabling *human* evaluation of this dataset; human evaluation is more reliable than automatic metrics to evaluate such systems (Celikyilmaz et al., 2020; Gatt and Krahmer, 2018). However, reliability of human judgment is substantially impacted by experimental setup (Novikova et al., 2018; Santhanam and Shaikh, 2019). There is little consensus on how human evaluations should be conducted, so results are often incomparable across evaluations.

To this end, we present a systematized evaluation framework on MTurk for the TellMeWhy text generation task – and release the framework for future

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 596–610
August 1–6, 2021. ©2021 Association for Computational Linguistics

researchers. The MTurk interface asks annotators to rate generated answers on their grammaticality and validity. We show that with our interface human answers are judged to be of high quality (99% grammatical, 96% valid) with strong inter-annotator agreement at 0.88 Fleiss Kappa. This indicates high agreement and also confirms the design of our interface.

Finally, we present baseline results for TellMeWhy and compare against our human ceiling. We finetune two large language models that have proven to be effective for a variety of tasks, GPT-2 (Radford et al., 2019) and T5 (Raffel et al., 2020), and a dedicated question answering model, UnifiedQA (Khashabi et al., 2020), to perform this task. Human evaluation is performed on their outputs from independent test data. All models significantly under-perform the human benchmark and are especially worse on questions where the answer cannot be simply copied over from text in the narrative. The results clearly demonstrate the difficulty for current models to convincingly answer such why-questions.

This paper's contributions are as follows: (1) we introduce TellMeWhy, a large dataset of English why-questions for narratives derived from ROCStories (Mostafazadeh et al., 2016a) and CATERS (Mostafazadeh et al., 2016b) along with answers from 3 distinct humans, (2) a systematized human evaluation interface to calibrate model outputs consistently, and (3) show that current models are ill-equipped to perform this task. We release the dataset and human evaluation suite at `http://lunr.cs.stonybrook.edu/tellmewhy`.

2 Related Work

2.1 Datasets containing why-questions

Most of the datasets related to why-questions fall into one or more of the following categories: (1) very small size, (2) not focused on stories, or (3) focused on connecting known events instead of answering reasoning questions.

Some corpora of why-questions have been collected manually: corpora described in Verberne et al. (2006) and Verberne et al. (2007) both comprise fewer than 400 questions and corresponding answers (one or two per question) formulated by native speakers. Dunietz et al. (2020) demonstrate that it is important to define what we want models to comprehend when building datasets for machine reading comprehension (MRC) tasks. They design templates of understanding corresponding to the four elements identified by Zwaan et al. (1995). For 201 questions, they design multiple-choice questions derived from (Lai et al., 2017) to test understanding of different categories of events. All of these are very small corpora that cannot be viably used to further a model's understanding of why-questions in stories.

Higashinaka and Isozaki (2008) extend an existing factoid QA system to answer why-questions by integrating corpus based features, calling it NAZEQA. Oh et al. (2012) extract a set of answer candidates from a web corpus, and perform re-ranking using SVMs to predict the right answer. Oh et al. (2019) use an adversarial learning framework to generate a vector representation from the passage to judge whether the passage actually answers the why-question. These papers focus on Japanese news (Fukumoto et al., 2007; Oh et al., 2012), including NTCIR-6, and most critically, all these datasets are very small.

Some prior work focuses on knowledge extraction, not the *reasons* behind the actions. Mrozinski et al. (2008) built a corpus of why-questions related to Wikipedia articles. These were general knowledge questions with solicited answers from paid workers. Dependency parsing can be used to rephrase why-questions into statements with a 'because' prompt to elicit explanations from models (Nie et al., 2019). PhotoshopQuiA (Dulceanu et al., 2018) contains questions and answers specifically about Photoshop.

NarrativeQA (Kočiský et al., 2018) provides a dataset of 1,567 stories (books and movie scripts) containing 46,765 wh-questions written and answered by human annotators. Unfortunately, only 9.78% are why-questions, which makes for a small collection. QuAIL (Rogers et al., 2020) has a small subset of multiple choice questions pertaining to causality in user stories. These datasets are targeted at broad abilities of reading comprehension, not specifically about explaining actions in stories.

Some recent datasets causally connect events in text, but they do not target answering why-questions. ATOMIC (Sap et al., 2019) consists of entries that describe a likely cause/effect of events. Most notably, ATOMIC is *non-contextual* so it is more about general knowledge, not interpreting a specific story/context. Perhaps most relevant is GLUCOSE (Mostafazadeh et al., 2020), a crowdsourced dataset of implicit commonsense

Dataset	Size	Domain
NTCIR-6	200	Japanese news
Mrozinski et al. (2008)	695	Wikipedia
PhotoshopQuiA	2,854	Product focused
NarrativeQA	4,573	Books+Movie scripts
Dunietz et al. (2020)	201	Exam questions

Table 1: Previous why-question corpora. NarrativeQA has 46,765 questions of which 4,573 are why-questions.

knowledge in the form of causal mini-theories grounded in narrative context. These theories are semi-structured inference rules. This dataset is not aimed at answering why-questions, but at creating direct relationships between events already mentioned in the story. They focus on capturing specific cause-enable type relations. Annotators were given a very constrained task – they had to select options from a drop down menu describing inference rules.

Abductive commonsense reasoning tests whether models can come up with a plausible explanation to connect a set of events. Bhagavatula et al. (2020) present ART with two abductive tasks: 1) given two observations, select one out of two plausible hypotheses, 2) and generate text connecting two events. This line of work focuses on connecting the dots between two events and does not address explaining *why* an action was performed. Our work crucially differs from these because the answer is often not in the story at all. StrategyQA (Geva et al., 2021) is a new dataset focusing on performing better implicit reasoning for multi-hop question answering tasks.

We summarize the different why-questions corpora in Table 1. None of them represent a large dataset focused on answering why-questions about actions in a narrative.

2.2 Human evaluation for NLG tasks

Among language generation tasks, machine translation has received the most attention in terms of human evaluation. Qualified crowd workers score output translations given the source or reference text to calibrate MT systems (Sakaguchi and Van Durme, 2018; Graham et al., 2013, 2014). WMT conducts annual evaluation of outputs of systems submitted to the shared task and uses it as one of the primary metrics (along with BLEU) to rank systems (Bojar et al., 2016, 2017, 2018; Barrault et al., 2019, 2020).

ChatEval (Sedoc et al., 2019) is an evaluation platform for chatbots. Zellers et al. (2020) present a leaderboard for their advice generation task. These platforms incorporate some manual analysis, but focus on very different tasks. None of their Mechanical Turk interfaces can be used for our task. We were unable to find a consistent interface for human evaluation of an open-ended question answering task. To address this flaw, we propose a standard human intelligence task (HIT) evaluation scheme for our dataset.

3 Dataset Creation

We want to test the abilities of models to understand the reasoning behind actions in a story. Therefore, we create a dataset of *why* questions that ask for explanations for actions performed in a story. Answering these questions requires an understanding of the events that are explicit in the story as well as access to implicit common-sense knowledge on how people use actions as parts of plans to achieve goals. To cover a wide-range of common situations, we utilize ROCStories (Mostafazadeh et al., 2016a), a collection of 45,496 five-sentence commonsense stories. We also develop a small "hidden" test set that was only used for the final evaluation using the CATERS (Mostafazadeh et al., 2016b) subset of ROCStories.

3.1 Why-Question Generation

Our strategy for creating *why* questions is simple. For each action in the narrative, we formulate a why question by applying simple template-based transformations. We dependency parse each sentence using SpaCy's en_core_web_sm model (Honnibal et al., 2020). We use the generated parse tree to rephrase the sentence into a question about the action described. The generated parse tree is used to extract the subject, object, and verb. We consider 3 types of sentences and design question templates accordingly: (1) sentences that have a primary and auxiliary verb, (2) sentences that only have a primary verb, and (3) sentences that only contain an auxiliary verb. For the first, the question template is: "Why {aux_verb} {subject} {verb} {object}?", for the second: "Why did {subject} {verb_lemma} {obj}?", and for the third; "Why {aux_verb} {subject} {obj}?".

This procedure yielded a little over 113k questions from ROCStories, and 489 questions from the CATERS portion. We selected at random 32,165 questions from stories that had at least three ques-

Split	# stories	# questions
Train	7558	23964
Dev	944	2992
Test	944	3099
Hidden Test	190	464
Total	9,636	30,519

Table 2: Dataset Statistics

tions[1]. We ensure that there is no overlap between the two subsets.

3.2 Collecting Answers

We crowd-sourced answers to these questions using Amazon Mechanical Turk. Figure 1a shows the interface used to collect these answers. Annotators were presented a narrative and asked to answer three *why* questions in free-form. For each question, they were also asked to provide judgments about the comprehensibility of the question, and whether the narrative explicitly contained the answer. They also selected the sentences from the narrative which influenced their answer (if any). To avoid variability in answer prefixes, we provide a prompt to start answering the question. We rephrase the sentence from which the question was generated to create these prompts. We consider the same categorisation of sentences described in subsection 3.1. For sentences that have both primary and auxiliary verbs, the answer prompt is of the form: “{subject} {aux_verb} {verb} {object} because...". When it only contains a primary verb, it is of the form: “{subject} {verb} {object} because...". If it only contains an auxiliary verb, it is of the form: “{subject} {aux_verb} {object} because...". We found, over several iterations of this HIT, that providing a prompt gave workers an initial direction and improved the quality of answers collected.

We ask three distinct annotators (three-way redundant task) to answer each of these questions. Annotators are not allowed to copy pieces of text to make up an answer. We discard questions that were deemed incomprehensible by any annotator.[2] With this process, we obtained 3 answers each from 30,055 questions from 9,636 stories (see Appendix B for more details). Table 2 shows basic statistics of the dataset. We refer to annotations from the CATERS data as the hidden test set. Examples of records in the dataset are presented in Table 3. The narrative does not explicitly contain an answer for the second question. We call these types the implicit-answer questions; they require extra common-sense inference to produce a plausible answer. Questions are categorised as implicit-answer if at least 2 out of 3 human annotators indicate that the answer cannot be explicitly found in the narrative. The annotators indicated as much and, based on their commonsense knowledge, provided plausible answers.

Story: Sandra got a job at the zoo. She loved coming to work and seeing all of the animals. Sandra went to look at the polar bears during her lunch break. She watched them eat fish and jump in and out of the water. She took pictures and shared them with her friends.
Question: Why did Sandra go to look at the polar bears during her lunch break?
Ans: she wanted to take some pictures of them.

Story: Cam ordered a pizza and took it home. He opened the box to take out a slice. Cam discovered that the store did not cut the pizza for him. He looked for his pizza cutter but did not find it. He had to use his chef knife to cut a slice.
Question: Why did Cam order a pizza?
Ans: Cam was hungry.

Table 3: TellMeWhy examples. The first is answerable directly from text in the story, but the second requires external knowledge. We only show one out of three available answers here.

3.3 Validating Answers

To ensure an even higher-quality test set, we conducted another round of crowdsourcing to validate the answers by the first set of crowd-workers on the CATERS portion (464 questions). This validation interface is show in Figure 1b. It also serves as the base design for our systematized human evaluation. Annotators are presented a story, a related question, and the three answers that were collected as described in Section 3.2.

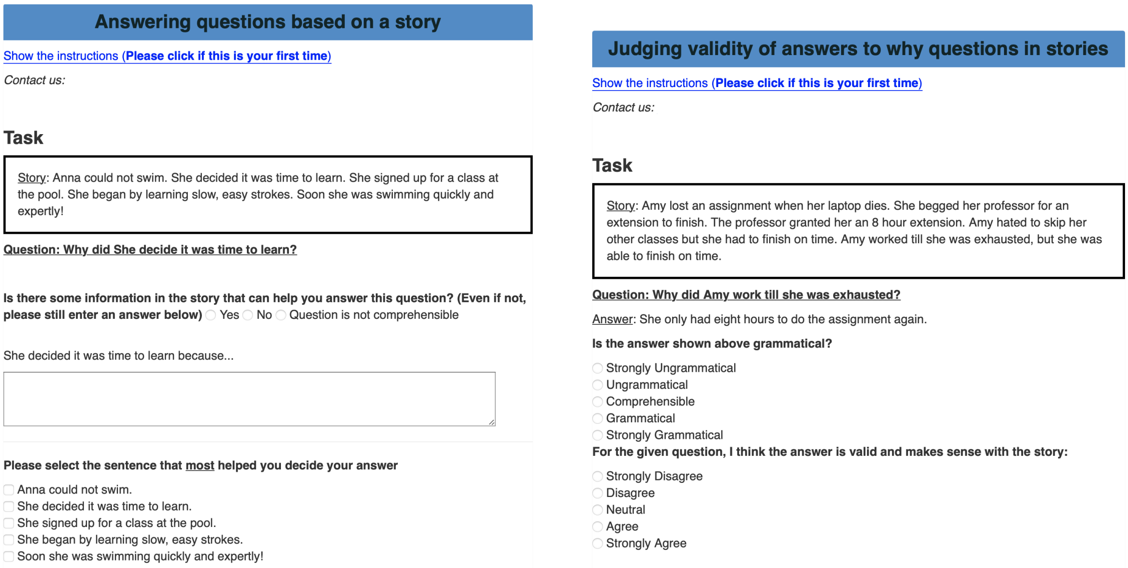
Three new annotators then rated two aspects of each answer:

(1) **Grammaticality** – Workers are asked to rate

---

[1] Since we ask annotators to read an entire story to answer these questions, avoiding stories with fewer questions optimizes reading time.

[2] On ROCStories we discarded 1,546 questions and on CATERS we discarded 25 questions



Answering questions based on a story

Task

Story: Anna could not swim. She decided it was time to learn. She signed up for a class at the pool. She began by learning slow, easy strokes. Soon she was swimming quickly and expertly!

Question: Why did She decide it was time to learn?

Is there some information in the story that can help you answer this question? (Even if not, please still enter an answer below) ○ Yes ○ No ○ Question is not comprehensible

She decided it was time to learn because...

Please select the sentence that most helped you decide your answer

- ☐ Anna could not swim.
- ☐ She decided it was time to learn.
- ☐ She signed up for a class at the pool.
- ☐ She began by learning slow, easy strokes.
- ☐ Soon she was swimming quickly and expertly!

(a) Task 1: Answer collection

Judging validity of answers to why questions in stories

Show the instructions (**Please click if this is your first time**)

Contact us:

Task

Story: Amy lost an assignment when her laptop dies. She begged her professor for an extension to finish. The professor granted her an 8 hour extension. Amy hated to skip her other classes but she had to finish on time. Amy worked till she was exhausted, but she was able to finish on time.

Question: Why did Amy work till she was exhausted?

Answer: She only had eight hours to do the assignment again.

Is the answer shown above grammatical?

- ○ Strongly Ungrammatical
- ○ Ungrammatical
- ○ Comprehensible
- ○ Grammatical
- ○ Strongly Grammatical

For the given question, I think the answer is valid and makes sense with the story:

- ○ Strongly Disagree
- ○ Disagree
- ○ Neutral
- ○ Agree
- ○ Strongly Agree

(b) Task 2: Answer validation

Figure 1: MTurk interfaces used to curate data from crowd-source workers

the grammaticality of each answer on 5-point Likert scales, ranging from 'Strongly Ungrammatical' to 'Strongly Grammatical'. An answer is strongly grammatical if it follows all the rules of English grammar. It is grammatical if there is a mistake in tense, number, punctuation or something minor. It is comprehensible if there are clear grammatical mistakes but its meaning can be inferred, and it is then considered to be neutral on the Likert scale.

(2) **Validity** – Workers are asked to rate the validity of each answer on a 5-point Likert scale. Given the story and question, the annotators check if the given answer 'is valid and makes sense with the story'. An answer is considered invalid if it does not give a plausible reason relevant to the question asked and instead states irrelevant information.

Annotators agreed (by majority) that 99.07% of answers are grammatical and 95.47% of answers are valid. On grammaticality, there is some disagreement in judgment 0.7% of the time, while there is some disagreement in judgment 1% of the time for answer validity. We measured the inter-rater reliability of annotators' judgments using weighted Fleiss's Kappa (Marasini et al., 2016) and follow the weighting scheme used by Bastan et al. (2020). This measure has a penalty for each dissimilar classification based on the distance between two classes. For instance, if two annotators classify a document as a positive, the agreement weight is 1, but if one classifies as a positive, and the other classifies as slightly positive the agreement weight is less. The weighted agreement score for this subset is 0.88 for grammaticality annotations and 0.81 for validity annotations, indicating that the annotations are highly reliable. More details can be found in Appendix C.2.

4 Dataset Analysis

One of the key distinguishing aspects of answering *why* questions is that, in addition to understanding explicitly stated events, they also require access to commonsense explanations that may be external to the narrative. We conduct some analyses to investigate the prevalence of this phenomenon: (i) We asked annotators to judge whether the answer to a question could be found stated explicitly or only implicitly in the narrative and find that at least two out of three annotators could not find explicit answers in the story 28.82% of the time. (ii) We also asked crowd-workers to indicate which sentences helped them answer the question. Out of 91,557 collected answers, we find that 39,661 answers were provided without an influential sentence from the story. (iii) Last, we observe that there is only a 57.04% lexical overlap between the words used in answers and the original narrative. This suggests that annotators included new inferred information in their answers, instead of just copying something from the story. We calculate lexical overlap as the number of common tokens in the narrative and the answer divided by the length of the answer.

We hypothesize that questions about the first action in a story are more difficult to answer since there is no prior information to provide an explicit answer. We find that 55.03% of such questions were judged to be implicit-answer questions by a majority of the assigned annotators. Such questions help test systems' ability to infer plausible answers rather than just copy answers from the text.

We also evaluated the diversity of the answers for each question using simple lexical overlap. Of the 30k questions, only 150 questions had over 90% overlap in all 3 answers, i.e., essentially, the 3 distinct annotators wrote the same answer. For 4,243 other questions, two out of three answers had over 90% overlap. But for the vast majority of 26,068 questions, we obtained 3 fairly diverse answers. The average overlap between them is 26.12%. On average, the answers were 7.59 words long.

Overall, this analysis indicates how TellMeWhy differs from prior datasets. The answers cannot always be retrieved or connected to other events in the given text.

5 Benchmarking

How well do large language models answer *why* questions on narratives and what are their failure modes? To answer these, we use TellMeWhy to benchmark the performance of multiple state-of-the-art models and provide an analysis of their performance.

Formally, given a story S as context and a related why-question Q, models are required to generate a plausible answer A for the question. Since the answers are open-ended texts we compare them on standard automatic evaluation metrics for generation but also conduct a human evaluation.

5.1 QA Models

GPT-2 (Radford et al., 2019) is a large transformer-based language model trained on an enormous web corpus, which has been shown to be effective on a wide-range of language related tasks including question answering. It was one of the first models trained on diverse data to outperform domain-specific language models.

We used Huggingface (Wolf et al., 2020) to finetune a pretrained GPT-2 model on TellMeWhy. As input, the model receives a concatenation of the narrative and the related question (in that order), and the target is the answer. The input and target are separated using the '[SEP]' token. We finetune the model with batch size 16, learning rate 1e-5 and maximum output length 25. The model is trained until the dev loss fails to improve for 3 iterations.

T5 (Raffel et al., 2020) is an encoder-decoder model pre-trained on a mixture of unsupervised and supervised tasks in a multi-task setting, where each task is converted into a text-to-text format. It is a text-to-text model, which means it can be trained on arbitrary tasks involving textual input and output. T5 has achieved the state of the art on many natural language understanding (NLU) tasks. More details about hyperparameter sweeps can be found in Appendix A.

We finetuned a pretrained T5-base model from HuggingFace (Wolf et al., 2020) on TellMeWhy. Since it is a natural language generation task related to a story, we use the SQuAD format specified in Appendix D.15 of Raffel et al. (2020) to format our inputs. Our narrative serves as the 'context' and the why-question is used as the 'question' in the selected input format. We train the model with batch size 16, learning rate 5e-5, maximum source length 75 and maximum answer length 30. The model is trained until the dev loss fails to improve for 3 iterations.

UnifiedQA (Khashabi et al., 2020) is a single pre-trained model that performs well across 20 different question answering datasets. It is built on top of a T5 model and simplifies finetuning by unifying the various formats used by T5. Its ability to perform both extractive and abstractive QA tasks makes it a suitable candidate for calibrating this task. A pretrained version of this model is available via HuggingFace (Wolf et al., 2020) under the name "allenai/unifiedqa-t5-base". The input format for this model is simple, just requiring the question and the narrative to be separated by a newline symbol. We train this model using learning rate 1e-5 (same as the original paper) and retain other hyperparameters from finetuning T5 as described above.

5.2 Automatic Evaluation

We evaluate all of the above models on both the test set and the hidden test set (questions from CATERS data). For automatic evaluation, we report BLEU (Papineni et al., 2002), ROUGE-L (Lin, 2004), BLEURT (Sellam et al., 2020) scores using the bluert-base-128 checkpoint, and BertScore (Zhang* et al., 2020) using the default roberta-large checkpoint. These numbers are presented in Table 4.

Evaluated on	Model	BLEU	RG-L F1	BLEURT	BertScore
Full Test Set	GPT-2-OO	0.04	0.07	-1.30	0.08
	GPT2-FT	1.3	0.13	-0.96	0.11
	T5-OO	5.67	0.13	-1.20	0.14
	T5-FT	**13.33**	0.24	-0.70	**0.34**
	UnifiedQA	13.03	**0.25**	**-0.71**	0.30
Implicit-Answer Qs in Test Set	GPT-2-OO	0.07	0.06	-1.30	0.05
	GPT2-FT	1.39	0.12	-1.02	0.09
	T5-OO	3.12	0.11	-1.24	0.12
	T5-FT	**7.27**	0.17	**-0.89**	**0.27**
	UnifiedQA	6.63	**0.18**	-0.89	0.24

Table 4: Performance of models on the full test set and on implicit-answer questions in the test set using automated metrics. RG-L denotes ROUGE-L. The OO suffix denotes the vanilla version of the model while the FT version denotes the finetuned version.

We select one human answer at a time and (using SacreBLEU (Post, 2018)) calculate the BLEU scores for model output with all three references, and select the maximum. Since BLEURT is a sentence level metric, to calculate the reported BLEURT, we average all the (output, reference) scores to obtain a corpus score for each reference. We then select the maximum BLEURT corpus score over all 3 human references. It is important to note that BLEURT was proposed as a metric for relative comparison, not absolute calibration. We also report BertScore F1[3] (Zhang* et al., 2020) as another semantic automatic evaluation metric. We report a max BertScore in the same way as BLEURT and BLEU: by taking the maximum score of the model output with each human answer taken one at a time.

Vanilla model results are obtained by loading an existing pretrained model from HuggingFace and running inference with the input formats described above. They are not trained on TellMeWhy. We see that vanilla pretrained models are unable to perform this task at all. Finetuning a pretrained model results in improvements since it better models the relationship between the story, the question, and a possible answer. On the full test set, both the finetuned T5 and the UnifiedQA model perform the best on our task. However, the overall performance of these models remains poor. In Table 4, we also see that models perform a lot worse on implicit-answer questions.

5.3 Human Evaluation

For open-ended text generation tasks like answering why-questions, the absence of an automatic evaluation that correlates well with human judgments is a major challenge (Chen et al., 2019; Ma et al., 2019; Caglayan et al., 2020; Howcroft et al., 2020).

We conduct a human evaluation on the hidden test set with a standardized interface to compare different models. We want to measure whether a model produces coherent and grammatical output and more importantly, whether the produced output is a valid answer for the given question. Our validation HIT subsection 3.3 showed a way to conduct human evaluation of answers provided by other crowd-workers. We modified this HIT design to evaluate generated answers from models. For a given question, we present just one answer from a single model and then ask the crowd-workers to assess its grammaticality and validity.

For each story, question, and a model's answer, we ask 3 distinct annotators to provide judgments about grammaticality and validity. This serves as the human evaluation interface for our task. A sample HIT can be seen in Figure 1b.

We perform human evaluation of the fine-tuned versions of T5 and UnifiedQA, the two models that performed the best on automatic metrics. We evaluate the outputs of these models on the hidden test set. We calculated inter-annotator agreement for these judgments using the method described in subsection 3.3, and they were >80%, indicating high agreement. The models mostly produce grammatical answers, but fail to adequately ex-

---

[3] idf and rescale_with_baseline flags are set to True.

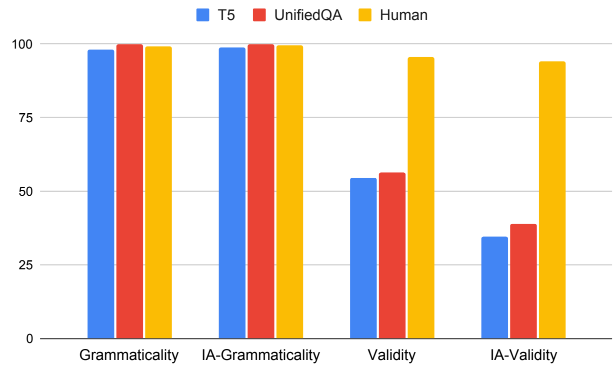

Figure 2: Human evaluated performance of answers. The IA prefix denotes performance on implicit-answer questions in the data.

plain many actions in the story. Figure 2 shows that, under human evaluation, models significantly under-perform humans at producing valid answers to why-questions. Models fare worse when the answers to the questions are external to the narrative.

Human evaluation is slow and expensive, so we performed a correlation analysis between the automated metrics and human judgments to gauge usefulness of popular automated metrics. Figure 3 shows that the embedding-based metrics are only weakly correlated with human validity judgments, while lexical metrics did even worse. None of the automatic metrics show a strong correlation, confirming our earlier assertion that human evaluation is the most appropriate way to analyze model performance on this open-ended generation task. BertScore has at least a moderate correlation with human validity judgments, and is therefore arguably the most useful for rapidly evaluating models during development. BLEU and BertScore improve their correlation with human judgments slightly as the number of human reference answers is increased; however, the increase is somewhat disappointing. Inexplicably, BLEURT's correlation actually decreases slightly with increasing human references, raising additional questions with respect to utilizing this metric. One possibility is that, by using an increasing number of references and taking the maximum score, BLEURT might overestimate the quality of answers as compared to human judgments.

Our human judgment interface can serve as a standard human evaluation of any future model's performance on our dataset, and we will make code available for automatically generating HITs for evaluating the outputs of any model. This standardized evaluation approach is similar in spirit to GENIE (Khashabi et al., 2021), a contemporary work that also presents an evaluation framework for a large set of generation tasks.

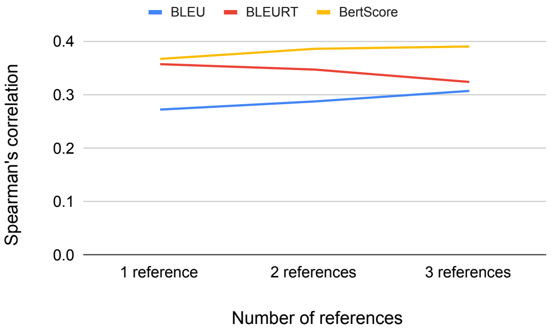

Figure 3: Correlation of automatic metrics with human validity judgment of model outputs. For each question, we have 3 crowdsourced human answers available to us. We selected a number of human answers randomly (X-axis) and calculated scores for each model output across different automatic metrics. Finally, we obtained Spearman's correlation (Y-axis) of these scores in comparison with Likert judgments provided by annotators for each human answer.

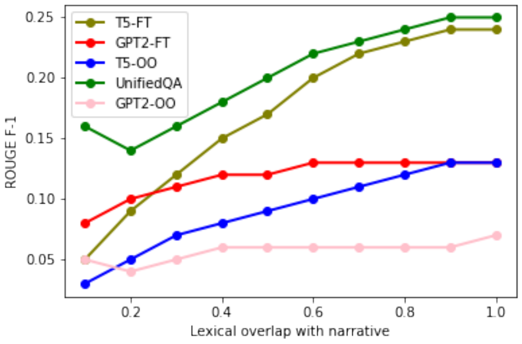
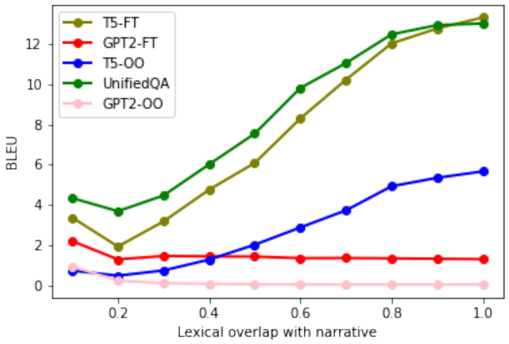
5.4 Analysis

In order to better understand when models are generating valid answers, we analyzed the correlation between model performance and a proxy for checking when human provided answers were in the input narrative. To this end, we aligned ROUGE F-1 scores with the lexical overlap of human answers and the story text. Figure 4a shows how ROUGE F-1 scores for our models increases as the lexical overlap also increases between the answers and corresponding story. The same is presented for BLEU in Figure 4b. Perhaps not surprisingly, this empirically shows that models do best when the answer is in the text, and suffer greatly when it is not (implicit answers). This further illustrates the value of TellMeWhy, as well as its challenge, that standard models are largely incapable of performing the reasoning needed to produce plausible answers that are assumed common knowledge by the story writer.

Table 5 also shows that the best performing models mainly learnt to copy complete or parts from the narrative to generate answers, treating this largely as an extractive task. On average, more than three-fourths of T5 and UnifiedQA's answers are



(a) ROUGE F-1 trend



(b) BLEU trend

Figure 4: Model performance on different metrics with change in lexical overlap between a question's answers (as provided by humans) and the related narrative.

System	Copied ans	Avg overlap
Vanilla GPT2	0%	23.09%
Finetuned GPT2	0%	28.94%
Vanilla T5	5.50%	53.71%
Finetuned T5	59.44%	85.91%
UnifiedQA	27.44%	76.51%
Human Answers	35.03%	57.04%

Table 5: Overlap between answers and the original narrative. This indicate how much original text models produce.

based on words in the narrative text. T5 is worse compared to UnifiedQA in terms of copying, with a much larger fraction of questions (59.44% vs 27.44) with high lexical overlap (i.e. lexical overlap > 90%). In comparison, the average narrative overlap for human answers is much lower than the best-performing models, since people are able to infer answers that are not in the text. If the models are to successfully answer *why* questions, they need to look beyond copying texts.

6 Conclusion

This paper introduces a large, novel QA dataset, **TellMeWhy**, containing questions about *why* characters in a narrative perform their depicted actions. This challenge problem complements the variety of existing QA datasets, addressing the scarcity of "why" questions. Using both automated metrics and human evaluation, we show that existing deep-learned language models perform quite poorly at answering such questions. We also illustrate the uniqueness of this challenge where the answer is sometimes in the story itself, but often not, thus requiring a richer model that can draw on commonsense knowledge or external reasoning abilities.

We believe that progress on answering such questions requires new systems that can reason about actions, plans, and goals in order to achieve a deeper understanding of narrative text, as was initially argued over four decades ago (Schank and Abelson, 1977). We hope that TellMeWhy encourages further research in this area.

Acknowledgement

A Hyperparameter Sweep

We describe the hyperparameters and the range of values we experimented with. The best hyperparameters are chosen on the basis of model loss on the validation set. For both GPT-2 (Radford et al., 2019) and T5 (Raffel et al., 2020), we conduct guided sweeps for learning rate, batch size and epochs. We experiment with 1e-5, 5e-5 and 1e-4 for learning rate. Batch sizes of 8, 16 and 32 were tried. Models were trained for 20, 30 and 50 epochs, and we found that models converged between 30 and 50 epochs. In the case of T5, we also experiment with different lengths of inputs and target outputs. We trained models with maximum source lengths of 50, 60 and 75 tokens. For target length, we experimented with 15, 25 and 30 tokens. The maximum output length is treated as a hyperparameter for GPT-2, and we tried 15, 20, 25 and 30 tokens.

B Dataset Creation

The method described in subsection 3.1 creates 489 questions from the 200 stories in the CATERS dataset – 36 stories with 1 question, 63 with 2, 59 with 3, 30 with 4, and 6 with 5. We collect 3 human answers for all questions. For ROCStories, this creates 113,213 questions from 45,496 stories – 7,555 stories with 1 question, 13,431 with 2, 13,349 with 3, 7356 with 4, and 1865 with 5. We randomly select 32,165 questions from stories with 3 or 5 questions, for ease and efficiency of collecting annotations. This is the smallest number for which we could gather 3 answers for at least 30,000 questions, which is a reasonable-sized dataset for training or fine-tuning large NLP models.

C Mechanical Turk tasks

C.1 Instructions

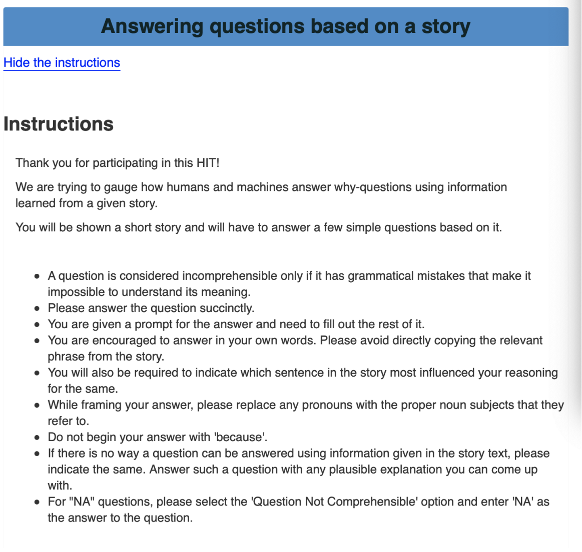
We present the instructions given to annotators for both the tasks in Figure 5. Annotators were given clear direction for both tasks. We restricted both tasks to master turkers. The second task (answer validity) was also used a sanity check for answers collected in the first task (answer collection). Using results of the answer validity task (mentioned in subsection 3.3), we see that humans provided high quality answers in the answer curation task.

C.2 Inter-annotator agreement

We use weighted Fleiss Kappa to calculate inter-rater reliability. The weights between different classes are shown in Table 6 where negative, slightly negative, neutral, slightly positive, and positive classes are shown with -2, -1, 0, 1, and 2. We follow the setup used in Bastan et al. (2020) for a similar multi-class labeling task.

	-2	-1	0	1	2
-2	1	$\cos \pi/8$	$\cos \pi/4$	$\cos 3\pi/8$	0
-1	$\cos \pi/8$	1	$\cos \pi/8$	$\cos \pi/4$	$\cos 3\pi/8$
0	$\cos \pi/4$	$\cos \pi/8$	1	$\cos \pi/8$	$\cos \pi/4$
1	$\cos 3\pi/8$	$\cos \pi/4$	$\cos \pi/8$	1	$\cos \pi/8$
2	0	$\cos 3\pi/8$	$\cos \pi/4$	$\cos \pi/8$	1

Table 6: Inter class weights used for computing inter annotated agreement



Answering questions based on a story

Hide the instructions

Instructions

Thank you for participating in this HIT!

We are trying to gauge how humans and machines answer why-questions using information learned from a given story.

You will be shown a short story and will have to answer a few simple questions based on it.

- A question is considered incomprehensible only if it has grammatical mistakes that make it impossible to understand its meaning.
- Please answer the question succinctly.
- You are given a prompt for the answer and need to fill out the rest of it.
- You are encouraged to answer in your own words. Please avoid directly copying the relevant phrase from the story.
- You will also be required to indicate which sentence in the story most influenced your reasoning for the same.
- While framing your answer, please replace any pronouns with the proper noun subjects that they refer to.
- Do not begin your answer with 'because'.
- If there is no way a question can be answered using information given in the story text, please indicate the same. Answer such a question with any plausible explanation you can come up with.
- For "NA" questions, please select the 'Question Not Comprehensible' option and enter 'NA' as the answer to the question.

Judging validity of answers to why questions in stories

Hide the instructions

Instructions

Thank you for participating in this HIT!

We are trying to gauge how humans and machines answer why-questions using information learned from a given story.

You will be shown a short story, a related question and a possible answer to that question.

You will have to answer a few simple questions based on it.

- Please read the story thoroughly.
- An answer is stongly grammatical if it follows all the rules of English grammar.
- It is grammatical if there is a mistake in tense, number, punctuation or something minor.
- It is comprehensible if there are clear grammatical mistakes but its meaning can be inferred.
- The validity of the answer is dependent on if the information presented in the answer can be inferred (implicitly or explicitly) from the story.
- An answer is considered invalid if it does not give a plausible reason for the question asked and states an irrelevant piece of information instead.
- The degree of relevance and validity of an answer can vary. Make sure you select the option you agree with most.

Dialogue in the Wild:
Learning from a Deployed Role-Playing Game with Humans and Bots

Kurt Shuster* **Jack Urbanek*** **Emily Dinan** **Arthur Szlam** **Jason Weston**

Facebook AI Research

Abstract

Much of NLP research has focused on crowdsourced static datasets and the supervised learning paradigm of training once and then evaluating test performance. As argued in de Vries et al. (2020), crowdsourced data has the issues of lack of naturalness and relevance to real-world use cases, while the static dataset paradigm does not allow for a model to learn from its experiences of using language (Silver et al., 2013). In contrast, one might hope for machine learning systems that become more useful as they interact with people. In this work, we build and deploy a role-playing game, whereby human players converse with learning agents situated in an open-domain fantasy world. We show that by training models on the conversations they have with humans in the game the models progressively improve, as measured by automatic metrics and online engagement scores. This learning is shown to be more efficient than crowdsourced data when applied to conversations with real users, as well as being far cheaper to collect.

1 Introduction

Humans learn to use language over the course of their lives from the interactions they have with the world and other people. Yet, the prevailing dominant paradigm in natural language processing (NLP) research is to build a fixed dataset from which to train a model and then freeze it, without any ability for the model to interact with humans using language at training time at all. While we need such interaction in order to study human-machine communication to its full extent, constraints usually inhibit such research. Firstly, conducting such experiments can be costly. Many datasets in NLP are collected with crowdsourcing, whereby one pays the crowdworkers to perform interaction and annotation tasks. This leads to several issues, not least that research budgets for paying crowdworkers mean that data will have a limit. Secondly, as crowdworkers are motivated by pay, not by interest in the tasks themselves, the data distribution may not match the desired one (de Vries et al., 2020).

In this work we study the ability of dialogue agents in an open world[1] to iteratively learn from conversations with intrinsically motivated humans. In order to engage humans at scale, we build and deploy a (free to play) game with a purpose (Von Ahn, 2006) whereby human players role-play characters and converse with other characters (that are our learning models) situated within the game world. We choose a rich fantasy game world, in order to maximize engagement. Our system iterates between collecting data of human-model interactions, retraining updated models on the newly collected data, and redeploying them. Simultaneously, it provides a natural metric to evaluate and compare models online using human continue rates (that is, how long human players continue playing).

We show that we can successfully collect, retrain and redeploy models, starting from a crowdsourced base model, that improve both offline automatic metrics and human continue rates. Our overall system is then engaging enough that we can collect data at a rate that is $1/5^{th}$ of the price per utterance of crowdsourcing, where the cost of our method is the cost of advertisements that make players aware of the game. Moreover, the data we collect is also more effective per utterance at improving continue rates due to being more on-distribution than crowdsourced data. As our models improve, these rates improve as well, as the continuation rate increases

---

* Equal Contribution.

[1] In this work we study dialogue that can be about any topic but within the scope of a fantasy game world. Note this differs from open-domain dialogue talking about our world, e.g. the game players can talk about the sauce recipe from Bredwell across the sea (see Fig. 1), but not about the pizza in Chicago.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 611–624
August 1–6, 2021. ©2021 Association for Computational Linguistics

– meaning relatively more data is collected. Overall, our work provides good evidence that lifelong dialogue learning in deployed systems with intrinsically motivated humans (rather than crowdworkers) can be successful, in particular by embedding such learning within games.

The training code and parameters of the models deployed, and the data collected in this work will be made publicly available for reproducibility and further research by the community.

2 Related Work

Open-Domain Dialogue Dialogue in the open-domain (chitchat) setting, which involves chat about any topic, rather than a specific goal-directed topic, is commonly studied in the train/valid/test static dataset paradigm utilizing supervised learning. A number of crowdsourced or scraped datasets have been developed to that end, including Daily Dialogue (Li et al., 2017), PersonaChat (Zhang et al., 2018), Empathetic Dialogues (Rashkin et al., 2019) and Wizard of Wikipedia (Dinan et al., 2019b); see Huang et al. (2020) for a review.

LIGHT In this work we specifically focus on dialogue setting of LIGHT (Urbanek et al., 2019). LIGHT focuses on situated characters playing character roles that can chat about any topic, within the context of a medieval fantasy world. This setting is known to be engaging for human role-players, and also alleviates some safety concerns in that the role-playing means they should not divulge personally identifying information. The authors crowdsourced a dialogue dataset consisting of 8.5k episodes and 111k utterances, which they publicly released. We refer to this as LIGHT MTurk data, or LIGHT data for short, in the rest of this paper. In this work we utilize this data to build a deployed system whereby players can converse with models, and we can study lifelong learning with these models using the information in these new conversations.

Lifelong Learning Lifelong learning is a machine learning paradigm whereby deployed models can interact with the world and iteratively improve themselves from the things they learn, eschewing the standard approach of a fixed training set from which a model is trained once (Silver et al., 2013). We note there are other closely related concepts to the topics in this work, such as incremental learning (Castro et al., 2018), continual reinforcement learning (Ring, 1994) and never-ending learning (Carlson et al., 2010; Mitchell et al., 2018).

Interactive Dialogue Learning Learning from dialogue interaction is common in reinforcement learning settings, where the feedback is a scalar rather than solely the dialogue messages themselves (Levin et al., 2000; Schatzmann et al., 2006; Rieser and Lemon, 2011; Liu and Lane, 2017; Serban et al., 2017), which is most common in a goal-oriented setting where completion of the goal can provide such rewards, but not so in chitchat settings (Roller et al., 2020), which do not have rewards.

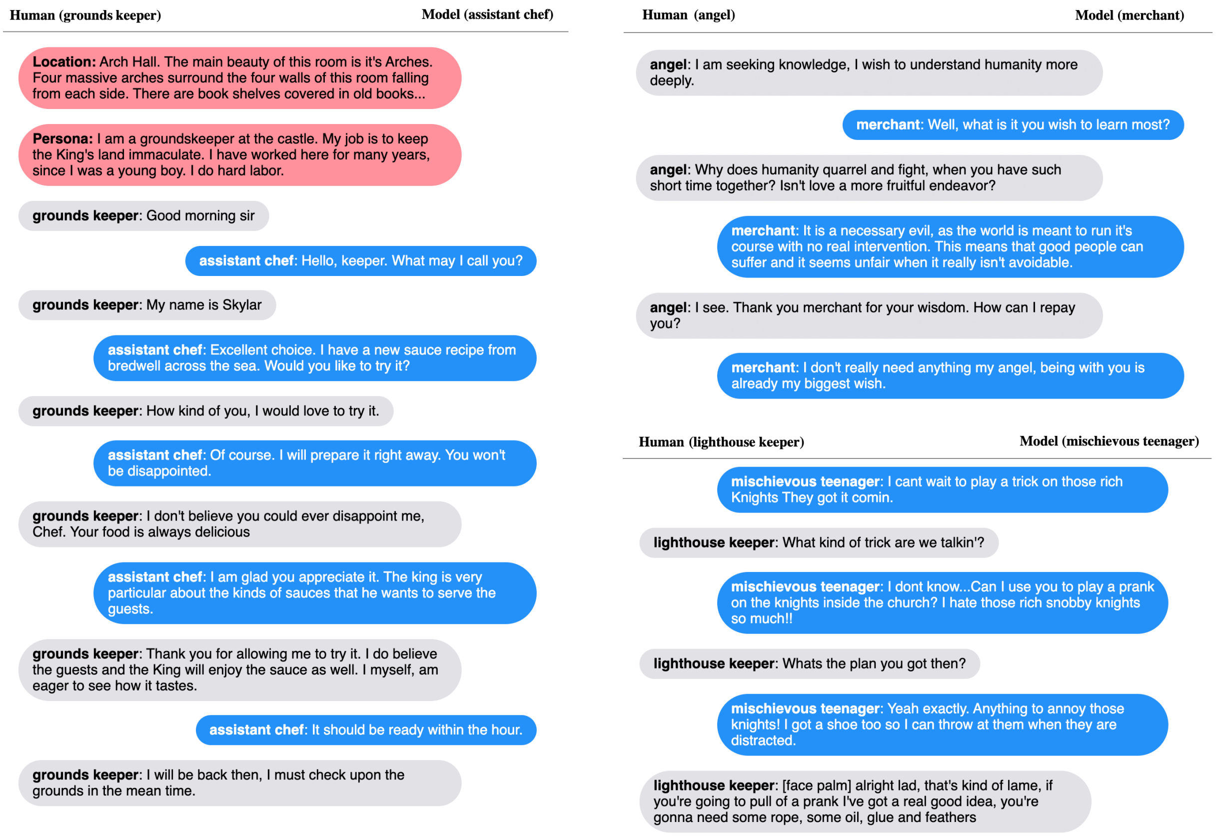
Closer to our work, is the self-feeding chatbot (Hancock et al., 2019), where dialogue models were used to collect data to improve themselves via crowdsourcing utilizing the PersonaChat task. Related approaches have also been applied to the cases of question answering (Li et al., 2016a,b), and in simulators (Mazumder et al., 2019; Nguyen and Daumé III, 2019) as well. Liu et al. (2018) applied such an approach to goal-oriented tasks. Our work differs from these works in that we study a deployed user-facing system in an open-ended game environment, rather than more limited data from paid crowdworkers. For other related works see Padmakumar and Mooney (2020).

Deployed Dialogue Systems While there are a number of deployed virtual assistants, many of these products are not ideal platforms for the research community. Their proprietary nature and commercial importance, coupled with privacy concerns, means they are neither accessible to researchers, nor amenable to public reproducible research. A near-exception is the Alexa challenge (Ram et al., 2018) which allows university-based researchers access to a commercial user-base for the span of the competition, however, the data and models are also not released to the rest of the research community, unlike in our work.

3 Dialogue as a role-playing game

In this section we describe the game that we will build and deploy, which is a role-playing game, designed to both train and evaluate dialogue agents.

Core Mini-Game The core game involves pairing two agents in a given setting – where one is a human player and the other is a dialogue agent with an underlying machine learning model. The two players are assigned characters, with given names and backstories (personas), and their current location and its description. See Figure 1 for examples.



Human (grounds keeper) Model (assistant chef)

Location: Arch Hall. The main beauty of this room is it's Arches. Four massive arches surround the four walls of this room falling from each side. There are book shelves covered in old books...

Persona: I am a groundskeeper at the castle. My job is to keep the King's land immaculate. I have worked here for many years, since I was a young boy. I do hard labor.

grounds keeper: Good morning sir

assistant chef: Hello, keeper. What may I call you?

grounds keeper: My name is Skylar

assistant chef: Excellent choice. I have a new sauce recipe from bredwell across the sea. Would you like to try it?

grounds keeper: How kind of you, I would love to try it.

assistant chef: Of course. I will prepare it right away. You won't be disappointed.

grounds keeper: I don't believe you could ever disappoint me, Chef. Your food is always delicious

assistant chef: I am glad you appreciate it. The king is very particular about the kinds of sauces that he wants to serve the guests.

grounds keeper: Thank you for allowing me to try it. I do believe the guests and the King will enjoy the sauce as well. I myself, am eager to see how it tastes.

assistant chef: It should be ready within the hour.

grounds keeper: I will be back then, I must check upon the grounds in the mean time.

Human (angel) Model (merchant)

angel: I am seeking knowledge, I wish to understand humanity more deeply.

merchant: Well, what is it you wish to learn most?

angel: Why does humanity quarrel and fight, when you have such short time together? Isn't love a more fruitful endeavor?

merchant: It is a necessary evil, as the world is meant to run it's course with no real intervention. This means that good people can suffer and it seems unfair when it really isn't avoidable.

angel: I see. Thank you merchant for your wisdom. How can I repay you?

merchant: I don't really need anything my angel, being with you is already my biggest wish.

Human (lighthouse keeper) Model (mischievous teenager)

mischievous teenager: I cant wait to play a trick on those rich Knights They got it comin.

lighthouse keeper: What kind of trick are we talkin'?

mischievous teenager: I dont know...Can I use you to play a prank on the knights inside the church? I hate those rich snobby knights so much!!

lighthouse keeper: Whats the plan you got then?

mischievous teenager: Yeah exactly. Anything to annoy those knights! I got a shoe too so I can throw at them when they are distracted.

lighthouse keeper: [face palm] alright lad, that's kind of lame, if you're going to pull of a prank I've got a real good idea, you're gonna need some rope, some oil, glue and feathers

Figure 1: Example collected dialogues from humans role-playing in our deployed system, conversing with models. (Left) a conversation complete with described location and player persona; (Right) excerpts from two other conversations (out of 41,131 collected) to demonstrate the diversity of the dialogue in the fantasy game world.

Each player's goal is to act out (role-play) their character's dialogue in the given situation. We refer to one such dialogue episode as a *mini-game*. Dialogue in the game is in English.

Role-Playing (Acting) Score We take advantage that role-playing is a pursuit that a large number of human players find fun (Horsfall and Oikonomou, 2011), and are hence naturally engaged in the open-ended nature of this process. However, to encourage and further motivate players to play their characters well, we introduce the concept of an (automated) dungeon master (DM), who will assess the quality of the player's role-playing. For each dialogue turn, we apply a learned model to the human player's dialogue, which assesses how likely their utterance is given the context. We convert this to a score, between 1 and 5 stars, that is presented to the human player, to reward them for good acting. While this signal is noisy, because our DM model is not perfect, it gives motivating feedback to the players to continue playing.

Game Loop Each dialogue (mini-game) consists of 6 turns of dialogue per agent (12 total). At the end of the mini-game the human player is presented with four choices: (i) choose to move to a new location, where they will continue to play this character, but meet a new character to converse with; (ii) stay in the same room but wait for a new character to arrive to converse with; (iii) change to role-play a completely new pair of characters in a new setting; or (iv) end the game. These choices encourage the player to choose another mini-game that they are most interested in, and the variety of mini-games gives different role-playing possibilities, making the dialogue data more diverse. Further details of the game are described in Appendix A.

Deployment and Advertising We deployed the game using Facebook Messenger on CPU-only servers, and used the publicly-available ad flow to advertise on Facebook. The target audience for our ads were people with interests in online gaming, role playing, and role playing games in particular. We also used lookalike audiences to those who engaged with the game. We ran ads like that shown in Figure 4 with a call-to-action for people to try out the game.

4 Lifelong Dialogue Learning

4.1 Models

Retrieval Models All the models we have currently deployed are retrieval models for safety reasons as we can vet each possible response by filtering the train set candidates (see Appendix A). In particular, we use the Poly-Encoder (PE) Transformer architecture as a base (Humeau et al., 2019), as it provides state of the art results compared to other retrieval models, whilst being tractable to deploy. PE encodes the context with a standard bidirectional transformer, but produces an encoding into a fixed small number of codes, N. We tried values of $N = 5$ and $N = 20$. Each label candidate then attends to these codes before producing a final matching score. The model is trained with cross-entropy given the correct label, and by subsampling negative examples from the given training batch.

Architecture and Training Choices We employ the 90M and 622M parameter models from (Roller et al., 2020) that have been pre-trained on 1.5B training examples from pushshift.io Reddit, which we then fine-tune. We also consider two other enhancements, chosen to mitigate problems that we observed with the models: (i) negative context training, whereby negatives are also selected from the immediate dialogue history as well as the batch which can help reduce a model's tendency to repeat itself (Holtzman et al., 2019; Welleck et al., 2020); and (ii) decoding control (See et al., 2019) whereby at decoding time responses are rescaled before scoring based on their specificity (normalized inverse document frequency). The latter can control the genericness of the responses, which is known to affect human judgments.

Generative Models In addition to the deployed models, we also train and evaluate generative models offline, where safety concerns are less important as the models are not user-facing. We employ an encoder-decoder Transformer architecture using the state of the art pre-trained 2.7 billion parameter BlenderBot model (Roller et al., 2020), which we fine-tune on our task.

Acting Score Model We can apply a retrieval model to also score the human's role-playing abilities. In this case, the context is the entire dialogue history, setting and the player's character persona as input to the encoder, while the candidates to score are the ones from the training set, as usual, plus additionally the human's (player's) actual response. The score given to the user is then proportional to the human response's rank amongst all the candidates[2].

4.2 Iterative Data Collection and Training

After collecting a certain amount of episodes of conversational data between humans and models, one can consider using this data for training. We utilize the following observation: while the model utterances may contain many mistakes, it is assumed that a human sufficiently engaged provides high quality responses, even if the model responses are mistakes, and can thus be treated as gold, and used as a fully supervised signal. We thus separate the dialogue data into all possible (context, next utterance) pairs, and then only consider the pairs with human next utterances as training data. We also compare this to further filtering this set by scoring the quality of the human utterances, discarding those episodes (mini-games) with lower quality. We use the acting score model previously described for this purpose, summing the scores obtained across an episode, and discarding the episode if this value is less than C, where C is a hyperparameter tuned on the validation set.

After training our model from a given round of collection, we can go back to the collection process utilizing instead the new model that has been trained on more data. The hypothesis is that the higher quality the model is: (i) the higher quality the human data will be as well; and (ii) the more likely the human players are to converse longer, increasing the data set size by larger amounts.

4.3 Deployment-based Evaluation

Apart from the collection-training cycle of our deployed lifelong learning setup, one can also in parallel perform evaluation. For each separate mini-game (episode of dialogue) we can potentially deploy a *different* model for human-model conversation. We maintain a pool of models with differing architectures or hyperparameters, and select randomly from the pool in each episode. For any given episode we record whether the player continued playing to the next mini-game or not, which

---

[2] The player is awarded 2 stars if their response is in the top 2000, 3 stars in the top 1000, and 4 stars in the top 100.

we refer to as the continue rate. We can measure the quality of a model using its averaged continue rate over all players and episodes. In this way we can also perform model selection online.

5 Experiments

5.1 Rounds of Learning

We performed three rounds of our lifelong learning setup.

Round 1 consists of models trained on LIGHT MTurk data only. We train the retrieval model variants described in Section 4.1, and deploy them within the game.

Round 2 consists of models trained on LIGHT MTurk data + 50,982 examples collected from the deployment of the Round 1 models, and again deploy these within the game.

Round 3 consists of models trained on LIGHT MTurk data + 50,982 examples from Round 1 deployment + an additional 180,010 examples collected from Round 2 deployment.

5.2 Data Collection

While our setup is a lifelong learning setup and the models are still currently deployed and collecting data, for this paper we froze the collection at a given point in order to provide a data release and provide experimental results. The data statistics for the total newly collected dataset, called LIGHT WILD, over all rounds is shown in Table 1. Validation and test sets were extracted from a portion of the data[3] from Round 2.

Table 2 compares this dataset to several existing commonly used open-domain dialogue datasets. The number of episodes and dialogue utterances is larger than many existing datasets, e.g. four times as many as LIGHT MTurk, and almost eight times that of Empathetic Dialog. Uniquely, our dataset contains human-model conversations, hence the total number of human utterances is actually half of the utterances, which is still twice as large as the number in LIGHT MTurk. Our dataset also has a large degree of diversity, which is important for tasks in general, and especially for open-domain dialogue. The number of unique locations and roles that can be played by speakers (characters) is large (587 and 630, respectively). The number of players of the game at the time of freezing was over 13,000, which also makes the diversity far larger than typical crowdsourced datasets, e.g. LIGHT MTurk involved 1,052 crowdworkers and Empathetic Dialog involved 810 crowdworkers. Finally, the number of unique tokens is larger in LIGHT WILD, indicating its diversity of language.

5.3 Analysis of Results

5.3.1 Performance by Round

While we only deployed retrieval models, we report experiments training both retrieval models and generative models on the data from the three rounds, selecting best hyperparameters using the validation set. We report the performance on three different test sets: LIGHT (MTurk) Seen and Unseen test sets (Urbanek et al., 2019), where unseen means that the test locations do not overlap with the training set locations, and our WILD test set. The results are given in Table 3. They show a steady increase in the Hits@1/20 metric (Top 1 accuracy given 19 random distractors) for the retrieval models over the rounds on all three test sets, and a similar decrease in perplexity (PPL) for the generative models. In particular there is a large jump in the performance on the WILD Test set between Rounds 1 and 2 as the training set switches from crowdsourced to in-distribution WILD data, and a further increase in Round 3 as more data is again collected and retrained on. While our WILD data is of a different distribution to the two LIGHT (MTurk) test sets, the data collection from our lifelong learning setup still gives gains on those tests as well. Our reported numbers, as far as we are aware, are the best reported numbers on these datasets, e.g. the original LIGHT paper reports 76.5% and 70.5% for the Seen and Unseen test sets, respectively (compared to our 87.72% and 83.48%). Overall, we see clear gains from the extra data collected in our setup.

5.3.2 Lifelong Learning Curves

We construct learning curves given all the collected data to analyze the performance gain per new training example. We plot Hits@1/20 accuracy on the WILD validation set against the number of training examples, comparing data from WILD collection to LIGHT (Mturk). We also consider a 50/50 mix, where we equally sample from LIGHT MTurk and WILD to provide the next training example.

Figure 2 (left) shows the results. We observe that on a per-example basis our WILD data gives

---

[3] For validation and test we only use complete conversations, and where the player scored ≥ 9 stars, to build higher quality evaluation sets.

Data Type	Num. Epsiodes	Num. Utterances	Num. Human Utterances	Unique Locations	Unique Characters
Training	41,131	461, 984	230,992	587	630
Validation	500	5,936	2,968	231	463
Test	1000	11,822	5,911	296	569

Table 1: Data statistics of our lifelong learning deployment at the point where we froze collection for experiments reported within the paper and subsequent data release.

Dataset	Num. Episodes	Num. Utterances	Num. Human Utterances	Unique Tokens	Avg. Human Utt. Length	Number of Humans
PersonaChat (Zhang et al., 2018)	8,939	131,438	131,438	18,688	11.9	UNKNOWN
Wiz. of Wikipedia (Dinan et al., 2019b)	18,430	166,787	166,787	52,490	19.7	UNKNOWN
Empathetic Dialog (Rashkin et al., 2019)	24,850	64,636	64,636	19,458	15.3	810
Daily Dialog (Li et al., 2017)	22,236	87,170	87,170	20,673	14.5	UNKNOWN
LIGHT MTurk (Urbanek et al., 2019)	8,538	110,877	110,877	33,789	18.3	1,052
LIGHT WILD *(this paper)*	41,131	461,984	230,992	47,526	11.9	13,188

Table 2: Comparison of statistics of the dialogue data collected during deployment (bottom row) compared to several existing (mostly crowdsourced) datasets. Our data is around twice as large in terms of human utterances than these datasets, and 4x as large in terms of dialogue utterances (as our data consists of human-model conversations), while the cost to collect our data was only $1/5^{th}$ of the price per utterance of LIGHT MTurk, see Sec. 5.3.3.

more accuracy gains than LIGHT MTurk data, e.g. 83.59% for WILD compared to 80.63% for LIGHT, when limiting WILD to the same training set size as the total size of LIGHT. As the WILD dataset is more than twice as large this monotonically improves further, up to 85.95% using all of the WILD data. We observe that the improvements have not saturated and that further lifelong learning will bring further model improvements. Combining the two data sources, as shown in the LIGHT+WILD plot, brings yet further gains, up to 87.2%. Overall, our collected WILD data has high quality as a learning signal for training models.

5.3.3 Cost Learning Curves

We plot similar learning curves, but as a function of the cost to collect the data instead of the number of training examples instead, see Figure 2 (right). Although we do not pay players to play the game, we did spend money to advertise the game online in order to attract players. We compare the cost per WILD example relatively to the cost per LIGHT (MTurk) example, where the x-axis is scaled in units that are multiples of the cost required to achieve 80.63% using WILD data (as this is the performance of using all the LIGHT MTurk data together). We observe that it costs over 8x more to achieve the same accuracy using LIGHT (MTurk) data (see dashed horizontal line). The actual cost per utterance of WILD data is around $1/5^{th}$ of the price of LIGHT MTurk data[4], but more than that, it is also relatively more effective per utterance in terms of metrics. For the same amount spent there is a large gap between the two systems, for example using all the WILD data gives a performance of 85.95%, whereas for the same spend LIGHT MTurk only achieves ∼77.5%. Overall, WILD deployment is relatively a very cost effective strategy.

5.3.4 Deployment-based Evaluation

Our lifelong learning setup deploys multiple models (see Sec. 4.3) at the same time randomly assigning them to concurrent users per episode (minigame). We can thus directly compare the quality of models via their continue rate.

Continue rates during Round 2 of collection comparing several model variants are given in Table 4. Continue rates are in the range of 68%-75%, depending on the model, and we observe some clear trends. Most importantly, LIGHT+WILD trained models are superior to LIGHT only trained models, showing that our deployment/train cycle produces better models as judged by humans. Secondly, other factors in model design are important too, and our setup can effectively evaluate those. In particular, it was found that both our negative context training and decoding control enhancements (see Sec. 4.1) improve the continue rate, with both

---

[4] This is the cost of the 462k WILD utterances starting from a crowdsourced model base trained on 111k LIGHT utterances giving 573k utterances in total (see §5.1), comparing to collecting an additional 462k examples via crowdsourcing.

	Retrieval Model (Hits@1/20 ⇑)			Generative Model (PPL ⇓)		
Model	LIGHT Test	LIGHT Test Unseen	WILD Test	LIGHT Test	LIGHT Test Unseen	WILD Test
Round 1	87.12	82.43	81.61	12.67	11.81	13.42
Round 2	87.65	82.70	84.60	12.57	11.74	12.31
Round 3	87.72	83.48	87.63	12.54	11.75	11.79

Table 3: Three rounds of training in our lifelong dialogue learning setup. Both retrieval and generative models trained on the data from the three rounds improve across both metrics on all three test sets.

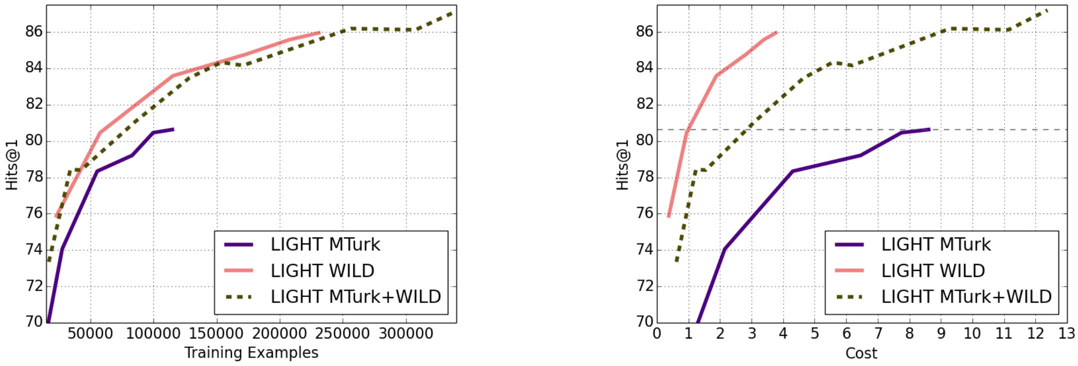


Figure 2: Hits@1/20 Accuracy on the LIGHT WILD validation set as a function of the number of training examples (left) or the cost of data collection (right). The cost axis is in units scaled by the cost of LIGHT WILD collection required to achieve the same performance as using the entire LIGHT MTurk dataset; it is more than 8× cheaper to use LIGHT WILD examples than LIGHT MTurk examples to achieve an accuracy of 80.63%. We also show performance for models which equally sample data from LIGHT MTurk+WILD datasets for training; utilizing all the data from both sources yields the best performance. However, LIGHT WILD data gives better accuracy improvements per training example (left plot).

Data	Neg.Ctxt	Dec.Ctrl	Continue Rate
LIGHT	yes	no	72.2 ± 1.9%
LIGHT	yes	yes	74.1 ± 2.0%
LIGHT+WILD	yes	no	73.6 ± 1.8%
LIGHT+WILD	yes	yes	75.2 ± 2.0%

Table 4: Deployment-based Evaluation, comparing several metrics on data collected during Round 2 of collection for 90M PE models.

Model variation	Δ Continue Rate
+ WILD train data (Round 2)	+1.3 ± 0.7%
90M → 622M parameters PE	−3.2 ± 0.7%
+ Negative context training	+2.6 ± 1.3%
+ Decoding control	+2.5 ± 1.1%

Table 5: Deployment-based Evaluation: changes in continue rates for various model variants.

methods used together improving more. We confirm these conclusions in Table 5 where we show the change in continue rates when independently adjusting one of these factors, by averaging over model continue rates for other factors of variation.

We also observe the unexpected result that the larger models perform worse than the small models across the board on continue rates. Deeper analysis given in appendix D suggests that while the larger model makes less mistakes, it is more often seen as boring, which impacts a player's desire to continue playing. Understanding and controlling this trade-off should be studied further.

5.3.5 Data Quality

Not every player is as engaged in the game as every other player, or produces as high quality dialogue. We hypothesize that we can predict which players produce higher quality data via the acting score model (Sec. 4.1), and that such higher quality data is relatively better for training models.

Figure 3 (right) shows the distribution over the WILD training set of predicted quality using the acting score model. We observe 83.7% of the episodes have a score above the minimum value of 6 (there are 6 turns, and on each turn a score between 1-4 is awarded, explaining the spike at the value of 6). Scores below 6 indicate incomplete dialogues, which only account for 4.0% of the data.

To assess whether these scores are indeed indicators of data quality, we selected an equal amount

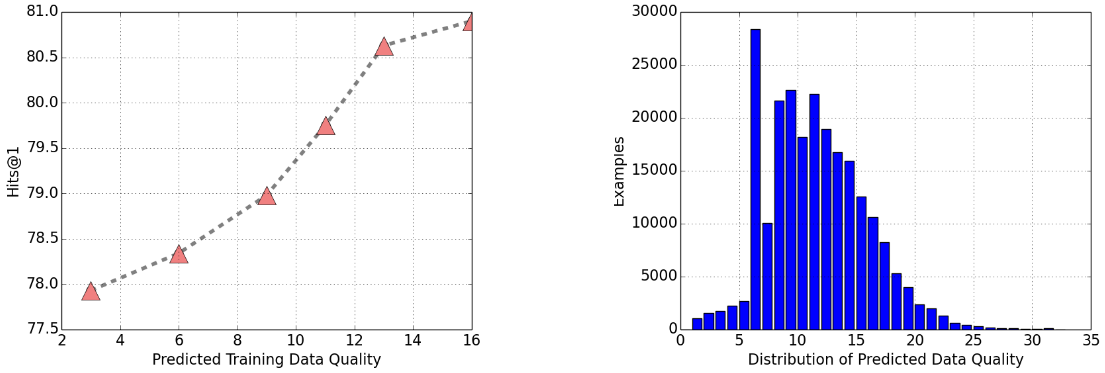

Figure 3: **Predicted Data Quality**. Left: Hits@1/20 accuracy on the WILD validation set when training with LIGHT MTurk + 10,000 examples from the WILD training set of a given predicted quality level, see Sec. 5.3.5. Data that is predicted to be higher quality yields improved validation accuracies. Right: The distribution of data quality predictions over the training set. A spike is seen at quality bin 6 because that is the lowest score one can achieve when completing a full episode (1 star per turn is awarded at minimum). Values lower than bin 5 indicate incomplete low-scoring episodes.

of 10,000 examples from each of the bins (1-5), (6), (7), . . . , (16) (grouping 1-5 together to make that group large enough) and compared them as training sources. We train a set of retrieval models on these training sources, where each model also has access to all of the LIGHT MTurk data (111k examples) in addition to the WILD 10k from their respective bins. The results are given in Figure 3 (left). We observe a monotonic improvement on the WILD validation set with increasing predicted quality. We see similar, but smaller gains on the LIGHT (Seen) validation set as well, e.g. 86.59% for quality bin 6, and 87.11% for quality bin 16.

While we can clearly select lower or higher quality data, we can also ask the question whether some of the data is so low quality we should simply remove it from the training data in order to get better performance. Experiments show that is not the case, and that even the lowest quality data does provide a useful signal, e.g. performance drops slightly from 87.06% to 86.69% on the WILD validation set if we remove bins lower than 6, but otherwise training on all other data, and to 85.38% if we remove bins lower than 9.

5.3.6 Analysis of Data Distribution

We can compare the dialogue data collected within our deployed system to crowdsourced data from LIGHT MTurk. We analyze over and underexpressed words in our dataset compared to the latter.

Calculating the top 70 most overexpressed words, all overexpressed at least 3.5x relative to crowdsourced data, we note several interesting observations about our data's distribution. There are more natural endings to conversations: e.g. "goodbye" (4×) and "bye" (4×) are overexpressed. There are overexpressed words associated with aggression: "stab" (8.5×), "dagger" (6.1×), "club" (5.5×), "kills" (4.9×), "blade" (4.2×). There are overexpressed words associated with overtly friendly actions as well: "smiles" (12.9×), "nods" (10.9×), "kiss" (6.1×), "hug" (3.7×), and "bows" (5.9×). There are more mentions of adventuring: "quest" (5.4×), and other similar words not in the top 70 are overexpressed as well, such as "adventure" (2.5×) and "mission" (2.1×). There is an increased use of slang: "ur" (93×), "u" (28×), "yo" (5×), "dude" (6×). We note that some emojis exist as well that do not appear in the crowdsourced data.

In contrast, looking at the 70 most underexpressed words, all underexpressed by a factor of at least 1.3×, we observed the following patterns. There are less mentions of village and farm life: "peasant", "fields" (both 2× underexpressed), "farm" and "crops" (both 1.9×), "harvest" (1.8×), "villagers" (1.7×), and "work" (1.4×). There are less mention of passages of time: "week" (2.1×), "year" (1.9×), "days" (1.8×).

Overall, we see a pattern that game players seek more exciting conversations, involving more emotional, action-packed interactions such as seeking quests, whereas crowdworkers are more even-keeled, and discuss dry topics such as last year's harvest or taxes with more frequency. This is not unexpected as players often seek immediacy and larger-than-life experiences (Grodal et al., 2000).

6 Conclusion

We have presented an approach for training dialogue agents during deployment with organic users utilizing a role-playing game between humans and bots. Detailed experiments show that one can collect high quality data that improves both automatic offline metrics and user engagement metrics. We find this exciting because this shows that it is possible to build continually improving models that learn from interacting with humans in the wild which represents a paradigm shift away from the limited static dataset setup that is prevalent in much of the work of the community. We make our code and data publicly available, and note our setup can be applied more generally, e.g., incorporating both dialogue and actions, or situated in other domains.

A Further Game Details

Other Gamification Steps The acting scores (between 1-5 stars per turn) are accumulated, and a player's total score is presented on a leaderboard compared to all other players, providing further motivation to reach the top of the leaderboard. We also award "badges" if, for a given dialogue, a certain number of points is collected (11 for 1 badge, 16 for 2): the badges represent the characters in the game, motivating the desire to role-play all the characters in the game, and collect all the badges.

License Agreement and Public Release Upon entry to the game, players are asked to agree to the use and release of the resulting game data as a publicly available dataset for research purposes. They are urged to stick to their assigned characters in the game, and hence should not use any personally identifying information, which the terms also tell them explicitly not to share. In the released data, no other information about the player is retained except for the messages they send in the game.

Game Safety We employ a safety classifier (Dinan et al., 2019a) on both human and model turns. For safety reasons, we limit our deployed dialogue models to be retrieval models, so that we could vet the entire set of candidates for offensive language before run-time (we evaluate generative models in an offline setting only). The set of settings and character personas were all also vetted for offensive language. Additionally, gender bias concerns have been previously studied within the available LIGHT MTurk training set (Dinan et al., 2020), and we make use of that publicly available data here as well. We note that, compared to other deployed dialogue systems, there is an extra level of indirection due to playing characters in a game that makes language relatively less offensive. For example, a thief in the game saying "I'm going to steal your money" to another game character is far less offensive compared to a digital assistant saying it directly to a human user.

B Game Screenshots

We show game screenshots in Figures 5 and 6.

C Using WILD Model responses

In our main results we use the human utterances collected from the role-playing game to form the WILD dataset targets, the hypothesis being that model utterances may or not be correct, and so are not as good a signal. A contrasting view could see training on the model utterance data as a kind of distillation of the previous model's knowledge. To test the performance of WILD human vs. model utterances, we conducted further experiments comparing them to each other. We observe a significant drop in Hits@1/20 performance using the model utterances for training on the WILD validation set (86.05% for human utterances, and 73.96% for model), and similarly on the LIGHT validation set (82.32% for human, and 77.56% for model).

A similar trend emerges when evaluating our generative models. As before, we see a drop in performance when training on WILD model utterances vs. training on WILD human utterances, manifesting as significant increases in perplexity on the WILD validation set (12.05 for human utterances, and 15.15 for model) as well as the LIGHT validation set (13.71 for human utterances, and 14.76 for model).

With the generative models, we additionally explored multi-task training with both the model and human utterances. In this regime, we introduced a special control token to indicate whether the desired response was produced by a model or a human; at inference time, we always provide the "human" control token. Including the control tokens in the training setup yields lower perplexities compared to vanilla multi-task training on both the WILD validation set (12.10 with control, 12.34 without) and the LIGHT validation set (13.60 with, 13.65 without). We note that, overall, multi-task training yields marginally worse performance on the WILD validation set and marginally better performance on the LIGHT validation set (see numbers in previous paragraph).

D Comparing Small and Large Model Variants

We evaluated the differences between the small and large retrieval models (Sec. 4.1) during deployment to analyze the differences between them. Results for both large and small models are shown in Table 7. The expectation tends to be that larger models would perform better, especially when the automatic metrics reflected this case. To eliminate the possibility that difficulty in tuning the decoding control differed between the small and large models, we launched a task to crowdworkers to evaluate the models shown in rows 3 and 8 of Table 4. These

Model	Contradiction	Mistaken Identity or Location	Off-topic	Repetitive or Boring	Rating	Count
90M PE	3.9%	9.1%	8.4%	2.1%	3.67	88
622M PE	3.0%	5.3%	6.0%	5.3%	3.69	91

Table 6: Percentage of utterances flagged with an issue alongside overall satisfaction, by model.

correspond to the small and large models trained with LIGHT + WILD data without decoding control, further noted as LW90M and LW622M.

Workers were asked to have a 12-turn conversation with a model (6 turns each), and evaluate each model utterance with respect to some of the most common mistakes we observed models making. They were then asked to provide an overall score for the model, answering "How much fun did you have Role-playing with your chat partner? Would you have a similar conversation with this chat partner in the future?". Results are given in Table 6, listing the percentage of utterances falling into each mistake type.

We observed that LW622M avoided a number of common mistakes when compared to LW90M, contradicting itself less frequently, assuming the role of the wrong character or using a wrong location less frequently, and going off-topic less frequently. These types of mistakes were common complaints of players interacting with our game, and all seemed to be related to having somewhat bad experiences. LW622M also had a higher percentage of conversations without any listed issues, with 34.1% compared to 27.3% for LW90M.

LW622M however was rated as being repetitive or boring more than twice as frequently as the smaller model. This difference could be supported in that LW622M used utterances that were on average 2 words shorter than those of LW90M over these evaluations. This issue could explain the phenomenon where players are more likely to leave after interacting with a larger model than a smaller one. The only thing really encouraging unpaid players to continue interacting with our models is that they are fun and engaging, and while it is possible to overlook the model making a mistake if it is still somewhat fun, it is likely less possible to remain engaged when the model is actually boring and repetitive.

While LW622M is a better model across several aspects, it is clear from our live deployment evaluations that something is lost in scaling up from LW90M. Comparing these models with real players lets us see this issue, and moving forward should lead us to search for a model that does not become more boring when learning to not make mistakes.

Model	Train Data	Negative Context	Decoding Control	Continuation Rate
90M PE	LIGHT	yes	no	$72.2 \pm 1.9\%$
90M PE	LIGHT	yes	yes	$74.1 \pm 2.0\%$
90M PE	LIGHT + WILD	yes	no	$73.6 \pm 1.8\%$
90M PE	LIGHT + WILD	yes	yes	$75.2 \pm 2.0\%$
622M PE	LIGHT	no	no	$68.2 \pm 1.4\%$
622M PE	LIGHT	yes	no	$69.9 \pm 1.9\%$
622M PE	LIGHT	yes	yes	$69.9 \pm 2.0\%$
622M PE	LIGHT + WILD	yes	no	$70.6 \pm 2.1\%$
622M PE	LIGHT + WILD	yes	yes	$71.8 \pm 1.9\%$

Table 7: Deployment-based Evaluation, comparing several metrics on data collected during round 2.

E Observations on Gamification

Just as the design of a crowdsourcing task will affect the cost and quality of data, this is likely even more the case in the design of a game. If the design is poor, players will not play it at all; whereas in contrast to paying crowdworkers, if players really like a game, they are willing to pay to play it. Accordingly, the plots we presented in Figure 2 represent the results of our particular game design; there may well be a design with vastly more cost efficient learning rates. While a full of study of the elements of game design is outside of the scope of this paper, we note that for adjustments we did make to the game after initial deployment we observed large changes in user behavior. For example, after the addition of the three user controls for how to continue the game loop after an episode is finished (as described in Sec. 3), compared to only a single choice, we saw an increase in the continue rate by $3.3 \pm 1.6\%$ when using the same model.

Model quality also affects cost and quality of the data collected. Noting the effects of changing gamification options (alongside other hard-to-track circumstances) we only report continue rate comparisons between models relative to runs in the same batch. Still, players' enjoyment of these models (as estimated by continue rate in Table 4) directly changes how much they engage with the game. As such it is more expensive to test models that are worse for the game experience (which we would consider fair from a player perspective). Hence, as models improve, costs actually go down, enabling to collect data at higher rate.

Go: Large cliffs

You are in the Large cliffs.
Towering cliffs of gray granite line the coast. A few meters of sand lie between the ocean and the base of the cliffs.
A mountain lion is here.
You are carrying a dustpan and a hand plow.

Hail, Lion King.

mountain lion. What are you doing here goat?

I am looking for succulent, hard to reach grasses.

🏅🏅🏅 (3 Star!!)

mountain lion. Must be hard to find this far up the mountain?

That's why I have my plough to scrape and look for extra goodies in the soil! What about you?

⭐⭐⭐ (3 Star!!)

mountain lion. My master is visiting the maidens cottage and I am able to exercise in the meadow in the mean time.

Who is your master?

mountain lion. He is a noble man. You shouldnt ask questions about my master.

Fine. What kind of exercises are you doing?

mountain lion. Lots of cardio, squats, and bench presses! I may be a servant, but I have a lot of time to workout!

You look so tough and strong! Very envious!

⭐⭐⭐ (3 Star!!)

mountain lion. Ach, well, its been many a year since Ive been called strong. Although I was once a fierce warrior in my day!

Swish! A portal door opens in the thin air. The Dungeon Master strides out and turns to you. Good work! The Dungeon Master gives you a badge to celebrate your role-playing skills: 🦙 You already had one of these, but the more the merrier I suppose.
You've collected 6 badges so far.
Your score increased by 12 points from your role-playing skills!

Deep Learning against COVID-19: Respiratory Insufficiency Detection in Brazilian Portuguese Speech

Edresson Casanova[1], Lucas Gris[2], Augusto Camargo[3], Daniel da Silva[2], Murilo Gazzola[1], Ester Sabino[4], Anna S. Levin[4], Arnaldo Candido Jr[2], Sandra Aluisio[1], Marcelo Finger[3†]

[4]Faculdade de Medicina, University of São Paulo, São Paulo/SP, Brazil

Abstract

Respiratory insufficiency is a symptom that requires hospitalization. This work investigates whether it is possible to detect this condition by analyzing patient's speech samples; the analysis was performed on data collected during the first wave of the COVID-19 pandemic in 2020, and thus limited to respiratory insufficiency in COVID-19 patients. For that, a dataset was created consisting of speech emissions of both COVID-19 patients affected by respiratory insufficiency and a control group. This dataset was used to build a Convolution Neural Network to detect respiratory insufficiency using speech emission MFCC representations. Methodologically, dealing with background noise was a challenge, so we also collected background noise from COVID-19 wards where patients were located. Due to the difficulty in filtering noise without eliminating crucial information, noise samples were injected in the control group data to prevent bias. Moreover, we investigated (i) two approaches to address the duration variance of audios, and (ii) the ideal number of noise samples to inject in both patients and the control group to prevent bias and overfitting. The techniques developed reached 91.66% accuracy. Thus we validated the project's Leading Hypothesis, namely that it is possible to detect respiratory insufficiency in speech utterances, under real-life environmental conditions; we believe our results justify further enquiries into the use of automated speech analysis to support health professionals in triage procedures.

1 Introduction

This work started as part of the academic initiative to help in the effort to deal with the COVID-19 pandemic in a severely affected region in Brazil. COVID-19 is an infectious disease caused by the virus SARS-CoV-2. This illness is mainly associated to severe acute respiratory syndrome, although it is harmful to other organs, like heart, kidney and brain. About 82% of cases are mild or moderate, while the rest are severe or grave, demanding hospitalization or intensive care. The most vulnerable groups are people over the 60's, and people with specific medical conditions such as diabetes, obesity, hypertension and heart disease. According to WHO[1], in August 3 2020, more than 19.2 million people in the world had contracted COVID-19, with a Case Fatality Ratio of CFR=2.8%. Respiratory Insufficiency (RI) is a symptom that requires hospitalization, which is aggravated due to a frequent COVID-19 condition called *silent hypoxia*, low blood oxygen concentration without breath shortness (Tobin et al., 2020).

This work ***leading hypothesis*** states that *it is possible to detect respiratory insufficiency by analyzing spoken utterances in real-life conditions*, typically a moderately large sentence, thus subscribing to the view of *speech as a biomarker*. This work aims at validating this leading hypothesis using deep learning techniques.

If the hypothesis holds, it will motivate further enquiries on the use of automated speech analysis to support health professionals; with infectious diseases such as COVID-19, a serious concern involves deciding whether an RI suspect should stay in social isolation or be directed to a medical facility. Project SPIRA[2][3] was initiated to investigate the feasibility of supporting medical triage of patients with COVID-19 symptoms by remotely detecting respiratory insufficiency through automated speech utterance analysis, where no other resources are

available other than a phone line or a cellphone app. A positive result may motivate further research into speech-based remote detection of respiratory problems originating from other causes, such as heart condition, airway obstruction, severe asthma, H1N1, etc.

This research started as a response to the peak of the first COVID-19 wave in 2020, when health infrastructure was overloaded, so no doctors nor nurses were available for data collection, and there was no triage point available for research. Thus, COVID-19 patient utterances were collected mostly by medical students at COVID-19 wards from patients with blood oxygenation below 92%, as an indication of respiratory insufficiency, and control data was collected by voice donations over the internet, assumed healthy, with no access to blood oxygenation. Recordings were made in out-of-studio conditions, using portable recording equipment employed in noisy wards. On the other hand, conditions for healthy voice donations over the Internet and using diverse sound equipment had a large variation. This *audio data in-the-wild* approach was assumed from the start as part of the challenge of validating the leading hypothesis. Part of the methodological novelty of this work lies on how to deal with these conditions. This task required a multidisciplinary group involving medical doctors, linguists, speech therapists and computer scientists, all of which were aware of those conditions and challenges facing us.

This work proposes a machine learning method to detect respiratory insufficiency by analyzing voice audio recordings of sentences long enough to feature respiratory pauses in speech. The test is very cheap, requiring only a voice sample from each patient and maybe employed where no other medical equipment is available.In order to tackle the audio analysis, we propose the use of deep artificial neural networks over Mel Frequency Cepstral Coefficients (MFCCs) (Logan et al., 2000) extracted from patient's audios.

The code and datasets are publicly available at `https://github.com/SPIRA-COVID19/SPIRA-ACL2021`, under a CC BY-SA 4.0 license.

This paper is organized as follows: Section 2 discusses related work. In Section 3, the dataset acquired, the preprocessing steps, the noise insertion procedure, the proposed model and experiments are described, respectively. Afterwards, the models obtained are evaluated and discussed in Section 4. Finally, Section 5 presents the conclusions and final thoughts.

2 Related work

COVID-19 is a recent disease. However, even before the eruption of the pandemic, we could already find in the literature a few explorations of speech as a biomarker (Botelho et al., 2019; Trancoso et al., 2019; Nevler et al., 2019), with some recent recommendations (Robin et al., 2020).

Several initiatives can be found on the Web that record human voice in order to assess the presence and the gravity of COVID-19, e.g. the COVID-19 Sounds data collection initiative (Brown et al., 2020) and startup initiative aiming to develop a pre-diagnostic tool[4]. Those works aim to diagnose COVID-19 from voice or breathing or coughing sounds, and there are some initial positive results on COVID-19 detection in asymptomatic individuals (Laguarta et al., 2020). Unlike our approach, no work aimed specifically at respiratory insufficiency or at patient triage, but they propose to employ some form of artificial intelligence processing.

In similarity to our goals, there have been recent proposals of applications for the triage of patients using natural language processing of texts extracted from radiology reports (Hassanpour et al., 2017) and patient questionnaires (Spasić et al., 2019). So language, both as text and now as speech, is being used for patient screening.

Moreover, Neural Networks and Convolutional Neural Networks (CNNs) have been used in noisy environments mostly, but not exclusively, for fault diagnosis (Zhang et al., 2018; Munir et al., 2019), noise reduction in voice processing (Maas et al., 2012) and medical ECG diagnosis (Acharya et al., 2017). On the other hand, *noise injection* was a technique used in the past to avoid overfitting in training Neural Networks (Matsuoka, 1992; Grandvalet et al., 1997; Zur et al., 2009), as opposed to avoiding classification biases, as in our approach.

3 Methodology

In order to build a neural network model for the proposed task, it is necessary to gather a dataset containing voices of healthy individuals and COVID-19 patients (Section 3.1). The resulting dataset required several preprocessing treatments and noise treatment, as discussed in Sections 3.2 and 3.3. The next step was to propose several neural models to

---

[4] https://www.voicemed.io/

investigate the best one for the task (Section 3.4) evaluated according to experiments carried over the dataset (Section 3.5).

3.1 Dataset

The dataset creation was composed of two parts and an "appendix". The first part consisted of audios gathered via Web by a system specifically designed for this task[5], from May to July of 2020. Healthy volunteers were asked to donate audio samples via a web interface. This allowed us to build our control group. In order to do that, the system URL was disclosed through local news and social networking. The resulting dataset part is composed, after elimination of blank samples, of more than 6 thousands voice donors. No blood oxygen saturation information was available for the control group.

In the second part, we collected audios from patients infected by SARS-CoV-2 from June to July of 2020. This collection was performed in COVID-19 wards in two university hospitals, in São Paulo city, Brazil, restricted to patients with blood oxygenation level (SpO2) inferior to 92%, as an indication of respiratory insufficiency. This allowed us to collect 536 samples from patients in different age groups. Several problems led to discarding patient voice samples, chiefly among which were collectors whispering during collection; a large set of collection instructions was assembled during the period in which voice collection took place. It is important to note that São Paulo is a local and international hub, with a large migrant and immigrant population. Hospitals received COVID-19 patients from the city as well as from adjoining regions. Collection was absolutely anonymous, so no one knows who were the patients and controls, and no ethnographic information is available. On the other hand, this allowed us to release the data.

As a COVID-19 ward is a noisy environment, an "appendix" was built for this dataset, consisting of samples of pure background noise at the ward (no voice), typically collected at the start of a collection session. This is an important piece of information, as the ward noise is very different from the background noise found in the control group, and consists of a *data bias* that has to be controlled during experiments.

The gathered audios contain three utterances:

- Utterance 1, a moderately long sentence containing 31 syllables, designed by linguists to allow for spontaneous breathing breaks, while being relatively simple to be spoken, even by low literacy voice donors: *"O amor ao próximo ajuda a enfrentar o coronavírus com a força que a gente precisa."* ("Love of neighbor helps in strengthening the fight against Coronavirus.");
- Utterance 2, a well known nursery rhyme for donors having reading difficulties, due to lack or reading glasses in hospital, or other types of reading impediments: *"Batatinha quando nasce, espalha a rama pelo chão, nenezinho quando dorme põe a mão ao coração"* ("When small potatoes germinate, branches sprout on the ground; when baby sleeps, hands rest over the heart");
- Utterance 3, a widely known song, on the lines of "Happy birthday to you": *"Parabéns a você, nesta data querida, muitas felicidades, muitos anos de vida"* ("Happy birthday to you, on this dear date, lots of happiness, many years of life").

Collecting longer utterances was totally impractical in a COVID-19 ward. The collection had to be adapted to what was possible in that context.

We identified several issues with the original dataset that need to be addressed. First, there is class imbalance, as we have fewer positive instances (COVID-19 patients) than negative ones (healthy individuals from the control group). Second, it is sex imbalanced, as a greater number of healthy women participated in the process than healthy men. Additionally, there are more men in COVID-19 wards than women. Third, there is an age imbalance, as there are more elderly in hospital care than young people in our observations. Fourth, we also detected utterance imbalance, as utterance 1 was more common among patients; healthy people typically recorded all proposed utterances. Fifth, the control group presented popping and crackling noise, possible due to the characteristics from the recording devices. Furthermore, as mentioned above, wards tend to be noisy environments.

We addressed most of the dataset issues by sample balancing, taking advantage of the greater number of control group samples. Only audios from utterance 1 were selected and the number of samples used in experiments was balanced by class and sex, but not by age, to avoid drastically reduc-

---

[5] https://spira.ime.usp.br/coleta/

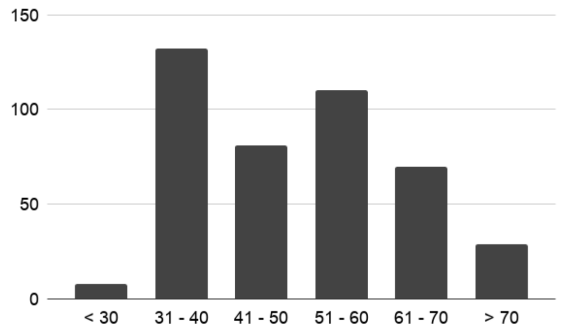

Figure 1: Distribution of Ages in the Dataset

ing the available data. Overall age distribution is presented in Figure 1.

We also had to discard audio containing the collector's (whispering) voice. The most serious issue for bias removal, though, is the presence of ward background noise in patient audios; we observed that it is easier to insert ward noise in the control group than to remove it from the patients' signal. This process will be addressed in Section 3.2.

The dataset was divided in training, validation and test, as is usual in statistical learning. We selected audios with the best signal-noise ratio to use in the test set, and the second best audios were used for validation. The aim of this partitioning is to detect training overfitting.

Information of the resulting filtered dataset is presented in Table 1.

3.2 Pre-processing

In general, the majority of the audios in the dataset was sampled at 48kHz. We pre-processed these files using Torch Audio 0.5.0 in the following way. First, for dimensionality reduction reasons, we re-sampled these audios at 16kHz. Second, we extracted the MFCCs using a 400ms window employing Fast Fourier Transform (FFT) (Brigham and Morrow, 1967), with hop length 160 and 1,200 FFT components, of which we retained only 40 coefficients. Before the MFCC feature extraction process though, we need to address the difference of duration present in our data.

The duration of our samples in the dataset varies, in which audios from the positive class are slightly longer than audios from the negative class, as presented in Table 1. We have developed two approaches to deal with this phenomenon. First, we applied padding in the instances during training. This is equivalent to complete the audios with silence so that all audios have the same duration. Second, we have extracted fixed length fragments from the audios. This approach aims to prevent the model from performing the classification giving too much importance to the audio length. In order to augment the training data, windowing with 1 second steps was applied to extract audio fragments.

3.3 Noise Insertion During Training

Ward noise is a serious bias source, as confirmed by our preliminary experiments (Section 4). In this scenario, a neural network can be biased during training by focusing only on background noise. One possible alternative would be noise filtering, but besides the possibility of inserting extra biases due to differential noise suppression in patient and control audio samples, there is also the possibility of suppressing important low-energy information that allows for the distinction between healthy and respiratory affected speech samples.

To address this issue, we decided to record pure background noise samples from COVID-19 wards and to inject into patients and control group audios. In total, 16 samples with approximately 1 minute each were recorded.

The inserted noise can also be a cause of bias, as the model can extract specific features from the noise recording. To avoid this kind of bias, we decided to inject noise in all samples. We had the option of inserting in training, validation and testing samples, which will be described in Section 4. We can also control the amount of noise samples inserted in each audio.

In our experiments, we investigate the ideal number of noise samples to inject in both patients and the control group. This had a big impact in overfitting prevention, as a form of unbiased learning, as described in Section 4. During training, at each epoch, audio samples can be injected with one or more distinct noise samples. Each time a given audio is used for training, noise samples are drawn from the noise base. Besides that, the start point of each noise sample is also randomized. Finally, we also draw a factor to change the intensity of the sample. This factor is constrained by a maximum amplitude value, which was determined from the analysis of patient audio noises. The aim is to insert noises as similar as possible to already pre-existing noise. We also executed the same experiment three times with different random seeds to obtain better measures of the noise insertion impact.

Table 1: Filtered dataset information

Sets	Control			Patients			Total Audios	Total Duration (s)
	Male	Female	Mean Duration (s)	Male	Female	Mean Duration (s)		
Training	59	84	8.15	83	66	13.18	292	3110
Validation	8	8	7.75	8	8	10.78	32	296
Test	22	26	7.77	28	32	9.43	108	983

The test and validation sets were created in such a way to allow overfitting detection as they are composed mostly of audios with very limited amount of noise. As a result, we cannot apply k-fold Cross Validation and similar methods. We compensate this by running the same experiment three times with different random seeds. This fact, together with the dynamic noise insertion during training, allows us to obtain averaged accuracy for each experiment.

3.4 Proposed Model

Several models were tested in preliminary experiments and we describe the one that led to the best results.

This process involved three main aspects: (a) the topology and model parameters; (b) the main hyper-parameters; (c) regularization. The last is especially important, since our dataset contains several issues that can lead to overfitting.

Regarding topology and model parameters, preliminary experimental results showed that CNNs applied to MFCCs are useful to analyze this kind of problem. Other preliminary experiments investigated spectrograms and topologies like fully-connected and recurrent networks, which showed lower performance than the chosen topology. Figure 2 presents the chosen model's main features including layers, filters, kernels, number of neurons and activation functions. The following conventions are adopted in the figure: kernel size is represented by K; convolutional dilation size (Yu and Koltun, 2015) is represented by D; and fully connected layers are represented by FC. The input size is omitted because these parameters changed according to the experiment and will be detailed in Section 3.5. We investigated the use of Mish activation function (Misra, 2019), due to its regularization effects during training, which helps prevent overfitting.

Regarding the main hyper-parameters, we have used the Binary Cross-Entropy as loss, and Adam optimizer (Kingma and Ba, 2014). The initial learning rate was set to 10^{-3}, and the Noam's decay scheme (Vaswani et al., 2017) was applied on each 1,000 steps. For each experiment presented in Section 3.5, we trained the model for 1,000 epochs using a batch size of 30.

Regarding regularization, overfitting mitigation is a major concern given our dataset noise characteristics. Therefore, several approaches for regularization were applied. Besides Mish as an activation function, we used three other strategies. First, a global weight decay of 0.01 was applied. Second, a dropout of 0.70 was used in all layers, except in the output layer. Last, we applied group normalization (Wu and He, 2018) after each convolutional layer. The group normalization was applied on pairs of convolution filters. Therefore, the number of groups is half the number of filters.

3.5 Experiments

For the experiments we explored three main aspects with respect to noise insertion and duration variance: (a) overfitting impact; (b) padding vs windowing approach (using four second windows or adding padding); and (c) the ideal number of noise samples. Table 2 presents the proposed experiments and their results.

First we investigated if the model can overfit when trained over original audios (experiments 1.x). In this series of experiments, we trained the model using both approaches of duration variance.

Second we analyzed two approaches to address the duration variance: audio padded to the maximum length of the dataset; windowing using the approach described in Section 3.2 (experiments 2.x). Specifically, we presented padding application only in experiments 1.1 and 2.1 because experiments showed that the windowed approach led to more robust results. When padding is used, the accuracy is calculated as usual. However, in windowed experiments, several audio fragments are extracted and their predictions averaged for the classification decision. Regarding window size, we have chosen four seconds, considering our smallest audio in the

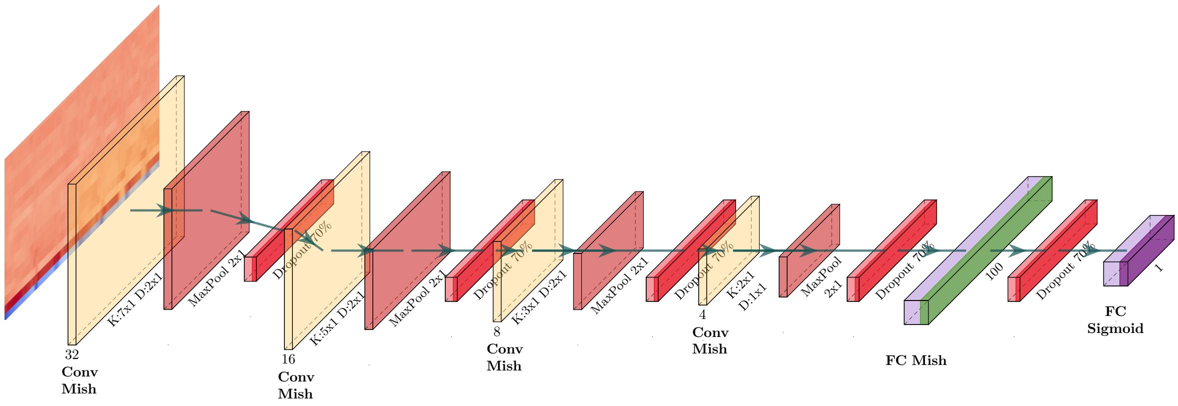

Figure 2: CNN topology proposed with four convolutional layers and two fully connected layers

Table 2: Proposed experiments and results

Description	Exp.	Duration Approach	Noise Samples		Accuracy (without noise in test samples)	Accuracy (with noise in test samples)	Training time (h)
			Patient	Control			
Overfitting Analysis	1.1	Padding	0	0	98.15 ± 0.93	50.93 ± 0.53	4.25
	1.2	Windowing	0	0	98.15 ± 0.53	50.93 ± 0.93	9.07
Duration Variance Analysis	2.1	Padding	0	1	61.11 ± 8.40	74.07 ± 1.93	4.77
	2.2	Windowing	0	1	66.67 ± 3.74	86.11 ± 2.98	9.58
Noise Insertion Analysis	3.1	Windowing	1	1	80.56 ± 2.45	68.52 ± 1.41	6.57
	3.2	Windowing	1	2	84.26 ± 6.17	83.33 ± 3.34	12.27
	3.3	Windowing	2	2	88.89 ± 0.53	85.19 ± 0.93	13.00
	3.4	Windowing	2	3	74.07 ± 5.10	85.19 ± 1.85	13.67
	3.5	Windowing	3	3	91.67 ± 2.98	87.04 ± 0.93	14.70
	3.6	Windowing	3	4	62.96 ± 8.35	74.07 ± 2.45	11.85
	3.7	Windowing	4	4	88.89 ± 1.41	83.33 ± 1.07	10.40
	3.8	Windowing	4	5	56.48 ± 5.10	72.22 ± 9.99	9.83
	3.9	Windowing	5	5	70.37 ± 15.8	69.44 ± 9.27	10.55
	3.10	Windowing	5	6	51.85 ± 3.51	61.11 ± 2.98	11.18
	3.11	Windowing	6	6	74.07 ± 10.7	74.07 ± 8.83	11.98
	3.12	Windowing	6	7	50.00 ± 0.53	54.63 ± 3.51	12.63

dataset contains 4.6 seconds and new data samples can be even smaller.

Third we examine the ideal number of noise samples to be inserted to prevent overfitting (experiments 3.x), using the best duration approach according to experiments 2.x. For each experiment, we tested the model using both noise insertion and no noise insertion to analyze performance.

Our model was implemented using Pytorch 1.5.1. We ran the experiments on a NVIDIA Titan V GPU with 12GB RAM in a server with Intel(R) Core(TM) i7-8700 CPU and 16GB of RAM.

4 Results and Discussion

To better understand bias and overfitting we used a test set containing only audios with a minimal amount of noise. The accuracy of each experiment is presented in Table 2, both with and without artificial insertion of ward noise in test samples.

Experiments 1.x showed the model is biased without noise insertion in the training set. We note a high accuracy in experiments 1.1 and 1.2 without noise in training and testing; in contrast, when noise is inserted in all test samples, it classifies all samples as coming from patients. We interpret this as a strong indication that the model is biased by the presence of noise in the patient samples.

Experiments 2.x showed that windowing (2.2) is preferable over padding (2.1), as described in Section 3; the model performs better when the windowed approach is used, that is, 66% using windowing against 61% using padding. We consider this as evidence of susceptibility to bias by padding. In fact, padding inserts a considerable amount of silence, specially in patient samples, and the windowed approach works as a data augmentation technique, as more instances are generated in this process.

Experiment 3.x were used to determine the optimal amount of noise insertion. Note that sometimes better results were obtained without noise in test samples and sometimes the other way around. In general, the bias is greatly reduced by inserting at least one noise sample on the negative instances. As expected, the insertion of too much noise decreases the model performance. The best overall accuracy was obtained in experiment 3.5, which reached 91% accuracy in the task. For experiment 3.5, we obtained F1 = 0.90, without noise insertion; with noise insertion, F1 = 0.87.

Figure 3 presents the loss variation of the best model (experiment 3.5) during training. Early stopping is used to get the best iterations after approximately 20k steps.

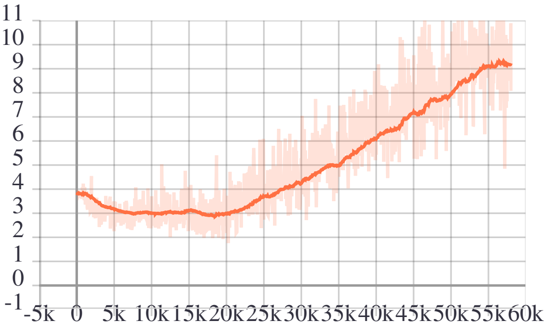

Figure 3: Validation Loss for Experiment 3.5 during Training

Figure 4 shows the model performance over the number of noise samples inserted. With respect to the number of noise samples, our experiments suggest that a number of 2 to 4 noise insertions in each audio provides best accuracy. In each case, two possibilities have been tested, namely the insertion of an equal number of noise samples in each training audio, and the insertion of one extra noise sample to control audio, assuming that patient audios already have the original ward noise. It was initially expected that the insertion of an extra noise sample in control audios would produce better results; surprisingly, the opposite effect was observed. The possible explanation for this observation is that there are times when wards are calmer and silent and the insertion of noise in control audios leads to bias. This is especially true for testing samples, due to the criteria used to build the testing set.

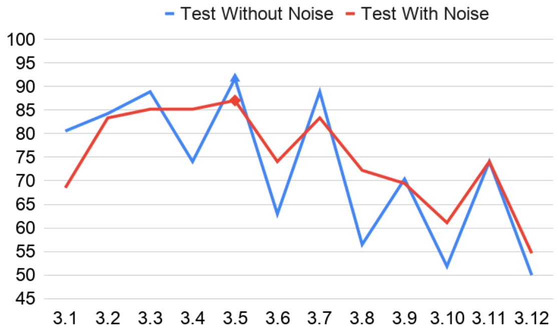

Figure 4: Sample Noise Analysis for the Best Experiments

5 Conclusions and future work

In the effort to tackle the COVID-19, we have developed a method to classify real-life speech audio signals on whether or not that signal originated from a person suffering from respiratory insufficiency. In this effort, we obtained 91.67% accuracy, thus validating the hypothesis that such a detection is feasible, and that human speech can be treated as a biomarker in this case.

One important consequence of this work was the construction of a dataset containing voice samples of COVID-19 patients with respiratory insufficiency and also a set of samples of environmental noise, which were central in treating real-life sound samples. Noise insertion was chosen as the more adequate option when contemplating the biases that would be incurred by filtering procedures. In particular, it made sense to add ward noise to the existing ward samples as a way to balance the biases that were incurred by the necessary addition of ward noise to control data. In this way, all data (patient and control) suffered from similar manipulation, avoiding editing bias, and experiments showed that such a procedure produced best results. This aimed at preventing the models from memorizing ward noise and editing distortion information instead of COVID-19 features.

There was a considerable difficulty to collect voice data from infected patients during the pandemic. The size of the patient dataset reflects the limitations on collections in COVID-19 wards. Moreover, the use of audio from different environments was absolutely unavoidable, as we only had access to patients in COVID-19 wards, where no control subjects were available. Therefore, control data had to be collected in a different environment. As a result, the amount of data was scarce, and data augmentation techniques were designed for such a setting; our results indicate that it was not an excessive amount of data augmentation, as consistent results were obtained over a large variety of experiments. We hope that with the weakening of the emergency situation, it could become easier to collect data from patients with respiratory insufficiency.

Future work includes augmenting the dataset with audios collected at the triage point, whether in hospital admission rooms, or through a remote admission system. In this way, speech audio signals from both sufferers and non-sufferers of respiratory insufficiency would be obtained under similar conditions. This would allow us to extend this study to other respiratory illnesses besides COVID-19. Also, other neural architectures can be explored, as well as smarter feature engineering.

Abstract

Machine Reading Comprehension (MRC) is an important testbed for evaluating models' natural language understanding (NLU) ability. There has been rapid progress in this area, with new models achieving impressive performance on various benchmarks. However, existing benchmarks only evaluate models on in-domain test sets without considering their robustness under test-time perturbations or adversarial attacks. To fill this important gap, we construct AdvRACE (Adversarial RACE), a new model-agnostic benchmark for evaluating the robustness of MRC models under four different types of adversarial attacks, including our novel distractor extraction and generation attacks. We show that state-of-the-art (SOTA) models are vulnerable to all of these attacks. We conclude that there is substantial room for building more robust MRC models and our benchmark can help motivate and measure progress in this area. We release our data and code at `https://github.com/NoviScl/AdvRACE`.

1 Introduction

The goal of Machine Reading Comprehension (MRC) is to examine whether the model can understand the text and perform certain types of reasoning. To this end, many MRC benchmarks have been constructed in different domains, styles, and languages (Rajpurkar et al., 2016; Lai et al., 2017; Dua et al., 2019b; Cui et al., 2019, *inter alia*). While most of these benchmarks use leaderboards to compare different models' performance on in-domain test sets, they have ignored the important aspect of evaluating models' robustness.

The research on robustness of MRC models can be generally categorised into two directions: generalization to out-of-domain distributions and robustness under test-time perturbations. Regarding generalization to out-of-domain distributions, Talmor and Berant (2019) and the MRQA shared task (Fisch et al., 2019) investigated how well do MRC models trained on source datasets generalize on unseen datasets in different domains.

On evaluating MRC models under test time perturbations, previous works (Jia and Liang, 2017; Gan and Ng, 2019) evaluate models under only one specific attack. However, truly robust models should perform well on different types of perturbed test inputs instead of just one. In this work, we cover diverse types of adversarial attacks to allow for a more comprehensive evaluation of model robustness. Dua et al. (2019a) performed a set of synthetic perturbations to test models' robustness. However, their perturbations are only applicable to specific types of questions, yielding limited number of valid examples, limiting their usefulness in revealing model weakness. This may be because that they only performed perturbations on the questions. In contrast, our proposed methods are applied to different components (passages, questions, distractors) of the dataset and at different levels (sentence and character levels). In section 4.2, we show that all of our perturbations incur significant performance drops on SOTA models, leaving large room for future improvement.

Instead of constructing a new dataset from scratch, we leverage on an existing MRC dataset RACE (Lai et al., 2017), where we apply our proposed attacks on the RACE test set to form our AdvRACE benchmark. We choose to construct our benchmark based on RACE because: 1) The multiple-choice format supports more types of attacks. We generated new distractors to replace the original ones as a novel attack method. 2) RACE covers a diverse set of linguistic phenomena and reasoning types, and has been used widely for evaluating NLU performance (Yang et al., 2019; Liu

et al., 2019; Lan et al., 2020).

Our AdvRACE benchmark contains four test sets for four different adversarial attacks: AddSent, CharSwap, Distractor Extraction (DE) and Distractor Generation (DG). The performance under each attack allows for fine-grained and comprehensive analysis of model robustness. In addition, the advantages of our work include: 1) The pipeline we use to construct AdvRACE is highly efficient and transferable. It can be easily adopted on other MRC datasets to construct the corresponding adversarial test sets. 2) All of our adversarial perturbations are model-agnostic and do not require access to model parameters. Thus it allows for the evaluation of any model to reveal their weaknesses in robustness. 3) Our perturbations are label-preserving. Our human annotations ensured the high quality of our adversarial test sets (section 4.1).

2 Related Work

Adversarial attacks in NLP. Various adversarial attack methods have been proposed for NLP tasks. One type is white-box attack where perturbations are constructed based on models' gradients or parameters to exploit their weakness (Alzantot et al., 2018; Ebrahimi et al., 2018; Wallace et al., 2019). However, such attacks cannot be directly applied when there is no access to model internal parameters. Another type is black-box attack where the perturbation is constructed without accessing model parameters and is often based on heuristic rules or produced by specifically designed models (Jia and Liang, 2017; Ribeiro et al., 2018; Iyyer et al., 2018). While the above approaches construct attacks automatically, there are also attempts on human-in-the-loop adversarial example generation where human annotators are employed to write new test data that can fool the models into making wrong predictions (Nie et al., 2020; Wallace et al., 2018). However, such approach requires significant human and time resources, which may not be easily accessible.

Robustness benchmarks for MRC. Tang et al. (2020) created a Chinese MRC robustness benchmark by constructing distracting questions via retrieval from existing database and human writing. Wu et al. (2020) applied various common synthetic perturbations on the SQuAD dataset to analyse the factors affecting model robustness. Ribeiro et al. (2020) provided a general framework for automatically identifying various types of failures in NLP systems with CheckList. Our adversarial attacks have similar goals as the invariance test in CheckList. However, their template-based checks only examine limited failure types, thus less effective in revealing weaknesses in model robustness as shown by the relative small drop of model performances under invariance tests, as compared to our proposed attacks on MRC.

3 Adversarial Attacks

In this section, we describe the different types of adversarial attacks explored in AdvRACE. In Table 1, we present a comparison of our AdvRACE benchmark with other works on automatic construction of adversarial attacks.

In multiple-choice MRC, distractors naturally play an important part in affecting the difficulty of the dataset. Hence, we propose a novel type of adversarial attack method by constructing new sets of distractors to replace the original ones. We present two different methods of constructing new

Original	**Passage:** "Thanks for coming," Everett said, shaking hands with Mr. Hanson, the town councilor. "I'm curious about the ideas in your letter." Mr. Hanson nodded toward the parking lot near where they stood. ... Everett was relieved that the community representative seemed receptive to the idea. Mr. Hanson studied the photograph, and then asked, "If town council provides the money, how will you and your friends contribute?" Everett felt optimistic now. **Question:** Everett was trying to persuade Mr. Hanson to _ . **Answer:** provide money for a skateboard park **Options: 1.** beautify the neighbourhood **2.** build an art centre for children **3.** cut the area of the parking lot
AddSent	**Passage:** "Thanks for coming," Everett said, shaking hands with Mr. Hanson, the town councilor. "I'm curious about the ideas in your letter." Table 2: Examples of each attack applied on the same original test example. ***Italic*** parts are altered by our adversarial attack perturbations.

distractors: distractor extraction (DE) and distractor generation (DG). Apart from them, we have also experimented four other types of adversarial attack methods: distracting information insertion (AddSent), character swap (CharSwap), word replacement and paraphrase. Among them, we find that WordReplace and Paraphrase do not work well on RACE, hence being excluded from our final AdvRACE benchmark. We provide examples of each adversarial attack in Table 2. The details of the two failed attempts can be found in the Appendix.

3.1 Distractor Extraction

For distractor extraction, we aim to extract spans from the passages as new distractors. This is motivated by the observation that most passages contain distracting sequences that are relevant to the question while semantically different from the correct answer. Such distracting sequences can be especially effective as current MRC models reply largely on text matching (Si et al., 2019).

The key challenge is how do we extract such distracting sequences from the passages without annotated supervised data. In order to solve this challenge, we propose a novel distractor extraction method. We first turn RACE into span-extraction format and adopt the span-extraction QA model used in Devlin et al. (2019) except that we use ALBERT as our backbone model. During training, we insert the correct answers of RACE questions into the passages as the gold answer span. The ALBERT span extractor is trained to select the answer span from the passage. During inference, we use the trained model to extract spans from the passages for the test questions but without inserting the correct answer. In this way, since the answers in RACE have not appeared in the passages in verbatim, there are no gold answer spans for the test examples. However, the extracted spans with high probability can be considered as likely options for the question, which can serve as strong distractors. For post-processing, we select 3 distractors among the top 20 candidate spans that have low lexical overlap with each other and also low lexical overlap with the correct answer, so that they are diverse and label-preserving.

3.2 Distractor Generation

Another way to construct new distractors is to generate them based on the passage and question. We

	BERT	**RoBERTa**	**XLNet**	**ALBERT**	*Average*	**Valid**	**Correct**

Average	40.9 (*-40.3%*)	62.4 (*-25.4%*)	56.6 (*-29.2%*)	66.3 (*-22.9%*)			

Table 3: Left: Attack results on different models. Right: Human evaluation results. *Numbers* in brackets are the percentage drop in performance. Average is computed over all the adversarial test sets for each model, and over all models for each adversarial attack.

frame it as a sequence-to-sequence (Seq2Seq) task where the input is the concatenation of the passage and question, and the output is the distractor. Previous distractor generation works (Gao et al., 2019; Zhou et al., 2020) adopted this approach. However, none of these works has explored using the generated distractors as a way for attacking MRC models. In our work, we use the filtered data from Gao et al. (2019) for training the DG model, where distractors with low semantic relevance with the passages are pruned. For the backbone model, we adopt UniLM (Dong et al., 2019), a competitive pretrained model unifying NLU and NLG. We use beam search to find the top k (beam size, we used $k = 50$) candidate distractors and select the top 3 among them so that their Jaccard distance between each other is larger than 0.5, to ensure diversity of the 3 selected distractors. We provide additional DE and DG examples in Table 9.

3.3 AddSent

Inspired by the method proposed by Jia and Liang (2017), we propose an improved AddSent method to make use of the human-written distractors in RACE rather than generating new fake answers to construct strong distracting sequences to insert into the original passages. The motivation is to add distracting information that appears similar to the question and the distractors so that it can better mislead models. We use the following procedure to construct the perturbations:

1. We change all nouns and numbers in the questions to their nearest word in GloVe (Pennington et al., 2014) embedding space with the same part-of-speech.
2. We replace adjectives, adverbs, verbs in the questions with their antonym in WordNet (Fellbaum, 2000) with the same part of speech. We only change one word in each question to its antonym to prevent confusions caused by multiple negations (e.g., 'likely to obey' being changed to 'unlikely to disobey').
3. If no words are changed during Step 1 and 2 (28.9% of test questions), we insert the negation word 'not' at the appropriate position in the question. The first three steps ensure that there is a flip in the semantic meaning of the original question.
4. We randomly sample a distractor from the original three distractors of the question, and concatenate it with the altered question.
5. We insert the concatenated sequence into a random position of the passage.
6. We repeat Step 1 to 5 one more time with different replacement words from GloVe and WordNet, and using a different distractor. This makes the perturbation more misleading for the model since there is more matching.

3.4 CharSwap

It is shown in Belinkov and Bisk (2018) that NMT performance drops significantly when there are spelling errors in the data. We adapt their approach in MRC to swap two adjacent letters in a word without altering the first or last letters. Although they show that with more tokens altered, the performance gets worse, empirically we find that applying such perturbation to all words in the dataset sometimes impacts the readability of the text and cause difficulty even for humans to perform well. As a result, we only apply the CharSwap perturbation to the following words with character length of four and above: 1) The non-stopwords in the question. 2) Non-stopwords in the passage that have also appeared in the question and its corresponding options. This is based on the observation that these words are usually keywords for solving the question. There are a total of 7.1% words being altered using this method.

4 Evaluation

We apply the four attacks in Section 3 on the original RACE test set to form AdvRACE, which results in four sets of adversarial test sets: AddSent, CharSwap, DE, and DG. Each adversarial test set has 4,934 examples, same as the original RACE test set. We perform human and model evaluations on these test sets.

4.1 Human Evaluation

We randomly sample 50 questions from each adversarial test set in AdvRACE as well as the original test set, and ask paid corporate professional data annotators to answer the MRC questions. To assess the validity of our adversarial data, we add an additional option for each question: unanswerable. If the annotator chooses unanswerable for a question, we further ask the annotator to choose the specific reason why the question is unanswerable, which includes the following options: missing key information, conflicting information, uninterpretable content, no correct options, multiple correct options. The results are shown in the last 2 columns of Table 3. **Valid** rate measures how many examples are considered by the annotators as interpretable (semantically and syntactically acceptable) and answerable. **Correct** rate measures how many examples are answered correctly by the annotators. All the four adversarial test sets have high valid rate close to 100%. The correct rate of the four adversarial test sets are also above the turker performance of 73.3% as reported in Lai et al. (2017). These indicate that the four adversarial test sets in AdvRACE remain well solvable for humans. We also manually analysed the examples answered wrongly by the human annotators. For all the four adversarial test sets, we find that the drop in human performance (correct rate) is due to unrelated human errors (e.g., misunderstanding of the original text) rather than caused by our perturbations.

4.2 Model Evaluation

For model evaluation, all the models are trained on the original RACE training set, tuned hyperparameters on the original RACE dev set, and tested on our AdvRACE benchmark. We evaluate four competitive models: BERT-Large, XLNet, RoBERTa-Large, ALBERT-xxLarge. We concatenate each candidate answer with the corresponding passage and question, then encode each of these four concatenated sequences and pass the representations of the first position of each sequence (i.e., representations of the `[CLS]` token) through a fully-connected layer for answer prediction. The results are presented in Table 3. In addition to reporting the accuracy of each model on each test set, we also report the percentage performance drop relative to the performance on the original test set for the adversarial test sets.

From the results, we find that: 1) BERT is the most vulnerable among these four models (by comparing the average percentage drop in performance in the last row). Models that achieve higher performance on the original test set generally suffer less relative performance drop from the adversarial attacks. 2) Distractor extraction is more effective than distractor generation in terms of attacking the models, probably due to the fact that these models rely heavily on text matching (Si et al., 2019). 3) All of the adversarial attacks in our AdvRACE benchmark incur a significant drop of models' performance, which is much more effective than previous attempts (Dua et al., 2019a) in revealing weaknesses of the most competitive MRC models.

4.3 Adversarial Training

A common baseline to defend such adversarial attacks is to add adversarial examples in training, *i.e.*, adversarial training. We experiment such strategy as a baseline, and find that adversarial training is not a truly reliable defense method as it largely exploits dataset artifacts. We present the detailed adversarial training experiments as well as the follow-up analysis in the Appendix (section D). We believe that better defense techniques are needed to reliably improve model robustness for MRC.

5 Conclusion

In this work, we present AdvRACE, a benchmark that evaluates MRC models under diverse types of adversarial attacks. AdvRACE consists of our proposed distractor extraction and generation attacks as well as improved versions of existing attacks adapted to work effectively on MRC. The performance of four competitive MRC models drops significantly on AdvRACE, indicating the effectiveness of our methods for analysing model weaknesses. We hope our work can motivate the development of more robust models that perform well on different perturbations.

Impact Statement

Our AdvRACE dataset was constructed based on the original RACE dataset, which was released under an MIT license, allowing for free reuse. We have also obtained the permission from the original authors of RACE to use it to construct AdvRACE for research purposes.

The human annotators involved in this project are all full-time employed corporate annotators, who are well-compensated and work in good working conditions.

We believe that building robust and reliable MRC models is crucial for them to be deployed in real-life applications. Our work is far from enough to thoroughly measure the true robustness of MRC models. We hope that it will be a first step leading to more efforts along this direction.

Appendix

A Failed Attacks

We introduce the two attacks that we explored but did not work well: Word Replacement and Paraphrase.

A.1 Word Replacement

For word replacement attack (WordReplace), we adopt the state-of-the-art method: SememePSO (Zang et al., 2020), and we used RoBERTa as the target model to generate the adversarial examples. Then we transferred these adversarial examples to attack other models. The original SememePSO attack was applied on sentence classification tasks. Since the input of RACE is much longer, in order to keep the running time within budget constraints, we have set the population size to 10 and number of maximum optimization iterations to 5. We have also tried simple random replacement strategies (randomly select a candidate to replace the original word) which is not effective in attacking the models. The results are shown in Table 4, we find that although the attack is effective in attacking the target model RoBERTa, it is much less effective on other models, which does not satisfy our model-agnostic requirement, and hence this attack is not included in AdvRACE.

A.2 Paraphrase

For Paraphrase, we adopted the Syntactically Controlled Paraphrase Network (SCPN) (Iyyer et al., 2018) which generates paraphrases of a sentence based on the given parse templates. The original method was proposed to attack single-sentence text classification problems. We generate paraphrases for sentences in the passages as an attack. We generated the Paraphrase test set with SCPN, using the top two levels of the linearized parse tree of the sentence as the input parse template. We have tried using other templates (such as using the most frequent parse template in the test set passage sentences) that are different from the original parse of the sentences, which results in more syntactic variances, but also lower valid rate. As shown in Table 4, although it is model-agnostic, during human evaluation, we find that 15 out of the 50 randomly sampled examples are labeled as unanswerable. Among the 15 unanswerable examples, 13 examples are labeled as missing key information, the other 2 are labeled as uninterpretable. This suggests that it is difficult to generate high-quality label-preserving adversarial examples by paraphrasing for MRC. Due to the low validity rate of the paraphrased examples, we exclude Paraphrase in AdvRACE to ensure that our benchmark is solvable for human.

	BERT	**RoBERTa**	**XLNet**	**ALBERT**
Original	68.5	83.7	79.9	86.0
WordReplace	64.2	70.7	74.7	80.5
Paraphrase	59.4	72.3	68.2	73.7

Table 4: Performance on WordReplace and Paraphrase test set in comparison with performance on the original RACE test set.

B Dataset Statistics

Each adversarial test set in AdvRACE contains 4934 questions, which corresponds to 1407 passages. The average length of each component is shown in Table 5.

Test Set	**Passage Len**	**Question Len**	**Option Len**
Original	316.2	11.0	6.3
AddSent	350.6	11.0	6.3
CharSwap	316.2	11.0	6.3
DE	316.2	11.0	6.8
DG	316.2	11.0	5.7

Table 5: Dataset Statistics of the original RACE test set and the adversarial test sets in AdvRACE.

C Model Benchmarking Hyper-parameters

The four models being benchmarked in the paper are: BERT-large, XLNet, ALBERT-xxlarge and RoBERTa-large. For both finetuning on the original RACE training set and adversarial training, we use learning rate 1.5e-5, weight decay 0.1, warmup ratio 0.06, max sequence length 512, batch size 32, max number of epochs 4. All experiments are done on Tesla V100 GPUs.

D Adversarial Training

Adversarial training (AT) is a common method to improve the robustness of NLP models where adversarial examples are added into the training data. In this section, we first examine how different AT strategies improve the model performance on various adversarial attacks. Next, we analyse the reasons behind the performance improvement

and highlight important flaws of using adversarial training as defense.

D.1 Adversarial Training Experiments

Previous works have used adversarial training to improve model robustness under specific attacks (Jia and Liang, 2017; Wang and Bansal, 2018). In this section, we first explore this targeted adversarial training setting where we randomly sample 25% of training data, apply the attack on the sampled training data, and add the perturbed data into the original training set as augmentation. Furthermore, we explore a mix adversarial training setting, where we add all the four types of adversarial data into the original training set together. In this setting, each adversarial attack is applied to 25% of the training data, so the resultant augmented training data has double size of the original training set.

We use RoBERTa for all the adversarial training experiments with the same hyperparameters. The experiment results are shown in Table 6, where the first column is the model's performance on the original RACE test set, the middle four columns are results of targeted adversarial training where each of the individual adversarial attack data is added in training. The last column shows results for the mix adversarial training where all the four types of AT data are added during training. We outline a few interesting findings from our experiments:

- Adversarial training on one type of adversarial data only improves model's performance on the attack that the model is adversarially trained on, while generally decreasing its performance on other test sets.
- Adversarial training on Distractor Extraction improves the model's performance on AddSent as well, possibly because that it makes the model rely less on simple text matching. Adversarial training on Distractor Generation significantly improves the model's performance on the DE test set, while adversarial training on DE also moderately improves the model performance on the DG test set, possibly due to the similar distractor replacement format of the two attack methods.
- Mix Adversarial training significantly improves the model's performance on all the adversarial test sets with slight drop on the original test set.

D.2 Understanding the effects of Adversarial Training

While it appears that adversarial training has significantly improved the model's performance under adversarial attacks, it is unclear whether it has really made the model more robust. Moreover, we find that on AddSent, DE, and DG, the adversarially augmented model achieves higher performance on the adversarial test set than the original test set, which may suggest overfitting. Hence, we analyse what is learned by the model during AT.

- **AddSent Adversarial Training**

We hypothesize that there exists spurious patterns in the AT data which are exploited by the model. To test this hypothesis, we construct a diagnosis test set by inserting the concatenation of the question and the correct answer into the passage, which does not change the labels and adds additional lexical matching for the correct answer. In Table 7, three models: RoBERTa finetuned on the original training set (Orig), under AddSent adversarial training (AddSent-AT), and under mix adversarial training (Mix-AT) are evaluated on the AddSent test set as well as our diagnosis test set. Comparing the first line with the second line, we find that RoBERTa finetuned on the original training set achieves much higher accuracy on the diagnosis test test, indicating that the insertion of correct answers makes it easier for the model to identify the correct answer. However, AddSent-AT and Mix-AT achieve miserable performance on the diagnosis test set, indicating such adversarially trained models are exploiting spurious patterns to score well and the model will fail when such patterns do not apply in the new test set. Hence it is likely that the high performance after AT is an overestimate, and better measures should be taken as defense to ensure improvement in the model's robustness.

- **DE and DG Adversarial Training**

To examine the exploiting of spurious statistical cues in the extracted and generated distractors, we employ partial data training (Kaushik and Lipton, 2018; Si et al., 2019) where we train and test RoBERTa on RACE without the passages and questions (i.e., we only input the options to the model). Under this setting, it is impossible for humans to correctly answer the questions since only the options are provided. As shown in Table 8, we train RoBERTa on: the original training set, DE adversarial training data, and DG adversarial training data, and test on their respective test sets. Under such option-only (PQ-remove) setting, RoBERTa achieves performance that is much higher than random on the original, DE, and DG test sets. This indicates that all the three datasets (original, DE and DG) have spurious statistical cues that are exploited to achieve high performance in the option-only setting. Moreover, models are exploiting such cues in DE and DG datasets to a much larger extent compared to on the original dataset. Thus, adding these examples into training may lead to an overestimate of the model's performance as the model can easily exploit these spurious patterns to increase the performance.

In summary, we find that the adversarially trained models may not be more robust, and the high scores achieved by adversarial training may have overestimated the models' robustness. We believe that more reliable defense methods should be developed to improve the model's robustness without exploiting spurious statistical cues as a shortcut. We leave such exploration to future work.

E Additional Examples

We present more examples of our DE and DG attacks in Table 9.

DE	**Passage:** I personally would be more concerned for the teenager who has to become independent without having any familiarity with working. The biggest reason teens should be allowed to work is that it is a healthy way of earning money. My dad told me, “Having a job is a good way to save up for things you are going to need or want to do. You get a lot more out of things if you are financially responsible for them.” Kids need the freedom to choose how to spend their money. The sooner they have an income, the sooner they can learn how to use money wisely. If they are not allowed to work in high school, they may run into trouble in the future. **Question:** The author’s father advised him to _ . **Answer:** earn money to get what he wants **Predicted:** work
DE	**Passage:** In a world with limited land, water and other natural resources, the harm from the traditional business model is on the rise. Actually, the past decade has seen more and more forests disappearing and the globe becoming increasingly warm. People now realize that this unhealthy situation must be changed, and that we must be able to develop in sustainable ways. That means growth with low carbon or development of sustainable products. In other words, we should keep the earth healthy while using its supply of natural resources. Today, sustainable development is a proper trend in many countries. According to a recent study, the global market for low-carbon energy will become three times bigger over the next decade. China, for example, has set its mind on leading that market, hoping to seize chances in the new round of the global energy revolution. **Question:** What is the main purpose of the passage? **Answer:** To introduce a new business model. **Predicted:** sustainable development
DE	**Passage:** Phyllis Lee of Singapore knew something wasn’t right. Her younger son, Alex, then six years old, was getting good grades in his private kindergarten classes. But Lee realized something was wrong when Alex came home one day, crying, with “zeroes” on his Chinese spelling test. Lee decided to investigate. According to Lee, the teacher would frequently describe Alex’s Chinese writing as ’ghost writings’ and made him a laughing stock in class instead of helping him out. Lee, 46, spent the next 12 months teaching Alex and still helps him when necessary. She not only taught him the formation of the Chinese words but also their origin so that he could understand better, often taking more than an hour to read a simple paragraph. Visits to the library and surfing the Internet kept her up to speed on teaching materials. Alex’s grades improved and by the end of Year One, he had become one of the top students in Chinese in his class. Alex is keeping an A - plus average in all subjects, and his mother’s involvement is a big reason behind it. **Question:** Alex arrived home with tears because _ . **Answer:** he failed in the Chinese exam **Predicted:** “zeroes” on his Chinese spelling test
DG	**Passage:** A new survey finds that more than eighty percent of Internet users in the United States search for health information online. The survey found that searching online is one of the leading ways that people look for a second opinion though doctors are still the main source of health information. Forty-four percent of people are actually looking for doctors or other providers when they search for health information online. Another finding of the survey: Two-thirds of Internet users look online for information about a specific disease or medical condition. The Internet has also become an important source of emotional support for people with health problems. Susannah Fox says one in five Internet users has gone online to find other people who have the same condition. It was more popular among people with more serious health issues–one in four people living with chronic diseases. They are so eager to find other people online who share their health concerns. The rise of social networking has made it easier for people with rare diseases to connect with each other and feel less alone. **Question:** By using social networking, patients with rare diseases can _ . **Answer:** get emotional comfort **Predicted:** find other people online
DG	**Passage:** I was personally discouraged by an adult during my high school. After telling her what university I wanted to attend, she plainly told me I would not get in. I was completely shocked and angry at her statement. The adult may have not intended to hurt me with her words, but it had an after effect. The meeting made me think she had no belief that I could possibly succeed in the future. After that it caused me to try to avoid any future meeting with adults until absolutely necessary. We are all human; therefore, we can all understand that some days are more challenging. But when people allow situations of stress to consume them, they cannot perform their best. People should pay attention to how their reactions could affect the person they are interacting with. adults who come off in a rude and aggressive way through communication have an effect on teenagers’ mind. Adults whether in schools, or any other institutions should work to tear down walls gently and create a safe space for the person they are serving. These adults should also help and contribute to a person’s academic, personal and professional growth. High school is an important time when young people need someone to believe in them. In conclusion, I would like to add that it is not completely up to adults only. Students are responsible for seeking help from adults who are in authority positions. They are also responsible for the way they approach adults in their academic surroundings. Students can expect to be treated in a respectful way when they express at the beginning. Generally the responsibility lies on both parties. When both sides can communicate in a polite manner then the complete environment of the school has the potential to develop well. **Question:** The passage is mainly about _ . **Answer:** the adults’ role in school **Predicted:** adults and teenagers

Abstract

Pre-trained Transformer-based neural language models, such as BERT, have achieved remarkable results on varieties of NLP tasks. Recent works have shown that attention-based models can benefit from more focused attention over local regions. Most of them restrict the attention scope within a linear span, or confine to certain tasks such as machine translation and question answering. In this paper, we propose a syntax-aware local attention, where the attention scopes are restrained based on the distances in the syntactic structure. The proposed syntax-aware local attention can be integrated with pretrained language models, such as BERT, to render the model to focus on syntactically relevant words. We conduct experiments[1] on various single-sentence benchmarks, including sentence classification and sequence labeling tasks. Experimental results show consistent gains over BERT on all benchmark datasets. The extensive studies verify that our model achieves better performance owing to more focused attention over syntactically relevant words.

1 Introduction

Recently, Transformer (Vaswani et al., 2017) has performed remarkably well, standing on the multi-headed dot-product attention which fully takes into account the global contextualized information. Several studies find that self-attention can be enhanced by local attention, where the attention scopes are restricted to important local regions. Luong et al. (2015); Yang et al. (2018); Xu et al. (2019); Nguyen et al. (2020) utilize dynamic or fixed windows to perform local attention. Strubell et al. (2018); Zhang et al. (2020); Bugliarello and Okazaki (2020) explore to utilize syntax to restrain attention for better performance, but each of them confines to a certain task.

In this work, we propose a **s**yntax-aware **l**ocal **a**ttention (**SLA**) which is adaptable to several tasks, and integrate it with BERT (Devlin et al., 2019). We first apply dependency parsing to the input text, and calculate the distances of input words to construct the self-attention masks. The local attention scores are calculated by applying these masks to the dot-product attention. Then we incorporate the syntax-aware local attention with the Transformer global attention. A gate unit is employed for each token in each layer, which determines how much attention is paid to syntactically relevant words. We lift weights from existing pre-trained BERT, and evaluate our models on several single-sentence benchmarks, including sentence classification and sequence labeling tasks. Experimental results show that our method achieves consistent performance gains over BERT and outperforms previous syntax-based approaches on the average performance. Furthermore, we compare our syntax-aware local attention with the window-based local attention. We find that the syntax-aware local attention is more involved in the aggregation of local and global attention. The attention visualization also validates the syntactic information supports to capture important local regions.

To summarize, this paper makes the following contributions: i) SLA can capture the information of important local regions on the syntactic structure. ii) SLA can be easily integrated to Transformer, which allows initialization from pre-trained BERT by increasing very few parameters. iii) Experiments show the effectiveness of SLA on various single-sentence benchmarks.

2 Related Work

2.1 Transformer Attention

Transformer (Vaswani et al., 2017) use stacked self-attentions to encode contextual information for input tokens. The calculation of self-attention depends on the three components of queries $\mathbf{Q}$, keys $\mathbf{K}$ and values $\mathbf{V}$, which are projected from the hidden vectors of the previous layer. Then the attention output $\mathbf{A}$ of one head is computed as follows:

$$\begin{aligned} \mathbf{M}_{ij} &= \begin{cases} 0, & \text{allow to attend} \\ -\infty, & \text{prevent from attending} \end{cases} \\ \mathbf{A} &= \text{softmax}\left(\frac{\mathbf{Q}\mathbf{K}^T}{\sqrt{d}} + \mathbf{M}\right)\mathbf{V} \end{aligned} \quad (1)$$

where d is the dimension of keys and the mask matrix $\mathbf{M}$ controls whether two tokens can attend each other. Within the standard self-attention layer, global attention mechanism is employed that each token provides information to other tokens in the input sentence.

2.2 Local Attentions

Local attention involves limiting each token to attend to a subset of the other tokens in the input. Many works utilize a fixed or dynamic window to derive the important local regions. Luong et al. (2015) first propose a Gaussian-based local attention and increase BLEU scores for neural machine translation. Yang et al. (2018) improve the method of Luong et al. (2015) by predicting a central position and window size to model localness. Compared with Yang et al. (2018), Nguyen et al. (2020) attempt to derive the local window span by a soft-masking method. However, Levy and Goldberg (2014) suggest that more informative representations can be learned from the syntactic structure, instead of a window of surrounding tokens. Strubell et al. (2018) propose to train one attention head to attend to each token's syntactic parent for semantic role labeling. Zhang et al. (2020) also leverage the syntactic information to self-attention, but confine to question answering. Thus, we explore to take advantage of the syntactic structure to improve the model performance on various benchmarks.

3 Approach

In this section, we first introduce the syntax-aware local attention, and then integrate it with standard Transformer attention. As shown in Figure 1, we extend the Transformer layer with the syntax-aware local attention. Syntax-based masking is applied to the dot-product of queries and keys. The final attention scores are computed by incorporating local attention with standard global attention. We stack new layers and initialize weights from pre-trained BERT.

3.1 Syntax-aware Local Attention

We derive syntactic structure from dependency parsing, and treat it as an undirected tree. Each token x_i is mapped to a tree node v_i, and the distance of node v_i and v_j is denoted by $dis(v_i, v_j)$. However, the input may be an ungrammatical sentence in some tasks, and the dependency parser is not very accurate. Thus, we calculate the distance from neighboring tokens of x_i to token x_j as:

$$D(i,j) = \min dis(v_k, v_j), \quad k \in [i-1, i+1] \quad (2)$$

The motivation is that many attention heads specialize in attending heavily on the next or previous token (Clark et al., 2019). Then, in order to determine whether token x_j can attend to token x_i, a threshold m is applied to restrict the distance $D(i,j)$. For simplification, the mask matrix $\mathbf{M}^{loc}$ calculation can be formulated as:

$$\mathbf{M}_{ij}^{loc} = \begin{cases} 0, & D(i,j) \leq m \\ -\infty, & otherwise \end{cases} \quad (3)$$

Given the query $\mathbf{Q}$ and key $\mathbf{K}$ projected from the hidden vectors $\mathbf{H}$, the syntax-aware local attention scores $\mathbf{S}^{loc}$ are formally defined as:

$$\mathbf{S}^{loc} = \text{softmax}(\frac{\mathbf{QK}^T}{\sqrt{d}} + \mathbf{M}^{loc}) \quad (4)$$

where d is the dimension of keys. In this local attention, two tokens can attend to each other only if they are close enough in the dependency tree.

3.2 Attention Aggregation

As shown in Figure 1, the final attention is the aggregation of syntax-aware local attention and Transformer attention. We denote the Transformer attention scores by $\mathbf{S}^{glb}$. A gated unit is used to combine the global and local attention scores. The gate value g_i for each token x_i is calculated as follows:

$$g_i = \sigma(\mathbf{W}_g h_i + b_g), \quad (5)$$

where h_i is the hidden vector of token x_i from the previous layer, $\mathbf{W}_g$ is a learnable linear transformation and b_g is the bias. Then the attention output $\hat{\mathbf{A}}_i$ is calculated as a weighted average over values $\mathbf{V}$, and the weights are derived from global and local attention scores:

$$\hat{\mathbf{A}}_i = (g_i \mathbf{S}_i^{loc} + (1-g_i)\mathbf{S}_i^{glb})\mathbf{V}. \quad (6)$$

A larger gate value means more focused attention over syntactically relevant words. It can be seen that, if all the outputs of gated units are equal to 0, we could obtain the standard Transformer attention. Compared with the original architecture, our self-attention layer has one more input ($\mathbf{M}_{loc}$) and two more trainable parameters ($\mathbf{W}_g$ and b_g). Thus, we can easily lift weights from existing pre-trained BERT models.

4 Experiments

4.1 Experimental Setup

Benchmarks We use two English single-sentence classification datasets from the GLUE benchmark (Wang et al., 2018). We test on the CoLA and SST-2 datasets for acceptability and sentiment classification. Besides, we evaluate our method on two sequence labeling tasks: named entity recognition (NER) and grammatical error detection (GED). We use the CoNLL-2003 and FCE datasets for NER and GED, respectively. The training procedures are introduced in Appendix A.1.

Configuration All the training experiments are based on BERT. We use the uncased version of BERT for CoLA and SST-2, and the cased version for CoNLL-2003 and FCE. We derive dependency tree using Spacy[2]. More implementation details are reported in Appendix A.2.

Baselines We apply the syntax-aware local attention (**SLA**) to BERT. In addition to comparing with BERT, we also investigate the following approaches:

SGNet Zhang et al. (2020) present a syntax-guided self-attention layer, where each word is limited to interact with all of its syntactic ancestor words. Then they stack this layer on the top of the pre-trained BERT model[3], instead of modifying the Transformer architecture.

LISA Strubell et al. (2018) restrict each token to attend to its syntactic parent in one attention head[4]. We apply it to BERT and add the corresponding supervision at the last attention head in each Transformer layer.

Besides, we implement the window-based local attention (**WLA**), which allows each token to attend to the neighboring tokens within a window size $2k+1$ (varying k in $\{3,4,5\}$). Then it is also integrated with BERT as shown in Section 3.2.

4.2 Main Results

Experimental results are shown in Table 1. We report results on the dev set of CoLA and SST-2 and the test set of CoNLL-2003 and FCE. We employ t-tests to see if the mean difference differed from 0 between the standard attention and our proposed attention. It can be seen that our

Table 1: Results on single-sentence benchmarks. Results with "$*$" are taken from Liu et al. (2019). "↑" means statistically significant improvement over the BERT baseline with p-value < 0.05. Reported results are averaged over 5 runs. "Params" is short for the number of model parameters. "MCC" is short for the Matthews correlation coefficient.

method achieves consistent gains over BERT on single-sentence classification and sequence labeling tasks. Specifically, our model exceeds the published BERT results by 3.9% correlation coefficient on CoLA and 1.1% accuracy on SST-2. For the NER task, even though our reimplementation didn't achieve the performance (92.8 F1) reported by Devlin et al. (2019), our model still outperforms it in large-size. More importantly, the syntax-aware local attention yields state-of-the-art results with 0.7 absolute improvements on FCE.

Besides, the proposed local attention outperforms other approaches leveraging syntactic information on the average performance. Compared with BERT, the syntax-aware local attention improves performances consistently but the window-based local attention can't. This suggest that BERT can benefit from more attention over syntactically relevant words on several datasets.

However, there are still some gaps between our model and the state-of-the-art models on these datasets. We argue that our method just modifies the standard Transformer attention without changing its main architecture, but those models are trained by using more advanced pre-training methods (Sun et al., 2020), larger-scale datasets (Raffel et al., 2019), or learning framework (Li et al., 2020).

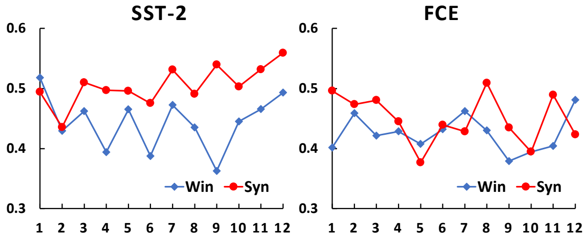

Figure 2: Gate values in different layers on SST-2 and FCE datasets. The blue polyline means that we incorporate the window-based local attention with global attention, and the red polyline corresponds to the syntax-aware local attention.

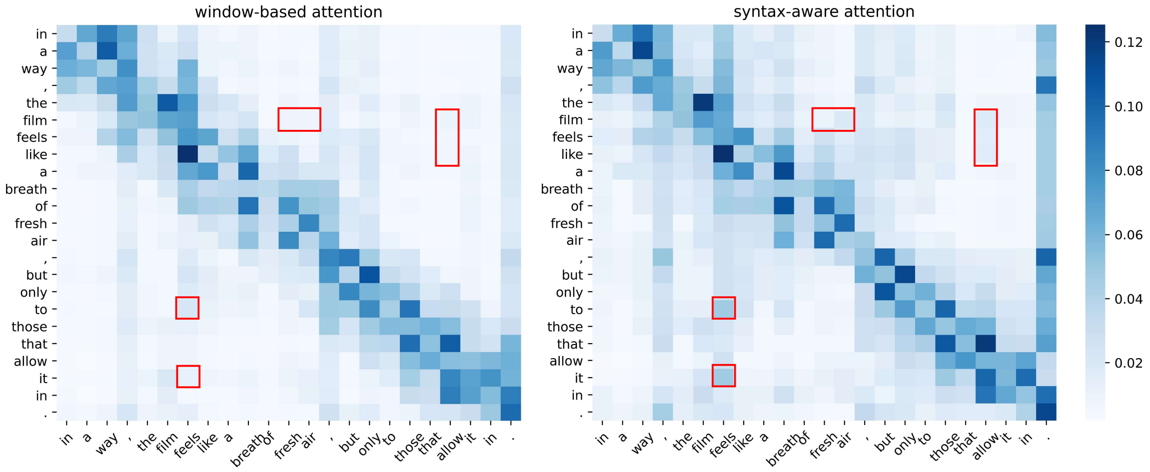
4.3 Analysis

Gated Unit in Each Layer It can be seen from Equation (6) that a larger gate value means a more important role of local attention in the attention aggregation. We analyze the gate values in different layers on SST-2 and FCE datasets. The gated unit outputs are collected from the best-trained base-size models, and are averaged over all input tokens in each layer.

As shown in Figure 2, on the SST-2 dataset, the syntax-aware local attention has higher values than the window-based local attention in most layers. Even if the sentences of the FCE dataset are ungrammatical, our attention plays a more important role in 8 of 12 layers. It indicates that our



Input: In a way, the film feels like a breath of fresh air, but only to those that allow it in.

Figure 3: Visualization of attention scores averaged over all heads and all layers. This case is selected from the SST-2 dev set. The red rectangle indicates higher scores on the right side but lower scores on the left side.

Models	QNLI Acc	RTE Acc	MRPC Acc	STS PCC
BERT	**91.7**	**68.6**	87.3	89.5
+SLA	91.4	67.8	**88.5**	**89.9**

Table 2: Experimental results on sentence-pair classification datasets. All models are base-size and results are reported on their dev sets. "PCC" is short for the Pearson correlation coefficient.

local attention is more important in the attention score calculation process. Besides, Table 1 and Figure 2 illustrate that our model achieves better performances owing to more attention on syntactically relevant words.

Attention Visualization In order to compare the syntax-aware attention with the window-based attention, we plot their attention scores in Figure 3. As formulated in Equation (6), the attention scores are calculated from the aggregation of global and local attention. We mainly focus on the interactions of tokens, except for `[CLS]` and `[SEP]`. Then the attention scores are averaged over all heads and layers. This visualization validates the effectiveness of incorporating syntactic information into self-attention. As shown in Figure 3, we can see that there are many informative tokens overlooked by the window-based method (left) but captured by our method (right). For instance, the syntax-aware attention allows the tokens "*fresh air*" and "*allow*" to strongly attend to the token "*film*", but these tokens are paid less attention in the window-based attention.

Testing on Sentence-Pair Classification We attempt to evaluate our model on sentence-pair classification datasets. Given a single sentence, we can easily apply dependency parsing and restrain the attention scopes inside the sentence. But for pairwise classification, one problem is how to limit the scopes between a pair of sentences. So a naive approach is adopted, that each token in a sentence can attend to all tokens in another sentence. We conduct experiments on four pairwise classification datasets from GLUE benchmark (Wang et al., 2018), which cover paraphrase, textual entailment and text similarity.

Experimental results are shown in Table 2. The syntax-aware local attention achieves better performances on MRPC and STS, but doesn't perform well on RTE and QNLI. We suspect that it is because the cross-sentence interactions are more important for textual entailment task.

5 Conclusion

This work verifies that BERT can be further promoted by incorporating syntactic knowledge to the local attention mechanism. With more focused attention over the syntactically relevant words, our model achieves better performance on various benchmarks. Additionally, the extensive experiments demonstrate the universality of our syntax-aware local attention.

A Appendices

A.1 Training Procedure

We extend the Transformer encoder layer and lift weights from BERT to our model. Following Devlin et al. (2019), we apply the fine-tuning procedure for various NLP tasks. For classification tasks, the final output of the first token `[CLS]` is taken as the representation of the input. The probability that the input sentence X is labeled as class c is predicted by a linear transformation with softmax:

$$P(c\,|X) = \text{softmax}(\mathbf{W}_c h_{\texttt{[CLS]}} + b_c) \tag{7}$$

where $h_{\texttt{[CLS]}}$ is the representation of the token `[CLS]`, $\mathbf{W}_c$ and b_c are task-specific parameters. For labeling tasks, we apply the BIO annotation (Ratinov and Roth, 2009) to label outputs and compute the probability that token x_i belongs to class c as:

$$P(c\,|x_i) = \text{softmax}(\mathbf{W}_t h_i + b_t) \tag{8}$$

where h_i is the representation of the token x_i, $\mathbf{W}_t$ and b_t are task-specific parameters. Finally, the training objective for all tasks is to minimize the cross-entropy loss.

A.2 Implementation Details

We apply the whitespace tokenization to the input sentence, and obtain the dependency tree using the Spacy parser[5]. However, the BERT inputs are tokenized by WordPiece tokenizer, which means one word may be split into several sub-words. To address this issue, for each word in the dependency tree, the sub-words split by WordPiece tokenizer share the same masking value in the calculation of syntax-aware local attention.

An important detail is that BERT represents the input by adding a `[CLS]` token at the beginning as the special classification embedding and separating sentences with a `[SEP]` token. Clark et al. (2019) find that these special tokens are attached with a substantial amount of BERT's attention. Thus, the `[CLS]` and `[SEP]` tokens are guaranteed to be present and are never masked out in our local attention.

We use the uncased version of BERT for CoLA and SST-2, and the cased version for CoNLL-2003 and FCE. During the training, we empirically select the threshold m from $\{3,4\}$. The maximum sequence length is set to 128 for all tasks. We use Adam (Kingma and Ba, 2015) as our optimizer, and perform grid search over the sets of the learning rate as $\{$2e-5, 3e-5$\}$ and the number of epochs as $\{3,5,10\}$ for most tasks. In particular, we use smaller learning rates $\{$5e-6, 1e-5, 2e-5$\}$ and train more epochs $\{30, 60\}$ on CoNLL-2003, but the average F1 of the best 5 runs still hasn't reached the results reported by Devlin et al. (2019). The batch size is fixed to 32 to reduce the search space, and we evaluate models every 500 training steps for all datasets. Furthermore, we experiment with the window-based attention on BERT, which allows each token to pay more attention to the neighboring tokens within a window size $2k+1$. We vary the k within $\{3,4,5\}$, and also incorporate the attention scores with global attention scores.

A.3 Testing on Chinese Benchmarks

The ChnSentiCorp dataset is used for sentiment classification task. We treat the ChnSentiCorp as single-sentence datasets although there are some examples including multiple sentences. The MSRA NER and CGED datasets are selected for named entity recognition and grammatical error detection in Chinese. The accuracy (Acc) is used as the metric of ChnSentiCorp, the precision, recall and F_1 are used as metrics of MSRA NER and CGED. In particular, for a fair comparison with the results of iFLYTEK's single model (Fu et al., 2018), we construct the CGED test set from CGED 2016 and 2017 test sets. Then we report detection-level results computed by the official evaluation tool.

Table 3 shows the main results on Chinese datasets. All results are reported on their test set. The proposed syntax-aware local attention outperforms the window-based attention and the basic BERT on all evaluated datasets. We attain 95.7 accuracy on ChnSentiCorp and 94.9 F1 on MSRA NER. Besides, BERT+SLA outperforms the state-of-the-art with a large margin on CGED.

Abstract

In the Chinese medical insurance industry, the assessor's role is essential and requires significant efforts to converse with the claimant. This is a highly professional job that involves many parts, such as identifying personal information, collecting related evidence, and making a final insurance report. Due to the coronavirus (COVID-19) pandemic, the previous offline insurance assessment has to be conducted online. However, for the junior assessor often lacking practical experience, it is not easy to quickly handle such a complex online procedure, yet this is important as the insurance company needs to decide how much compensation the claimant should receive based on the assessor's feedback. In order to promote assessors' work efficiency and speed up the overall procedure, in this paper, we propose a dialogue-based information extraction system that integrates advanced NLP technologies for medical insurance assessment. With the assistance of our system, the average time cost of the procedure is reduced from 55 minutes to 35 minutes, and the total human resources cost is saved 30% compared with the previous offline procedure. Until now, the system has already served thousands of online claim cases.

1 Introduction

In the Chinese medical insurance industry, the assessor's role is essential in handling protection claims. The insurance assessor may work for the insurance company or be a third-party administrator assessor. The claimant approaches the insurance assessor to evaluate the disease that has affected them. For example, if the claimant has lung cancer, the insurance assessor would check the medical cost and decide if they are claimable. Once the assessor has finished collecting the evidence and related claimant information (i.e., disease history, medication experience, in-hospitalized information, etc.), a final detailed case report will be made and sent to the insurance company.

The traditional insurance assessment procedure is carried out offline where the assessor conducts an onsite interview with the claimant. Due to the coronavirus (COVID-19) pandemic, the previous offline insurance assessment has to be interrupted temporarily, and thus many claimants can not get their insurance compensation in time. Some of them, meanwhile, may also suffer job loss[1]. To help these claimants, many insurance companies shift the offline procedure to the online platform in which insurance assessors can communicate with claimants via video connection. In this way, claimants can submit their applications and get compensations entirely online. On the other hand, the online assessment also helps the insurance company save expenses as the assessor can quickly approve qualified applications or screen out applications that do not conform to the claims on the online platform.

However, limited by the complexity of the insurance assessment procedure and the instability of the online environment, simply providing a video connection for insurance assessors and claimants is still insufficient. We summarize three primary challenges for the current online procedure: (1) Instability. The online video connection may sometimes be unstable, and the assessor may not distinguish the claimant's words. (2) Complexity. The insurance assessment procedure is very complex, and not all assessors are sufficiently experienced. The junior assessors, in particular, need much assistance to complete their work expertly, and even some senior assessors still have room for improvement. (3) Time-consuming. Recording the key information and writing the insurance report is te-

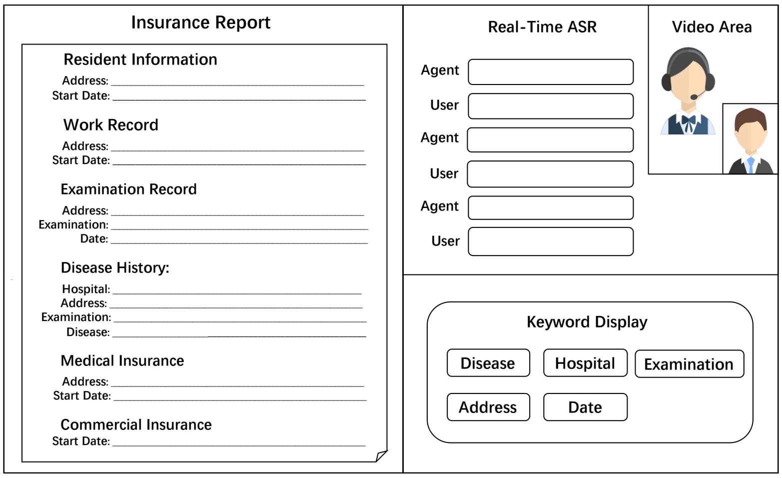

Figure 1: The illustration of the front end of Intelligent Insurance Assessment System.

dious for most assessors, and junior assessors may even forget some important information during the inquiry.

To this end, we propose an **I**ntelligent **I**nsurance **A**ssessment **S**ystem, called **IIAS** (shown in Figure 1) for medical insurance assessment. The system aims at promoting the work efficiency of the insurance assessor through dialogue-based information extraction. For these purposes, We use recent NLP technologies, such as streaming automatic speech recognition (ASR) (Moritz et al., 2020; Mani et al., 2020), large scale pre-trained language models (Devlin et al., 2019; Cui et al., 2019), sentence similarity learning (Chen et al., 2017; Peng et al., 2020), named entity recognition/linking (NER/EL) (Le and Titov, 2018; Devlin et al., 2019) and dialogue state tracking (DST) (Ouyang et al., 2020; Zhang et al., 2020b), to ensure high performance while requiring only a small amount of annotated data.

Our IIAS alleviates the cognitive workload of assessors in several steps: (1) Our streaming ASR transforms speech signal into the conversation text in real-time, and our sentence similarity learning method labels corresponding topics for each conversation on-the-fly. (2) Our NER component then extracts raw entities from the real-time conversation text, and the EL part links the raw entities into the unified insurance knowledge base (KB) for getting all possible keywords. (3) Our DST method, including question and negation identification modules, tracks the state of dialogue context for filtering irrelevant keywords.

To the best of our knowledge, this is the first work to propose an intelligent system for insurance assessment. The main contributions of our work are concluded as follows.

- We propose a dialogue-based information extraction system that shifts the previous insurance assessment procedure online and provides necessary intelligent assistance for the assessor.
- We apply recently advanced NLP technologies to address the problem of online insurance assessment. Our methods significantly improve the assessor's work efficiency, where the average time cost of the insurance assessment procedure is reduced from 55 minutes to 35 minutes.
- Our system has already been deployed in the real world. Until now, it has served thousands of online insurance claim cases, which delivers potential value to the insurance industry.

2 System Framework and Technique Details

Figure 2 shows the architecture of IIAS with key components such as streaming ASR, dialogue segmentation, keyword extraction (NER and EL), keyword filtering (question and negation identification), and downstream applications (keyword display and report filling).

As previously mentioned, recording the information during the assessment is tedious for most insurance assessors. In order to increase the efficiency of information collection and reduce the assessor's cognitive workload, IIAS provides a keyword-based feature that first displays keywords

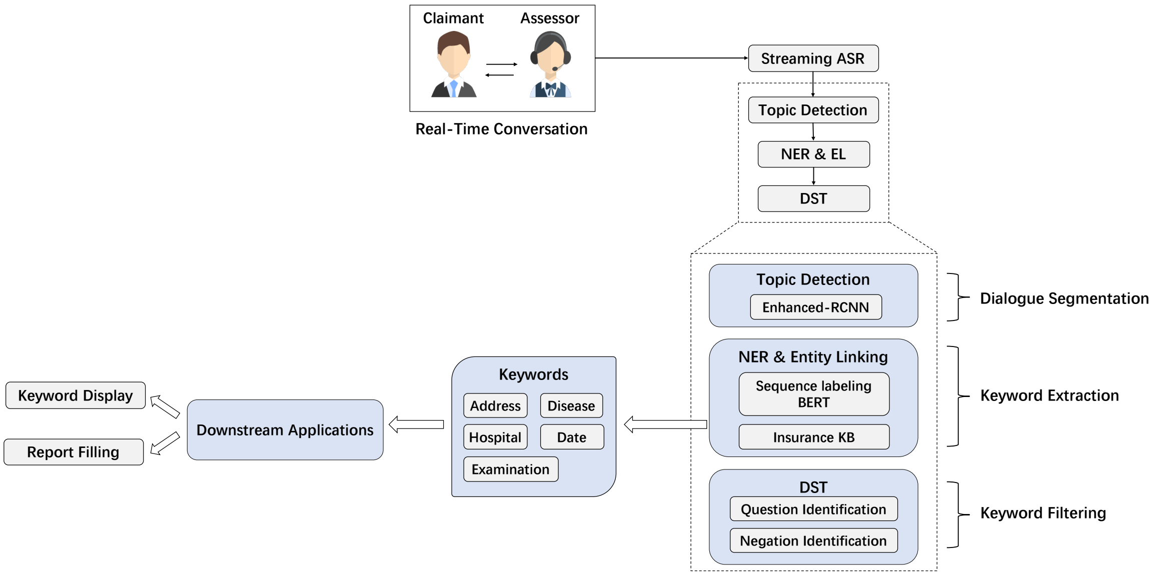

Figure 2: The Architecture of Intelligent Insurance Assessment System.

on the system dashboard and then intelligently suggests the related content when assessors are filling in the insurance report.

For better understanding, we discuss the technical details for each key component in the following subsections. Besides, we also present the partial experimental result corresponded to each component.

2.1 Dialogue Segmentation

Dialogue segmentation aims at detecting the topic of the real-time conversation text. As the insurance assessment procedure is conducted according to the content that needs to be filled in the insurance report, different dialogue between the assessor and claimant is focused on different topics. These topics can be seen as different questions that the claimant needs to answer. For example, the assessor may start with the topic about the claimant's work address, and then inquire about when the disease starts and where the claimant receives the treatment, and finally inquire about the doctor's advice and in-hospitalized information. Here we use the sentence similarity learning method to map the assessor utterance into the corresponding topic.

First, we order the one-to-many mapping relationship between the topic and standard questions that most assessors inquire in the insurance assessment procedure. We select the representative utterance from the assessor as the standard question. The standard question is a set of questions that represent different topics across all assessors. We select the standard question by running HDBSCAN clustering algorithm (McInnes et al., 2017) followed with a human adjustment. Since the ways of inquiry among assessors are different, and the ASR results are sometimes affected by the outside speech signals, we use the Enhanced-RCNN model (Peng et al., 2020) to calculate the similarity score between the utterance and selected standard questions, and get the topic of the utterance if the score is greater than the threshold (the default value is 0.5) or follow the topic of the previous utterance if the score is less than the threshold.

After the dialogue segmentation, the whole dialogue is segmented into many parts that belong to different topics so that the keywords extracted in the following process can be linked with these topics in real time. We evaluate the performance of dialogue segmentation by 200 online cases with the human annotation. The accuracy of segmentation reaches 90%.

2.2 Keyword Extraction

In the insurance assessment scenario, the keyword contains five types[2], and their values are not within a limit number. Therefore, any string fragment of assessor or claimant utterance may become a keyword. Traditional slot filling methods with classification models in the task-oriented dialogue system cannot predict unseen slot values in a pre-defined value list and are not appropriate to our scenario. To solve the problem, we convert the keyword extraction as a sequence labeling task and use the

---

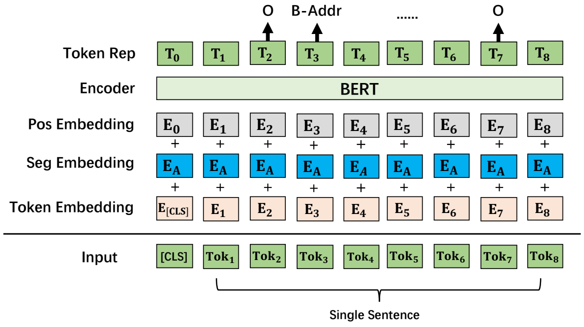

Figure 3: The sequence labeling BERT model for NER.

Entity Type	Addr.	Hos.	Dis.	Date.	Exam.
F1-Score (%)	78.2	78.3	83.1	85.1	85.4

Table 1: Test performance of the NER/EL model on five entity types.

BERT-based NER model (Devlin et al., 2019).

We first pre-annotate the keyword type in the utterance as `Addr`, `Hos`, `Dis`, `Date`, `Exam` or `Other` (non-named entity) and follow the official tutorial in NER[3]. The visual representation of BERT-based NER model is shown in Figure 3. For fine-tuning, we feed the final hidden representation for each token into a classification layer over the NER label set, and the predictions are non-autoregressive and no CRF (Devlin et al., 2019). After the NER process, we get the raw entities extracted from the utterances. As the word accuracy of ASR is about 85%, some of the derived entities may be misrecognized (correct entity type but with a wrong form). In order to alleviate the negative effect of the ASR module, we use the EL model (Le and Titov, 2018) to recognize and disambiguate the raw entities to the insurance KB that contains the normalized address, hospital and disease information for getting all possible keywords.

To measure the NER/EL model's performance separately, we take the F1-Score as the evaluation metric. The experimental results on the human-annotated testing set are shown in Table 1. The results show that the NER/EL models achieve good performance on all five entity types as the average F1-score has reached 82%.

2.3 Keyword Filtering

During the insurance assessment procedure, the assessor always asks the claimant many detailed questions. As a result, a part of entities extracted by the previous keyword extraction process may come from the assessor's question text and actually do not need to be displayed or suggested if the claimant's following response has negative semantics. To filter the irrelevant keywords extracted by the previous process and increase the accuracy of keyword display and report filling, we design a DST method for keyword filtration. Like the application in the task-oriented dialogue system, the DST method tracks the keyword's state (addition or deletion) and contains two major modules: question identification and negation identification. The assessor's conversion text is first fed to the question identification module. Suppose the text is identified to be a question. In that case, the extracted keyword from it will be reserved temporarily and only displayed (or recommended) once they are confirmed by the claimant (decided by the negation identification module).

2.3.1 Question Identification

Question identification determines whether the current utterance belongs to part of the insurance assessor's inquiry. We convert question identification as the binary classification task and utilize the text classification model to solve it.

We utilize the LSTM (Hochreiter and Schmidhuber, 1997), one of the most popular text classification models, as the base model. In this case, the input $x = \{x_1, x_2, ..., x_T\}$ is the text transformed by the ASR module where x_t is the word after segmentation. The output is a label y indicating whether the text is a question or not.

Based on the observation, the insurance assessment's topic distribution is diverse, and the accuracy of question identification is highly relevant to the concrete topic (i.e., resident/work address, medication experience, or disease history). Therefore, training a single model for covering all the topics is actually not the best solution in our scenario, and it is necessary to train different identification models for different topics. However, the total amount of manually labeled data is not large enough to train multiple classifiers for every topic. To alleviate this issue, we adopt the adversarial multi-task training method (Liu et al., 2017; Yang et al., 2020). Compared with the multi-task training method, the adversarial-based training method improves the question identification model's performance for general purposes and a particular topic with only a few labeled data.

Experimental results on different training meth-

---

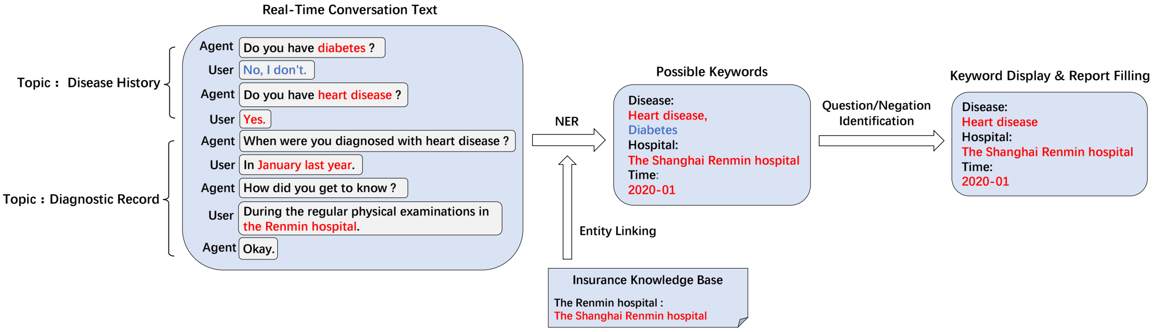

Figure 4: An example of IIAS workflow. In this example, the real-time conversation text is segmented into two topics, and keywords extracted from the utterances are first filtered, and then displayed on the system dashboard, and finally suggested when the assessor fills in the insurance report.

Model	**Accuracy (%)**
Single Model	61.2
Multi-task Model	75.1
Adversarial Multi-task Model	**78.4**

Table 2: Test Performance on Question Identification.

ods are presented in Table 2. The results show that the adversarial multi-task model achieves the best accuracy among three compared models, which indicates that the adversarial learning method is more appropriate to the insurance scenario that the topic distribution of question is unbalanced.

2.3.2 Negation Identification

After the question identification module, the following claimant's utterance is feed to the negation identification module. The keywords extracted from the question are only displayed on the system dashboard if the claimant confirms. Here we use the BERT-based binary-classification model (Devlin et al., 2019) for negation identification. The input is the current claimant utterance with the previous two rounds of utterances from the assessor and claimant (we use `[SEP]` to separate them). The output is the label indicating whether the current utterance has negative semantics or not (the final layer is a two-class softmax layer). From the performance on the human-annotated testing set, the negation identification module's accuracy is 92%.

The ablation study on the DST method's contribution (question and negation identification modules) is present in the experiment section.

2.4 Applications

Based on the previous three steps, the system gets filtered keywords extracted from the real-time conversion text, and these keywords are classified into different topics simultaneously.

To help the assessor better do their job, we identify two types of generic applications for derived keywords: keyword display and report filling. The keyword display aims at displaying information extracted from the real-time conversation text on the system dashboard. Furthermore, the report filling aims at recommending related contents when the assessor fills in the specific part of the insurance report. For ensuring a good user experience, we sort extracted keywords by the reversed order of utterances in the dialogue and limit the maximal number of recommended contents as 5. We show an example to illustrate the IIAS workflow in Figure 4. The figure shows how IIAS extracts the information from the real-time conversation text and uses them for the downstream applications.

For the insurance assessor, keyword display and report filling significantly alleviate the workload of remembering all the claimant information during the inquiry procedure. To further evaluate IIAS's overall contribution to the assessor's work, we conduct different experiments in the experiment section.

3 Experiments

3.1 Insurance Assessment Dataset

We manually construct an insurance assessment dataset from the real-world environment and use it for evaluating the performance of IIAS. The dataset consists of 200 online cases, and each case contains two parts: a multi-turn dialogue and a corresponding insurance report that the assessor needs to fin-

Items	Train	Test
Num of dialogs	5000	200
Average Rounds Per Dialog	497.6	501.2
Average Keywords Per Dialog	25.3	27.9

Table 3: Statistics of Insurance Assessment Dataset.

ish. To ensure the high quality of the dataset, we employ five real insurance assessors to fill in the insurance report by selecting a string fragment of the utterance from the given multi-turn dialogue. Here we screen out forms in the insurance report that cannot be filled based on the given multi-turn dialogue. Table 3 shows the detailed statistics of the insurance assessment dataset.

In order to protect data privacy, the usage of the claimant's private data must be authorized. We have obtained explicit permissions from the claimant to use their personal private data before the insurance assessment. If a claimant disapproves of the authorization, we will not use her/his data. For the authorized user privacy data, we have a series of strict processes to ensure the data remain confidential.

3.2 Experimental Setup

3.2.1 Method in Comparison

As far as we know, there is no similar research work in the insurance industry. To examine the effectiveness of IIAS, we compare it with the retrieval-based system on the report filling performance. Different from IIAS that is mainly based on the real-time ASR and speaker recognition, the retrieval system suggests retrieved results from the pre-constructed KB based on the conversation text. For example, the system will recommend *top-k* relevant disease nouns in the KB when the assessors fill in the form about what disease the claimant is diagnosed with. To be aligned with IIAS, we limit the retrieved number k in the retrieval system as 5.

The major limitations of the retrieval system are that the content that needs to be filled may only exist in the conversation text but not appear in the pre-constructed KB.

3.2.2 Evaluation Metrics

The evaluation process is divided into offline and online parts.

Offline Evaluation: We choose the recall as the metric to evaluate the system performance of report filling. The recall measures the ratio of suggested correct content to all ground-truth content that needs to be filled.

Online Evaluation: We choose the time-saving and efficiency-improving as metrics because our work's primary purpose is to alleviate assessors' workload and reduce the insurance assessment procedure's time cost.

3.3 Evaluation Results and Discussions

The experimental results[4] on the report filling performance between IIAS and the retrieval system are shown in Table 4 and Table 5.

We summarize our observations as follows:

(1) Our IIAS is generally better than the retrieval system on the record filling's performance for most topics. This shows that using the method based on speaker recognition is more effective with less dependence on the pre-constructed KB.

(2) For entities of `Addr` type, the retrieval system achieves comparative performance than IIAS. This indicates that the address entities are relatively fixed and easy to be included in the pre-constructed KB. For this type of entity, the retrieval system is more appropriate.

(3) For entities of `Exam` and `Dis` types, our system achieves much better performance than the retrieval system. This shows that for those entity types that are diverse and hard to be included by the pre-constructed KB, using the NER/EL methods to extract keywords from the utterances is more appropriate.

3.4 Ablation Study

We perform the ablation study to validate the contribution of the DST method (question and negation identification). Since the DST method filters out irrelevant keywords extracted by the NER/EL modules, we choose the *hospital* and *disease* types that frequently appear in the assessor's utterances for the experiment.

The experimental results are presented in Table 6. Here we evaluate the precision of the keyword extraction. The results show that with the addition of the DST method, the keyword extraction's precision is significantly promoted. This indicates that the DST method effectively filters the error keywords, which is beneficial for improving system performance.

---

[4] To make a fair comparison, we do not compare the recall ratio on the `Date` type because the value of `Date` cannot be included by the pre-constructed KB in the retrieval system.

3.5 Online Performance

From the statistical result for three months after the system deployment, the average time cost of the insurance assessment procedure is reduced from 55 minutes to 35 minutes, and the overall human resources cost is saved 30% compared with previous offline insurance assessment.

Moreover, with the assistance of our IIAS, the insurance company provides more job opportunities for junior assessors. This indicates that IIAS has effectively lowered the bar of insurance assessment jobs.

4 Deployment Details

Our proposed approach consists of different NLP components that are trained individually. We deploy them on two GPUs (Tesla P100 16G) and provide a unified HTTP interface for the back-end system.

To support multiple users, the computation cost needs to be well distributed across different GPUs. For each GPU, we set up two independent processes. A load-balancing module is then employed to distribute the users' requests to different processes based on the working loads. Based on the stress test, the online service's average response time is less than 150ms and can support a peak QPS of 35.

5 Discussions on Technique Limitations

In this section, we discuss the limitations of techniques in IIAS. Based on the observation of system results and feedback from the insurance assessors, the limitations are from three parts:

(1) **ASR Results**: The performance of two applications (keywords display and report filling) heavily relies on the ASR module, but the ASR errors are the major problem of our system. The ASR error may result in correct entity type but with a wrong form, which indicates that optimizing the ASR module should be a top priority for future research.

(2) **Reasoning Problem**: The current system cannot solve the problem that requires complex reasoning, such as date recognition (e.g., last Sunday or three days ago.). However, many date recognitions during the insurance assessment procedure require reasoning. As a result, we plan to include reasoning ability into the system in the future.

(3) **Accumulative Errors**: The current system is based on a multi-model approach where different NLP components such as topic detection, NER/EL, and question/negation identifications are trained individually and combined. This type of pipeline approach is easy to lead to accumulative errors. We have tried to replace the current approach with the end-to-end summarization method based on text-generation. However, text-generation models always require many training data and their predictions are sometimes uncontrollable (the inference time is also slow if we use the pre-trained model

like GPT-2 (Radford et al., 2019)). Although now the end-to-end method cannot be applied in the real-world setting (especially in our insurance scenario that requires controllability), it has some advantages and is still part of our plan.

For these limitations, we are working on a new solution to improve the current system.

6 Related Work

With the advances in NLP, agent-assist systems have been used in various domains, including technical support, reservation systems, and banking applications (Fadnis et al., 2020). In this section, we briefly introduce some related technologies used in IIAS.

6.1 Sentence Similarity Learning

Sentence similarity learning is a fundamental and important NLP task which may be greatly enhanced by modeling the underlying semantic representations of compared sentences. In particular, a model should not be susceptible to variations of wording or syntax used to express the same idea. Moreover, a good model should also have the capacity to learn sentence similarity regardless of the length of the text and also needs to be efficient when applied to real-world applications (Chen et al., 2017; Peng et al., 2020).

In the scene of insurance assessment, both efficiency and accuracy are of equal importance. Therefore we use the recent proposed Enhanced-RCNN model (Peng et al., 2020) that achieves good performance on Chinese paraphrase identification datasets for learning sentence similarity.

6.2 Named Entity Recognition and Linking

Named entity recognition is the NLP task of tagging entities in the text with the corresponding type and recent large-scale language model pretraining methods such as ELMo (Peters et al., 2018), and BERT (Devlin et al., 2019) further enhanced the performance of NER, yielding state-of-the-art performances (Sutton et al., 2007; Li et al., 2019).

Entity linking is the task of recognizing and disambiguating named entities to a knowledge base (Hoffart et al., 2011; Le and Titov, 2018). EL can be split into two classes of approaches:

- **End-to-End:** processing a piece of text to extract the entities and then disambiguate these extracted entities to the correct entry in a given knowledge base.
- **Disambiguation-Only:** directly takes gold standard named entities as input and only disambiguates them to the correct entry in a given knowledge base.

6.3 Dialogue State Tracking

Dialogue state tracking is an important component in task-oriented dialogue systems to identify users' goals and requests as a dialogue proceeds (Zhu et al., 2019). The traditional DST system assumes that each slot's candidate values are within a limit number. However, this assumption does not apply to slots with an unlimited number of values in advance. It is more difficult for zero-shot domains like the scene of insurance assessment to predefine the slot values in advance (Ma et al., 2019; Ouyang et al., 2020).

Some recent researches are on converting fixed slot values into the substring of the dialogue context (Xu and Hu, 2018; Zhang et al., 2020a; Gao et al., 2019). In this way, many researchers have proposed many neural networks to complete DST tasks in a reasonable way (Perez and Liu, 2017; Zhang et al., 2020b). Inspired by the recent progress, we also use the approach that treats the dialogue context as the source of slot values.

7 Conclusions and Future Work

In this paper, we presented a dialogue-based information extraction system that helps the insurance assessor better perform their job. The system combines different NLP technologies like sentence similarity learning, NER/EL, and DST methods in a novel way. While there has been considerable work done for each of the independent modules/models, this systematic way of combining them enables the platform to quickly deliver what may be of significant value to the insurance industry.

In the future, we would like to try to replace the current pipeline method with the end2end method based on text-generation when the accumulated annotated data is enough.

8 Ethical Considerations

Below we present the ethical considerations in terms of data authorization, privacy, and trust in real-world deployments.

- We have obtained explicit permissions from the claimant to use their personal private information data, including text and audio provided in the insurance assessment procedure for improving the system service.

- The personal private information from the claimant is never used or stored for the commercial purpose.

Prediction or Comparison: Toward Interpretable Qualitative Reasoning

Mucheng Ren, Heyan Huang* and Yang Gao

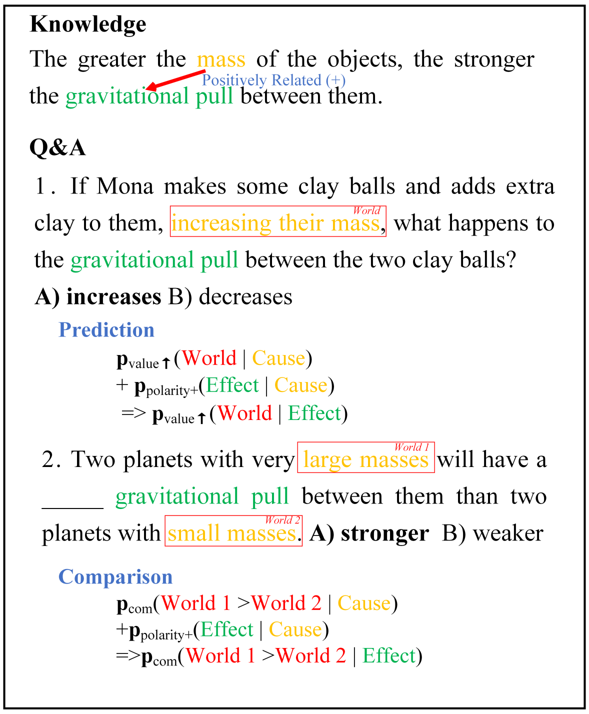
Abstract

Qualitative relationships illustrate how changing one property (e.g., moving velocity) affects another (e.g., kinetic energy) and constitutes a considerable portion of textual knowledge. Current approaches use either semantic parsers to transform natural language inputs into logical expressions or a "black-box" model to solve them in one step. The former has a limited application range, while the latter lacks interpretability. In this work, we categorize qualitative reasoning tasks into two types: prediction and comparison. In particular, we adopt neural network modules trained in an end-to-end manner to simulate the two reasoning processes. Experiments on two qualitative reasoning question answering datasets, QuaRTz and QuaRel, show our methods' effectiveness and generalization capability, and the intermediate outputs provided by the modules make the reasoning process interpretable.



Knowledge

The greater the mass of the objects, the stronger the gravitational pull between them.

Q&A

1. If Mona makes some clay balls and adds extra clay to them, increasing their mass, what happens to the gravitational pull between the two clay balls?
A) increases B) decreases

Prediction

$\mathbf{p}_{\text{value}\uparrow}$(World | Cause)
+ $\mathbf{p}_{\text{polarity+}}$(Effect | Cause)
=> $\mathbf{p}_{\text{value}\uparrow}$(World | Effect)

2. Two planets with very large masses will have a _____ gravitational pull between them than two planets with small masses. **A) stronger** B) weaker

Comparison

$\mathbf{p}_{\text{com}}$(World 1 >World 2 | Cause)
+$\mathbf{p}_{\text{polarity+}}$(Effect | Cause)
=>$\mathbf{p}_{\text{com}}$(World 1 >World 2 | Effect)

Figure 1: Examples from QuaRTz dataset.

1 Introduction

Qualitative relationships abound in our world, especially in science, economics, and medicine. Since Question Answering (QA) has been significantly developed in recent years, various challenging datasets have been proposed (Lai et al., 2017; Rajpurkar et al., 2018; Yang et al., 2018; Choi et al., 2018; Dua et al., 2019), and one often encounters the context and questions about qualitative relationships. Figure 1 shows an example that requires reasoning about the qualitative relationship between the mass and the gravitational pull, where the knowledge sentence states that the mass is positively correlated with the gravitational pull, and the questions describe different scenarios that test the flexible application of the knowledge.

Therefore, understanding the qualitative relationships behind the context and applying the qualitative textual knowledge for reasoning is essential. However, the most current datasets on qualitative reasoning are much smaller than standard Question Answering datasets, making the task challenging and receiving limited attention. At present, in the two mainstream qualitative relationship question datasets, QuaRel (Tafjord et al., 2019a) and QuaRTz (Tafjord et al., 2019b), the existing methods can be divided into two categories, symbolic reasoning based on a semantic parser (Krishnamurthy et al., 2017; Tafjord et al., 2019a) and a "black-box" model based on representations (Mitra et al., 2019; Tafjord et al., 2019b; Asai and Hajishirzi, 2020; Mitra et al., 2020).

The two types of methods have their advantages and disadvantages. On one hand, symbolic reasoning provides solid explanations for the problem-solving process, but existing semantic parsers are

trained to translate natural-language sentences into a task-specific logical representation that naturally increases the demand for additional annotated data and has limited generalization capability. On the other, approaches based on pre-trained language models that solve the task in one step achieve stunning results at the expense of limited interpretability.

To tackle the issues mentioned above, in this paper, we propose a neural network module-based approach that provides good interpretability while achieving better results. Specifically, inspired by human cognitive processes, we group the qualitative reasoning questions into two categories: **Prediction** and **Comparison**. As the example in Figure 1 shows, each category requires different reasoning chains. In **Prediction**, the question asks to directly predict the effect on an occurrence of the cause on an entity in the situation. In **Comparison**, the question asks to compare the effects on the two entities. Then we adopt neural modules to model each step in these two reasoning chains, and all modules are trained in an end-to-end manner.

The practice of first summarizing the questions and then modeling the different reasoning chains step by step has three advantages: First, it has good generalization ability. The two reasoning chains summarized cover the vast majority of qualitative reasoning problems, so there is no need to design logical expressions for specific tasks. Second, it achieves better performance, because complex qualitative reasoning tasks are broken down into simple sub-tasks, with the modules required to complete only simple sub-tasks. Third, it provides better interpretability, because each module can provide a transparent intermediate output.

Experimental results on the QuaRel (Tafjord et al., 2019a) and QuaRTz (Tafjord et al., 2019b) datasets demonstrate the effectiveness and generalization capability of our proposed approach. It surpasses the state-of-the-art model by a large margin (absolute difference ranging from 1.8% to 4.4%). Furthermore, analyses of the intermediate outputs and a human evaluation show that each module in our approach performs well on its corresponding sub-task and clarifies interpretability.

2 Related Work

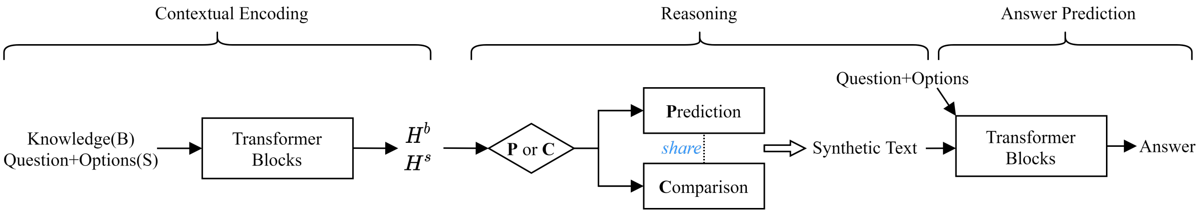
Qualitative Reasoning: This type of reasoning is an indispensable part of artificial intelligence. Forbus (1984) and Weld and De Kleer (2013) propose formal models for qualitative reasoning when the research filed is emerging. However, there has been little work on reasoning with textual qualitative knowledge. Tafjord et al. (2019a) solves such tasks using semantic parsing and a symbolic solver; this type of method naturally falls short on performance when compared to neural systems. Meanwhile, some works tackle tasks using a data-driven "black-box" model based on representations computed by language models, which achieves superior performance (Tafjord et al., 2019b; Mitra et al., 2019; Asai and Hajishirzi, 2020; Mitra et al., 2020). Our work enjoys the performance improvement that a neural network brings but also provides interpretability.

Neural Network Modules: These modules were first adopted in the Visual Question Answering (VQA) domain (Johnson et al., 2017; Andreas et al., 2016; Hu et al., 2017). Due to the interpretable, modular, and inherently compositional nature of neural network modules, they were further extended to natural language (Gupta and Lewis, 2018; Jiang and Bansal, 2019; Jiang et al., 2019). Gupta et al. (2019) extend neural module networks to answer compositional questions. Ren et al. (2020) and Liu and Gardner (2020) further introduce neural network modules on one complex reasoning task ROPES (Lin et al., 2019). In this work, we explore the effectiveness of neural network modules on a qualitative reasoning task.

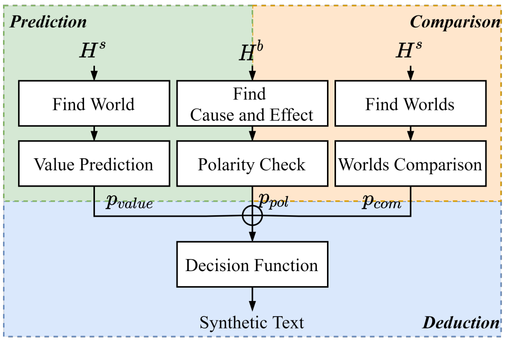
3 Method

Our work solves the question through a three-step process illustrated in Figure 2a:

1. The *Contextual Encoding* component encodes the concatenation of knowledge, the question, and options into contextual representations.
2. The *Reasoning* component arranges different reasoning chains according to the type of problem, where Prediction and Comparison contain multiple neural modules. A synthetic text is generated by the decision function based on the evidence collected from the reasoning chains.
3. The *Answer Prediction* component takes the concatenation of the question, options, and the generated synthetic text instead of given knowledge as the input and returns the answer option with the highest salience scores.



a) Overall Pipeline of our model



b) Reasoning Module

$p_{val}(W\|C)$	$p_{pol}(E\|C)$	***Prediction:* Synthetic Text**
↑	+	World will cause more Effect.
↑	-	World will cause less Effect.
↓	+	World will cause less Effect.
↓	-	World will cause more Effect.

$p_{com}(W_1, W_2)$	$p_{pol}(E\|C)$	***Comparison:* Synthetic Text**
>	+	World 1 will cause more Effect than World 2.
>	-	World 1 will cause less Effect than World 2.
<	+	World 1 will cause less Effect than World 2.
<	-	World 1 will cause more Effect than World 2.

c) Decision Function

Figure 2: The overall diagram of our proposed model. Given background knowledge B and statement S formed by the question and options, we first generate the contextual representations. Then we synthesize a text by collecting the evidence provided by the **Prediction** or **Comparison** module, where the detailed structure is shown in b). Last, we predict the answer with the aid of the synthetic text.

3.1 Contextual Encoding

We selected RoBERTa (Devlin et al., 2019; Liu et al., 2019) as the encoder to encode the background knowledge, the question, and two answer options together and output contextualized embeddings. In particular, we concatenated the question with two answer options as statement $S = \{s_i\}_{i=1}^m$, similar to the examples shown in Figure 1. Furthermore, we joined given background knowledge $B = \{b_j\}_{j=1}^n$ and the statement with the special tokens used in language models as $\langle s \rangle\, b_1, \ldots, b_n \,\langle /s \rangle\, \langle /s \rangle\, s_1, \ldots, s_m \,\langle /s \rangle$, which was further fed into RoBERTa containing a series of successive transformer blocks,

$$\boldsymbol{H^b}, \boldsymbol{H^s} = \text{Transformers}(B, S), \qquad (1)$$

where $\boldsymbol{H^b} \in \mathbb{R}^{n \times d}$, $\boldsymbol{H^s} \in \mathbb{R}^{m \times d}$ are contextual representations of the knowledge and the statement, respectively, and d is the dimension for the hidden states. The representations $\boldsymbol{H^b}, \boldsymbol{H^s}$ are padded into fixed length and served as the global variables in the *Reasoning* part.

3.2 Reasoning

The architecture of the reasoning component is shown in Figure 2b. In particular, we designed the different reasoning chains depending on the question type. Specifically, both reasoning chains were constructed by several end-to-end modules, and some modules were shared. Then the evidence collected from each module is summarized for the final deduction.

3.2.1 Prediction

Find Cause and Effect: To answer the Prediction-type question like the first example shown in Figure 1, we first need to understand what the knowledge describes, i.e., figure out the cause and effect properties (e.g., *mass* and *gravitational pull*). To achieve this, we applied a multilayer perceptron (MLP) over background knowledge representations $\boldsymbol{H^b}$ and then used a softmax function to normalize the projected logits and get attention scores over all knowledge tokens for the cause property and the effect property respectively,

$$\boldsymbol{p}_c^b = \text{softmax}(\text{MLP}(\boldsymbol{H^b}; \theta_c)) \in \mathbb{R}^n, \qquad (2)$$

$$\boldsymbol{p}_e^b = \text{softmax}(\text{MLP}(\boldsymbol{H^b}; \theta_e)) \in \mathbb{R}^n, \qquad (3)$$

where $\boldsymbol{p}_c^b$ and $\boldsymbol{p}_e^b$ are the attention vectors over knowledge in terms of the cause and effect properties, and θ's are trainable parameters in the MLP.

Take Figure 1 as an example: $\boldsymbol{p}_c^b$ is the attention over background tokens, whose value is much larger for *mass* than the other tokens.

Polarity Check: We further need to judge the polarity of the qualitative relationship between the cause and effect properties (e.g., *mass* and *gravitational pull* are positively related). To achieve that, we first applied cause and effect property attention vectors on the knowledge representation $\boldsymbol{H^b}$ to obtain the weighted ones. Then we took the average of the weighted representations and concatenated them together. After that, another MLP followed by a softmax function computed the probabilities based on the representations,

$$\boldsymbol{p}_{pol} = \mathrm{softmax}(\mathrm{MLP}((\boldsymbol{H^b}^T\boldsymbol{p_c^b}; \boldsymbol{H^b}^T\boldsymbol{p_e^b}); \theta_{pol})), \tag{4}$$

where $\boldsymbol{p}_{pol} = [\boldsymbol{p}_{pol+}, \boldsymbol{p}_{pol-}]$ denotes the probability of positive and negative correlations, θ_{pol} is a learnable parameter of the MLP. In the example shown in Figure 1, $\boldsymbol{p}_{pol+}$ is supposed to be larger than $\boldsymbol{p}_{pol-}$.

Find World: Furthermore, we should return to the statement and find out the world that happened in the statement (e.g., *increasing their mass*). To achieve that, we used the same setting as the*Find Cause and Effect Property* module,

$$\boldsymbol{p}_w^s = \mathrm{softmax}(\mathrm{MLP}(\boldsymbol{H^s}; \theta_w)) \in \mathbb{R}^m, \tag{5}$$

where $\boldsymbol{p_w^s}$ is the attention vectors over the statement for the world, and θ is the learnable parameters of the MLP.

Value Prediction: Moreover, we need to decide whether the attribute value in World is an increment ($\boldsymbol{p}_{val\uparrow}$) or decrement($\boldsymbol{p}_{val\downarrow}$; e.g., *increase their mass* is an increment). To achieve that, we derive representations of the world by averaging statement representation $\boldsymbol{H^b}$ weighted by the world attention vector, $\boldsymbol{p_w^s}$. Then, another MLP was stacked with softmax to get the probabilities,

$$\boldsymbol{p}_{val} = \mathrm{softmax}(\mathrm{MLP}((\boldsymbol{H^s}^T\boldsymbol{p_w^s}); \theta_{val})), \tag{6}$$

where $\boldsymbol{p}_{val} = [\boldsymbol{p}_{val\uparrow}, \boldsymbol{p}_{val\downarrow}]$ denotes the probability that the attribute value is incremented or decremented, and θ_{val} is a learnable parameter of the MLP. In the example shown in Figure 1, $\boldsymbol{p}_{val\uparrow}$ is supposed to be larger than $\boldsymbol{p}_{val\downarrow}$.

3.2.2 Comparison

The Comparison reasoning chain contains two modules that are shared with the Prediction reasoning chain, *Find Cause and Effect*, and *Polarity Check*. However, the Comparison chain differs from the Prediction chain in two modules.

Find Worlds: In the Comparison-type question like the second example shown in Figure 1, the statement asks to compare the effects on the two entities. Thus, two worlds appeared in the statement instead of one (e.g., *large masses* and *small masses*). To achieve that, we took the same straightforward method as the *Find World* module,

$$\boldsymbol{p}_{w1}^s = \mathrm{softmax}(\mathrm{MLP}(\boldsymbol{H^s}; \theta_{w1})) \in \mathbb{R}^m, \tag{7}$$

$$\boldsymbol{p}_{w2}^s = \mathrm{softmax}(\mathrm{MLP}(\boldsymbol{H^s}; \theta_{w2})) \in \mathbb{R}^m, \tag{8}$$

where $\boldsymbol{p_{w1}^s}, \boldsymbol{p_{w2}^s}$ are the attention vectors over the statement for worlds 1 and 2, and θ's are learnable parameters of the MLP.

Worlds Comparison: This module aims to compare the worlds in terms of the cause property. For example, world 1 (*larger masses*) is more relevant to *the greater the mass* than world 2 (*smaller masses*) in Figure 1. To achieve that, we adopted a bilinear function to evaluate the relevance between each world's cause property and the cause property in background knowledge, which is further normalized into a probability with softmax,

$$\begin{aligned}\boldsymbol{p}_{com} = \mathrm{softmax}((&\boldsymbol{H^b}^T\boldsymbol{p}_c^b)^T\boldsymbol{W}_{com}(\boldsymbol{H^s}^T\boldsymbol{p}_{w1}^s),\\ &(\boldsymbol{H^b}^T\boldsymbol{p}_c^b)^T\boldsymbol{W}_{com}(\boldsymbol{H^s}^T\boldsymbol{p}_{w2}^s)),\end{aligned} \tag{9}$$

where $\boldsymbol{W_{com}} \in \mathbb{R}^{d \times d}$ is a trainable matrix, and p_{com} denotes the probability that the world is relevant to the cause property.

3.2.3 Deduction

The Deduction module aims to conduct the reasoning by considering the evidence computed from each module in the reasoning chain. In particular, we applied the decision functions as shown in Figure 2c for each reasoning type to generate the synthetic text.

We take the examples in Figure 1 as an illustration. From the *Find Cause and Effect*, and *Polarity Check* modules, we conclude a positive relationship existed between the cause *mass* and the effect *gravitational pull*, so we denote $\boldsymbol{p}_{pol}(\boldsymbol{Effect}|\boldsymbol{Cause})$ as $+$.

For Prediction, the *Value Prediction* module states that the attribute value of the world in terms of cause property is an increment. Thus, we denote $\boldsymbol{p}_{val}(\boldsymbol{W}orld|\boldsymbol{C}ause)$ as ↑. Therefore, the world must also have an increment on the effect property due to the positive relationship between the cause and effect. In this way, we generated a synthetic text by slot-filling as follows: *large mass* will cause **more** *gravitational pull*.

Similarly, for Comparison, the *Worlds Comparison* module showed that compared with world 2, world 1 was more relevant to the cause property in the background knowledge. Thus, we denote $\boldsymbol{p}_{com}(World1, World2)$ as $>$ (i.e., $\boldsymbol{p}_{com}(World1|Cause) > \boldsymbol{p}_{com}(World2|Cause)$). In this way, we rendered world 1 larger than world 2 in terms of the effect property because of the positive polarity. Then, a synthetic text was also be generated.

3.2.4 Reasoning Type Classification

As the reasoning type is not available during the inference time, we added a classifier based on the statement representations, which is defined as follows:

$$\boldsymbol{s} = \frac{1}{m}\sum_{i}^{m} \boldsymbol{H}_{\boldsymbol{i}}^{\boldsymbol{s}} \in \mathbb{R}^{d}, \tag{10}$$

$$\boldsymbol{p}_{cla} = \sigma(MLP(\boldsymbol{s}; \theta_{cla})), \tag{11}$$

where $\boldsymbol{s}$ can be viewed as an embedding of the statement, θ_{cla} is the trainable parameter in the MLP, and σ is an activation function. $\boldsymbol{p}_{cla}$ denotes the classification scores.

3.3 Answer Prediction

In the Answer Prediction component, we replaced the given background knowledge with the synthetic text from the Reasoning component. Then we combined it with the question and answer choice $A = \{a_k\}_{k=1}^{2}$ as $\langle s\rangle\ SyntheticText\ \langle/s\rangle\ \langle/s\rangle\ q; a_k\ \langle/s\rangle$. We used the final hidden vector corresponding to the first input token ($\langle s\rangle$) as the aggregate representation. We further predicted the probabilities of an answer being the answer choice a_k in the same manner as in Liu et al. (2019).

3.4 Model Training

Two models (i.e., reasoning and answer prediction) are learned in our approach.

Reasoning The loss function for reasoning is defined as

$$\ell_{Reason} = -\sum_{\boldsymbol{y}\in\boldsymbol{Y}} \alpha_{\boldsymbol{y}} \gamma_{\boldsymbol{y}} \tilde{\boldsymbol{y}}^{T} log(\boldsymbol{y}). \tag{12}$$

$\boldsymbol{Y} = \{\boldsymbol{p}_{\boldsymbol{w}}^{\boldsymbol{s}} \in \mathbb{R}^{m}, \boldsymbol{p}_{\boldsymbol{w_1}}^{\boldsymbol{s}} \in \mathbb{R}^{m}, \boldsymbol{p}_{\boldsymbol{w_2}}^{\boldsymbol{s}} \in \mathbb{R}^{m}, \boldsymbol{p}_{\boldsymbol{e}}^{\boldsymbol{b}} \in \mathbb{R}^{n}, \boldsymbol{p}_{\boldsymbol{c}}^{\boldsymbol{b}} \in \mathbb{R}^{n}, \boldsymbol{p}_{val} \in \mathbb{R}^{2}, \boldsymbol{p}_{com} \in \mathbb{R}^{2}, \boldsymbol{p}_{cla} \in \mathbb{R}^{2}\}$ are predictions of different modules, $\tilde{\boldsymbol{y}}^{T} \in \{0,1\}^{m}$ or $\tilde{\boldsymbol{y}}^{T} \in \{0,1\}^{n}$ or $\tilde{\boldsymbol{y}}^{T} \in \{0,1\}^{2}$ are corresponding gold labels, $\gamma_{\boldsymbol{y}} \in \{0,1\}^{2}$ denotes whether the loss function should use the label (as some annotations would be missed due to different reasoning type), and $\alpha_{\boldsymbol{y}}$ is the weight for each module y.

Answer Prediction: We took the standard binary cross entropy loss ℓ_{AP} as the training objective of the Answer Prediction component.

During the inference time, we first determined the reasoning type based on the classification score obtained in section 3.2.4. Then we followed the Deduction module to synthesize corresponding text and further fed it into the trained Answer Prediction model. The answer choice with the highest probability was selected as the final answer.

4 Experiment Setup

4.1 Datasets

Datasets QuaRTz (Tafjord et al., 2019b) and QuaRel (Tafjord et al., 2019a), were used to evaluate the proposed model. Both datasets require reasoning about textual qualitative relationships and provide well-defined annotations used for symbolic reasoning. The detailed statistics are in Table 1.

Auxiliary Supervision: The loss function for the Reasoning component takes two different types of supervision, i.e., span supervision (e.g., cause, effect spans in the knowledge) and binary logits supervision (value prediction, world comparison, and reasoning type). The QuaRTz dataset provides the annotations for the property descriptions and property values, but not every instance in the dataset contains such annotations (2280 out of 2696 are annotated completely). Furthermore, some annotations are not standard and must be further processed to satisfy the training objective. Therefore, we mitigated these issues by generating an additional auxiliary from hypothesis and manual annotating. The detailed guidelines and labeled examples are in Appendix A.2. All modules in the Reasoning component are trained only on the QuaRTz (the

Statistics	Train	Dev	Test
QuaRTz	2,696	384	784
QuaRel	1,941	278	552

Table 1: Statistics of the datasets

proportion of Prediction and Comparison questions is 2296:400).

4.2 Implementation Details

We used the pre-trained language model RoBERTa-large in the experimentation[1]. In particular, we trained all modules in the Reasoning component end-to-end on one Nvidia RTX8000 48GB GPU and used two GPUs for the Answer Prediction component. We tuned the Reasoning component parameters according to the averaged performance of all modules and tuned the parameters in the Answer Prediction component based on the final accuracy. We selected F1 scores and accuracy as the evaluation metrics. Specifically, we set α_y's in equation 12 as follows: 0.1 for span-based loss, 0.2 for the *World Comparison, Value Prediction*, and *Reasoning Type Classification*. The detailed hyperparameters and search bounds are described in the Appendix A.1.

4.3 Compared Models

QUASP and QUASP+: The models proposed by Tafjord et al. (2019a) which extend type-constrained semantic parsing to address the problem of tracking different "worlds" in questions.

BERT and RoBERTa: The standard multiple-choice QA frameworks are based on a powerful pre-trained language model (Devlin et al., 2019; Liu et al., 2019). As described in section 3.3, it took the concatenation of knowledge, the question, and answer options as the input and used the first token representation for classification.

gvQPS+: Instead of introducing a semantic parser, this model applies the generate-validate framework (Mitra et al., 2019). It first generates a natural language description of the logical form and validates whether the natural language description is followed from the input text.

DeepEKR: Similar to Mitra et al. (2019), this model replaces the parser with a neural network, softening the symbolic representation (Mitra et al., 2020).

Model	QuaRTz		QuaRel	
	Dev	Test	Dev	Test
Random	50.0	50.0	50.0	50.0
QUASP	-	-	62.1	56.1
QUASP+	-	-	68.9	68.7
BERT	-	67.7	-	53.0
BERT(PFT on RACE)	-	79.8	-	79.9
gvQPS+	-	-	-	76.6
DeepEKR	-	79.8	-	81.15
RoBERTa	86.8*	85.7*	81.1(84.5*)	80.0(83.3*)
LG(DA)	-	-	84.5	84.7
LG(DA+Reg)	-	-	85.1	85.0
Ours	**89.6**	**89.9**	**89.5**	**86.8**

Table 2: Performance of different models on both datasets, where PFT stands for pre-finetune, and * means the result we implemented.

LG(DA,Reg): The RoBERTa-based model leverages logical and linguistic knowledge to augment labeled training data (DA) and then uses a consistency-based regularizer (Reg) to help the training (Asai and Hajishirzi, 2020).

5 Experimental Results

5.1 Question Answering Performance

The performance of the development and test of QuaRTz and QuaRel is shown in Table 2. Our model outperformed the existing state-of-the-art models (RoBERTa and LG with DA+Reg) by a large margin (2.8% and 4.2% absolute difference on QuaRTz, 4.4%, and 1.8% on QuaRel). These results illustrate that compared to the semantic parser-based model and the one-step "black box" model, our approach that imitates human cognitive behaviors is more capable of conducting qualitative reasoning and generalization.

Furthermore, compared with the semantic parser-based methods (i.e., the first group in the table), almost all language model-based methods achieved superior performance, demonstrating the power of the pre-trained language model. However, these models are mostly data-driven. The BERT model without pre-finetuning on RACE (Lai et al., 2017) was unable to converge on QuaRel. Furthermore, the data augmentation technique resulted in a 4.7% improvement in the LG(DA) model, proving the one-step "black box" model has high demand for training resources. Nonetheless, our approach, without any additional training data, still achieves

Reasoning Type Classification	$\boldsymbol{p}_{cla}$	-	-	88.0

Table 3: Performance in the Reasoning component.

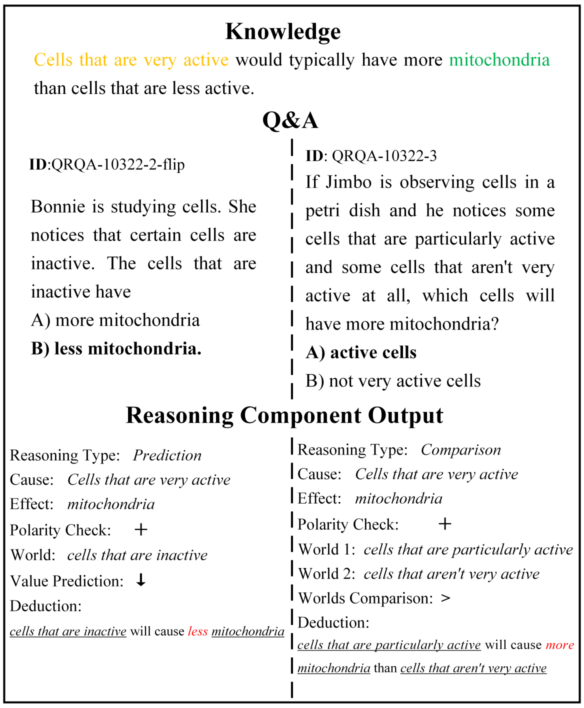
better performance, demonstrating its effectiveness and rationality.

5.2 Reasoning Component Performance

In the Reasoning component, we designed multiple neural network modules for two reasoning chains. Each module was designed to accomplish its subtask and provide an intermediate prediction that explains the reasoning process in a human cognitive manner. To evaluate the effectiveness of each module, we converted the attention vectors over the context into a text span and the probability scores into a predicted class. The conversion details are in the Appendix A.3. Table 3 shows the performance results for each module.

Find Cause and Effect, *Find World*, and *Find Worlds*, three modules that should detect concerned text spans from the context, all achieved adequate F1 scores. There are two reasons why our model did not score very well on a span extraction task like extractive machine reading comprehension (e.g., SQuAD[2]). First, the text span in our task is not as accurately defined as the answer in MRC. Generally, the length of the text span is long, and the boundary is fuzzy. Second, our approach computed the attention score for each token in the context and leveraged it softly, and thus less sensitive to boundary detection. However, when we used fuzzy F1 scores as the evaluation metrics (introduced in (Ren et al., 2020), which were marked as 1 as long as the original F1 was not equal to 0), the scores for all modules increased by a large margin, proving the reasoning ability.

Polarity Check, *Value Prediction*, and *World Comparison*, three modules that require classification capability based on the given span prediction of the upstream modules, achieved high accuracy (88.8%, 91.5%, and 84.6%), indicating the rationality of our end-to-end sequential model design. Additionally, We could argue that determining whether an attribute is incremental or decremental is a relatively simple task for language models.



Knowledge

Cells that are very active would typically have more mitochondria than cells that are less active.

Q&A

ID:QRQA-10322-2-flip

Bonnie is studying cells. She notices that certain cells are inactive. The cells that are inactive have

A) more mitochondria

B) less mitochondria.

ID: QRQA-10322-3

If Jimbo is observing cells in a petri dish and he notices some cells that are particularly active and some cells that aren't very active at all, which cells will have more mitochondria?

A) active cells

B) not very active cells

Reasoning Component Output

Reasoning Type: *Prediction*
Cause: *Cells that are very active*
Effect: *mitochondria*
Polarity Check: +
World: *cells that are inactive*
Value Prediction: ↓
Deduction:
cells that are inactive will cause *less* *mitochondria*

Reasoning Type: *Comparison*
Cause: *Cells that are very active*
Effect: *mitochondria*
Polarity Check: +
World 1: *cells that are particularly active*
World 2: *cells that aren't very active*
Worlds Comparison: >
Deduction:
cells that are particularly active will cause *more* *mitochondria* than *cells that aren't very active*

Figure 3: An example from QuaRTz with visualized intermediate outputs provided by our model.

The *Reasoning Type Classification* module obtained a good-enough performance (90.1%), the recall value for Prediction type was 88.0%, and the recall value for Comparison type was 76.7%. The result is acceptable as some questions could be solved simultaneously in a Prediction and a Comparison manner. For example, the Comparison question in Figure 1 can also be considered a Prediction if we care only about the world with high priority (i.e., *two planets with very large mass*). This phenomenon somehow increased the fault tolerance and improved the generality of our method.

Case study: Our approach provides intermediate outputs that sufficiently explain the reasoning process, which can lead to interpretability. Figure 3 presents examples of the transparent reasoning process run by our model. More examples can be found in the Appendix A.5. The knowledge states the relationship between *active cells* and *mitochondria*, while two questions describe different scenarios to test the application of this knowledge.

As shown in Figure 3, our model outputs several intermediate results through the Reasoning component. First, it identifies the reasoning chain type for

---

[2] `https://rajpurkar.github.io/SQuAD-explorer/`

each question; the left one is prediction, while the right one requires comparison. Then, each module in the corresponding reasoning chain outputs its prediction. For example, the *Find Cause and Effect* module captured the cause property and the effect property in the knowledge. Then the *Polarity Check* module correctly figured out the positive relationship between them. The examples indicate that our approach not only conducts final answer prediction but also explains the machine understanding and reasoning process.

5.3 Human Evaluation

In the Answer Prediction component, we fed the generated synthetic text instead of given knowledge into the model. To further measure the effect of synthetic text on answer prediction, we introduced the human evaluation widely used in NLG field. We assembled ten well-educated volunteers and gave each person 30 randomly sampled questions from QuaRTz, half of which provided knowledge, half of which provided our synthetic text. Then we asked the participants to rate the question on a 5-point scale for each following metric: *fluency* (does it read coherently), *informativeness* (how much information is contained), *explicitness* (does it describe the relation clearly), and *relevance* (is it relevant to the question). We also measured the time consumption for problem-solving by giving knowledge or synthetic text. Table 4 shows the results.

The given knowledge had higher scores for *fluency* and *informativeness* because the knowledge sentences were manually extracted from a large corpus and may contain multiple relations among multiple properties, while the synthetic text was generated by slot-filling and described only the relation mentioned in the question. Furthermore, the synthetic text achieved superior scores for *explicitness* and *relevance*, which indicates our Reasoning component is successful in understanding and reasoning between the question and knowledge and expressed the explicit relationship in a way close to the description in the question scenario. Additionally, this is shown in that the participants took less time to answer questions with synthesized text.

5.4 Error Analysis

We randomly sampled 60 examples for error analysis and more than half were caused by wrong predictions in the Reasoning component (48 out of 60). The other errors were in two main categories.

	Given Knowledge	**Synthetic Text**
Fluency	**4.3**	3.9
Informativeness	**4.5**	3.3
Explicitness	3.4	**4.4**
Relevance	3.8	**4.6**
Time Consumption(s)	31.1	**24.3**

Table 4: Human evaluation results.

Incomplete Knowledge: These errors occurred when the question mentioned only a world without any attribute value description; e.g., the question aimed to predict the gravitational pull for the Sun, and knowledge told that a larger mass causes a larger gravitational pull. To answer this question, we need to know that the sun has a large mass.

Incomplete Synthetic Text: Two reasons cause such errors. One is that the boundaries are not well-defined when attention vectors are turned into text, resulting in a lack of fluency or loss of information. The other is a mismatch between the knowledge and the question; e.g., the knowledge talks about the distance, but the question describes hugging. Thus, the generated synthetic text does not provide enough information to solve the problem.

6 Conclusion

In this paper, we aimed to solve the qualitative reasoning task in an interpretable manner. Inspired by human cognition, we first summarized the questions into two categories, Prediction and Comparison. Then an end-to-end trained Reasoning component that contains two reasoning chains was designed. Both reasoning chains contained multiple neural modules that provide transparent intermediate predictions for the understanding and reasoning process. The experimental results showed the effectiveness of our approach, and the analysis of each module and case study demonstrated the superior interpretability compared with the "black-box" model. Moreover, we found that some questions could be solved by both reasoning chains, thus increasing the default tolerance and generalization capability. Furthermore, a human evaluation was conducted to validate the function of the synthetic text and provide an additional explanation for the superior performance achieved by our method. However, the error analysis showed the inadequacy under complicated scenarios. Therefore, our future work will focus on applying interpretable reasoning on complex reasoning tasks. The annotated data and models are shared publicly [3].

A.2 Auxiliary Supervision Construction

Figure 4 shows one labelled example. The official dataset already provides detailed annotations for both knowledge and question, where some annotations could be directly introduced in our training objective. For the example, "para_anno" tells the cause and effect properties described in the knowledge, and the polarity among them would be marked as positive if the "effect_dir_sign" is the same as the "casue_dir_sign", otherwise will be marked as negative.

However, some annotations are still missing, e.g., reasoning type. We introduce two methods to get additional labels. On the one hand, We made some hypotheses. For example, if "question_anno" contains "more_effect_xxx" and "less_effect_xxx" simultaneously, we would consider this question as a comparison type. On the other, we annotate the samples manually. For the questions without qualified annotation, we label them by hand. Particularly, we find the text spans in the knowledge and question, then transform the annotations to the machine-readble form automatically.

A.3 Conversion Instruction

For *Find Cause and Effect*, *Find World*, and *Find Worlds* modules, we should convert the attention

Knowledge

An object with greater mass or greater velocity has more kinetic energy.

Q&A

Milo threw both a basketball and a baseball through the air. If the basketball has more mass then the baseball, which ball has more kinetic energy?

A) Basketball B) Baseball

Figure 4: An example with auxiliary supervision.

vector output into a text span.

First, the token with the highest probability is selected. After that, we check left and right from the selected word position and extend it if the probability of each neighbor is larger than the threshold. The threshold value is determined based on F1 scores.

For the rest modules, we select the predicted class with the highest probability.

A.4 Ablation Study on sub-tasks

We decompose the complex qualitative reasoning task into several simple sub-tasks according to logic and then train several sub-tasks together. Naturally, as the number of tasks increases, errors accumulate, but our method ultimately performs better. To further examine the rationality of our work, we conduct an ablation study on partial modules.

Modules	**Cause**		**Effect**		**Polarity**
	F1	Fuzzy F1	F1	Fuzzy F1	Accuracy
Find Cause and Effect + Polarity Check	**72.6**	**82.3**	**67.0**	**78.4**	**88.8**
only Find Cause and Effect	71.7	81.8	66.8	75.5	58.6
only Polarity Check	8.3	14.3	9.6	16.7	83.3

Table 7: Ablation study on Find Cause and Effect and Polarity Check modules.

Table 7 shows the ablation study result on *Find Cause and Effect* and *Polarity Check* modules. The model achieves the best performance when we train two modules together. However, when we remove any module, i.e., focus on a single sub-task, the corresponding performance deteriorates. This may due to our approach, which mimics human cognitive design, enables the model to make better use of information from upstream modules to facilitate training. Therefore, our model could finally achieve superior performance.

A.5 More Examples

We present more example with intermediate outputs that correctly answered by our model in Table 8.

Abstract

Emotion cause analysis (ECA) has been an emerging topic in natural language processing, which aims to identify the reasons behind a certain emotion expressed in the text. Most ECA methods intend to identify the clause which contains the cause of a given emotion, but such clause-level ECA (CECA) can be ambiguous and imprecise. In this paper, we aim at span-level ECA (SECA) by detecting the precise boundaries of text spans conveying accurate emotion causes from the given context. We formulate this task as sequence labeling and position identification problems and design two neural methods to solve them. Experiments on two benchmark ECA datasets show that the proposed methods substantially outperform the existing ECA models [1].

1 Introduction

The task of emotion cause analysis (ECA) (Lee et al., 2010a), which is to extract the causes of an emotion expression from a given context, has gained increasing attention recently.

Most existing studies (Gui et al., 2016, 2017; Li et al., 2018, 2019; Xia et al., 2019) formulate ECA as a clause-level task (dubbed as CECA), which tries to extract the clauses that contain the emotion cause content. In CECA, a clause is typically a text segment separated by punctuation marks (e.g., ‘,’, ‘.’, ‘?’, ‘!’, etc.) in the given context. In the following example, the clause $[x_3]$ will be extracted as it contains the reason “the risk of infringement” that stimulates the emotion *afraid*.

Example 1. [2] $[x_1]$ *The claim for damages caused by infringement has legal basis,* $[x_2]$ *and it is logical and reasonable.* $[x_3]$ *We can’t give up the good character of friendship and mutual assistance just because we are <u>afraid</u> of* ***the risk of infringement****.* $[x_4]$ *Give up food for being afraid of being choked.* $[x_5]$ *We should adhere to the traffic rules.*

However, determining the clause containing the stimulus is sub-optimal and inaccurate for ECA. In Example 1, while among the 5 clauses $[x_3]$ is the best, its main content “We can’t give up . . . assistance” is not the cause of *afraid*. Such gap motivates a strong need of pinpointing more precise or finer-grained cause expressions which can convey the specific reasons of an emotion.

Some studies (Gao et al., 2015a,b; Neviarouskaya and Aono, 2013) try to extract emotion cause triples (a triple like (noun, verb, noun)) or emotion cause phrases. The extracted triples or phrases are usually not a complete emotion cause expression since the words in these triples or phrases are typically not continuous. Bi et al. (2020) proposed a new task for emotion and emotion cause span pair and classification task. Lee et al. (2010a) summarized seven groups of linguistic cues which could serve as indicators of cause events. Ghazi et al.. (2015) built a Conditional Random Fields (CRF) learner to extract emotion cause spans with a set of manually engineered features. These two approaches are labor-intensive and prone to the sub-optimal design of features.

We study the Span-level ECA (SECA) based on state-of-the-art neural approach by focusing on detecting the boundaries of cause spans. We approach to the boundary detection in two different ways via sequence tagging and start/end position identification both in an end-to-end fashion. The emotion cause span is usually a sequence of consecutive tokens which convey exact reasons of the emotion and need to be inferred from the whole context. More specifically, we obtain the emotion

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 676–682
August 1–6, 2021.

cause span by 1) mapping each token in the input context to a label indicating the ranges of spans; 2) pointing to the start and end positions of the span directly in the given context. The main contributions of our work are three-fold:

- We formulate SECA task as sequence tagging and position identification problems for boundary detection of emotion cause spans, and propose neural models to tackle this task.
- Different from previous ECA approaches, a pointer network is introduced to identify the start and end positions of emotion cause in our work. This is the first time to introduce the pointer network to ECA task.
- Experiments on two benchmark datasets show that our models substantially outperform the state-of-the-art ECA approaches at both span and clause levels.

2 Related Work

Lee et al. (2010b) first proposed a task on ECA and constructed a small-scale Chinese emotion cause corpus. Based on this corpus, Chen et al. (2010) proposed a rule based method for this task. Gui et al. (Gui et al., 2014) extended the rule-based method to Chinese microblog text. Gao et al. (Gao et al., 2015b,a) treated the emotion cause as a list of triples (a triple like (noun, verb, noun)). They structured a microblog post as a set of triples to determine which triple is the emotion cause. Shuntaro et al.(Yada et al., 2017) defined emotion cause as the nearest clause describing events of the cause of the emotion. Gui et al. (2016) constructed a public ECA dataset based on news corpus and proposed a multi-kernel-based method for CECA. All these methods rely on either manual rules or feature engineering.

Gui et al. (2017) first proposed a deep neural model for CECA. Following that, many CECA methods were developed with deep learning (Gui et al., 2017; Li et al., 2018; Yu et al., 2019; Ding et al., 2019; Li et al., 2019; Xia et al., 2019; Fan et al., 2019). Li et al. (2019; 2018) improved the performance of CECA by considering the contextual information of the emotion. Xia et al. (2019) proposed a hierarchical network for CECA based on Transformer encoder to capture different types of features. Fan et al. (2019) utilized the discourse information and clause position for the task. Xia et al. (2019) and Chen et al. (2020a) proposed two variant tasks of ECA for extracting emotion and cause clause pairs. And then, many deep learning models (Wu et al., 2020; Chen et al., 2020b,c; Wei et al., 2020; Singh et al., 2021) were designed to tackle emotion cause pair extraction task.

Little work has been done for SECA. Lee et al. (Lee et al., 2010a) summarized the generalized rules for detecting the emotion causes of the emotion in Chinese. Based on manually crafted linguistic cues, Ghazi et al. (2015) built a CRF learner to identify emotion cause spans. However, these models are oversimplified and reliant on the ad-hoc features designed, thus are not generalized well.

3 Methodology

In this section, we first introduce two types definition of SECA. Then we describe our designed models.

3.1 Problem Formulation

Given a context S, which includes a sequence of n tokens $S = [w_1, w_2, \ldots, w_n]$, the emotion expression $E = [e_1, e_2, \ldots, e_m]$ and at least one emotion cause span, SECA task aims to detect the boundaries of emotion cause spans from S which stimulate the emotion expression.

Firstly, this task can be formulated as sequence labeling problem, of which the goal is to obtain the correct sequence of labels:

$$L = [l_1, l_2, \ldots, l_n] \tag{1}$$

where $l_i \in \{B, I, O\}$, and B, I and O denote the beginning, inside of and outside of cause span, respectively, indicating the ranges of spans.

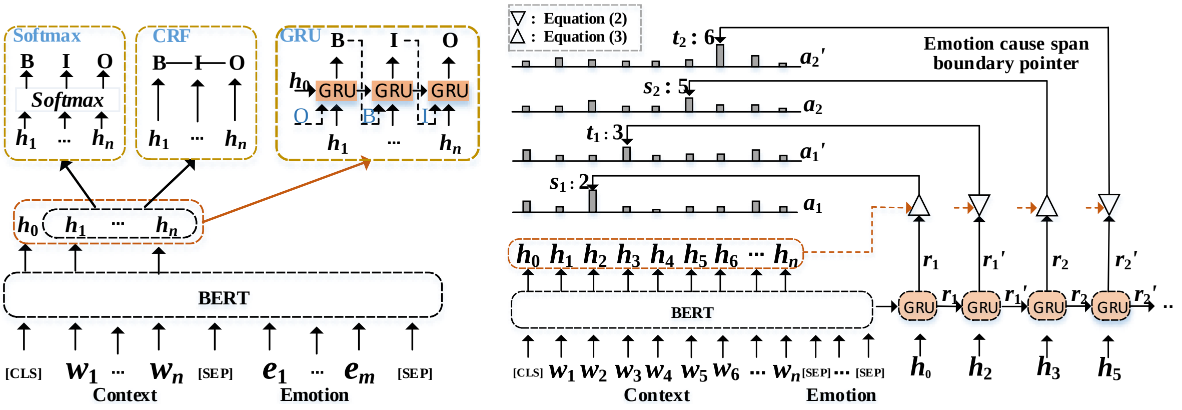
Secondly, this task also can be formulated as a position identification problem, where the goal is to get a list of correct start-end positions of emotion cause spans:

$$\mathcal{B} = [(s_1, t_1), (s_2, t_2), \ldots] \tag{2}$$

where s_i and t_i are the start and end token indices of the i-th cause span in the context, respectively.

3.2 Model Description

We use BERT (Devlin et al., 2019) as the backbone of our models due to it has strong contextualized representation ability. The context S and the emotion E are concatenated by forming a combined sequence as the input fed into BERT:



(a) Sequence labeling models.

(b) Start/End position identification model.

Figure 1: The architectures of the proposed boundary detection models for SECA.

$[\text{CLS}], w_1, \ldots, w_n, [\text{SEP}], e_1, \ldots e_m, [\text{SEP}]$, where [CLS] and [SEP] are special tokens. Then, BERT receives the sequence and outputs the representation of each token in the combined sequence. The contextualized representations of each token $w_i \in S$ and the token [CLS] can be given as:

$$h_i = \text{BERT}(w_i), \quad h_0 = \text{BERT}([\text{CLS}]) \qquad (3)$$

where h_0 and $h_i \in \mathbb{R}^{d_b}$ and d_b is the vector dimension of the last layer of BERT. Based on the BERT encoding, we introduce the two types of span boundary detection models for SECA. An overview of our models are shown in Figure 1.

3.2.1 Sequence Labeling Models

We use three common ways to predict the labels of an input sequence. The first is the softmax function direct tag prediction which is straightforward to compute. The second is CRF, a well-known statistical graphical model which has demonstrated state-of-the-art accuracy on many sequence labeling tasks (Liu et al., 2014; Jin and Yu, 2021). The third is a variant of RNN (Goller and Kuchler, 1996) (e.g. GRU, LSTM) which generates tags sequentially by predicting the next label considering its previously predicted labels.

Softmax. Based on the token representation obtained in Equation (3), the probability distribution over the label set can be computed as:

$$p(l_i) = \text{softmax}(W_1 h_i + b_1) \qquad (4)$$

where $W_1 \in \mathbb{R}^{d_b \times d_l}$ and $b_1 \in \mathbb{R}^{d_l}$ are learnable parameters, $p(l_i) \in \mathbb{R}^{d_l}$ is the label probability distribution of the i-th word and d_l is the size of label set.

CRF. CRF obtains the probability of a whole sequence:

$$p(L|S) = \frac{\exp(\text{score}(S, L))}{\sum_{L' \in \mathcal{L}} \exp(\text{score}(S, L'))} \qquad (5)$$

where $\mathcal{L}$ is the set of all candidate label sequences of the context. Here, we omit the detail of this classical prediction model (see Lafferty et al. (2001)).

GRU. The GRU version of RNN is effective and easy to train (Ma et al., 2019). At each predicting step, we update the hidden state h_i of token w_i using:

$$\tilde{h}_i = \text{GRU}(\tilde{h}_{i-1}, \ell(l_{i-1}) \oplus h_i) \qquad (6)$$

where $\tilde{h}_i \in \mathbb{R}^{d_g}$ and d_g is the number of the GRU units, $\ell(l_{i-1}) \in \mathbb{R}^{d_\ell}$ is the embedding vector of previous label l_{i-1} and d_ℓ is the size of label embedding. Then, the probability distribution of l_i can be obtained by:

$$p(l_i) = \text{softmax}(W_2 \tilde{h}_i + b_2) \qquad (7)$$

where $W_2 \in \mathbb{R}^{d_g \times d_l}$, $b_2 \in \mathbb{R}^{d_l}$ are training parameters.

3.2.2 Position Identification Model

Point network was first proposed by Vinyals et al. (2015), which is suitable for our positions identification task thanks to the fact that it is able to select positions from the input. Here we adopt it to generate the start and end positions of spans in turn. Because the number of cause spans is not fixed, we set a parameter $\mathcal{C}$ to control how many spans to generate, and allow the two end points in (s_i, t_i) to take an integer value in $[0, n]$. For the k-th span (s_k, t_k), we first get its start index s_k. An attention mechanism is used to obtain the attention weight α_{kj} of the j-th token (for all $j \in [0, n]$) as follows:

$$\begin{aligned} a_{kj} &= \frac{\exp(q_{kj})}{\sum_{j'=0}^{n} \exp(q_{kj'})} \\ q_{kj} &= v^{\top} \tanh(h_j W_3 + r_k W_4) \end{aligned} \tag{8}$$

where $W_3 \in \mathbb{R}^{d_b \times d_v}$, $W_4 \in \mathbb{R}^{d_r \times d_v}$ and $v \in \mathbb{R}^{d_v}$ are learnable parameters (d_v is the size of v), r_k is the hidden vector obtained by GRU:

$$r_k = \mathrm{GRU}(h_{t_{k-1}}, r'_{k-1}) \tag{9}$$

where t_{k-1} is the index of end position of the (k-1)-th span and $r'_{k-1} \in \mathbb{R}^{d_r}$ (d^r is the number of GRU units) is hidden vector obtained by GRU for predicting t_{k-1} (see below). Then, we set s_k as the highest attention weight from attention vector $a_k = [a_{k0}, \ldots, a_{kn}]$.

To predict the end index t_k of the k-th span, the same attention mechanism is used to get the attention weight a'_{kj}:

$$\begin{aligned} a'_{kj} &= \frac{\exp(\hat{q}_{kj})}{\sum_{j'=0}^{n} \exp(\hat{q}_{kj'})} \\ \hat{q}_{kj} &= v^{\top} \tanh(h_j W_3 + r'_k W_4) \\ r'_k &= \mathrm{GRU}(h_{s_k}, r_k) \end{aligned} \tag{10}$$

where W_3, W_4 and v are learnable parameters. Similarly, the end index t_k can be identified by taking the maximum value in a'_k.

4 Experiments and Results

We evaluate the proposed methods on the Chinese ECA (**CHI**) dataset (Gui et al., 2016) and English ECA (**ENG**) dataset (Ghazi et al., 2015). On both datasets, cause spans are manually annotated and each context contains an emotion expression (or emotion category) and at least one cause span. The CHI dataset contains 2,105 instances and 2,147 cause spans. The ENG dataset contains 820 instances, and each contains one span only.

We use pre-trained *BERT-Base Chinese* and *BERT-Base Uncased* to encode the CHI and ENG datasets, respectively. We also choose the pre-trained span-level *SpanBERT-Base-cased* (n/a for Chinese) as the encoder on ENG dataset. We follow the default settings of BERT (Devlin et al., 2019) for fine-tuning. Adam (Kingma and Ba, 2015) optimizer is used with learning rate 1e-5. The epoch is set to 10. The size of label embedding is 50. $\mathcal{C}$[3] is set to 3 on CHI and 1 on ENG which are the maximum number of cause spans in the respective *training* set. We follow the settings of previous works to split the datasets for train/dev/test (Ghazi et al., 2015; Gui et al., 2017). Hyper-parameters are tuned on the dev set.

Model	P^s	R^s	F_1^s
	CHI		
Lee et al. (2010a)	0.197	0.161	0.177
Gui et al. (2017)	0.187	0.181	0.184
BERT$_{base}$+Softmax	0.483	**0.574**	0.525
BERT$_{base}$+GRU	0.481	0.567	0.520
BERT$_{base}$+CRF	0.564	0.570	**0.566**
BERT$_{base}$+Pointer	**0.570**	0.526	0.547
	ENG		
Ghazi et al. (2015)	0.666	0.593	0.628
BERT$_{base}$+Softmax	0.838	0.876	0.856
BERT$_{base}$+GRU	0.883	0.868	0.875
BERT$_{base}$+CRF	0.866	0.890	0.878
BERT$_{base}$+Pointer	**0.910**	**0.891**	**0.901**
BERT$_{span}$+Softmax	0.830	**0.891**	0.859
BERT$_{span}$+GRU	0.893	0.879	0.886
BERT$_{span}$+CRF	0.858	0.883	0.870
BERT$_{span}$+Pointer	**0.904**	0.890	**0.897**

Table 1: SECA results based on span-level metrics.

We have BERT (**BERT**$_{base}$) and SpanBERT (**BERT**$_{span}$) as pre-trained models, and **Softmax**, **CRF**, **GRU** and pointer network (**Pointer**) as prediction models.

4.1 SECA Result

On CHI dataset, we compare our model with the rule based model (Lee et al., 2010a) and the word ECA model that outputs cause words (Gui et al., 2017), which is somewhat similar to our work. On ENG dataset, the CRF-based model in (Ghazi et al., 2015) is the only span-level baseline. For evaluation, we use span precision (P^s), recall (R^s) and F1 score (F_1^s) which are defined as

$$\begin{aligned} P^s &= \frac{\text{\# of correct cause spans}}{\text{\# of predicted cause spans}} \\ R^s &= \frac{\text{\# of correct cause spans}}{\text{\# of gold cause spans}} \\ F_1^s &= \frac{2 \times P^s \times R^s}{P^s + R^s} \end{aligned} \tag{11}$$

---

[3] If the number of emotion cause span(s) is less than $\mathcal{C}$, $(0, 0)$ is used for padding the correct list $\mathcal{B}$.

Table 1 shows that all our models strongly outperform the baselines, indicating our method is effective. More specifically, on CHI dataset our models BERT$_{base}$+Softmax, BERT$_{base}$+GRU, BERT$_{base}$+CRF and BERT$_{base}$+Pointer outperform the strong baseline model in Gui et al. (2017) by relative F_1^s improvements of 34.1%, 33.6%, 38.2% and 36.3%, respectively. The improvement is very significant with p-value less than 0.001 in t-test. With BERT encoder, Pointer performs the best on ENG and the second best on CHI, suggesting that pointer network is basically effective. Pointer is relatively worse than CRF on CHI because the number of spans it outputs is fixed as three while an instance on CHI may have less than three spans, rendering a small disadvantage. But generally, using pointer network for span boundary detection provides a strong alternative to classic CRF. It is a bit surprising that BERT$_{span}$ does not show advantage over BERT$_{base}$ here. We conjecture that given the small ENG dataset we cannot perform strong fine-tuning to make a big difference. In addition, the performance on ENG is much higher than on CHI because the context is generally much shorter making the task easier.

4.2 CECA Result

We can directly output clauses containing the predicted cause spans to compare with the rule based SECA model (2010a) and some strong CECA models (Gui et al., 2017; Li et al., 2018; Ding et al., 2019; Li et al., 2019; Xia et al., 2019; Fan et al., 2019; Hu et al., 2021). We only use **CHI** here since no clause labels are available and no previous work for CECA was done on English data for us to compare with. Following previous works (Gui et al., 2017; Xia et al., 2019), we use clause precision (P^c), recall (R^c), and F1 score (F_1^c) as evaluation metrics:

$$\begin{aligned} P^c &= \frac{\text{\# of correct cause clauses}}{\text{\# of predicted cause clauses}} \\ R^c &= \frac{\text{\# of correct cause clauses}}{\text{\# of gold cause clauses}} \\ F_1^c &= \frac{2 \times P^c \times R^c}{P^c + R^c} \end{aligned} \quad (12)$$

Model	P^c	R^c	F_1^c
Lee et al. (2010a)	0.675	0.429	0.524
Gui et al. (2017)	0.708	0.684	0.700
Li et al. (2018)	0.772	0.689	0.727
Ding et al. (2019)	0.762	0.691	0.742
Li et al. (2019)	0.784	0.759	0.771
Xia et al. (2019)	0.770	0.766	0.768
Fan et al. (2019)	0.811	0.773	0.791
Hu et al. (2021)	0.786	0.757	0.771
BERT$_{base}$+Softmax	0.828	**0.908**	0.866
BERT$_{base}$+GRU	0.825	0.903	0.862
BERT$_{base}$+CRF	**0.864**	0.873	**0.867**
BERT$_{base}$+Pointer	0.834	0.844	0.838

Table 2: CECA results on **CHI** benchmark dataset.

Table 2 shows that our proposed models outperform all the state-of-the-art CECA baselines. We attribute this to the fact that the BERT's contextualized representation capacity and our SECA models are supervised by the finer-grained span-level annotations directly, which can effectively guide model to learn more precise cause-related information. This advantage cannot be taken easily by the baseline approaches due to the nature of their clause-level supervision. Moreover, simply mapping the predicted spans to clauses for output makes Softmax become comparable with CRF and puts Pointer the last in terms of CECA performance. This is not surprising because an inaccurate span might still result in the right clause which just contains the predicted span. We also notice that rule based model performs worse than all the feature-learning models because that the manual rules hardly adopt to different datasets and feature-learning model can learn effective features according to the different datasets.

5 Conclusion

In this paper, we aim at span-level emotion cause analysis and propose neural sequence labeling and position identification models to detect the boundaries of emotion cause spans. The experiments conducted on two benchmark datasets of different languages demonstrate the effectiveness of the proposed approach, which achieves a new state-of-the-art performance on both span-level and clause-level ECA tasks.

Abstract

BERT has been used for solving commonsense tasks such as CommonsenseQA. While prior research has found that BERT does contain commonsense information to some extent, there has been work showing that pre-trained models can rely on spurious associations (e.g., data bias) rather than key cues in solving sentiment classification and other problems. We quantitatively investigate the presence of structural commonsense cues in BERT when solving commonsense tasks, and the importance of such cues for the model prediction. Using two different measures, we find that BERT does use relevant knowledge for solving the task, and the presence of commonsense knowledge is positively correlated to the model accuracy.

1 Introduction

Pre-trained language models (Peters et al., 2018; Radford et al., 2019; Devlin et al., 2019; Liu et al., 2019b) give competitive results on a variety of NLP tasks (Zhou and Zhao, 2019; Joshi et al., 2019; Liu and Lapata, 2019; Cui et al., 2020). It has been shown that they can effectively capture syntactic features (Goldberg, 2019), semantic information (Liu et al., 2019a) and factual knowledge (Petroni et al., 2019), which provides support for the success in downstream tasks.

Recently, there has been some debate about whether commonsense knowledge can be learned by a language model trained on large corpora. While Davison et al. (2019), Bosselut et al. (2019) and Rajani et al. (2019) argue that pre-trained language models can directly identify commonsense facts, Lin et al. (2019) and Klein and Nabi (2019) believe that structured commonsense knowledge is not captured well.

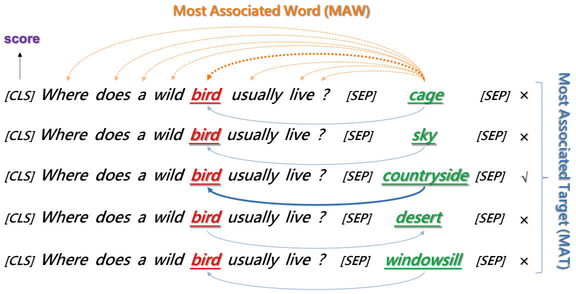

Figure 1: Two methods used to study structured commonsense knowledge in pre-trained Transformer. Commonsense link is drawn from the Target Concept (Answer Concept) to the Source Concept (Question Concept).

Pre-trained language models have achieved empirical success when fine-tuned on specific commonsense tasks such as COSMOS QA (Huang et al., 2019), SWAG (Zellers et al., 2018), and CommonsenseQA (Talmor et al., 2019). One possible reason of the high performance is that there exist *superficial cues* or *spurious associations* in the dataset, which enables models to answer questions without understanding the task (Niven and Kao, 2019; Yu et al., 2020; Kaushik et al., 2020). For example, a model can choose the spurious cue word "meadow" as a feature for positive reviews simply because "meadow" occurs frequently in positive documents. It remains an interesting research question whether commonsense knowledge plays a central role among statistical cues that BERT has when solving commonsense tasks. In other words, we are interested in investigating whether BERT solves commonsense tasks using commonsense knowledge.

We try to provide quantitative answers by mainly using the CommonsenseQA dataset, which asks a model to solve a multiple-choice problem. As shown in Figure 1, given a question and five candidate answers, a model should select one candidate answer as the output. The current state-of-the-art

pre-trained language models solve the problem by representing the question jointly with each candidate answer (we call such a question-answer pair a *sentence* thereafter), and using pre-trained language models as the main encoder. Scoring of each sentence is based on a sentence-level hidden vector, and the candidate answer that corresponds to the highest-scored sentence is taken as the output.

We investigate the presence of commonsense cues in the BERT representation of a sentence by examining **commonsense links** from the **answer concepts** to its related contextualized **question concepts**. Figure 2 shows one example, where the question concept is "bird", and the correct answer is the answer concept connected through an ATLOCATION link in the CONCEPTNET knowledge graph. Such related concepts are *not* explicitly used in a BERT model for making prediction, and therefore its strength in the BERT representation is not necessarily optimized in task fine-tuning. We call such cues *structured commonsense*, which is a source of knowledge that we can explicitly measure. We take two methods for measuring structured commonsense in BERT, including directly measuring the attention weights (Clark et al., 2019) and measuring attribution scores by considering gradients (Mudrakarta et al., 2018).

We conduct two sets of experiments to quantitatively measure commonsense links in different situation. In the first set, we examine the presence of commonsense links directly in the BERT representation both before and after fine-tuning (Section 5). In the second set of experiments, we investigate the correlation between commonsense links with model predictions (Section 6). While the former can serve as a probing task for understanding commonsense learned by pre-training, the latter can serve as a means for understanding whether a model learns to make better use of commonsense knowledge through supervised fine-tuning.

Results suggest that BERT does have commonsense knowledge from pre-training, just as syntactic and word sense information. In addition, through fine-tuning, BERT relies more on commonsense cues in making prediction. The evidence is quantitatively demonstrated by stronger commonsense links in the representation, and a salient correlation between model predictions and commonsense link strengths, despite the fact that neither the answer concept nor the related question concept in a commonsense link is directly connected to the output layer. Interestingly, results also indicate that the stronger the structured commonsense knowledge is, the more accurate the model is. In addition to CommonsenseQA dataset, we observe similar phenomenon on Wikipedia and OMCS, demonstrating the generalization of our findings. To our knowledge, we are the first to investigate key statistical cues when BERT solves the CommonsenseQA task, providing several evidences that commonsense knowledge is indeed made use of. We release our code at `https://github.com/Nealcly/commonsense`.

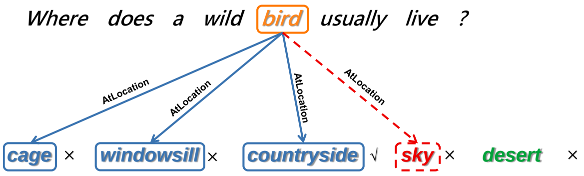

Figure 2: From CONCEPTNET to CommonsenseQA.

2 Related Work

There has been much recent work exploiting the underlying knowledge embedded in BERT representations. Peters et al. (2018) find that lower layers and higher layers in ELMo contain more syntactic and semantic information, respectively. Tenney et al. (2019), Liu et al. (2019a) and Jawahar et al. (2019) use probing models on hidden states to analyze linguistic information within pre-trained language models. Goldberg (2019) assess BERT's syntactic abilities by masking the verb, and comparing the prediction probability of the original verb with incorrect verbs. Our method is similar to Clark et al. (2019) and Htut et al. (2019), who focus on attention heads. The difference lies in that our primary goal is to investigate what information is learned and made use of when solving commonsense tasks. Therefore, our investigation is *task-centered*.

There has also been work investigating data bias and spurious associations. Gururangan et al. (2018) and Poliak et al. (2018) show that classifiers achieve accuracies around 69% on SNLI (Bowman et al., 2015) by using partial input. Kaushik et al. (2020) demonstrate BERT solve sentiment analysis and NLI by heavily relying on spurious associations. Our work is in line in investigating statistical cues. Different from the above investigations, we use probing methods to verify the presence and importance of the key feature, namely commonsense knowledge, in solving commonsense QA, rather than focusing on adversarial cases.

Commonsense reasoning is a challenging task in natural language processing. Traditional methods rely heavily on hand-crafted features (Rahman and Ng, 2012; Bailey et al., 2015) and external knowledge bases (Schüller, 2014). With recent advances in deep learning, pre-trained language models have been used as a powerful method for such tasks. Trinh and Le (2018) use a pre-trained language model to score candidate sentences for the Pronoun Disambiguation and Winograd Schema Challenge (Levesque et al., 2012). Klein and Nabi (2020) use a sentence-level loss to enhance commonsense knowledge in BERT. Mao et al. (2019) demonstrate that pre-trained language models fine-tuned on SWAG (Zellers et al., 2018) are able to provide commonsense grounding for story generation. For commonsense question answering, pre-trained language models with fine-tuning give the state-of-the-art performance (Zellers et al., 2018; Huang et al., 2019; Talmor et al., 2019). Though the above work show usefulness of BERT on comonsense tasks, little work has been done investigating the mechansim for BERT solving the tasks. Our work thus complements existing research in this aspect.

There is also a line of work leveraging CONCEPTNET to enhance model's commonsense reasoning ability. Lin et al. (2019) inject path information from question concepts to answer concepts to a model. Ye et al. (2019) use CONCEPTNET to construct pre-training dataset for BERT. Lv et al. (2019) extract evidence from CONCEPTNET and Wikipedia to build a relational graph for CommonsenseQA. We use CONCEPTNET for measuring commonsense knowledge in BERT.

3 Task and Model

We review the main experimental dataset CommonsenseQA (Section 3.1), before showing the structure of a state-of-the-art model (Section 3.2).

3.1 Dataset

CommonsenseQA (Talmor et al., 2019) is a multiple-choice question answering dataset constructed based on the knowledge graph CONCEPTNET (Speer et al., 2017), which is composed of a large set of triples taking the form $\langle$source concept, relation, target concept$\rangle$, such as $\langle$BIRD, ATLOCATION, COUNTRYSIDES$\rangle$. Given a source concept BIRD and the relation type ATLOCATION, there are three related target concepts CAGE, WINDOWSILL and COUNTRYSIDE in CONCEPTNET.

As shown in Figure 2, in the development of the CommonsenseQA dataset, crowd-workers are requested to generate question and candidate answers based on the *source concept* and three related target concepts in CONCEPTNET, respectively. Following Talmor et al. (2019), we call the source concept in the question as *question concept*, and the target concept in the answer as *answer concept*. Each question corresponds to only one correct *answer concept* among the three related CONCEPTNET target concepts. In addition, two more incorrect answer concepts are added, which do not correlate with the question concept in CONCEPTNET, resulting in 5 candidate answers for each question. We define *commonsene link* as the link from the answer concept to the question concept.

The CommonsenseQA dataset is designed to avoid salient bias in surface patterns. First, the lexical overlap between the correct answer and the question is similar to that between the question and incorrect candidates. Second, commonsense links are not superficial patterns that can be learned from training data. In particular, the percentage of answer-question-concept pairs in test examples that also exist in the gold training examples is 15.78%, which suggests that the main source of strong commonsense links, if observed, comes mainly from the pre-trained BERT model itself.

In order to analyze implicit structured commonsense knowledge, which is based on the link from the answer concept to the question concept, we filter out questions which do not contain explicit mentions to the *question concept* in its CONCEPTNET form (e.g. paraphrase). The resulting dataset CommonsenseQA* contains 74 fewer instances.

3.2 Model

We adopt the method of Talmor et al. (2019), using BERT (Devlin et al., 2019). In particular, given a question q and 5 candidate answers $a_1, ..., a_5$, we concatenate the question with each answer to obtain 5 question-answer pair sequences (i.e. sentences) $s_1, \ldots, s_5$, respectively. In each sentence, we use a special symbol `[CLS]` in the beginning, a symbol `[SEP]` between the question and the candidate answer, a symbol `[SEP]` in the end.

BERT uses L stacked Transformer layers (Vaswani et al., 2017) to encode each sentence. The last layer hidden state of the `[CLS]` token is used for linear scoring with softmax normalization. The candidate among $s_1, \ldots, s_5$ with the highest score is chosen as the prediction. More details of our implementation are shown in Appendix C.

4 Analysis Methods

As mentioned earlier, we analyze commonsense links using the attention weight (Clark et al., 2019) and the corresponding attribution score (Sundararajan et al., 2017; Mudrakarta et al., 2018). We report results in one random execution for each experiment. We additionally tried five runs for each experiments, and found that the result variation is small (Appendix B).

4.1 Attention Weights

Given a sentence, attention weights in Transformer can be viewed as the relative importance weight between each token and the other tokens when producing the next layer representation (Kovaleva et al., 2019; Vashishth et al., 2020). In particular, given a sequence of input vectors $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_{|H|}]$, its self-attention representation uses each vector as a query to retrieve all context vectors in $\mathbf{H}$, yielding a matrix of attention weights $\alpha \in \mathbb{R}^{|H| \times |H|}$.

The value of α is computed using the scaled dot-product of the query vector of representation $\mathbf{Q} = \mathbf{W}^Q\mathbf{H}$ and the key vector of representation $\mathbf{K} = \mathbf{W}^K\mathbf{H}$, followed by softmax normalization

$$\alpha = softmax(\frac{\mathbf{Q}\mathbf{K}^\top}{\sqrt{d_k}}), \tag{1}$$

where d_k is the dimension size of the key vector $\mathbf{K}$. $\alpha_{i,j}$ represents the attention strength from $\mathbf{h}_i$ to $\mathbf{h}_j$. For multi-head attention, $\mathbf{H}$ is linearly projected T times to find T sets of queries, keys, and values, where T is the number of heads. The attention operation of each head is performed in parallel, with the results being concatenated. We use $\alpha^{m,n}$ to denote the n-th attention head in the m-th layer. The attention weights $\alpha^{m,n}$ are used as a first measure of commonsense link strengths.

4.2 Attribution Scores

Kobayashi et al. (2020) point out that analyzing only attention weights can be insufficient for investigating the behavior of attention heads. As a supplement, gradient-based feature attribution methods have been studied to interpret the contribution of each input feature to the model prediction in back-propagation (Baehrens et al., 2010; Mudrakarta et al., 2018; Hao et al., 2020). Analysis of both attention weights and the corresponding attribution scores allows us to more comprehensively understand commonsense links in BERT.

We employ an attribution technique called *Integrated Gradients* (Sundararajan et al., 2017). Intuitively, integrated gradients works by simulating the process of pruning the specific attention head (from the original attention weight α to a zero vector α'), and calculating the integrated gradients in back-propagation. The attribution score directly reflects how much a change of attention weights affects model outputs. A higher attribution score represents more importance of the corresponding individual attention weight. Suppose that $F(x)$ represents the BERT model output for CommonsenseQA given an input x. The attribution of attention head $\alpha_t t \in [1, \ldots, T]$ in a Transformer layer can be computed by comparing with a set of baseline weights α':

$$Atr(\alpha^t) = (\alpha^t - \alpha'^t) \otimes \int_{x=0}^{1} \frac{\partial F(\alpha' + x(\alpha - \alpha'))}{\partial \alpha^t} dx \tag{2}$$

where $\otimes$ denotes element-wise multiplication, $\alpha = [\alpha^1, \ldots, \alpha^T]$. Intuitively, $F(\alpha' + x(\alpha - \alpha'))$ is closer to $F(\alpha')$ when x is closer to 0, and closer to α when x is closer to 1. Therefore, $\int_{x=0}^{1} \frac{\partial F(\alpha' + x(\alpha - \alpha'))}{\partial \alpha^t} dx$ gives the amortized gradient with all different x. $Atr(\alpha^t) \in \mathbb{R}^{n \times n}$ denotes the attribution score which corresponding to the attention weight α^t. $Atr(\alpha^t_{i,j})$ is represented for the interaction from token $\mathbf{h}_i$ to $\mathbf{h}_j$. We set the uninformative baseline α' as zero vector. Following Sundararajan et al. (2017), we approximate $Atr(\alpha^t)$ via a gradient summation function,

$$Atr(\alpha^t) ::= (\alpha^t - \alpha'^t) \otimes \sum_{i=1}^{s} \frac{\partial F(\alpha' + i/s(\alpha - \alpha'))}{\partial \alpha'^t} \times \frac{1}{s}, \tag{3}$$

where s is the number of approximation steps for computing integrated gradients. We set s to 20 based on the empirical results.

5 The Presence of Knowledge

We first conduct a set of experiments to investigate commonsense link strengths in BERT representations of question-answer pairs (i.e. sentences). Intuitively, if the link weight from the answer concept to the question concept is higher than those from the answer concept to other question words, then

	Statistics		**MAW Accuracy**				**Random**

RELATEDTO	62.22	18.44	9-0	9

Table 2: The average and maximum MAW accuracies of BERT-FT for different commonsense relations. We exclude the relation types with frequencies of occurrence less than 9. L-H represents the best performing attention head for each relation.

we have evidence of BERT using commonsense cues according to CONCEPTNET. As mentioned earlier, rather than the question concept, the representation of the `[CLS]` token is directly connected to the output layer for candidate scoring. Hence there is no direct supervision signal from the output layer to the link weight during fine-tuning, and better prediction does not necessarily indicate strong commonsense links.

5.1 Probing Task

Without losing generality, we call both attention weights in Section 4.1 and attribution weights in Section 4.2 *link weight*. We evaluate link weights by calculating the **most associated word** (MAW), namely the question concept word that receives the maximum link weight from the answer concept among all question words. MAW is measured for each individual attention head in each layer.

Denote the hidden states of the whole question, question concept and answer concept as $[\mathbf{h}_1, \ldots, \mathbf{h}_{|q|}]$, $[\mathbf{h}_{b_s}, \ldots, \mathbf{h}_{e_s}]$ and $[\mathbf{h}_{b_t}, \ldots, \mathbf{h}_{e_t}]$, respectively. If the answer concept is composed of multiple tokens, we consider the link weight from the answer concept to the question token $\mathbf{h}_i$ ($i \in [1, |q|]$) as the mean of the link weights over all answer tokens $\alpha_i = \frac{1}{e_t - b_t}\sum_{j=b_t}^{e_t} \alpha_{j,i}$. For the n-th attention head in the m-th layer, if the question concept receives the maximum link weight from the answer concept (i.e., $\mu^{m,n} = \arg\max_i \alpha_i^{m,n}$, $\mu^{m,n} \in [b_s, e_s]$), we consider that this attention head gives the correct MAW.

We take two different measures of MAW accuracies, calculating the average accuracy among all attention heads, and the accuracy of the most-accurate head, respectively. Previous work probing syntactic information from attention head takes the second method (Clark et al., 2019; Htut et al., 2019). We additionally measure the average in order to comprehensively evaluate the prevalence of commonsense cues in BERT.

The average MAW accuracy is measured by:

$$acc^{avg} = \frac{\sum_{m=1}^{12}\sum_{n=1}^{12}\sum_{d=1}^{D} \mathbb{1}(\mu^{m,n} \in [b_s, e_s])}{12 \times 12 \times D}.$$

The maximum MAW accuracy is measured by:

$$acc^{max} = \max_{m=1}^{12}\max_{n=1}^{12} \frac{\sum_{d=1}^{D} \mathbb{1}(\mu^{m,n} \in [b_s, e_s])}{D},$$

where D represents the number of instances for evaluation.

In theory, if link weights for each attention head are randomly distributed, the average and maximum MAW accuracies should be both

$$acc^{baseline} = \frac{\sum_{d=1}^{D} \frac{e_s - b_s}{|q|}}{D},$$

which reflects the fact that the representation does not contain explicit correlation between the answer concept and its related question concept. In contrast, MAW accuracies significantly better than this baseline indicates that commonsense knowledge is contained in the representation.

5.2 Results

The results for off-the-shelf BERT (BERT) and a BERT model fine-tuned on CommonsenseQA

(BERT-FT) are shown in the first row of Table 1. First, looking at the original non-fine-tuned BERT, the *maximum* MAW accuracy of each layer significantly outperforms[1] the random baseline. This shows that commonsense links are a part of BERT representation of a sentence in general, just as syntactic (Goldberg, 2019) and semantic (Liu et al., 2019a) knowledge. Second, BERT-FT outperforms BERT in terms of both the average MAW accuracy and the maximum MAW accuracy, with a relatively large boost on the average MAW accuracy, which shows that structured commonsense features are enhanced by supervised training on commonsense tasks.

We explore the best performing attentions head for each relation type in Table 2, finding that certain attention heads capture specific commonsense relations. There is no single attention head that does well for all relation types, both with fine-tuning and without fine-tuning, which is similar to the previously finding for syntactic heads (Raganato and Tiedemann, 2018; Clark et al., 2019).

To further differentiate commonsense cues from superficial association, we measure the co-occurrence between each word in the question and answer concept in 1 million English Wikipedia documents. There is only 1.85% question concept word among the highest co-occurring words of each answer concepts, which partly shows that the strong commonsense links do not heavily rely on superficial pattern.

5.3 Additional Datasets.

Since this set of experiments concerns the representation only, we take additional two unlabeled corpora in addition to CommonsenseQA. In particular, we extract sentences from Open Mind Common Sense (OMCS) [2] and Wikipedia, if there existing one and only one source-target concept pair in this sentence, yielding two large-scale datasets. The detailed statistics are shown in Table 1. The results are consistent with the CommonsenseQA dataset, which shows the generation ability of our methods.

6 Co-relating Knowledge with Task

We further conduct a set of experiments to draw the correlation between commonsense links and model prediction. The goal is to investigate how BERT makes use of commonsense knowledge for making a prediction in the CommonsenseQA task. In particular, we compare the link weights across the five answer candidates for the same question, and find out the candidate that is the most associated with the relevant question concept. This candidate is called the **most associated target** (MAT). Correlations are drawn between MATs and the model prediction for each question. Intuitively, the more the MATs are correlated with the model predictions, the more evidence we have that the model makes use of commonsense cues in making prediction.

Table 3: MAT^{overlap} and MAS^{overlap} in the top layer.

Both attention weights and the corresponding attribution scores are used, because now we are considering model prediction, for which gradients play a role and can be measured. For all experiments, the trend of attribute scores is consistent with that measured using attention weights.

6.1 Probing Tasks

Formally, given a question q and 5 candidate answers $a_1, \ldots, a_5$, we make comparisons across five candidate sentences $s_1, \ldots, s_5$. In each candidate sentence, we calculate the link weight from the answer concept to the question concept according to CONCEPTNET. Denote the hidden states of the question concept and the answer concept as $[\mathbf{h}_{b_s}, \ldots, \mathbf{h}_{e_s}]$ and $[\mathbf{h}_{b_t}, \ldots, \mathbf{h}_{e_t}]$, respectively. The link weight of the answer-question-concept pair (α_{a2q}) is the average between each answer concept token and each question concept token

$$\alpha_{a2q} = \frac{\sum_{i=b_s}^{e_s} \sum_{j=b_t}^{e_t} \alpha_{j,i}}{(e_s - b_s)(e_t - b_t)}$$

Among the five candidates in each instance, we take the one with the highest α_{a2q} as the most associated target MAT, denoted as $s^{\text{MAT}} \in [1, 5]$.

---

[1] $p \leq 0.01$ using t-test; similar for subsequent mentions.

[2] Open Mind Common Sense (OMCS) corpus is the source corpus of ConceptNet.

(a) Measured by attention weights.

#H	#Ins	Model Acc.	#H	#Ins	Model Acc.
0	158	20.89	7	69	78.26
1	135	28.15	8	63	82.54
2	119	52.10	9	57	92.98
3	132	53.79	10	47	89.36
4	93	62.37	11	44	97.73
5	106	66.04	12	36	100.00
6	88	68.18	-	-	-

(b) Measured by attribution.

#H	#Ins	Model Acc.	#H	#Ins	Model Acc.
0	89	10.11	5	171	72.51
1	114	22.81	6	119	81.51
2	148	51.35	7	85	82.35
3	156	56.41	8	43	74.72
4	207	66.67	9	13	84.62

Table 4: The relationship between the MAT head count and the model prediction accuracy. #H denotes how many heads yield the correct MAT prediction. #Ins denotes the instance number.

As a baseline for MAT, we further define **most associated sentence** (MAS) as the candidate answer that has the maximum link weight from the answer concept to the `[CLS]` token among the five candidates. The reason is that gradients are back-propagated from the `[CLS]` token rather than the question concept or the answer concept. By comparing MAT and MAS, we can have useful information on whether MAT is an influencing factor for the model decision.

We measure the correlation between MAT ($s^{\text{MAT}} \in [1,5]$), the model prediction ($s^{model} \in [1,5]$) and the gold-standard answer ($s^{golden} \in [1,5]$) by using two metrics, including the overlapping rate between MATs and model predictions, and the accuracy of MATs.

The **overlapping rate of MATs** is defined as:

$$\text{MAT}^{overlap} = \frac{\sum_{d=1}^{D} \mathbb{1}(s_d^{\text{MAT}} = s_d^{model})}{D}$$

The **accuracy of MATs** is defined as the percentage of Mats that equals the gold answer:

$$\text{MAT}^{acc} = \frac{\sum_{d=1}^{D} \mathbb{1}(s_d^{\text{MAT}} = s_d^{golden})}{D}$$

Similar to MAW, MAT and MAS can be measured for each attention head, and we calculate the average and maximum values across different heads.

6.2 Commonsense Link and Model Output

We measure the MAT performance of BERT-FT, and a BERT model that is fine-tuned for the output layer only (BERT-probing). The latter is a linear probing model (Liu et al., 2019a). Intuitively, if the probing model can solve the commonsense task accurately, then the original non-fine-tuned BERT likely encodes the rich commonsense knowledge.

Table 3 shows the relative strengths of MATs and MASs according to the 12 attention heads in the top Transformer layer. First, for both models, the overlapping rates of MATs are significantly ($p \leq 0.01$) larger than that with MASs. This suggests that the link weight from the answer concept to the question concept is more closely-related to the model prediction as compared to the link weight from the answer concept to the `[CLS]` token, despite that model output scores are calculated on the `[CLS]` token. The results give strong evidence that commonsense cues from BERT are relied on for model decision. Second, when fine-tuned with training data, the model gives an even stronger correlation between MAT and the model prediction. This suggests that the model can *learn* to make use of commonsense cues for making prediction, which partly shows how a BERT model solves CommonsenseQA.

Figure 3 shows the overlapping rate between MAT and model prediction at each Transformer layer. Both the maximum and the average overlapping rates across the 12 layers are shown. The random overlapping rate of 20% is drawn as a reference. It can be seen from the figure that the maximum overlapping rate of BERT-probing is significantly larger than the random baseline, which shows that the model prediction is associated with the relevant structured commonsense cues. In addition, after fine-tuning, the BERT-FT model shows a tendency of weakened maximum MAT overlapping rate on lower Transformer layers and much strengthened MAT overlapping rate on higher layers, and in particular the top layer. The trend of MAT measured by attribution score is consistent with attention weights. This suggests that fine-tuned model relies more on the commonsense structure in the top layer for making prediction.

We compare the co-occurrence between question concepts and candidate answer concepts in 1 million English Wikipedia documents, and find that only 18.2% gold answers has the most co-occurrence with the question concept among 5 answer candidates, which is even lower than the random baseline (20%), showing that CommonsenseQA cannot be solved by solely relying on superficial patterns.

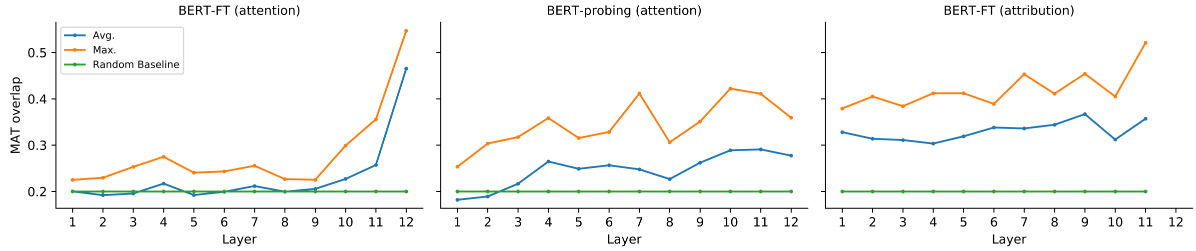

Figure 3: MAT^{overlap} across different layers.

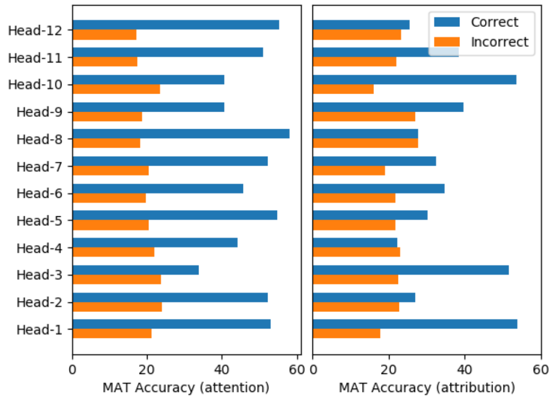

Figure 4: MAT^{acc} of each attention head in the top layer with correct and incorrect model predictions. "Red" and "Blue" indicate the model performance if attention head-n gives correct and incorrect prediction, respectively.

6.3 Commonsense Link and Model Accuracy

Table 4 shows the correlation between MAT accuracies and model prediction accuracies. Each row shows a different number of heads in the top layer for which the MAT corresponds to the correct answer candidate, together with the number of test instances for such cases, and the model prediction accuracy on the instances. There is an obvious trend where increased MAT accuracies correspond to increased model prediction accuracies, which shows that making use of structured commonsense cues leads to better model prediction.

Figure 4 shows the MAT accuracies of each attention head in the top layer for the test instances with correct and incorrect model predictions, respectively. The MAT accuracies of correctly predicted instances are larger than those of incorrectly predicted instances by a large margin. The finding is consistent with Table 4, which shows that structured commonsense cues are a key factor in BERT making the correct decision.

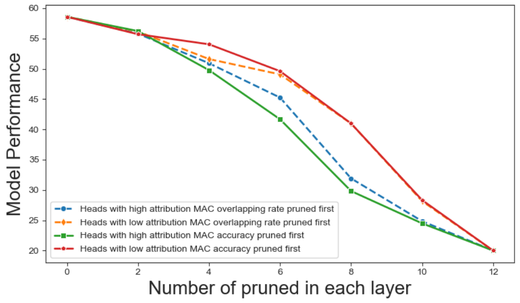

Figure 5: Model performance on the CommonsenseQA development set when different heads are pruned.

	BERT-FT			BERT-probing		
	MAT^{overlap}		Model	MAT^{overlap}		Model
L	Max	Avg	Acc	Max	Avg	Acc
12	54.14	45.87	58.59	36.88	28.42	39.23
11	46.56	26.65	56.50	37.66	27.11	35.48
10	37.40	27.86	53.36	39.84	28.50	33.74
9	34.61	24.01	51.53	30.08	24.76	32.52
8	31.82	21.39	49.35	25.81	21.53	33.57
7	31.73	24.40	48.74	37.05	24.04	32.96
6	31.56	23.64	45.95	31.21	24.02	32.00
5	34.44	25.01	44.99	33.39	24.03	32.43
4	44.73	34.13	40.28	41.06	27.67	33.83
3	44.20	32.48	37.58	25.81	21.02	21.88
2	23.71	19.47	26.68	23.63	20.74	20.40
1	23.45	19.50	23.02	20.58	18.81	19.27

Table 5: Performance of MAT^{overlap} across different layers. L-n represents adding the output classifier on the hidden state of layer-n. Our BERT-FT model (layer-11) gives 58.15% accuraies, which is slightly higher than the reported results of 55.57% on Lin et al. (2019). It achieves 58.59% on our dataset CommonsenseQA*.

We further evaluate the model performance after pruning specific heads. We sort all the attention heads in each layer according to their MAT performance by attribution scores, and then prune these heads in order. Following Michel et al. (2019), we replace the pruned head with zero vectors. Figure 5 shows the model performance on the development set. As the number of pruned heads increases, the model performance decreases, which conforms to intuition. In addition, the model performance drops much more rapidly when the attention heads with higher MAT performances are pruned first, which demonstrates that capturing commonsense features is crucial to strong model prediction.

6.4 Commonsense Link and BERT Layer

We further investigate two specific questions on the commonsense knowledge usage. First, which layer does BERT rely on the most for making its decision. Second, does the commonsense knowledge that BERT uses come more from pre-training or fine-tuning. We compare 12 model variations by connecting the output layer on each of the Transformer layer, respectively. Table 5 shows the model accuracies and the MAT overlapping rates. First, BERT-probing gives the best performance when prediction is made on the top layer, and the accuracy generally decreases as the layer moves to the bottom. This indicates that relevant commonsense knowledge is more heavily distributed towards higher layers during pre-training. Our experimental settings here are the same as the probing task for syntactic information by Liu et al. (2019a), who find that syntactic information is distributed more heavily towards lower BERT layers.

With fine-tuning, we observe stronger improvements of both model accuracies and MAT overlaps on higher layers when comparing BERT-FT and BERT-probing. This demonstrates that commonsense knowledge on higher layers is more useful to the CommonsenseQA task. Interestingly, comparing layer 11 and layer 10, the model accuracy after fine-tuning is similar, but the MAT overlap of layer 11 is significantly larger. This can suggest that the structured commonsense knowledge that we probe attributes only partly to the overall useful knowledge for CommonsenseQA.

7 Conclusion

We conducted quantitative analysis to investigate how BERT solves the CommonsenseQA task, aiming to gain evidence on the key source of information involved in the disambiguation process. Empirical results demonstrated that BERT encodes structured commonsense knowledge, and is able to leverage such cues on the downstream CommonsenseQA task. Our analysis has further revealed that with fine-tuning, BERT learns to make better use of commonsense features on higher layers. These suggest that BERT can learn to make use of truly relevant commonsense cues rather than superficial patterns for CommonsenseQA.

Abstract

In multi-hop QA, answering complex questions entails iterative document retrieval for finding the missing entity of the question. The main steps of this process are sub-question detection, document retrieval for the sub-question, and generation of a new query for the final document retrieval. However, building a dataset that contains complex questions with sub-questions and their corresponding documents requires costly human annotation. To address the issue, we propose a new method for weakly supervised multi-hop retriever pre-training without human efforts. Our method includes 1) a pre-training task for generating vector representations of complex questions, 2) a scalable data generation method that produces the nested structure of question and sub-question as weak supervision for pre-training, and 3) a pre-training model structure based on dense encoders. We conduct experiments to compare the performance of our pre-trained retriever with several state-of-the-art models on end-to-end multi-hop QA as well as document retrieval. The experimental results show that our pre-trained retriever is effective and also robust on limited data and computational resources.

1 Introduction

Multi-hop QA is the task of answering complex questions that requires reasoning across multiple documents (Nogueira and Cho, 2017; Nie et al., 2019; Sun et al., 2019; Fang et al., 2020; Zhao et al., 2020). The core components of multi-hop reasoning are identifying the missing entity in the question and generating a new query with the missing entity. Figure 1 shows an example of the reasoning process in multi-hop QA. In the example, the missing entity, which we call bridge entity, of the question is *"Jupiter"*. To answer the question, the correct document for the sub-question "the largest planet in the Solar System," should be retrieved. Supervised training of the multi-hop QA models for these intermediate reasoning steps requires a dataset of complex questions, sub-questions, and their corresponding documents. However, building such dataset requires costly human annotation and cannot be done at scale (Min et al., 2019; Wolfson et al., 2020).

When there is limited annotated supervision signal, weakly supervised pre-training can be a solution (Devlin et al., 2019; Liu et al., 2019) which has shown effectiveness in open-domain QA (Lee et al., 2019; Guu et al., 2020). Unlike open-domain QA, it is not trivial to apply a pre-training method to multi-hop QA due to the complexity in generating weak supervision data. In open-domain QA, weak supervision is generated by selecting a document from a corpus and extracting a sentence from the document. The sentence becomes a pseudo question, and the document becomes a pseudo supporting document to be predicted by retrievers. This two-step process for weak supervision cannot be directly applied in multi-hop QA since each multi-hop question refers to multiple documents.

In this paper, we propose a novel weakly supervised pre-training method for multi-hop retriever, **LOUVRE** (**L**earning fr**O**m m**U**lti-hop **V**ariation of document **RE**lations). Our method contains three core elements: 1) a pre-training task, 2) a scalable method to generate pre-training data with weak supervision, and 3) a model to pre-train a retriever for multi-hop QA. Specifically, we define a task for pre-training, "Next Document Prediction" (NDP), which is to retrieve documents for sub-questions. We then propose "Bridge Entity Re-Phrasing" to generate the pre-training data. "Bridge Entity Re-Phrasing" generates complex questions that contain sub-questions of the bridge entities and their corresponding documents. To generate a complex question using a bridge entity without human effort, we

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 694–704
August 1–6, 2021.

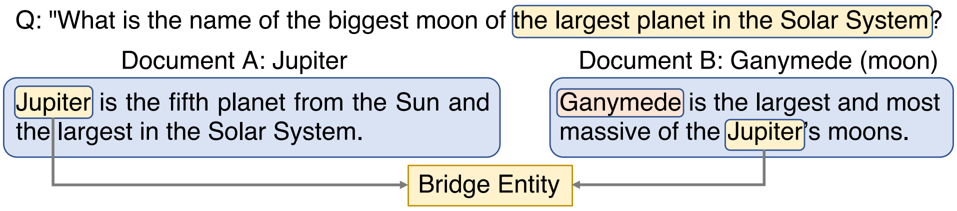

Figure 1: An example of chain reasoning in multi-hop QA. Answering the question requires finding *"the largest planet in the Solar System"* which is the bridge entity *"Jupiter."* With the retrieved document A, the question has enough information to retrieve the correct answer in document B.

use two documents connected by Wikipedia hyperlinks. The hyperlinked entity becomes the bridge entity, and the introductory phrase of the entity becomes the sub-question in the complex question. This approach enables our weak supervision data generation to be scalable, as shown in Figure 2. We use a dense retriever consisting of a question encoder and a document encoder for the pre-trained model structure (Karpukhin et al., 2020; Xiong et al., 2021). The two encoders calculate vector representations of questions and documents. Document retrieval is performed by comparing the vectors with MIPS (maximum inner product search).

Pre-training multi-hop retriever with our weak supervision method brings three benefits: significant performance improvement, robustness on few-shot settings, and computational efficiency. We evaluate our weakly supervised pre-trained retriever with two types of experiments on HOTPOTQA dataset: supporting documents prediction and end-to-end multi-hop QA. In both experiments, LOUVRE outperforms previous multi-hop retrievers. Also, we fine-tune LOUVRE on 1% of training data and show that the performance of LOUVRE is comparable to the baselines. We evaluate the performance of LOUVRE according to the computational efficiency. The results show that LOUVRE requires less inference time than baselines.

Contributions of this paper are as follows: 1) we propose a novel scalable weakly supervised pre-training method for multi-hop retrievers, 2) we provide the implementation of LOUVRE and the pre-trained checkpoint publicly available [1], 3) we show the effect of our pre-training method in multi-hop QA with various experimental results.

2 Related Work

Distant Supervision in Open-Domain QA: Many open-domain QA datasets only provide question-answer pairs; some also provide weakly annotated supporting documents, but they are predicted by simple heuristics (Joshi et al., 2017; Berant et al., 2013). Document retrieval has suffered from insufficient strong supervision issues. Hence, document retrieval has suffered from lack of strong supervision. To resolve this issue, Karpukhin et al. (2020) use a document retrieved by TF-IDF as the supporting document of the given question. Weak supervision is also an effective method in the distant supervision setting of open-domain QA. Lee et al. (2019) use ICT (inverse cloze task) to generate pseudo question-document pairs and pre-train their retriever. They select documents from Wikipedia and extract sentences from the documents. The selected sentence-document pairs become pseudo-question-document pairs. Guu et al. (2020) propose a pre-training method for a language model that uses knowledge retriever (document retriever). They train the knowledge retriever only with the language modeling loss without using any supervision signal of supporting documents. Although pre-training methods show effectiveness in open-domain QA, they are limited to single-hop retrievers.

Multi-Hop QA: To overcome the lack of supervision signal in multi-hop QA, weak supervision methods have been proposed. Qi et al. (2019) propose a sub-question generation method. They use heuristically generated pseudo-questions as supervision for the question generation model. Perez et al. (2020) generate weak supervision for question decomposition by mapping a complex question to multiple single-hop questions in existing QA datasets. They use complex questions in HOTPOTQA (Yang et al., 2018) and single-hop questions in SQuAD 2.0 (Rajpurkar et al., 2018). Another method to train multi-hop QA models without human annotated datasets is by taking two simple questions and generating a complex question (Pan et al., 2020). They generate complex ques-

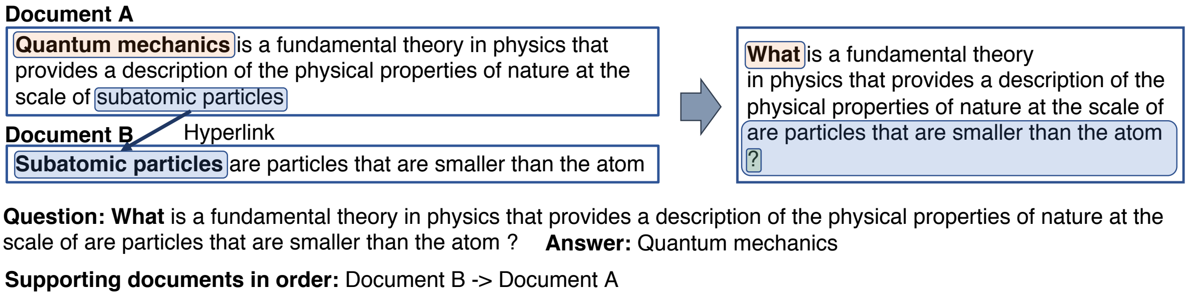

Figure 2: Proposed pre-training data generation process. Two documents connected by Wikipedia hyperlink are selected. In "Bridge Entity Re-Phrasing" process, document B which describes the entity "subatomic particles" is used to re-phrase the entity in document A. After replacing the answer entity, "Quantum mechanics", the complex question and its corresponding supporting documents are generated.

tions with GPT-2 (Radford et al., 2019) fine-tuned on SQuAD1.1. Our work improves upon previous research by providing a more general method that leverages a large open corpus with retriever pre-training.

3 Method

We propose an effective and scalable pre-training method that provides weak supervision of the complex questions with sub-questions and their corresponding supporting documents.

3.1 Next Document Prediction

We propose the "Next Document Prediction" (NDP) task for pre-training. NDP refers to the process of recurrent document retrieval used in (Qi et al., 2019; Asai et al., 2020; Xiong et al., 2021). We apply the common definitions in the existing studies to our "Next Document Prediction" task. We define NDP as the task that predicts documents in the reasoning sequence $[d_1, ..., d_n]$ recurrently as follows:

$$d_k = \text{Retriever}(q, D_{k-1}), \tag{1}$$

where q is a question, d_k is a predicted document at step k, and D_{k-1} is a set of documents retrieved in the previous steps, $\{d_1, ..., d_{k-1}\}$.

3.2 Bridge Entity Re-Phrasing

Our pre-training requires a dataset of questions, sub-questions, and their corresponding reasoning chains (i.e., a sequence of documents). We propose "Bridge Entity Re-Phrasing" for generating this pre-training dataset. "Bridge Entity Re-Phrasing" takes two steps: entity selection and re-phrasing. Figure 2 provides an overview of our data generation process. We provide the detailed description of "Bridge Entity Re-Phrasing" in the following paragraphs.

The "Bridge Entity Re-Phrasing" process requires informative entities and the description of the entity. We assume that an entity with a Wikipedia hyperlink is an informative entity. Also, hyperlink entities often have Wikipedia articles describing the entities. The hyperlink entity becomes the bridge entity. In Figure 2, document A and document B are connected with the bridge entity, *"subatomic particles"*. We re-phrase the selected entity with the first line of the document. In Figure 2, *"subatomic particles"* is re-phrased with the first line in document B. When the bridge entity appears in the question, multi-hop retrievers easily find the bridge document using only the word. To prevent this issue, we remove the bridge entity from document B. The generated document becomes the document to be used for question-answer pair generation.

Generating a question-answer pair from a single document has been studied by pre-training research in open-domain QA (Lee et al., 2019; Guu et al., 2020). We extend their work to generate questions, reasoning chains, and answers. We randomly select an entity from the merged document and replace the entity with the word *"what"*. In Figure 2, "Quantum mechanics" is the entity word and replaced with "what." The new sentence becomes a pseudo-question, and the replaced entity becomes the answer. Since document B contains the bridge entity, the pseudo-question reasoning chain becomes $[\text{document B}, \text{document A}]$.

3.3 Model Architecture

Model structure for our pre-training is subject to two requirements: general model structure and recurrent retrieval. We use multi-hop dense retriever

(Xiong et al., 2021) which meets the two requirements and is based on the DPR (dense passage retriever) (Karpukhin et al., 2020). DPR consists of a question encoder E_Q and a document encoder E_D, both of which are based on RoBERTa-base. Documents are retrieved by MIPS (maximum inner product search) with similarity between the question vectors and the document vectors as follows:

$$\mathrm{sim}(q, d) = E_Q(q)^\intercal E_D(d). \tag{2}$$

MDR retrieves documents recurrently by taking the previously retrieved documents as input. MDR concatenates the question q and the retrieved documents $\{d_1, ..., d_{k-1}\}$ and calculates a question vector for k-th step as follows:

$$d_k = \mathrm{argmax}_d(E_Q(q, d_1, ..., d_{k-1})^\intercal E_D(d)), \tag{3}$$

where d is a document in the corpus.

We train the dense encoder to assign the highest probability for the ground truth document among the documents in the huge corpus. The loss function for our pre-training is as follows:

$$L_{\mathrm{NBP}}(q_k, d_k) = \\ - \log \frac{e^{\mathrm{sim}(q_k, d_k)}}{e^{\mathrm{sim}(q_k, d_k)} + \sum_{d \in \mathrm{neg}(d_k)} e^{\mathrm{sim}(q_k, d)}}, \tag{4}$$

where q_k is a concatenation of q and D_{k-1}, and $\mathrm{neg}(d_k)$ is a set of documents excluding d_k. Since computing the softmax over the whole corpus is computationally expensive, we use in-batch negatives for $\mathrm{neg}(d_k)$ (Karpukhin et al., 2020).

4 Experimental Setup

4.1 Pre-Training Details

We generate our pre-training data from 5,233,329 Wikipedia articles provided by Yang et al. (2018). We select all sentences that contain at least one hyperlinked entity to generate pseudo questions and randomly select "answer" entities from the sentences [2]. Our data generation process builds 13.9 million question-document-answer triples. We pre-train our dense retriever with a batch size of 256 for 200K+ steps. We use Adam with a warm-up ratio of 0.1 and set the learning rate to 2×10^{-5}. We use a machine with eight V100 (32G) GPUs.

	TF-IDF	Wiki	RR	Eff
LOUVRE				
- eff	✓	✓		✓
- Wiki		✓		
- reranking			✓	
- reranking-Wiki		✓	✓	

Table 1: The five variations of LOUVRE. Each column represents sparse retrieval (TF-IDF), Wikipedia hyperlinks (Wiki), reranking (RR), and efficient fine-tuning (Eff). "Eff" represents whether the model uses efficient hyper-parameter setting, a batch size of 32 and a number of epochs of 15.

4.2 Fine-Tuning Details

We use TF-IDF negatives in addition to in-batch negatives for fine-tuning as in Karpukhin et al. (2020); Xiong et al. (2021). We set the number of TF-IDF negatives to 2. We use the Adam optimizer with a warm-up rate of 0.1 and set the learning rate to 2×10^{-5}. We set the batch size to 32, the number of epochs to 15. To achieve better performance, we additionally fine-tune our model with another hyper-parameter setting: a batch size of 150 and a longer training time of 50 epochs.

4.3 Tasks

Supporting Document Prediction: In this task, retrievers and rerankers predict supporting documents for each question in HOTPOTQA dataset (Yang et al., 2018). The models predict possible combinations of supporting documents. Formally, when a question, q_i, has been taken as input of the model, the models yield a ranked list of K-sets of documents, $L_i = [\{d_a, d_b\}]_{n=1}^{K}$. Each $\{d_a, d_b\}$ is a pair of candidate supporting documents. In HOTPOTQA, the number of supporting documents is fixed to 2. We use the 5 million Wikipedia articles as the knowledge source.

End-to-End Multi-Hop QA: We evaluate the supporting facts prediction performance and the answer prediction performance of LOUVRE on HOTPOTQA full wiki setting (Yang et al., 2018).

4.4 Multi-Hop Retrieval Strategy

We propose five variations of LOUVRE based on existing multi-hop retrieval strategies. Multi-hop document retrievers leverage three strategies for performance improvement and computational efficiency: sparse retrieval methods such as TF-IDF (Nie et al., 2019), Wikipedia hyperlinks (Asai et al.,

---

[2] We use spaCy for entity recognition

2020), and reranking (Xiong et al., 2021). Sparse retrieval methods select a small number of candidate documents relevant to the given question and are used to narrow down the search space of dense retrievers. We use TF-IDF and keyword matching as Nie et al. (2019) to retrieve 200 candidate documents. Existing multi-hop retrievers select reasoning paths (document chains) from documents connected with Wikipedia hyperlinks. We iteratively select the next-hop documents from the documents connected with the previously retrieved documents. Rerankers take the candidate reasoning paths (pairs of documents) from the retriever and predict the most probable reasoning path. We use the reranker proposed by Xiong et al. (2021). Table 1 shows the detailed information of these five variations.

4.5 Baselines

We compare our model to two types of multi-hop retrievers with and without reranking. For retrievers, we use TF-IDF, DPR (Karpukhin et al., 2020), Cognitive Graph (Ding et al., 2019), GOLDEN Retriever (Qi et al., 2019), and MDR (Xiong et al., 2021). For rerankers, we use SemanticRetrievalMRS (Nie et al., 2019), PathRetriever (Asai et al., 2020), MDR-reranking (Xiong et al., 2021), and HopRetriever (Li et al., 2020). We describe detailed experimental settings of each baseline in Appendix A.

4.6 Metric

We use five evaluation metrics: EM, F1, R@K, PathR@K, and AR@K. EM and F1 measure answer prediction and supporting fact prediction performance of multi-hop QA models (Yang et al., 2018). In addition to R@K, which measures the performance of supporting document prediction, we use another metric PathR@K to evaluate how well the retriever predicts the entire set of supporting documents. Since the readers predict answers by reading each path, PathR@K is a more appropriate estimate of answer prediction. The definitions of R@K and PathR@K are:

$$\begin{aligned} \text{R@K} &= \mathbb{1}(G \subseteq D) \\ \text{PathR@K} &= \mathbb{1}((G = P_1) \vee ... \vee (G = P_K)), \end{aligned} \tag{5}$$

where $G = \{g_i, g_j\}$ is the set of ground truth supporting documents, D is the set of retrieved documents, and $P_i = \{d_a, d_b\}$ is a reasoning path ranked at i.

In our experimental setting, D is set to all documents in $\bigcup_{i=1}^{K/2} P_i$. AR@K measures the percentage of predictions that at least one passage in the top K predicted paths contains the answer text.

5 Results & Discussion

LOUVRE overcomes limited supervision in multi-hop QA with our weakly supervision data. Training with additional data brings progress in three ways: overall retrieval performance improvement, 2) robustness on a few-shot setting, and 3) overall improvement in the end-to-end multi-hop QA. We verify these improvements on the two tasks described in section 4: supporting document prediction and end-to-end multi-hop QA.

5.1 Supporting Document Prediction

In this experiment, we demonstrate the efficacy of LOUVRE with document retrieval experiments. First, we show the performance gain that comes from using our pre-trained model. Then, we show that the result becomes more significant in few-shot settings.

Effect of Our Pre-Training: We compare LOUVRE with MDR which is a multi-hop retriever fine-tuned on RoBERTa-base. We use the same fine-tuning method as MDR but initialize the parameters with LOUVRE. Table 2 shows the results. LOUVRE achieves 1.1% absolute performance improvement than when using RoBERTa (65.9); PathR@1 of LOUVRE is 67.0. Also, LOUVRE outperforms MDR in other evaluation metrics. In reranking experiments, we use the same reranking model as MDR-rerank. The only difference between LOUVRE-rerank and MDR-rerank is the parameter initialization method in the fine-tuning step same as the retriever experiment. These results show that our pre-training method is effective even after reranking; PathR@1 of LOUVRE-rerank is 83.2, and PathR@1 of MDR-rerank is 81.2.

Weak Supervision and Training Time: LOUVRE's pre-training method uses additional training with the multi-hop weak supervision dataset and results in the performance improvement shown above. To verify that the performance gap between RoBERTa and LOUVRE is not from the additional training time that LOUVRE uses in pre-training, we train RoBERTa with much a longer training time, 50 epochs, and compare with LOUVRE.

In Figure 3, we show the performance of RoBERTa fine-tuned for $\{2, 5, 15, 50\}$ epochs and

		Wiki link	PathR@1	R@10	R@20	AR@1

Table 2: Performance of retrievers. LOUVRE outperforms baseline retrievers and rerankers. Wiki link denotes whether the model uses Wikipedia hyperlinks.

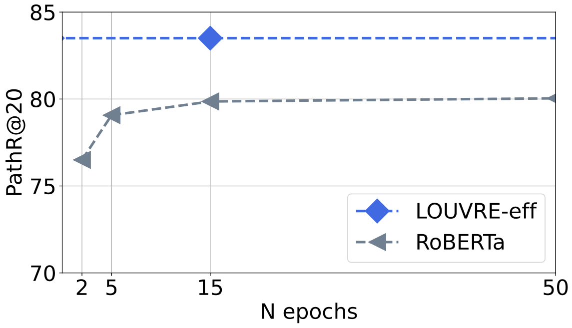

Figure 3: Comparison of LOUVRE-eff fine-tuned for 15 epochs with RoBERTa fine-tuned for 2 to 50 epochs. The performance of RoBERTa flattens at 15 epochs.

	R		PathR	
	@10	@20	@8	@20
LOUVRE-eff	**80.4**	**83.0**	**81.9**	**83.5**
- 1% train data	75.5	80.0	77.1	81.5
- zeroshot	44.8	55.8	48.3	59.0
- w/o pre-training	75.7	78.5	76.9	79.8
DPR-zeroshot	39.0	51.6	42.8	56.6

Table 3: Supporting document prediction performance of retrievers.

the performance of LOUVRE fine-tuned for 15 epochs. The performance of RoBERTa stabilizes at approximately 80% in terms of PathR@20 after 15 epochs. This result shows that the main factor of the performance improvement from our pre-training method is not merely from longer training time but the unique information for multi-hop retrievers provided by our weak supervision.

Retrieval Performance of Variations of LOUVRE-eff: Table 2 shows the effect of using LOUVRE. Similar results are observed in LOUVRE-eff. Table 3 shows the same experiments as Table 2 but in efficient fine-tuning setting, a small batch size and a short train time. We compare LOUVRE-eff with the retrieval performance of LOUVRE-eff without our pre-training method, which is fine-tuned on RoBERTa. Applying our pre-training method increases the retrieval performance by 4.7% point (R@10); R@10 of LOUVRE-eff is 80.4 and R@10 of LOUVRE-eff without pre-training is 75.7. Taking the results in Table 2 (the performance gain from our method with a big batch size/train epochs is 1.1) and the results in Table 3, we see the performance gain increases as there is more limitation on computation time.

Robustness on Few-shot Settings: Pre-training alleviates the model's drastic performance drop when the number of training data is insufficient. We demonstrate the robustness of LOUVRE on few-shot settings with different sizes of train data. We

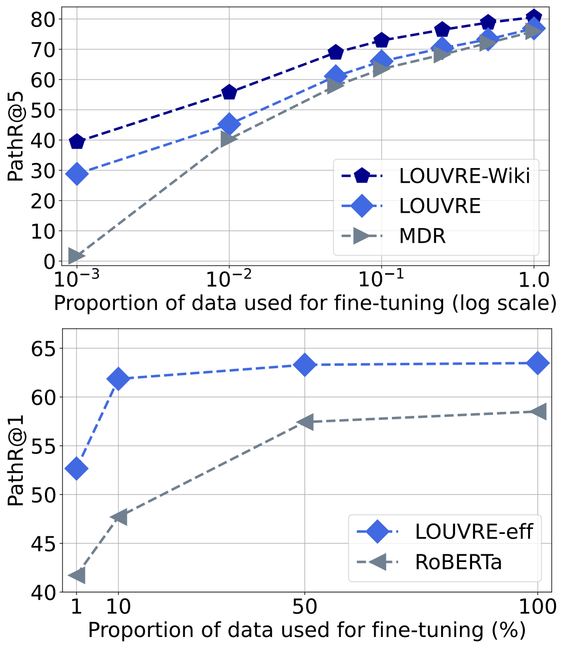

Figure 4: Retrieval performance of LOUVRE, LOUVRE-eff, and RoBERTa. The only difference between each model in the comparison models, (LOUVRE and MDR) and (LOUVRE-eff and RoBERTa), is the pre-trained model being used for parameter initialization.

fine-tune LOUVRE and MDR on a small portion of the HotpotQA train set within 0.1% to 100%. Figure 4 shows that the performance gap between LOUVRE and MDR increases as the size of train data decreases. When we use 0.1% of HotpotQA train data, almost 30% of LOUVRE's predictions contain correct supporting documents; the performance of MDR with the same amount of train data is close to 0. We conduct the same experiment with LOUVRE-Wiki and verify that using Wikipedia hyperlinks improves the robustness on a few-shot setting by 10.5% point in terms of PathR@5 when there is only 0.1% train data.

We conduct the same experiment with a small batch size of 32 and 10 epochs. Figure 4 illustrates the retrieval performance of LOUVRE-eff and LOUVRE-eff without our pre-training (RoBERTa) depending on the proportion of the data used for fine-tuning. It is worth noting that LOUVRE-eff fine-tuned with 10% data outperforms RoBERTa with 100% and shows little performance degradation compared to fine-tuning with 100%. We report the detailed results of LOUVRE-eff (1%) in Table 2. Table 2 shows that LOUVRE-eff (1%) achieves comparable performance to MDR trained on full data with a larger batch size and a longer train time; R@10 of LOUVRE-eff (1%) is 2.0% point lower than R@10 of MDR, which is 97% of the performance of MDR.

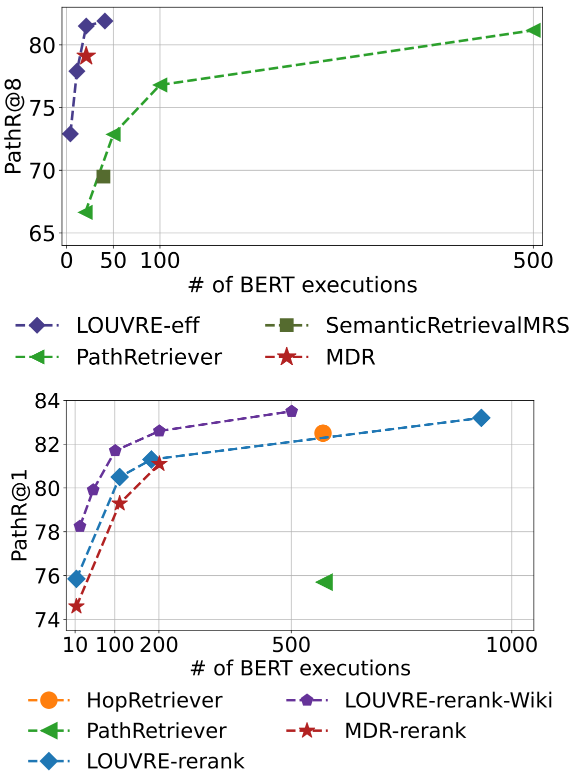

Figure 5: The retrieval performance of baselines and their computational efficiency. The beam sizes used for each model are as follows: $[3, 10, 20, 40]$ for LOUVRE-eff, $[3, 10, 13, 30]$ for LOUVRE-rerank, $[10, 10, 50, 100, 100]$ for LOUVRE-rerank-wiki, and $[3, 10, 100]$ for MDR-rerank. We use the input size of the reranker of each model as follows: $[9, 100, 169, 900]$ for LOUVRE-rerank, $[10, 40, 50, 100, 400]$ for LOUVRE-rerank-wiki, and $[9, 100, 100]$ for MDR. We evaluate PathRetriever with different number of initial n-documents retrieved by TF-IDF; $n \in \{20, 50, 100, 500\}$.

Furthermore, we evaluate the zero-shot performance of LOUVRE-eff and compare to DPR not fine-tuned on HotpotQA. To adapt DPR to the multi-hop retrieval task, we replace encoders in LOUVRE-eff with DPR encoders. We report this result in Table 3. In Table 3, LOUVRE-zeroshot achieves higher performance (R@10: 44.8 and R@20: 55.8) than DPR-zeroshot (R@10: 39.0 and R@20: 51.6).

Computational Efficiency: We compare the inference time of baselines and LOUVRE, with the number of BERT-base executions needed for each question. We exclude the inference time for document indexing which can be done a pri-

	Answer		Support		Joint

Table 4: End-to-end multi-hop QA performance of models on HOTPOTQA test set.

Retriever	#BERT	Joint F1
Reader: BERT		
- PathRetriever-eff	50^+	56.85
- LOUVRE-eff	50^+	**60.23**
Reader: ELECTRA		
- MDR	450^+	66.55
- LOUVRE-Wiki	450^+	**66.87**

Table 5: The end-to-end multi-hop performance of LOUVRE-eff and LOUVRE-Wiki on HOTPOTQA test set with the same inference speed as baselines.

ori. The number of BERT executions for each baseline is derived from each paper and its implementation. We measure the inference time of LOUVRE, PathRetriever, and MDR in various hyper-parameter settings by adjusting the number of beam size and the number of documents retrieved by the sparse retriever, TF-IDF. The number of BERT executions of MDR, LOUVRE-eff, and LOUVRE-eff with a beam size of b is calculated as follows: #BERT $= 1$(question encoding)$+$ b(question-passage encoding). The inference time of MDR-rerank, LOUVRE-rerank, and LOUVRE-rerank-wiki involves another factor, the input size of the reranker. The inference time of these reranking models with a beam size of b and a input size of r becomes #BERT $= 1 + b + r$. For PathRetriever, we vary the number of documents retrieved by the sparse retriever, TF-IDF. Figure 5 illustrates that LOUVRE is more effective and efficient than the baselines because it yields better retrieval performance with a much smaller number of BERT executions.

5.2 End-to-End Multi-Hop QA

In this section, we demonstrate that the end-to-end multi-hop QA pipeline using LOUVRE retains the three outcomes of LOUVRE: overall performance improvement, robustness on a few-shot setting, and the fast inference speed. We use multi-hop QA pipelines of MDR and PathRetriever. All the components of the multi-hop QA pipelines except the retriever are fixed. We plug in each baseline retriever and LOUVRE to the pipeline and evaluate the end-to-end performance of each model.

End-to-End Performance: Table 4 shows the end-to-end multi-hop QA performance of baselines and LOUVRE. In this experiment, we replace the retriever of MDR's pipeline with LOUVRE-rerank. We set the beam size to 30 and the input size of the reranker to 900. LOUVRE outperforms baselines with a Joint F1 of 67.08. Table 5 shows the performance of LOUVRE-Wiki using the same inference time as MDR. In this experiment, we use a beam size of 100 and the reranker's input size of 350. MDR uses a beam size of 200 and the reranker's input size of 250. LOUVRE-Wiki outperforms MDR by 0.32% point in terms of Joint F1. We conduct the same experiment with LOUVRE-eff and PathRetriever. Table 5 shows the results. LOUVRE-eff in Table 5 represents the end-to-end pipeline of PathRetriever-eff using LOUVRE-eff as the initial candidate document retriever not TF-IDF. We set the number of initial candidate documents of LOUVRE-eff and PathRetriever-eff to 50. LOUVRE-eff outperforms PathRetriever-eff by 3.38% point without any loss of computational efficiency. We provide the detailed experimental results of LOUVRE-eff in Appendix B.

End-to-End Performance of Variations of LOUVRE-eff: Table 6 shows the end-to-end performance of each model on different inference time, size of train data, and pre-training. We evaluate two types of LOUVRE-eff. LOUVRE-eff (RR) represents the same pipeline used in Table 5. LOUVRE-eff (w/o RR) represents the pipeline that consists of LOUVRE-eff and the reader. Comparison between PathRetriever(500^+)

	RR	#BERT	Joint F1
PathRetriever	✓	500$^+$	59.5
- fast inference	✓	100$^+$	58.6
- fast inference	✓	50$^+$	56.7
LOUVRE-eff	✓	100$^+$	60.5
- fast inference	✓	50$^+$	60.1
LOUVRE-eff		41	57.9
- 1% train set		41	57.1
- w/o pre-training		41	54.3
- fast inference		5	53.3

Table 6: End-to-end multi-hop QA performances of baseline models and LOUVRE on HotpotQA dev set. #BERT denotes the number of BERT-base executions in supporting document prediction and the number of documents that the reader takes as input. We exclude the inference time of the supporting sentence selector. We use the same reader model as PathRetriever.

and LOUVRE-eff (100$^+$) shows that applying LOUVRE-eff to PathRetriever increases Joint F1 by 1 with 5 times faster inference speed. We conduct the same experiment by reducing the number of documents retrieved by LOUVRE-eff and achieve 0.6% point higher Joint F1 than PathRetriever with 10 times faster inference speed.

We conduct ablation studies with two factors of retrievers: 1) size of train data and 2) pre-training. We fix the reader with BERT-wwm fully fine-tuned on HotpotQA train set. Table 6 shows the results. When we train LOUVRE-eff with only 1% of the train set, the end-to-end performance drops by 0.8% point. However, using RoBERTa with the whole train set decreases the performance by 3.6% point. This result indicates that our pre-training methods bring more significant improvement to the end-to-end multi-hop QA pipeline when the size of the train data is small.

Decreasing the search space of multi-hop retrievers increases the retriever's computational efficiency but results in a significant performance drop. We demonstrate the robustness of LOUVRE-eff when the computation time is limited. We decrease the beam size of LOUVRE-eff to 2 and the number of output paths to 2; the total number of BERT executions of this model is #BERT $=$ $1 + 2$(beam size) $+$ 2(input size). Table 6 shows that LOUVRE-eff achieves 89% of PathRetriever's performance with almost 100 times faster inference speed of PathRetriever. We adjust the inference speed of PathRetriever and compare it with LOUVRE-eff (w/o RR). LOUVRE-eff (w/o RR) outperforms PathRetriever (50$^+$) by 1.2% point with less computation time. LOUVRE-eff (w/o RR) trained only with 1% train data even outperforms PathRetriever (50$^+$).

6 Conclusion

Answering complex questions includes reasoning across multiple documents. Recent studies have found that reasoning requires learning sub-question detection and relevant document retrieval to predict n correct answer with supporting facts. However, building such datasets requires costly human annotation and has limited scalability. To address this issue, we proposed a weakly supervised pre-training method for multi-hop retriever, LOUVRE. Our pre-training method contains three elements: "Next Document Prediction" task, "Bridge Entity Re-Phrasing", and a model. We demonstrated the efficacy of LOUVRE and its robustness on few-shot settings with extensive experiments on supporting document retrieval task and end-to-end multi-hop QA task. We also showed that our method performs very well at a much lower inference cost.

A Appendix: Baselines

Retrievers: Retrievers encode questions and documents independently, and search documents by comparing the question vector and the document vectors. Retrievers are computationally efficient compared to rerankers since the document vectors can be indexed before the questions are given. In **TF-IDF**, to get the list of supporting documents from the retrieved documents, we rearrange the ranked documents $[d_1, d_2, d_3, d_4, ...]$ to $[\{d_1, d_2\}, \{d_3, d_4\}, ...]$. **DPR** (Karpukhin et al., 2020) is a single-hop document retrieval model. We compare LOUVRE to the performance of DPR fine-tuned on HOTPOTQA reported from Xiong et al. (2021). **Cognitive Graph** (Ding et al., 2019) and **GOLDEN Retriever** (Qi et al., 2019) are multi-hop document retrieval models. We report the performance of Cognitive Graph reported from Asai et al. (2020) and the performance of GOLDEN Retriever reported from Qi et al. (2019). We fine-tune LOUVRE with the same training method proposed in **MDR** (Xiong et al., 2021); thus, the performance difference between LOUVRE and MDR only results from our pre-training method. We report the performance of MDR from Xiong et al. (2021).

Abstract

Existing rumor detection strategies typically provide detection labels while ignoring their explanation. Nonetheless, providing pieces of evidence to explain why a suspicious tweet is rumor is essential. As such, a novel model, LOSIRD, was proposed in this paper. First, LOSIRD mines appropriate evidence sentences and classifies them by automatically checking the veracity of the relationship of the given claim and its evidence from about 5 million Wikipedia documents. LOSIRD then automatically constructs two heterogeneous graph objects to simulate the propagation layout of the tweets and code the relationship of evidence. Finally, a graphSAGE processing component is used in LOSIRD to provide the label and evidence. To the best of our knowledge, we are the first one who combines objective facts and subjective views to verify rumor. The experimental results on two real-world Twitter datasets showed that our model exhibited the best performance in the early rumor detection task and its rumor detection performance outperformed other baseline and state-of-the-art models. Moreover, we confirmed that both objective information and subjective information are fundamental clues for rumor detection.

1 Introduction

With the prevalence of social media platforms, rumors have been a serious social problem. Notably, existing rumor detection methods roughly formulate this task as a natural language classification task. The goal of the task is to simply label a given textual claim as rumor or non-rumor. Nevertheless, only a verdict to a suspicious statement is insufficient for people to understand and reason why a claim is a rumor. For example, Fig.1 is the comparison figure of existing rumor detection methods and a rumor detection method that provides evidence. The claim in Fig. 1 is a half-truth, which is highly deceptive. For such rumors, providing a label only is unconvincing. Thus, we believe that a good rumor detection system should have 2 essential functions including, a rumor identifying function and evidence providing function.

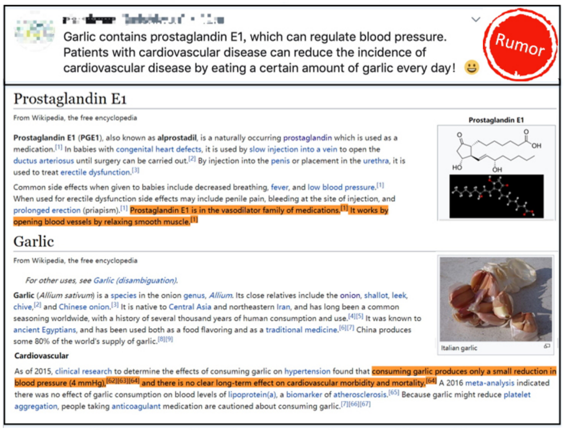
Garlic contains prostaglandin E1, which can regulate blood pressure. Patients with cardiovascular disease can reduce the incidence of cardiovascular disease by eating a certain amount of garlic every day! 😃

(a) Genral rumor detection system



[redacted]
Garlic contains prostaglandin E1, which can regulate blood pressure. Patients with cardiovascular disease can reduce the incidence of cardiovascular disease by eating a certain amount of garlic every day! 😃

Prostaglandin E1

From Wikipedia, the free encyclopedia

Prostaglandin E1 (**PGE1**), also known as **alprostadil**, is a naturally occurring prostaglandin which is used as a medication.[1] In babies with congenital heart defects, it is used by slow injection into a vein to open the ductus arteriosus until surgery can be carried out.[2] By injection into the penis or placement in the urethra, it is used to treat erectile dysfunction.[3]

Common side effects when given to babies include decreased breathing, fever, and low blood pressure.[1] When used for erectile dysfunction side effects may include penile pain, bleeding at the site of injection, and prolonged erection (priapism).[1] Prostaglandin E1 is in the vasodilator family of medications.[1] It works by opening blood vessels by relaxing smooth muscle.[1]

Garlic

From Wikipedia, the free encyclopedia

For other uses, see Garlic (disambiguation).

Garlic (*Allium sativum*) is a species in the onion genus, *Allium*. Its close relatives include the onion, shallot, leek, chive,[2] and Chinese onion.[3] It is native to Central Asia and northeastern Iran, and has long been a common seasoning worldwide, with a history of several thousand years of human consumption and use.[4][5] It was known to ancient Egyptians, and has been used both as a food flavoring and as a traditional medicine.[6][7] China produces some 80% of the world's supply of garlic.[8][9]

Cardiovascular

As of 2015, clinical research to determine the effects of consuming garlic on hypertension found that consuming garlic produces only a small reduction in blood pressure (4 mmHg),[62][63][64] and there is no clear long-term effect on cardiovascular morbidity and mortality.[64] A 2016 meta-analysis indicated there was no effect of garlic consumption on blood levels of lipoprotein(a), a biomarker of atherosclerosis.[65] Because garlic might reduce platelet aggregation, people taking anticoagulant medication are cautioned about consuming garlic.[7][66][67]

(b) a rumor detection system that provides evidence

Figure 1: Comparison figure of rumor detection results of two different systems. The orange highlights in Fig.1 (b) are pieces of evidence retrieved from Wikipedia. From those evidence sentences, readers can easily judge if the given claim is a half-truth and clearly understand why that claim is a rumor.

Rumor detection that provides evidence has the following benefits: (1) Improve detection performance. (2) Improve the user experience. (3) Provide a basis for manual review. (4) Improve the accuracy of early rumor detection. (5) Intercept the spread of similar rumors.

Despite having numerous advantages, rumor detection that provides evidence is extremely hard. If none of the labeled evidence information is included in a rumor detection training dataset, the deep learning network is unlikely to generate these textual evidence contents by itself. Unfortunately,

Table 1: Comparison characteristics table of subjective and objective information.

Subjectivity infor	**Objective infor**
easy access	need crawl
extensive	rare
one-sidedness	comprehensive
conflicting	consistency
has noise	high purity

the datasets currently used for rumor detection cannot be used as evidence.

To find out what type of information that can be used as evidence, two different kinds of information, subjective information and objective information, are discussed in this part (Merigo et al., 2016; Zorio-Grima and Merello, 2020). Under the field of rumor detection, subjective information refers to source tweets, comments, etc, while objective information refers to the information on Wikipedia or Baidu Encyclopedia, etc. Through our comprehensive analysis, we found that subjective information and objective information shows distinct-different characteristics, which are summarized in Table 1. The objective information is consistency and high purity, can be used as evidence, and the subjective information also contains certain clues for debunking rumors.

To take advantage of both subjective information and objective information, a novel model, LOSIRD, is proposed in this paper. This is notoriously challenging, the difficulties lie in: (1) The model should have a strong retrieval ability. (2) The model should have a Natural Language Inference(NLI) ability. (3) The model needs to be able to process the topology information.

Fig.2 shows a high-level view of its architecture. This model is divided into two modules i.e., ERM (Evidence Retrieval Module) and RDM (Rumor Detection Module). Inspired by the concept of transfer learning, a two-stage training approach was used for our LOSIRD model. In the first training phase, a widely used fact-checking database was utilized for training the ERM module. In the second training phase, two rumor detection datasets were used to train and evaluate the model.

The main contribution of this paper is four folds:

1. This study, for the first time, arguably proposes a rumor detection model that provides evidence.
2. We are the first to propose two novel graph objects to simulate the propagation lay out of tweets and embedding the relationship of evidence and the claim rumor detection task.
3. Our LOSIRD achieved the highest detection accuracy and outperformed state-of-the-art models in the rumor detection task.
4. Our LOSIRD is more generalizable and robust in the early detection of rumor.

2 Related work

2.1 Evidence Retrieval

The evidence retrieval task is highly correlated with the rumor detection task. One of the most widely used datasets for evidence retrieval is FEVER[1]. Majority of researchers handle the fever share task by following the FEVER organizers' pipeline approach, retrieve and verify the evidence in three steps (Hanselowski et al., 2018; Malon, 2018). Zhou et al. (2019a) formulated claim verification as a graph reasoning task and provides two kinds of attention. Liu et al. (2020) presented KGAT combining edge kernels and node kernels to better embedding and filtering the evidence. Zhong et al. (2020) constructed two semantic-level topologies to enhance verification performance. Yoneda et al. (2018) employed a four-stage model for the fever share task.

2.2 Rumor Detection

The existing rumor detection deep learning methods can be divided into three categories, feature-driven method, content-driven method, and hybrid-driven method.

Feature-Driven approaches, like machine learning methods, rely on a variety of characteristics to identify rumors. Rath et al. (2017) proposed a new concept of believability for automatic identification of the users spreading rumors.

Content-Driven approaches are a kind of method base on natural language processing. Many researchers adopted deep learning models to handle this task (Rath et al., 2017; Ma et al., 2016; Yu et al., 2017; Chen et al., 2018; Ma et al., 2018). Monti et al. (2019) proposed a propagation-based Fake News Detection by GCN. Nguyen (2019) detected rumor using Multi-modal Social Graph. Sujana et al. (2020) proposed a multiloss hierarchical BiLSTM model for fake news detection.

---

[1] http://fever.ai/task.html

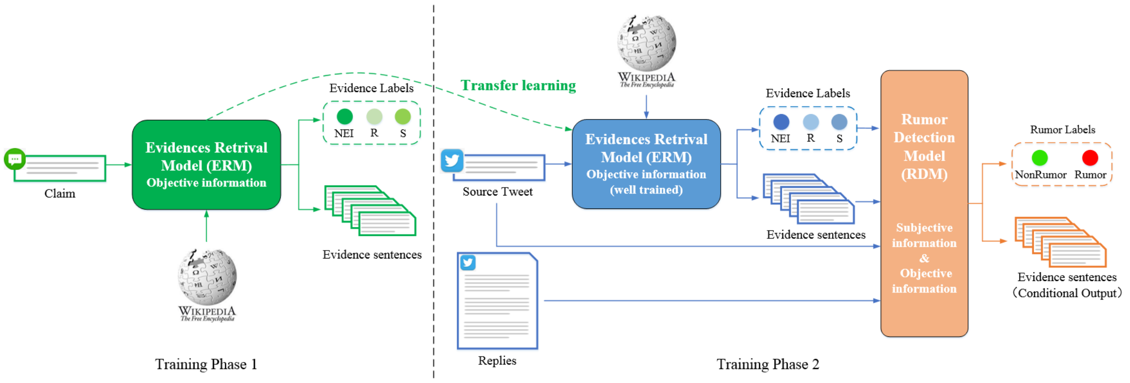

Figure 2: The architecture of our LOSIRD model. The claim and source tweet are essentially the same thing in this paper, "Claim" means the model is training using the Fever dataset, while "source tweet" indicates the PHEME datasets are used.

Hybrid-Driven approaches incorporate both feature engineering and text information representation to detect rumors (Liu and Wu, 2018; Yang et al., 2018). Ruchansky et al. (2017) proposed a model called CSI for rumor detection, which uses articles and extracts user characteristics to debunk rumors. Lu and Li (2020) classified rumor by extracting user's features from their profiles and social interactions. Li et al. (2020b) used GraphSEGA to encode the conversation structure. Li et al. (2020a) crawled user-follower information and built a friendly network based on the follow-followers relationship. Castillo et al. (2011) used tweets and re-posts information to detect rumors. Kochkina et al. (2018); Li et al. (2019) proposed a multi-task learning method to joint training of the main and auxiliary tasks, improving model's rumor detection the performance. Liu et al. (2015) aggregated common sense and investigative journalism of Twitter users for rumor detection. Ma et al. (2017) encoded post's propagation structure for rumor detection. Detect rumors in microblog posts using propagation structure via kernel learning.

2.3 Comparison

The highlights of our model include providing evidence, covering two heterogeneous structure graph information, combining both evidence clues and replies information in detecting rumor. Our model exhibited a stronger simulation ability, better scalability, and better persuasive ability.

3 The LOSIRD Model

3.1 Problem Statement

We formulated this rumor detection task as a hybrid task that combines the evidence retrieval sub-task and rumor prediction sub-task.

The evidence retrieval sub-task was defined as: Given a claim, the target of this sub-task was to match textural evidence from Wikipedia and reason the relationship between those potential evidence sentences and the given claim as "SUPPORTED", "REFUTED" or "NOT ENOUGH INFO (NEI)". We defined the Wikipedia as an objective information corpus: $Wiki = \{D_1, D_2, ..., D_{|w|}\}$, D_i as a document from Wikipedia. One document comprised several sentences describing one entity in Wikipedia. The goal of this sub-task was to retrieve evidence, classify the relationship of the evidence and the given claim C i.e., $f_{ERM} : C \rightarrow \{(y_e, E); E \in Wiki\}$, y_e is the predicted evidence label of the claim, E is retrieved evidence set of the claim which contains several sentence-level pieces of evidence.

The rumor prediction sub-task was defined as: Given a claim, that claim's replies, that claim's retrieved evidence set and evidence label, the model detected whether the claim was a rumor or non-rumor and provide the evidence. We defined the rumor dataset in this sub-task as $\Psi = \{T_1, T_2, ..., T_{|\Psi|}\}$, where T_i is a tweet in the dataset. $T_i = \{C_i, P_i, E_i, y_{e_i}\}$, where C_i is the ith source tweet in the rumor dataset, P_i is the source tweet's reply posts, E_i and y_{e_i} are the corresponding C_i retrieved evidence set and evidence label. Given a tweet T the function of this task was defined as

$f_{RDM} : T \to \{(y_r, E); E \in Wiki\}$, y_r was the predicted rumor label.

3.2 ERM

Mainly following (Liu et al., 2020) and (Hanselowski et al., 2018), we adopted a three-step pipeline module for retrieval evidence, called ERM. The architecture of the ERM is shown in Fig. 3. It contains three main steps ,i.e., Document retrieval: employs a keyword matching algorithm to crawling related files in Wikipedia. Evidence retrieval: extract sentence-level evidence from the retrieved articles. Claim verification: based on the sentence-level evidence, it predicts the relationship of the claim and the evidence as "Supported", "Refuted", or "NEI". Specifically, the ERM first leverages semantic NLP tool-kits to extract potential entities from the given a claim. With the parsed entities, top k highest-ranked Wikipedia articles were filtered by the MediaWiki API. And then, from those retrieved documents, the ERM extracts objective facts as the predicted evidence in the form of sentences that are relevant for the claim. Finally, a verification component of ERM performs prediction over the given statement and retrieved evidence, and verifies the relationship between the claim and evidence as supporting, refuting, or NEI.

3.3 RDM

Fig. 4 shows the structure of RDM. Since the source tweet forms different topology between replies and the evidence, two heterogeneous graph objects, the conversation tree-shaped graph and the evidence star-shaped graph, were structured in RDM.

3.3.1 Two heterogeneous graphs

Conversation tree-shaped structure is a peculiar reply relationship topology that forms naturally from social media and carries a vital clue for rumor detection (Belkaroui et al., 2014; Pace et al., 2016). Of note, the conversation structure is tree-shaped. Where the root of the tree is the source tweet, each node represents a comment, and each node is connected by its reply relationship.

Evidence star-shaped structure suggests that each piece of evidence is a supplementary description to the source tweet, hence each evidence sentence directly related to the source tweet forms a star topology. In this star-shaped structure, the node of the source tweet is in the center and all the evidence nodes surround the source tweet representing an angle in the star structure.

3.3.2 Rumor Detection Module

The rumor detection module contains four components: (1) a word vector encoding component. (2) a sentence embedding component. (3) a graph processing component. (4) a classifier component.

In RDM, a deep BiLSTM was utilized to extract the information among words and generate a sentence representation. The obtained sentence vector was passed into a graph processing component, the GraphSAGE (Hamilton et al., 2017) model was used as its backbone. The GraphSAGE effectively handled variable graphs. Since the output of the previous component is a set of sentence vectors does not contain structural information. Therefore, before passing this information into the graph processing component two graph objects, the conversation tree-shaped object and the evidence star-shaped object were constructed respectively.

The creation of the conversation graph object:

$$\begin{aligned} G_p &= (V_p, E_p) \\ V_p &= [c, p_1, p_2, .., p_j] \\ E_p &= \{(c, p_1), ...(p_n, p_m), ...\} \end{aligned} \tag{1}$$

where G_p is the ith event's conversation graph object, it's vertex set is V_p and edge set is E_p. The vertex set includes all the post in the event, and the edge set E_p means the reply relationship between each post. c and p_j are the tweet embedding results from the BiLSTM component, we selected the last hidden state of BiLSTM as a sentence embedding result.

The creation of the evidence graph object:

$$\begin{aligned} G_e &= (V_e, E_e) \\ V_e &= [c, e_1, e_2, .., e_k] \\ E_e &= \{(c, e_1), (c, e_2), ..., (c, e_k)\} \end{aligned} \tag{2}$$

where G_e is an evidence graph object consisting of a vertex set V_e and an edge set E_e. The vertex set V_e includes a source post c and evidence sentences, while the edge set E_e represents the relationship between the evidence and the source post, e_k represents the evidence sentence embedding results from the BiLSTM component.

At the beginning of the forward propagation step, the feature of each node was assigned to the nodes

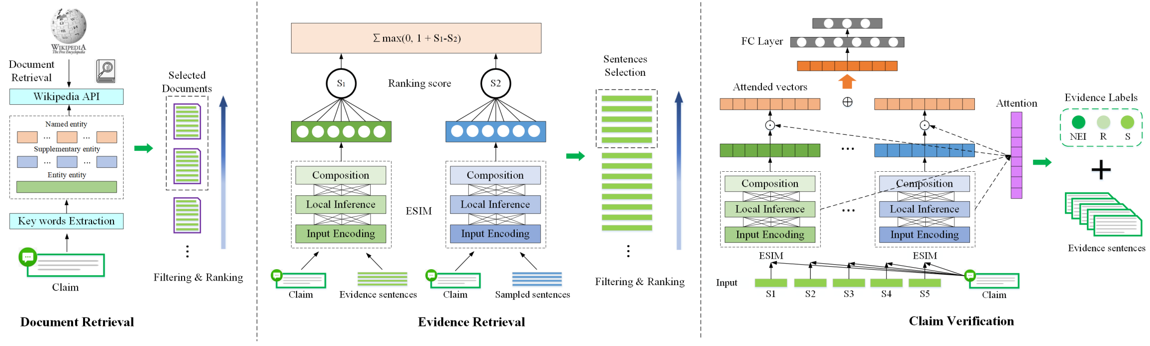

Figure 3: The architecture of the ERM.

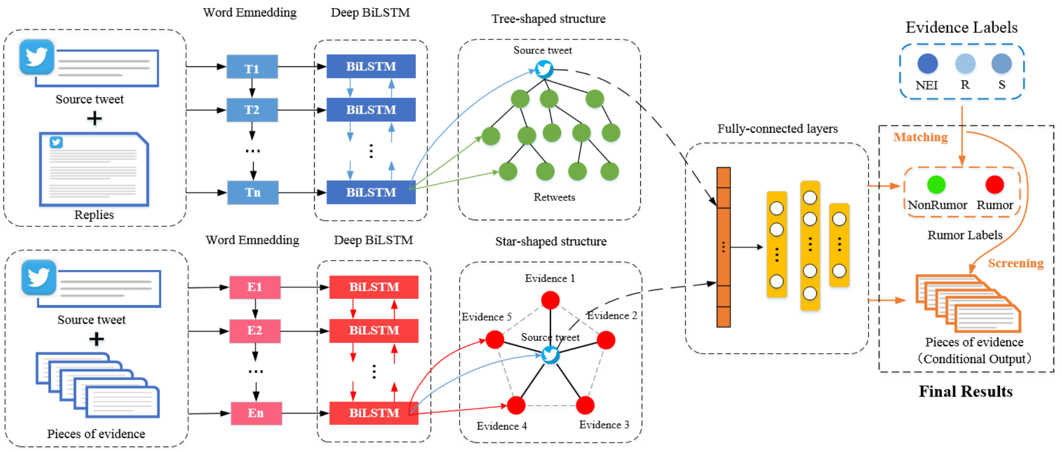

Figure 4: The architecture of the RDM.

in the hidden state as follows:

$$\begin{aligned}[h^0_{p_0}, h^0_{p_1}, ..., h^0_{p_j}] &\longleftarrow [c, p_1, p_2, .., p_j] \\ [h^0_{e_0}, h^0_{e_1}, ..., h^0_{e_k}] &\longleftarrow [c, e_1, e_2, .., e_k]\end{aligned} \tag{3}$$

where $h^0_{p_j}, h^0_{e_k}$ are the initial hidden states of the nodes of the conversation graph object and the evidence graph object in GraphSAGE.

The node's hidden state in GraphSAGE updates by constantly aggregating its immediate neighbors' hidden state, combining them with its own state and generate it's new hidden state.This process makes the nodes gain incrementally richer information (Hamilton et al., 2017):

$$\begin{aligned}h^k_{p_{N(v)}} &\longleftarrow AGG^{pool}_k(\{h^{k-1}_{p_u}, \forall u \in N(V_p)\}) \\ h^k_{p_v} &\longleftarrow \sigma(W^k_p \cdot CON(h^{k-1}_{p_v}, h^k_{p_{N(v)}}))\end{aligned} \tag{4}$$

$$\begin{aligned}h^k_{e_{N(v)}} &\longleftarrow AGG^{pool}_k(\{h^{k-1}_{e_u}, \forall u \in N(V_e)\}) \\ h^k_{e_v} &\longleftarrow \sigma(W^k_e \cdot CON(h^{k-1}_{e_v}, h^k_{e_{N(v)}}))\end{aligned} \tag{5}$$

where $h^k_{p_{N(v)}}, h^k_{e_{N(v)}}$ is the aggregated their neighborhood vectors, k is the depth of the information transmission updates (the number of times the graph information is updated), N is the neighborhood function, $N(v)$ is the set of the node's immediate neighborhood, and AGG^{pool}_k is the aggregation function and CON is the concatenation function.

Three aggregators are provided in GraphSAGE, and in this article we chose the Max Pooling aggregator. Here's the formula:

$$\begin{aligned}AGG^{pool}_k =& max(\{\sigma(W_{pool} \cdot h^k_{graph_{N(v)}} + \\ & b_{pool}), \forall u_i \in N(v)\})\end{aligned} \tag{6}$$

where max is the element-wise max operator, and σ is a nonlinear activation function.

After k iterations of information transmission based on the conversation structure and star structure, final representations of the conversation embedding results and evidence embedding results were obtained:

$$\begin{aligned}p &\longleftarrow h^k_{p_v}, \forall v \in V_p \\ e &\longleftarrow h^k_{e_v}, \forall v \in V_e\end{aligned} \tag{7}$$

p, e are the replies and the evidence of the ith event.

Table 2: The statistic of FEVER dataset.

Split	SUPPORTED	REFUTED	NEI
Train	80,035	29,775	35,659
Dev	6,666	6,666	6,666
Test	6,666	6,666	6,666

Table 3: The statistic of rumor datasets.

Statistic	PHEME2017	PHEME2018
Users	49,345	50,593
Posts	103,212	105,354
Events	5,802	6,425
Avg posts/event	17.8	16.3
Rumor	1,972	2,402
Non-rumor	3,830	4,023

Max aggregator is used to aggreate the information into fixed size.

Thereafter, the information of these two parts concatenated together then passed into a multilayer perceptron for the final prediction. The formula is as follows:

$$y_r = Softmax(V \cdot (p \oplus e) + b_y) \qquad (8)$$

where V and b_y are parameters in the output layer.

4 Experiment and Results

4.1 Datasets

Fever dataset was used to train the evidence retrieval module. The statistic of the FEVER dataset is shown in Table 2. Two widely used rumor datasets, PHEME 2017 and PHEME 2018[1], were used to train and evaluate the whole proposed model, as shown in Table 3[2].

4.2 Experimental Setup

To evaluate the rumor detection performance of our model, we compared our proposed models with other popular rumor detection models, including some of the current state-of-the-art models. In the text processing stage, we clean the text information by removing useless expressions and symbols, uniform case, etc. We use Twitter 27B pre-trained GloVe data with 200 dimensions for word embedding and set the maximum vocabulary to 80,000. For the rumor detection module The hidden size of BiLSTM is 128, and the number of layers is 2. The batch size of graphSAGE is 64. We use Adam with a 0.0015 learning rate to optimize the model, with the dropout rate set to 0.5. For the evidence retrieval, we set the learning rate in ESIM is 0.002, drop out rate is 0, batch size is 64, activation fuction is relu. For the claim verification, we set the the learning rate in ESIM is 0.002, drop out rate is 0.1, batch size is 128,activation fuction is relu.We split the datasets, reserve 10% of the events as the validation set, and the rest in a ratio of 3:1 for training and testing partitions.

- **CNN**: a convolutional neural model for rumor detection (Chen et al., 2017).
- **BiLSTM**: a bidirectional LSTM model for debunking rumors (Augenstein et al., 2016).
- **BERT**: a fine-tuned BERT to detect rumors (Devlin et al., 2019).
- **CSI**: a state-of-the-art model detecting rumor by scoring users based on their behavior (Ruchansky et al., 2017).
- **DEFEND**: a state-of-the-art model learns the correlation between the source article's sentences and user profiles (Shu et al., 2019).
- **RDM**: a state-of-the-art model integrating GRU and reinforcement learning to detect rumors at an early stage (Zhou et al., 2019b).
- **CSRD**: a state-of-the-art model that detect rumors by modeling conversation structure (Li et al., 2020b).
- **LOSIDR**: our model, leverages objective facts and subjective views for interpretable rumor detection.

4.3 Experimental Results

The main experimental results are shown in Table 4. The LOSIRD outperformed the other best-competing methods on PHEME 17 and PHEME 18. Its accuracy was 91.4% in PHEME 2017 and 92.5% in PHEME 2018. Moreover, the precision, recall, and F1 were all higher than 90% in both two datasets. Such promising results confirmed the effectiveness of evidence information and the topology message processing method in rumor detection. For the CNN, BiLSTM, DEFEND, and RDM models, they typically concatenated posts as a single line based on the publish time, while ignoring the

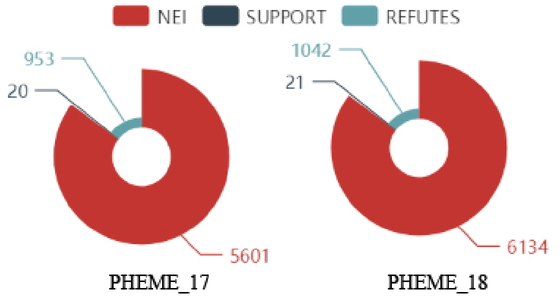

Figure 5: The distribution of the retrieved evidence.

conversation structure information. Nonetheless, the structure was crucial for encoding the posts to comprehensive and precise representations. The CSI and CRNN processed topology information, but only the subjective information was adopted in those models causing insufficiency in information extraction.

4.4 Evidence Impact Study

In this section, we discussed whether the evidence facilitates rumor detection and determined the extent of the impact of the evidence in debunking rumor. Notably, the evaluated datasets were the PHEME 2017 and PHEME 2018.

4.4.1 Distribution of Retrieved Evidence

To accurately evaluate the retrieved evidence, the distribution of the retrieved evidence based on its evidence label was analyzed. Two pie charts were constructed to reflect their distribution situations. As shown in Fig. 5, most of the retrieved evidence was irrelevant to the given claim, and about 14.8% of the retrieved evidence sentences had sufficient information that supports or refutes the given claim. Despite the proportion of supports and refutes being not large, this result was commendable and better than our expectations.

Table 5: Retrieved evidence probability analysis result.

Dataset	Original	Refutes	Increment
PHEME 17	33.30%	75.80%	42.50%
PHEME 18	36.60%	70.92%	34.30%

4.4.2 Retrieved Evidence Probability Analysis

We further evaluated the impact of evidence by statistically calculating the probability gap between rumor in original data and rumor in data that labeled refutes. The outcome is shown in Table 5. The probabilities of rumor in original data were about 35% in both datasets, while the probabilities of rumor in data that labeled refutes were around 73%, which was much higher than in original data. Specifically, rumor in data that labeled refutes increased to 42.5% on PHEME 17 and 34.3% on PHEME 18. This strongly confirmed that the retrieved evidence was a vital clue for rumor detection.

4.4.3 Influence Analysis of the Evidence on Deep Learning Model

To further illustrate the influence of evidence on rumor detection and analyze the impact of evidence on deep learning models, three NLP models, CNN, BILSTM, and BERT, were deliberately selected as the examination models in this subsection. We concatenated the suspicious claim and its evidence sentences and inputted them into the three models, respectively. The experimental results shows in Fig. 6. The horizontal axis represented a different number of evidence sentences, 0 means only source tweet, while 1 to 5 means source tweet plus 1 to 5 evidence sentences. Also, this paper analyzed the performance before and after the evidence was filtered which was represented as each chart with two

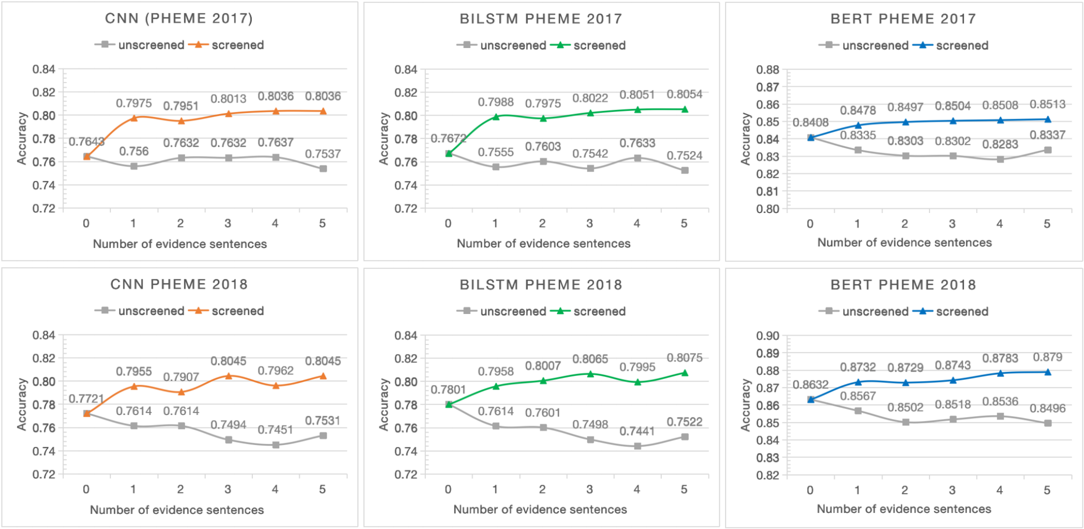

Figure 6: Influence analysis of the evidence on the performance of deep learning models.

lines i.e., one for the unscreened evidence (filter the NEI evidence) and the other for the screened evidence. The broken lines of unscreened in all the charts showed a downward trend. This indicated that the NEI evidence contained a certain amount of useless information there by making the detection process harder. Furthermore, after dropping the NEI evidence, all the models achieved an improvement by an increase of 5% accuracy on average. This demonstrated that the filtered evidence significantly helps the deep learning models in debunking rumors.

4.5 Early Detection Performance

To evaluate the early rumor detection performance of our model, 9 test sets that reflected real-world scenarios of rumors spreading on Twitter were created. Each test set included a different number of replies, ranging between 5 replies and 45 replies. The test subset was sampled based on the publication timestamp. As shown in Fig. 7, even though the number of posts was only 5, our LOSIRD model had more than 91% accuracy in PHEME 2017 dataset and PHEME 2018 dataset. Additionally, the broken line diagram showed that the curve of our model was significantly stable, indicating satisfactory robustness and high performance in early rumor detection. Besides, our model effectively made use of the objective information from Wikipedia, hence, it did not rely on subjective information from replies of the users thereby achieving satisfactory performance in the early stage of rumor propagation.

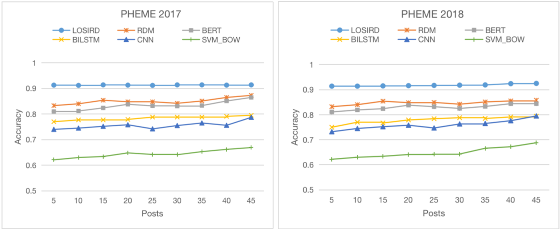

Figure 7: Early rumor detection performance.

5 Conclusion

In this paper, we proposed a LOSIRD, a novel interpretative model for rumor detection. Notably, the LOSIRD debunking rumor mechanism depends on both objective facts and subjective views. Objective fact sentences retrieved from 5,416,537 Wikipedia articles were sufficiently utilized to help LOSIRD in analyzing the veracity of a suspicious claim. Meanwhile, the information in subjective views was extracted by simulating the propagation of subjective views based on the conversation structure. Results on two public Twitter datasets showed that our model improved rumor detection performance by a certain margin compared to the state-of-the-art baselines. Further, we analyzed the impact of objective facts for rumor detection and analyzed the effectiveness of the conversation structure. The experiments revealed that both objective facts and subjective views were vital clues for debunking rumor. Moreover, we believe that our model will be used for rumor detection and other text classification tasks on social media.

Abstract

Chinese Spell Checking (CSC) aims to detect and correct erroneous characters for user-generated text in Chinese language. Most of the Chinese spelling errors are misused semantically, phonetically or graphically similar characters. Previous attempts notice this phenomenon and try to utilize the similarity relationship for this task. However, these methods use either heuristics or handcrafted confusion sets to predict the correct character. In this paper, we propose a Chinese spell checker called REALISE, by directly leveraging the multimodal information of the Chinese characters. The REALISE model tackles the CSC task by (1) capturing the semantic, phonetic and graphic information of the input characters, and (2) selectively mixing the information in these modalities to predict the correct output. Experiments[1] on the SIGHAN benchmarks show that the proposed model outperforms strong baselines by a large margin.

Phonetically Similar Case		
Sent.	晚饭后他递给我一平(píng, *flat*)红酒。	
Cand.	晚饭后他递给我一杯(bēi, *cup*)红酒。	✗
	晚饭后他递给我一瓶(píng, *bottle*)红酒。	✓
	晚饭后他递给我一箱(xiāng, *box*)红酒。	✗
Trans.	He handed me a *bottle* of red wine after dinner.	
Graphically Similar Case		
Sent.	每天放学我都会轻(qīng, *light*)过这片树林。	
Cand.	每天放学我都会路(lù, *pass*)过这片树林。	✗
	每天放学我都会经(jīng, *go*)过这片树林。	✓
	每天放学我都会走(zǒu, *walk*)过这片树林。	✗
Trans.	I *go* through this wood every day after school.	

Table 1: Two examples of Chinese spelling errors and their candidate corrections. “Sent./Cand./Trans.” are short for sentence/candidates/translation respectively. The wrong/candidate/correct characters with their pronunciation and translation are in red/orange/blue color.

1 Introduction

The Chinese Spell Checking (CSC) task aims to identify erroneous characters and generate candidates for correction. It has attracted much research attention, due to its fundamental and wide applications such as search query correction (Martins and Silva, 2004; Gao et al., 2010), optical character recognition (OCR) (Afli et al., 2016), automatic essay scoring (Dong and Zhang, 2016). Recently, rapid progress (Zhang et al., 2020; Cheng et al., 2020) has been made on this task, because of the success of large pretrained language models (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019).

In alphabetic languages such as English, spelling errors often occur owing to one or more wrong characters, resulting in the written word not in the dictionary problem (Tachibana and Komachi, 2016). However, Chinese characters are valid if they can be typed in computer systems, which causes that the spelling errors are de facto misused characters in the context of computer-based language processing. Considering the formation of Chinese characters, a few of them were originally pictograms or phono-semantic compound characters (Jerry, 1988). Thus, in Chinese, the spelling errors are not only the misused characters with confusing semantic meaning, but also the characters which are phonetically or graphically similar (Liu et al., 2010, 2011). Table 1 shows two examples of Chinese spelling error. In the first example, phonetic information of “平” (flat) is needed to get the correct character “瓶” (bottle) since they share the same pronunciation “píng”. The second example needs not only phonetic, but also graphic information of the erroneous character “轻” (light). The

correct one, “经” (go), has the same right radical as “轻” and similar pronunciation (“qīng” and “jīng”). Therefore, considering the intrinsic nature of Chinese, it is essential to leverage the phonetic and graphic knowledge of the Chinese characters along with the textual semantics for the CSC task.

In this paper, we propose REALISE (**Read**, **Listen**, and **See**), a Chinese spell checker which leverages the semantic, phonetic and graphic information to correct the spelling errors. The REALISE model employs three encoders to learn informative representations from textual, acoustic and visual modalities. First, BERT (Devlin et al., 2019) is adopted as the backbone of the semantic encoder to capture the textual information. For the acoustic modality, *Hanyu Pinyin* (pinyin), the romanization spelling system for the sounds of Chinese characters, is used as the phonetic features. We design a hierarchical encoder to process the pinyin letters at the character-level and the sentence-level. Meanwhile, for the visual modality, we build character images with multiple channels as the graphic features, where each channel corresponds to a specific Chinese font. Then, we use ResNet (He et al., 2016) blocks to encode the images to get the graphic representation of characters.

With the representation of three different modalities, one challenge is how to fuse them into one compact multimodal representation. To this end, a selective modality fusion mechanism is designed to control how much information of each modality can flow to the mixed representation. Furthermore, as the pretrain-finetune procedure has been proven to be effective on various NLP tasks (Devlin et al., 2019; Dong et al., 2019; Sun et al., 2020), we propose to pretrain the phonetic and the graphic encoders by predicting the correct character given input in the corresponding modality.

We conduct experiments on the SIGHAN benchmarks (Wu et al., 2013; Yu et al., 2014; Tseng et al., 2015). By leveraging multimodal information, REALISE outperforms all previous state-of-the-art models by a large margin. Compared to previous methods using confusion set (Lee et al., 2019) to capture the character similarity relationships, such as the SOTA SpellGCN (Cheng et al., 2020), REALISE achieves an averaging 2.4% and 2.6% F1 improvements at detection-level and correction-level. Further analysis shows that our model performs better on the errors which are not defined in the handcrafted confusion sets. This indicates that leveraging the phonetic and graphic information of Chinese characters can better capture the easily-misused characters.

To summarize, the contributions of this paper include: (i) we propose to leverage phonetic and graphic information of Chinese characters besides textual semantics for the CSC task; (ii) we introduce the selective fusion mechanism to integrate multimodal information; (iii) we propose acoustic and visual pretraining tasks to further boost the model performance; (iv) to the best of our knowledge, the proposed REALISE model achieves the best results on the SIGHAN CSC benchmarks.

2 Related Work

2.1 Chinese Spell Checking

The CSC task is to detect and correct spelling errors in Chinese sentences. Early works design various rules to deal with different errors (Chang et al., 2015; Chu and Lin, 2015). Next, traditional machine learning algorithms are brought to this field, such as Conditional Random Field and Hidden Markov Model (Wang and Liao, 2015; Zhang et al., 2015). Then, neural-based methods have made great progress in CSC. Wang et al. (2018) treat the CSC task as a sequence labeling problem, and use a bidirectional LSTM to predict the correct characters. With the great success of large pretrained language models (e.g., BERT (Devlin et al., 2019)), Hong et al. (2019) propose the FASpell model, which use a BERT-based denoising autoencoder to generate candidate characters and uses some empirical measures to select the most likely ones. Besides, the Soft-Masked BERT model (Zhang et al., 2020) leverages a cascading architecture where GRU is used to detect the erroneous positions and BERT is used to predict correct characters.

Previous works (Yu and Li, 2014; Wang et al., 2019; Cheng et al., 2020) using handcrafted Chinese character confusion set (Lee et al., 2019) aim to correct the errors by discovering the similarity of the easily-misused characters. Wang et al. (2019) leverage the pointer network (Vinyals et al., 2015) by picking the correct character from the confusion set. Cheng et al. (2020) propose a SpellGCN model which models the character similarity through Graph Convolution Network (GCNs) (Kipf and Welling, 2016) on the confusion set. However, the character confusion set is predefined and fixed, which cannot cover all the similarity relations, nor can it distinguish the divergence in the similarity

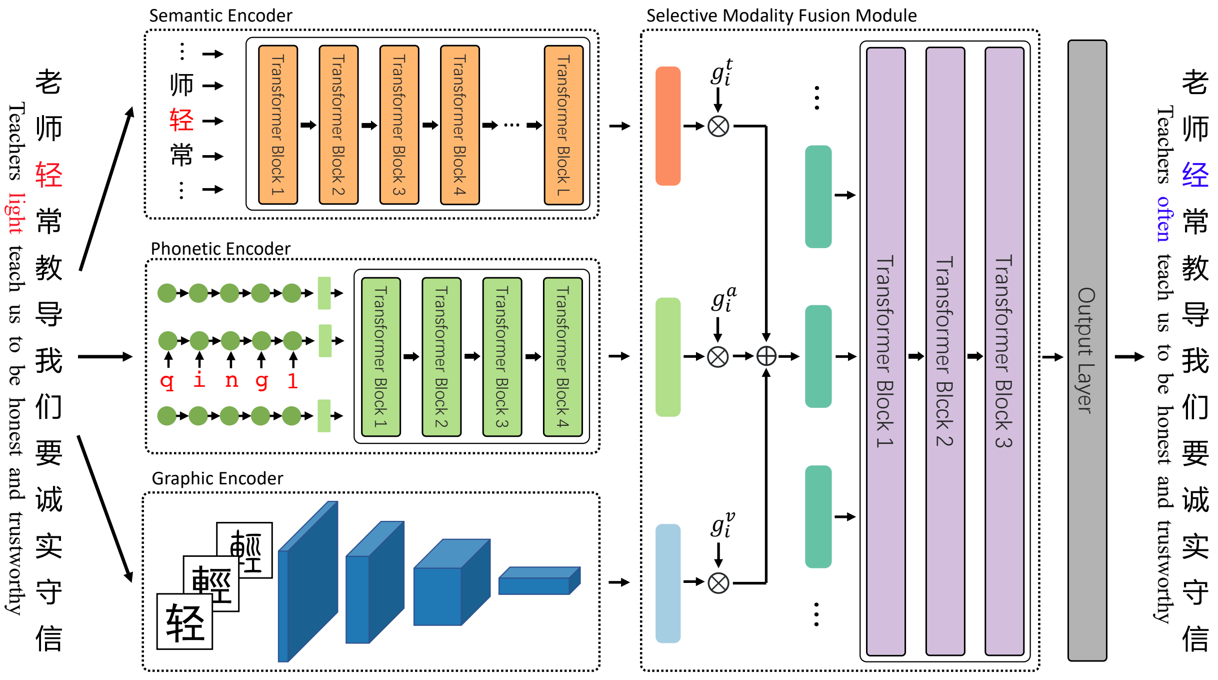

Figure 1: Architecture overview of the REALISE model. The semantic, phonetic and graphic encoders, are used to capture the information in textual, acoustic and visual modalities. The fusion module selectively fuses the information from three encoders. In the example input, to correct the erroneous character, “轻” (qīng, light), we need not only the contextual text information, but also the phonetic and graphic information of the character itself.

of Chinese characters. In this work, we discard the predefined confusion set and directly use the multimodal information to discover the subtle similarity relationship between all Chinese characters.

2.2 Multimodal Learning

There has been much research to integrate information from different modalities to achieve better performance. Tasks such as Multimodal Sentiment Analysis (Zadeh et al., 2016; Zhang et al., 2019), Visual Question Answering (Antol et al., 2015; Chao et al., 2018) and Multimodal Machine Translation (Hitschler et al., 2016; Barrault et al., 2018) have made much progress. Recently, multimodal pretraining models have been proposed, such as VL-BERT (Su et al., 2020), Unicoder-VL (Li et al., 2020), and LXMERT (Tan and Bansal, 2019). In order to incorporate the visual information of Chinese characters into language models, Meng et al. (2019) design a Tianzige-CNN to facilitate some NLP tasks, such as named entity recognition and sentence classification. To the best of our knowledge, this paper is the first work to leverage multimodal information to tackle the CSC task.

3 The REALISE Model

In this section, we introduce the REALISE model, which utilizes the semantic, phonetic, and graphic information to distinguish the similarities of Chinese characters and correct the spelling errors. As shown in Figure 1, multiple encoders are firstly employed to capture valuable information from textual, acoustic and visual modalities. Then, we develop a selective modality fusion module to obtain the context-aware multimodal representations. Finally, the output layer predicts the probabilities of error corrections.

3.1 The Semantic Encoder

We adopt BERT (Devlin et al., 2019) as the backbone of the semantic encoder. BERT provides rich contextual word representation with the unsupervised pretraining on large corpora.

The input tokens $\mathbf{X} = (x_1, \ldots, x_N)$ are first projected into $\mathbf{H}_0^t$ through the input embedding. Then the computation of Transformer (Vaswani et al., 2017) encoder layers can be formulated as:

$$\mathbf{H}_l^t = \text{Transformer}_l(\mathbf{H}_{l-1}^t), l \in [1, L] \quad (1)$$

where L is the number of Transformer layers. Each layer consists of a multi-head attention module and a feed-forward network with the residual connection (He et al., 2016) and layer normalization (Ba et al., 2016). The output of the last layer $\mathbf{H}^t = \mathbf{H}^t_L = (h^t_1, \ldots, h^t_N)$ is used as the contextualized semantic representation of the input tokens in textual modality.

3.2 The Phonetic Encoder

Hanyu Pinyin (pinyin) is the romanization for Chinese to "spell out" the sounds of characters. We use it to calculate the phonetic representation in this paper. The pinyin of a Chinese character consists of three parts: initial, final, and tone. The initial (21 in total) and final (39 in total) are written with letters in the English alphabet. The 5 kinds of tones (take the final "a" as an example, { ā, á, ǎ, à, a }) can be mapped into numbers $\{1, 2, 3, 4, 0\}$. Though the vocabulary size of pinyin for all Chinese characters is a fixed number, we use a sequence of letters in REALISE to capture the subtle phonetic difference between Chinese characters. For example, the pinyin of "中" (middle) and "棕" (brown) are "zhōng" and "zōng" respectively. The two characters have very similar sounds but quite different meanings. We thus represent pinyin as a symbol sequence, e.g., $\{z, h, o, n, g, 1\}$ for "中". We denote the pinyin of the i-th character in the input sentence as $\boldsymbol{p}_i = (p_{i,1}, \ldots, p_{i,|\boldsymbol{p}_i|})$, where $|\boldsymbol{p}_i|$ is the length of pinyin $\boldsymbol{p}_i$.

In REALISE, we design a hierarchical phonetic encoder, which consists of a character-level encoder and a sentence-level encoder.

The Character-level Encoder is to model the basic pronunciation and capture the subtle sound difference between characters. It is a single-layer uni-directional GRU (Cho et al., 2014), which encodes the pinyin of the i-th character x_i as:

$$\tilde{h}^a_{i,j} = \text{GRU}(\tilde{h}^a_{i,j-1}, E(p_{i,j})) \tag{2}$$

where $E(p_{i,j})$ is the embedding of the pinyin symbol $p_{i,j}$, and $\tilde{h}^a_{i,j}$ is the j-th hidden states of the GRU. The last hidden state is used as the character-level phonetic representation of x_i.

The Sentence-level Encoder is a 4-layer Transformer with the same hidden size as the semantic encoder. It is designed to obtain the contextualized phonetic representation for each Chinese character. As the independent phonetic vectors are not distinguished in order, we add the positional embedding to each vector in advance. Then, we pack these phonetic vectors together, and apply the Transformer layers to calculate the contextualized representation in acoustic modality, denoted as $\mathbf{H}^a = (h^a_1, h^a_2, ..., h^a_N)$. Note that owing to the Transformer architecture, this representation is also normalized.

3.3 The Graphic Encoder

We apply the ResNet (He et al., 2016) as the graphic encoder. The graphic encoder has 5 layers of ResNet blocks (denoted as ResNet5) followed by a layer normalization (Ba et al., 2016) operation. We formulate this procedure as follows:

$$\begin{aligned} \tilde{h}^v_i &= \text{ResNet5}(\mathbf{I}_i) \\ h^v_i &= \text{LayerNorm}(\tilde{h}^v_i) \end{aligned} \tag{3}$$

where $\mathbf{I}_i$ is the image of the i-th character x_i in the input sentence, and LayerNorm means layer normalization.

In order to extract graphic information effectively, each block in ResNet5 halves the width and height of the image, and increases the number of channels. Thus, the final output is a vector with the length equal to the number of output channels, i.e., both height and width become 1. Furthermore, we set the number of output channels to the hidden size in the semantic encoder for the follow-up modality fusion. We denote the representation in visual modality of the input sentence as $\mathbf{H}^v = (h^v_1, h^v_2, \ldots, h^v_N)$.

The character image of x_i is read from preset font files. Since the scripts of Chinese characters have evolved for thousands of years, to capture the graphic relationship between character as much as possible, we select three fonts, namely Gothic typefaces (黑体, hēitǐ) in both Simplified and Traditional Chinese, and Small Seal Script (小篆, xiǎozhuàn). The three fonts correspond to the three channels of the character images, whose size is set to 32 × 32 pixel.

3.4 Selective Modality Fusion Module

After applying the previously mentioned semantic, phonetic and graphic encoders, we get the representation vectors $\mathbf{H}^t$, $\mathbf{H}^a$ and $\mathbf{H}^v$ in textual, acoustic and visual modalities. To predict the final correct Chinese characters, we develop a selective modality fusion module to integrate these vectors in different modalities. This module fuses information in two levels, i.e., character-level and sentence-level.

First, for each modality, a selective gate unit is employed to control how much information can flow to the mixed multimodal representation. For example, if a character is misspelled due to its similar pronunciation to the correct one, then more information in the acoustic modality should flow into the mixed representation. The gate values are computed by a fully-connected layer followed by a sigmoid function. The inputs include the character representation of three modalities and the mean of the semantic encoder output $\mathbf{H}^t$ to capture the overall semantics of the input sentence. Formally, we denote the gate values for the textual, acoustic and visual modalities as g^t, g^a and g^v. The mixed multimodal representation $\tilde{h}_i$ of the i-th character is computed as follows:

$$\begin{aligned}
\bar{h}^t &= \frac{1}{N}\sum_{i=1}^{N} h_i^t \\
g_i^t &= \sigma(\mathbf{W}^t \cdot [h_i^t, h_i^a, h_i^v, \bar{h}^t] + b^t) \\
g_i^a &= \sigma(\mathbf{W}^a \cdot [h_i^t, h_i^a, h_i^v, \bar{h}^t] + b^a) \\
g_i^v &= \sigma(\mathbf{W}^v \cdot [h_i^t, h_i^a, h_i^v, \bar{h}^t] + b^v) \\
\tilde{h}_i &= g_i^t \cdot h_i^t + g_i^a \cdot h_i^a + g_i^v \cdot h_i^v
\end{aligned} \tag{4}$$

where $\mathbf{W}^t$, $\mathbf{W}^a$, $\mathbf{W}^v$, b^t, b^a, b^v are learnable parameters, σ is the sigmoid function, and $[\cdot]$ means the concatenation of vectors.

Then, we apply the Transformer to fully learn the semantic, phonetic and visual information at the sentence-level. The mixed representations of all characters are packed together into $\mathbf{H}_0 = [\tilde{h}_1, \tilde{h}_2, ..., \tilde{h}_N]$, and the probability distribution $\hat{y}_i$ of what the i-th character should be is derived as:

$$\begin{aligned}
\mathbf{H}_l &= \text{Transformer}_l(\mathbf{H}_{l-1}), l \in [1, L'] \\
\hat{y}_i &= \text{softmax}(\mathbf{W}^o h_i + b^o), h_i \in \mathbf{H}_{L'}
\end{aligned} \tag{5}$$

where L' is the number of Transformer layers, $\mathbf{W}^o$ and b^o are learnable parameters.

3.5 Acoustic and Visual Pretraining

While acoustic and visual information is essential to the CSC task, equally important is how to associate them with the correct character. In order to learn the acoustic-textual and visual-textual relationships, we propose to pretrain the phonetic and the graphic encoders.

For the phonetic encoder, we design an Input Method pretraining objective, that the encoder should recover the Chinese character sequence given the input pinyin sequence. This is what the Chinese input methods do. We add a linear layer on the top of the encoder to transform the hidden states to the probability distributions over the Chinese character vocabulary. We pretrain the phonetic encoder with the pinyin of the sentences with spelling errors in the training data, and make it recover the character sequences without spelling errors.

Training Set	#Sent	Avg. Length	#Errors
SIGHAN13	700	41.8	343
SIGHAN14	3,437	49.6	5,122
SIGHAN15	2,338	31.3	3,037
Wang271K	271,329	42.6	381,962
Total	277,804	42.6	390464
Test Set	**#Sent**	**Avg. Length**	**#Errors**
SIGHAN13	1,000	74.3	1,224
SIGHAN14	1,062	50.0	771
SIGHAN15	1,100	30.6	703
Total	3,162	50.9	2,698

Table 2: Statistics of the used datasets. All the training data are merged to train the REALISE model. The test sets are used separately to evaluate the model performance.

For the graphic encoder, we design an Optical Character Recognition (OCR) pretraining objective. Given the Chinese character images, the graphic encoder learns the visual information to predict the corresponding character over the Chinese character vocabulary. This is like what the OCR task does, but our recognition is only conducted on the character level and typed scripts. During the pretraining, we also add a linear layer on the top to perform the classification.

Finally, we load the pretrained weights of the semantic encoder, phonetic encoder, and graphic encoder, and conduct the final training process with the CSC training data.

4 Experiments

In this section, we introduce experimental details and results on the SIGHAN benchmarks (Wu et al., 2013; Yu et al., 2014; Tseng et al., 2015). We then verify the effectiveness of our model by conducting ablation studies and analyses.

4.1 Data and Metrics

Following previous works (Wang et al., 2019; Cheng et al., 2020), we use the SIGHAN training data and the generated pseudo data (Wang et al., 2018, denoted as Wang271K) as the training set. We evaluate our model on the SIGHAN test sets

Dataset	Method	Detection Level				Correction Level

Table 3: The performance of our model and all baseline models on SIGHAN test sets. The "†" symbol means we apply post-processing (Section 4.2) to the model outputs on SIGHAN13. Results of ReaLiSe on all SIGHAN test sets outperforms all the corresponding baselines with a significance level $p < 0.05$.

in 2013, 2014 and 2015 (denoted as SIGHAN13, SIGHAN14 and SIGHAN15). Table 2 shows the data statistics. Originally, the SIGHAN datasets are in the Traditional Chinese. Following previous works (Wang et al., 2019; Cheng et al., 2020; Zhang et al., 2020), we convert them to the Simplified Chinese using the OpenCC tool[2].

Results are reported at the detection level and the correction level. At the detection level, a sentence is considered to be correct if and only if all the spelling errors in the sentence are detected successfully. At the correction level, the model must not only detect but also correct all the erroneous characters to the right ones. We report the accuracy, precision, recall and F1 scores on both levels.

4.2 Implementation Details

The ReaLiSe model is implemented using PyTorch framework (Paszke et al., 2019) with the Transformer library (Wolf et al., 2020). The architecture of the semantic encoder is same as the $\text{BERT}_{\text{BASE}}$ (Devlin et al., 2019) model (i.e. 12 transformer layers with 12 attention heads, hidden size of 768). We initialize the semantic encoder with the weights of BERT-wwm model (Cui et al., 2019). For the phonetic sentence-level encoder, we set the number of layers to 4, and initialize its position embedding with BERT's position embedding. The selective modality fusion module has 3 transformer layers, i.e., $L' = 3$, and the prediction matrix $\mathbf{W}^o$ is tied with the word embedding matrix of the semantic encoder. All the embeddings and hidden states have the dimension of 768. We use the Pillow library to extract the Chinese character images. When processing the special tokens (e.g. `[CLS]` and `[SEP]` of BERT), we use the tensor with all zero values as their image inputs. We train our ReaLiSe model with the AdamW (Loshchilov and Hutter, 2017) optimizer for 10 epochs. The learning rate is set to 5e-5, the batch size is set to 32, and the model is trained with learning rate warming up and linear decay.

In the SIGHAN13 test set, the annotation quality is relatively poor, that quite a lot of the mixed usage of auxiliary "的", "地", and "得" are not annotated (Cheng et al., 2020). Therefore, a well-performed model may obtain bad scores on it. To alleviate the problem, Cheng et al. (2020) proposes

---

[2] `https://github.com/BYVoid/OpenCC`

to continue finetuning the model on the SIGHAN13 training set before testing. We argue that it's not a good practice because it reduces the model performance. Instead, we use a simple and effective post-processing method. We simply remove all the detected and corrected "的", "地", and "得" characters from the model output and then evaluate with the ground truth of SIGHAN13 test set.

4.3 Baselines

We compare ReaLiSe with the following baselines: **KUAS** (Chang et al., 2015), **NTOU** (Chu and Lin, 2015), **NCTU-NTUT** (Wang and Liao, 2015), **HanSpeller++** (Zhang et al., 2015), **LMC** (Xie et al., 2015) mainly utilize heuristics or traditional machine learning algorithms, such as n-gram language model, Conditional Random Field and Hidden Markov Model. **Sequence Labeling** (Wang et al., 2018) treats CSC as a sequence labeling problem and applies a BiLSTM model. **FASpell** (Hong et al., 2019) utilizes a denoising autoencoder (DAE) to generate candidate characters. **Soft-Masked BERT** (Zhang et al., 2020) utilizes the detection model to help the correction model learn the right context. **SpellGCN** (Cheng et al., 2020) incorporates the predefined character confusion sets to the BERT-based correction model through Graph Convolutional Networks (GCNs). **BERT** (Devlin et al., 2019) is to directly fine-tune the BERT$_{\text{BASE}}$ model with the CSC training data.

4.4 Main Results

Table 3 shows the evaluation scores at detection and correction levels on the SIGHAN 13/14/15 test sets. The ReaLiSe model performs significantly better than all the previous state-of-the-art models on all test sets. It can be seen that, by capturing valuable information from acoustic and visual modalities, ReaLiSe yields consistent gain with a large margin against BERT. Specifically, at the correction-level, ReaLiSe exceeds BERT by 5.2% F1 on SIGHAN13, 3.8% F1 on SIGHAN14, and 4.4% F1 on SIGHAN15. The results on SIGHAN13 are improved significantly with simple post-processing described in Section 4.2.

There are several successful applications of BERT on the CSC task, such as FASpell and SpellGCN, which also consider the Chinese character similarity. They attempt to calculate the similarity as the confidence of filtering candidates, or construct similarity graphs from predefined confusion sets. Instead, in our method, multiple encoders are directly applied to derive more informative representation from the acoustic and visual modalities. Compared with SpellGCN (Cheng et al., 2020), the SOTA CSC model, our ReaLiSe model achieves an averaging 2.4% F1 improvements at detection-level and an averaging 2.6% F1 improvements at correction-level. This indicates that, compared with other extensions of BERT, the explicit utilization of multimodal information of Chinese characters is more beneficial to the CSC task.

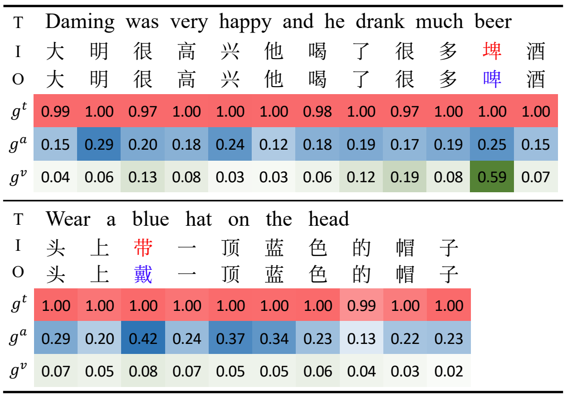
Model	Acc	Pre	Rec	F1
	Detection Level			
BERT	78.4	74.6	74.5	74.5
ReaLiSe	82.0	77.9	78.5	78.1
- Phonetic	81.2	76.4	77.7	77.0
- Graphic	81.4	77.3	77.2	77.2
- Multi-Fonts	81.2	76.3	77.9	77.0
- Pretraining	81.5	76.5	78.1	77.2
- Selective-Fusion	81.3	76.8	77.4	77.1
	Correction Level			
BERT	76.9	72.3	72.3	72.3
ReaLiSe	81.0	76.5	77.0	76.7
- Phonetic	80.2	74.8	76.1	75.4
- Graphic	80.5	75.8	75.6	75.7
- Multi-Fonts	80.3	74.9	76.4	75.5
- Pretraining	80.6	75.2	76.8	75.9
- Selective-Fusion	80.5	75.4	76.0	75.7

Table 4: Ablation results of the ReaLiSe model averaged on SIGHAN test sets. We apply the following changes to ReaLiSe: removing the phonetic encoder (- Phonetic), removing the graphic encoder (- Graphic), using only one font to build the graphic inputs (- Multi-Fonts), removing acoustic and visual pretraining (- Pretraining), replacing the selective modality fusion mechanism with simple summation (- Selective-Fusion).

With the simple post-processing as described in Section 4.2, results of each model on the SIGHAN13 test set are improved significantly. Compared with BERT and SpellGCN, we can see that, after the post-processing, the ReaLiSe model is ahead of all the baseline models.

4.5 Ablation Study

We explore the contribution of each component in ReaLiSe by conducting ablation studies with the following settings: 1) removing the phonetic encoder, 2) removing the graphic encoder, 3) using only one font (Gothic typefaces in Simplified Chinese) for the graphic encoder, 4) removing the acoustic and visual pretraining objectives, 5) replacing the selective modality fusion mechanism with simple summation.



T	Daming was very happy and he drank much beer											
I	大	明	很	高	兴	他	喝	了	很	多	埤	酒
O	大	明	很	高	兴	他	喝	了	很	多	啤	酒
g^t	0.99	1.00	0.97	1.00	1.00	1.00	0.98	1.00	0.97	1.00	1.00	1.00
g^a	0.15	0.29	0.20	0.18	0.24	0.12	0.18	0.19	0.17	0.19	0.25	0.15
g^v	0.04	0.06	0.13	0.08	0.03	0.03	0.06	0.12	0.19	0.08	0.59	0.07

T	Wear a blue hat on the head									
I	头	上	带	一	顶	蓝	色	的	帽	子
O	头	上	戴	一	顶	蓝	色	的	帽	子
g^t	1.00	1.00	1.00	1.00	1.00	1.00	1.00	0.99	1.00	1.00
g^a	0.29	0.20	0.42	0.24	0.37	0.34	0.23	0.13	0.22	0.23
g^v	0.07	0.05	0.08	0.07	0.05	0.05	0.06	0.04	0.03	0.02

Figure 2: Selective modality fusion visualization. "I" is the input sentence. "O" is the output of REALISE (also the ground truth), and "T" is the translation. g^t, g^a, g^v are the gate values for the textual, acoustic, and visual modality respectively. We highlight the wrong/correct characters in red/blue color.

Table 4 shows the averaged scores[3] on three SIGHAN test sets. The main motivation of this paper is to discover the character similarity relationships by incorporating the acoustic and visual information. If removing the phonetic or graphic encoder, we can see that the model performance drops at two levels but still outperforms BERT significantly. This suggests that the checking model can benefit from the multimodal information. No matter which component we remove, the performance of REALISE drops, which fully demonstrates the effectiveness of each part in our model.

4.6 Analysis of the Selective Modality Fusion Module

Figure 2 gives two examples to analyze the selective modality fusion module. In the first example, the acoustic and visual selective gate values of "埤", i.e. g^a and g^v, are much larger than most other characters since "埤(pí)" and "啤(pí)" have the same pronunciation and right radical "卑". This shows that the selective fusion module can judge whether to introduce phonetic or graphic information into the mixed representation. The second example shows a similar trend for the pronunciation of "带(dài)" and "戴(dài)". More selective fusion visualization can be found in the Appendix A.2.

Besides, we calculate the averaged gate values of erroneous characters for each modality on SIGHAN15. The largest one is the textual modality that the value is almost equal to 1.0. The second one is the acoustic modality that the averaged value is 0.334, and the smallest one is the visual modality that the value is 0.229. It means that the information from the semantic encoder is the most important for correcting the spelling errors. The acoustic modality is more important than the visual modality, which is consistent with the fact that the spelling errors caused by similar pronunciations are more frequent than errors caused by similar character shapes (Liu et al., 2010).

In:	我打算去法国流行，你要不要跟我一起去? I am going to popular to France, would you like to go with me?
Out:	我打算去法国旅行，你要不要跟我一起去? I am going to travel to France, would you like to go with me?
In:	回国之后，我跟快去你家。 After returning home, I will go to your house with.
Out:	回国之后，我很快去你家。 After returning home, I will go to your house soon.

Table 5: Examples of the input and output of our REALISE model. We highlight the wrong/correct characters in red/blue color.

4.7 Case Study

In the first example in Table 5, "流" is the erroneous character. If ignoring the Chinese character similarities, we can find that there are multiple candidate corrections to replace the "流" character. For instance, we can replace it with "游" and the English translation is "*I am going to parade in France*". However, the REALISE's output is the best correction, because "流(liú)" and "旅(lˇü)" have a similar pronunciation. In the second example, not only the phonetic information, but also the visual information is important for correcting "跟(gēn)" to "很(hěn)". In detail, the two characters share the same final "en" in pronunciation, and have the same right radical "艮".

The errors in the above examples are not corrected by SpellGCN, since they are not defined as confusing character pairs in the handcrafted confusion sets (Lee et al., 2019). Specifically, in the SIGHAN15 test set, there are 16% erroneous-corrected character pairs not in the predefined confusion sets. SpellGCN corrects 64.6% of them but REALISE performs better with 73.5% correction. Besides, for the easily-confused pairs in the predefined sets, SpellGCN corrects 82.5% of them and REALISE corrects 85.8%. This indicates that leveraging multimodal information of Chinese charac-

---

[3] Full ablation results can be found in the Appendix A.1.

ters helps the model generalize better in capturing the character similarity relationships.

5 Conclusion

In this paper, we propose a model called REALISE for Chinese spell checking. Since the spelling errors in Chinese are often semantically, phonetically or graphically similar to the correct characters, REALISE leverages information in textual, acoustic and visual modalities to detect and correct the errors. The REALISE model captures information in these modalities using tailored semantic, phonetic and graphic encoders. Besides, a selective modality fusion mechanism is proposed to control the information flow of these modalities. Experiments on the SIGHAN benchmarks show that the proposed REALISE outperforms the baseline models using only textual information by a large margin, which verifies that leveraging acoustic and visual information helps the Chinese spell checking task.

Figure 3: Selective modality fusion visualization. "I" is the input sentence. "O" is the output of REALISE (also the ground truth), and "T" is the translation. g^t, g^a, g^v are the gate values for the textual, acoustic, and visual modality respectively. We highlight the wrong/correct characters in red/blue color.

A Appendix

A.1 Ablation

We conduct an ablation study to verify the effectiveness of the proposed method. Table 6 (on Page 13 in Appendix) shows the detailed ablation results on each SIGHAN test set, where the following settings are conducted:

1. **- Phonetic**: removing the phonetic encoder.
2. **- Graphic**: removing the graphic encoder.
3. **- Multi-Fonts**: using only one font (Gothic typefaces in Simplified Chinese) for the graphic encoder.
4. **- Pretraining**: removing the acoustic and visual pretraining objectives.
5. **- Selective-Fusion**: replacing the selective modality fusion mechanism with simple summation.

We can see that, when we remove anything from our model, the REALISE performance drops consistently, and it drops most apparently in the SIGHAN14 test set. These results suggest that each part of our model is an effective means for boosting the checking performance.

A.2 Selective Modality Fusion Visualization

We show more examples in Figure 3. We can see that, if the misused characters are phonetically similar to the correct ones, the acoustic gate values tend to be larger, and if they are graphically similar, the visual gate values are larger.

TransSum: Translating Aspect and Sentiment Embeddings for Self-Supervised Opinion Summarization

Ke Wang, Xiaojun Wan
Wangxuan Institute of Computer Technology, Peking University
The MOE Key Laboratory of Computational Linguistics, Peking University
`{wangke17,wanxiaojun}@pku.edu.cn`

Abstract

In this paper, we propose a novel self-supervised opinion summarization framework TransSum, which models opinion summaries as translations operating on the low-dimensional aspect and sentiment embedding spaces. Specifically, we propose two contrastive objectives to learn the crucial aspect and sentiment embeddings of reviews, by taking advantage of the intra- and inter-group invariances that have not been considered in previous studies. Furthermore, these embeddings can be used to reduce opinion redundancy and construct highly relevant reviews-summary pairs to train a supervised multi-input opinion summarization model. Experimental results on three different domains show that TransSum outperforms several strong baselines in generating informative, relevant and low-redundant summaries, unveiling the effectiveness of our approach.

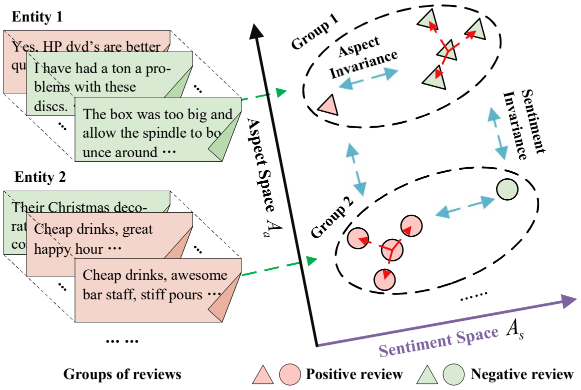

Figure 1: The proposed TransSum targets at learning corresponding aspect and sentiment embeddings for reviews (green arrows) through contrastive learning based on the aspect and sentiment invariances (blue arrows). These embeddings are used to construct reviews-summary pairs of high relevance (red arrows), so as to train a supervised multi-input opinion summarization model. Best view in color.

1 Introduction

Opinion summarization, which focuses on automatically generating summaries that reflect salient opinion information expressed in a group of documents (e.g., user reviews of a product in Figure 1), has been receiving great attention due to its usefulness and effectiveness for displaying massive opinion texts (Ku et al., 2006; Cheung et al., 2009; Chu and Liu, 2019). For example, a representative review summary of a product can not only replace large amounts of reviews for potential customers to read, but also provide more explanations than a simple overall sentiment rating, such as “ What is the biggest complaint on the iPod ‘screen’ ?”.

However, compared with supervised summarization in the domain of news articles, the annotated training data for opinion summarization is expensive to acquire. Due to the lack of gold-standard summaries for training, most existing works focus on unsupervised opinion summarization and treat it as a normal multi-document summarization task. They either struggle to reduce the opinion redundancy efficiently or output summaries lacking relevance to input reviews. Particularly, many previous studies focus on extractive approaches (Paul et al., 2010; Fabbrizio et al., 2014; Rossiello et al., 2017; Narayan et al., 2019), which copy texts from the input reviews but tend to be redundant and less informative (Chu and Liu, 2019). Some recently proposed abstractive methods are based on unsupervised representation learning, such as autoencoder (Chu and Liu, 2019; Amplayo and Lapata, 2019; Brazinskas et al., 2020a) or variational autoencoder (Brazinskas et al., 2020b; Angelidis et al., 2020), but mainly focus on the content transformation within each group of reviews. Other studies aim to create synthetic reviews-summary pairs to train a supervised multi-document summarization model (Amplayo and Lapata, 2019; Brazinskas et al., 2020b; Amplayo and Lapata, 2020; Amplayo

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 729–742
August 1–6, 2021.

et al., 2021), such as sampling a review from a corpus of product reviews and treating it as a summary of the remaining reviews, but such settings may lack rationality to guarantee the relevance of reviews and constructed pseudo-summaries.

In an effort to overcome these challenges, we propose a novel self-supervised framework for opinion summarization, TransSum, which consists of two main modules and does not require any gold summaries for training. (i) In the translation-based review modeling module, we expect to represent reviews with only their corresponding aspect and sentiment embeddings (as shown in Figure 1) with the purpose of reducing unnecessary information. We decompose each review into the aspect and sentiment embeddings through reconstruction and contrastive learning (van den Oord et al., 2018; He et al., 2020) based on two novel intra- and inter-group invariances: First, the real-world reviews in a group may discuss various opinions covering different aspects, but they are dependent with a specific entity (e.g., reviews about a specific product). Hence, the aspect information of the reviews in the same group should be closer than that of different groups (i.e, aspect invariance in Figure 1), that is, the distances between intra-group reviews should be less than the ones between inter-group reviews in the aspect embedding space. Second, the sentiment information of reviews with the same sentiment label should be closer than that of different sentiment labels (i.e, sentiment invariance in Figure 1), that is, the distances between reviews with the same sentiment should be less than the ones between reviews with different sentiments in the sentiment embedding space. (ii) In our multi-input opinion summarization module, we reduce opinion redundancy by combining similar embeddings, and use reviews with similar aspects (embeddings) to construct reviews-summary pairs of high relevance, which are used to train a supervised multi-input summarization model.

We conduct extensive experiments to show the superiority of our method. Experimental results on three different domains show that our method outperforms several strong baselines in generating informative, relevant, low-redundant and fluent summaries. We also perform ablation studies to analyze the effectiveness of the modules in our method.

In summary, our main contributions are:

- To the best of our knowledge, we are the first to generate opinion summaries from only the aspect and sentiment embeddings, which unlocks the critical bottleneck for unsupervised opinions modeling and takes a step forward towards more complex and controllable designs.
- We propose a novel self-supervised framework (TransSum) to generate opinion summaries without access to expensive annotations by disentangling reviews into aspect and sentiment embeddings and automatically constructing highly relevant reviews-summary pairs for model training.
- Experimental results on three domains show that our approach outperforms several strong baselines, especially in terms of relevance and non-redundancy.

2 TransSum

2.1 Overview

As aforementioned, a good opinion summary needs to cover major opinions/sentiments on different aspects of the entity (e.g., a movie, product, business) discussed in a group of reviews. Inspired by this observation, we propose a self-supervised framework (titled TransSum), aiming to generate opinion summaries without access to expensive annotations by interpreting them as translations operating on the aspect and sentiment embeddings.

As noted in a recent theoretical model of importance in summarization (Peyrard, 2019), a good summary should meet three requirements: (i) minimum redundancy, (ii) maximum relevance with the input document(s), and (iii) maximum informativeness. Based on the observation that reviews are usually created to express users' sentiments on certain aspects of a specific entity (e.g., the price and battery of a PC), we reasonably define informativeness, the amount of new information contained in the opinion summary relative to the background knowledge, as the aspect and sentiment information. The purpose is to reduce unnecessary information in the opinion summary, such as personal information or other irrelevant details.

Specifically, TransSum consists of two main components: **(1)** A translation-based review modeling module that learns only aspect and sentiment embeddings from each review for opinion summarization, to keep only the key and useful information (requirement iii). The aspect and sentiment embeddings of reviews are learned through reconstruction and two contrastive objectives, which take advantage of aspect and sentiment invariance of intra- and inter-group reviews (detailed in Sec 2.3). **(2)** A multi-input opinion summarization module that learns to generate the summary from the redundancy-reduced combination of the aspect and sentiment embeddings of input reviews (requirement i). It is trained by synthetic reviews-summary pairs of high relevance (requirement ii), which are constructed based on the assumption that reviews with the same aspect information (embeddings) are likely to express similar opinions (detailed in Sec 2.4).

2.2 Notations

More formally, let $\mathbb{D}$ denote a review corpus in a domain (e.g., Products' reviews), which consists of m groups of reviews. For each group $\boldsymbol{G}$, we assume that it contains n reviews $\{\boldsymbol{r}_1, \cdots, \boldsymbol{r}_i \cdots, \boldsymbol{r}_n\}$ about a specific entity e (e.g., a product), n is not a fixed number. For each review $\boldsymbol{r}_i$ in $\boldsymbol{G}$, we define its number of tokens $\boldsymbol{r}_i$ as $|\boldsymbol{r}_i|$, that is, $\boldsymbol{r}_i = \{\boldsymbol{r}_i^{(1)}, \cdots, \boldsymbol{r}_i^{(|\boldsymbol{r}_i|)}\}$, and use $\boldsymbol{r}_{-i} = \{\boldsymbol{r}_1, \cdots, \boldsymbol{r}_{i-1}, \boldsymbol{r}_{i+1}, \cdots, \boldsymbol{r}_n\}$ to represent the remaining $n-1$ reviews. Each review has a binary sentiment label x (i.g., positive or negative), which indicates the overall sentiment polarity of the review. The aspect and sentiment embeddings of $\boldsymbol{r}_i$ are denoted as $\boldsymbol{a}_i \in \mathbb{R}^{|\boldsymbol{r}_i| \times k}$ and $\boldsymbol{s}_i \in \mathbb{R}^{|\boldsymbol{r}_i| \times k}$. E and D are encoder and decoder respectively.

The goal of opinion summarization is to generate a summary $\boldsymbol{y}$ that covers opinions mentioned in the group of reviews, in other words, $\boldsymbol{y}$ can be considered *"a representative review"* that can replace the group of reviews $\{\boldsymbol{r}_1, \cdots, \boldsymbol{r}_i \cdots, \boldsymbol{r}_n\}$ in terms of informativeness. Note that we cannot access gold-standard opinion summaries for each group of reviews, as the human-annotated summaries do not exist in most domains.

2.3 Translation-Based Review Modeling

The translation-based review modeling module aims to learn aspect and sentiment embeddings for reviews (the left block in Figure 2).

For each review $\boldsymbol{r}_i$ in the group $\boldsymbol{G}$, we encode it using a Transformer (Vaswani et al., 2017) encoder E, and the output encoding $\boldsymbol{h}_i \in \mathbb{R}^{|\boldsymbol{r}_i| \times k}$ is:

$$\boldsymbol{h}_i = E(\boldsymbol{r}_i) = (\boldsymbol{h}_i^{(1)}, \cdots, \boldsymbol{h}_i^{(|\boldsymbol{r}_i|)}), \qquad (1)$$

where k is the embedding dimension. Inspired by Zhong et al. (2019), we initialize the token embeddings of E with the ones of the BERT-base model (Devlin et al., 2019). Then we use projection matrices $\boldsymbol{A}_a \in \mathbb{R}^{k \times k}$ and $\boldsymbol{A}_s \in \mathbb{R}^{k \times k}$ to project $\boldsymbol{h}_i$ to the aspect and sentiment spaces as $\boldsymbol{a}_i$ and $\boldsymbol{s}_i$ (the blue and red squares in Figure 2), respectively.

$$\boldsymbol{a}_i = \boldsymbol{h}_i \boldsymbol{A}_a = (\boldsymbol{a}_i^{(1)}, \cdots, \boldsymbol{a}_i^{(|\boldsymbol{r}_i|)}) \qquad (2)$$

$$\boldsymbol{s}_i = \boldsymbol{h}_i \boldsymbol{A}_s = (\boldsymbol{s}_i^{(1)}, \cdots, \boldsymbol{s}_i^{(|\boldsymbol{r}_i|)}) \qquad (3)$$

For later use, we further denote $\hat{\boldsymbol{a}}_i = \frac{1}{|\boldsymbol{r}_i|}\sum_{j=1}^{|\boldsymbol{r}_i|} \boldsymbol{a}_i^{(j)}$ ($\hat{\boldsymbol{a}}_i \in \mathbb{R}^k$) and $\hat{\boldsymbol{s}}_i = \frac{1}{|\boldsymbol{r}_i|}\sum_{j=1}^{|\boldsymbol{r}_i|} \boldsymbol{s}_i^{(j)}$ ($\hat{\boldsymbol{s}}_i \in \mathbb{R}^k$) to represent the mean vectors of the embeddings, repectively.

Translation-Based Reconstruction: We assume that each review is "an opinion summary" of the user's intention and attitude, and model the review as the translation from aspect and sentiment embeddings, that is, $\boldsymbol{c}_i = \boldsymbol{a}_i + \boldsymbol{s}_i$ (the yellow square in Figure 2):

$$\boldsymbol{c}_i = \{\boldsymbol{a}_i^{(1)} + \boldsymbol{s}_i^{(1)}, \cdots, \boldsymbol{a}_i^{(|\boldsymbol{r}_i|)} + \boldsymbol{s}_i^{(|\boldsymbol{r}_i|)}\}, \qquad (4)$$

To maximize informativeness and reduce unnecessary information, we hope to reconstruct $\boldsymbol{r}_i$ from only the embeddings $\boldsymbol{c}_i$ with a decoder D. The reconstruction loss is:

$$\mathcal{L}_{rec} = \mathbb{E}_{\boldsymbol{r}_i \sim \mathbb{D}}[\ell(D(\boldsymbol{c}_i), \boldsymbol{r}_i)], \qquad (5)$$

where ℓ is the cross entropy loss (de Boer et al., 2005) and D is a Transformer (Vaswani et al., 2017) decoder with cross-attention on $\boldsymbol{c}_i$. Following previous arts (Amplayo et al., 2021; ElSahar et al., 2020), we adopt label smoothing method (Szegedy et al., 2016) on $\boldsymbol{r}_i$ instead of computing with categorical distributions.

Contrastive Learning of Aspect and Sentiment Embeddings: We perform contrastive learning to learn the aspect and sentiment embeddings, based on the following two contrastive objectives: (i) the aspect embeddings of intra-group reviews should be "closer" to each other than the ones of inter-group reviews, and (ii) the sentiment embeddings of reviews with the same sentiment label should be "closer" to each other than the ones of reviews with different sentiment labels, even if they are in different groups.

More concretely, for the aspect embedding $\boldsymbol{a}_i$, we except to make its similarity with a "similar" sample $\boldsymbol{a}_i^+$ far greater than the one with a "dissimilar" sample $\boldsymbol{a}_i^-$, that is, $Sim(\hat{\boldsymbol{a}}_i, \hat{\boldsymbol{a}}_i{}^+) \gg$

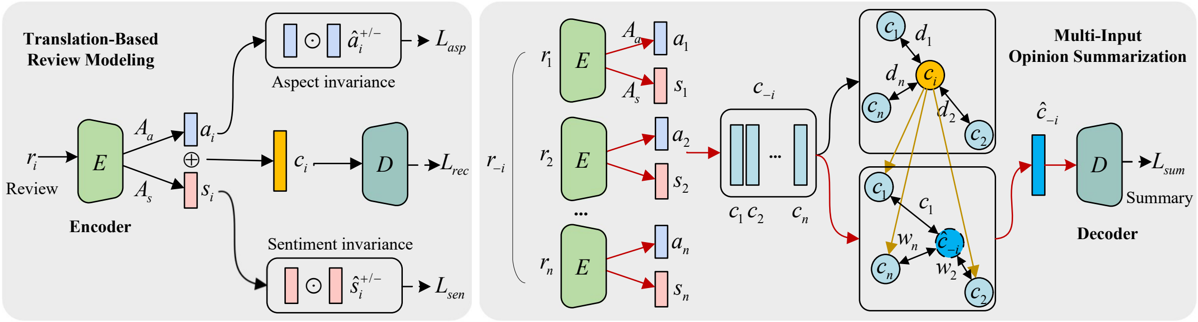

Figure 2: Architecture of TransSum, which consists of two main components: (1) a translation-based review modeling module that learns aspect and sentiment embeddings, and (2) a multi-input opinion summarization module that learns to generate summaries that are low-redundant and highly relevant to the input reviews. The encoder and decoder are shared, and the red arrows indicate the data flow in the inference phase. Best view in color.

$Sim(\hat{\boldsymbol{a}}_i, \hat{\boldsymbol{a}}_i{}^-)$. $\boldsymbol{a}_i^+$ is the aspect embedding of a review sampled from the same group, and $\boldsymbol{a}_i^-$ is the aspect embedding of a review sampled from other groups. In this work, we use the dot product between embeddings to measure similarity (i.e., Sim), which can be regarded as a measure of the angle between the two embeddings in the vector space. As a consequence, the aspect-based contrastive objective is:

$$\mathcal{L}_{asp} = -\mathbb{E}_{\boldsymbol{r}_i\sim\mathbb{D}}\Big[\log \frac{\exp(Sim(\hat{\boldsymbol{a}}_i, \hat{\boldsymbol{a}}_i{}^+))}{\exp(Sim(\hat{\boldsymbol{a}}_i, \hat{\boldsymbol{a}}_i{}^+)) + \exp(Sim(\hat{\boldsymbol{a}}_i, \hat{\boldsymbol{a}}_i{}^-))}\Big], \tag{6}$$

As for the sentiment embedding $\boldsymbol{s}_i$, the "similar" sample $\boldsymbol{s}_i^+$ is the sentiment embedding of a review sampled from different groups but with the same sentiment label, and the "dissimilar" sample $\boldsymbol{s}_i^-$ is the sentiment embedding of a review sampled from different groups and with a different sentiment label. Hence, the sentiment-based contrastive objective is defined as follows:

$$\mathcal{L}_{sen} = -\mathbb{E}_{\boldsymbol{r}_i\sim\mathbb{D}}\Big[\log \frac{\exp(Sim(\hat{\boldsymbol{s}}_i, \hat{\boldsymbol{s}}_i{}^+))}{\exp(Sim(\hat{\boldsymbol{s}}_i, \hat{\boldsymbol{s}}_i{}^+)) + \exp(Sim(\hat{\boldsymbol{s}}_i, \hat{\boldsymbol{s}}_i{}^-))}\Big]. \tag{7}$$

To the best of our knowledge, we are the first to go beyond the intra-group information modeling by further considering the inter-group level contrastive learning of aspect and sentiment embeddings.

To further enlarge the disagreements among the aspect/sentiment projection matrix and reduce the redundancy of parameters, we additionally add a regularization loss to encourage uniqueness:

$$\mathcal{L}_{reg} = ||\boldsymbol{A}_a^T \boldsymbol{A}_a - \boldsymbol{I}||^2 + ||\boldsymbol{A}_s^T \boldsymbol{A}_s - \boldsymbol{I}||^2, \tag{8}$$

where $\boldsymbol{I}$ is the identity matrix.

2.4 Multi-Input Opinion Summarization

After learning aspect and sentiment low-dimensional embeddings of reviews, we can construct reviews-summary pairs of high relevance based on the similarity of aspect embeddings, so as to train a supervised multi-input opinion summarization model (the right block in Figure 2).

Although real-world reviews in a group discuss various viewpoints covering different aspects under consideration, they are in fact focused on the same entity. In other words, they may repeat discussions about certain aspects many times, and may also include their own unique aspects. However, opinions on the same aspects are likely to be the same in real scenarios, e.g., knowing that most users complain about the high price of a product, the next price-focused review is likely to give a negative view. Based on this observation, we expect to reduce redundancy in similar aspects and use reviews with similar aspects to construct a high-quality data set whose reviews-summary data pairs are highly relevant.

High-Relevance Dataset Creation: We expect to find a subset of $\boldsymbol{r}_{-i}$ in which reviews are similar to $\boldsymbol{r}_i$ in the aspect embedding space, and use $\boldsymbol{r}_i$ as the target (pseudo) opinion summary of this subset of reviews. We have noticed that in real reviews, the majority of views on the same aspect are consistent with each other, so we believe most reviews-summary pairs created in this way can be used for training a model to capture and summarize the major opinions of the input reviews. More sophisticated ways for dataset creation will be left for further study.

In practice, we assign a weight w to each review in $\boldsymbol{r}_{-i}$, that is, assigning small values to low-relevance reviews instead of looking for a subset of only high-relevance reviews (as shown by the yellow arrows in Figure 2). For each review $\boldsymbol{r}_j$ in $\boldsymbol{r}_{-i}$, we calculate the distance between it and $\boldsymbol{r}_i$ in the aspect embedding space as:

$$d_j = Sim(\hat{\boldsymbol{a}}_j, \hat{\boldsymbol{a}}_i), d_j \in \boldsymbol{d}_{-i}, \tag{9}$$

where $\boldsymbol{d}_{-i} = \{d_1, \cdots, d_{i-1}, d_{i+1}, \cdots, d_n\}$. Then we construct the reviews-summary pair $< \boldsymbol{r}_{-i}, \boldsymbol{r}_i >$ with the following weights $\boldsymbol{w}_{-i}$, which will be used later:

$$w_j = \frac{\exp(d_j)}{\sum_{d_z \in \boldsymbol{d}_{-i}} \exp(d_z)}, w_j \in \boldsymbol{w}_{-i}. \tag{10}$$

Note that some previous arts (Brazinskas et al., 2020b; ElSahar et al., 2020; Brazinskas et al., 2020a; Amplayo et al., 2021) adopted a leave-one-out self-supervision setting (Besag, 1975) similar to ours. But they did not take into account the relevance between each review and the pseudo summary, which can be considered as our special case with a uniform distribution $\boldsymbol{w}_{-i} = (\frac{1}{n-1}, \cdots, \frac{1}{n-1})$.

Embedding-Based Redundancy Reduction: Aside from creating a high-relevance synthetic dataset, we can use the learned embeddings to reduce redundancy. We regard the embedding differences of different reviews as their natural variation, and perform a weighted pooling operation to remove redundant information (similar embeddings). Therefore, we obtain $\hat{\boldsymbol{c}}_{-i}$ based on multiple inputs $\{w_1\boldsymbol{c}_1, \cdots, w_{i-1}\boldsymbol{c}_{i-1}, w_{i+1}\boldsymbol{c}_{i+1}, \cdots, w_n\boldsymbol{c}_n\}$. Note that $\boldsymbol{w}$ is a uniform distribution in the inference phase, that is, the weight of each input review is equal.

Finally, we generate the opinion summary of $\boldsymbol{r}_{-i}$ and the summarization loss $\mathcal{L}_{sum}$ is:

$$\mathcal{L}_{sum} = \mathbb{E}_{\boldsymbol{r}_i \sim \mathbb{D}}[\ell(D(\hat{\boldsymbol{c}}_{-i}), \boldsymbol{r}_i)], \tag{11}$$

where D is the decoder shared with the previous module and we also adopt label smoothing technique (Szegedy et al., 2016) on $\boldsymbol{r}_i$.

2.5 Training

Finally, we optimize the sum of the above losses:

$$\mathcal{L}_{final} = \mathcal{L}_{rec} + \mathcal{L}_{asp} + \mathcal{L}_{sen} + \mathcal{L}_{reg} + \mathcal{L}_{sum}. \tag{12}$$

We also explore non-equal weighting of the losses but do not find a meaningful difference in outcomes. We perform beam search decoding in the inference stage.

	Train	**Dev**	**Test**
Yelp	13,369 / 97.1	100 / 8.0	100 / 8.0
Amazon	192,742 / 24.9	28 / 8.0	32 / 8.0
RT	2,458 / 83.3	536 / 98.0	737 / 100.3

Table 1: Statistics of three datasets in different domains (i.e., businesses, products and movies). The format in the cells is "Number of entities / Average number of reviews per entity".

3 Experiments

Datasets: We conduct experiments on three opinion summarization benchmarks in different domains, including: (1) **Yelp** (Chu and Liu, 2019) which contains business customer reviews from the Yelp Dataset Challenge[1]; (2) **Amazon** (Brazinskas et al., 2020b) which includes a large corpus of product reviews for four Amazon categories (i.e., Electronics, Clothing, Shoes and Jewelry, Home and Kitchen, and Health and Personal Care)[2]; (3) **Rotten Tomatoes (RT)** (Wang and Ling, 2016) which has a large set of reviews for various movies written by critics[3]. The detailed statistics of the three datasets are shown in Table 1. For Yelp and Amazon, there are no gold standard summaries for large training corpora, but the small development and test sets have summaries written by Amazon Mechanical Turk (AMT) crowd-workers. In RT, each set of reviews has a gold-standard opinion summary written by an editor, but we do not use ground truth summaries for training due to the unsupervised setting. Note that all reviews have a binary sentiment label (e.g., positive or negative). For Yelp and Amazon which have 1–5 scale ratings, we mark reviews with scores below 3 as negative and the rest as positive. The implementation details of our method are shown in supplementary materials.

Compared Methods: We compare TransSum with several state-of-the-art unsupervised summary generation methods, and some of them can be essentially considered as special cases of our method.

For extractive systems where summaries are created by selecting a subset of salient sentences from the input reviews, they include: (1) **LexRank** (Erkan and Radev, 2004), a PageRank-like algorithm which selects the review closest to the centroid of a group as the summary; (2) **W2VCent**,

---

[2] https://github.com/abrazinskas/Copycat-abstractive-opinion-summarizer

[3] https://web.eecs.umich.edu/∼wangluxy/data.html

a centroid-based multi-document summarization method that uses word embeddings (Mikolov et al., 2013) instead of TF-IDF to represent each sentence (Rossiello et al., 2017); and (3) **Multi-Lead-1** (See et al., 2017) which constructs the summary by selecting the leading sentences from each review of a group. Additionally, we also report the **upper bound** of extractive methods, i.e., the highest-scoring review in a group when computing ROUGE-L (Lin and Hovy, 2003) against reference summaries.

We also compare with six state-of-the-art abstractive models where summaries are generated from scratch, including: (1) **Opinosis** (Ganesan et al., 2010), a graph-based method that uses token-level redundancy to generate summaries; (2) **MeanSum** (Chu and Liu, 2019), an auto-encoder that generates summaries by reconstructing the mean of review encodings, which is in fact special cases of our method without contrastive transformations of aspect and sentiment embeddings and high-relevance dataset creation; (3) **OpinionDigest** (Suhara et al., 2020), a combination of an aspect-based sentiment analysis model and a phrase-to-review seq2seq model, which can be seen as using opinion phrases to model summaries rather than using the aspect and sentiment embeddings as we do; (4) **DenoiseSum** (Amplayo and Lapata, 2020), which create a synthetic dataset by treating a review and its noisy versions as the summary and pseudo-review input, instead of using the aspect similarity of real-world reviews like ours; (5) **CopyCat** (Brazinskas et al., 2020b), a hierarchical variational auto-encoder which learns a latent code of the summary and uses a leave-one-out self-supervision setting, and it can be regarded as a special case where TransSum does not consider the relevance of input reviews and the constructed summaries; and (6) **PlanSum** (Amplayo et al., 2021), which uses adversarial learning to learn the aspect and sentiment distributions of reviews, instead of the intra- and inter-group contrastive transformations we use. Note that we do not compare with methods using gold summaries, such as Brazinskas et al. (2020a).

3.1 Main Results

3.1.1 Automatic Evaluation

For automatic summary evaluation, we report the classical ROUGE (Lin and Hovy, 2003) scores on test sets. We report F-measure scores of ROUGE-1 (**R1**), ROUGE-2 (**R2**) and ROUGE-L (**RL**) in the experiments.

Table 2 contains the automatic evaluation results on three different datasets. From the results, we can see that: (1) Although extractive methods (e.g., LexRank, W2VCent and Multi-Lead-1) achieve comparable results, their upper bounds are affected by the data sets used. For example, the upper bound results of R2 and RL on Yelp are much lower than the other two, perhaps because most sentences on the Yelp dataset contain more redundant information. (2) Among abstractive models, OpinionDigest and CopyCat perform much better than Opinosis and MeanSum, showing the effectiveness of using opinion phrases or specific distributions to model opinion summaries. But our method surpasses them by a wide margin, indicating that the aspect and sentiment embeddings learned by contrastive learning are beneficial for modeling opinion summaries. (3) Impressively, we observe a large improvement brought by the creation of synthetic datasets (i.e., DenoiseSum, CopyCat and PlanSum), showing the usefulness of using reviews as pseudo-summaries. However, our method is superior to them, illustrating the importance of considering the relevance of the constructed reviews-summary pairs. (4) Overall, our model outperforms all baseline models on three datasets over all three metrics. It is also worth noting that TransSum even surpasses the upper bound of extractive methods on Yelp with an increase of 5.55, 2.3, and 2.2 points in ROUGE-1/2/L.

3.1.2 Human Evaluation

Further, we conduct a human evaluation to evaluate the quality of generated summaries more accurately.

We focus on five criteria: (1) the aspect-based informativeness indicator (**Aspect**) focuses on whether the summary covers common aspects discussed in the reviews, (2) the sentiment-based informativeness indicator (**Sentiment**) focuses on whether it agrees with their overall sentiment about different aspects. (3) the relevance indicator (**Relevance**) reflects whether the summary is relevant to the input reviews, (4) the non-redundancy indicator (**Non-Redundancy**) measures whether the summary contains unnecessary repetition, and (5) the fluency indicator (**Fluency**) shows whether the summary is well-formed and grammatical. We show the detailed questions in **supplementary materials**. We sampled 50, 32, and 50 review groups

Table 4: Ablation study of different losses. $\mathcal{L}_{sum}$ is a basic loss, so all combinations in the table include it.

from the Yelp, Amazon, and RT test sets with human-annotated summaries, respectively. Then we employ five graduate students to evaluate each tuple containing summaries from LexRank (strong extractive baseline), PlanSum (strong abstractive baseline), TransSum (Ours) and the gold-standard summaries according to the criteria. Note that the order in which the summaries are presented to the judges is random. We use Best-Worst Scaling (Louviere et al., 2015), which has been shown to produce more reliable results than ranking scales (Kiritchenko and Mohammad, 2016). Specifically, each score is computed as the percentage of times it was selected as best minus the percentage of times it was selected as worst, and ranges from -1 (unanimously worst) to +1 (unanimously best).

The results are shown in Table 3. As shown, summaries generated by TransSum have better aspect- and sentiment-based informativeness, indicating that our model can effectively capture the salient opinion information. We find that extractive summaries tend to be more general or even irrelevant (e.g. LexRank on Yelp), but our model performs very well in terms of relevance. Our method also excels baselines in non-redundancy and fluency, showing that summaries generated TransSum are low-redundant and fluent. We show examples of generated summaries of our model and comparison systems in supplementary materials.

3.2 Ablation Study

3.2.1 Loss Effectiveness Analysis

We present in Table 4 various ablation studies on the three datasets, which assess the contribution of different losses. We report the ROUGE-L score on test sets.

Compared to the only reconstruction loss (i.e., row#1), the contrastive learning of aspect and sentiment embeddings (i.e., row#2 and row#3) can bring improvements of 1.27/0.67/0.57 and 1.18/0.59/0.37 points on three datasets, respectively. From row#5 and row#4, we observe that the reconstruction and

#	Model Variants	Yelp	Amazon	RT
1	TransSum	20.31	20.49	18.35
2	w/o BERT embeddings	20.05	20.14	18.05
3	w/o label smoothing	20.08	20.21	18.12
4	w/o beam search	20.02	20.08	17.99
5	w/o summary modeling	18.51	18.82	16.72
6	w/o weighted pooling	19.83	19.95	17.88

Table 5: Ablation study of different components. “w/o” means “without”.

regularization losses are also useful for improving results. The last row shows that all our proposed losses in TransSum are helpful, especially $\mathcal{L}_{asp}$ and $\mathcal{L}_{sen}$, demonstrating the effectiveness of our model.

3.2.2 Module Effectiveness Analysis

To investigate the importance of the model’s individual components, we perform ablations by removing the initialized BERT embeddings, label smoothing, beam search, the translation-based review modeling module, and weighted pooling operation (i.e., $\boldsymbol{w}_{-i}$ is a uniform distribution).

From the results in Table 5, all components play a role, yet the most significant drop (i.e., row#5) in ROUGE-L when the translation-based review modeling module is removed, demonstrating the great effectiveness of the aspect and sentiment embeddings learned through contrastive learning. Interestingly, even without learning aspect and sentiment embeddings, using high-relevant reviews-summary pairs created by only entangled representations (i.e., row#5) can also achieve competitive results. This further shows the importance of considering the relevance between reviews and pseudo-summaries.

4 Related Work

Unsupervised Opinion Summarization aims to automatically generate summaries for a group of opinions about a specific entity (e.g., user reviews of a product), and does not require any gold summaries (Ku et al., 2006; Kim et al., 2011; Chu and Liu, 2019). Most previous works focus on extractive approaches, which select a subset of salient sentences from the inputs based on topic-words (Paul et al., 2010; Fabbrizio et al., 2014), word-frequencies (Erkan and Radev, 2004; Nenkova and Vanderwende, 2005), word embeddings (Rossiello et al., 2017) or textual graphs (Radev et al., 2004). However, due to their shortcomings of copying text from the input (Banko and Vanderwende, 2004), studies of abstractive summarization methods have increased tremendously (Ganesan et al., 2010; Perez-Beltrachini et al., 2019; Zou et al., 2020; Mukherjee et al., 2020). Most of these abstractive works model the problem of opinion summarization as a normal multi-document summarization task, using an auto-encoder framework with attention (Chu and Liu, 2019; Amplayo and Lapata, 2019; Brazinskas et al., 2020a), variational distributions (Brazinskas et al., 2020b; Angelidis et al., 2020), or abstract meaning representations (Liu et al., 2015). Few of them pay attention to the opinion information, and model the opinion summary with opinion phrases (Suhara et al., 2020) or the aspect and sentiment distributions (Amplayo et al., 2021). To the best of our knowledge, we are the first to model opinion summaries with only aspect and sentiment embeddings, which are learned through two novel contrastive objectives based on the aspect and sentiment invariances.

Our work is also related to **contrastive learning**, which a popular unsupervised learning paradigm in the field of computer vision and speech, aiming to enlarge the embedding disagreements of different instances for representation learning (van den Oord et al., 2018; Ye et al., 2019; He et al., 2020). Although there have been studies using contrastive learning for summary evaluation (Wu et al., 2020), to our best knowledge, we are the first to use the contrastive transformation on natural textual samples to directly help summary generation, and open the door to research on modeling opinion summaries with aspect and sentiment embeddings.

5 Conclusion

In this paper, we propose a novel self-supervised framework TransSum, to generate opinion summaries with only the aspect and sentiment embeddings, which are beneficial for maximizing informativeness, reducing redundancy of repeated opinions in reviews, and creating synthetic datasets of highly relevant reviews-summary pairs for training. Extensive evaluation and ablation studies show our model outperforms competitive systems in generating informative, high-relevant, low-redundant and fluent summaries. We believe that the viewpoint from modeling opinion summaries with only aspect and sentiment embeddings proposed in this study may pave a new way to design more complex and controllable systems for unsupervised opinion summarization.

A Implementation Details

We implement our method on top of the Transformer-base (Vaswani et al., 2017) implemented in Fairseq (Ott et al., 2019). The token embeddings of BERT-base (Devlin et al., 2019) used for initialization are provided by Transformers (Wolf et al., 2020). The dimension k is 768 and the number of the attention heads is 4. Both the encoder and decoder have 6 layers, and the maximum sequence length l is set to 200. The beam size of the beam search is set to 5. We set the dropout rate to 0.1 and Adam (Kingma and Ba, 2015) with learning rate to 1e-5, $\beta_1 = 0.9$ and $\beta_2 = 0.999$. We implement our model based on PyTorch and use four TITAN X graphic cards for learning.

B Human Evaluation Questions

- **Aspect-based informativeness**: The summary sentences should cover common aspects discussed in the group of reviews.
- **Sentiment-based informativeness**: The summary sentences should agree with the overall sentiment about different aspects in the group of reviews.
- **Relevance**: The summary sentences should relevant to the input reviews.
- **Non-Redundancy**: The summary sentences should not contains unnecessary repetition.
- **Fluency**: The summary sentences should be grammatically correct, easy to read and understand.

Input Reviews
1. The best reason to see The Haunting is the sheer sumptuousness of its creepy-crawly set designs.
2. Has an unseen enchantment, so aptly sets spinning like a huge magnificent gyroscope on a string
3. In The Haunting, the moviemakers succeed in something very difficult: creating a haunted house with real personality and terror.
4. All the stops are pulled out to provide a state-of-the-art, slam-bang movie experience.
5. Looking terrified and screaming is really all that's required in David Self's inane script.
6. Director Jan de Bont, known for the razzle he put into the exciting movie Speed and the subsequent dud Twister, proves himself unable to break away from depending on dazzle to substitute for substance.
7. To my surprise, I find myself recommending The Haunting on the basis of its locations, its sets, its art direction, its sound design, and the overall splendor of its visuals.
8. It's all hokum from beginning to end.
9. A flat, draggy exercise in cheesy special effects and grandiose art direction palming itself off as a horror film.
10. More hokey than haunting.
11. When The Haunting finally limps to its conclusion, you may feel like booing the screen.
12. This all-flash, no-substance–and no scare–thriller is a textbook example of soulless, money-burning Hollywood hype products.
13. One of the most misguided big-screen diversions to come along in some time, considering the clear potential it has.
14. so thoroughly misguided and muddled Dreamworks, the studio foisting this bomb on the public, ought to hire a special corps of ushers to hand out sympathy cards to patrons as they exit the theater.
15. This is as far from the Poverty Row gasps of The Blair Witch Project as you can get, and more fun.
16. I wouldn't waste more than the price of a video rental on this one.
17. High-tech remake is dumb and overblown.
18. All logic is deadened by the obnoxious special effects!
19. Once the screaming begins, so will your laughing
20. Glossy but lackluster.
21. It's just a conglomeration of cheap fright tactics and a booming bass track meant to get you to jump out of your seat.
22. An exercise in missed opportunities and bad filmmaking!
23. The Haunting is a muddled mess that defies any rationality.
24. The only thing scary about the new version is realizing that someone keeps giving director Jan De Bont money to make movies.
25. The characters are on the dramatic equivalent of Death Row.
......

Gold	sophisticated visual effects fail to offset awkward performances and an uneven script .
LexRank	the characters are on the dramatic equivalent of death row .
PlanSum	the haunting is a very good movie, but it's a lot of fun, and the filmmakers have been raised by the original.
Ours	unfortunately , this is one haunting with the obnoxious special effects that are bloated and wretchedly overdone !

Abstract

Image-text matching has been a popular research topic which bridges vision and language through semantic understanding. Recent works mainly focus on exploring the interactions between images and sentences to improve the performance without considering inference efficiency. Specifically, for the large scale databases, it is unacceptable to perform such time-consuming mechanisms between a query (text/image) and each candidate datapoint (image/text) in the whole retrieval set during inference. To tackle this problem, we propose a novel hashing based efficient inference module called HEI, which can be plugged into the existing framework to speed up the inference step without reducing the retrieval performance. In details, HEI learns to map the original datapoints into short binary hash codes and coarsely preserve the heterologous matching relationship. Thus, in the inference phase, the proposed HEI module uses the hash codes to quickly select a few candidate datapoints from the retrieval set for a given query. Then, the image-text matching model fine ranks the candidate set to find the matching datapoint. Extensive experiments on two widely used benchmark MS-COCO and Flickr30k with four baseline methods demonstrate the efficiency and effectiveness of our proposed HEI module.

1 Introduction

Language and vision understanding plays a fundamental role for human to understand the real world. A large amount of works has been proposed to bridge these two modalities. Image-text matching is one of the fundamental topics in this field, which benefits a series of downstream applications, such as visual captioning(Zhang et al., 2019; Wang et al., 2018) and visual grounding (Chen et al., 2018; Plummer et al., 2017). Specifically, given an image (text), its target is to match the closest textual description (image) for the image (text).

Early works (Karpathy and Fei-Fei, 2015; Wang et al., 2016; Niu et al., 2017; Faghri et al., 2017) achieve this goal by learning two modality-specific deep neural networks to directly map all the datapoints from the two modality into a common joint space without using attention mechanism, and then measures their similarities by feature distances in the joint space. Compared with these methods, recent works (Lee et al., 2018; Liu et al., 2019; Wang et al., 2019; Chen et al., 2020) mainly focus on incorporating variant attention mechanisms into the image-text matching models to explore the fine-grained interactions between vision and language. By using the attention mechanisms, the image-text matching models are able to filter out irrelevant information, and find the fine-grained cues to achieve a great matching performance. For example, CAMP (Wang et al., 2019) takes comprehensive and fine-grained cross-modal interactions into account, and also properly handles negative pairs and irrelevant information with an adaptive gating scheme to improve the matching performance.

Although existing attention mechanism based methods achieve great performance, they do not take the inference efficiency into account. Specifically, for the large scale databases, due to the attention mechanisms being time-consuming, it is unacceptable to perform such complex attention mechanisms between the query (text/image) and each candidate datapoint (image/text) in the whole retrieval set during inference. Thus, it is critical to improve the inference speed of these methods.

Intuitively, if a small candidate set containing positive datapoints can be quickly selected out, the image-text matching models can greatly speed up through only fine ranking such a small candidate set instead of the whole retrieval set. Then the key

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 743–752
August 1–6, 2021.

challenge is how to quickly select such a small candidate set. Hashing is widely used in the field of data search with fast retrieval speed. Besides, although it can hardly perform the accurate matching, hashing is capable of quickly selecting a high quality candidate set containing the positive datapoints.

Hence, in this paper, we propose a novel hashing based efficient inference module, called HEI, which can be plugged into the existing attention mechanism based image-text matching framework to speed up the inference step without reducing the retrieval performance. Specifically, a matching score based hashing loss is proposed, which consists of two items: one is used to make Hamming similarity between hash codes of matching datapair be as large as possible; the other item is to make the Hamming similarity between hash codes of mismatching datapair no larger than their corresponding matching score. By minimizing the proposed hashing loss, the HEI module is optimized to map the original datapoints into short binary hash codes and coarsely preserve the heterologous matching relationship between datapoints. Thus, the trained HEI module can be used to speed up the inference step without reducing the retrieval performance. Extensive experiments on two widely used benchmark MS-COCO and Flickr30k with four baselines demonstrate the effectiveness of our proposed HEI module.

2 Related Work

2.1 Text-image Matching

Recently, many image-text matching methods have been proposed, which can be roughly grouped into one-to-one matching methods learning correspondence between the whole image and text, and many-to-many matching methods learning correspondence between the regions of image and the words of text.

The one-to-one matching methods (Wang et al., 2016; Kiros et al., 2014; Zhang and Lu, 2018; Zheng et al., 2020) mainly aim to explore the heterologous relationship globally by mapping the whole images and the full texts into a common feature space. However, owing to these methods doing not explore the correspondence between image regions and text words, it might lead to learn sub-optimal features, which will damage the text-image matching performance.

By utilizing variant cross-modal attention mechanisms, many-to-many matching methods can explore the correspondence between image regions and text words, thus, these attention mechanism based methods can achieve the state-of-the-art performance. For instance, BFAN (Liu et al., 2019) is proposed to eliminate partial irrelevant words and regions from the shared semantic in image-text pairs to achieves state-of-the-art performance on several benchmark datasets. IMRAM (Chen et al., 2020) proposes a recurrent attention memory which incorporates a cross-modal attention unit and a memory distillation unit to refine the correspondence between image regions and text words. However, those attention mechanisms used by the many-to-many matching methods are usually complicated with high computation complexity. Hence, it is unacceptable to perform such time-consuming attention mechanisms between the query (text/image) and each candidate datapoint (corresponding to image/text) in the whole retrieval set during inference especially for the large scale databases.

Different from previous methods, our model explores hashing technology to improve the inference speed of the existing many-to-many text-image matching methods without reducing their performance.

2.2 Cross-Modal Hashing

The core of cross-modal hashing is to project the datapoints of different modalities into compact binary hash codes, meanwhile, preserve the semantic similarity of original datapoints. Then, in the cross-modal retrieval phase, the datapoints of the retrieval set can be sorted by the Hamming distance between their corresponding binary hash codes calculated by the ‘XOR’ operation, which has fast retrieval speed. Due to this advantage, a mount of cross-modal hashing methods have been proposed (Hu et al., 2020; Su et al., 2019; Lin et al., 2020; Tu et al., 2020; Shi et al., 2019). For example, SDCH (Lin et al., 2020) utilizes a semantic label branches to preserve semantic information of the learned features by integrating with inter-modal pairwise loss, cross-entropy loss and quantization loss.

However, due to these hashing methods belonging to approximate nearest neighbour (ANN) searching technology, they can hardly to accurately find the matching datapoint for a query. Hence, few works explore the hashing technology for text-image matching. To our best knowledge, this is the first work to explore the use of hashing to improve the inference speed of existing attention mecha-

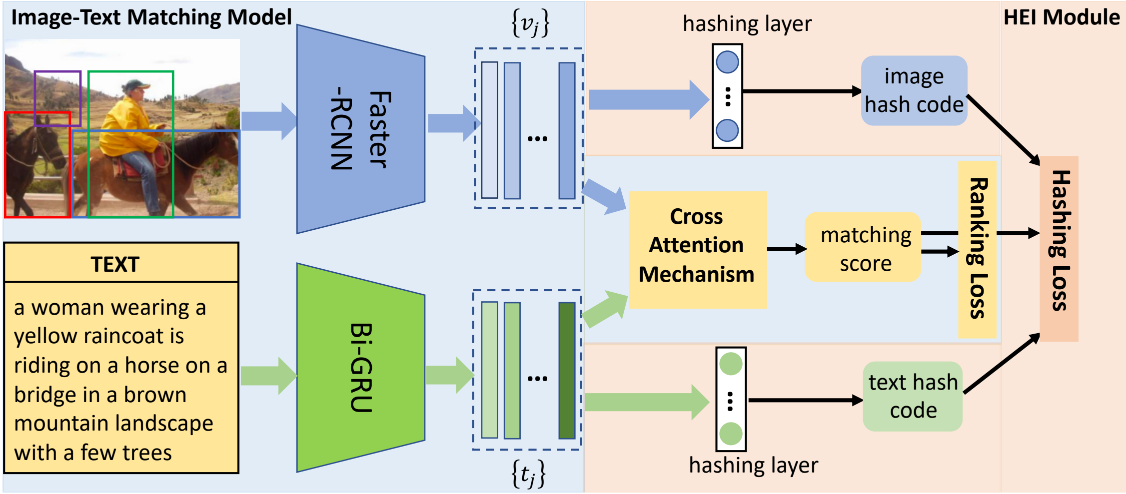

Figure 1: The architecture of image-text method with the HEI module.

nism based image-text matching methods.

3 Methodology

As shown in Figure 1, different from the architecture of existing matching models, our framework introduces an extra hashing based efficient inference module, called HEI, which consists of an image modal hashing layer and a text modal hashing layer, and each hashing layer is a fully-connected layer with k units where k is the hash codes length.

3.1 Problem formulation and notations

Without loss of generality, suppose there are datasets with M images $\boldsymbol{X} = \{\boldsymbol{x}_i\}_{i=1}^{M}$ and N texts $\boldsymbol{Y} = \{\boldsymbol{y}_i\}_{i=1}^{N}$. Given an image $\boldsymbol{x}_i$ with its region-level visual features denoted as $\boldsymbol{V}_i = [\boldsymbol{v}_1^i, \cdots, \boldsymbol{v}_m^i]$, and a text $\boldsymbol{y}_j$ with its word-level textual features denoted as $\boldsymbol{T}_j = [\boldsymbol{t}_1^j, \cdots, \boldsymbol{t}_n^j]$, the goal of image-text matching is to calculate a matching score $\boldsymbol{s}_{ij}$ for the image $\boldsymbol{x}_i$ and the text $\boldsymbol{y}_j$ based on their features $\boldsymbol{V}_i$ and $\boldsymbol{T}_j$. Moreover, if the image $\boldsymbol{x}_i$ and the text $\boldsymbol{y}_j$ are matching, the matching score $\boldsymbol{s}_{ij}$ should be large, otherwise $\boldsymbol{s}_{ij}$ should be small.

Furthermore, the goal of hashing based efficient inference module is to learn the two modality-specific hashing layer which can map their corresponding modal datapoints into binary hash codes with the heterologous matching relationship preserved.

3.2 Cross-modal Feature Representation

3.2.1 Image region-level visual features

To obtain the region-level visual features $\boldsymbol{V}_i = [\boldsymbol{v}_1^i, \cdots, \boldsymbol{v}_m^i]$ of the image $\boldsymbol{x}_i$, we first employ the Faster R-CNN (Ren et al., 2016) model using ResNet-101 (He et al., 2016) as the backbone, which is pre-trained on the Visual Genomes dataset (Krishna et al., 2017) by (Anderson et al., 2018), to extract the top m region proposals of the image. Then, by average-pooling the spatial feature map, a feature vector $\boldsymbol{v}_j^{i\prime} \in \mathcal{R}^{2048}$ for the j^{th} region proposal is calculated. Finally, We obtain the d-dimentional region features with a linear projection layer:

$$\boldsymbol{v}_j^i = \boldsymbol{W}_v \boldsymbol{v}_j^{i\prime} + \boldsymbol{b}_v \tag{1}$$

where $\boldsymbol{W}_v$ and $\boldsymbol{b}_v$ are to-be-learned parameters, and $\boldsymbol{v}_j^i$ is the visual feature for the j^{th} region of image $\boldsymbol{x}_i$.

3.2.2 Text word-level textual features

To obtain the textual features of a input text $\boldsymbol{y}_j$ with n words, we first embed each word $\boldsymbol{w}_i$ of the input text $\boldsymbol{y}_j$ into a 300-dimensional vector $\boldsymbol{t}_i^{j\prime}$. Then, to enhance the word-level feature with sufficient context information, we use a single-layer bi-directional GRU (Cho et al., 2014) with d-dimensional hidden to summarize information from both forward and backward directions of the input text $\boldsymbol{y}_j$:

$$\begin{aligned} \overrightarrow{\boldsymbol{h}_i^j} &= \overrightarrow{GRU}(\overrightarrow{\boldsymbol{h}_{i-1}^j}, \boldsymbol{t}_i^{j\prime}), \\ \overleftarrow{\boldsymbol{h}_i^j} &= \overleftarrow{GRU}(\overleftarrow{\boldsymbol{h}_{i-1}^j}, \boldsymbol{t}_i^{j\prime}). \end{aligned} \tag{2}$$

where $\overrightarrow{\boldsymbol{h}_i^j}$ and $\overleftarrow{\boldsymbol{h}_i^j}$ denote hidden states from the forward GRU and the backward GRU, respectively. Then, the textual feature of the word $\boldsymbol{w}_i^j$ in the text $\boldsymbol{y}_j$ is defined as:

$$\boldsymbol{t}_i^j = \frac{\overrightarrow{\boldsymbol{h}_i^j} + \overleftarrow{\boldsymbol{h}_i^j}}{2} \tag{3}$$

3.3 General Attention Framework

Existing attention mechanism based image-text matching methods mainly learn to associate shared semantics between the region-level feature $\boldsymbol{V}_i$ of image $\boldsymbol{x}_i$ and word-level feature $\boldsymbol{T}_j$ of text $\boldsymbol{y}_j$ through variant cross-attention mechanisms to calculate the matching score $\boldsymbol{s}_{ij}$, which can be formulated as follows:

$$\boldsymbol{s}_{ij} = CAM(\boldsymbol{V}_i, \boldsymbol{T}_j; \boldsymbol{W}) \tag{4}$$

where $CAM(\cdot; \boldsymbol{W})$ denotes the cross-modal attention mechanism and $\boldsymbol{W}$ is the set of learnable parameters. For example, in BFAN (Liu et al., 2019), $CAM(\cdot; \boldsymbol{W})$ denotes the Focal attention mechanism proposed in the original paper.

Then to maximize matching scores of the matching image-text pairs and minimize the ones of the mismatching datapairs, a hinge-based triplet ranking loss with emphasis on the hard negatives are used as the loss function. Specifically, given a pair of matching image-text $\boldsymbol{x}_i$ and $\boldsymbol{y}_j$, we denote their matching score as $\boldsymbol{s}_{ij}$; $\bar{j} = argmax_{t \neq j} \boldsymbol{s}_{it}$ denotes the hard negative when using the image to match text; $\bar{i} = argmax_{t \neq i} \boldsymbol{s}_{tj}$ denotes the hard negative when using the text to match image, then the ranking loss is formulated as:

$$\mathcal{L}_{rank} = [\alpha - \boldsymbol{s}_{ij} + \boldsymbol{s}_{i\bar{j}}]_+ + [\alpha - \boldsymbol{s}_{ij} + \boldsymbol{s}_{\bar{i}j}]_+ \tag{5}$$

where α is the margin for the ranking loss, and $[a]_+ = max(0, a)$.

Finally, after optimizing the matching model, given a query datapoint, it will be used to calculated the matching score with each datapoint in the retrieval set to find the most matching one by the cross-attention mechanism. However, the cross-attention mechanism is time-consuming which means it unacceptable to calculate a matching score between the query and each point in retrieval set with the attention mechanism during inference. Thus, we propose a hashing based efficient inference module to improve the inference speed.

3.4 Hashing based Efficient Inference module

Specifically, the input of the HEI module is the fragment-level feature of datapoint, i.e., the region-level feature $\boldsymbol{V}_i$ for an image modal input $\boldsymbol{x}_i$ or the word-level feature $\boldsymbol{T}_j$ for a text modal input $\boldsymbol{y}_j$. We further aggregate the fragment-level feature $\boldsymbol{V}_i$ ($\boldsymbol{T}_i$) into an instance-level feature $\hat{\boldsymbol{v}}_i$ ($\hat{\boldsymbol{t}}_i$) for an image (text) datapoint $\boldsymbol{x}_i$ ($\boldsymbol{y}_i$):

$$\hat{\boldsymbol{v}}_i = \sum_{j=1}^{m} a_j \boldsymbol{v}_j^i; \quad a_j = \frac{\boldsymbol{v}_j^{iT} \boldsymbol{w}_v}{\sum_{k=1}^{m} \boldsymbol{v}_k^{iT} \boldsymbol{w}_v}. \tag{6}$$

$$\hat{\boldsymbol{t}}_i = \sum_{j=1}^{n} q_j \boldsymbol{t}_j^i; \quad q_j = \frac{\boldsymbol{t}_j^{iT} \boldsymbol{w}_t}{\sum_{k=1}^{n} \boldsymbol{t}_k^{iT} \boldsymbol{w}_t}. \tag{7}$$

where $\boldsymbol{w}_t$ and $\boldsymbol{w}_v$ denote learnable parameter. Then by forwarding the instance-level feature $\hat{\boldsymbol{v}}_i$ ($\hat{\boldsymbol{t}}_i$) into the image (text) modal hashing layer, the hash codes $\boldsymbol{b}_i^v$ ($\boldsymbol{b}_i^t$) of image $\boldsymbol{x}_i$ (text $\boldsymbol{y}_i$) can be generate as:

$$\begin{aligned} \boldsymbol{b}_i^v &= sgn(\mathcal{H}_x(\hat{\boldsymbol{v}}_i; \boldsymbol{\Theta}_v)) \in \{-1, 1\}^k \\ \boldsymbol{b}_i^t &= sgn(\mathcal{H}_y(\hat{\boldsymbol{t}}_i; \boldsymbol{\Theta}_t)) \in \{-1, 1\}^k \end{aligned} \tag{8}$$

where $\mathcal{H}_x(\hat{\boldsymbol{v}}_i; \boldsymbol{\Theta}_v)$ denotes the image modal hashing layer and $\boldsymbol{\Theta}_v$ denotes the set of parameters in the image hashing layer; k is the length of hash codes; $\mathcal{H}_y(\hat{\boldsymbol{t}}_i; \boldsymbol{\Theta}_t)$ represents the text modal hashing layer and $\boldsymbol{\Theta}_t$ represents the set of parameters in the text hashing layer; $sgn(\cdot)$ is an element-wise sign function, which returns 1 if the element is positive and returns -1 otherwise.

Furthermore, the core of hashing based efficient inference module is to learn two modality-specific hashing layer to map the datapoints into binary hash codes which are used to select a few candidate datapoints from the retrieval set for an query. To achieve this goal, the learned hash codes should coarsely preserve the heterologous matching relationship between datapoints, i.e., if two datapoints are matching, then the Hamming distance between their corresponding binary hash codes should be small, otherwise it should be large.

Considering that the Hamming distance between $\boldsymbol{b}_i^v$ and $\boldsymbol{b}_j^t$ can be difined as: $D_H(\boldsymbol{b}_i^v, \boldsymbol{b}_j^t) = 0.5(k - \boldsymbol{b}_i^{vT} \boldsymbol{b}_j^t)$, where k denotes the code length. It means when $\frac{1}{k} \boldsymbol{b}_i^{vT} \boldsymbol{b}_j^t$ is close to 1, the Hamming distance $D_H(\boldsymbol{b}_i^v, \boldsymbol{b}_j^t)$ is close to 0; and when $\frac{1}{k} \boldsymbol{b}_i^{vT} \boldsymbol{b}_j^t$ is close to -1, the Hamming distance $D_H(\boldsymbol{b}_i^v, \boldsymbol{b}_j^t)$

is close to k. Thus, $\frac{1}{k}\boldsymbol{b}_i^{vT}\boldsymbol{b}_j^t$ can be used to denote the Hamming similarity between $\boldsymbol{b}_i^v$ and $\boldsymbol{b}_j^t$, and measure the heterologous matching relationship preserved by $\boldsymbol{b}_i^v$ and $\boldsymbol{b}_j^t$. Furthermore, as the mathching score $\boldsymbol{s}_{ij} \in [0, 1]$ of image $\boldsymbol{x}_i$ and text $\boldsymbol{y}_j$ computed by the cross-attention mechanism may preserve the heterologous matching relationship to a certain extent, then we can use it as soft target to supervise the learning of similarity between hash codes of mismatching data pairs. Owing to $\frac{1}{k}\boldsymbol{b}_i^{vT}\boldsymbol{b}_j^t \in [-1, 1]$, we re-scale $\boldsymbol{s}_{ij}$ as $\hat{\boldsymbol{s}}_{ij} = 2\boldsymbol{s}_{ij} - 1 \in [-1, 1]$.

Thus, based on these observations, we proposed a matching score based hashing loss:

$$\begin{aligned}\mathcal{L}_1 = &\frac{1}{|N_i^+|}\sum_{j\in N_i^+}(\frac{1}{k}\boldsymbol{b}_i^{vT}\boldsymbol{b}_j^t - 1)^2 \\ &+ \frac{1}{\sum\limits_{j\in N_i^-}\boldsymbol{I}_{ij}}\sum_{j\in N_i^-}\boldsymbol{I}_{ij}(\frac{1}{k}\boldsymbol{b}_i^{vT}\boldsymbol{b}_j^t - \hat{\boldsymbol{s}}_{ij})^2\end{aligned} \tag{9}$$

$$\boldsymbol{I}_{ij} = \begin{cases} 1, & \frac{1}{k}\boldsymbol{b}_i^{vT}\boldsymbol{b}_j^t > \hat{\boldsymbol{s}}_{ij}, \\ 0, & otherwise. \end{cases} \tag{10}$$

where N_i^+ denotes the set of text datapoints which are matching with the image $\boldsymbol{x}_i$, and N_i^- denotes the set of text datapoints which are not matching with the image $\boldsymbol{x}_i$; $\boldsymbol{s}_{ij}$ denotes the matching score between the image $\boldsymbol{x}_i$ and text $\boldsymbol{y}_j$;

It can be found that the first item of $\mathcal{L}_1$ is to make $\frac{1}{k}\boldsymbol{b}_i^{vT}\boldsymbol{b}_j^t$ be close to 1, i.e., make the Hamming distance between the hash codes of matching datapair be small. The second item of $\mathcal{L}_1$ is constructed to penalize the mismatching datapair that the Hamming similarity between their hash codes is larger than their matching score s_{ij}, i.e., the goal of $\mathcal{L}_1$ is to make the Hamming distance between their hash codes be large. Thus, by minimizing the hashing loss $\mathcal{L}_1$, the learned binary hash codes can coarsely preserve the heterologous matching relationship.

Furthermore, as the $sgn(\cdot)$ function is indifferentiable at zero and the derivation of it will be zeros for a non-zero input, the parameters of hashing model will not be updated with the backpropagation algorithm when minimizing the hashing loss function $\mathcal{L}_1$. Thus, we directly discard the $sgn(\cdot)$ function to ensure the parameters of our hashing model can be updated, and use $\tanh(\cdot)$ to approximate the $sgn(\cdot)$ function to make each element of output of hashing layer can be close to "+1" or "-1". Then the final hashing loss function can be formulated as follows:

$$\begin{aligned}\mathcal{L}_h = &\frac{1}{|N_i^+|}\sum_{j\in N_i^+}(\frac{1}{k}\hat{\boldsymbol{b}}_i^{vT}\hat{\boldsymbol{b}}_j^t - 1)^2 \\ &+ \frac{1}{\sum\limits_{j\in N_i^-}\boldsymbol{I}_{ij}}\sum_{j\in N_i^-}\boldsymbol{I}_{ij}(\frac{1}{k}\hat{\boldsymbol{b}}_i^{vT}\hat{\boldsymbol{b}}_j^t - \hat{\boldsymbol{s}}_{ij})^2.\end{aligned} \tag{11}$$

where $\hat{\boldsymbol{b}}_i^v = tanh(\mathcal{H}_x(\hat{\boldsymbol{v}}_i; \boldsymbol{\Theta}_v))$ and $\hat{\boldsymbol{b}}_j^t = tanh(\mathcal{H}_y(\hat{\boldsymbol{t}}_j; \boldsymbol{\Theta}_t))$

3.5 Inference

After training the image-text matching model and HEI module well, we can generate the hash codes $\{\boldsymbol{b_i^v}\}_{i=1}^N$ ($\{\boldsymbol{b_i^t}\}_{i=1}^M$) for all the images $\{\boldsymbol{x_i}\}_{i=1}^M$ (text $\{\boldsymbol{y_i}\}_{i=1}^N$) in the retrieval set using the HEI module. When given a query image $\boldsymbol{x}_q$ (text $\boldsymbol{y}_q$), we also use HEI module map it into a hash code $\boldsymbol{b_q^v}$ ($\boldsymbol{b_q^t}$), and calculate the Hamming distances between $\boldsymbol{b_q^v}$ ($\boldsymbol{b_q^t}$) and each code in $\{\boldsymbol{b_i^t}\}_{i=1}^M$ ($\{\boldsymbol{b_i^v}\}_{i=1}^N$). Then, we sort the texts (images) in the retrieval set in ascending order according to the Hamming distances, and select a few of the top texts (images) as the candidate set. Finally, we only need to do the fine-grained matching in the candidate set to find the matching datapoints.

4 Experiments

4.1 Datasets

We evaluate the performance of the proposed HEI module on two public used datasets: **Flickr30K** (Plummer et al., 2015) and **MS-COCO** (Lin et al., 2014). Specifically, Flickr30k contains 31783 images collected from the Flickr website. Each image is accompanied with five human annotated sentences descriptions. Following the setting of previous works (Wang et al., 2019; Liu et al., 2020), this dataset is split into 29,000 images, 1,000 images, and 1,000 images for training set, validation set, and testing set respectively. We report the performance evaluation of image-text retrieval on 1000 testing set. MS-COCO is another large-scale image-caption benchmark which consists of about 123,287 images with each image also roughly annotated with five sentence descriptions. Following the widely used split (Karpathy et al., 2014; Chen et al., 2020), we use 113,287 images for training, 1000 images for validation and 5000 images for testing. Moreover, we evaluate our method on both the 5 folds of 1K test images and the full 5K test images for MS-COCO.

Table 2: Comparison in terms of R@N scores and time cost of two retrieval tasks on MS-COCO 1K

4.2 Evaluation

Following the setting in (Chen et al., 2020; Liu et al., 2020), we evaluate the performance of our proposed approach by reporting Recall@K (K = 1, 5, 10) values for bi-directional matching tasks, i.e. matching texts given an image query (Text Retrieval) and matching images given a text query (Image Retrieval). The Recall computes the proportion of correct image or text being retrieved among top K results. In addition, we also record the inference time in seconds to evaluate the efficiency of our proposed HEI.

4.3 Baselines

To evaluate the performance of our proposed HEI, some state-of-the-art attention mechanism based image-text matching methods are selected as our baselines, including BFAN (Liu et al., 2019), CAMP (Wang et al., 2019), IMRAN (Chen et al., 2020) and GSMN (Liu et al., 2020). It should be noted that the proposed HEI focuses on exploring a novel and efficient hashing based efficient inference module that can be universally plugged into existing attention mechanism based image-text methods to speed up the inference speed rather than redesigning a new cross-modal attention mechanism to improve their matching performance.

4.4 Implementation Details

All our experiments are implemented in PyTorch and conducted on a NVIDIA Tesla V100 GPU. For representing visual modality, the amount of regions in each image is $m = 36$, and the dimensionality

Table 3: Comparison in terms of R@N scores and time cost of two retrieval tasks on MS-COCO 5K

of the final region representation vectors is set as 1024. Moreover, the dimensionality of hidden state (i.e., $\overrightarrow{\boldsymbol{h}_i^j}$ and $\overleftarrow{\boldsymbol{h}_i^j}$ in Formula (2)) in the GRU is also set as 1024. The length of hash codes is set as 64. In the training phase, we first train the base cross-modal attention module for 20 epochs, then train the HEI module jointly. We adopt SGD with a mini-batch size of 128 and a learning rate within 10^{-2} to 10^{-3} to optimize the HEI modul. The optimization algorithm for the base cross-modal attention module is the same with the ones defined in the original method, for example, when plugging HEI module into GSMN, the optimization algorithm for cross-modal attention module is Adam.

4.5 Main results

We conduct extensive experiments on Flickr30K and MS-COCO. The image-text matching results on Flickr30K, MS-COCO dataset with 1K test points and 5K test points are shown in Table 1, 2 and 3, respectively. ”method”-HEI denotes the method using the proposed HEI module, for example, BFAN-HEI means plugging HEI into BFAN to speed up the inference speed. Similarly, ”method”-random denotes randomly selecting 50% datapoints from retrieval set as the candidate set to speed up the inference speed of the method.

Based on the results shown in these tables, the following observations can be got: (1) our proposed HEI module can greatly improve the matching efficiency of all the four baselines almost without reducing the matching performance, and even slightly improve the performance of some baselines. For example, as shown in Table 1, comparing GSMN-HEI with GSMN, GSMN-HEI achieves an increase of 0.1% on the R@1 metric in the text retrieval task, and greatly reduces the inference time from 518.32 seconds to 99.30 seconds. The reason why plugging the HEI module can slightly improve the performance maybe that for some query, there are some false positive datapoints which can misguide the image-text model, but the Hamming distance between the hash codes of queries and the ones of false positive datapoints are large, i.e., the false positive datapoints will not be selected as the candidate points. Thus, without the effect of the false positive datapoints, the image-text model can find the matching points successfully and improve the retrieval performance. (2) The proposed HEI module can map datapoints into hash codes with the original heterologous matching relationship coarsely preserved. For instance, as shown in Table 1, 2 and 3, all the methods with the proposed HEI module achieve not only better performance than the methods with the randomly selected candidate, but also lower inference time. It means that the number of datapoints in the candidate set selected by our proposed HEI module is smaller but the possibility of the candidate set containing the matching datapoint is higher.

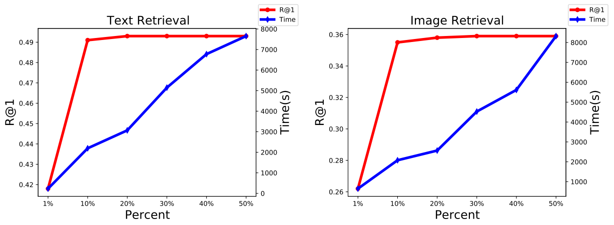
4.6 Discussion

4.6.1 Ablation study

To further investigate the impact of the length of hash codes, we construct there variants of HEI module with code length being 16, 32, and 128 bits with two baselines on Flickr30K, respectively. The re-

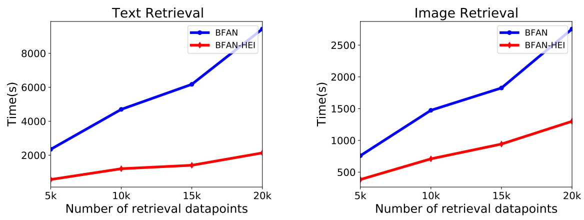
Method	Text Retrieval				Image Retrieval			
	R@1	R@5	R@10	Time(s)	R@1	R@2	R@10	Time(s)
BFAN-HEI$_{16bits}$	0.687	0.903	0.958	20.85	0.485	0.742	0.810	11.02
BFAN-HEI$_{32bits}$	0.685	0.907	0.957	21.03	0.498	0.765	0.838	11.17
BFAN-HEI$_{128bits}$	0.690	0.913	0.961	21.46	0.500	0.771	0.846	11.55
BFAN-HEI	0.692	0.912	0.962	21.31	0.499	0.772	0.846	11.38
GSMN-HEI$_{16bits}$	0.719	0.911	0.956	99.13	0.506	0.756	0.821	50.84
GSMN-HEI$_{32bits}$	0.731	0.916	0.966	99.22	0.519	0.779	0.847	50.92
GSMN-HEI$_{128bits}$	0.734	0.919	0.965	99.51	0.520	0.788	0.855	51.23
GSMN-HEI	0.734	0.919	0.967	99.31	0.524	0.790	0.860	51.02

Table 4: Comparison in terms of R@N scores and time cost of two retrieval tasks on Flickr30K



(a) (b)

Figure 2: The Figure 2(a) and (b) denotes the results of BFAN-HEI on MS-COCO(5k) in text retrieval task and image retrieval task, respectively. Moreover, in each figure, the axis X denotes selecting how much percentage of points in the retrieval set as candidate set, and the axis Y for the red line is in the left which is the value of R@1, and the axis Y for the blue line is in the right which denotes the inference time taken for the transaction in seconds.



(a) (b)

Figure 3: Compare the inference time of BFAN and the one of BFAN-HEI in large retrieval set under the condition that BFAN-HEI achieves the same performance of BDAN

sults are shown in Table 4. From these results, it can be found: (1) The length of hash codes rarely influence the inference time that each baseline with a different hash code length of HEI consumes nearly the same inference time. This is because that the speed of the "XOR" operation between hash codes is far faster than the ones of the cross-modal attention mechanism. Thus, it implicitly demonstrates the availability of speeding up the inference speed of baselines by using the proposed HEI to fast select the candidate set. (2) The matching performance first increases as the hash code length varies from 16 to 64, and then tend to be stable when the length varies from 64 to 128. Thus, for the other experiments, the hash code length is set as 64.

4.6.2 Efficiency and performance

We also conduct experiments to further investigate the trade-off between inference efficiency and matching performance.

As the results shown in Figure 2, with the size of candidate increasing, the matching performance of BFAN-HEI (the red lines) increase rapidly and then tend to stable, and BFAN-HEI consumes more inference time (the blue lines). It can be found that when selecting only 20% of datapoints in the retrieval set as the candidate set by the proposed HEI module, BFAN-HEI can already achieve the best performance, and greatly reduce the inference time. Thus, it demonstrates the effectiveness of our proposed HEI module.

4.6.3 Scalability for the large retrieval set

To further investigate the scalability of the proposed HEI module for the large retrieval set, when doing experiments on the MS-COCO (1K) with the BFAN baseline, we directly use training data to expand the data volume of the retrieval set. The curves of inference time w.r.t. the volume of retrieval set are shown in Figure 3. It can be found that with volume of the retrieval set increasing, our proposed HEI module can still be used to speed up the inference speed without reducing the matching performance, which demonstrates the scalability of our proposed HEI module for large retrieval sets.

5 Conclusion

In this paper, we have proposed a novel Hashing based Efficient module, called HEI, which can be plugged into the existing image-text matching methods to speed up the inference step without reducing the matching performance. Extensive experiments on two widely used benchmark MS-COCO and Flickr30k with four baseline methods demonstrate the efficiency and effectiveness of our proposed HEI module.

Can the Transformer Learn Nested Recursion with Symbol Masking?

Abstract

We investigate if, given a simple symbol masking strategy, self-attention models are capable of learning nested structures and generalise over their depth. We do so in the simplest setting possible, namely languages consisting of nested parentheses of several kinds. We use encoder-only models, which we train to predict randomly masked symbols, in a BERT-like fashion. We find that the accuracy is well above random baseline, with accuracy consistently above 50% both when increasing nesting depth and distances between training and testing. However, we find that the predictions made correspond to a simple parenthesis counting strategy, rather than a push-down automaton. This suggests that self-attention models are not suitable for tasks which require generalisation to more complex instances of recursive structures than those found in the training set.

1 Introduction

Self-attention models (Vaswani et al., 2017) enjoy broad use in NLP tasks. The best attention-based models can tackle several tasks using a unified sentence encoding (and perhaps decoding) module (Raffel et al., 2020), with applications ranging from classification to inference and generation. They provide state of the art results for all such tasks, displacing the already very successful recurrent neural networks, in particular the LSTM and its variants. The availability of large pretrained models (Devlin et al., 2019) is another strong point in their favour.

However, the generalisation capabilities of self-attention models are still not well understood, and the present work is part of an ongoing effort to understand their capabilities. We study in particular their ability to learn context-free languages, which are characterised by the nested structures. For this purpose, we control the inputs to the model to the maximum, while focusing on the defining characteristic of context-free languages, namely matching opening and closing brackets. This corresponds to learning *generalised Dyck languages* (see table 2). In particular, we investigate the following questions:

1. Can self-attention generalise to matching open/close parenthesis at longer distances?
2. Can self-attention generalise to matching open/close parenthesis at deeper nesting levels distances?

There is a already a small body of work dealing with this question (see sec. 5), but our contribution is specific in the following two respects: i) We use the popular BERT-like training regime (predict a percentage of randomly masked tokens), ii) We concentrate on generalising to (much) deeper nesting.

Beyond theoretical considerations, matching brackets have applications in the NLP-style treatment of constructed languages (in particular) programming languages, for example translating between programs and their natural language descriptions.

2 Data Sets

We define the language $\mathcal{D}_n$ as the set of strings generated by the following context-free rules: $E ::= \varepsilon; E ::= EE; E ::= oEc$, where (o, c) stands for a pair of matching parenthesis pairs. The index n stands for the number of possible pairs. In all of our tests, we will use $n = 5$ (corresponding for example to the pairs `()` , `[]`, `{}`, <> and «»), and thus we drop the subscript from now on.

We are interested in various characteristics of the strings of $\mathcal{D}$. First, we consider the distance between a closing parenthesis and the cor-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 753–760
August 1–6, 2021.

responding opening parenthesis. Given a string s of length $2N$ (N is the number of matching pairs), we will call $\delta(s)$ an array of length $2N$ such that if s_i is a closing parenthesis, $\delta(s)_i$ is the distance between s_i and the closing parenthesis. If s_i is an opening parenthesis, $\delta(s)_i$ is 0. For example, if $s =$“`{()<[](«»)>}`”, $\delta(s) = [0, 0, 1, 0, 0, 1, 0, 0, 1, 3, 9, 11]$. The second characteristic that we consider is the amount of nesting between closing and opening parentheses. We call this characteristic η(s), and likewise we define it for each closing parenthesis, and let it be zero for opening parentheses.

For example, if $s =$“`{()<[](«»)>}`”, $\eta(s) = [0, 0, 1, 0, 0, 1, 0, 0, 1, 2, 3, 4]$.

To generate a string with N matching pairs, we perform a random walk between opposite corners of a square grid of width and height N, such that one is not allowed to cross the diagonal. When not restricted by the boundary, a step can be taken either along the x or y axis with equal probability. A step along the x axis corresponds to open a parenthesis, and one along the y axis corresponds to closing one. The kind of parenthesis pair is chosen randomly and uniformly. We call the distribution of input strings sampled by this procedure D. In all our experiments we set $N = 10$ (which is enough to illlustrate our points) and we thus omit the superscript in what follows.

We also want control the maximum distance between opening and closing parentheses (so that we never train on too long distances). We do so by discarding elements s of D such that $\delta(s)_i > d$ for some i, and call the resulting distribution $D[MaxDist = d]$.

Often we want to control the maximum depth that our model is trained or tested on. For this purpose, we generate strings s which exhibit at least one index i such that $\eta(s)_i = d$, but no index j such that $\eta(s)_j > d$. These paths can be generated by constraining the path on the grid to touch a diagonal at distance d to the origin diagonal, and we call the corresponding distribution $D[MaxDepth = d]$.

3 Model and masking strategy

We implement a variation of the transformer model as introduced by (Vaswani et al., 2017). In the model each input symbol is associated with a vector embedding of size K. A sequence of opening and closing brackets is represented by a matrix of size (N, K).

Following Devlin et al. (2019), our model then applies a series of multi-head self-attention layers organised in a hierarchical structure, such that the second layer operates on the representations generated in the first layer, and so on. We use a BERT-like, non auto-regressive architecture: each layer attends to every position in the input, including itself. Then a softmax classifier is employed to predict the symbol at the current position. Hence, we use a masking strategy to train and test the model (otherwise it could simply use the current symbol for prediction).

For training, we follow the masking strategy presented by Devlin et al. (2019). We mask 15% of the closing parenthesis tokens at random, where in 80% of the cases we replace the token with a mask token, in 10% of the cases with a random token, and in the remaining 10% of the cases we replace it with the same token.

For testing, after sampling a string s, we pick a random position i such that s_i is a closing parenthesis. Then we mask all subsequent symbols, and let the model predict s_i. There is a single possible closing parenthesis type for s_i, corresponding to the opening parenthesis found earlier in the string. The prediction is considered successful if the model predicts the right type of closing parenthesis.

4 Experiments & Results

Our experiments consists in training the language model for a limited version of the Dyck family (for example by limiting nesting depth (η) or maximum distance (δ)), and testing what the performance is in a more general case. Thus, because there are five types of parenthesis pairs in all our experiments, the random baseline is $\frac{1}{5} = 20\%$.

4.1 Generalisation to Longer Distances

In the first experiment we investigate whether the model is capable of predicting closing parenthesis at long distance from the corresponding opening parentheses, whereas it has only seen short-distances in the training data. More precisely, we train the model on strings from $D[MaxDist = 9]$ and test it on $D[MaxDist = 19]$.

We present an overview of the results in table 1. Our experiments show that the (2 layers, 8 heads) model generalises the best. Using fewer heads appears to be more detrimental to the model's accuracy than the number of layers. This is true even though the (8,2) model has many more parameters

Table 1: Mean accuracy and standard deviation over 10 runs on generalisation to longer distances for each model configuration.

Layers	Heads	Accuracy
4	4	0.814(± 0.013)
8	2	0.643(± 0.005)
2	8	0.844(± 0.008)

than the (2,8) model (see appendix).

The aggregated numbers however hide much of the reality of the generalisation capabilities as a function of distance. Therefore we further break down the accuracy by distance to the corresponding opening parenthesis in figure 1. The (8,2) model fails to learn parenthesis matching at short distances, but its accuracy is better for longer distances. In contrast the (4,4) and (2,8) models do well for adjacent parentheses, but their accuracy drops quickly until reaching a minimum at distance 13, dipping below 50% accuracy —however still above chance. Perhaps surprisingly, all models do very well at very long distances. These very long distances correspond to matching parentheses at the beginning of the input with parentheses at the end (that is, when we mask the fewest number of input symbols).

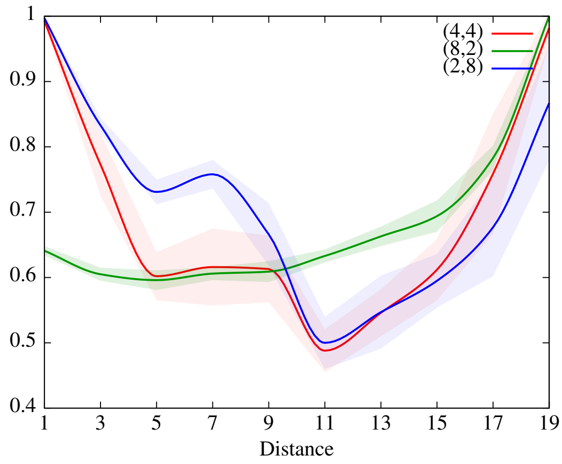

Figure 1: Mean model accuracy for closing parenthesis depending on a distance to corresponding opening parenthesis, over 10 runs. Shaded areas correspond to standard deviation.

4.2 Generalisation to Deeper Nesting

In the second experiment we test whether the model can generalise to deeper nesting depths. That is, we train the model on $D[MaxDepth = 3]$ and test it on $D[MaxDepth = 9]$

Table 2: Mean accuracy and standard deviation over 10 runs on generalisation to deeper nesting for each model configuration.

Layers	Heads	Accuracy
4	4	0.654(± 0.012)
8	2	0.518(± 0.005)
2	8	0.672(± 0.008)

We present an overview of the results in table 2. Looking at the results we see a similar pattern in terms of aggregated accuracy as in the previous experiment: the (2,8) setup performs the best, followed by (4,4) and finally (8,2). Breaking down accuracy by nesting depth (figure 2) reveals that the difference resides chiefly in the (8,2) model failing to predict shallow nesting.

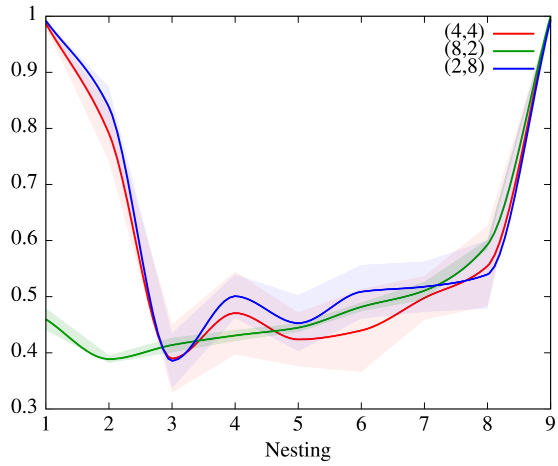

Figure 2: Mean model accuracy for closing parenthesis depending on a distance to corresponding opening parenthesis over 10 runs. Shaded areas correspond to standard deviation.

4.3 Analysis of attention heads

We have analysed attention heads by manual inspection of softmax score for attention heads for each layer, on several sequence from our training set (see Appendix for the corresponding heat maps).

Looking at the behaviour of the attention heads we note that the first layer in the (2,8) and (4,4) models focuses its attention on the previous symbol. Then, in the final layer of the (2,8) model the attention of the start of the sequence focuses on the end, and vice-versa.

In the (4,4) model, the second layer appears to often focus on the non-masked symbols while in the third layer the attention is distributed more evenly between masked and non-masked symbols. A notable feature of the third layer is that a lot of self-attention occurs on the masked symbols. In the final layer, the attention of all symbols is put almost exclusively on the masked symbols.

The (8,2) model is the only model which does not have a clear layer that looks at the preceding token. It appears that in the (8,2) model, the earlier layers focus their attention on the beginning of the sequence, then it moves towards the latter part of the sequence. The heat maps also show that the (8,2) model focuses heavily on certain symbols, which are the least frequent symbols used in the sequence, for later layers. In earlier layers the model appears to focus on the frequent symbols. This analysis is compatible with the (8,2) model using a symbol counting method.

In summary, the (4,4) model appears to first look at the previous symbol in the sequence. There are two steps of searching where first the model ignores the masked symbols and distributes the attention over the other symbols. In the second step, the model again focuses all around the sequence, but the masked symbols receive a lot of attention. For the (2,8) model, the behaviour is more straightforward. First it looks at the previous symbol, then all around the sequence. To the best of our knowledge, the (8,2) model is counting symbols by distributing its attention on frequent and less frequent symbols.

5 Related work

Studying the ability of language models to learn Dyck languages is emerging as a standard way to test the ability to generalise to deeper nesting levels. Before self-attention, this test was applied to RNNs. Bernardy (2018) proposed non-standard stack-based RNN models, which can approach perfect accuracy for generalised Dyck-language, although the accuracy of standard RNNs was higher than random but far from perfect. Hewitt et al. (2020) presented a theoretical proof that RNNs are able to learn Dyck languages with maximum nesting depth m using $O(m)$ memory. Sennhauser and Berwick (2018) present contrasting evidence, concluding that LSTMs can learn very limited range of rules.

A number of studies have considered self-attention models, especially in the past year. Ebrahimi et al. (2020) investigated self-attention models using Dyck languages, and claimed that self-attention models with a starting symbol are able to generalise to longer sequences and deeper structures without learning recursion, as competitive LSTM models do. In contrast to us, they studied models trained autoregressively only. Bhattamishra et al. (2020) studies how autoregressive Transformer architecture learns a subset of formal languages, including Dyck language and its generalisations. In contrast to our study, they examine Shuffle-Dyck languages, which allows constructions like "`( [ ) ]`" and provide theoretical and experimental evidence that the Transformer is capable of learning such a language. On the other hand, Hahn (2020) points at the limitation of using self-attention models. He indicates that in theory the LSTM should perform better than the autoregressive Transformer, because the transformer cannot emulate a stack, general finite-state automata, or use recursion.

6 Conclusion and future work

Our experiments show that, with a random masking strategy, the transformer is able to discover a way to make good predictions when generalising to longer distances and deeper nesting. However, this strategy is not using the history of opening and closing parentheses in a way a push-down automaton would.

Indeed, the analysis reveals that the best accuracy is obtained when few symbols have been masked. This can be explained by the model having learned a counting strategy. When a single symbol is masked, predicting the kind of missing parenthesis can be done by subtracting the number of closing parentheses by the number of opening parentheses for each type, and predict the type which exhibits a discrepancy. For short distances our (2,8) and (4,4) models were able to learn to remember preceding symbols and act accordingly. We suspect that for intermediate levels of nesting and distance, the models act according to a mixture of the above two strategies.

In consequence, we recommend not to use a BERT-like masking strategy for applications where generalising to longer distances or deeper nesting is critical. Rather, auto-regressive models should be used, such as auto-regressive attention or RNNs.

Acknowledgments

The research reported in this paper was supported by grant 2014-39 from the Swedish Research Council, which funds the Centre for Linguistic Theory and Studies in Probability (CLASP) in the Depart-

ment of Philosophy, Linguistics, and Theory of Science at the University of Gothenburg.

A Experimental setup and reproducibility information

Our implementation is based on pytorch, with a custom re-implementation of the transformer architecture, exactly following (Vaswani et al., 2017). The runtime is under one day for the whole set of experiments using a Titan X (Pascal) GPU.

The hyperparameters we use are listed in table 3.

Table 3: Hyperparameters used and the number of data examples used.

Parameter	Value
Optimiser	Adam
Learning rate	0.0001
Epochs	10
Batch size	512
Training examples	102400
Validation examples	20480

In our experiments we consider three different transformer architectures, corresponding to different values for the number of multi-head self-attention layers, and the size of the heads. Specifically, we considers the setups presented in section 4

Table 4: Model configurations and the number of parameters in each configuration

Layers	Heads	Parameters
8	2	897 292
4	4	1 191 820
2	8	1 781 452

In each case, we have used 64-dimensional embeddings throughout the models.

Rationalization through Concepts

Abstract

Automated predictions require explanations to be interpretable by humans. One type of explanation is a rationale, i.e., a selection of input features such as relevant text snippets from which the model computes the outcome. However, a single overall selection does not provide a complete explanation, e.g., weighing several aspects for decisions. To this end, we present a novel self-interpretable model called ConRAT. Inspired by how human explanations for high-level decisions are often based on key concepts, ConRAT extracts a set of text snippets as concepts and infers which ones are described in the document. Then, it explains the outcome with a linear aggregation of concepts. Two regularizers drive ConRAT to build interpretable concepts. In addition, we propose two techniques to boost the rationale and predictive performance further. Experiments on both single- and multi-aspect sentiment classification tasks show that ConRAT is the first to generate concepts that align with human rationalization while using only the overall label. Further, it outperforms state-of-the-art methods trained on each aspect label independently.

Figure 1: An illustration of ConRAT. Given a beer review, ConRAT identifies five excerpts that relate to particular concepts of beers (i.e., the explanation), depicted in color, from which it computes the outcome.

1 Introduction

Neural models have become the standard for many tasks, owing to their large performance gains. However, their adoption in decision-critical fields is more limited because of their lack of interpretability, particularly with textual data.

One of the simplest means of explaining predictions of complex models is by selecting relevant input features. Attention mechanisms (Bahdanau et al., 2015) model the selection using a conditional importance distribution over the inputs, but the resulting explanations are noisy (Jain and Wallace, 2019; Pruthi et al., 2020). Multi-head attention (Vaswani et al., 2017) extends attention mechanisms to attend information from different perspectives jointly. However, no explicit mechanisms guarantee a logical connection between different views (Voita et al., 2019; Kovaleva et al., 2019). Another line of research includes rationale generation methods (Lei et al., 2016; Chang et al., 2020; Antognini et al., 2021b). If the selected text input features are short and concise – called a rationale – and suffice on their own to yield the prediction, it can potentially be understood and verified against domain knowledge (Chang et al., 2019).

The key motivation for this work arises from the limitations of rationales. Rationalization models strive for one overall selection to explain the outcome by maximizing the mutual information between the rationale and the label. However, useful rationales can be multi-faceted, where each facet relates to a particular “concept” (see Figure 1). For example, users typically justify their opinions of a product by weighing explanations: one for each aspect they care about (Musat and Faltings, 2015).

Inspired by how human reasoning comprises concept-based thinking (Armstrong et al., 1983; Tenenbaum, 1999), we aim to discover, in an unsupervised manner, a set of concepts to explain the outcome with a weighted average, similar to multi-head attention. In this work, we relate concepts to semantically meaningful and consistent excerpts across multiple texts. Unlike topic modeling, where documents are described by a set of latent topics comprising word distributions, our latent concepts relate to text snippets that are relevant for the prediction.

Another motivation for this study is to generate interpretable concepts. The explanation of an outcome should rely on concepts that satisfy the desiderata introduced in Alvarez-Melis and Jaakkola (2018). They should 1. preserve relevant information, 2. not overlap with each other and be diverse, and 3. be human-understandable. Figure 1 shows an example of concepts in the beer domain.

In this work, we present a novel self-explaining neural model: the concept-based rationalizer (ConRAT) (see Figure 1 and 2). Our new rationalization scheme first identifies a set of concepts in a document and then decides which ones are currently described (binary selection). ConRAT explains the prediction with a linear aggregation of concepts. The model is trained end-to-end, and the concepts are learned in an unsupervised manner. In addition, we design two regularizers that guide ConRAT to induce interpretable concepts and propose two optional techniques, knowledge distillation and concept pruning, in order to boost the performance further.

We evaluate ConRAT on both single- and multi-aspect sentiment classification with up to five target labels. Upon training ConRAT only on the overall aspect, the results show that ConRAT generates concepts that are relevant, diverse, and non-overlapping, and they also recover human-defined concepts. Furthermore, our model significantly outperforms strong supervised baseline models in terms of predictive and explanation performance.

2 Related Work

Developing interpretable models is of considerable interest to the broader research community. Researchers have investigated many approaches to improve the interpretability of neural networks.

2.1 Interpretability.

The first line of research aims at providing post-hoc explanations of an already trained model. For example, gradient and perturbation-based methods attribute the decision to important input features (Ribeiro et al., 2016; Sundararajan et al., 2017; Lundberg and Lee, 2017; Shrikumar et al., 2017). Other studies identified the causal relationships between input-output pairs (Alvarez-Melis and Jaakkola, 2017; Goyal et al., 2019). In contrast, our model is inherently interpretable as it directly produces the prediction with an explanation.

Another line of research has developed interpretable models. Quint et al. (2018) extended a variational auto-encoder with a differentiable decision tree. Alaniz and Akata (2019) proposed an explainable observer-classifier framework whose predictions can be exposed as a binary tree. However, these methods have been designed for images only, while our work focuses on text input.

The works most relevant to ours relate to interpretable models from the rationalization field (Lei et al., 2016; Bastings et al., 2019; Yu et al., 2019; Chang et al., 2020; Jain et al., 2020; Paranjape et al., 2020). These methods justify their predictions by selecting rationales (i.e., relevant tokens in the input text). However, they are limited to explain only the prediction with mostly one text span and rely on the assumption that the data have low internal correlations (Antognini et al., 2021b). Chang et al. (2019) extended previous methods to extract an additional rationale in order to counter the prediction. In our work, ConRAT produces multi-faceted rationales and explains the prediction through a linear aggregation of the extracted concepts. However, if we set the number of concepts to one, ConRAT reduces to a special case of a rationale model.

2.2 Explanations through Concepts.

Researchers have proposed multiple approaches for concept-based explanations. Kim et al. (2018) designed a post-hoc technique to learn concept activation vectors by relying on human annotations that characterize concepts of interest. Similarly, Bau et al. (2017); Zhou et al. (2018) generated visual explanations for a classifier. Our concepts are learned in an unsupervised manner and not defined a priori.

Few studies have learned concepts on images in an unsupervised fashion. Li et al. (2018) explained predictions based on the similarity of the input to "prototypes" learned during training. Alvarez-Melis and Jaakkola (2018) used an auto-encoder to extract relevant concepts and explain the prediction. Ghorbani et al. (2019) designed an unsupervised concept discovery method to explain trained models. Koh et al. (2020) employed the discovered concepts to predict the target label. Our work's key difference is that we focus on text data, while all these methods treat only image inputs.

To the best of our knowledge, Bouchacourt and Denoyer (2019) is the only study that has proposed a self-interpretable concept-based model for text data using reinforcement learning. It computes the predictions and provides an explanation in terms of the presence or absence of concepts in the input (i.e., text excerpts of variable lengths). However, their method achieves poor overall performance. In addition, it is unclear whether the discovered concepts are interpretable. Conversely, ConRAT is differentiable, clearly outperforms strong models in terms of predictive and explanation performance, and it infers relevant, diverse, non-overlapping, and human-understandable concepts.

2.3 Topic Modeling.

Topic models, such as latent Dirichlet allocation (Blei et al., 2003), describe documents with a mixture of latent topics. Each topic represents a word distribution. Some studies combined topic models with recurrent neural models (Dieng et al., 2017; Zaheer et al., 2017). However, the goal of these generative models and the topics remains different than this work's. We aim to build a self-interpretable model that predicts and explains the outcome with latent concepts.

3 Concept-based Rationalizer (ConRAT)

Figure 2 depicts the architecture of our proposed self-explaining model: the Concept-based Rationalizer (ConRAT). Let X be a random variable representing a document composed of T words $(x_1, x_2, \ldots, x_T)$, y the ground-truth label, and K the desired numbers of concepts.[1] Given a document X and a label y, our goal is to explain the prediction $\hat{y}$ by finding a set of K concepts C_1, $\ldots, C_K$ that are masked versions of X. ConRAT learns concepts by maximizing the mutual information between $\boldsymbol{C}$ and y. We guide ConRAT to create separable and consistent concepts via two regularizers to make them human-understandable.

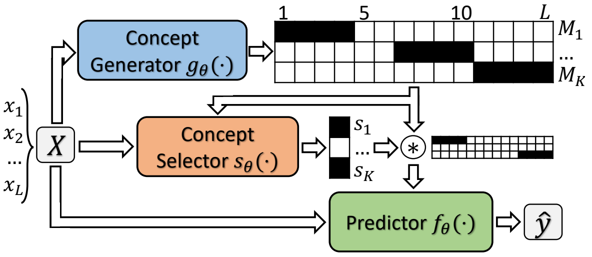

Figure 2: The proposed self-explaining model ConRAT. The model predicts and explains $\hat{y}$. Given a document X, the concept generator produces one binary mask per concept. The concept selector decides which concepts are present in the input. The predictor aggregates each selected concept's prediction to compute $\hat{y}$.

3.1 Model Overview

ConRAT is divided into three submodels: a **Concept Generator** $g_\theta(\cdot)$, which finds the concepts $C_1, \ldots, C_K$; a **Concept Selector** $s_\theta(\cdot)$, which detects whether a concept C_k is present or absent (i.e., $s_k \in \{1, 0\}$) in the input X; and a **Predictor** $f_\theta(\cdot)$, which predicts the outcome $\hat{y}$ based on the concepts $\boldsymbol{C}$ and their presence scores S.

3.1.1 Concept Generation

Inspired by the selective rationalization field (Lei et al., 2016), we define "concept" as a sequence of consecutive words in the input text. Previous studies extracted only one concept C_1 that is sufficient to explain the target variable y. In our work, a major difference is that we aim to find K concepts $C_1, \cdots, C_K$ that represent different topics or aspects and altogether explain the target variable y. We interpret the model as being linear in the concepts rather than depending on one overall selection of word. More formally, we define a concept as follows:

$$C_k = M_k \odot X, \tag{1}$$

where $M_k \in \mathbb{S}$ denotes a binary mask, $\mathbb{S}$ is a subset of $\mathbb{Z}_2^T$ with some constraints (introduced in Section 3.2), and $\odot$ is the element-wise multiplication of two vectors.

We parametrize the binary masks $\boldsymbol{M} \in \mathbb{Z}_2^{K \times T}$ with the concept generator model $g_\theta(\cdot)$, based on a bi-directional recurrent neural network. Following previous rationalization research (Yu et al.,

---

[1] Our method is easily adapted for regression problems.

2019; Chang et al., 2020), we force $g_\theta(\cdot)$ to select one chunk of text per concept with a pre-specified length $\ell \in [1, T]$.[2] Instead of predicting the mask M_k directly, $g_\theta(\cdot)$ produces a score for each position t. Then, it samples the start position t_k^* of the chunk for each C_k using the straight-through Gumbel-Softmax (Maddison et al., 2017; Jang et al., 2017). Finally, we compute M_k as follows:

$$\begin{aligned} T^* &\sim Gumbel(g_\theta(X)), \\ M_{k,t} &= \mathbb{1}\left[t \in [t_k^*, min(t_k^* + \ell - 1, T)]\right], \end{aligned} \tag{2}$$

where $\mathbb{1}$ denotes the indicator function. Although the equation is not differentiable, we can employ the straight-through technique (Bengio et al., 2013) and approximate it with the gradient of a causal convolution and a convolution kernel of an all-one vector of length ℓ.

3.1.2 Concept Selection

A key objective of ConRAT is to produce semantically consistent and separable concepts. So far, the generator $g_\theta(\cdot)$ generates K concepts for any input document. However, some documents might mention only a subset of those. Thus, the goal of the concept selector model $s_\theta(\cdot)$ is to enable ConRAT to ignore absent concepts.

Specifically, for each concept C_k, the model first computes a concept representation H_{C_k} using a standard attention mechanism (Bahdanau et al., 2015) (the tokens whose $M_{k,t} = 0$ are masked out). Then, we take the dot product of H_{C_k} with a weight vector, followed by a sigmoid activation function to induce the log-probabilities of a relaxed Bernoulli distribution (Jang et al., 2017). Finally, we sample the presence score $s_k \in \{0, 1\}$ of each concept independently:

$$S \sim RelaxedBernoulli(s_\theta(X, \boldsymbol{M})). \tag{3}$$

3.1.3 Prediction

As inputs, the predictor $f_\theta(\cdot)$ takes the document X, the masks $\boldsymbol{M}$, and the presence scores S for all concepts. First, we extract the concepts, which are masked versions of X. Differently than in Equation 1, the concepts are ignored if $s_k = 0$:

$$C_k = (M_k * s_k) \odot X. \tag{4}$$

Second, the model produces the hidden representation h'_{C_k} with another recurrent neural network, followed by a LeakyReLU activation function (Xu et al., 2015). Then, it computes the logits of y by applying a linear projection for each concept:

$$P_k = W h'_{C_k} + b, \tag{5}$$

where W and b are the projection parameters. Finally, f_θ computes the final outcome as follows:

$$p(y|C, \boldsymbol{M}, X) = softmax(\sum_{k=1}^{K} \alpha_k P_k s_k), \tag{6}$$

where α_k are model parameters that can be interpreted as the degree to which a particular concept contributes to the final prediction.

3.2 Unsupervised Discovery of Concepts

The above formulations integrate the explanation into the outcome computation. However, M_k is by definition faithful to the model's inner workings but not comprehensible for the end-user. Following Alvarez-Melis and Jaakkola (2018), we aim the concepts to follow three desiderata:1. **Fidelity**: they should preserve relevant information, 2. **Diversity**: they should be non-overlapping and diverse, and 3. **Grounding**: they should have an immediate human-understandable interpretations.

The hard constraint in Equation 2 naturally enforces the grounding by forcing the concept to be a sequence of ℓ words. For the fidelity, it is partly integrated in ConRAT by the prediction loss, which is the cross-entropy between the ground-truth label y and the prediction $\hat{y}$: $\mathcal{L}_{pred} = CE(\hat{y}, y)$. Recall that the concepts are substitutes of the input that are sufficient for the prediction. We emphasize the word "partly" because nothing prevents ConRAT from picking up spurious correlations.

We propose two regularizers to encourage ConRAT in finding non-overlapping, relevant, and dissimilar concepts. The first favors the orthogonality of concepts by penalizing redundant rows in $\boldsymbol{M}$:

$$\mathcal{L}_{overlap} = ||\boldsymbol{M}\boldsymbol{M}^T - \ell \cdot \mathbb{1}\,||_F^2, \tag{7}$$

where $||\cdot||_F$ stands for the Frobenius norm of a matrix, $\mathbb{1}$ denotes the identity matrix, and ℓ the pre-specified concept length. However, $\mathcal{L}_{overlap}$ alone does not prevent ConRAT from learning little relevant concepts. Therefore, we propose a second regularizer to encourage fidelity and diversity

---

[2] In early experiments, we relaxed the length constraint and generated instead K differentiable masks with continuity regularizers. However, this variant produced majorly inferior results. We hypothesize that there are too many constraints to optimize with only the target label as a strong signal.

by minimizing the cosine similarity between the concept representations H_{C_k} (see Section 3.1.2):

$$\mathcal{L}_{div} = \frac{1}{K}\frac{1}{K-1}\sum_{\substack{k_1,k_2=1\\k_1\neq k_2}}^{K} cos(H_{C_{k_1}}, H_{C_{k_2}}). \quad (8)$$

In both regularizers, we do not consider the presence scores S because a model could always select only one concept; this strategy is not optimal and reduces to a special case of rationale models (i.e., S would become a one-hot vector).

To summarize, the concepts are learned in an unsupervised manner and align with the three desiderata mentioned above: diversity is achieved with $\mathcal{L}_{overlap}$ and $\mathcal{L}_{div}$; fidelity is enforced by $\mathcal{L}_{pred}$ and $\mathcal{L}_{div}$, and the hard constraint in Equation 2 ensures the grounding. Finally, we train ConRAT end-to-end and minimize the loss jointly $\mathcal{L} = \mathcal{L}_{pred} + \lambda_O\mathcal{L}_{overlap} + \lambda_D\mathcal{L}_{div}$, where λ_O and λ_D control the impact of each regularizer.

3.3 Improving Overall Performance Further

The purpose of self-explaining models is to compute outcomes while being more interpretable. However, one key point is to achieve predictive performance comparable to that of black-box models. We propose two techniques to further improve both interpretability and performance; however, ConRAT does not require these techniques to outperform other methods, as we will see later.

Knowledge Distillation. We can train ConRAT not only via the information provided by the true labels but also by observing how a teacher model behaves (Hinton et al., 2015). In that case, we introduce the teacher model $T_\theta(\cdot)$, which is a simple recurrent neural network similar to the predictor f_θ. It is trained one the same data, but it uses the whole input X instead of subsets selected by each C_k. The overall training loss becomes $\mathcal{L} = \mathcal{L}_{pred} + \lambda_O\mathcal{L}_{overlap} + \lambda_D\mathcal{L}_{div} + \lambda_T(\hat{y}_{T_\theta} - \hat{y}_{f_\theta})^2$.

Pruning Concepts. Depending on the number of concepts and the pre-specified length, the total number of selected words can be close to or higher than the document length.[3] In practice, it is hard to extract meaningful concepts in such settings. To alleviate this problem, we propose to prune concepts at inference and select the top-k concepts that overlap the least with the others. More specifically, we compute the overlap as follows: for each sample in the validation set, we measure the average overlap ratio between M_{k_1} and M_{k_2} for each concept-pair $(C_{k_1}, C_{k_2}), k_1 \neq k_2$. Then, we select the top-k concepts whose scores are the lowest. Finally, to compute the new prediction $\hat{y}$, we update $s_k = 1$ if C_k is in the top-k or $s_k = 0$ otherwise.

Table 1: Statistics of the review datasets.

4 Experiments

4.1 Datasets

We evaluate the quantitative performance of ConRAT using two binary classification datasets. The first one is the single-aspect Amazon Electronics dataset (Ni et al., 2019). We followed the filtering process in Chang et al. (2019) to keep only the reviews that contain evidence for both positive and negative sentiments. Specifically, we considered the first 50 tokens after the words "pros:" and "cons:" as the rationale annotations for the positive and negative labels, respectively. We randomly picked 24,000 balanced samples with ratings of four and above or two and below.

The second dataset comprises the multi-aspect beer reviews (McAuley et al., 2012) used in the field of rationalization (Lei et al., 2016; Yu et al., 2019). Each review describes various beer aspects: Appearance, Aroma, Palate, Taste, and Overall; users also provided a five-star rating for each aspect. However, we only use the overall rating for ConRAT. The dataset includes 994 beer reviews with sentence-level aspect annotations. Following the evaluation protocol in Bao et al. (2018); Chang et al. (2020), we binarized the ratings ≤ 2 as negative and ≥ 3 as positive. We sampled 60,000 balanced examples. Our setting is more challenging than those in previous studies because we assess the performance on all aspects (instead of three) and consider all examples for the sampling (instead of de-correlated subsets), reflecting the real data distribution. Table 1 shows the data statistics.

---

[3] e.g., if a document contains 200 tokens and we aim to extract 10 concepts of 20 tokens, all words should be selected.

4.2 Baselines

We consider the following baselines. **RNP** is a generator-predictor framework proposed by Lei et al. (2016) for rationalizing neural prediction. The generator selects text spans as rationales, which are then fed to the classifier for the final prediction. Yu et al. (2019) introduced **RNP-3P**, which extends RNP to include the complement predictor as the third player. It maximizes the predictive accuracy from unselected words. The training consists of an adversarial game with the three players. **Intro-3P** (Yu et al., 2019) improves RNP-3P by conditioning the generator on the predicted outcome of a teacher model. **InvRAT** is a game-theoretic method that competitively rules out spurious words with strong correlations to the output. The game-theoretic approach **CAR** aims to infer a rationale and a counterfactual rationale that counters the true label. We follow Chang et al. (2020) and consider for all methods their hard constraint variant (i.e., selecting one chunk of text) with different lengths for generating rationales.

RNP-3P and Intro-3P are trained with the policy gradient (Williams, 1992). The others estimate the gradients of the rationale selections using the straight-through technique (Bengio et al., 2013).

All rationalization methods, except CAR, strive for a single overall selection ($K = 1$) to explain the outcome. For the multi-aspect dataset, we train and tune each baseline independently for each aspect. The key difference with ConRAT is that the model is only trained on the overall aspect label and infers one rationale of K concepts; the baselines are trained K times to infer one rationale of one concept.

4.3 Experimental Details

To seek fair comparisons, we try to keep a similar number of parameters across all models, and we employ the same architecture for each player (generators, predictors, and discriminators/teachers) in all models: bi-directional gated recurrent units (Chung et al., 2014) with a hidden dimension 256. We use the 100-dimensional GloVe word embeddings (Pennington et al., 2014), Adam (Kingma and Ba, 2015) as optimization method with a learning rate of 0.001. We set the convolutional neural network in the concept selector similarly to (Kim et al., 2015) with 3-, 5-, and 7-width filters and 50 feature maps per filter. For ConRAT, we set the regularizer factors as follow: $\lambda_O = 0.05$, $\lambda_D = 0.05$, and $\lambda_T = 0.5$. We use the open-source implementation for all models, and we tune them by maximizing the prediction accuracy on the dev set with 16 random searches. For reproducibility purposes, we include additional details in Appendix A.

4.4 RQ 1: Can ConRAT find evidence for factual and counterfactual rationales?

We aim to validate whether ConRAT can identify the two evidences for positive and negative sentiments. We set the concept length $\ell = 30$, we compare the generated rationales with the annotations, and we report the precision, recall, and F1 score. In this experiment, no teacher is used in ConRAT.

Table 2 contains the results. The top rows contain the results when only the factual rationales are considered for the evaluation, and ConRAT-1 uses only one concept. We see that ConRAT surpasses the baselines in finding rationales that align with human annotations, and it also matches the test accuracy with the baselines. Interestingly, we note that the baselines achieving the highest accuracy underperform in finding the correct rationales.

For the factual and counterfactual rationales, CAR finds one rationale to support the outcome and another one to counter it, in an adversarial game. However, the concepts inferred by ConRAT are not guaranteed to align with the rationales as there is no explicit signal to infer counterfactual concepts. Thus, we increase the number of concepts up to six and prune ConRAT to consider only the two most dissimilar concepts (see Section 3.3).

The bottom of Table 2 show the results. With only two concepts, ConRAT-2 outperforms CAR

Table 3: Objective performance of rationales for the multi-aspect beer reviews. ConRAT only uses the overall label and ignores the other aspect labels. All baselines are trained separately on each aspect rating. **Bold** and underline denote the best and second-best results, respectively.

* The model is only trained on the overall label and does not have access to the other ground-truth labels.

in terms of test accuracy and matches the performance for the factual rationales, but it poorly identifies counterfactual rationales. However, there is a major improvement when we increase the number of concepts and use pruning. Indeed, the word distribution of the factual and counterfactual rationales are different, hence captured with pruning. ConRAT's factual rationales are better than those of all models. The counterfactual ones get closer to those produced by CAR. We show later in Section 4.6 that pruning helps in achieving better correlation with human judgments but is not required.

4.5 RQ 2: Are concepts inferred by ConRAT consistent with human rationalization?

We investigate whether ConRAT can recover all beer aspects by using only the overall ratings. Because beer reviews are smaller in length than Amazon ones, we set the concept length ℓ to 10 and 20. We fix the number of concepts to ten and prune ConRAT to keep five. We manually map them to the closest aspect for comparison. We trained the teacher model, used in Intro-3P and ConRAT, and obtained 91.4% accuracy. More results and illustrations are available in Appendix B and C.

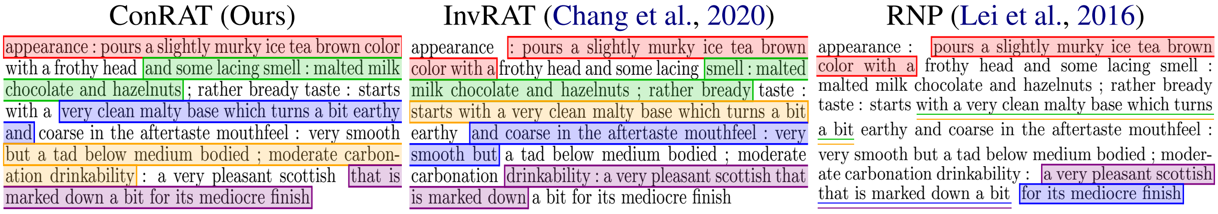
Objective Evaluation. Similar to Section 4.4, we compare the generated rationales with the human annotations on the five aspects and the average performance. The main results are shown in Table 3. On average, ConRAT achieves the best performance while trained only on the overall ratings. This shows that the generated concepts, learned in an unsupervised manner, are separable, consistent, and correlated with human judgments to a certain extent. For the concept length $\ell = 20$, ConRAT produces significant superior results for all aspects, whereas the difference with InvRAT is less pronounced for $\ell = 10$. Finally, ConRAT's concepts lead to the highest accuracy and respect the grounding desideratum, thanks to the teacher.

We hypothesize that the baselines underperform due to the high correlations among the aspect ratings. Thus, they are more prone to pick up spurious correlations between the input features and the output. By considering multiple concepts simultaneously, ConRAT reduces the impact of spurious correlations. Regarding Intro-3P and RNP-3P, both suffer from instability issues due to the policy gradient (Chang et al., 2020; Yu et al., 2019).

We visualize an example in Figure 3. We observe that ConRAT induces interpretable concepts, while the best baselines suffer from spurious correlations. By reading our concepts alone, humans will easily predict the aspect label and its polarity.

Subjective Evaluation. We conduct a human evaluation using Amazon's Mechanical Turk (details in Appendix B.2) to judge the understandability of the concepts. Following Chang et al. (2019), we sampled 100 balanced reviews from the holdout set for each aspect, model, and concept length, resulting in 5,000 samples. We showed the examples in random order. An evaluator is presented with the concept generated by one of the five methods (unselected words are not visible). We credit a success when the evaluator guesses the true aspect label and its sentiment. We report the success rate as the performance metric. A random guess has a 10% success rate.

Figure 4 shows the main results. Similar to the objective evaluation, ConRAT reaches the



ConRAT (Ours)

appearance : pours a slightly murky ice tea brown color with a frothy head and some lacing smell : malted milk chocolate and hazelnuts ; rather bready taste : starts with a very clean malty base which turns a bit earthy and coarse in the aftertaste mouthfeel : very smooth but a tad below medium bodied ; moderate carbonation drinkability : a very pleasant scottish that is marked down a bit for its mediocre finish

InvRAT (Chang et al., 2020)

appearance : pours a slightly murky ice tea brown color with a frothy head and some lacing smell : malted milk chocolate and hazelnuts ; rather bready taste : starts with a very clean malty base which turns a bit earthy and coarse in the aftertaste mouthfeel : very smooth but a tad below medium bodied ; moderate carbonation drinkability : a very pleasant scottish that is marked down a bit for its mediocre finish

RNP (Lei et al., 2016)

appearance : pours a slightly murky ice tea brown color with a frothy head and some lacing smell : malted milk chocolate and hazelnuts ; rather bready taste : starts with a very clean malty base which turns a bit earthy and coarse in the aftertaste mouthfeel : very smooth but a tad below medium bodied ; moderate carbonation drinkability : a very pleasant scottish that is marked down a bit for its mediocre finish

Figure 3: Concepts generated (with ℓ=10) for a beer review. Underline highlights ambiguities. The color depicts the aspects: Appearance, Aroma, Palate, Taste, and Overall . **ConRAT is trained only on the overall label**.

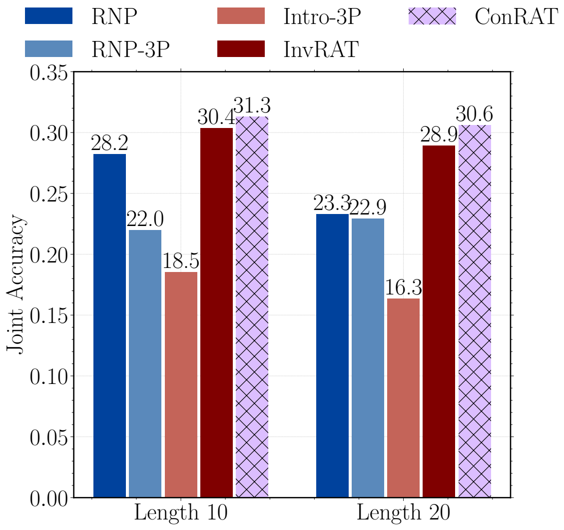


Figure 4: Subjective performance of rationales for the multi-aspect beer reviews. Evaluators need to guess both the sentiment and what aspect the concept is about, which makes random guess only 10%.

best performance, followed by InvRAT. Moreover, ConRAT only requires a single training on the overall aspect. It emphasizes that the discovered concepts satisfy the fidelity and diversity desiderata and better correlate with human judgments compared with supervised baselines.

4.6 RQ 3: How does the number of concepts K in ConRAT affect the performance?

We study the impact of the number of concepts K in ConRAT on the performance, as discussed in Section 4.5. We set the number of concepts to the number of aspects (K=5) and then increase it to K=10 and K=20. We prune ConRAT to keep only the five most dissimilar concepts (see Section 3.3).

Results are shown in Table 4. First, we observe that the performance is already better than the baselines in Table 3 with K=5. Second, when increasing K and pruning ConRAT, the performance is boosted further. However, we remark that the interpretability of the concepts follows a bell curve and significantly decreases when K=20. One potential reason is that we expect overlaps between the discriminative concepts that relate to beer aspects.[4] Thus, the five most dissimilar concepts might align less with human-defined concepts.

Table 4: Impact of the number of concepts in ConRAT on the objective performance for the beer reviews.

			Average		
	#Concepts	**Acc.**	**P**	**R**	**F**
$\ell = 20$	$K = 5$	90.95	48.96	37.59	41.37
	$K = 10$	**91.35**	**50.02**	**41.96**	**44.86**
	$K = 20$	90.24	37.78	31.19	32.84
$\ell = 10$	$K = 5$	89.64	47.60	19.23	26.90
	$K = 10$	**91.25**	**48.12**	**20.11**	**27.97**
	$K = 20$	91.05	35.71	14.84	20.71

4.7 RQ 4: How does each module of ConRAT contribute to the overall performance?

Finally, we analyze the importance of each module in an ablation study. To avoid any bias from pruning, we set the number of concepts to five.[5]

Table 5 shows the results. When ConRAT ignores the overlapping or the diversity regularizer, we observe a large drop in the rationale performance. This is expected as the diversity desideratum is not encouraged anymore. However, we remark that the sentiment prediction accuracy increases, which is certainly caused by spurious correlation with the ground-truth label. When all concepts are considered ($s_k = 1 \ \forall k$), we note that the sentiment accuracy stays similar. However, the objective performance decreases by 10% for the precision and more than 20% for the recall and F1 score. These results align with prior work: users write opinions about the topics they care about (Musat and Faltings, 2015; Antognini

---

[4] As shown in Table 1, the mean length of beer reviews is 184 words. With ℓ=20 and C=20, 400 words are highlighted.

[5] We obtain similar results with K=10 and K=20.

Table 5: Ablation study of ConRAT with five concepts.

Model	Acc.	*Average* P	R	F
ConRAT	89.64	47.60	19.23	26.90
- No $\mathcal{L}_{overlap}$	91.05	31.50	13.16	18.37
- No $\mathcal{L}_{div}$	90.85	34.49	11.69	16.95
- No $s_\theta(\cdot)$:$s_k = 1 \forall k$	89.74	43.13	14.95	21.42
- No Teacher	86.52	45.31	19.65	26.99

et al., 2021a). ConRAT reduces the noise at training by selecting concepts described in the current document. Finally, the teacher model helps ConRAT to boost the sentiment accuracy by more than 3% absolute score, without affecting the rationale quality.

5 Conclusion

Providing explanations for automated predictions carries much more impact, increases transparency, and might even be vital. Previous works have proposed using rationale methods to explain the prediction of a target variable. However, they do not properly capture the multi-faceted nature of useful rationales. We proposed ConRAT, a novel self-explaining model that extracts a set of concepts and explains the outcome with a linear aggregation of concepts, similar to how humans reason.

Our second contribution is two novel regularizers that guide ConRAT to generate interpretable concepts. Experiments on both single- and multi-aspect sentiment classification datasets show that ConRAT, by using only the overall label, is the first to provide superior rationale and predictive performance compared with supervised state-of-the-art methods trained for each aspect label. Moreover, ConRAT produces concepts considered superior in interpretability when evaluated by humans.

A Additional Training Details

We tune all models on the dev set. We truncate all reviews to 320 tokens for the beer dataset and 400 tokens for Amazon reviews. We have operated a random search over 16 trials. All baselines, except CAR, are tuned for each aspect (80 trials in total for the five aspects). We chose the models achieving the lowest validation accuracy. Most of the time, all models converged under 30 epochs. The range of hyperparameters are the following for ConRAT (similar for other models):

- Learning rate: $[0.0005, 0.00075, 0.001]$;
- Batch size: $[128]$;
- Hidden size: $[256]$;
- λ_D: $[0.01, 0.05, 0.1, 0.25, 0.5, 0.75, 1.0]$;
- λ_O: $[0.01, 0.05, 0.1, 0.25, 0.5, 0.75, 1.0]$;
- λ_T: $[0.5, 0.6]$;
- Dropout: $[0.0, 0.1]$;
- Weight decay: $[0.0, 10^{-8}, 10^{-10}]$;
- Gumbel temperature in $f_\theta(\cdot)$: $[1.0; 1.5]$;
- Gumbel temperature in $s_\theta(\cdot)$: $[1.0; 1.5]$;

B.1 Objective Evaluation

The results for the concept length $\ell = 5$ is shown in Table 6.

Moreover, we report in Table 7 the performance for the **unsupervised** sentiment prediction task for the aspects whose labels are not available to ConRAT: Appearance, Aroma, Palate, and Taste. As we can see, ConRAT achieves competitive results compared to **supervised** baselines.

B.2 Human Evaluation Details

We use Amazon's Mechanical Turk crowdsourcing platform to recruit human annotators to evaluate the quality of extracted justifications and the generated justifications produced by each model. To ensure high-quality of the collected data, we restricted the pool to native English speakers from the U.S., U.K., Canada, or Australia. Additionally, we set the worker requirements at a 98% approval rate and more than 1,000 HITS.

The user interface used to judge the quality of the justifications extracted from different methods, in Section 4.5, is shown in Figure 5.

B.3 Subjective Evaluation

All results (for the joint, the aspect, and the polarity accuracy) are shown in Figure 6. In total, we used 7,500 samples ($100 \times 5 \times 5 \times 3$).

We also studied the error rates on each aspect. The Aroma and Palate aspects cause the highest error for all models. One possible reason is that users confuse these with the aspect Taste, hence their high correlations in rating scores (Antognini et al., 2021b).

C Extra Visualizations

Additional samples of generated rationales are shown in Figure 7, 8, 9, and 10. We can observe that baselines suffer from spurious correlations: the rationale for the aspect Aroma, Palate, and Taste are often exchanged, or several rationales pick the same text snippets. On the other hand, ConRAT finds better concepts while only trained on the overall aspect label. As it has been shown in prior work (Lei et al., 2016; Chang et al., 2020; Antognini et al., 2021b) rationale methods suffer from the high correlation between rating scores because each model is trained independently for each aspect. Therefore, they rely on the assumption that the data have low internal correlations, which does not reflect the real data distribution. By contrast, ConRAT alleviates this problem be finding all concepts in one training.

Table 6: Objective performance of rationales for the multi-aspect beer reviews with the concept length set to five. ConRAT only uses the overall rating and does not have access to the other aspect labels. All baselines are trained separately on each aspect label. **Bold** and underline denote the best and second-best results, respectively.

Abstract

Given a video, video grounding aims to retrieve a temporal moment that semantically corresponds to a language query. In this work, we propose a **P**arallel **A**ttention **N**etwork with **Seq**uence matching (SeqPAN) to address the challenges in this task: multi-modal representation learning, and target moment boundary prediction. We design a self-guided parallel attention module to effectively capture self-modal contexts and cross-modal attentive information between video and text. Inspired by sequence labeling tasks in natural language processing, we split the ground truth moment into begin, inside, and end regions. We then propose a sequence matching strategy to guide start/end boundary predictions using region labels. Experimental results on three datasets show that SeqPAN is superior to state-of-the-art methods. Furthermore, the effectiveness of the self-guided parallel attention module and the sequence matching module is verified.[1]

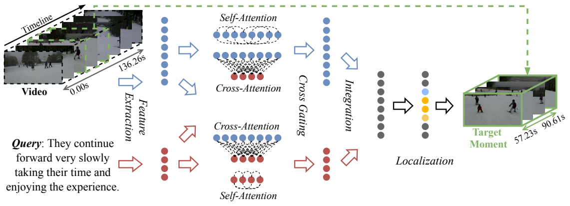

Figure 1: The overview of our procedures for video grounding, with an example of retrieving the temporal moment from an untrimmed video by a given language query.

1 Introduction

Video grounding is a fundamental and challenging problem in vision-language understanding research area (Hu et al., 2019; Yu et al., 2019; Zhu and Yang, 2020). It aims to retrieve a temporal video moment that semantically corresponds to a given language query, as shown in Figure 1. This task requires techniques from both computer vision (Tran et al., 2015; Shou et al., 2016; Feichtenhofer et al., 2019), natural language processing (Yu et al., 2018; Yang et al., 2019), and more importantly, the cross-modal interactions between the two. Many existing solutions (Chen et al., 2018; Liu et al., 2018a; Xu et al., 2019) tackle video grounding problem with *proposal-based* approach. This approach generates proposals with pre-set sliding windows or anchors, computes the similarity between the query and each proposal. The proposal with highest score is selected as the answer. These methods are sensitive to the quality of proposals and are inefficient because all proposal-query pairs are compared. Recently, several one-stage *proposal-free* solutions (Chen et al., 2019; Lu et al., 2019a; Mun et al., 2020) are proposed to directly predict start/end boundaries of target moments, through modeling video-text interactions. Our solution, SeqPAN, is a proposal-free method; hence our key focuses are *video-text interaction modeling* and *moment boundary prediction*.

Video-text interaction modeling. In order to model video-text interaction, various attention-based methods have been proposed (Gao et al., 2017; Yuan et al., 2019a; Mun et al., 2020). In particular, transformer block (Vaswani et al., 2017) is widely used in vision-language tasks and proved to be effective for multimodal learning (Tan and Bansal, 2019; Lu et al., 2019b; Su et al., 2020; Li et al., 2020). In video grounding task, fine-grain scale unimodal representations are important to achieve good localization performance. However, existing solutions do not refine unimodal representations of video and text when doing cross-modal reasoning, and thus limit the performance.

To better capture informative features for multimodalities, we encode both self-attentive contexts and cross-modal interactions from video and query. That is, instead of solely relying on sophisticated

cross-modal learning as in most existing studies, we learn both intra- and inter-modal representations simultaneously, with improved attention modules.

Moment boundary prediction. In terms of the length, target moment is usually a very small portion of the video, making positive (frames in target moment) and negative (frames not in target moment) samples imbalanced. Further, we aim to predict the exact start/end boundaries (*i.e.,* two video frames[2]) of the target moment. If we view from the space of video frames, sparsity is a major concern, *e.g.,* catching two frames among thousands. Recent studies attempt to address this issue by auxiliary objectives, *e.g.,* to discriminate whether each frame is foreground (positive) or background (negative) (Yuan et al., 2019b; Mun et al., 2020), or to regress distances of each frame within target moment to ground truth boundaries (Lu et al., 2019a; Zeng et al., 2020). However, the "sequence" nature of frames or videos is not considered.

We emphasize the "sequence" nature of video frames and adopt the concept of sequence labeling in NLP to video grounding. We use named entity recognition (NER) (Lample et al., 2016; Ma and Hovy, 2016) as an example sequence labeling task for illustration in Figure 2. Video grounding is to retrieve a sequence of frames with start/end boundaries of target moment from video. This is analogous to extract a multi-word named entity from a sentence. The main difference is that, words are discrete, so word annotations (*i.e.,* B, I, E, and O tags) in sentence are discrete. In contrast, video is continuous and the changes between consecutive frames are smooth. Hence, it is difficult (and also not necessary) to precisely annotate each frame. We relax the annotations on video sequence by specifying video regions, instead of frames. With respect to the target moment, we label B, I, E and O (BIEO) regions on video (see Figure 3) and introduce label embeddings to model these regions.

Our contributions. In this research, we propose a **P**arallel **A**ttention **N**etwork with **Seq**uence matching (SeqPAN) for video grounding task. We first design a *self-guided parallel attention (SGPA)* module to capture both self- and cross-modal attentive information for each modality simultaneously. In SGPA module, a cross-gating strategy with self-guided head is further used to fuse self- and cross-modal representations. We then propose a *sequence matching (sq-match)* strategy, to identify BIEO regions in video. The label embeddings are incorporated to represent label of frames in each region for region recognition. The sq-match guides SeqPAN to search for boundaries of target moment within constrained regions, leading to more precise localization results. Experimental results on three benchmarks demonstrate that both SGPA and sq-match consistently improve the performance; and SeqPAN surpasses the state-of-the-art methods.

2 Related Work

Existing solutions to video grounding are roughly categorized into proposal-based and proposal-free frameworks. In proposal-based framework, common structures include ranking and anchor-based methods. *Ranking-based* methods (Liu et al., 2018b; Hendricks et al., 2017, 2018; Chen and Jiang, 2019; Ge et al., 2019; Zhang et al., 2019b) solve this task with two-stage propose-and-rank pipeline, which first generates proposals and then uses multimodal matching to retrieve most similar proposal for a query. *Anchor-based* methods (Chen et al., 2018; Yuan et al., 2019a; Zhang et al., 2019c; Wang et al., 2020b) sequentially assign each frame with multiscale temporal anchors and select the anchor with highest confidence as the result. However, these methods are sensitive to the proposal quality; and comparison of all proposal-query pairs is computational expensive and inefficient.

Proposal-free framework includes regression and span-based methods. *Regression-based* methods (Yuan et al., 2019b; Lu et al., 2019a; Chen et al., 2020a,b) tackle video grounding by learning cross-modal interactions between video and query, and directly regressing temporal time of target moments. *Span-based* methods (Ghosh et al., 2019; Rodriguez et al., 2020; Zhang et al., 2020a; Lei et al., 2020; Zhang et al., 2021) address video grounding by borrowing the concept of extractive question answering (Seo et al., 2017; Huang et al., 2018), and to predict the start and end boundaries of target moment directly.

In addition, there are several works (He et al.,

---

[2] The "frame" is a general description, which can refer to a frame in a video sequence or a unit in the corresponding video feature representation.

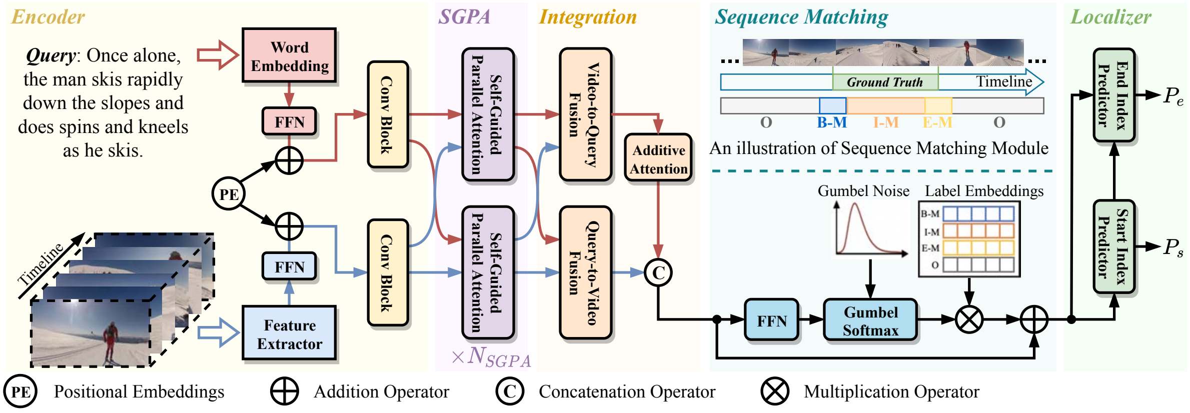

Figure 3: The architecture of the Parallel Attention Network with Sequence Matching (SeqPAN) for video grounding.

2019; Wang et al., 2019; Cao et al., 2020; Hahn et al., 2020; Wu et al., 2020a,b) that formulate this task as a sequential decision-making problem and adopt reinforcement learning to observe candidate moments conditioned on queries. Other methods, *e.g.,* weakly supervised learning methods (Mithun et al., 2019; Lin et al., 2020; Wu et al., 2020a), 2D map model of temporal relations between video moments (Zhang et al., 2020b), ensemble of top-down and bottom-up methods (Wang et al., 2020a), joint learning video-level matching and moment-level localization (Shao et al., 2018), have also been explored. Some works (Shao et al., 2018; Cao et al., 2020; Liu et al., 2020; Wang et al., 2020a) use either additional resources/features or different evaluation metrics, so their results are not directly comparable with many others, including ours.

3 Proposed Method

Let $V = [f_t]_{t=0}^{T-1}$ be an untrimmed video with T frames; $Q = [q_j]_{j=0}^{M-1}$ be a language query with M words; t^s and t^e denote start and end time point of ground-truth temporal moment. We define and tackle video grounding task in feature spaces. Specifically, we split the given video V into N clip units, and use pre-trained feature extractor to encode them into visual features $\boldsymbol{V} = [\boldsymbol{v}_i]_{i=0}^{N-1} \in \mathbb{R}^{d_v \times N}$, where d_v is visual feature dimension. Then the $t^{s(e)}$ are mapped to the corresponding indices $i^{s(e)}$ in the feature sequence, where $0 \leq i^s \leq i^e \leq N-1$. For the query Q, we encode words with pre-trained word embeddings as $\boldsymbol{Q} = [\boldsymbol{w}_j]_{j=0}^{M-1} \in \mathbb{R}^{d_w \times M}$, where d_w is word dimension. Given the pair of $(\boldsymbol{V}, \boldsymbol{Q})$ as input, video grounding aims to localize a temporal moment starting at i^s and ending at i^e.

3.1 The SeqPAN Model

The overall architecture of the proposed SeqPAN model is shown in Figure 3. Next, we present each module of SeqPAN in detail.

3.1.1 Encoder Module

Given visual features $\boldsymbol{V} \in \mathbb{R}^{d_v \times N}$ of the video and word embeddings $\boldsymbol{Q} \in \mathbb{R}^{d_w \times M}$ of the language query, we map them into the same dimension d with two FFNs[3], respectively. The encoder module mainly encodes the individual modality separately. As position encoding offers a flexible way to embed a sequence, when the sequence order matters, we first incorporate a position embedding to every input of both video and query sequences. Then, we adopt stacked 1D convolutional block to learn representations by carrying knowledge from neighbor tokens. The encoded representations are written as:

$$\begin{aligned} \boldsymbol{V}' &= \texttt{ConvBlock}(\texttt{FFN}_\texttt{v}(\boldsymbol{V}) + \boldsymbol{E}_p) \\ \boldsymbol{Q}' &= \texttt{ConvBlock}(\texttt{FFN}_\texttt{q}(\boldsymbol{Q}) + \boldsymbol{E}_p) \end{aligned} \tag{1}$$

where $\boldsymbol{V}' \in \mathbb{R}^{d \times N}$ and $\boldsymbol{Q}' \in \mathbb{R}^{d \times M}$; $\boldsymbol{E}_p$ denotes the positional embeddings. Both position embeddings and convolutional block are shared by the video and text features.

3.1.2 Self-Guided Parallel Attention Module

A self-guided parallel attention (SGPA) module (see Figure 4) is proposed to improve multimodal representation learning. Compared with standard transformer (TRM) encoder, SGPA uses two parallel multi-head attention blocks to learn both *uni-modal* and *cross-modal* representations simultaneously, and merge them with a cross-gating strategy[4].

---

[3] We denote the single-layer feed-forward network as FFN ($\texttt{FFN}(\boldsymbol{X}) = \boldsymbol{W} \cdot \boldsymbol{X} + \boldsymbol{b}$) in this work.

[4] A detailed comparison of SGPA and standard TRMs is summarized in Appendix.

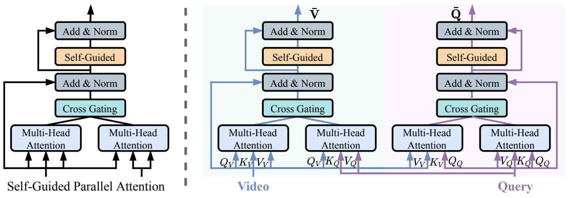

Figure 4: Self-Guided Parallel Attention (SGPA). Left: the structure of SGPA; Right: the parallel streams of encoding visual and textual inputs.

Taking video modality as an example, the attention process is computed as:

$$\begin{aligned}\hat{\boldsymbol{V}}_{\text{S}} &= V_V \cdot \sigma_s\Big(\frac{Q_V^\top K_V}{\sqrt{d}}\Big)\\ \hat{\boldsymbol{V}}_{\text{C}} &= V_Q \cdot \sigma_s\Big(\frac{Q_V^\top K_Q}{\sqrt{d}}\Big)\end{aligned} \tag{2}$$

where σ_s denotes Softmax function; Q_V, K_V and V_V are the linear projections of $\boldsymbol{V'}$; Q_Q, K_Q and V_Q are linear projections of $\boldsymbol{Q'}$; $\hat{\boldsymbol{V}}_{\text{S}}$ encodes the self-attentive contexts within video modality; and $\hat{\boldsymbol{V}}_{\text{C}}$ integrates information from query modality according to cross-modal attentive relations. The self- and cross-modal representations are then merged together by a cross-gating strategy:

$$\hat{\boldsymbol{V}} = \sigma\big(\texttt{FFN}(\hat{\boldsymbol{V}}_{\text{C}})\big) \odot \hat{\boldsymbol{V}}_{\text{S}} + \sigma\big(\texttt{FFN}(\hat{\boldsymbol{V}}_{\text{S}})\big) \odot \hat{\boldsymbol{V}}_{\text{C}} \tag{3}$$

where σ denotes Sigmoid function and $\odot$ represents Hadamard product. The cross-gating explicitly interacts features obtained from the self- and cross-attention encoders to ensure both are fully utilized, instead of relying on only one of them. Finally, we employ a self-guided head to implicitly emphasize the informative representations by measuring the confidence of each element in $\hat{\boldsymbol{V}}$ as:

$$\bar{\boldsymbol{V}} = \sigma\big(\texttt{FFN}_\sigma(\hat{\boldsymbol{V}})\big) \odot \texttt{FFN}(\hat{\boldsymbol{V}}) \tag{4}$$

The refined representations $\bar{\boldsymbol{Q}}$ for the query modality are obtained in a similar manner (*e.g.,* swapping visual and query features).

3.1.3 Video-Query Integration Module

This module further enhances the cross-modal interactions between visual and textual features. It utilizes context-query attention (CQA) strategy (Yu et al., 2018) and aggregates text information for each visual element[5] (see Figure 3). Given $\bar{\boldsymbol{V}}$ and $\bar{\boldsymbol{Q}}$, CQA first computes the similarities, $\mathcal{S} \in \mathbb{R}^{N\times M}$, between each pair of $\bar{\boldsymbol{V}}$ and $\bar{\boldsymbol{Q}}$ features. Then two attention weights are derived by $\mathcal{A}_{\text{VQ}} = \mathcal{S}_r \cdot \bar{\boldsymbol{Q}}^\top$ and $\mathcal{A}_{\text{QV}} = \mathcal{S}_r \cdot \mathcal{S}_c^\top \cdot \bar{\boldsymbol{V}}^\top$, where $\mathcal{S}_r$/$\mathcal{S}_c$ are row-/column-wise normalization of $\mathcal{S}$ by Softmax. The query-aware video representations $\boldsymbol{V}^Q$ is computed by:

$$\boldsymbol{V}^Q = \texttt{FFN}\big([\bar{\boldsymbol{V}}; \mathcal{A}_{\text{VQ}}^\top; \bar{\boldsymbol{V}} \odot \mathcal{A}_{\text{VQ}}^\top; \bar{\boldsymbol{V}} \odot \mathcal{A}_{\text{QV}}^\top]\big) \tag{5}$$

where $\boldsymbol{V}^Q \in \mathbb{R}^{d\times N}$. Similarly, video-aware query representations $\boldsymbol{Q}^V \in \mathbb{R}^{d\times M}$ can be derived by swapping visual and textual inputs in CQA module. Then we encode $\boldsymbol{Q}^V$ into sentence representation $\boldsymbol{q}$ with additive attention (Bahdanau et al., 2015) and concatenate it with each element of $\boldsymbol{V}^Q$ as $\boldsymbol{H} = [\boldsymbol{h}_1, \dots, \boldsymbol{h}_n]$, where $\boldsymbol{h}_i = [\boldsymbol{v}_i^Q; \boldsymbol{q}]$. Finally, the query-attended visual representation is computed as $\bar{\boldsymbol{H}} = \texttt{FFN}(\boldsymbol{H}) \in \mathbb{R}^{d\times N}$.

3.1.4 Sequence Matching Module

As illustrated in Figure 3, we considers the frames within ground truth moment and several neighboring frames as foreground, while the rest as background. Then, we split the foreground into **B**egin, **I**nside, and **E**nd regions. For simplicity, we assign each region a label, *i.e.,* "B-M" for begin, "I-M" for inside, "E-M" for end region, and "O" for background. B-M/E-M explicitly indicate potential positions of the start/end boundaries. We also specify orthogonal label embeddings $\boldsymbol{E}_{\text{lab}} \in \mathbb{R}^{d\times 4}$ to represent those labels, and to infuse label information into visual features after region label predictions.

Note our approach is different from Lin et al. (2018) on temporal action proposal generation task, where the target proposal is split into start, centre, and end regions. The probability of a frame belonging to each of three regions is predicted separately in a regression manner, leading to three separate probability sequences, one for each region. The maximum probabilities in the sequences are used to guide proposal generations. In contrast, we formulate matching process as a multi-class classification problem and predict a concrete region label for each frame, *i.e.,* same as a sequence labeling task in NLP. Label embeddings are then assigned to the frames based on the labels of the predicted region.

A straightforward solution to predict the confidence of an element belonging to each region is multi-class classifier:

$$\boldsymbol{H}_{\text{seq}} = \texttt{FFN}_{\text{seq}}(\bar{\boldsymbol{H}}), \quad \boldsymbol{S}_{\text{seq}} = \sigma_s(\boldsymbol{H}_{\text{seq}}) \in \mathbb{R}^{4\times N} \tag{6}$$

where $\boldsymbol{S}_{\text{seq}}$ encodes the probabilities of each visual element in different regions. Then label index with

---

[5] We provide a detailed computation process in appendix.

highest probability from $\boldsymbol{S}_{\text{seq}}$ is selected to represent the predicted label for each visual element:

$$\boldsymbol{L}_{\text{lab}} = [\arg\max(\boldsymbol{S}_{\text{seq}}^{j})]_{j=0}^{N-1} \in \mathbb{R}^{N} \tag{7}$$

However, a major issue here is that Eq. 7 needs to sample from a discrete probability distribution, which makes the back-propagation of gradients through $\boldsymbol{S}_{\text{seq}}$ in Eq. 6 infeasible for optimizer. To make back-propagation possible, we adopt the Gumbel-Max (Gumbel, 1954; Maddison et al., 2014) trick to re-formulate Eq. 7 as:

$$\hat{\boldsymbol{L}}_{\text{lab}} = \left[\texttt{Onehot}(\arg\max(\boldsymbol{H}_{\text{seq}}^{j} + \boldsymbol{g}))\right]_{j=0}^{N-1} \tag{8}$$

where $\hat{\boldsymbol{L}}_{\text{lab}} \in \mathbb{R}^{4\times N}$. Then, we utilize the Gumbel-Softmax (Jang et al., 2017; Maddison et al., 2017) to relax the $\arg\max$ so as to make Eq. 8 being differentiable[6]. Formally, we use Eq. 9 to approximate Eq. 8 as:

$$\bar{\boldsymbol{L}}_{\text{lab}} = \sigma_s\big((\boldsymbol{H}_{\text{seq}} + \boldsymbol{g})/\tau\big) \in \mathbb{R}^{4\times N} \tag{9}$$

where τ is annealing temperature. As $\tau \rightarrow 0^{+}$, $\bar{\boldsymbol{L}}_{\text{lab}} \approx \hat{\boldsymbol{L}}_{\text{lab}}$, while $\tau \rightarrow \infty$, each element in $\bar{\boldsymbol{L}}_{\text{lab}}$ will be the same and the approximated distribution will be smooth. Note we use Eq. 8 during forward pass while Eq. 9 for backward pass to allow gradient back-propagation. As the result, the embedding lookup process is differentiable and the label-attended visual representations is derived as:

$$\widetilde{\boldsymbol{H}} = \boldsymbol{E}_{\text{lab}} \cdot \hat{\boldsymbol{L}}_{\text{lab}} + \bar{\boldsymbol{H}} \tag{10}$$

The training objective is defined as:

$$\mathcal{L}_{\text{seq}} = f_{\text{XE}}(\bar{\boldsymbol{L}}_{\text{lab}}, \boldsymbol{Y}_{\text{lab}}) + \|\boldsymbol{E}_{\text{lab}}^{\top}\boldsymbol{E}_{\text{lab}} \odot (\boldsymbol{1} - \boldsymbol{I})\|_{\text{F}}^{2} \tag{11}$$

where $\boldsymbol{Y}_{\text{lab}}$ denotes the ground truth sequence labels, $\boldsymbol{1}$ is the matrix with all elements being 1 and $\boldsymbol{I}$ is the identity matrix. The second term in Eq. 11 is the orthogonal regularization (Brock et al., 2019), which ensures $\boldsymbol{E}_{\text{lab}}$ to keep the orthogonality.

3.1.5 Localization Module

Finally, we present a conditioned localizer to predict the start and end boundaries of the target moment. The localizer consists of two stacked transformer blocks and two FFNs. The scores of start and end boundaries are calculated as:

$$\begin{aligned} \boldsymbol{H}_{\text{s}} &= \texttt{TRM}_s(\widetilde{\boldsymbol{H}}),\ \boldsymbol{S}_s = \boldsymbol{W}_s[\boldsymbol{H}_{\text{s}}; \widetilde{\boldsymbol{H}}] + \boldsymbol{b}_s \\ \boldsymbol{H}_{\text{e}} &= \texttt{TRM}_e(\boldsymbol{H}_{\text{s}}),\ \boldsymbol{S}_e = \boldsymbol{W}_e[\boldsymbol{H}_{\text{e}}; \widetilde{\boldsymbol{H}}] + \boldsymbol{b}_e \end{aligned} \tag{12}$$

where $\boldsymbol{S}_{s/e} \in \mathbb{R}^{N}$. $\boldsymbol{W}_{s/e}$ and $\boldsymbol{b}_{s/e}$ are the weight and bias of start/end FFNs, respectively. Note the representations of end boundary ($\boldsymbol{H}_{\text{e}}$) are conditioned on that of start boundary ($\boldsymbol{H}_{\text{s}}$) to ensure the predicted end boundary is always after start boundary. Then, the probability distributions of start/end boundaries are computed by $\boldsymbol{P}_{s/e} = \texttt{Softmax}(\boldsymbol{S}_{s/e}) \in \mathbb{R}^{N}$. The training objective is:

$$\mathcal{L}_{\text{loc}} = \frac{1}{2} \times \left[f_{\text{XE}}(\boldsymbol{P}_s, \boldsymbol{Y}_s) + f_{\text{XE}}(\boldsymbol{P}_e, \boldsymbol{Y}_e)\right] \tag{13}$$

where f_{XE} is cross-entropy function, $\boldsymbol{Y}_{s/e}$ is one-hot labels for start/end (i^s/i^e) boundaries.

3.2 Training and Inference

The overall training loss of SeqPAN is: $\mathcal{L} = \mathcal{L}_{\text{loc}} + \mathcal{L}_{\text{seq}}$, to be minimized during the training process. During inference, the predicted start and end boundaries of a given video-query pair are generated by maximizing the joint probability as:

$$\begin{aligned} (\hat{i}^s, \hat{i}^e) &= \arg\max_{\hat{a}^s, \hat{a}^e} \boldsymbol{P}_s(\hat{a}^s) \times \boldsymbol{P}_e(\hat{a}^e) \\ &\text{s.t.: } 0 \leq \hat{i}^s \leq \hat{i}^e \leq N-1 \end{aligned} \tag{14}$$

where $\hat{i}^s$ and $\hat{i}^e$ are the best start and end boundaries of predicted moment for the given video-query pair. Let $\mathcal{T}$ be the duration of given video, the predicted start/end time are computed by $\hat{t}^{s(e)} = \hat{i}^{s(e)}/(N-1) \times \mathcal{T}$. With the predicted $(\hat{t}^s, \hat{t}^e)$ and ground truth (t^s, t^e) time intervals, the measure, temporal intersection over union (IoU), is computed as:

$$\text{IoU} = \max\left(0, \frac{t^e_{\text{min}} - t^s_{\text{max}}}{t^e_{\text{max}} - t^s_{\text{min}}}\right) \in [0, 1] \tag{15}$$

where $t^{s(e)}_{\text{min}\,/\,\text{max}} = \min / \max(\hat{t}^{s(e)}, t^{s(e)})$.

4 Experiments

4.1 Experimental Setting

Datasets. We conduct the experiments on three benchmark datasets: Charades-STA (Gao et al., 2017), ActivityNet Captions (Krishna et al., 2017) and TACoS (Regneri et al., 2013). **Charades-STA**, collected by Gao et al. (2017) from Charades (Sigurdsson et al., 2016) dataset, contains $16,128$ annotations (*i.e.,* moment-query pairs), where $12,408$ and $3,720$ annotations are for train and test. **ActivityNet Captions** (**ANetCaps**) contains 20K videos taken from ActivityNet (Heilbron et al., 2015) dataset. We follow the setup in (Chen et al., 2020a; Lu et al., 2019a; Wu et al., 2020b; Yuan

et al., 2019b; Zhang et al., 2020a) with $37,421$ and $17,505$ annotations for train and test. **TACoS** contains 127 cooking activities videos from Rohrbach et al. (2012). We follow Gao et al. (2017) with $10,146$, $4,589$, and $4,083$ annotations are used for train, validation, and test, respectively.

Evaluation Metric. (i) "R@n, IoU=μ", which denotes the percentage of test samples that have at least one result whose IoU with ground-truth is larger than μ in top-n predictions; (ii) "mIoU", which denotes the average IoU over all test samples. We set $n = 1$ and $\mu \in \{0.3, 0.5, 0.7\}$.

Implementation Details. We follow (Ghosh et al., 2019; Mun et al., 2020; Rodriguez et al., 2020; Zhang et al., 2020a) and use 3D ConvNet pretrained on Kinetics dataset (Carreira and Zisserman, 2017) to extract RGB visual features from videos; then we downsample the feature sequence to a fixed length. The query words are lowercased and initialized with GloVe (Pennington et al., 2014) embedding. We set hidden dimension d to 128; SGPA blocks to 2; annealing temperature to 0.3; and heads in multi-head attention to 8; Adam (Kingma and Ba, 2015) optimizer with batch size of 16 and learning rate of 0.0001 is used for training.

More details of dataset statistics and the hyperparameter settings are summarized in Appendix.

4.2 Comparison with State-of-the-Arts

We compare SeqPAN with the following state-of-the-arts. 1) *Proposal-based* methods: TGN (Chen et al., 2018), ACL (Ge et al., 2019), CBP (Wang et al., 2020b), SCDM (Yuan et al., 2019a), MAN (Zhang et al., 2019a); 2) *Proposal-free* methods: DEBUG (Lu et al., 2019a), ExCL (Ghosh et al., 2019), VSLNet (Zhang et al., 2020a), GDP (Chen et al., 2020a), LGI (Mun et al., 2020), TMLGA (Rodriguez et al., 2020), DRN (Zeng et al., 2020); 3) *Others*: TSP-PRL (Wu et al., 2020b) and 2D-TAN (Zhang et al., 2020b). The best results are in **bold** and the second bests are in *italic*. In all result tables, the scores of compared methods are reported in the corresponding works.

The results on the Charades-STA are summarized in Table 1. SeqPAN surpasses all baselines and achieves the highest scores over all metrics. Observe that the performance improvements of SeqPAN are more significant under more strict metrics. The results show that SeqPAN can produce more precise localization results. For instance, compared to LGI, SeqPAN achieves 5.86% absolute improvement by "R@1, IoU=0.7", and 1.40% by "R@1, IoU=0.5". Table 2 reports the results on ANetCaps. SeqPAN is superior to baselines and achieves the best performance on "R@1, IoU=0.7" and mean IoU. As reported in Table 3, similar observations hold on TACoS. Note 2D-TAN (Zhang et al., 2020b) pre-processes the TACoS dataset, making it is slightly different from the original one. We also conduct experiments on their version for a fair comparison. SeqPAN outperforms the base-

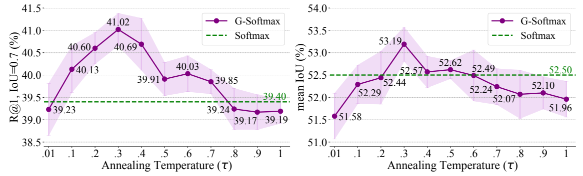
lines over all evaluation metrics on both versions.

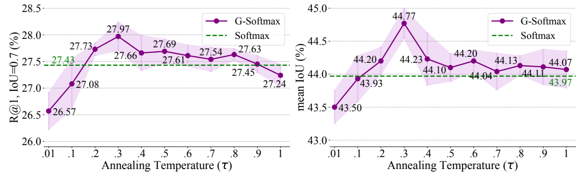
4.3 Discussion and Analysis

We perform in-depth ablation studies to analyze the effectiveness of the SeqPAN. We run all the experiments 5 times and report 5-run average.

Analysis on Self-Guided Parallel Attention. The SGPA (see Figure 4) is a variant of transformer (TRM), designed for learning cross-modality interactions between visual and text features. Here, we compare SGPA with standard TRMs. To better reflect the performance of different TRMs, we remove the sequence matching component and only use a single block (*i.e.,* $N_{\text{SGPA}} = 1$) in this experiment. The results are reported in Table 4. Observe that SGPA is superior to TRMs on both datasets. Co-TRM performs better on Charades-STA but worse on ANetCaps comparing with Se-TRM. Compared to Se-TRM and Co-TRM, SGPA learns both self-modal contexts and cross-modal interactions, which is approximately equivalent to parallel connection of two modules.

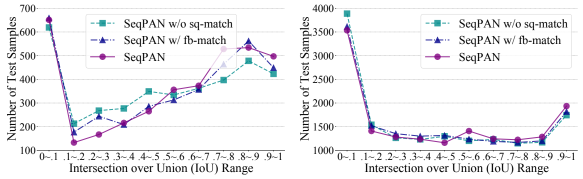


(a) Charades-STA



(b) ActivityNet Captions

Figure 6: The impact of annealing temperature τ in sequence matching on Charades-STA and ANetCaps.



(a) Charades-STA (b) ActivityNet Captions

Figure 7: Plots of the number of predicted test samples within different IoU ranges on Charades-STA and ANetCaps.

Impact of SGPA block numbers N_{SGPA}. We now study the impact of SGPA block numbers on Charades-STA and ANetCaps. We evaluate five different values of N_{SGPA} from 1 to 5. The performance across the number of SGPA blocks in SeqPAN are plotted in Figures 5(a) and 5(b). Best performance is achieved at $N_{\text{SGPA}} = 2$ on both datasets. In general, along with increasing N_{SGPA}, the performance of SeqPAN first increases and then gradually decreases, on both datasets. We also note that performance on Charades-STA is not very sensitive to the setting of N_{SGPA}.

Analysis on Sequence Matching. The conventional matching strategy (Yuan et al., 2019b; Lu et al., 2019a; Mun et al., 2020) (denoted by fb-match) is to predict whether a frame is inside or outside of target moment, *i.e.,* foreground or background. In SeqPAN, we predict begin-, inside- and end-regions, and introduce label embeddings ($\boldsymbol{E}_{\text{lab}}$) to represent each region. The prediction process also uses the Gumbel-Max trick. In this experiment, we analyze the effects of label embeddings and Gumbel-Max trick in sequence matching.

Summarized in Table 5, both Gumbel-Max trick (denoted by G) and label embeddings contribute

Method	sq-match		Charades-STA				ActivityNet Captions			
			R@1, IoU $= \mu$			mIoU	R@1, IoU $= \mu$			mIoU
	G	$\boldsymbol{E}_{\text{lab}}$	$\mu = 0.3$	$\mu = 0.5$	$\mu = 0.7$		$\mu = 0.3$	$\mu = 0.5$	$\mu = 0.7$	
SeqPAN w/ fb-match	-	-	70.27(0.75)	56.96(0.46)	38.95(0.27)	51.84(0.40)	*59.99*(0.25)	43.71(0.19)	26.72(0.29)	43.23(0.23)
SeqPAN w/o sq-match	✘	✘	69.62(0.54)	55.29(0.30)	36.71(0.48)	51.13(0.25)	59.03(0.35)	42.65(0.32)	26.29(0.13)	42.51(0.36)
SeqPAN w/ Gumbel	✔	✘	*71.64*(0.64)	*57.61*(0.26)	*39.26*(0.31)	*52.15*(0.45)	59.74(0.42)	*43.85*(0.35)	*27.12*(0.20)	*43.69*(0.24)
SeqPAN	✔	✔	**72.70**(0.51)	**60.15**(0.50)	**41.02**(0.36)	**53.19**(0.38)	**61.12**(0.39)	**45.09**(0.37)	**27.97**(0.27)	**44.77**(0.23)

Table 5: Ablation studies of sequence matching strategy in SeqPAN, where the values in bracket denote standard deviation.

to the grounding performance improvement. In addition, consistent improvements are observed by incorporating G and $\boldsymbol{E}_{\text{lab}}$ into the model. SeqPAN is superior to SeqPAN w/ fb-match over all evaluation metrics. The performance improvements are more significant under more strict metrics. The results show that sq-match is more effective than the fb-match strategy. Regional indication of potential positions of start/end boundaries does help the model to produce accurate predictions.

Impact of Annealing Temperature τ. We then analyze the impact of annealing temperature τ of Gumbel-Softmax in sequence matching module. Gumbel-Softmax distributions are identical to a categorical distribution when $\tau \to 0^+$. With $\tau \to \infty$, its distribution is smooth. We evaluate 11 different τ values from 0.01 to 1.0, where 0.01 is used to approximate 0.0 since 0.0 is not divisible. The results are compared against vanilla Softmax as a baseline. For vanilla Softmax, we multiply the probability distribution of labels with $\boldsymbol{E}_{\text{lab}}$, to aggregate label information into the visual representations.

Figure 6 plots the results of different τ's on Charades-STA and ANetCaps, respectively. We observe similar patterns on the four sets of results. The best performance is achieved when $\tau = 0.3$ over both metrics on both datasets. From Figure 6(a), when τ is too small or too large (*i.e.,* the probability distribution from Gumbel-Softmax becomes too sharp or too smooth), Gumbel-Softmax performs poorer than vanilla Softmax. This result suggests that a proper annealing temperature τ is crucial to achieve good performance. Similar observations hold on ANetCaps (see Figure 6(b)).

4.4 Qualitative Analysis

Figure 7 shows the number of predicted test samples within different IoU ranges on Charades-STA and ANetCaps. Here, we compare SeqPAN with two of its variants: (i) removal of sequence matching module, and (ii) replacement of sequence matching with fb-match. All three variants show similar patterns. Nevertheless, within the higher IoU ranges, *e.g.,* IoU ≥ 0.5 on both datasets, SeqPAN and the variant with fb-match outperform the variant without sequence matching. The results show that having auxiliary objectives (*e.g.,* foreground/background or sequential regions) is helpful in video grounding task. Results in Figure 7 also show that our sequence matching is more effective than fb-match, for highlighting the correction regions for predicting start/end boundaries.

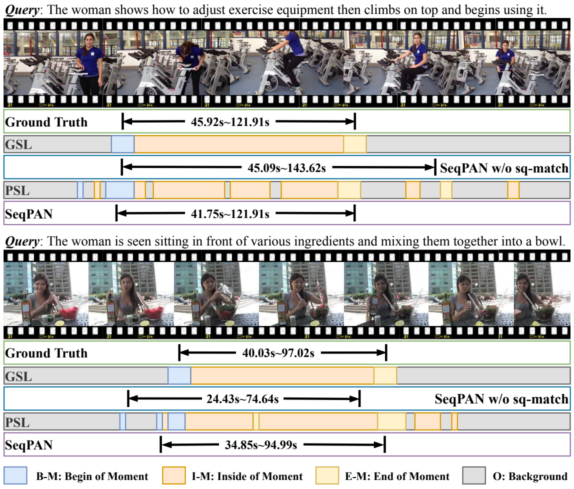


Figure 8: Qualitative results of SeqPAN and SeqPAN w/o sq-match on ANetCaps. "GSL" is the ground truth sequence labels; "PSL" is the predicted labels by sq-match of SeqPAN.

Figure 8 depicts two video grounding examples from the ANetCaps dataset. From the two examples, the moments retrieved by SeqPAN are closer to the ground truth than that are retrieved by SeqPAN without utilizing the sq-match strategy. Besides, the start and end boundaries predicted by SeqPAN are roughly constrained within the pre-set potential start and end regions. In addition, the predicted sequence labels (PSL) in Figure 8 also reveal the weakness of sq-match strategy. The predicted labels by sq-match strategy are not continuous, where multiple start, inside, and end regions are generated. In consequence, the localizer may be affected by wrongly predicted regions and leads to inaccurate results. To further constrain the generated regions is part of our future work.

5 Conclusion

In this work, we propose a Parallel Attention Network with Sequence matching (SeqPAN) to address the language query-based video grounding problem. We design a parallel attention module to improve the multimodal representation learning by capturing both self- and cross-modal attentive information simultaneously. In addition, we propose a sequence matching strategy, which explicitly indicates the potential start and end regions of the target moment to allow the localizer precisely predicting the boundaries. Through extensive experimental studies, we show that SeqPAN outperforms the state-of-the-art methods on three benchmark datasets; and both the proposed parallel attention and sequence matching modules contribute to the grounding performance improvement.

This appendix contains two sections. Section A provides (A.1) a detailed comparison between the proposed SGPA and standard transformer blocks, (A.2) technical details of the video-query integration module, and (A.3) categorical reparameterization used in the sequence matching module. Section B describes statistics on the benchmark datasets and parameter settings in our experiments.

A Additional Comparison and Technical Details

A.1 SGPA versus Standard Transformers

Two ways are mainly used to adopt the transformer block for multi-modal representation learning:

- Transformer block with the self-attention (Se-TRM), which encodes visual and textual inputs in separate streams, shown in Figure 9(a).
- Transformer block with the cross-attention (Co-TRM), which encodes both visual and textual inputs with interactions through co-attention, shown in Figure 9(b).

Several works (Lu et al., 2019a; Chen et al., 2020a; Zhang et al., 2020a) adopt Se-TRM to learn visual and textual representations in video grounding task. Se-TRM separately encodes each modality, it focuses on learning the refined unimodal representations within each modality for video and text respectively. Without any connection between two modalities, Se-TRM cannot use information from other modality to improve the representations.

Co-TRM[7] is commonly used as a basic component in various vision-language methods (Tan and Bansal, 2019; Lu et al., 2019b; Lei et al., 2020). Co-TRM relies on co-attention to learn the cross-modal representations for both visual and textual inputs. However, Co-TRM lacks the ability to encode self-attentive context within each modality.

The cascade of Se-TRM and Co-TRM is also used in recent vision-language models (Tan and Bansal, 2019; Lu et al., 2019b; Zhu and Yang, 2020; Lei et al., 2020) to learn both unimodal and cross-modal representations. In general, there are two cascade forms: 1) stacking Co-TRM upon Se-TRM (SeCo-TRM) in Figure 10(a); and 2) stacking Se-TRM upon Co-TRM (CoSe-TRM) in Figure 10(b). These stacked TRMs learn the unimodal and cross-modal information in a sequence manner. Hence, their final outputs focus more on either the self-attentive contexts or cross-modal interactions. Our SGPA combines advantages of both Se-TRM and Co-TRM, but not through cascade. As shown in Figure 9(c), SGPA contains two parallel multi-head attention blocks. One block takes single modality as input and the other takes both modalities as inputs. Thus, SGPA is able to learn both unimodal and cross-modal representations simultaneously. Then, a cross-gating strategy is designed to fuse the self- and cross-attentive representations. We also employ a self-guided head to replace the feed forward layer in transformer block. This design implicitly emphasizes informative representations by measuring the confidence of each element.

Methods	R@1, IoU $= \mu$		
	$\mu = 0.3$	$\mu = 0.5$	$\mu = 0.7$
Charades-STA			
Se-TRM	68.84 (0.46)	51.92 (0.54)	34.58 (0.18)
Co-TRM	69.03 (0.49)	52.34 (0.50)	35.07 (0.32)
SeCo-TRM	69.11 (0.24)	52.63 (0.49)	35.17 (0.22)
CoSe-TRM	69.08 (0.26)	52.82 (0.43)	35.09 (0.50)
PA	69.21 (0.27)	54.37 (0.46)	36.22 (0.49)
SGPA	69.47 (0.32)	54.63 (0.43)	36.36 (0.24)
ActivityNet Captions			
Se-TRM	57.64 (0.38)	40.76 (0.35)	25.10 (0.30)
Co-TRM	57.39 (0.29)	40.55 (0.45)	24.85 (0.47)
SeCo-TRM	57.47 (0.38)	40.70 (0.24)	25.07 (0.21)
CoSe-TRM	57.72 (0.41)	40.85 (0.17)	25.16 (0.15)
PA	58.27 (0.13)	41.59 (0.24)	25.88 (0.28)
SGPA	58.40 (0.31)	41.72 (0.19)	26.07 (0.16)

Table 6: Comparison between SGPA with standard transformer blocks on Charades-STA and ANetCaps, where PA is the SGPA without self-guided head (*i.e.,* replaced by FFN) The scores in bracket denotes standard deviation.

Table 6 reports the performance of SGPA and standard TRMs on Charades-STA and ANetCaps datasets. Here, we regard both SeCo-TRM and CoSe-TRM as single block. The results show that both PA (a SGPA variant without self-guided head) and SGPA are superior to standard TRMs.

A.2 Video-Query Integration Computation

This section presents the detailed computation process of video-query integration (see Section 3.1.3).

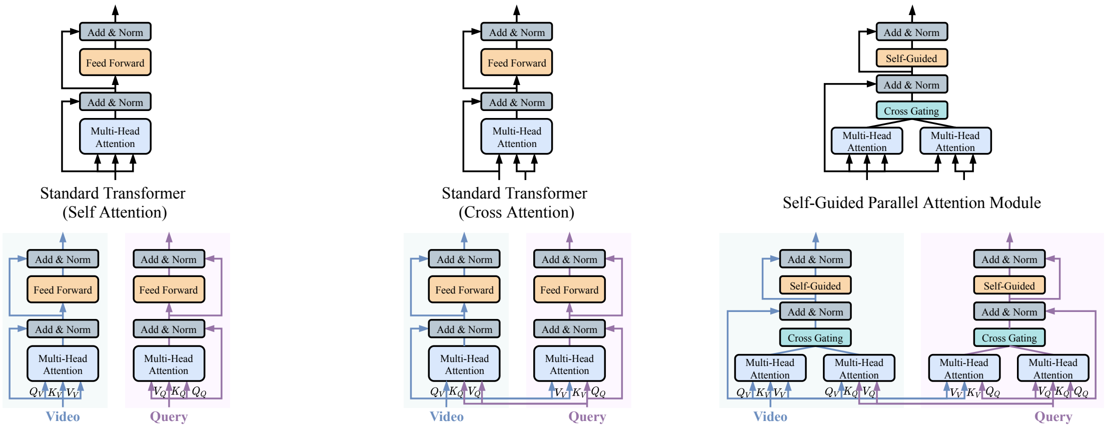
Given two inputs $\boldsymbol{X} \in \mathbb{R}^{d \times N_x}$ and $\boldsymbol{Y} \in \mathbb{R}^{d \times N_y}$, the context-query attention first computes similarities between each pair of $\boldsymbol{X}$ and $\boldsymbol{Y}$ elements as:

$$\mathcal{S} = \boldsymbol{X}^{\top} \cdot \boldsymbol{W} \cdot \boldsymbol{Y} \tag{16}$$

where $\boldsymbol{W} \in \mathbb{R}^{d \times d}$ and $\mathcal{S} \in \mathbb{R}^{N_x \times N_y}$. Then X-to-Y and Y-to-X attention weights are computed by:

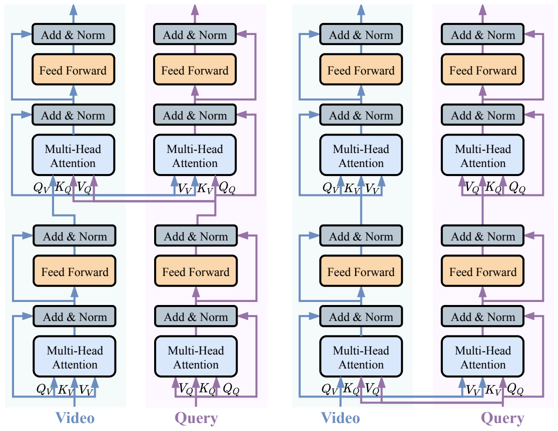
---

[7] It is also known as co-attentional, multi-modal or cross-modal transformer block in different works.



(a) Transformer Block (Self Attn) (b) Transformer Block (Cross Attn) (c) Self Guided Parallel Attention (Ours)

Figure 9: The structures of standard transformer blocks and self-guided parallel attention module. Top: the structure of each module; Bottom: the parallel streams of encoding visual and textual inputs. (a) The standard transformer block with self-attention; (b) The standard transformer block with cross-attention; (c) The self-guided parallel attention (SGPA) module.



(a) SeCo-TRM Block (b) CoSe-TRM Block

Figure 10: The structures of SeCo-TRM and CoSe-TRM.

$$\mathcal{A}_{\text{XY}} = \mathcal{S}_r \cdot \boldsymbol{Y}^\top \in \mathbb{R}^{N_x \times d}$$
$$\mathcal{A}_{\text{YX}} = \mathcal{S}_r \cdot \mathcal{S}_c^\top \cdot \boldsymbol{X}^\top \in \mathbb{R}^{N_x \times d} \tag{17}$$

where $\mathcal{S}_r$ and $\mathcal{S}_c$ are the row- and column-wise normalization of $\mathcal{S}$ by Softmax function. The final output of context-query attention is calculated as:

$$\boldsymbol{X}^Y = \texttt{FFN}\big([\boldsymbol{X}; \mathcal{A}_{\text{XY}}^\top; \boldsymbol{X} \odot \mathcal{A}_{\text{XY}}^\top; \boldsymbol{X} \odot \mathcal{A}_{\text{YX}}^\top]\big) \tag{18}$$

where $\odot$ denotes element-wise multiplication, ";" represents concatenation operation, and $\boldsymbol{X}^Y \in \mathbb{R}^{d \times N_x}$. In this way, the information of $\boldsymbol{Y}$ is properly fused into $\boldsymbol{X}$.

By setting $\boldsymbol{X} = \bar{\boldsymbol{V}} \in \mathbb{R}^{d \times N}$ and $\boldsymbol{Y} = \bar{\boldsymbol{Q}} \in \mathbb{R}^{d \times M}$, we can derive the query-aware video representations $\boldsymbol{V}^Q \in \mathbb{R}^{d \times N}$. Similarly, the video-aware query representations $\boldsymbol{Q}^V \in \mathbb{R}^{d \times M}$ is obtained by setting $\boldsymbol{X} = \bar{\boldsymbol{Q}}$ and $\boldsymbol{Y} = \bar{\boldsymbol{V}}$.

Next, we encode $\boldsymbol{Q}^V = [\boldsymbol{q}_0^V, \ldots, \boldsymbol{q}_{M-1}^V]$ into sentence representation $\boldsymbol{q}$ with additive attention:

$$\boldsymbol{\alpha} = \texttt{Softmax}\big(\boldsymbol{W}_\alpha \cdot \boldsymbol{Q}^V)\big) \in \mathbb{R}^M$$
$$\boldsymbol{q} = \sum_{i=0}^{M-1} \alpha_i \times \boldsymbol{q}_i^V \in \mathbb{R}^d \tag{19}$$

where $\boldsymbol{W}_\alpha \in \mathbb{R}^{1 \times d}$. The $\boldsymbol{q}$ is then concatenated with each element of $\boldsymbol{V}^Q$ as $\boldsymbol{H} = [\boldsymbol{h}_1, \ldots, \boldsymbol{h}_n] \in \mathbb{R}^{2d \times N}$, where $\boldsymbol{h}_i = [\boldsymbol{v}_i^Q; \boldsymbol{q}]$. Finally, the query-attended visual representation is computed as

$$\bar{\boldsymbol{H}} = \boldsymbol{W}_h \cdot \boldsymbol{H} + \boldsymbol{b}_h \tag{20}$$

where $W_h \in \mathbb{R}^{d \times 2d}$ and $b_h \in \mathbb{R}^d$ denote the learnable weight and bias, and $\bar{\boldsymbol{H}} \in \mathbb{R}^{d \times N}$.

A.3 Categorical Reparameterization

This section provides a brief introduction of the categorical reparameterization strategy used in sequence matching module (see Section 3.1.4).

Categorical reparameterization, *e.g.,* reinforce-based approaches (Sutton et al., 2000; Schulman et al., 2015), straight-through estimators (Bengio et al., 2013) and Gumbel-Softmax (Jang et al., 2017; Maddison et al., 2017), is a strategy that enables discrete categorical variables to back-propagate in neural networks. It aims to estimate smooth gradient with a continuous relaxation for categorical variable. In this work, we use Gumbel-Softmax to approximate the sequence labels from a probability distribution. Then those labels are applied to lookup the corresponding embeddings for region representation in the sequence matching module of SeqPAN.

Dataset	Domain	N_{V} (train/val/test)	N_{A} (train/val/test)	$\bar{N}_{\text{A/V}}$	N_{Vocab}	$\bar{L}_V$ (s)	$\bar{L}_Q$	$\bar{L}_M$ (s)
Charades-STA	Indoors	$5,338$/-/$1,334$	$12,408$/-/$3,720$	2.42	$1,303$	30.59	7.22	8.22
ActivityNet Captions	Open	$10,009$/-/$4,917$	$37,421$/-/$17,505$	3.68	$12,460$	117.61	14.78	36.18
TACoS (Gao et al., 2017)	Cook	$75/27/25$	$10,146/4,589/4,083$	148.17	$2,033$	287.14	10.05	5.45
TACoS (Zhang et al., 2020b)			$9,790/4,436/4,001$	143.52	$1,983$	287.14	9.42	25.26

Table 7: Statistics of the evaluated video grounding benchmark datasets, where N_{V} is number of videos, N_{A} is number of annotations, $\bar{N}_{\text{A/V}}$ denotes the average number of annotations per video, N_{Vocab} is the vocabulary size of lowercase words, $\bar{L}_V$ denotes the average length of videos in seconds, $\bar{L}_Q$ denotes the average number of words in the sentence queries and $\bar{L}_M$ represents the average length of temporal moments in seconds.

Let $\boldsymbol{x} = (x_1, \ldots, x_l)$ be a categorical distribution, where l is the number of categories, x_c is the probability score of category c and $\sum_{c=1}^{l} x_c = 1$. Given the *i.i.d.* Gumbel noise $\boldsymbol{g} = (g_1, \ldots, g_l)$ from $\texttt{Gumbel}(0, 1)$ distribution[8], the soft categorical sample can be computed as:

$$\boldsymbol{y} = \texttt{Softmax}\big((\log(\boldsymbol{x}) + \boldsymbol{g})/\tau\big) \qquad (21)$$

where $\tau > 0$ is annealing temperature, and Eq. 21 is referred as Gumbel-Softmax operation on $\boldsymbol{x}$. As $\tau \to 0^+$, $\boldsymbol{y}$ is equivalent to the Gumbel-Max form (Gumbel, 1954; Maddison et al., 2014) as:

$$\hat{\boldsymbol{y}} = \texttt{Onehot}\big(\arg\max(\log(\boldsymbol{x}) + \boldsymbol{g})\big) \qquad (22)$$

where $\hat{\boldsymbol{y}}$ is an unbiased sample from $\boldsymbol{x}$ and thus we can draw differentiable samples from the distribution during training. Note, when input $\boldsymbol{x}$ is unnormalized, the $\log(\cdot)$ operator in Eq. 21 and 22 shall be omitted (Jang et al., 2017; Dong and Yang, 2019). During inference, discrete samples can be drawn with the Gumbel-Max trick directly.

B Dataset and Parameter Settings

B.1 Dataset Statistics

The statistics of the evaluated benchmark datasets are summarized in Table 7. **Charades-STA** dataset consists of $6,672$ videos and $16,128$ annotations (*i.e.,* moment-query pairs) in total. **ActivityNet Captions (ANetCaps)** dataset is taken from the ActivityNet (Heilbron et al., 2015). The average duration is about 120 seconds and each video contains 3.68 annotations on average. **TACoS** dataset contains 127 cooking activities videos with average duration of 4.79 minutes, and $18,818$ annotations in total. We follow the same train/val/test split as Gao et al. (2017). Besides, Zhang et al. (2020b) pre-processes the TACoS dataset, hence their version is slightly different from the original version. Detailed statistics are summarized in Table 7.

B.2 Hyper-Parameter Settings

We follow (Ghosh et al., 2019; Mun et al., 2020; Rodriguez et al., 2020; Zhang et al., 2020a) and use 3D ConvNet pre-trained on Kinetics dataset (*i.e.,* I3D[9]) (Carreira and Zisserman, 2017) to extract visual features from videos. The maximal visual feature sequence lengths are set to 64, 100, and 256 for Charades-STA, ActivityNet Captions, and TACoS, respectively. This setting is based on the average video lengths in the three datasets. The feature sequence length of a video will be uniformly downsampled if it is larger than the pre-set threshold, or zero-padding otherwise. For the language queries, we lowercase all the words and initialize them with GloVe (Pennington et al., 2014) embeddings[10]. The word embeddings and extracted visual features are fixed during training.

For other hyper-parameters, we use the same settings for all datasets. The dimension of the hidden layers is 128; the head number in multi-head attention is 8; the number of SGPA blocks (N_{SGPA}) is 2; the annealing temperature τ of Gumbel-Softmax is 0.3; The Dropout (Srivastava et al., 2014) is 0.2. The maximal training epochs $E = 100$ is used, with batch size of 16 and early stopping tolerance of 10 epochs. We adopt Adam (Kingma and Ba, 2015) optimizer, with initial learning rate of $\beta_0 = 0.0001$, weight decay 0.01, and gradient clipping 1.0, to train the model. The learning rate decay strategy is defined as $\beta_e = \beta_0 \times (1 - \frac{e}{E})$, where e denotes the e-th training epoch.

The SeqPAN is implemented using TensorFlow `1.15.0` with CUDA `10.0` and cudnn `7.6.5`. All the experiments are conducted on a workstation with dual NVIDIA GeForce RTX 2080Ti GPUs.

MusicBERT: Symbolic Music Understanding with Large-Scale Pre-Training

Mingliang Zeng, Xu Tan*, Rui Wang, Zeqian Ju, Tao Qin, Tie-Yan Liu
Microsoft Research Asia
{v-minzeng,xuta,ruiwa,v-zeju,taoqin,tyliu}@microsoft.com

Abstract

Symbolic music understanding, which refers to the understanding of music from the symbolic data (e.g., MIDI format, but not audio), covers many music applications such as genre classification, emotion classification, and music pieces matching. While good music representations are beneficial for these applications, the lack of training data hinders representation learning. Inspired by the success of pre-training models in natural language processing, in this paper, we develop MusicBERT, a large-scale pre-trained model for music understanding. To this end, we construct a large-scale symbolic music corpus that contains more than 1 million music songs. Since symbolic music contains more structural (e.g., bar, position) and diverse information (e.g., tempo, instrument, and pitch), simply adopting the pre-training techniques from NLP to symbolic music only brings marginal gains. Therefore, we design several mechanisms, including OctupleMIDI encoding and bar-level masking strategy, to enhance pre-training with symbolic music data. Experiments demonstrate the advantages of MusicBERT on four music understanding tasks, including melody completion, accompaniment suggestion, genre classification, and style classification. Ablation studies also verify the effectiveness of our designs of OctupleMIDI encoding and bar-level masking strategy in MusicBERT.

1 Introduction

Music understanding, including tasks like genre classification, emotion classification, music pieces matching, has attracted lots of attention in both academia and industry. A better understanding of melody, rhythm, and music structure is not only beneficial for music information retrieval (Casey et al., 2008) but also helpful for music generation (Huang et al., 2018; Sheng et al., 2020). Similar to natural language, music is usually represented in symbolic data format (e.g., MIDI) (Jackendoff, 2009; McMullen and Saffran, 2004) with sequential tokens, and some methods (Mikolov et al., 2013a,b) from NLP can be adopted for symbolic music understanding. Since the labeled training data for each music understanding task is usually scarce, previous works (Liang et al., 2020; Chuan et al., 2020) leverage unlabeled music data to learn music token embeddings, similar to word embeddings in natural language tasks. Unfortunately, due to their shallow structures and limited unlabeled data, such embedding-based approaches have limited capability to learn powerful music representations.

In recent years, pre-trained language models (e.g., BERT) have been verified to be powerful for representation learning from large-scale unlabeled text corpora (Devlin et al., 2018; Radford et al., 2019; Yang et al., 2019; Song et al., 2019; Brown et al., 2020; Song et al., 2020). However, it is challenging to directly apply the pre-training techniques from NLP to symbolic music because of the difference between natural text data and symbolic music data. First, since music songs are more structural (e.g., bar, position) and diverse (e.g., tempo, instrument, and pitch), encoding symbolic music is more complicated than natural language. The existing pianoroll-like (Ji et al., 2020) and MIDI-like (Huang and Yang, 2020; Ren et al., 2020) representations of a song are too long to be processed by pre-trained models. For example, the length of a music song encoded by REMI (Huang and Yang, 2020) has an average length of 15,679, as shown in Table 1. Due to the limits of computational resources, the length of sequences processed by a Transformer model is usually cropped to below 1,000. Thus such representations cannot capture sufficient information for song-level tasks. Accord-

August 1–6, 2021.

ingly, an effective, efficient, and universal symbolic music encoding method is needed for music representation learning. Second, due to the complicated encoding of symbolic music, the pre-training mechanism (e.g., the masking strategy like the masked language model in BERT) should be carefully designed to avoid information leakage in pre-training. Third, as pre-training relies on large-scale corpora, the lack of large-scale symbolic music corpora limits the potential of pre-training for music understanding.

Encoding	OctupleMIDI	CP-like	REMI-like
Tokens	**3607**	6906	15679

Table 1: The average number of tokens per song on LMD dataset with different encoding methods.

In this paper, we develop MusicBERT, a large-scale pre-trained model with carefully designed music encoding and masking strategy for music understanding.

- We design a novel music encoding method called OctupleMIDI, which encodes each note into a tuple with 8 elements. These 8 elements represent the different aspects of the characteristics of a musical note, including time signature, tempo, bar, position, instrument, pitch, duration, and velocity. OctupleMIDI has several advantages: 1) It largely reduces the length of a music sequence (4x shorter than REMI (Huang and Yang, 2020) and 2x shorter than CP (Hsiao et al., 2021)), thus easing the modeling of music sequences by Transformer considering that music sequences themselves are very long. 2) It is note centric. Since each note contains the same 8-tuple structure and covers adequate information to express various music genres, such as changing time signature and long note duration, OctupleMIDI is much simpler and more universal than previous encoding methods.

- We carefully analyze the masking strategies for symbolic music understanding and propose a bar-level masking strategy for MusicBERT. The masking strategy in original BERT for NLP tasks randomly masks some tokens, which will cause information leakage in music pre-training. For example, some attributes are usually the same in a segment of consecutive tokens, such as time signature, tempo, instrument, bar, and position. Therefore, the masked tokens can be easily predicted by directly copying from the adjacent tokens since they are probably the same. Meanwhile, adjacent pitches usually follow the same chord so that a masked pitch token can be easily inferred from the adjacent tokens in the same chord. Therefore, we propose a bar-level masking strategy, which masks all the tokens of the same type (e.g., time signature, bar, instrument, or pitch) in a bar to avoid information leakage and encourage effective representation learning.

- Last but not least, we collect a large-scale and diverse symbolic music dataset, denoted as Million MIDI Dataset (MMD), that contains more than 1 million music songs, with different genres, including Rock, Electronic, Rap, Jazz, Latin, Classical, etc. To our knowledge, it is the largest in current literature, which is 10 times larger than the previous largest dataset LMD (Raffel, 2016) in terms of the number of songs as shown in Table 2. Thus, this dataset greatly benefits representation learning for music understanding.

We fine-tune the pre-trained MusicBERT on four downstream music understanding tasks, including melody completion, accompaniment suggestion, genre classification, and style classification, and achieve state-of-the-art results on all the tasks. Furthermore, ablation studies show the effectiveness of the individual components in MusicBERT, including the OctupleMIDI encoding, the bar-level masking strategy, and the large-scale corpus.

The main contributions of this paper are summarized as follows:

- We pre-train MusicBERT on a large-scale symbolic music corpus that contains more than 1 million music songs and fine-tune MusicBERT on some music understanding tasks, achieving state-of-the-art results.

- We propose OctupleMIDI, an efficient and universal music encoding for music understanding, which leads to much shorter encoding sequences and is universal for various kinds of music.

- We design a bar-level masking strategy as the pre-training mechanism for MusicBERT, which significantly outperforms the naive token-level masking strategy used in natural language pre-training.

2 Related Works

2.1 Symbolic Music Understanding

Inspired by word2vec (Mikolov et al., 2013a,b) in NLP, previous works on symbolic music understanding learn music embedding by predicting a music symbol based on its neighborhood symbols. Huang et al. (2016); Madjiheurem et al. (2016) regard chords as words in NLP and learn chords representations using the word2vec model. Herremans and Chuan (2017); Chuan et al. (2020); Liang et al. (2020) divide music pieces into non-overlapping music slices with a fixed duration and train the embeddings for each slice. Hirai and Sawada (2019) cluster musical notes into groups and regard such groups as words for representation learning. However, the word2vec-based approaches mentioned above only use relatively small neural network models and take only a few (usually 4-5) surrounding music tokens as inputs, which have limited capability compared with recently developed deep and big pre-trained models like BERT (Devlin et al., 2018), which takes a long sentence (e.g., with 512 words/tokens) as input. In this paper, we pre-train big/deep models over a large-scale music corpus and use more context as input to improve symbolic music understanding.

2.2 Symbolic Music Encoding

There are two main approaches to encode symbolic music: pianoroll-based and MIDI-based.

In pianoroll-based methods (Ji et al., 2020; Brunner et al., 2018), music is usually encoded into a 2-dimensional binary matrix, where one dimension represents pitches, and the other represents time steps. Each element in the matrix indicates whether the pitch is played at that time step. As a result, a note is always divided into multiple fixed intervals, which is inefficient, especially for long notes.

MIDI is a technical standard for transferring digital instrument data. Many works in symbolic music (Oore et al., 2020; Huang et al., 2018) encode music pieces based on MIDI events, including note-on, note-off, time-shift, etc. REMI (Huang and Yang, 2020) improves the basic MIDI-like encoding using note-duration, bar, position, chord, and tempo. Inspired by REMI (Huang and Yang, 2020), PopMAG (Ren et al., 2020) and Compound Word (CP) (Hsiao et al., 2021) compress the attributes of a note, including pitch, duration, and velocity, into one symbol and reduces duplicated position events. Although such MIDI-like approaches avoid redundancy for long notes, they still need multiple tokens to represent the attributes, position, and metadata of a single note, which can be further compressed. This paper proposes OctupleMIDI, a MIDI-based encoding method, which is efficient due to the reduced sequence length and universal to support various music genres.

2.3 Masking Strategies in Pre-training

Masking strategies play a key role in NLP pre-training. For example, BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) randomly mask some tokens in an input sequence and learn to predict the masked tokens. Furthermore, since adjacent tokens may form a word or a phrase, some works consider masking consecutive tokens. For example, MASS (Song et al., 2019) randomly masks a fragment of several consecutive tokens in the input, and SpanBERT (Joshi et al., 2020) randomly masks contiguous spans instead of tokens. However, symbolic music is different from language. First, symbolic music contains structural (e.g., bar, position) and diverse information (e.g., tempo, instrument, and pitch), while natural language can be regarded as homogeneous data, which only contains text. Second, music and language follow different rules. Specifically, the language rules include grammar and spelling, while the music rules include beat, chord, etc. Accordingly, the masking strategies for symbolic music need to be specifically designed; otherwise, it may limit the potential of pre-training because of information leakage, as we analyzed before. In this paper, we carefully design a bar-level masking strategy for symbolic music pre-training.

3 Methodology

In this section, we introduce MusicBERT, a large-scale Transformer model for symbolic music understanding. We first overview the model structure and then describe the OctupleMIDI encoding and masking strategy for pre-training. At last, we describe the large-scale music corpus with over 1 million songs used in MusicBERT pre-training.

3.1 Model Overview

As shown in Figure 1, MusicBERT pre-trains a Transformer encoder (Vaswani et al., 2017; Devlin et al., 2018), with masked language modeling where some tokens in the input music sequence are masked and are predicted in the model output. To

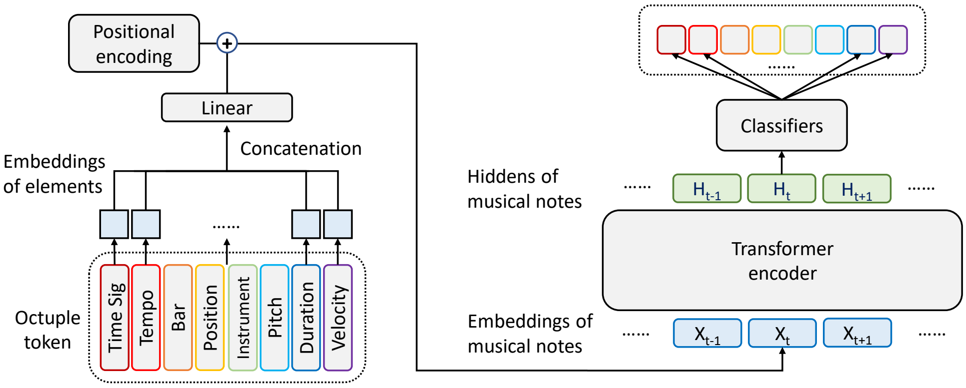

Figure 1: Model structure of MusicBERT.

encode the music sequence more efficiently, we propose a novel encoding method called OctupleMIDI, which encodes a symbolic music piece into a sequence of octuple tokens (an 8-tuple) that contains 8 basic elements related to a music note (we introduce OctupleMIDI in detail in Sec. 3.2). To convert the octuple tokens in each sequence step into the input of the Transformer encoder, we concatenate the embeddings of the 8 elements and use a linear layer to convert them into a single vector. Then, the converted vector is added with the corresponding position embeddings and taken as the input of the Transformer encoder. To predict each of the 8 tokens in the 8-tuple from the Transformer encoder, we add 8 different softmax layers to map the hidden of the Transformer encoder to the vocabulary sizes of 8 different element types, respectively.

3.2 OctupleMIDI Encoding

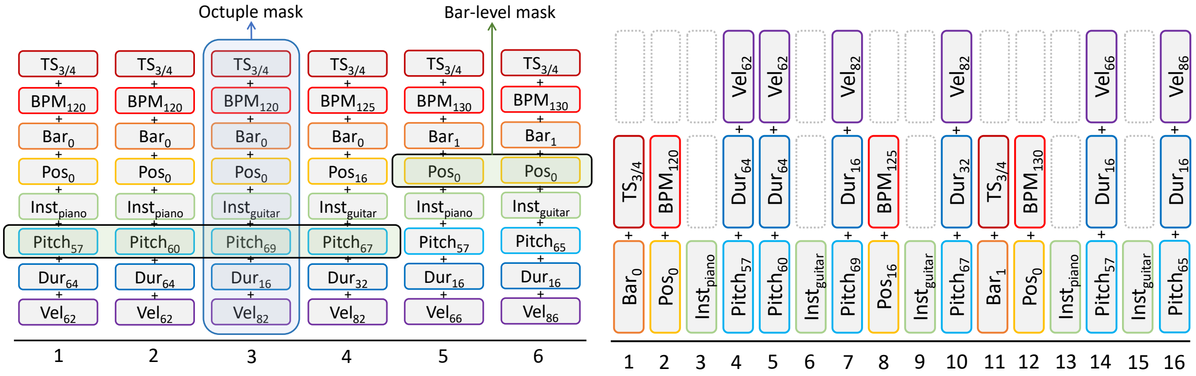
Previous works (Liang et al., 2020) encode the symbolic music in a pianoroll-like way, which is not efficient since a note is always divided into multiple fixed small intervals (e.g., a quarter note is represented with 8 consecutive tokens). MIDI-like approaches (Huang and Yang, 2020; Ren et al., 2020; Hsiao et al., 2021) encode a note into several tokens based on MIDI events, making encoding much shorter, and has been widely used in music generation tasks. However, previous MIDI-like representations are still long for the Transformer structure due to computation complexity and learning efficiency. Accordingly, we propose a compact symbolic music encoding method called OctupleMIDI for music understanding tasks. As shown in Fig. 2, OctupleMIDI encodes 6 notes into 6 tokens, which is much shorter than 33 tokens with REMI (Huang and Yang, 2020) and 16 tokens with CP (Hsiao et al., 2021). Meanwhile, OctupleMIDI is general for various kinds of music. For example, OctupleMIDI supports changeable time signature and tempo.

In OctupleMIDI, we use sequences of octuple tokens to represent symbolic music. Each octuple token corresponds to a note and contains 8 elements, including time signature, tempo, bar, position, instrument, pitch, duration, and velocity. We introduce the details of each element as follows:

- Time signature. A time signature is denoted as a fraction (e.g., 2/4), where the denominator is a power of two in range [1, 64], representing the length of a beat (measured by note duration, e.g., a quarter note in 2/4), and the numerator is an integer in range [1, 128], representing the number of beats in a bar (e.g., 2 beats in 2/4). The value of the fraction measures the duration of a bar normalized by a whole note (e.g., 2/4 means that the duration of a bar is a half note). We consider the duration of a bar is no more than two whole notes. Otherwise, we divide a long bar into several equal-duration bars no longer than two whole notes. Therefore, there are 254 different valid time signatures in OctupleMIDI.

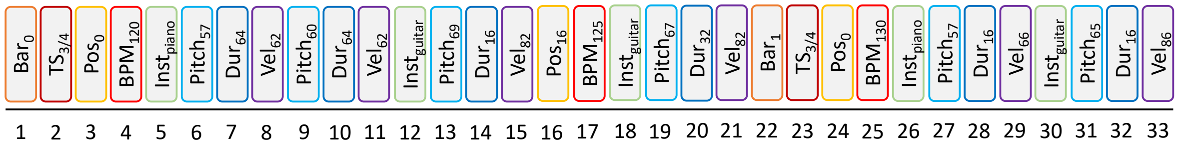
- Tempo. Tempo is measured in beats per minute (BPM), which describes the pace of music. In most music samples, tempo values are in range [24, 200]. For OctupleMIDI encoding, we quantize tempo values to 49 different values from 16 to 256, forming a geometric sequence.

- Bar and position. We use bar and position to indicate the on-set time of a note hierarchically. In the coarse level, we use 256 tokens ranging from 0 to 255 to represent the bar, supporting up to 256 bars in a music piece, which is sufficient in most cases. In the fine-grained level (inside each bar),



(a) OctupleMIDI encoding.

(b) CP-Like encoding.



(c) REMI-Like encoding.

Figure 2: Different encoding methods for symbolic music.

we use position with a granularity of 1/64 note to represent the on-set time of a note, starting from 0 in each bar. Therefore, we need 128 tokens to represent position since the duration of a bar is no more than two whole notes, as described above. For example, in a bar with a time signature of 3/4, the possible value of position is from 0 to 47.

- Instrument. According to the MIDI format, we use 129 tokens to represent instruments, where 0 to 127 stands for different general instruments such as piano and bass, and 128 stands for the special percussion instrument such as drum.

- Pitch. For notes of general instruments, we use 128 tokens to represent pitch values following the MIDI format. However, for notes of percussion instruments, there are no pitches but percussion types (e.g., bass drum, hand clap). Therefore, we use another 128 "pitch" tokens to represent percussion type for percussion instruments.

- Duration. To support the long note duration (up to 60 whole notes in the common music genre) with a fixed set of duration tokens, we propose a mixed resolution method: using high resolution (e.g., sixty-fourth note) when the note duration is small and using a low resolution (e.g., thirty-second note or larger) when the note duration is large. Specifically, we use 128 tokens to represent duration, starting from 0, with an increment of sixty-fourth note for the first 16 tokens, and double the increment (i.e., thirty-second note) every time for next 16 tokens. The duration for percussion instruments is meaningless, so we always set them to 0.

- Velocity. We quantize the velocity of a note in the MIDI format into 32 different values with an interval of 4 (i.e., 2, 6, 10, 14, . . . , 122, 126).

An example of a music sequence in OctupleMIDI encoding is shown in Fig. 2a.

3.3 Masking Strategy

Inspired by the masked language model in BERT (Devlin et al., 2018), we randomly mask some elements in the input sequence of octuple tokens and predict the masked ones. A naive masking strategy is to randomly mask some octuple tokens (mask all the elements in an octuple token), which is denoted as octuple masking as shown in Fig. 2a. However, considering the specific rules of music, such naive strategy will cause information leakage, and thus cannot well learn the contextual representation.

A music song consists of multiple bars, which can be regarded as highly internally related units. An octuple token can be easily inferred from the adjacent tokens in the same bar. Specifically, time signature, tempo, and bar usually remain the same in the same bar. Instrument and position values in the same bar follow regular patterns, where the instrument is limited to a small-scale fixed set of values, and the position values are non decreasing. Moreover, a chord is a fixed combination of pitches, which always appear in adjacent positions. Accordingly, we propose a novel bar-level masking strategy, where the elements with the same type in the same bar are regarded as a unit and are masked simultaneously. In this way, information leakage can be avoided, and better contextual representation can be learned through pre-training. An example of bar-level masking is shown in Fig. 2a.

For the masked elements, 80% of them are replaced with $[MASK]$, 10% of them are replaced with a random element, and 10% remain unchanged, following the common practice (Devlin et al., 2018; Joshi et al., 2020; Liu et al., 2019). Inspired by RoBERTa (Liu et al., 2019), we remove the next sentence prediction task in pre-training and adopt a dynamic masking strategy, where the masked sequence is generated every time when feeding a sequence to the model.

3.4 Pre-training Corpus

A large-scale music dataset is necessary to learn good music representations from pre-training. However, previous symbolic music datasets are usually of small scale: 1) the MAESTRO dataset (Hawthorne et al., 2019) contains only one thousand piano performances; 2) the GiantMIDI-Piano dataset (Kong et al., 2020a,b) contains slightly larger but still only ten thousands of piano performances; 3) the largest open-sourced symbolic music dataset by now is the Lakh-MIDI Dataset (LMD) (Raffel, 2016), which contains about 100K songs.

To pre-train a powerful model with good music representations, we build a large-scale symbolic music corpus with over 1.5 million songs. Specifically, we first crawled a large amount of music files, cleaned files that are malformed or blank, and then converted those files into our symbolic music encoding. Since OctupleMIDI encoding is universal, most MIDI files can be converted to our encoding without noticeable loss of musical information. We found that these music files may have almost identical music content even if their hash values are different. Therefore, we developed an efficient way to deduplicate them: we first omitted all elements except instrument and pitch in the encoding, then got hash values of the remaining sequence and use it as the fingerprint of this music file, which is further used for deduplication. After cleaning and deduplication, we obtained 1.5 million songs with 2 billion octuple tokens (musical notes). We denote our dataset as Million-MIDI Dataset (MMD). We compare the sizes of different music datasets in Table 2.

Dataset	Songs	Notes (Millions)
MAESTRO	1,184	6
GiantMIDI-Piano	10,854	39
LMD	148,403	535
MMD	**1,524,557**	**2,075**

Table 2: The sizes of different music datasets. Since LMD also consists of MIDI files from various websites, we perform the same cleaning and deduplication process as used in MMD and get 148,403 songs in LMD.

4 Experiments and Results

In this section, we first introduce the pre-training setup for MusicBERT, and then fine-tune MusicBERT on several downstream music understanding tasks to compare it with previous approaches. Finally, more method analyses are conducted to verify the effectiveness of the designs in MusicBERT.

4.1 Pre-training Setup

Model Configuration We pre-train two versions of MusicBERT: 1) MusicBERT$_{\text{small}}$ on the small-scale LMD dataset, which is mainly for a fair comparison with previous works on music understanding such as PiRhDy (Liang et al., 2020) and melody2vec (Hirai and Sawada, 2019), which are also pre-trained on LMD; 2) MusicBERT$_{\text{base}}$ on the large-scale MMD dataset, for pushing the SOTA results and showing the scalability of MusicBERT. The details of the two MusicBERT models are shown in Table 4. We use our proposed bar-level masking strategy with a masking probability of 15%. In addition, we use tokens of 8 duplicated elements to represent the class token and the end of sequence token. They are also masked with a 15% probability.

Pre-training Details The average sequence length of OctupleMIDI representation of a song is 3607 tokens as shown in Table 1, which is too long to model in Transformer. Therefore, we randomly sample segments with a length of 1024 tokens for pre-training. Following Liu et al. (2019), we pre-train MusicBERT on 8 NVIDIA V100 GPUs for 4 days, and there are 125,000 steps in total, with a

Table 3: Results of different models on the four downstream tasks: melody completion, accompaniment suggestion, genre classification, and style classification. We choose four baseline models: Melody2vec (Hirai and Sawada, 2019) is widely used in music understanding tasks, tonnetz (Chuan and Herremans, 2018) and pianoroll (Dong et al., 2018) are classical methods for music representation, PiRhDy (Liang et al., 2020) is a new model that significantly outperforms previous models in all four downstream tasks. Results of melody2vec on accompaniment suggestion task are emitted since it only encodes melody part of music.

MusicBERT	small	base

Pre-training dataset	LMD	MMD

Table 4: The model configurations of MusicBERT.

batch size of 256 sequences, each has a maximum length of 1024 tokens. We use Adam (Kingma and Ba, 2014) optimizer with β_1=0.9, β_2=0.98, ϵ=1e-6 and L_2 weight decay of 0.01. The learning rate is warmed up over the first 25,000 steps to a peak value of 5e-4 and then linearly decayed. Dropout value on all layers and attention weights are set to 0.1.

4.2 Fine-tuning MusicBERT

We fine-tune MusicBERT on four downstream tasks: two phrase-level tasks (i.e., melody completion and accompaniment suggestion) and two song-level tasks (i.e., genre and style classification). For the two phrase-level tasks, the learning rate is warmed up over the first 50,000 steps to a peak value of 5e-5 and then linearly decayed until reaching 250,000 total updates. For the two song-level tasks, the learning rate is warmed up over the first 4,000 steps to a peak value of 5e-5 and then linearly decayed until reaching 20,000 total updates. The batch size is set to 64 sequences for both tasks. Other settings are the same as pre-training. We compare MusicBERT with previous works on symbolic music understanding, including PiRhDy (Liang et al., 2020) and melody2vec (Hirai and Sawada, 2019).

4.2.1 Melody Completion

Melody completion (Liang et al., 2020) is to find the most matched consecutive phrase in a given set of candidates for a given melodic phrase. There are 1,793,760 data pairs in the training set and 198,665 data groups in the test set in this task (Liang et al., 2020). Each training data pair consists of one positive sample and one negative sample, while each test data group consists of 1 positive sample and 49 negative samples. We use mean average precision (MAP) and HITS@k (k=1, 5, 10, 25, indicating the rate of correctly chosen phrase in the top k candidates) as evaluation metrics, making comparisons with PiRhDy (Liang et al., 2020), melody2vec (Hirai and Sawada, 2019), pianoroll (Dong et al., 2018), tonnetz (Chuan and Herremans, 2018). As shown in Table 3, MusicBERT$_{\text{small}}$ outperforms all previous works on the same pre-training dataset LMD, indicating the advantage of MusicBERT on learning representations from melodic context. MusicBERT$_{\text{base}}$ with a larger model and pre-training corpus can further achieve better results, showing the effectiveness of large-scale pre-training.

4.2.2 Accompaniment Suggestion

Accompaniment suggestion (Liang et al., 2020) is to find the most related accompaniment phrase in a given set of harmonic phrase candidates for a given melodic phrase. There are 7,900,585 data pairs in the training set, each consisting of one positive sample and one negative sample, and 202,816 data groups in the test set (Liang et al., 2020). Each group in the test set consists of N positive samples and (50-N) negative samples when there are N accompaniment tracks in the MIDI file of that sample. We use mean average precision (MAP) and HITS@k as metrics, making comparisons with PiRhDy (Liang et al., 2020), pianoroll (Dong et al., 2018), tonnetz (Chuan and Herremans, 2018). As shown in Table 3, MusicBERT models perform much better than previous works, indicating the advantages of MusicBERT in understanding harmonic context.

4.2.3 Genre and Style Classification

Genre classification and style classification (Ferraro and Lemström, 2018) are multi-label classification tasks. Following Ferraro and Lemström (2018), we use the TOP-MAGD dataset for genre classification and the MASD dataset for style classification. TOP-MAGD contains 22,535 annotated files of 13 genres, and MASD contains 17,785 files of 25 styles. We evaluate MusicBERT on TOP-MAGD and MASD using 5-fold cross-validation and use the F1-micro score as the metric (Liang et al., 2020; Ferraro and Lemström, 2018; Oramas et al., 2017). Due to the limitation of computational resources, for songs with more than 1,000 octuple tokens, we randomly crop segments with 1,000 tokens. On average, the selected segment covers more than 1/4 of a music song according to Table 1, which is enough to capture sufficient information for identifying genres and styles. As shown in Table 3, MusicBERT models significantly outperform previous works, indicating that MusicBERT can perform well on song-level tasks.

4.3 Method Analysis

In this subsection, we analyze the effectiveness of each design in MusicBERT, including OctupleMIDI encoding, bar-level masking strategy, and the pre-training itself. We conduct experiments on MusicBERT$_{\text{small}}$ with a maximum sequence length of 250 due to the huge training cost of MusicBERT$_{\text{base}}$. For simplicity, we treat melody completion and accompaniment suggestion as binary classification tasks: classifying matched and not matched melody or accompaniment pairs, instead of ranking a group of pairs by predicted match score. We use the accuracy percentage score as the metric for these two binary classification tasks.

Effectiveness of OctupleMIDI We compare our proposed OctupleMIDI encoding with REMI (Huang and Yang, 2020) and CP (Hsiao et al., 2021) by training MusicBERT$_{\text{small}}$ models with each encoding respectively and evaluate on downstream tasks. As shown in Table 5, for song-level tasks (i.e., genre and style classification), OctupleMIDI significantly outperforms REMI and CP based encoding, since the model can learn from a larger proportion of a music song with the compact OctupleMIDI encoding, given all encoding methods use the same length of sequence for pre-training. For phrase-level tasks (melody completion and accompaniment suggestion), the input sequence length is usually less than the truncate threshold. Thus, benefiting from the short representation, OctupleMIDI significantly reduces the computational complexity of the Transformer encoder, which is only 1/16 of that with REMI-like encoding and 1/4 of that with CP-like encoding. Moreover, according to Table 5, OctupleMIDI performs better than the other two encoding methods on phrase-level tasks.

Encoding	Melody	Accom.	Genre	Style
CP-like	95.7	87.2	0.719	0.510
REMI-like	92.0	86.5	0.689	0.487
OctupleMIDI	**96.7**	**87.9**	**0.730**	**0.534**

Table 5: Results of different encoding methods. "Accom." represents accompaniment suggestion task.

Effectiveness of Bar-Level Masking We compare our proposed bar-level masking strategy with two other strategies: 1) Octuple masking, as mentioned in Sec. 3.3 and Fig. 2a; 2) Random masking, which randomly masks the elements in the octuple token similar to the masked language model in BERT. We use the same masking ratio for all these strategies. As shown in Table 6, our proposed bar-level masking can effectively boost results on downstream tasks.

Mask	Melody	Accom.	Genre	Style
Random	96.3	87.8	0.708	0.533
Octuple	96.0	87.3	0.722	0.530
Bar	**96.7**	**87.9**	**0.730**	**0.534**

Table 6: Results of different masking strategies.

Effectiveness of Pre-training To show the advantage of pre-training in MusicBERT, we compare the performance of MusicBERT$_{\text{small}}$ with and without pre-training. As shown in Table 7, pre-training achieves much better scores on the four downstream tasks, demonstrating the critical role of pre-training on symbolic music understanding.

Model	Melody	Accom.	Genre	Style
No pre-train	92.4	76.9	0.662	0.395
MusicBERT	**96.7**	**87.9**	**0.730**	**0.534**

Table 7: Results with and without pre-training.

5 Conclusion

In this paper, we developed MusicBERT, a large-scale pre-trained model for symbolic music understanding. Instead of simply adopting the pre-training methods from NLP to symbolic music, we handle the distinctive challenges in music pre-training with several careful designs in MusicBERT, including the efficient and universal OctupleMIDI encoding, the effective bar-level masking strategy, and the large-scale symbolic music corpus with more than 1 million music songs. MusicBERT achieves state-of-the-art performance on all of the four evaluated symbolic music understanding tasks, including melody completion, accompaniment suggestion, genre classification, and style classification. Method analyses also verify the effectiveness of each design in MusicBERT. For future work, we will apply MusicBERT on other music understanding tasks such as chord recognition and structure analysis to boost the performance.

Evaluating the Efficacy of Summarization Evaluation across Languages

Fajri Koto **Jey Han Lau** **Timothy Baldwin**

Abstract

While automatic summarization evaluation methods developed for English are routinely applied to other languages, this is the first attempt to systematically quantify their panlinguistic efficacy. We take a summarization corpus for eight different languages, and manually annotate generated summaries for focus (precision) and coverage (recall). Based on this, we evaluate 19 summarization evaluation metrics, and find that using multilingual BERT within BERTScore performs well across all languages, at a level above that for English.

1 Introduction

Although manual evaluation (Nenkova and Passonneau, 2004; Hardy et al., 2019) of text summarization is more reliable and interpretable, most research on text summarization employs automatic evaluations such as ROUGE (Lin, 2004), METEOR (Lavie and Agarwal, 2007), MoverScore (Zhao et al., 2019), and BERTScore (Zhang et al., 2020b) because they are time- and cost-efficient.

In proposing these metrics, the authors measured correlation with human judgments based on English datasets that are not representative of modern summarization systems. For instance, Lin (2004) use DUC[1] 2001–2003 for ROUGE (meaning summaries were generated with largely outdated extractive summarization systems); Zhao et al. (2019) use the TAC[2] dataset for MoverScore (again, featuring summaries from largely defunct systems; see Peyrard (2019) and Rankel et al. (2013)); and Zhang et al. (2020b) developed BERTScore based on a machine translation corpus (WMT). In contemporaneous work, Bhandari et al. (2020) address this issue by annotating English CNN/DailyMail summaries produced by recent summarization models, and found disparities over results from TAC.

Gold summary : Info-A; Info-B; Info-C	
System summary:

Bad *focus,* and Bad *coverage*	: Info-D; Info-E; Info-F

Figure 1: Illustration of focus and coverage.

Equally troublingly, ROUGE has become the default summarization evaluation metric for languages other than English (Hu et al., 2015; Scialom et al., 2020; Ladhak et al., 2020; Koto et al., 2020b), despite there being no systematic validation of its efficacy across other languages. The questions we ask in this study, therefore, are twofold: (1) *How well do existing automatic metrics perform over languages other than English?* and (2) *What automatic metric works best across different languages?*

In this paper, we examine content-based summarization evaluation from the aspects of precision and recall, in the form of *focus* and *coverage* to compare system-generated summaries to ground-truth summaries (see Figure 1). As advocated by Koto et al. (2020a), focus and coverage are more interpretable and fine grained than the harmonic mean (F1 score) of ROUGE. This is also in line with the review of Hardy et al. (2019) on linguistic properties that have been manually evaluated in recent summarization research, who found precision and recall to be commonly used to complement ROUGE F1.

While it may seem more natural and reliable to evaluate focus and coverage based on the source document than the ground-truth summary, we use the ground-truth summary in this research for the following reasons. First, historically, validation of automatic evaluation metrics for summarization has been based primarily on ground-truth summaries (not source documents). Second, ROUGE (Lin,

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 801–812
August 1–6, 2021. ©2021 Association for Computational Linguistics

2004) was initially motivated and assessed based on coverage over the DUC datasets[3] (Lin and Hovy, 2002) using annotations based on reference summaries (not source documents). Third, although it is certainly possible to generate different summaries for the same source document, we argue that the variance in content is actually not that great, especially for single-document summarization. Lastly, basing human evaluation (of focus and coverage) on the source article leads to more complicated annotation schemes, and has been shown to yield poor annotations (Nenkova and Passonneau, 2004; Fabbri et al., 2020).

In summary, this paper makes three contributions: (1) we carry out the first systematic attempt to quantify the efficacy of automatic summarization metrics over 8 linguistically-diverse languages, namely English (EN), Indonesian (ID), French (FR), Turkish (TR), Mandarin Chinese (ZH), Russian (RU), German (DE), and Spanish (ES); (2) we evaluate an extensive range of traditional and model-based metrics, and find BERTScore to be the best metric for evaluating both focus and coverage; and (3) we release a manually-annotated multilingual resource for summarization evaluation comprising 4,320 annotations. Data and code used in this paper is available at: https://github.com/fajri91/Multi_SummEval.

2 Related Work

As with much of NLP, research on automatic summarization metrics has been highly English-centric. Graham (2015) comprehensively evaluated 192 ROUGE variations based on the DUC-2004 (English) dataset. Bhandari et al. (2020) released a new (English) evaluation dataset by annotating CNN/DailyMail using simplified Pyramid (Nenkova and Passonneau, 2004). First, semantic content units (SCUs) were manually extracted from the reference, and crowd-workers were then asked to count the number of SCUs in the system summary. Their annotation procedure does not specifically consider focus, but is closely related to the coverage aspect of our work. Similarly, Fabbri et al. (2020) annotated the (English) CNN/DailyMail dataset for the four aspects of coherence, consistency, fluency, and relevance. While their work does not specifically study focus and coverage, relevance in their work can be interpreted as the harmonic mean of focus and coverage.

There is little work on summarization evaluation for languages other than English, and what work exists is primarily based on summaries generated by unsupervised extractive models dating back more than a decade, for a small handful of languages. Two years prior to ROUGE, Saggion et al. (2002) proposed a summarization metric using similarity measures for English and Chinese, based on cosine similarity, unit overlap, and the longest common subsequence ("LCS") between reference and system summaries. In other work, Saggion et al. (2010) investigated coverage, responsiveness, and pyramids for several extractive models in English, French, and Spanish.

To the best of our knowledge, we are the first to systemically quantify the panlinguistic efficacy of evaluation metrics for modern summarization systems.

3 Evaluation Metrics

We assess a total of 19 different evaluation metrics that are commonly used in summarization research (noting that lesser-used metrics such as FRESA (Saggion et al., 2010) and RESA (Cohan and Goharian, 2016) are omitted from this study).

ROUGE (Lin, 2004) measures the lexical overlap between the system and reference summary; based on the findings of Graham (2015), we consider 7 variants in this paper: ROUGE-1 (unigram), ROUGE-2 (bigram), ROUGE-3 (trigram), ROUGE-L (LCS), ROUGE-S (skip-bigram), ROUGE-SU (skip-bigram plus unigram), and ROUGE-W (weighted LCS).[4]

METEOR (Lavie and Agarwal, 2007) performs word-to-word matching based on word-alignment, and was originally developed for MT but has recently been used for summarization evaluation (See et al., 2017; Chen and Bansal, 2018; Falke and Gurevych, 2019; Amplayo and Lapata, 2020).[5]

BLEU (Papineni et al., 2002) is a precision-based metric originally developed for MT, which measures the n-gram match between the reference and system summary. Based on the findings of Graham (2015), we use BLEU-4 according to the SacreBLEU implementation (Post, 2018).[6]

MoverScore (Zhao et al., 2019) measures the Euclidean distance between two contextualized BERT representations, and relies on soft align-

---

[4] https://github.com/bheinzerling/pyrouge

[5] http://www.cs.cmu.edu/~alavie/METEOR/

[6] https://github.com/mjpost/sacrebleu

ments of words learned by solving an optimisation problem.[7] We adapt use the default configuration (n-gram=1) over 5 different pre-trained models, as detailed below. Note that MoverScore is symmetric (i.e. MoverScore(x, y) = MoverScore(y, x)), and as such is not designed to separately evaluate precision and recall.

BERTScore (Zhang et al., 2020b) computes the similarity between BERT token embeddings of system and reference summaries based on soft overlap, in the form of precision, recall, and F1 scores.[8] Zhang et al. (2020b) found that layer selection (i.e. which layer to source the token embeddings from) is critical to performance. Since layer selection in the original paper was based on MT datasets, we perform our own layer selection using a similar methodology as the authors, specifically considering precision and recall for focus and coverage, respectively.

For both MoverScore and BERTScore, we experiment with two classes of BERT-style model: (1) multilingual models, in the form of cased and uncased multilingual BERT (Devlin et al., 2019), and base and large XLM-R (Conneau et al., 2020), for a total of 4 models;[9] and (2) a monolingually-trained BERT for the given language, as listed in the Appendix. While we expect monolingual BERT models to perform better, we also focus on multilingual models, both to confirm whether this is the case, and to be able to draw findings for languages without monolingual models.

4 Experimental Setup

For each language, we sample 135 documents from the test set of a pre-existing (single-document) summarization dataset: (1) CNN/DailyMail (English: Hermann et al. (2015)); (2) Liputan6 (Indonesian: Koto et al. (2020b)); (3) LCSTS (Chinese: Hu et al. (2015)); and (4) MLSUM (French, Turkish, Russian, German, Spanish: Scialom et al. (2020)). We source summaries based on two popular models: pointer generator network (See et al., 2017) and BERT (Liu and Lapata, 2019; Dong et al., 2019),[10] and have 3 annotators annotate focus and coverage for each reference–system summary pair.[11] The motivation for using BERT-based systems is that our study focuses on non-English summarization, where BERT-based models dominate.[12] The total number of resulting annotations is: 8 languages × 135 documents × 2 models × 2 criteria (= focus and coverage) × 3 annotators = 12,960.

Lang	**Quality (%)**	**Pearson correlation (r)**		
		Agreement		**Focus–**
		Focus	**Coverage**	**Coverage**
EN	90	0.47	0.46	0.58
ID	97	0.64	0.63	0.80

TR	97	0.74	0.79	0.74
ZH	92	0.61	0.60	0.78
RU	98	0.60	0.64	0.78
DE	90	0.78	0.83	0.89
ES	95	0.60	0.61	0.76

Table 1: Analysis of the annotations for each language, in terms of: (1) average quality control score of approved HITs (%); (2) one-vs-rest human agreement (r); and (3) correlation (r) between focus and coverage.

For annotation, we used Amazon Mechanical Turk[13] with the customized Direct Assessment ("DA") method (Graham et al., 2015; Graham et al., 2017), which has become the de facto for MT evaluation in WMT. For each HIT (100 samples), DA incorporates 10 pre-annotated samples for quality control. Crowd-sourced workers are given two texts and asked the question (in the local language): *How much information contained in the second text can also be found in the first text?* We combine focus and coverage annotation into 1 task, as the only thing that differentiates them is the ordering of the system and reference summaries, which is opaque to the annotators.[14] Workers responded by scoring based via a slider button (continuous scale of 1–100).[15]

For each HIT, we create 10 samples for quality control: 5 samples are random pairs (should be

[8] https://github.com/Tiiiger/bert_score

[9] Note that both multilingual BERT and XLM were explicitly trained over all eight target languages used in this paper.

[10] English, Indonesian and Chinese summaries were generated with the Liu and Lapata (2019) model, and the Dong et al. (2019) model was used for the MLSUM-based languages.

[11] Summaries for all datasets except LCSTS were sourced from the authors of the dataset. For LCSTS, we trained the two models ourselves based on the training data.

[12] BERT-based summaries are representative of transformer-based model, and the ROUGE score gap over state-of-the-art models (Zhang et al., 2020a) for English is only ∼2 points.

[13] https://www.mturk.com

[14] For focus, the first text is the reference and the second text the system summary; for coverage, the order is reversed.

[15] See Appendix for the MTurk annotation interface for each language.

Table 2: Pearson correlation (r) between automatic metrics and human judgments (for Pointer Generator and BERT models combined). We compute the precision and recall of ROUGE and BERTScore for focus and coverage, respectively. BERTScore uses the optimized layer, and other metrics are computed using the default configuration of the original implementation.

Model	**Universal layer**	
	Focus	**Coverage**
mBERT (cased)	12	5
mBERT (uncased)	12	6
XLM-R (base)	4	4
XLM-R (large)	10	9

Table 3: Recommended layers for multilingual models.

scored 0) and the remaining 5 samples are repetitions of the same summary with minor edits (should be scored 100). For each language, we asked a native speaker to translate all instructions and the annotation interface. For a single HIT, we paid USD$13, and set the HIT approval rate to 95%. For HITs to be included in the annotated data, a quality control score of at least 7 out of 10 needed to be achieved. HITs below this threshold were re-run (ensuring they were not completed by a worker who had already completed that HIT), until three above-threshold annotations were obtained.[16] For each language, the HIT approval rate is set to 95% (with the number of HITs approved varying across languages). The annotation for English was restricted to US-based workers, and for other languages except Chinese was based on countries where the language is an official language.[17]

To obtain focus and coverage values, we follow standard practice in DA in z-scoring the scores from each annotator, and then averaging.

5 Results

5.1 Annotation Results

In Table 1, we present the results of the human annotation. We first normalize the ratings from each HIT into a z-score, and one-vs-rest Pearson correlation (excluding quality control items) to provide an estimate of human agreement/performance.[18] For all languages, we observe that the average quality and human agreement is moderately high. However, the agreement does vary, and it affects the interpretation of the correlation scores when we assess the automatic metrics later. Note also that we get the lowest score for English, meaning the results for non-English languages are actually more

---

[16] We approved all HITs with at least 30 minutes working time and a minimum quality control score of 5, irrespective of whether they passed the higher quality-control threshold required for the ground truth.

[17] In MTurk, we did not set a specific location for Chinese because we found there are no workers in China.

[18] We follow Lau et al. (2020) in computing one-vs-rest correlation: we randomly isolate a worker's score (for each sample) and compare it against the mean score of the rest using Pearson's r, and repeat this for 1000 trials to get the mean correlation.

robust.[19]

Although focus and coverage are positively correlated in Table 1, the distribution of scores varies quite a bit between languages: English annotation variance is higher than the other languages, and has the lowest correlation between focus and coverage ($r = 0.57$); for French, Russian, and Spanish, summaries generally have low focus and coverage (for more details, see scatterplots of focus-coverage in Figure 2 of the Appendix).

5.2 Correlation with Automatic Evaluation

In Table 2 we present the Pearson correlation between the human annotations and various automatic metrics, broken down across language and focus vs. coverage, and (naively) aggregated across languages in the form of the average correlation. We also include the one-vs-rest annotator correlation (Section 5.1) in the last row, as it can be interpreted as the average performance of a single annotator. Recognizing the sensitivity of Pearson's correlation to outliers (Mathur et al., 2020), we manually examined the distribution of scores for all language–system combinations for outliers (and present all scatterplots in Figure 2 of the Appendix).

The general pattern is consistent across languages: BERTScore performs better than other metrics in terms of both focus and coverage. This finding is consistent with that of Fabbri et al. (2020) wrt expert annotations of relevance (interpreted as the harmonic mean of our focus and coverage). ROUGE-1 and ROUGE-L are overall the best versions of ROUGE, while BLEU-4 performs the worst. For coverage, METEOR tends to be competitive with ROUGE-1, especially for EN, FR, DE, and ES, in large part because these languages are supported by the METEOR lemmatization package.

For some pre-trained models, MoverScore is competitive with BERTScore, although the average correlation is lower, especially for coverage.

We perform layer selection for BERTScore by selecting the layer that produces the highest correlation. For monolingual BERT the selection is based on the average correlation across the two summarization models, while for the multilingual models it is based on overall result across the 8 languages × 2 models. Table 3 details the recommended layer for computing BERTScore for each of the multilingual models.[20]

We observe that BERTScore with monolingual BERT performs the best, at an average of 0.72 and 0.77 for focus and coverage, resp., but only marginally above the best of the multilingual models, namely mBERT uncased (0.72 and 0.76, resp.). Given that layer selection here was performed universally across all languages (to ensure generalizability to other languages), our overall recommendation for the best metric to use is BERTScore with mBERT uncased.

When we compare the metric results to the one-vs-rest single-annotator performance from Table 1, we see a positive correspondence between the relative scores for annotator agreement and metric performance, which we suspect is largely an artefact of data quality (i.e. the metrics are assessed to perform better for languages with high agreement because the quality of the ground-truth is higher), but further research is required to confirm this. Generally the best metrics tend to outperform single-annotator performance substantially (>0.10), suggesting these metrics are more reliable than a single annotator.

6 Conclusion

In this work, we developed a novel dataset for assessing automatic evaluation metrics for focus and coverage across a broad range of languages and datasets. We found that BERTScore is the best metric for the vast majority of languages, and advocate that this metric be used for summarization evaluation across different languages in the future, supplanting ROUGE.

Acknowledgments

We are grateful to the anonymous reviewers for their helpful feedback and suggestions. The first author is supported by the Australia Awards Scholarship (AAS), funded by the Department of Foreign Affairs and Trade (DFAT), Australia. This research was undertaken using the LIEF HPC-GPGPU Facility hosted at The University of Melbourne. This facility was established with the assistance of LIEF Grant LE170100200.

---

[19] The relative quality for different languages largely coincides with the findings of Pavlick et al. (2014).

[20] Recommended layers for monolingual BERT are detailed in the Appendix.

Abstract

The capacity of empathy is crucial to the success of open-domain dialog systems. Due to its nature of multi-dimensionality, there are various factors that relate to empathy expression, such as communication mechanism, dialog act and emotion. However, existing methods for empathetic response generation usually either consider only one empathy factor or ignore the hierarchical relationships between different factors, leading to a weak ability of empathy modeling. In this paper, we propose a multi-factor hierarchical framework, CoMAE, for empathetic response generation, which models the above three key factors of empathy expression in a hierarchical way. We show experimentally that our CoMAE-based model can generate more empathetic responses than previous methods. We also highlight the importance of hierarchical modeling of different factors through both the empirical analysis on a real-life corpus and the extensive experiments. Our codes and used data are available at `https://github.com/chujiezheng/CoMAE`.

1 Introduction

Empathy, which refers to the capacity to understand or feel what another person is experiencing (Rothschild, 2006; Read, 2019), is a critical capability to open-domain dialog systems (Zhou et al., 2018b). As shown in previous research, empathetic conversational models can improve user satisfaction and receive more positive feedback in numerous domains (Klein, 1998; Liu and Picard, 2005; Brave et al., 2005; Fitzpatrick et al., 2017; Liu et al., 2021). Recently, there have also been numerous works devoted to improving the dialog models' ability to understand the feelings of interlocutors (Rashkin et al., 2019; Lin et al., 2019; Majumder et al., 2020), which makes the dialog models more empathetic to a certain extent.

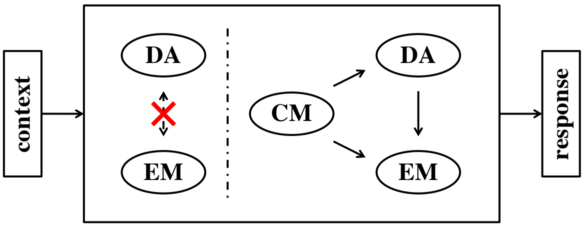

Figure 1: Our proposed hierarchical framework: CoMAE (right). The directed arrows denote dependencies. We also present the framework (left) of EmpTransfo (Zandie and Mahoor, 2020) for comparison.

However, empathy is a multi-dimensional construct (Davis et al., 1980) rather than merely recognizing the interlocutor's emotion (Lin et al., 2019) or emotional responding (Zhou et al., 2018a). It consists of two broad aspects related to *cognition* and *affection* (Omdahl, 2014; Paiva et al., 2017). The cognitive aspect requires understanding and interpreting the situation of the interlocutor (Elliott et al., 2018), which is reflected in the **dialog act** taken in the conversation (De Vignemont and Singer, 2006), such as questioning (e.g., *What's wrong with it?*), consoling (e.g., *You'll get through this*), etc. The affective aspect relates to properly expressing **emotion** in reaction to the experiences and feelings shared by the interlocutor, such as admiration (e.g., *Congratulations!*), sadness (e.g., *I am sorry to hear that*), etc. Very recently, Sharma et al. (2020) further characterizes the text-based expressed empathy based on the above two aspects as three **communication mechanisms**, which is a more higher-level and abstract factor that relates to empathy expression.

In this paper, we propose a novel framework named **CoMAE** for empathetic response generation (Section 3), which contains the aforemen-

tioned three key factors of empathy expression: **Co**mmunication **M**echanism (CM), dialog **A**ct (DA) and **E**motion (EM). Specifically, when model these empathy factors simultaneously, we adopt a **hierarchical** way instead of following previous works that treat multiple factors independently, such like EmpTransfo (Zandie and Mahoor, 2020) that considers both DA and EM (see Figure 1 for comparison). Such approaches hold the hypothesis that different factors are independent of each other, which is intuitively unreasonable. In fact, our empirical analysis (Section 4) on a Reddit corpus (Zhong et al., 2020) shows that there are obvious hierarchical relationships between different factors, which confirms the soundness and necessity of hierarchical modeling.

We then devise a CoMAE-based model on top of the pre-trained language model GPT-2 (Radford et al., 2019) (Section 5), and compare the model performance with different combinations of empathy factors and hierarchical modeling. Automatic evaluation (Section 6.3) shows that combining all the three factors hierarchically can achieve the best model performance. Manual evaluation (Section 6.4) demonstrates that our model can generate more empathetic responses than previous methods. Extensive experiments (Section 6.5) further highlight the importance of hierarchical modeling in terms of the selection and realization of empathy factors.

The contributions of this paper can be summarized in three folds:

- Based on the nature of multi-dimensionality of empathy expression, we propose a novel framework, CoMAE, for empathetic response generation. It hierarchically models three key factors of empathy expression: communication mechanism, dialog act and emotion.
- On top of GPT-2, we devise a CoMAE-based model. Experimental results show that our model can generate more empathetic responses than previous methods.
- We empirically analyze the necessity of hierarchical modeling, and highlight its importance especially in terms of the selection and realization of different empathy factors.

2 Related Work

2.1 Factors Related to Empathy Expression

Empathy is a complex multi-dimensional construct (Davis et al., 1980) which consists of two broad aspects related to *cognition* and *affection* (Omdahl, 2014; Paiva et al., 2017). As shown in Section 1, the two aspects are reflected in the dialog act (DA) taken and the emotion (EM) expressed in the conversation respectively.

Based on the theoretical definition of empathy, Sharma et al. (2020) characterize the text-based expressed empathy as 3 communication mechanisms (CM): emotional reaction (ER) (e.g., *I feel really sad for you*), interpretation (IP) (e.g., *This must be terrifying*, *I also have similar situations*), and exploration (EX) (e.g., *Are you still feeling alone now?*).[1] These communication mechanisms are also applied in the recently proposed task of empathetic rewriting (Sharma et al., 2021).

Besides, Zhong et al. (2020) propose that persona, which refers to the social face an individual presents to the world (Jung, 2016), has been shown to be highly correlated with personality (Leary and Allen, 2011), which in turn influences empathy expression (Richendoller and Weaver III, 1994; Costa et al., 2014). While Zhong et al. (2020) do not explain the explicit connection between persona and empathy expression, they suggest that different speakers may have different "styles" for expressing empathy.

2.2 Empathetic Response Generation

In the past years, empathetic response generation has attracted much research interest (Rashkin et al., 2019; Lin et al., 2019; Majumder et al., 2020; Zandie and Mahoor, 2020; Sun et al., 2021). Rashkin et al. (2019) suggest that dialog models can generate more empathetic responses by recognizing the interlocutor's emotion. Lin et al. (2019) propose to design a dedicated decoder to respond each emotion of the interlocutor, which makes the generation process more interpretable. Majumder et al. (2020) adopt the idea of emotional mimicry (Hess and Fischer, 2014) to make the generated responses more empathetic. Inspired by the advances in generative pre-trained language models (Radford et al., 2018, 2019), EmpTransfo (Zandie and Mahoor, 2020) uses GPT (Radford et al., 2018) to generate empathetic responses.

Unlike previous works that only consider the EM factor in empathy modeling, EmpTransfo takes both DA and EM into account. The fundamental

---

[1] As shown in (Sharma et al., 2020), the three communication mechanisms can be properly combined in one utterance. We refer the readers to their original paper for more details about the three communication mechanisms.

difference of EmpTransfo from our work lies in two points: (1) our work further considers communication mechanism in modeling empathy, and (2) we analyze and explore in depth the importance of hierarchically modeling of these empathy factors.

3 CoMAE Framework and Formulation

Our proposed CoMAE framework is shown in Figure 1. CoMAE uses CM as a high-level factor that provides a coarse-grained guidance for empathy expression, and then takes DA and EM to achieve the fine-grained realization. Formally, given the context x, CoMAE divides the generation of the empathetic response y into four steps: (1) predict **CM** C_y conditioned on the context, (2) predict **DA** A_y conditioned on both the context and CoM, (3) predict **EM** E_y based on all the conditions, and (4) generate the final response y. The whole process is formulated as Equation 1:

$$\begin{aligned}\mathbb{P}(y, C_y, A_y, E_y|x) = \mathbb{P}(y|x, C_y, A_y, E_y)\cdot \quad (1)\\ \mathbb{P}(E_y|x, C_y, A_y)\mathbb{P}(A_y|x, C_y)\mathbb{P}(C_y|x).\end{aligned}$$

Note that EM is conditioned on DA, because we intuitively think the expressed emotion is the effect rather than the cause of taking some dialog act. In the other words, one may not adopt the dialog act just for the purpose of expressing some emotion. Hence, realizing the emotion expression as expected is also important in our task, which is the motivation of that we analyze the realization of different factors in Section 6.5.

It is also worth noting that while CoMAE only contains the three factors, such hierarchical framework can be naturally extended to more factors that relate to empathy expression. For instance, Zhong et al. (2020) suggest that persona plays an important role in empathetic conversations. Due to that persona may contain the information about the speaker's style of adopting DA or expressing EM, when integrating persona into empathetic response generation, being conditioned on DA and EM may lead to better performance.

4 Data Preparation and Analysis

While no empathetic conversation corpora provide annotations of diverse empathy factors, there are abundant publicly available resources that make automatic annotation feasible. In this section, we first introduce our used corpus and the resources and tools used in automatic annotation, then we show our empirical analysis to verify the hierarchical relationships between different empathy factors.

4.1 Corpus

Zhong et al. (2020) propose a large-scale empathetic conversation corpus[2] crawled from Reddit. It has two different domains: Happy and Offmychest. The posts in the Happy domain mainly have positive sentiments, while those in the Offmychest domain are usually negative. We adopted their corpus for study for two major reasons: (1) the corpus is real-life, scalable and naturalistic rather than acted (Rashkin et al., 2019), and (2) the manual annotation in (Zhong et al., 2020) shows that most of the last responses are empathetic (73% and 61% for Happy and Offmychest respectively).

4.2 Annotation Resources

Communication Mechanism (CM)[3] Sharma et al. (2020) provide two corpora annotated with CM: TalkLife (`talklife.co`) and Reddit (`reddit.com`), while only the latter is publicly accessible and we thus used the Reddit part. Note that in their original paper, each mechanism is differentiated as three classes of "no", "weak", or "strong". Due to the unbalanced distribution of three classes, we merged "weak" and "strong" into "yes". Finally, we differentiated each mechanism as two classes: "no" or "yes".

Dialog Act (DA)[4] Welivita and Pu (2020) propose a taxonomy of DA (referred as "intent" in the original paper) for empathetic conversations. They first annotate 15 initial types of DA on the ED corpus (Rashkin et al., 2019), and finally obtain 8 high-frequency types of DA with other types merged as others (**8+others**), which are shown in Figure 2.

Emotion (EM)[5] We considered the taxonomy proposed in (Demszky et al., 2020), which contains 27 emotions and a neutral one, because: (1) it has a wide coverage of emotion categories with clear definitions, and (2) the annotated corpus is large-scale and also crawled from Reddit. However, we noted that the original emotion distribution is unbalanced and the too fine-grained taxonomy may lead to the sparsity of partial emotions. Considering the task

Classifiers	Corpora	# classes	Acc	F1-macro
CM-ER	Reddit	2	81.2	76.9
CM-IP	Reddit	2	85.7	85.7
CM-EX	Reddit	2	96.4	92.5
DA	ED	9	92.0	87.8
EM	Reddit	10	60.5	60.4

Table 1: Performance of the classifiers. "ED" refers to the corpus of EMPATHETICDIALOGUES (Rashkin et al., 2019).

scenario of empathetic conversation, we adopted the clustering results in (Demszky et al., 2020) and modified the original taxonomy as 9 emotions and a neutral one (**9+neutral**), which are also shown in Figure 2. We show the mapping between our adopted emotions and the original emotions in Appendix A.

4.3 Classifiers

We fine-tuned the RoBERTa[6] (Liu et al., 2019) classifiers for CM, DA and EM, whose performance is summarized in Table 1. They all achieve reasonable performance, ensuring the quality of automatic annotation.

However, we noted that the source domain (Rashkin et al., 2019) of the DA classifier is different from the target domain (Reddit). To verify the quality of DA annotation, we recruited three workers from Amazon Mechanical Turk to judge whether the utterance is consistent with the annotated DA. From the utterances that are not annotated with "others", we randomly sampled 25 utterances for each DA (totally 200) to avoid the impact of unbalanced distribution. Finally, the ratio of being judged as consistent is 0.78 with Fleiss' Kappa $\kappa = 0.621$ (Fleiss, 1971), which indicates substantial agreement ($0.6 < \kappa < 0.8$) and that the automatic annotation of DA is also reliable.

4.4 Data Filtering and Annotation

Following the original data split of (Zhong et al., 2020), we first filtered those conversations where there are more than two speakers (about 15%) to ensure that the last utterance is related to the post. We used the aforementioned classifiers to automatically annotate each utterance with DA and EM, and annotate each final response additionally with CM. We found that the last responses that are not annotated with any CM are more likely to be non-empathetic, thus we filtered the conversations containing such responses (about 40%). Finally, the sizes of Train / Valid / Test-Happy / Test-Offmychest are 125,963 / 16,371 / 11,136 / 6,413 respectively. We show the detailed statistics of automatic annotation in Appendix B.

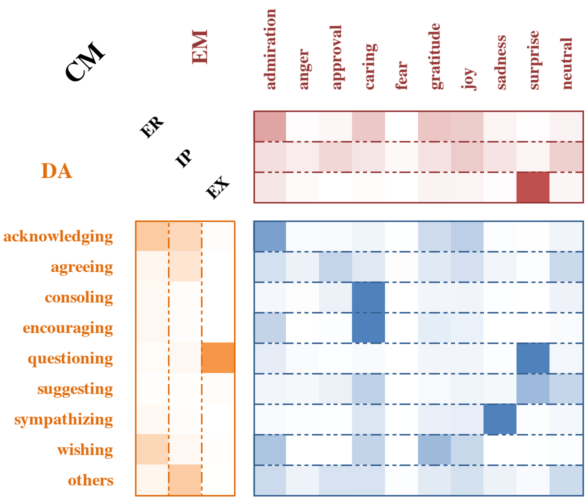

Figure 2: Heat maps of the conditional distributions between the three empathy factors. The **orange** / **red** / **blue** maps are the distributions of **DA** / **EM** / **EM** conditioned on **CM** / **CM** / **DA** respectively.

4.5 Analysis

In order to verify the hierarchical relationships between the three factors, we counted the distribution frequency of each (X, Y)[7] pair, where (X, Y) is one of the three factor pairs: (CM, DA), (CM, EM), (DA, EM). We approximated the statistical frequency of (X, Y) as their joint probability distribution $\mathbb{P}(X, Y)$. We then normalized $\mathbb{P}(X, Y)$ along the X dimension to obtain the conditional distribution of Y given X: $\mathbb{P}(Y|X)$.

Figure 2 shows the heat maps of the conditional distributions of the three factor pairs. The heat maps reveal obvious patterns of the occurrence of Y given X. For instance, when one adopts the DA *encouraging*, he usually expresses the EM *caring* instead of *approval* or *joy*. If one expresses empathy with the CM *exploration (EX)*, he almost always adopts the DA *questioning* and expresses the EM *surprise*. Hence, considering the hierarchical relationships between different empathy factors is reasonable and natural, and is also necessary for better empathy modeling.

---

[7] X or Y is the random variable that represents CM, DA, or EM.

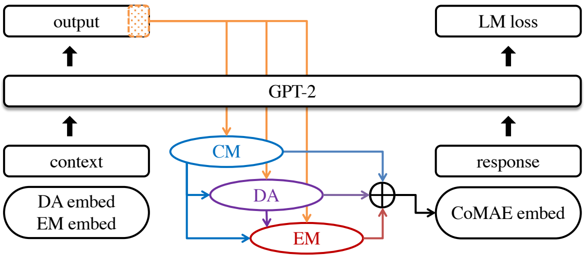

Figure 3: The overall architecture of our CoMAE-based model. The position and speaker embeddings are omitted for simplicity. The orange dashed block denotes the output hidden state at the last position of the context.

5 Methodology

5.1 Model Architecture

Our devised CoMAE-based model uses GPT-2 as the backbone (Radford et al., 2019). The overall architecture is shown in Figure 3.

Firstly, our model takes the dialog context x as input. The context x is the concatenation of history utterances: $x = (u_1, u_2, \ldots, u_N)$, where N is the length of dialog history. Any two adjacent utterances are also separated by the special token `[EOS]`. Each history utterance u_i contains a sequence of tokens: $u_i = (u_{i,1}, u_{i,2}, \ldots, u_{i,l_i})$, where l_i is the length of u_i. Each utterance u_i is labeled with the corresponding speaker $k_{u_i} \in \{0, 1\}$ (only 2 speakers). We denote the annotated DA and EM of each utterance u_i as $A_{u_i} \in [0, 9)$ and $E_{u_i} \in [0, 10)$ respectively. Suppose that the token id and the position id of $u_{i,j}$ are denoted as $w_{u_{i,j}} \in [0, |\mathcal{V}|)$ ($\mathcal{V}$ is the vocabulary) and $p_{u_{i,j}} \in [0, 1024)$ (the maximum input length is 1024) respectively, the representation of each token $u_{i,j}$ is the summation of the following embeddings:

$$\begin{aligned} \boldsymbol{e}_{u_{i,j}} = \boldsymbol{M}_W \left[w_{u_{i,j}}\right] + \boldsymbol{M}_P \left[p_{u_{i,j}}\right] + \\ \boldsymbol{M}_K \left[k_{u_i}\right] + \boldsymbol{M}_A \left[A_{u_i}\right] + \boldsymbol{M}_E \left[E_{u_i}\right], \end{aligned} \tag{2}$$

where $\boldsymbol{M}_W \in \mathbb{R}^{|\mathcal{V}| \times d}, \boldsymbol{M}_P \in \mathbb{R}^{1024 \times d}, \boldsymbol{M}_K \in \mathbb{R}^{2 \times d}, \boldsymbol{M}_A \in \mathbb{R}^{9 \times d}, \boldsymbol{M}_E \in \mathbb{R}^{10 \times d}$ denote the embedding matrices of word, position, speaker, DA and EM respectively, and $[\cdot]$ denotes the indexing operation. We denote the output hidden states after feeding x into the model as $\boldsymbol{H}_x \in \mathbb{R}^{l_x \times d}$, where l_x is the total length of context x.

Next, we use the hidden state at the last position of the context, $\boldsymbol{h}_x = \boldsymbol{H}_x[-1] \in \mathbb{R}^d$, to hierarchically predict the CM, DA and EM of the target response. We first separately predict[8] $\widehat{C}_y^{(i)} \in \{0, 1\}$ for each $i \in \{\mathrm{ER}, \mathrm{IP}, \mathrm{EX}\}$, which indicates whether to adopt the CM i:

$$\begin{aligned} \boldsymbol{h}_C^{(i)} &= \mathbf{F}_C^{(i)} \left(\boldsymbol{h}_x\right) \in \mathbb{R}^d, & (3) \\ \widehat{C}_y^{(i)} &\sim \mathbb{P}\left(C_y^{(i)} \middle| x\right) = \operatorname{softmax}\left(\boldsymbol{M}_C^{(i)} \boldsymbol{h}_C^{(i)}\right), \\ \widehat{C}_y &= \left(\widehat{C}_y^{(\mathrm{ER})}, \widehat{C}_y^{(\mathrm{IP})}, \widehat{C}_y^{(\mathrm{EX})}\right), \\ \boldsymbol{e}_{\widehat{C}_y} &= \sum_{i \in \{\mathrm{ER},\mathrm{IP},\mathrm{EX}\}} \boldsymbol{M}_C^{(i)} \left[\widehat{C}_y^{(i)}\right], & (4) \end{aligned}$$

where each $\mathbf{F}_C^{(i)}$ is a non-linear layer activated with $\tanh$, and each $\boldsymbol{M}_C^{(i)} \in \mathbb{R}^{2 \times d}$ denotes the embedding matrix of the CM $i \in \{\mathrm{ER}, \mathrm{IP}, \mathrm{EX}\}$. Based on the context x and the predicted CMs $\widehat{C}_y$, we next predict DA:

$$\boldsymbol{h}_A = \mathbf{F}_A \left(\left[\boldsymbol{h}_x; \boldsymbol{e}_{\widehat{C}_y}\right]\right) \in \mathbb{R}^d, \tag{5}$$

$$\widehat{A}_y \sim \mathbb{P}\left(A_y \middle| x, \widehat{C}_y\right) = \operatorname{softmax}\left(\boldsymbol{M}_A \boldsymbol{h}_A\right), \tag{6}$$

where $[\cdot; \cdot]$ denotes vector concatenation and $\mathbf{F}_A$ is a non-linear layer. Note that we share the parameters of DA embeddings with the classification head (Equation 6), which is consistent with the way in GPT-2 (Radford et al., 2019) where the parameters of word embeddings are shared with the LM head (Equation 10). EM is predicted similarly but conditioned additionally on the predicted DA $\widehat{A}_y$:

$$\boldsymbol{h}_E = \mathbf{F}_E \left(\left[\boldsymbol{h}_x; \boldsymbol{e}_{\widehat{C}_y}; \boldsymbol{M}_A \left[\widehat{A}_y\right]\right]\right) \in \mathbb{R}^d, \tag{7}$$

$$\widehat{E}_y \sim \mathbb{P}\left(E_y \middle| x, \widehat{C}_y, \widehat{A}_y\right) = \operatorname{softmax}\left(\boldsymbol{M}_E \boldsymbol{h}_E\right), \tag{8}$$

where $\mathbf{F}_E$ is also a non-linear layer.

Finally, we add all the factors to obtain the fused embedding $\boldsymbol{e}_{\mathrm{CoMAE}}$ that controls the empathy expression of the response:

$$\boldsymbol{e}_{\mathrm{CoMAE}} = \boldsymbol{e}_{\widehat{C}_y} + \boldsymbol{M}_A \left[\widehat{A}_y\right] + \boldsymbol{M}_E \left[\widehat{E}_y\right].$$

The embedding of each input token $\widehat{y}_t$ in the response is as follows:

$$\begin{aligned} \boldsymbol{e}_{\widehat{y}_t} = \boldsymbol{M}_W \left[w_{\widehat{y}_t}\right] + \boldsymbol{M}_P \left[p_{\widehat{y}_t}\right] + \\ \boldsymbol{M}_K \left[k_y\right] + \boldsymbol{e}_{\mathrm{CoMAE}}. \end{aligned} \tag{9}$$

Suppose that the output hidden state corresponding to $\widehat{y}_t$ is $\boldsymbol{s}_t$, then we predict the next token $\widehat{y}_{t+1}$

---

[8] In the mathematical notation used in this paper, we distinguish the ground truth value and the predicted value of a variable X with the symbols X^* and $\widehat{X}$ respectively.

through the LM head:

$$\begin{aligned}\widehat{y}_{t+1} &\sim \mathbb{P}\left(y_{t+1}\left|\widehat{y}_{\leq t}; x, \widehat{C}_y, \widehat{A}_y, \widehat{E}_y\right.\right) \\ &= \operatorname{softmax}\left(\boldsymbol{M}_W \boldsymbol{s}_t\right),\end{aligned} \tag{10}$$

where the parameters of the LM head are shared with the word embedding matrix $\boldsymbol{M}_W$.

5.2 Training

The optimization object contains two parts. One part is the negative log likelihood loss $\mathcal{L}_{\text{NLL}}$ of the target response:

$$\mathcal{L}_{\text{NLL}} = -\frac{1}{l_y}\sum_{t=1}^{l_y} \ln \mathbb{P}\left(y_t^* \left| y_{<t}^*; x, C_y^*, A_y^*, E_y^*\right.\right),$$

where l_y is the length of the golden response. The other part is the prediction losses of CM $\mathcal{L}_C$, DA $\mathcal{L}_A$, and EM $\mathcal{L}_E$:

$$\mathcal{L}_C = -\sum_{i\in\{\text{ER,IP,EX}\}} \ln \mathbb{P}\left(C_y^{(i)*}\middle| x\right), \tag{11}$$

$$\mathcal{L}_A = -\ln \mathbb{P}\left(A_y^* \left| x, C_y^*\right.\right), \tag{12}$$

$$\mathcal{L}_E = -\ln \mathbb{P}\left(E_y^* \left| x, C_y^*, A_y^*\right.\right). \tag{13}$$

The complete optimization object is the summation of the above losses: $\mathcal{L} = \mathcal{L}_{\text{NLL}} + \lambda\left(\mathcal{L}_C + \mathcal{L}_A + \mathcal{L}_E\right)$, where λ is the weight of the prediction losses. We set λ to 1.0 in our experiments.

5.3 Discussion

It is worth noting that the supervision signals of predictions (from Equation 11 to 13) combined with hierarchical modeling (from Equation 3 to 8) enable the model to establish the connections between the embeddings of the three factors. For instance, in Equation 6, the embedding matrix of DA, $\boldsymbol{M}_A$, is multiplied with $\boldsymbol{h}_A$, which explicitly contains the information of the embedding matrices of CM, $\boldsymbol{M}_C^{(i)}$ (Equation 4 and 5). The case of Equation 8 is similar, where $\boldsymbol{M}_E$ is multiplied with $\boldsymbol{h}_E$ that directly relates to $\boldsymbol{M}_C^{(i)}$ and $\boldsymbol{M}_A$.

Hence, consider two models where one uses hierarchical modeling and the other does not (predicting each factor separately). When the two models are fed with the same empathy factors, saying the triplet (C_y, A_y, E_y) is designated validly, we can expect that the former model has better performance than the latter one. This conjecture will be verified in the automatic evaluation (Section 6.3).

6 Experiments

6.1 Compared Models

We investigated the model performance with different combinations of empathy factors and hierarchical modeling:
(1) **Vanilla**: the GPT-2 model directly fine-tuned on the corpus without adding any empathy factor;
(2) **+CM**, **+DA**, **+EM**: the GPT-2 models equipped with one of the three factors;
(3) **CM || DA**, **CM || EM**, **DA || EM**, **CM || DA || EM**: the models equipped with two or all of the three factors, but predicting each factor separately without hierarchical modeling;
(4) **CM → DA**, **CM → EM**, **DA → EM**, **CM → DA → EM**: the models that are similar to (3) but utilize the hierarchical relationships, where → denotes dependency.

Note that the baseline DA || EM is consistent with EmpTransfo[9] (Zandie and Mahoor, 2020), and CM → DA → EM is exactly our devised model described in Section 5.1.

6.2 Implementation Details

All the models were implemented with PyTorch[10] (Paszke et al., 2019) and the Transformers library[11] (Wolf et al., 2020). We used the pre-trained GPT-2 with the size of 117M parameters (768 hidden sizes, 12 heads, 12 layers) for all the models. The responses were decoded by Top-p sampling with $p = 0.9$ and the temperature $\tau = 0.7$ (Holtzman et al., 2019). We trained all the models with Adam (Kingma and Ba, 2014) optimizer with $\beta_1 = 0.9$ and $\beta_2 = 0.999$. The learning rate was 10^{-4} and was dynamically changed using the linear warmup (Popel and Bojar, 2018) with 4000 warmup steps. All the models were fine-tuned for 5 epochs with the batch size 16 on one NVIDIA RTX 2080Ti GPU. We selected the checkpoint for each model where the model obtains the lowest perplexity score on the Valid set.

6.3 Automatic Evaluation

The automatic evaluation uses the golden responses as reference to evaluate the responses generated by

---

[9] DA || EM has the same input representation except the speaker embeddings as EmpTransfo, but is instead fine-tuned from GPT-2 rather than GPT. Besides, we did not adopt the next sentence prediction (NSP) task as in (Zandie and Mahoor, 2020), because we empirically found that adding NSP leads to worse performance.

Table 2: Results of automatic evaluation. The best results are in **bold**. DA || EM is consistent with EmpTransfo (Zandie and Mahoor, 2020). CM → DA → EM is our devised model described in Section 5.1. Scores that are significantly worse than the best scores are marked with * (Student's t-test, p-value < 0.05).

models. However, when the responses are generated based on the predicted CM / DA / EM, it is not appropriate to compare the generated responses with the reference ones (Liu et al., 2016). Thus, in automatic evaluation we only considered the setting where the models are fed with the ground truth empathy factors. The results where the generated responses are based on the predicted factors will be analyzed in the later experiments.

The automatic metrics we adopted include perplexity (**PPL**), BLEU-2 (**B-2**) (Papineni et al., 2002), ROUGE-L (**R-L**) (Lin, 2004), and the BOW Embedding-based (Liu et al., 2016) **Greedy** matching score. The metrics except PPL were calculated with an NLG evaluation toolkit[12] (Sharma et al., 2017), where the generated responses were tokenized with NLTK[13] (Loper and Bird, 2002).

Results are shown in Table 2. We analyze the results from the following three perspectives:

General Performance Our model achieves the best performance on all the metrics on both domains, and most of the advantages over the competitors are statistically significant.

Impact of Empathy Factors The model performance vary from different combinations of empathy factors. First, considering more empathy factors always leads to better performance (e.g., CM → DA → EM > CM → EM > +EM > Vanilla). Second, EM brings the most gains to the model performance among the three factors. It may be because emotion is the most explicit factor that influences empathy expression (Sharma et al., 2020). In contrast, CM brings fewer gains than DA and EM. The reason may be that CM provides a high-level but coarse-grained guidance for empathetic response generation, lacking a fine-grained control like DA or EM. While the responses in the corpus of (Zhong et al., 2020) are not too long (≤ 30 words), we believe that CM plays an important role in generating longer empathetic responses, which may require the planning of multiple methanisms and more diverse usage of DA and EM.

Impact of Hierarchical modeling We noticed that for almost all the models that adopt multiple empathy factors, hierarchical modeling always leads to better performanc (e.g., CM → DA → EM > CM || DA || EM, DA → EM > DA || EM). This phenomenon is not trivial because the models with or without hierarchical modeling are all fed with the same empathy factors as the reference responses. It confirms our conjecture in Section 5.2 that hierarchical modeling can establish the connections between the embeddings of different factors, thus leading to a better capacity of empathy modeling. However, (CM, EM) is an exception. It may be due to that the pair (CM, EM) has a weaker correlation (the lowest manual information, Section 4.5) than other pairs.

6.4 Manual Evaluation

In manual evaluation, the models generate responses based on the empathy factors sampled from the predicted probability distributions. When sampling DA or EM, we used the Top-p filtering with $p = 0.9$ (Holtzman et al., 2019) to ensure the validness of the sampled results.

The manual evaluation is based on pair-wise comparison, and the metrics for manual evaluation include: **Fluency** (which response has better fluency and readability), **Coherence** (which response has better coherence and higher relevance to the context), and **Empathy** (which response shows bet-

Table 4: Results of the Hits@1/3 of predicting Y given that X is predicted rightly. "Prop." denotes the proportion of the cases where both models $X \mid\mid Y$ and $X \rightarrow Y$ predict X rightly. Scores that are significantly improved after using hierarchical modeling are marked with * (sign test, p-value < 0.001).

ter understanding of the partner's experiences and feelings, and which response expresses empathy in the way that the annotators prefer). The pair-wise comparison is conducted between three pairs of models: (1) CM → DA → EM vs. DA → EM, (2) CM → DA → EM vs. CM || DA || EM, and (3) DA → EM vs. DA || EM. We randomly sampled 100 conversations from each test set of two domains (totally 200), and recruited three workers from Amazon Mechanical Turk for annotation.

Results are shown in Table 3. From all the three pairs, we find that the responses generated by these GPT-2-based models have similar fluency. The results of (1) indicate that further considering CM can significantly improve the empathy of generated responses, while the coherence may slightly decrease.

	Models	CM	DA	EM
Happy	**CM || DA**	69.6*	76.2*	-
	CM → DA	**79.3**	**83.6**	-
	CM || EM	73.8*	-	78.0*
	CM → EM	**76.6**	-	**82.4**

	CM → DA	**71.4**	**74.8**	-
	CM || EM	65.4*	-	66.1*
	CM → EM	**71.1**	-	**74.6**
	DA || EM	-	63.7*	58.3*
	DA → EM	-	**79.5**	**75.1**
	CM || DA || EM	59.0*	60.8*	58.9*
	CM → DA → EM	**70.7**	**76.2**	**72.6**

Table 5: Realization scores. All the scores are significantly improved after using hierarchical modeling (sign test, p-value < 0.00001).

It may be because that the communication mechanisms like interpretation sometimes lead to the responses that are less relevant to the contexts (especially those sharing experiences). The results of (2) and (3) indicate that hierarchical modeling improves the coherence of generated responses. The more empathy factors are modeled, the larger improvement can be obtained.

6.5 Further Analysis of Hierarchical modeling

To give further insights of the superiority of hierarchical modeling, we analyzed (1) the prediction and (2) the realization of empathy factors.

Prediction For each pair (X, Y) in (CM, DA), (CM, EM), (DA, EM), we paired the models $X \mid\mid Y$ and $X \rightarrow Y$ for comparison. Our purpose is to observe whether the prediction of X improves that of Y after using hierarchical modeling. Note that when taking the ground truth as reference, it is not appropriate to directly judge the prediction accuracy by comparing $\widehat{Y}$ and Y^* if $\widehat{X} \neq X^*$. We thus computed the conditional probability that Y is predicted rightly given that X is predicted rightly: $\mathbb{P}\left(\widehat{Y} = Y^* \middle| \widehat{X} = X^*\right)$.

Results are shown in Table 4. While the accuracy of predicting X of $X \mid\mid Y$ and $X \rightarrow Y$ is close, the prediction of Y is significantly enhanced by hierarchical modeling. The results demonstrate that hierarchical modeling enables the model to select more proper empathy factors.

Realization Recall that in manual evaluation, the models generate a response based on the sampled empathy factors $\widehat{C}_y, \widehat{A}_y, \widehat{E}_y$. To verify whether these factors are well realized, we used the classifiers in Section 4.3 to identify the empathy factors displayed in the generated responses. Suppose that the identification results are $\widetilde{Z}_y, \forall Z \in \{C, A, E\}$, we computed the ratio of $\widehat{Z}_y = \widetilde{Z}_y$ as the realization score of Z.

Results are shown in Table 5. The realization of all the factors is significantly improved by hierarchical modeling. It is intuitive because hierarchical modeling can avoid the cases where the sampled factors are inappropriate or even conflicting, thus reducing the noise of empathy factors in response generation.

6.6 Case Study

We show the generated responses with different empathy factors in Figure 4. The adoption of the CM *emotional reaction* causes our model to express the same EM *admiration* (*i'm proud of you!*) as DA → EM (*good for you, man!*), while the two models generate the same sentence (*keep it up!*) when taking the DA *encouraging*. However, the further adoption of the CM *interpretation* causes our model to further share its own experiences and feelings (*i have been sober for about 10 years, and it's the best feeling ever*). As a result, with the enhancement of multiple empathy factors, the response generated by our model is more engaging and empathetic while maintaining the coherence.

Besides, we noticed another phenomenon occurring when all the three CMs are adopted. In this case, the three CMs are usually represented separately in different sentences (e.g., *I am so happy for you! I also had tried to be sober but failed. How did you make it?*), which is consistent with the results of empathetic rewriting (Sharma et al., 2021). Recall that we add the same CoMAE embeddings for all the tokens in the response during generation (Section 5.1). Such uniform operation seems non-optimal for the nonuniform realization of different CMs, especially when generating a longer empathetic response that contains multiple sentences with different CMs, DAs or EMs. We believe there is still much room of improvement when applying our CoMAE framework to longer response generation, like combining CoMAE's multi-factor hierarchical modeling with planning-based dialog generation methods (Ghazarian et al., 2021).

Post
you might remember me posting here when i had less than a month sober a little while back. well, yesterday i hit 100 days without alcohol and celebrated by solo hiking my state's tallest mountain!

Golden
ok that is an awesome pic! love it and the story thank you!

EM
you're doing great!

DA → EM
good for you, man! keep it up!

CM → DA → EM (Ours)
i'm proud of you! i have been sober for about 10 years, and it's the best feeling ever. keep it up!

Figure 4: Responses generated with different empathy factors. All the generated responses express the EM *admiration*. **DA → EM** takes the DA *encouraging*. **Ours** further adopts the CM *emotional reaction* and *interpretation*.

7 Conclusion

In this paper, we present a multi-factor hierarchical framework CoMAE for empathetic response generation. It contains three key factors of empathy expression: communication mechanism, dialog act and emotion, and models these factors in a hierarchical way. With our devised CoMAE-based model, we empirically demonstrate the effectiveness of these empathy factors, as well as the necessity and importance of hierarchical modeling.

As future work, the CoMAE framework can be naturally extended to more factors that relate to empathy expression, such as persona (Zhong et al., 2020), by exploring the hierarchical relationships between different factors.

A Emotion Mapping

In the original paper of (Demszky et al., 2020)[14], the authors provide the hierarchical clustering results of the 27 emotions (Figure 2 in their paper), which reflect the nested structure of their proposed emotion taxonomy. Based on the clustering results, we merged the emotions that are highly correlated with each other, and the mapping between our adopted emotions and the original emotions is shown in Table 6.

Ours	**Original**
admiration	admiration, pride
anger	anger, annoyance, disgust, disapproval
approval	approval, realization
caring	caring, desire, optimism
fear	fear, nervousness
gratitude	gratitude, relief
joy	joy, amusement, excitement, love
sadness	sadness, disappointment, embarrassment, grief, remorse
surprise	surprise, confusion, curiosity

Table 6: Mapping between our adopted emotions and the original emotions in (Demszky et al., 2020).

B Statistics of Annotation

We computed the proportions of the last responses annotated with ER / IP / EX. In the Happy domain, the proportions are 76.0% / 10.2% / 18.7%, while in the Offmychest domain are 57.1% / 21.4% / 27.9% respectively. The statistics of DA and EM are shown in Figure 5.

We can find several differences between two domains. In terms of **communication mechanism**, the responses in the Offmychest domain prefer *interpretation* and *exploration*, while *emotional reaction* occupies a larger proportion in the Happy domain. In terms of **DA**, the actions that provide support (such as *agreeing*, *consoling*, *suggesting*, and *sympathizing*) are more frequently adopted in the Offmychest domain. It is similar when it comes to **emotion**, where the emotions such as *approval* and *caring* are displayed more commonly when responding to the posts with negative sentiments. We also observed that the responses in the Offmychest domain may also display the emotions like *anger* and *sadness*, indicating that they do understand the experiences and feelings of the conversation partners.

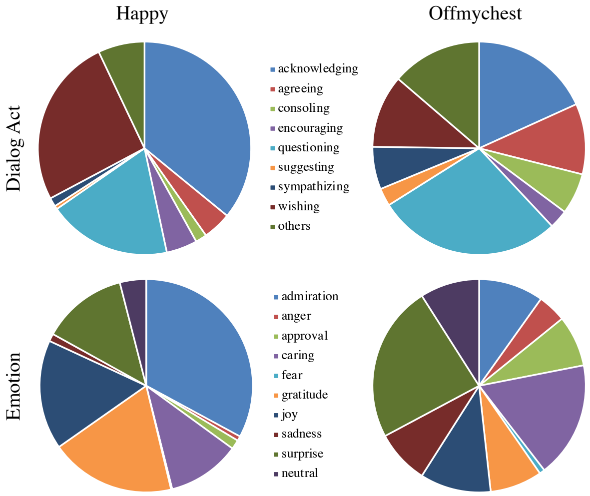

Figure 5: Statistics of the annotation results of DA and EM on the two domains.

Abstract

Keyphrase Prediction (KP) task aims at predicting several keyphrases that can summarize the main idea of the given document. Mainstream KP methods can be categorized into purely generative approaches and integrated models with extraction and generation. However, these methods either ignore the diversity among keyphrases or only weakly capture the relation across tasks implicitly. In this paper, we propose **UniKeyphrase**, a novel end-to-end learning framework that jointly learns to extract and generate keyphrases. In UniKeyphrase, stacked relation layer and bag-of-words constraint are proposed to fully exploit the latent semantic relation between extraction and generation in the view of model structure and training process, respectively. Experiments on KP benchmarks demonstrate that our joint approach outperforms mainstream methods by a large margin.

1 Introduction

Keyphrases are several phrases that highlight core topics or information of a document. Given a document, the KP task focuses on automatically obtaining a set of keyphrases. As a basic NLP task, keyphrase prediction is useful for numerous downstream NLP tasks such as summarization (Wang and Cardie, 2013; Pasunuru and Bansal, 2018), document clustering (Hulth and Megyesi, 2006), information retrieval (Kim et al., 2013).

Keyphrases of a document fall into two categories: *present keyphrase* that appears continuously in the document, and *absent keyphrase* which does not exist in the document. Figure 1 shows an example of a document and its keyphrases. Traditional KP methods are mainly extractive, which have been extensively researched in past decades (Witten et al., 2005; Nguyen and Kan, 2007; Medelyan et al., 2009; Lopez and Romary, 2010; Zhang et al., 2016; Alzaidy et al., 2019; Sun et al., 2020). These methods aim to select text spans or phrases directly in the document, which show promising results on present keyphrase prediction. However, extractive methods cannot handle the absent keyphrase, which is also significant and requires a comprehensive understanding of document.

Document: On selecting an optimal wavelet for detecting singularities in traffic and vehicular data. …… applications of wavelet transform s (wts) in traffic engineering have been introduced however , …… , second order difference , oblique cumulative curve , and short time fourier transform) . it then mathematically describes wts ability to detect singularities in traffic data . …… , it is shown that selecting a suitable wavelet largely depends on the specific research topic , and that the mexican hat wavelet generally gives a satisfactory performance in detecting singularities in traffic and vehicular data .

Present keyphrases: { wavelet transform, oblique cumulative curve, short time fourier, the mexican hat wavelet }

Absent keyphrases: { singularity detection, traffic data analysis }

Figure 1: An example of an input document and its expected keyphrases. Blue and red denote present and absent keyphrases, respectively.

To mitigate this issue, several generative methods (Meng et al., 2017; Chen et al., 2018; Ye and Wang, 2018; Wang et al., 2019; Chen et al., 2019b; Chan et al., 2019; Zhao and Zhang, 2019; Chen et al., 2020; Yuan et al., 2020) have been proposed. Generative methods mainly adopt the sequence-to-sequence (seq2seq) model with a copy mechanism to predict a target sequence, which is concatenated of present and absent keyphrases. Therefore, the generative approach can predict both kinds of keyphrases. But these methods treat present and absent keyphrases equally, while these two kinds of keyphrase actually have different semantic properties. As illustrated in Figure 1, all the present keyphrases are specific techniques, while the absent keyphrases are tasks or research areas.

Thus several integrated methods (Chen et al., 2019a; Ahmad et al., 2020) try to perform multi-

---

[*] Equal contribution.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 825–835
August 1–6, 2021.

task learning on present keyphrase extraction (PKE) and absent keyphrase generation (AKG). By treating present and absent keyphrase prediction as different tasks, integrated methods clearly distinguish the semantic properties for these two kinds of keyphrases. But integrated models suffer from two limitations. Firstly, these approaches are not trained in an end-to-end fashion, which causes error accumulation in the pipeline. Secondly, integrated methods just adopt a bottom shared encoder to implicitly capture the latent semantic relation between PKE and AKG, while this relation is essential for the KP task. As illustrated in Figure 1, the ground truth of PKE are specific techniques, which are all used for the "singularity detection" task in the "traffic data analysis" area. Such semantic relation between PKE and AKG can bring benefits for KP. Actually, semantic relations like "technique-task-area" between two tasks are common in the KP task. However, these integrated methods are weak at modeling it.

To address these issues, we propose a novel end-to-end joint model, UniKeyphrase, which adopts a unified pretrained language model as the backbone and is fine-tuned with both PKE and AKG tasks. What's more, UniKeyphrase explicitly captures the mutual relation between these two tasks, which brings benefits for keyphrase prediction: present keyphrases can provide an overall sense about salient parts of the document for AKG, and absent keyphrases viewed as high-level latent topics of the document can also supply PKE with global semantic information.

Specifically, UniKeyphrase employs two mechanisms to capture the relation from model structure and training process, respectively. Firstly, stacked relation layer is applied to repeatedly fuse PKE and AKG task representations to explicitly model the relation between the two sub-tasks. In detail, we adopt a co-attention based relation network to model the co-influence. Secondly, a bag-of-words constraint is designed for UniKeyphrase, which aims to provide some auxiliary global information of the whole keyphrases set during training.

Experiments conducted on the widely used public datasets show that our method significantly outperforms mainstream generative and integrative models. The contributions of this paper can be summarized as follows:

- We introduce a novel end-to-end framework UniKeyphrase for unified PKE and AKG.
- We design stacked relation layer (SRL) to explicitly capture the relation between PKE and AKG.
- We propose bag-of-words constraint (BWC) to explicitly feed global information about present and absent keyphrases to the model.

2 Related Works

2.1 Keyphrase Extraction

Most existing extraction approaches can be categorized into two-step extraction methods and sequence labeling approaches. Two-step extraction methods first identify a set of candidate phrases from the document by heuristics, such as essential n-grams or noun phrase (Hulth, 2003). Then, the candidate keyphrases are sorted and ranked to get predicted results. The scores can be learned by either supervised algorithms (Nguyen and Kan, 2007; Medelyan et al., 2009; Lopez and Romary, 2010) or unsupervised graph ranking methods (Mihalcea and Tarau, 2004; Wan and Xiao, 2008). For sequence labeling approaches, documents are fed to an encoder then the model learns to predict the likelihood of each word being a keyphrase (Zhang et al., 2016; Alzaidy et al., 2019; Sun et al., 2020).

2.2 Keyphrase Generation

Keyphrase generation focuses on predicting both present and absent keyphrases. Meng et al. (2017) first propose CopyRNN which is a seq2seq framework with attention and copy mechanism. Then a semi-supervised method for the exploitation of the unlabeled data is investigated by Ye and Wang (2018). Chen et al. (2018) employ a review mechanism to reduce duplicates. Chen et al. (2019b) focus on leveraging the title information to improve keyphrases generation. The latent topics of the document are exploited to enrich features by Wang et al. (2019). Zhao and Zhang (2019) utilize linguistic constraints to prevent model from generating overlapped phrases. Chan et al. (2019) introduce a reinforcement learning approach for keyphrase generation. Chen et al. (2020) propose an exclusive hierarchical decoding framework to explicitly model the hierarchical compositionality of a keyphrase set. Yuan et al. (2020) introduce a new model to generate multiple keyphrases as delimiter-separated sequences.

2.3 Integrated Methods

To explicitly distinguish the present and absent keyphrases, integrated extraction and generation approach have been applied to the KP task. Chen et al. (2019a) aim at improving the performance of the generative model by using an extractive model. Ahmad et al. (2020) propose SEG-Net, a neural keyphrase generation model that is composed of a selector for selecting the salient sentences in a document, and an extractor-generator that extracts and generates keyphrases from the selected sentences. In contrast to these methods, our joint approach can explicitly capture the relation between extraction and generation in an end-to-end framework.

3 Approach

In this section, we describe the architecture of UniKeyphrase. Figure 2 gives an overview of UniKeyphrase, which consists of three components: extractor-generator backbone based on UniLM, a stacked relation layer for capturing the relation between PKE and AKG, and bag-of-words constraint for considering the global view of two tasks in training. In the following sections, the details of UniKeyphrase are given.

3.1 Extractor-Generator Backbone

Given a document $\mathbf{X} = \{x_1, ..., x_m\}$, KP aims at obtaining a keyphrase set $\mathbf{K} = \{k_1, ..., k_{|K|}\}$. Naturally, $\mathbf{K}$ can be divided into present keyphrase set $\mathbf{K}_p = \{k^p_1, ..., k^p_{|K_p|}\}$ and absent keyphrase set $\mathbf{K}_a = \{k^a_1, , ..., k^a_{|K_a|}\}$ by judging whether keyphrases appear exactly in the source document. UniKeyphrase decomposes the KP into PKE and AKG, and jointly learns two tasks in an end-to-end framework.

UniKeyphrase treats PKE as a sequence labeling task and AKG as a text generation task. To jointly learn in an end-to-end framework, UniKeyphrase adopts UniLM (Dong et al., 2019) as the backbone network. UniLM is a pre-trained language model, which can perform sequence-to-sequence prediction by employing a shared transformer network and utilizing specific self-attention masks to control what context the prediction conditions on.

As shown in Figure 2, with a pre-trained UniLM layer, the contextualized representation for the source document can attend to each other from both directions, which is convenient for PKE. While the representation of the target token can only attend to the left context, as well as all the tokens in the source document, which can be easily adapted to AKG.

Specifically, for a document $\mathbf{X}$, all absent keyphrases will be concatenated as a sequence. Then we randomly choose tokens in this sequence, and replace them with the special token [MASK]. The masked sequence is defined as $\mathbf{K}^m_a$. We further concatenate document $\mathbf{X}$ and $\mathbf{K}^m_a$ with [CLS] and [SEP] tokens as the input sequence:

$$\mathbf{I} = \{[\text{CLS}]\, \mathbf{X}\, [\text{SEP}]\, \mathbf{K}^m_a\, [\text{SEP}]\} \quad (1)$$

Afterwards, we feed input sequence into UniLM and obtain output hidden state $\mathbf{H}$:

$$\mathbf{H} = \text{UNILM}(\mathbf{I}) \quad (2)$$

the hidden state $\mathbf{H} = \{h_1, ..., h_T\}$ (T is the number of input tokens in the UniLM) will be used as the input of stacked relation layer for jointly modeling PKE and AKG.

3.2 Stacked Relation Layer

Based on the UniLM, we can obtain the output hidden $\mathbf{H}$. Instead of directly using the UniLM hidden for PKE and AKG, we use the SRL to explicitly model the relation between these two tasks. Actually, modeling the cross-impact and interaction between different tasks in joint model is a common problem (Qin et al., 2020a,b, 2019).

Specifically, SRL takes the initial shared representations $\mathbf{P}^0 = \mathbf{A}^0 = \{h_1, ..., h_T\}$ as input and aims to obtain the finally task representations $\mathbf{P}^L$ and $\mathbf{A}^L$ (L is the number of stacked layers), which consider the cross-impact between PKE and AKG. Besides, SRL can be stacked to repeatedly fuse PKE and AKG task representations for better capturing mutual relation.

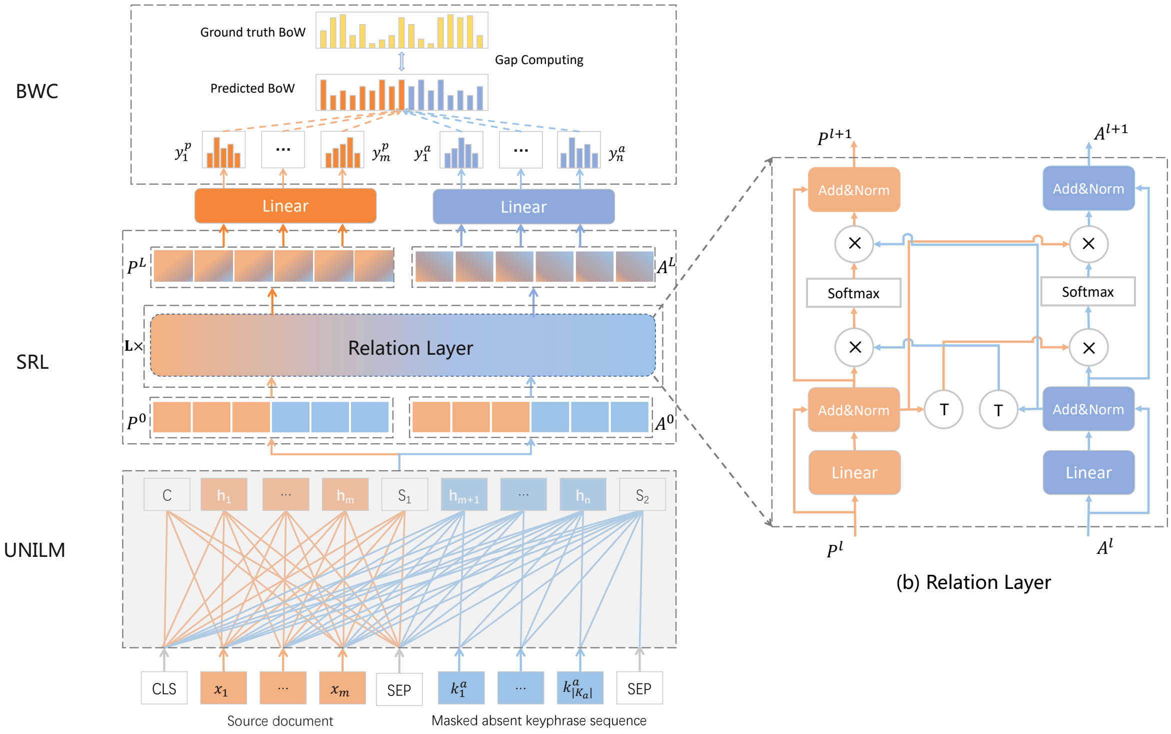
Formally, given the l^{th} layer inputs $\mathbf{P}^l = \{p^l_1, ..., p^l_T\}$ and $\mathbf{A}^l = \{a^l_1, ..., a^l_T\}$, stacked relation layer first apply two linear transformations with a ReLU activation over the input to make them more task-specific, which can be written as follow:

$$\mathbf{P}^{l'} = \text{LN}(\mathbf{P}^l + \max(0, \mathbf{W}^l_P \mathbf{P}^l + \mathbf{b}^l_P)) \quad (3)$$

$$\mathbf{A}^{l'} = \text{LN}(\mathbf{A}^l + \max(0, \mathbf{W}^l_A \mathbf{A}^l + \mathbf{b}^l_A)) \quad (4)$$

where LN represent the layer normalization function (Ba et al., 2016).

Then the relation between the two tasks will be integrated base on task-specific representations. In this paper, we adopt co-attention relation networks.



(b) Relation Layer

(a) UniKeyphrase

Figure 2: The architecture of our model

Co-Attention is an effective approach to model the important information of correlated tasks. We extend the basic co-attention mechanism from token level to task representations level. It can produce the PKE and AKG task representations considering each other. Therefore, we can transfer useful mutual information between two tasks. The process can be formulated as follows:

$$\mathbf{P}^{l+1} = \mathrm{LN}(\mathbf{P}^{l'} + \mathrm{softmax}(\mathbf{P}^{l'}(\mathbf{A}^{l'})^{\top})\mathbf{A}^{l'}) \quad (5)$$

$$\mathbf{A}^{l+1} = \mathrm{LN}(\mathbf{A}^{l'} + \mathrm{softmax}(\mathbf{A}^{l'}(\mathbf{P}^{l'})^{\top})\mathbf{P}^{l'}) \quad (6)$$

where $\mathbf{P}^{l+1} = \{p_1^{l+1}, ..., p_T^{l+1}\}$ and $\mathbf{A}^{l+1} = \{a_1^{l+1}, ..., a_T^{l+1}\}$ are the l^{th} layer updated representations.

After stacked relation layer, we can obtain the outputs $\mathbf{P}^L = \{p_1^L, ..., p_m^L\}$ and $\mathbf{A}^L = \{a_1^L, ..., a_n^L\}$. We then adopt separate decoders to perform PKE and AKG by using the task representations of corresponding position , which can be denoted as follows:

$$\mathbf{y}_i^p = \mathrm{softmax}(\mathbf{W}^p p_i^L + \mathbf{b}^p) \quad (7)$$

$$\mathbf{y}_j^a = \mathrm{softmax}(\mathbf{W}^a a_j^L + \mathbf{b}^a) \quad (8)$$

where $\mathbf{y}_i^p$ and $\mathbf{y}_j^a$ are the predicted distribution for present keyphrase and absent keyphrase respectively; $\mathbf{W}^p$ and $\mathbf{W}^a$ are transformation matrices; $\mathbf{b}_p$ and $\mathbf{b}_a$ are bias vectors.

3.3 Bag-of-Words Constraint

UniKeyphrase divides the KP task into two subtasks, PKE and AKG. These two sub-tasks are optimized separately, which lacks the awareness of global information about the total keyphrase set. Such global information can be the amount of all keyphrases or the common words between present and absent keyphrases. Bag of words (BoW) is a suitable medium for describing this information. In this paper, we feed global information to UniKeyphrase by constructing constraints based on the BoW of keyphrases. The word count in BoW can provide guidance about task relation for PKE and AKG training in a global view.

Specifically, we calculate the gap between the model predicted keyphrase BoW and ground truth keyphrase BoW, then add it into the loss. Hence UniKeyphrase can get a global view of keyphrases allocation and adjust two tasks during training.

We first collect present and absent keyphrase BoW from model. For present keyphrases, since PKE is a sequence labeling task, we collect all words that labeled as keyphrases, and construct present predicted BoW V^p. We use the sum of corresponding label probabilities as the count of word w in V^p:

$$V^p(w) = \sum_{i \in \mathcal{I}_w} max(\mathbf{y}_i^p) \tag{9}$$

where y_i^p denotes all predicted label probabilities at time step i. $\mathcal{I}_w$ is all position of word w in document. Maximum operation is used for selecting the probability of predicted label. For absent keyphrase, the generation probability of all steps are accumulated as predicted absent BoW $V^a(w)$.

$$V^a(w) = \sum_{j=1}^{N} \mathbf{y}_j^a(w) \tag{10}$$

After acquiring the predicted present and absent keyphrase BoW, we concatenate these two parts as the total predicted BoW V, then calculate the error compared with ground truth BoW $\hat{V}$. To reserve the word count information, we use Mean Square Error (MSE) function:

$$\mathcal{L}_{BoW} = \frac{1}{|\mathcal{V}|} \sum_{w \in \mathcal{V}} (V(w) - \hat{V}(w))^2 \tag{11}$$

It is worth noting that $\mathcal{V}$ is the collection of words that make up the ground truth keyphrases and predicted keyphrases. So the BWC only affects a small subset of the whole vocabulary for each sample. This can help reduce the noise and stabilize the training process.

In practice we increase the weight of BWC logarithmically from zero to a defined maximum value w_m, the weight of BWC on t step can be denoted as follows:

$$w_{BoW}(t) = log(\frac{e^{w_m} - 1}{t_{total}} t + 1) \tag{12}$$

where t_{total} is the total step of training. The reason to adjust the weight is the same as Ma et al. (2018). The BWC should take effect when predicted results are good enough. Therefore we first assign a small weight to BWC at the initial time, and gradually increase it when training.

3.4 Training

For the PKE task, objection is formulated as:

$$\mathcal{L}_{PKE} = -\sum_{i=1}^{M} \sum_{c=1}^{C} w_c \hat{\mathbf{y}}_i^{(c,p)} \log \left(\mathbf{y}_i^{(c,p)} \right) \tag{13}$$

where M refers to the length of document, C refers to the number of label, w_c is the loss weight for the positive label. $\hat{\mathbf{y}}_i^p$ refers the gold label.

For the AKG task, training objection is to maximize the likelihood of masked tokens, which is formulated as:

$$\mathcal{L}_{AKG} = -\sum_{i=1}^{N} \sum_{j=1}^{V_s} \hat{\mathbf{y}}_i^{(j,a)} \log \left(\mathbf{y}_i^{(j,a)} \right) \tag{14}$$

where N refers to the number of masked tokens, V_s refers to the size of vocabulary. $\hat{\mathbf{y}}_i^a$ refers the ground-truth word.

Considering the BWC, the overall loss of UniKeyphrase is formulated as:

$$\mathcal{L} = \mathcal{L}_{PKE} + \mathcal{L}_{AKG} + w_{BoW} \mathcal{L}_{BoW} \tag{15}$$

4 Experiments

4.1 Datasets and Evaluation

We follow the widely used setup of the deep KP task: train, validation and test on the `KP20K` (Meng et al., 2017) dataset, and give evaluation on three more benchmark datasets: `NUS` (Nguyen and Kan, 2007), `INSPEC` (Hulth, 2003) and `SEMEVAL` (Kim et al., 2010). We follow the pre-process, post-process, and evaluation setting of Meng et al. (2017, 2019); Yuan et al. (2020)[1]. Specifically, we use the partition of present and absent provided by Meng et al. (2017) and calculate F_1@5 and F_1@M (use all predicted keyphrases for F_1 calculation) after stemming and removing duplicates.

4.2 Experimental Setup

Setting: We reuse most hyper-parameters from pre-trained UNILM[2]. The layer number of SRL is set to 2. We use $w_m = 1.0$ when adjusting the weight of BWC. PKE loss weights w_c for the positive label is set to 5.0. we set batch size to 256, and maximum length to 384. During decoding, we use beam search for AKG, and beam size is set as 5. We train our model on the training set for 100 epochs. It takes about 40 minutes per epoch to train UniKeyphrase on 8 Nvidia Tesla V100 GPU cards with mixed-precision training. More details are provided in Appendix B.

---

[1] we follow the official GitHub repository to prepare datasets and evaluation scripts which are available on https://github.com/memray/OpenNMT-kpg-release.

[2] we use the official provided pre-trained model, which is available on https://unilm.blob.core.windows.net/ckpt/unilm1-base-cased.bin.

Table 1: Results on present keyphrase prediction.

Baselines: We compare two kinds of strong baselines (generative, integrated) to give a comprehensive evaluation on the performance of UniKeyphrase.

- **Generative**: Generative models can predict both present and absent keyphrases under the seq2seq framework. CatSeq (Yuan et al., 2020) is the classic setting of keyphrase seq2seq model. We report the performance of CatSeq and various improved models on it, including CatSeqTG (Chen et al., 2019b), CatSeq (TRM) (Ahmad et al., 2020) and CatSeqD (Yuan et al., 2020). A recently released model is also included for comparing, which is ExHiRD-h (Chen et al., 2020).
- **Integrated**: Integrated model often combine multiple modules to perform extractive and abstractive tasks. But they are not end-to-end. Two latest integrated models are recorded for comparison. including KG-KE-KR-M (Chen et al., 2019a) and SEG-NET (Ahmad et al., 2020)

4.3 Main Results

In this section, we show the experimental results of the baseline methods and our model on present keyphrase extraction and absent keyphrase generation. Besides, we also study the average number of unique predicted keyphrases per document to further show the advantages of our model.

4.3.1 Present and Absent Keyphrase Prediction

The present and absent keyphrase prediction performance of all methods are shown in Table 1 and Table 2. From the results, we can find that our joint framework outperforms most state-of-the-art generative baseline by a significant margin, which demonstrates the effectiveness of our UniKeyphrase. We notice that the UniKeyphrase does not outperform the SEG-NET on F_1@M for present keyphrase extraction on `NUS` dataset. One potential reason is that the source document length and sentence number of `NUS` are much larger than the KP20k training set. SEG-NET employs an additional sentence selector for filtering sentences without keyphrase, which is more adaptable for processing long documents like `NUS`.

4.3.2 Number of Predicted Keyphrases

The number of predicted keyphrases indicates the model's understanding of input documents. From the previous work (Chen et al., 2020), we find the average number of unique predicted keyphrases per document is much lower than the gold average keyphrase number in most datasets. The number of unique keyphrases predicted by UniKeyphrase and baselines is compared in Table 3. We can find that UniKeyphrase predicts more (especially in absent keyphrases) than baseline methods, which is closer to ground truth. Meanwhile, we find UniKeyphrase leads to predict more keyphrases than the ground-truth (especially on KP20k). We leave solving the over prediction keyphrases problem as our future work.

4.4 Ablation Study

In this section, we check the improvement brought by SRL and BWC. Several ablation experiments are conducted to analyze the effect of different components. The ablation experiment on `SemEval` is shown in Table 4. The results show the effectiveness of different components of our method to the final performance.

Effectiveness of stacked relation layer: In this setting, we conduct experiments on the multi-task framework where PKE and AKG promote each other only by the hidden state of UniLM, From

w/o SRL	38.5	37.6	2.9	3.1
w/o BWC	40.0	39.5	2.8	2.8

Table 4: Ablation study on SemEval dataset

the result, we can see that the performance drops both in present keyphrase and absent keyphrase without stacked relation layer. This demonstrates that explicitly modeling the relation between PKE and AKG with stacked relation layer can benefit them effectively.

Effectiveness of bag-of-words constraint: In this setting, we remove our bag-of-words constraint and there is no global constraint for two tasks. The results show a drop in KP performance, indicating that capturing the global constraint of the result by BWC is effective and important for our method.

4.5 Analysis

4.5.1 SRL Analysis

To better understand the SRL module, we analyze the impact of stacked layers and give a visualization of the inner state of SRL.

Analysis of SRL Layer Number: We explore the impact of the stack number of relation network. The comparison of total keyphrase prediction result, which regardless of the present or absent of keyphrases, are shown in Table 5. We can find that setting deeper layers could generally result in better performance when the number of stacked layers is less than three, which proves the effectiveness of stacked layers. It is worth noting that when the number of stacked layers is larger than two, the KP performance drops. We suppose that when the relation network becomes deeper, the over-interaction will lose the diversity of two task representations.

Model	Total F_1@M
UniLM based keyphrase generation	23.7
UniKeyphrase with 0 layer SRL	23.1
UniKeyphrase with 1 layer SRL	25.2
UniKeyphrase with 2 layer SRL	**25.3**
UniKeyphrase with 3 layer SRL	24.5

Table 5: Total keyphrase prediction on SemEval dataset by different setting. UniKeyphrase with 0 layer SRL means UniKeyphrase without SRL module.

Visualization Analysis for SRL: To better understand what the SRL network has learned, we compare the distance between the PKE representation and AKG representation in different settings. In detail, we randomly sample 2000 pairs of PKE representation vector and AKG representation vector on different positions from test data and compute euclidean metric in each pair. As shown in Figure 3, the blue points mean the Euclidean metric between PKE and AKG representation vector without SRL layer, while the yellow points mean the Euclidean metric with SRL layer.

From the Figure 3, we can find that the blue points are under the yellow points, which means the PKE and AKG representation vector without SRL is more similar. In other words, SRL has learned the task-specific representation. Also, the blue points are denser than the yellow points, which

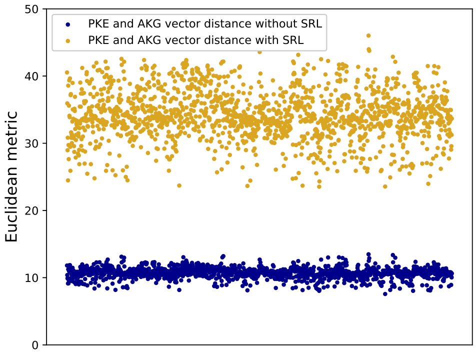

Figure 3: Distance between PKE representation and AKG representation on different settings.

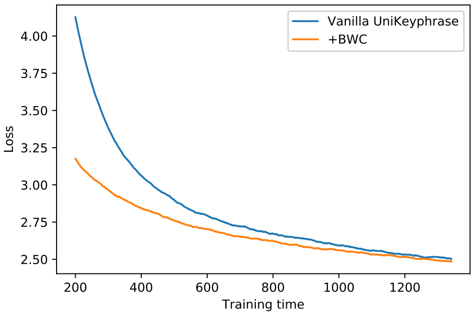

Figure 4: BWC's influence on total training loss (sequence labeling + text generation).

means the PKE and AKG representation with SRL is more diverse than the one without SRL on different samples.

4.5.2 BWC Analysis

Loss Compare: From Figure 4 we can see that the original total loss (labeling and generation) drops more with the help of BWC compared to the vanilla model. BWC actually is an enhancement on the original supervised signal from a global view. It guides the model to learn how many to predict and how to allocate present and absent keyphrases, while original loss only teaches what to predict in each position.

Bag-of-words Error: We also calculate the bag-of-words Error between ground truth and model predicted keyphrases, which is how many tokens are incorrectly predicted. As shown in Figure 5, UniKeyphrase with BWC achieves lower BoW Error compared with the vanilla model. It proves that BWC successfully guides the model to learn a better BoW allocation.

4.5.3 Joint Framework Analysis

In our UniKeyphrase model, we adopt pre-trained model UNILM for KP. So it is necessary to check

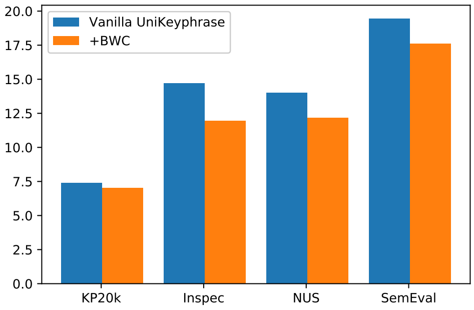

Figure 5: Bag-of-words Error comparison between vanilla and BWC.

that the gain on metrics of our proposed joint framework is not just come from the pre-trained model. In this section, we compare UniKeyphrase with directly using the pre-trained UNILM to perform generative KP.

Specifically, we train a sequence to sequence model for KP based on UNILM. Results are shown in Table 5. From the results, we find that all of the joint models with SRL can further outperform the generative method based on UNILM, demonstrating that the improvement of KP mainly come from our joint framework instead of pre-trained UNILM. We notice that the UniKeyphrase without SRL does not outperform the generative method based on UNILM, which show the significance of modeling the relation between the two sub-tasks in our joint framework.

5 Conclusion and Future Work

This paper focuses on explicitly establishing an end-to-end unified model for PKE and AKG. Specifically, we propose UniKeyphrase, which contains stacked relation layer to model the interaction and relation between the two sub-tasks. In addition, we design a novel bag-of-words constraint for jointly training these two tasks. Experiments on benchmarks show the effectiveness of the proposed model, and more extensive analysis further confirms the correlation between two tasks and reveals that modeling the relation explicitly can boost their performance.

Our UniKeyphrase can be formalized as a unified framework of NLU and NLG tasks. It is easy to transfer it to other extraction-generation NLP tasks. In the future, we will explore to adopt our framework to more scenarios.

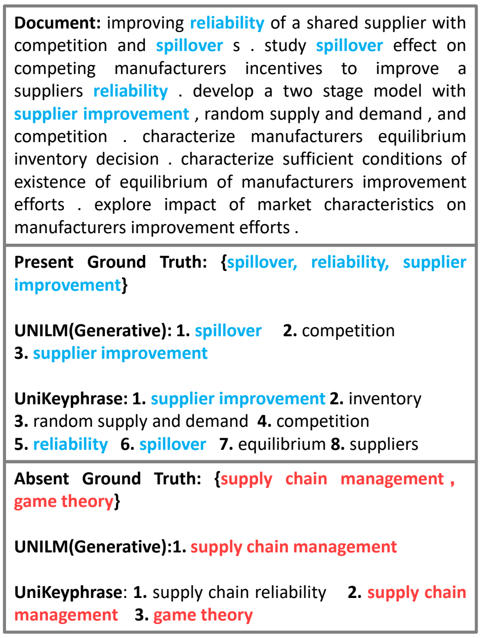
Relevant statistics about the dataset used in this paper is shown in Table 6.

B Experimental Details

The BWC does not bring extra parameters, hence the trainable parameters of UniKeyphrase come from UNILM and SRL. We use the base version of UNILM, which contains about 110M parameters. Follow UNILM, our model is implemented using PyTorch. The learning rate is 1e-5 and the proportion of warmup steps is 0.1. The masking probability of absent keyphrase sequence is 0.7. For the SRL module, dropout is applied to the output of each layer for regularization, the dropout rate is 0.5. In this paper, we try to set the number of layer by 2,3,4 and choose the best based on validation. For all experiments in this paper, we choose the model that performs best on the KP20k validation dataset.

C Preprocess

The input of UniKeyphrase is the same as BERT, which applies wordpiece tokenizer on raw sentences. So we use the "BIXO" labeling method, where B and I stand for Beginning and Inside of a word in keyphrases, and O denotes any token that Outside of any keyphrase. For any sub-word token in keyphrases(which starts with '##' in processed input) we use X to label it. For example, "voip conferencing system" will be tokenized into "v ##oi ##p con ##fer ##encing system" and be labeled as "B X X I X X I". We concatenate all the tokenized absent keyphrases into one sequence using a special delimiter " ; ". An example of absent keyphrase sequence will like "peer to peer ; content delivery ; t ##f ##rc ; ran ##su ##b".



Document: improving reliability of a shared supplier with competition and spillover s . study spillover effect on competing manufacturers incentives to improve a suppliers reliability . develop a two stage model with supplier improvement , random supply and demand , and competition . characterize manufacturers equilibrium inventory decision . characterize sufficient conditions of existence of equilibrium of manufacturers improvement efforts . explore impact of market characteristics on manufacturers improvement efforts .

Absent Ground Truth: {supply chain management , game theory**}**

UNILM(Generative):1. supply chain management

UniKeyphrase: **1.** supply chain reliability **2.** supply chain management **3.** game theory

Figure 6: Case study.

D Case Study

We give a case on the KP20k testset in Figure 6. For fairness, we compare with keyphrase generation based on UNILM since our joint models are based on its implementation. Blue and red denote correct present and absent keyphrases, respectively. As shown in Figure 6, UniKeyphrase successfully catches the deep semantic relation similar to the case in the introduction, but here are "methods" for the absent and "application" for the present. Having caught this relation, UniKeyphrase gives more accurate results(predicts absent keyphrases "game theory").

E Evaluation Details

We use F_1@5 and F_1@M as evaluation metric. For calculating F_1@5, since there is no explicit rank score for each predicted keyphrase, we calculate the rank score as follows:

Present: we calculate the average predicted label probabilities of all tokens in a keyphrase as the score. We tried several other scoring strategies like max, min, or the first token's probability as the score. The results show no significant difference(less than 0.1%).

Absent: following previous works, we pick up the top 5 keyphrases in sequence order. The 5 leftmost keyphrases in the predicted sequence are selected as the result.

As Good as New. How to Successfully Recycle English GPT-2 to Make Models for Other Languages

Abstract

Large generative language models have been very successful for English, but other languages lag behind, in part due to data and computational limitations. We propose a method that may overcome these problems by adapting existing pre-trained models to new languages. Specifically, we describe the adaptation of English GPT-2 to Italian and Dutch by retraining lexical embeddings without tuning the Transformer layers. As a result, we obtain lexical embeddings for Italian and Dutch that are aligned with the original English lexical embeddings. Additionally, we scale up complexity by transforming relearned lexical embeddings of GPT-2 small to the GPT-2 medium embedding space. This method minimises the amount of training and prevents losing information during adaptation that was learned by GPT-2. English GPT-2 models with relearned lexical embeddings can generate realistic sentences in Italian and Dutch. Though on average these sentences are still identifiable as artificial by humans, they are assessed on par with sentences generated by a GPT-2 model fully trained from scratch.

1 Introduction

Large pre-trained language models have brought unprecedented progress in NLP, but also concerns regarding the excessive computing power needed to train them (Strubell et al., 2019). Limited access to large amounts of computational resources, as well as environmental considerations, curb possibilities for less-resourced and less-researched languages. Additionally, models like GPT-2 (Radford et al., 2019) are trained on amounts of data that are not available for most languages. As a result of these limitations, language models are commonly trained for English, whereas reproductions in other languages may underperform or not exist.

That language models can benefit from information in other languages has been demonstrated by the effectiveness of multilingual BERT (mBERT) and XLM-RoBERTa (Conneau et al., 2020). However, for downstream tasks mBERT has been shown to be outperformed by monolingual models for higher resource languages whereas lower resource languages can still achieve better results without pre-trained language models (Nozza et al., 2020; Wu and Dredze, 2020).

Rather than pursuing a multilingual direction, we aim at exploiting existing language models and language similarities to create models for new languages. Specifically, we develop a multi-step procedure for adapting English GPT-2 (Radford et al., 2019) to Italian and Dutch. Dutch is genetically closely related to English, both being West-Germanic languages, while Italian is a more distant Romance language from the same Indo-European language family (Eberhard et al., 2020). It is however worth noticing that at sentence level English and Italian tend to have the same word order (SVO), while Dutch is SVO in main clauses, but SOV in subordinate ones; at noun phrase level, English and Dutch share constituent order (for example adjective-noun) while Italian is different (mostly noun-adjective). A GPT-2 based model has previously been trained from scratch for Italian (De Mattei et al., 2020). We can thus compare sentences generated by this model with sentences generated by our adapted model. For Dutch, no other GPT-2 based models exist, but similar BERT-based models have been trained from scratch (de Vries et al., 2019; Delobelle et al., 2020).

Procedure Overview and Contributions When training a new language model, weights of an existing pre-trained model for another language can be used for initialisation. The first step in our training procedure is to only retrain the lexical embeddings of the GPT-2 *small* model, without touching the Transformer layers. We show that retrained lexical embeddings are well aligned with the English vo-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 836–846
August 1–6, 2021.

cabulary and that GPT-2 is capable of generating realistic text in Italian and Dutch after this step. Next, we demonstrate that the lexical embeddings of larger GPT-2 models can be approximated by transforming the *small* lexical embeddings to the GPT-2 *medium* lexical embedding space. The least-squares regression method is the most effective transformation method for this scaling procedure. Human judgements show that generated sentences are often realistic, but become even more consistently so after additional finetuning of the Transformer layers. This improvement is stronger for Dutch than for Italian.

The steps in our pipeline yield GPT-2 based language models for Italian and Dutch which are made available on the Hugging Face model hub[1]; the source code is available on Github[2]. On the last page, we also include a 'recipe' for creating GPT-2 models for new languages.

2 Background

Previous and current research relevant for the present work is found in the more general field of transfer learning, with a specific focus on language transfer. We also discuss how our approach of translating lexical layers in different model sizes relates to work on aligning word embeddings.

2.1 Language transfer

Transfer learning can be an effective strategy to adapt models to lower-resource languages by initially training a model for a source language and then further training (parts of) the model for a target language. It has been successfully used to create machine translation models with little parallel data (Zoph et al., 2016) as well as other classic NLP tasks (Lin et al., 2019).

In machine translation a model can be adapted by initially training it for a high-resource language pair after which the model should be partially retrained for a low-resource language (Zoph et al., 2016; Nguyen and Chiang, 2017; Kocmi and Bojar, 2018). Retraining a randomly initialised lexical layer while freezing the rest of the model is an effective method to adapt a model to a new language, and dictionary based initialisation is not required to get the best performance (Zoph et al., 2016). Artetxe et al. (2020) show that a monolingual BERT model can be adapted from a source language to a different target language by retraining the lexical layer for the target language while freezing the Transformer layers in the model. Zero shot adaptation for downstream tasks is possible by finetuning the original source model with source language data and swapping lexical layers afterwards. Lexical layer retraining approaches may be effective despite the presence of source and target language dissimilarities if a downstream task does not require perfect data. However, these methods have not been applied yet to generative language models where dissimilarities can cause clear syntactic and lexical errors.

Language similarity plays a role in the effectiveness of transfer learning for language models. For instance, in machine translation French is a better parent model for Spanish than German (Zoph et al., 2016). Word order differences between languages can negatively influence transfer performance, and Kim et al. (2019) show that randomly swapping words in the source language, which forces the model to rely less on consistent word order, can improve performance in the target language. Overall, genetic similarity between source and target languages can play a role, but Lin et al. (2019) have shown that in practice the geographic distances between countries of origin, syntactic similarity and subword overlap are better predictors of transfer performance for machine learning, part-of-speech tagging, dependency parsing and entity linking.

2.2 Aligning word embeddings

Alignment of lexical embeddings, for example for multiple languages, is most prominently done with mapping-based approaches (Ruder et al., 2019). Typically, a function is determined that transforms one vector space to another based on a seed lexicon. This lexicon is a dictionary of anchor points that should result close together after transformation.

An influential method for learning a lexical embedding mapping is the least-squares linear transformation method by Mikolov et al. (2013). They observe that words and their translations in other languages show similar constellations of related words after such a transformation. An alternative method that is generally considered to be an improvement (Ruder et al., 2019) is the orthogonal procrustes solution. This method adds the constraint that the transformation matrix must be orthogonal. In practice this means that the transfor-

---

[1] `https://huggingface.co/GroNLP`

[2] `https://github.com/wietsedv/gpt2-recycle`

mation only contains rotations and reflections and no scaling and translation. This constraint enables length normalisation (Xing et al., 2015) and ensures monolingual invariance (Artetxe et al., 2016).

Mapping-based approaches rely on isomorphism, which means that a one-to-one token mapping between source and target lexical embedding spaces should be possible. This assumption is used for bilingual lexicon induction after alignment (Conneau et al., 2018). However, the isomorphism assumption highly depends on language similarity and (amount of) training data (Søgaard et al., 2018). Some more complex alignment methods like RCLS (Joulin et al., 2018) optimise for dictionary translation performance, which assumes isomorphism, but simpler methods like the orthogonal procrustes solution are more effective for downstream tasks like natural language inference (Glavaš et al., 2019). Mohiuddin et al. (2020) propose a solution to the isomorphism problem by learning a new shared embedding space with an auto-encoding neural model instead of trying to fit the embeddings of one language in the space of another language.

3 Resources

Models The models that we train are based on the pre-trained GPT-2 language models (Radford et al., 2019). GPT-2 is an auto-regressive Transformer-decoder based language model for English and comes in four sizes: small (12 layers), medium (24 layers), large (36 layers) and extra large (48 layers). Our experiments use the small (`sml`) and medium (`med`) model sizes.

Pre-training data The GPT-2 models are (further) pre-trained with Italian (`ita`) and Dutch (`nld`) data. The Italian pre-training data is the same dataset that was used to train the Italian GPT-2 small language model GepPpeTto (De Mattei et al., 2020). This dataset is a combination of Wikipedia data (2.8GB) and web texts from the ItWaC corpus (11GB; Baroni et al. 2009). Dutch data consists of a combination of Wikipedia (2.0GB), newspaper articles (2.9GB; Ordelman, Roeland J.F. et al. 2007), books (6.5GB) and articles from various Dutch news websites (2.1GB). Documents are filtered to only contain Dutch texts using the Wikipedia-trained fastText language identifier (Joulin et al., 2017), and are deduplicated based on exact sentence matches. The final Dutch pre-training data contains 13GB of plain text, of which 5% is reserved as development data.

Evaluation data The Italian models are tested using the same three corpora that were used to evaluate GePpeTto (De Mattei et al., 2020): Wikipedia, ItWaC, EUR-Lex (laws), newspapers and blog posts. A 5% subset of this data is used for development. For perplexity evaluation, the Dutch 500 million word, 22-genre SoNaR corpus is used (Oostdijk et al., 2013). The smaller 1 million word SoNaR-1 subcorpus is used as development data.

Tokenisation The datasets are tokenised using byte-pair-encoding (BPE). For better comparison, the Italian vocabulary is taken from the GePpeTto model (De Mattei et al., 2020). The Dutch BPE vocabulary is based on the full pre-training data and it has been ensured that every character that is used in the Dutch language is present as a single character token in the vocabulary. A large vocabulary size is beneficial because words are less often split in separate tokens, but vocabularies that are too large will have low token coverage for uncommon tokens.

Computation Training a model like GPT-2 is a computationally expensive task that requires access to costly hardware for long training times. All models discussed in this paper are trained with eight parallel NVIDIA V100 32GB GPUs on the Peregrine high performance computing cluster at the University of Groningen. For efficient implementation of the models, we use PyTorch (1.6.0; Paszke et al. 2019), PyTorch Lightning (0.9.0; Falcon 2019) and Transformers (3.0.2; Wolf et al. 2020). We implement four strategies to decrease general training time. First, the models are trained with 16-bit automatic mixed-precision training (Micikevicius et al., 2018). This decreases training time with a factor of two to three times. Second, we split each document in windows of 128 instead of 1024 tokens when we only train the lexical embeddings. Third, we minimise padding by using bucketed random sampling which means that sequences within minibatches have roughly the same length. Finally, we use maximum batch sizes that fit into GPU memory and use gradient accumulation in order to do backpropagation only for every 2000 examples. The models are trained with the Adam optimiser (Kingma and Ba, 2017) and initial learning rates are chosen based on the steepest loss slope with gradually increasing learning rates (Smith, 2017). The learning rate is reduced by 10% on when training loss reaches a plateau. More implementation details are given in the git repository.

4 Cross-language Transfer

We adapt GPT-2 for Italian and Dutch with minimal random initialisation. The lexical embeddings in GPT-2 are trained with an English BPE vocabulary. Therefore, they are not usable for the new languages and the lexical embedding layer has to be randomly initialised for the target vocabulary. This lexical embedding layer is used both as the first and the last layer of GPT-2 (tied weights). Relearning lexical embeddings with frozen Transformer layers prevents catastrophic forgetting in the Transformer layers when the embeddings are still random.

Relearning lexical embeddings Relearning lexical embeddings is nearly as computationally expensive as fully training the model, because backpropagation has to be done through the full model in order to update the lexical embeddings in the first layer of the model. However, loss values stabilize after only one to two epochs with lexical embedding relearning whereas full model training takes more training time. We retrain the lexical embeddings for the `sml` and `med` model for Italian and Dutch by training until loss on the validation data stops decreasing. When we retrain the `sml` model, the perplexities on our Italian and Dutch test data become 44.2 and 48.9 respectively. These perplexity scores show that the `sml` model can predict Dutch and Italian tokens reasonably well without having retrained the Transformer layers. Therefore, the English Transformer layers are at least partially language-independent and our relearning method automatically aligns lexical embeddings to the embedding space of the English model. However, if we retrain the `med` lexical layer for Italian and Dutch with the same method, test data perplexities are 81.2 and 185.0. These unsatisfactory `med` perplexities could be due to stopping training too early or to arriving at a suboptimal local optimum. Training for a longer time or trying different random initialisations defeats the purpose of minimising computational requirements. A more efficient method that uses the already learned `sml` embeddings is described in Section 5.

Vocabulary alignment The lexical embeddings of both the original English tokens as well as the relearned Italian and Dutch lexical embeddings can be considered to inhabit the same embedding space because the lexical embeddings of all three languages are tuned to minimise loss with the exact same Transformer layers. Therefore, tokens with similar meaning in different languages should be close to each other if the lexical embeddings are properly trained. Table 1 shows the closest Italian and Dutch tokens of a random sample of English tokens. These alignments show that the optimal lexical embeddings for both Italian and Dutch are often literal translations of English tokens. Thanks to similarity of context-dependent structures like syntax in these three languages, the English model can be adapted to Italian and Dutch. Based on this small sample, Dutch to English alignment seems to be slightly more accurate than Italian to English, but a more thorough study would be required to evaluate the actual relation between genetic similarity and alignment potential through this method.

English	**Italian**	**Dutch**
while	mentre	terwijl
genes	geni	genen
clothes	vestiti	kleren
musicians	composi[...]	artiesten
permitted	ammessa	toegelaten
Finally	infine	Eindelijk
satisfied	soddisfatto	tevreden
Accuracy:	85%	89%

Table 1: Alignment of closest tokens in the lexical embeddings of $\texttt{sml}_{\texttt{rle}}$ for Italian and Dutch. Accuracy scores are based on a manual evaluation by the authors of 200 random aligned tokens. Semantically correct subword matches are included.

Text generation Table 2 shows some examples of unconditioned text generation of the English `sml` with relearned lexical embeddings for Italian and Dutch. These examples show that the model can generate proper Italian and Dutch sentences, although it sometimes uses English word order where the correct word order differs in Dutch, or ignores grammatical gender agreement in Italian defaulting to the singular masculine, or doesn't always produce correctly Italian prepositional articles ("di la", en: *of the* vs "della", en: *of-the*). Phrases in italics in Table 2 highlight such mistakes.

The literal English translations, however, show that the models can generate proper Italian and Dutch grammar that differs from English. Italian and Dutch lexical embeddings are not only aligned with equivalent English tokens, but unexpected correct syntax shows that the grammatical functions of words have also been adapted. For example, in Ital-

Italian	**Literal English translation**

In een artikel in de Journal of Economicologie (1998), *The New York Times schrijft*:	In an article in the Journal of Economicology (1998), *The New York Times writes*:
Ik kan me niet voorstellen dat mensen van mijn generatie *zijn zo boos op mij te wachten*.	I can me not imagine that people of my generation *are so mad at me to wait*.
Ik heb niets gedaan om mijn moeder te helpen.	I have nothing done to my mother to help.

Table 2: A selection of generated sentences by the `sml` model with Italian and Dutch lexical embeddings. Phrases in italics are ungrammatical in the target language.

ian the noun-adjective order is opposite to English and realised correctly; also, the use of the definite article in front of a possessive pronoun is correctly introduced, while ungrammatical in English.

This shows that the relatively low-dimensional context-independent lexical embeddings in GPT-2 contain syntactic features of the tokens in addition to semantics, and confirms previous findings of high information density in the lexical layer of language models (de Vries et al., 2020). Therefore, language adaptation can be to some extent effective by adapting the lexical embedding layer without retraining Transformer layers at all.

5 Scaling up Complexity

Replacing the original lexical embeddings with lexical embeddings from a different target language seems an effective way to initialise full model transfer to that target language. However, relearning the lexical embeddings of a new vocabulary requires full forward and backward propagation through the whole model. Therefore, this becomes an increasingly more expensive task for larger model sizes. When multiple model sizes need to be transferred to a new language, the lexical embeddings do not need to be retrained from scratch. Instead, vocabulary alignment between the source and target languages for the smaller model could be used to initialise the embeddings for a larger model.

After relearning the lexical embeddings of the `sml` model for Italian and Dutch, we observed that tokens with similar meaning in different languages are close to each other in the embedding space. This alignment effect should also be present in properly trained lexical embeddings of larger models. Given that we have at our disposal known embeddings for all 50K English tokens for every model size, we can use these data points to transform model size `sml` to larger model size `med`.

Regardless of architecture, embeddings are only considered to be alignable if they are trained under identical conditions with the same type and amount of data (Levy et al., 2015; Ruder et al., 2019). Our goal differs from previous alignment efforts since instead of aligning languages, we align separately trained embeddings for different model sizes, trained on the same data with identical and fully parallel vocabularies in English. The embeddings differ in dimensionality (768d for `sml`, 1024d for `med`) and the different model sizes may influence the amount and density of information in the lexical embeddings.

5.1 Transformation methods

The 50K parallel English tokens can be used to find an optimal transformation between lexical embeddings of different model sizes. The completeness of this mapping due to shared vocabularies between models eliminates the need to use complex solutions like refinement or bootstrapping the lexicon (Artetxe et al., 2018). We compare three simple supervised alignment methods for transformation from source space `sml` to target space `med`.

Regression (lstsq) A classic approach for mapping lexical embeddings is mean-squared-error minimising linear regression with the least-squares method (Ruder et al., 2019; Mikolov et al., 2013). This method learns a transformation matrix $\boldsymbol{W}$ that minimises the Euclidean distance between source and target embeddings. The optimal matrix is ap-

	Italian		Dutch		
Model	**Int@1k**	**PPL**	**Int@1k**	**PPL**	**PPL (1 epoch)**
$\texttt{med}_{\texttt{rle}}$ (1 epoch)	0.38	-	185.02	-	-
$\texttt{sml}_{\texttt{rle}} \xrightarrow{proc} \texttt{med}$	**0.61**	8.12×10^{12}	**0.61**	5.02×10^{12}	52.69
$\texttt{sml}_{\texttt{rle}} \xrightarrow{lstsq} \texttt{med}$	0.56	**364.06**	0.56	**293.61**	**47.57**
$\texttt{sml}_{\texttt{rle}} \xrightarrow{1-nn} \texttt{med}$	0.37	2,764.19	0.36	1,101.59	50.25
$\texttt{sml}_{\texttt{rle}} \xrightarrow{10-nn} \texttt{med}$	0.37	20,715.80	0.35	11,871.66	56.88

Table 3: Scores for different transformation methods. Int@1K are the average 1k nearest English neighbours intersection (int) fractions between `sml` and transformed `med` embeddings. *PPL* is the perplexity on the test sets for Italian and Dutch. *PPL (1 epoch)* indicates the perplexity after one epoch of training, which is low if the transformed embeddings were close to a good local optimum.

proximated with stochastic gradient descent, and therefore this is not an exact solution.

Orthogonal Procrustes (proc) More recent alignment approaches constrain the transformation $\boldsymbol{W}$ to be an orthogonal matrix (Ruder et al., 2019; Artetxe et al., 2016). This constraint enables using the exact solution for the orthogonal Procrustes problem (Xing et al., 2015). The exact solution only rotates and reflects data points to be as close as possible to the target space without any scaling or translation, preserving monolingual invariance in the source embeddings (Artetxe et al., 2016).

Weighted K-Nearest Neighbours (knn) Unlike typical alignment approaches, we have a complete set of parallel data points in the source and target spaces (English). The unknown target language tokens can be approximated by taking the $\boldsymbol{K}$ nearest English tokens in the source `sml` embedding space and using the distance-weighted sum of these tokens in the target `med` embedding space.

5.2 Results after transformation

Table 3 shows `med` embedding similarity with source `sml` embeddings and perplexities on test data with transformed embeddings, as well as the transformed embeddings with one additional epoch of training. Results are consistent for Italian and Dutch. Nearest English neighbours are best preserved with the Orthogonal Procrustes method. However, the perplexity scores are extremely high for this method. The perplexity scores with the different methods vary in complete orders of magnitude. Based on this, the least-squares regression method outperforms the other methods. After one epoch of additional training with transformation initialised embeddings, the lstsq method still outperforms the other methods. It even outperforms the `sml` model with fully tuned lexical embeddings.

Model	**PPL**	
	`ita`	`nld`
$\texttt{sml}_{\texttt{rle}}$	44.19	48.85
$\texttt{sml}_{\texttt{rle}}$ `+ finetuning`	**42.45**	**39.59**
$\texttt{sml}_{\texttt{full}}{}^{*}$	193.15	219.34
$\texttt{med}_{\texttt{rle}}$ `+ finetuning`	42.51	44.68
`GePpeTto (sml)`	106.84	-

Table 4: Perplexities of the concatenated test data for the final models. The $\texttt{med}_{\texttt{rle}}$ model is in practice the $\texttt{sml}_{\texttt{rle}} \xrightarrow{lstsq} \texttt{med}$ model. * The $\texttt{sml}_{\texttt{full}}$ model is trained for the equivalent amount of time as the $\texttt{sml}_{\texttt{rle}}$ `+ finetuning` models, but with all layers unfrozen.

6 Full model finetuning

After obtaining lexical embeddings for Italian and Dutch to be plugged into the English GPT-2 models, the full models can be finetuned for the target language. The best performing lexical embeddings will be used to train the `sml` and `med` Italian and Dutch models. These are the lexical embeddings that are relearned from random initialisation for the `sml` model. For the `med` model, the lstsq transformed `sml` embeddings with additional training are used ($\texttt{sml}_{\texttt{rle}} \xrightarrow{lstsq} \texttt{med}_{\texttt{+rle}}$).

The relearned lexical embeddings reduce the risk of information loss while the model is adjusting to a new language. Nevertheless, information can still be lost during training. For instance for the `sml` Dutch model, validation loss increases with a learning rate of 10^{-4}, but this does not happen with a lower learning rate of 10^{-5}.

7 Obtained models and evaluation

For both Italian and Dutch, we evaluate three models: (i) the English `sml` model with relearned lexical embeddings; (ii) the `sml` model with additional finetuning to the target language; and (iii) the English `med` model with relearned lexical embeddings that were initialised by transforming `sml` embeddings with the least-squares method. For Italian, we also include the GPT-2 small based GePpeTto model (De Mattei et al., 2020), which was trained from scratch. This inclusion offers the opportunity of a direct comparison between a GPT-2 model trained from scratch and those obtained with our transfer approach. We run both an automatic and a human-based evaluation. For the former, we compare perplexity scores on unseen test data in different genres. For the latter, we collect and compare judgements over generated and gold texts by native speakers of Italian and Dutch.

7.1 Perplexity

Table 4 shows perplexity scores on concatenated multi-genre test data based on a strided moving window perplexity calculation.[3] Perplexities are calculated with Italian and Dutch vocabularies of 30K tokens. These results show that perplexities are low when only relearning the lexical embeddings for both Italian and Dutch. Further finetuning of the `sml` model seems to have the greatest effect for the Dutch language. The `med` models with relearned lexical embeddings have lower perplexity than the equivalent `sml` models. This shows that language transferability based on the lexical layer is not restricted to small model sizes. Moreover, we see that our proposed method results in lower perplexity scores than regular full model finetuning of the English model. The overall perplexity scores of Italian are closer to each other than the Dutch perplexities. We also tested perplexities by the different genres that make up both the Italian and the Dutch datasets (see Figure 5 and Figure 6 for details), and observed that while perplexities vary greatly per genre, the model ranking per genre is consistent with the global scores.

7.2 Human Judgements

The perplexity scores give an indication on how well a language is represented by language models, but this does not reliably tell how good the model is in a generative setting. For this, we resort to human judgements. Human assessments of generated texts are collected for the models that incorporate the crucial steps in our approach and achieve reasonable perplexity scores: the `sml` models with only relearned lexical embeddings, the finetuned `sml` models and the higher complexity `med` models with only relearned lexical embeddings based on transformed `sml` lexical embeddings.

Model	Social	News	Legal
$\texttt{sml}_{\texttt{rle}}$	134.64	67.14	16.95
$\texttt{sml}_{\texttt{rle}}$ `+ finetuning`	**118.19**	**55.63**	15.36
$\texttt{med}_{\texttt{rle}}$	123.64	59.18	**14.95**
$\texttt{GePpeTto}_{\texttt{sml}}$	179.47	80.83	34.71

Table 5: Perplexities for different genres within the Italian test data. Rankings are consistent with Table 4 except for the legal domain.

Model	Proceedings	News	Legal
$\texttt{sml}_{\texttt{rle}}$	44.47	239.14	52.01
$\texttt{sml}_{\texttt{rle}}$ `+ finetuning`	**36.35**	**171.83**	**42.92**
$\texttt{med}_{\texttt{rle}}$	40.62	234.52	45.01

Table 6: Perplexities for some SoNaR genres in Dutch. Models rankings are consistent across genres.

Texts are assessed in isolation by means of a *direct* evaluation (Novikova et al., 2018).[4] Subjects are presented with texts on the screen, and are asked whether the texts they see could have been written by a human. All subjects are pre-informed that some of the texts they will see are machine generated. Rather than discrete answers, we obtain continuous evaluations by offering the possibility of clicking anywhere on a bar whose extremes are "no" to the left and "yes" to the right.

The evaluation interface is made with PsychoPy3 (Peirce et al., 2019) and hosted with Pavlovia[5].

Italian models were evaluated by 24 participants (9 M, 15 F) with ages ranging from 26 to 63 with a median age of 46. The Dutch models were evaluated by 15 participants (11 M, 4 F) with ages ranging from 23 to 36 with a median age of 27.

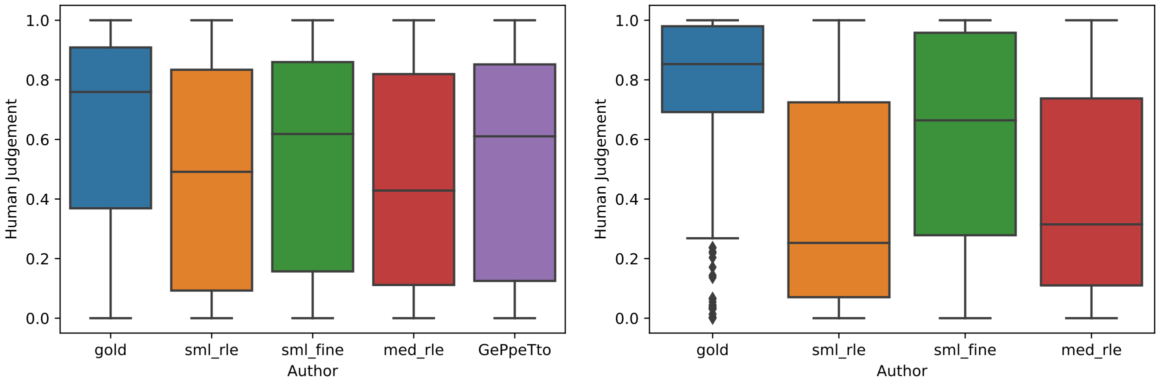
The three final models are evaluated for both languages; for Italian, we also add GePpeTto (De Mattei et al., 2020). Human written gold sentences

---

[3] Window sizes are 128 tokens and strides are 64 tokens except for GePpeTto. GePpeTto was trained with at most 100 tokens, so its window size is 100 with a 50 token stride.

[4] A direct evaluation is opposed to a comparative one, usually involving a ranking task (Novikova et al., 2018; De Mattei et al., 2020); this is left to future work.

[5] `https://pavlovia.org`



(a) Human judgement scores for Italian texts.

(b) Human judgement scores for Dutch texts.

Figure 1: Human judgement scores based on a continuous scale. Most judgements were close to 0 or 1.

were sampled from the test data as an additional condition. For each of these 5 Italian and 4 Dutch conditions, 100 sentences are evaluated. Each participant has evaluated 50 to 150 sentences and each sentence is evaluated by 3 to 5 participants. As a result, we obtain 1950 evaluations for 500 Italian texts and 1550 evaluations for 400 Dutch texts.

All artificial sentences are randomly generated without conditioning and with beam search (5 beams, with top 50 tokens or a summed probability of at least 90%), and a temperature of 3.0. Setting the temperature value >1 means decreasing the sampling probability of likely tokens, and therefore increases variation between generated samples.

Longer sentences have a higher chance to contain mistakes, so a model that generates longer sentences may have a disadvantage. However, explicitly controlling sentence length is not possible nor desired since sentence length may also be an indication of model quality. For both languages the randomly sampled gold sentences have more long sentences than the models, but the `sml` model with finetuning also sometimes generates longer sentences. We filter out sentences longer than 30 tokens to decrease sentence length effects on judgements. The remaining Italian sentences have median lengths of 18 or 22 words and the Dutch ones 16 or 17 words for the different conditions.

Figure 1 shows the distributions of human judgements per condition. Variance seems to be high due to the non-normally distributed scores as relatively many scores are close to zero, half or one. The model differences appear stronger for Dutch than Italian, but for both languages the subjects have given high scores to gold sentences. This is expected and indicates that the participants are able to correctly judge real human texts. Of the three trained models, the small model with additional finetuning achieves the highest scores.

For the Italian model comparison we use a linear mixed-effects model but with only author as fixed effect and random intercepts for participants and sentences. There is no significant effect for sentence length. The judgements on gold texts are significantly higher than all model judgements ($p < 0.005$) except for $\texttt{sml}_{\texttt{fine}}$. However, $\texttt{sml}_{\texttt{fine}}$ is not significantly better than GePpeTto nor the $\texttt{sml}_{\texttt{rle}}$ and $\texttt{med}_{\texttt{rle}}$ models ($p > 0.05$).

For Dutch we use a linear mixed-effects model with fixed effects for author and sentence length (in number of words) and random intercepts for participants and sentences. Sentence length has a significant negative effect ($p < 0.001$). All artificial authors score significantly lower than gold ($p < 0.001$). As for Italian, the $\texttt{sml}_{\texttt{fine}}$ model appears the best model, but in this case the judgement scores are significantly higher than for the other two models ($p < 0.001$). The $\texttt{sml}_{\texttt{rle}}$ and $\texttt{med}_{\texttt{rle}}$ models do not differ significantly from each other.

The human judgements show consistent results across the languages, but differences between Dutch judgements are stronger than for Italian. This seems to mirror the smaller perplexity differences for Italian than for Dutch. Whether demographic or cultural differences also play a role in this difference will need to be further investigated.

In sum, we see that the English GPT-2 models with relearned lexical embeddings are recognisable as artificial, whereas this problem is attenuated after additional finetuning. The `sml` model with additional finetuning performs at least as well as the GePpeTto model that was trained from scratch.

8 Conclusion

We have described methods to adapt GPT-2 to genetically related languages and to increase model complexity. Retraining lexical embeddings forces the model to learn representations that are aligned between English and the target language. GPT-2 is able to generate realistic text in another language, but human judgements reveal that additional finetuning of the full model is needed to generate realistic sentences more consistently. Relearned lexical embeddings show signs of syntactic adaptation to the new language, though not fully consistently.

Dutch is genetically closer to English than Italian, but our results do not prove that this method works better for Dutch. Future research on the relation between degrees and types of language similarity and transferability of models will enable more effective monolingual transfer, and possibly training better multilingual models by selecting optimal clusters of languages. This kind of work offers a privileged perspective into the information learned by generative language models and provides empirical ground for linguistic typology research (e.g., uncovering which linguistic aspects are more universal, and which more language-specific).

Relearning lexical embeddings using our method can still be considered an expensive solution, but training costs decrease when a smaller embedding space is scaled up to the embedding space of a larger model. In other words, approximating a good initialisation of the embedding weights decreases training time. This method also enables adaptation of (extra) large GPT-2 models to other languages.

If you can borrow pre-trained weights, why retrain models from scratch? In the right column we summarise the steps for the shortest path to train your own GPT-2 for another language.

Acknowledgments

We gratefully acknowledge the support of the Dutch Research Council (NWO Aspasia grant for M. Nissim) and the financial support of the Center for Groningen Language and Culture (CGTC). Additionally, we would like to thank Lorenzo De Mattei for sharing the Italian data with us. We would also like to thank the Center for Information Technology of the University of Groningen for providing access to the Peregrine high performance computing cluster. Finally, we thank the anonymous reviewers for their insightful feedback. Any mistakes remain our own.

Impact Statement

This work aims to minimize the environmental impact of training large neural language models by adapting existing models and by using smart initialisation of model weights. However, experiments in this paper still require the use of GPUs for extended periods of time which has environmental impact. Our final models are published and all models that automatically generates natural text could unfortunately be used maliciously. While we cannot fully prevent such uses once our models are made public, we do hope that writing about risks explicitly and also raising awareness of this possibility in the general public are ways to contain the effects of potential harmful uses. We are open to any discussion and suggestions to minimise such risks.

Create your own GPT-2 model

This paper describes several steps that are taken to transfer GPT-2 to a different language. The recommended shortest path to replicate this for another language is to follow these steps:

Vocabulary Create a new BPE vocabulary for your target language. The optimal size for your vocabulary depends on your language, so select the size by stepwise increments until the number of tokens per sentence slows to decrease.

Start small Re-initialise the lexical embeddings of the small GPT-2 model for your vocabulary size and only retrain the lexical embeddings.

Increase model size If you want to train a larger model size, fit a least-squares regression model to the English lexical embeddings in the small and larger model size and use the fitted model to transform your newly trained lexical embeddings to a larger model size.

Optimise your embeddings Do additional lexical embedding training in the target model size. Transformed embeddings are a good initialisation, but they are not perfect.

Finetune Unfreeze the full target model and do some finetuning to make sure that syntax differences are learned by the new model. Use a low learning rate like 10^{-5}.

Can Cognate Prediction Be Modelled as a Low-Resource Machine Translation Task?

Clémentine Fourrier **Rachel Bawden** **Benoît Sagot**
Inria, France
`firstname.lastname@inria.fr`

Abstract

Cognate prediction is the task of generating, in a given language, the likely cognates of words in a related language, where cognates are words in related languages that have evolved from a common ancestor word. It is a task for which little data exists and which can aid linguists in the discovery of previously undiscovered relations. Previous work has applied machine translation (MT) techniques to this task, based on the tasks' similarities, without, however, studying their numerous differences or optimising architectural choices and hyper-parameters. In this paper, we investigate whether cognate prediction can benefit from insights from low-resource MT. We first compare statistical MT (SMT) and neural MT (NMT) architectures in a bilingual setup. We then study the impact of employing data augmentation techniques commonly seen to give gains in low-resource MT: monolingual pretraining, backtranslation and multilinguality. Our experiments on several Romance languages show that cognate prediction behaves only to a certain extent like a standard low-resource MT task. In particular, MT architectures, both statistical and neural, can be successfully used for the task, but using supplementary monolingual data is not always as beneficial as using additional language data, contrarily to what is observed for MT.

1 Introduction

The Neogrammarians (Osthoff and Brugmann, 1878) formalised one of the main hypotheses of the then recent field of comparative linguistics, the regularity of sound changes: if a phone in a word, at a given moment in the history of a given language, evolves into another phone, then all occurrences of the same phone in the same phonetic context in the same language evolve in the same way.

Sound changes are usually identified by looking at the attested (or hypothesised) phonetic form of specific sets of words, called *cognates*, whose definition varies in the literature depending on the field.[1] We use an extension of the customary definition used in historical linguistics, as described for instance in (Hauer and Kondrak, 2011; List et al., 2017), which is the following: given two languages with a common ancestor, two words are said to be cognates if they are an evolution of the same word from said ancestor, having undergone the sound changes characteristic of their respective languages' evolution. We extend it by also allowing the ancestor word (from the parent language) to also be considered a cognate. For example, Latin *bonus* 'good' gave Italian *buono* 'id.', Spanish *bueno* 'id.' and Spanish *bono* 'id.' by inheritance, and they are all cognates, whereas Spanish *abonar* 'to fertilise', obtained by derivation, is related but not a cognate (Figure 1).

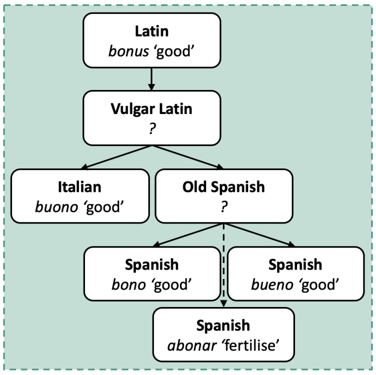

Figure 1: Related words in Italian and Spanish, both the outcome of Latin *bonus* 'good'. Plain arrows represent inheritance, dotted arrows derivation. "*?*" indicates that the word is not present in our database.

Cognate identification (finding cognate pairs in a multilingual word set) and prediction (producing

---

[1] Cognates have for example been defined as words sharing spelling and meaning, regardless of their etymology (Frunza and Inkpen, 2006, 2009), or words etymologically related no matter the relation (Hämäläinen and Rueter, 2019).

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 847–861
August 1–6, 2021.

likely cognates in related languages) are two of the fundamental tasks of historical linguistics. Over the last three decades, automatic cognate identification has benefited from advances in computational techniques, first using dictionary-based methods (Dinu and Ciobanu, 2014) and purely statistical methods (Mitkov et al., 2007; McCoy and Frank, 2018), then statistical methods combined with clustering algorithms (Hall and Klein, 2010, 2011; List et al., 2017; St Arnaud et al., 2017), statistical methods combined with neural classifiers (Inkpen et al., 2005; Frunza and Inkpen, 2006, 2009; Hauer and Kondrak, 2011; Dinu and Ciobanu, 2014) and neural networks only (Ciobanu and Dinu, 2014; Rama, 2016; Kumar et al., 2017; Soisalon-Soininen and Granroth-Wilding, 2019).

Automatic cognate prediction is less studied despite its interesting applications, such as predicting plausible new cognates to help field linguists (Bodt et al., 2018) and inducing translation lexicons (Mann and Yarowsky, 2001). In the last few years, it has been approached as an MT task, as it can be seen as modelling sequence-to-sequence correspondences. Using neural networks has been promising (Beinborn et al., 2013; Wu and Yarowsky, 2018; Dekker, 2018; Hämäläinen and Rueter, 2019; Fourrier and Sagot, 2020a), although in most works the hyper-parameters of the neural models were not optimised. Moreover, the differences between MT and cognate prediction have not been studied.

In this paper, we choose to study the application of MT approaches to the cognate prediction task. Our aim is to investigate whether the task can benefit from techniques commonly seen to improve standard low-resource MT. We first highlight the specific characteristics of cognate prediction, and (to our knowledge) provide the first detailed analysis of the expected differences with standard MT. We then compare MT architectures (bilingual SMT vs. bilingual and multilingual NMT) when applied to cognate prediction. We study how to leverage extra data in our NMT models, either monolingual (via backtranslation or pretraining) or multilingual (introducing new languages). We experiment with Latin and its Romance descendants Spanish and Italian for all our experiments, as well as added French and Portuguese in a data augmentation setting. We find that cognate prediction is only similar to standard MT to a certain extent: the task can be modelled well using standard MT architectures (adjusted for a low-resource setting), and extending neural architectures to a multilingual setting significantly improves the results. In such multilingual settings, further improvements can be obtained by leveraging data from extra languages. However, using extra monolingual data via backtranslation or pretraining is not always as beneficial as it is in standard MT settings.[2]

2 Related Work

2.1 Cognate Prediction

Cognate prediction is the task that aims to produce from words in a source language plausible cognates in a target language (according to the aforementioned definition of cognates). It is a lexical task that models regular, word-internal sound changes that transform words over time. It has been approached with phylogenetic trees combined with stochastic sound change models (Bouchard et al., 2007; Bouchard-Côté et al., 2009; Bouchard-Côté et al., 2013), purely statistical methods (Bodt et al., 2018), neural networks (Mulloni, 2007), language models (Hauer et al., 2019) and character-level MT techniques (Beinborn et al., 2013; Wu and Yarowsky, 2018; Dekker, 2018; Hämäläinen and Rueter, 2019; Fourrier and Sagot, 2020a; Meloni et al., 2021), because of its similarity to a translation task (modelling sequence-to-sequence cross-lingual correspondences between words).

2.2 Low-resource MT

Since data is scarce, we postulate that cognate prediction could benefit from low-resource MT settings techniques and architectural choices.

2.2.1 Architecture Comparison

Several papers comparing SMT with NMT (recurrent neural networks (RNNs) with attention) in low-resource settings conclude that SMT performs better, being more accurate and less prone to overfitting (Skadiņa and Pinnis, 2017; Dowling et al., 2018; Singh and Hujon, 2020). However, as Dowling et al. (2018) themselves note, they did not optimise hyper-parameters for NMT. Sennrich and Zhang (2019) analysed and reproduced previous comparisons, to conclude that SMT can actually be outperformed by NMT when architectures and hyper-parameters are carefully chosen, but only above a certain quantity of data.

---

[2] Both our code and data are freely available at `http://github.com/clefourrier/CopperMT`.

2.2.2 Leveraging Extra Data

Several techniques are commonly used in low-resource MT to mitigate the lack of parallel data: monolingual pretraining, backtranslation and using data from additional languages.

Monolingual pretraining (unsupervised) has, as in other NLP tasks, been highly beneficial to MT (Song et al., 2019; Conneau and Lample, 2019; Devlin et al., 2019; Liu et al., 2020). Before training on a translation task, model parameters are first pretrained using a language modelling objective, which enables the exploitation of monolingual data, more freely available than bilingual data.

Backtranslation originated in SMT (Bertoldi and Federico, 2009; Bojar and Tamchyna, 2011), and has been standard in NMT for several years (Sennrich et al., 2016; Edunov et al., 2018). Its goal is to artificially create larger quantities of parallel data from monolingual datasets, which are often more readily available. Target-side monolingual data is provided to a bilingual model trained in the opposite direction (target-to-source), which produces synthetic source-side data. The data is then filtered to keep the highest quality sentences. The newly generated dataset, made of synthetic source-side data parallel to real target-side data is then combined with the original bilingual set to train a new model.

Training multilingual NMT models has been shown to help low-resource scenarios by providing data in other languages and constraining the hidden representations to a shared, language-independent space. The amount of sharing between languages varies according to the approach, from multi-encoder, multi-decoder architectures (Luong et al., 2016), optionally sharing attention mechanisms (Firat et al., 2016a), to approaches with a single shared encoder and decoder (Ha et al., 2016; Johnson et al., 2017).

3 Differences between Cognate Prediction and MT

Cognate prediction and MT both focus on learning sequence-to-sequence correspondences. However, amongst the works using MT techniques for cognate prediction, little attention has been paid to their differences; the underlying linguistic assumptions and aims are quite distinct, which could impact the transferability of choices and techniques from MT.

Representation Units MT processes sentences split into individual (graphemic) units that can be of diverse granularity levels (characters, subwords or words). Cognate prediction, on the other hand, involves predicting sound correspondences from one cognate word to another, and so is best modelled using sequences of phones (like character-level MT).

Reordering and Alignment In MT, the correspondence between source and target sentences can involve long-distance reorderings, whereas the reorderings sometimes found in the correspondence between cognates are almost always local (e.g. metatheses). We therefore expect SMT, which is somewhat limited with respect to the modelling of long-distance context, to be less penalised in the cognate prediction setting than it usually is a standard MT setting.

Sample Length The input sequence to MT is the sentence, whereas for cognate prediction it is the word. Even with different segmentation granularities for MT, the average sequence length is generally much shorter for cognate prediction than for MT. Again, this could mean that SMT is less penalised than it is in the standard MT setup.

Modelled Relations MT involves symmetrical relations between sentences, whereas cognate prediction, as defined above, is inherently ambiguous in a counter-intuitive way (especially because it is structurally different from the usual MT ambiguity, where many valid translations exist for the same input). The cognate task models both symmetrical and asymmetrical relationships between cognates: parent-to-child (e.g. LA→ES), i.e. modelling sequences of regular sound changes, is non-ambiguous, whereas child-to-parent (e.g. ES→LA) and as a result, child-to-child (e.g. IT↔ES) is intrinsically ambiguous, as two distinct sounds in the parent language can result in the same outcome in the child language. When two distinct sounds in the child language are the outcome of the same sound in the parent language, it is always because their (word-internal) phonetic contexts were different in the parent language. In other words, the parent-to-child direction is (virtually) non-ambiguous, but might require taking the phonetic context into account. However, the child-to-parent direction is intrinsically ambiguous, which results from the fact that a sound in the child language can be the regular outcome of more than one sound in the parent language: for instance Spanish /b/ comes from Latin /p/ in *abría* (from Latin *aperīre*) but from Latin /b/ in *habría* (from Latin *habeō*).

Ambiguity Management When using cognate prediction as a tool to aid linguists, as in (Bodt and List, 2019), our aim is not to predict **the** single correct answer, but to provide a list of plausible candidates. In MT however, while many translations can be produced by the model (some better than others—including poor ones), it is possible to simply use the best ranked translation. In cognate prediction, as a consequence of the inherent ambiguity of the task discussed above, at most one prediction is correct, other predictions could have been correct (i.e. they are compatible with the phonetic laws involved), while other predictions are incorrect. A linguist would be interested in all correct or plausible predictions, not just the best ranked one, and there is therefore a need for n-best prediction.

Relevance of Leveraging Extra Data Whereas MT models could theoretically be trained on any sentence pair that are translations of each other, cognate prediction is far more limited in terms of which data can be used; cognacy relations only link a limited number of words in specific language pairs, limiting not only available parallel data but also the potential for synthetic data (e.g. via backtranslation). Using generic translation lexicons may help, but, as they do not only contain cognate pairs, all non-cognate pairs they contain (parallel borrowings from a third language and etymologically unrelated translations) are effectively noise for our task (Fourrier, 2020).

4 Experimental setup

Bearing in mind these differences, we seek to determine whether MT architectures and techniques are well suited to tackling the task of cognate prediction, paying attention to avoid the pitfalls raised by Sennrich and Zhang (2019) by carefully selecting architecture sizes and other hyper-parameters.

For our baselines, we train several character-level[3] MT models (SMT vs. RNNs and Transformers) in a bilingual setup, training a single model for each language pair.

We then assess the impact of techniques commonly used to improve MT in low-resource scenarios. We first investigate the impact of using monolingual data for all 3 architecture types, via pretraining and backtranslation,[4] then take advantage of the ability of NMT to accommodate multilingual architectures to experiment with a multi-encoder multi-decoder architecture (Firat et al., 2016b) involving all language directions.

Finally, we test whether there can be any benefit from combining multilinguality with either pretraining or backtranslation.

4.1 Data

Our datasets (detailed below) are bilingual cognate lexicons for all our experiments, extended with monolingual lexicons for backtranslation and pretraining (see Table 1). As we focus on sound correspondences, we phonetise our datasets. Each word is phonetised into IPA using `espeak` (Duddington, 2007-2015), then cleaned to remove diacritics and homogenise double consonant representations. For example, *conocer* 'to know' is phonetised as [konoθɛɾ], then split into phones (segmented into [k, o, n, o, θ, ɛ, ɾ]).

BILINGUAL	LA–IT	LA–ES	ES–IT
#words	5,109	4,271	1,804
#phones	77,771	63,131	24,576
#Unique phones	34	39	38
Avg. word length	7.62	7.40	6.81
MONOLINGUAL	ES	IT	LA
#words	78,412	99,949	18,639
#phones	626,175	815,562	142,955
#Unique phones	38	40	29
Word length	7.98	8.24	7.67

Table 1: Dataset statistics for our lexicons.

Bilingual Lexicons Our bilingual cognate lexicons contain cognate pairs (between 657 and 5,109 depending on the language pair), extracted from the etymological database EtymDB2 (Fourrier and Sagot, 2020b) following (Fourrier and Sagot, 2020a) for extraction and duplicate management, then phonetised as described above. We use the lexicons containing Latin, Italian and Spanish (LA–IT, LA–ES, ES–IT) in all experiments. They respectively contain 5,109, 4,271 and 1,804 words for a total of 77,771, 63,131 and 24,576 phones (ES–IT being considerably smaller), with on average 40 different and unique phones.

We run all experiments on three different train/dev/test splits in order to obtain confidence scores. For the bilingual (baseline) and multilingual setups, each split is obtained by sampling sentences 80%/10%/10% randomly.

---

[3] We use here the customary term "character-level MT," although in our case, characters correspond to phones.

[4] We detail what pretraining and backtranslation means for our SMT models in Section 4.4.

Monolingual Lexicons Monolingual datasets are used for the monolingual pretraining and back-translation experiments. They were extracted from a multilingual translation graph, YaMTG (Hanoka and Sagot, 2014), by keeping all unique words for each language of interest. To remove noise, words containing non-alphabetic characters were discarded (punctuation marks, parentheses, etc.). The final datasets (cleaned and phonetised) contain between 18,639 and 99,949 unique words (the LA set is more than 4 times smaller than the others).

4.2 MT Architectures

4.2.1 SMT

We train a separate SMT model for each language direction using the MOSES toolkit (Koehn et al., 2007). Our bilingual training data is aligned with `GIZA++` (Och and Ney, 2003). The target data for the pair is used to train a 3-gram language model using `KenLM` (Heafield, 2011). We tune our models using `MERT` based on BLEU on the dev set.

4.2.2 NMT

We compare two encoder-decoder NMT models: the RNN (bi-GRU) with attention (Bahdanau et al., 2015; Luong et al., 2015) and the Transformer (Vaswani et al., 2017). We use the multilingual Transformer implementation of `fairseq` (Ott et al., 2019), and extend the library with an implementation of the multilingual RNN with attention (following the many-to-many setting from (Firat et al., 2016a) but with separate attention mechanisms for each decoder).[5] Each model is composed of one encoder per input language, and one decoder (and its own attention) per output language.[6] We train each model for 20 epochs (which is systematically after convergence), using the Adam optimiser (Kingma and Ba, 2015), the cross-entropy loss, and dev BLEU as selection criterion.

4.2.3 Hyper-parameter Selection

We ran optimisation experiments for all possible bilingual and multilingual architectures, using three different data splits for each parameter combination studied, and choosing the models performing best across seeds. Our initial parameters were selected from preliminary experiments (in bold in Table 2).

Parameters	Values studied
1) Learning rate × Batch size	{0.01, **0.05**, 0.001} × {10, 30, **65**, 100}
2) Embed. dim. × Hidden dim.	{8, 12, 16, **20**, 24} × {18, 36, **54**, 72}
3) Number of layers	**1**, 2, 4
4) Number of heads	**1**, 2, 3, 4
4) Attention type	None, Bahdanau, Luong (**dot**, concat, general)

Table 2: Parameter exploration experiments for NMT models. In bold, the initial parameters at each step.

Table 2 contains the successive parameter exploration steps: at the end of a step, we automatically selected (according to average dev BLEU) the step-best value, used as input parameter for the next parameter exploration step.[7] The final best parameters are given in Appendix A.1. Smaller learning rates (0.005 and 0.001) are better, while there is no observable pattern to the best batch sizes or numbers of layers. Interestingly, however, for the RNNs, the best results are obtained with the highest hidden dimension irrespective of the embedding size (72 vs. 20 or 24), whereas, for the Transformers, best results are obtained with the largest embedding size irrespective of the hidden dimension (24 vs. 54 or 72). Increasing the number of layers or using more than 1 head almost always increases performance.

4.3 Evaluation

For our task, we use the most commonly used MT evaluation metric, BLEU (Papineni et al., 2002), using the `sacreBLEU` implementation (Post, 2018). It is based on the proportion of 1- to 4-grams in the prediction that match the reference.

In standard MT, BLEU can under-score the many valid translations that do not match the reference. For cognate prediction, however, we expect a single correct prediction in most cases (there are a few exceptions such as variants due to gender distinctions specific to the target language). This makes BLEU better suited to the cognate prediction task than it is to standard MT.[8]

---

[5] These implementations are used in all setups, bilingual (using one language as source and one as target) as well as multilingual.

[6] In a multilingual setup, encoders, decoders and attention mechanisms can either be shared between languages or be language-specific. In preliminary experiments, using independent items proved to be the most effective. We also observe that a coherent phonetic embedding space is learned during training (described in Appendix A.2).

[7] When looking at multilingual models, we chose the model performing best on most languages, as measured by comparing the sum of the ranks (according to their average performance per language) of each model over all language pairs.

[8] BLEU is also more adapted than an exact match, as it allows us to compare how close the prediction is to the reference and in cognate prediction does not suffer from the same problems as in standard MT.

4.4 Leveraging Extra Data

Monolingual pretraining For NMT, one way to take advantage of additional monolingual data is to teach the model to "map" each language to itself by using an identity function objective on the monolingual data for the model's target language.[9] Using monolingual target data during pretraining allows each target decoder to have access to more target data (which avoids overfitting), while we expect it to be beneficial to encoders too, since our source and target languages tend to share common sound patterns in cognate prediction, being closely related. In practice, we pretrain the model for 5 epochs[10] using the identity function objective together with the initial cognate prediction objective (on the original bilingual data) and then fine-tuned on the cognate task as before for 20 epochs.

For SMT, model parameters cannot be pretrained as in NMT, so in the guise of pretraining, we take the nearest equivalent: we use target-side monolingual data to train an extra language model.

For each language pair, the monolingual dataset we use is composed of 90% of the target monolingual data. The bilingual data is the same as before.

Backtranslation For each architecture type, we use the previously chosen models to predict 10-best results for each seed from the monolingual target-side data, and construct synthetic cognate pairs from monolingual lexicons and source-side predictions. For each word, we keep the first prediction of the 10 that also appears in the relevant monolingual source language lexicon as our new source, and the initial source as target (this is akin to filtering back-translated data (e.g. to in-domain data) in MT, a standard practice). We discard pairs with no prediction match.

This large back-translated bilingual dataset is extended with our original training set. For NMT, it is used to train a new model for 10 epochs,[10] which is then fine-tuned for 20 epochs with the original bilingual training set. For SMT, it is used (instead of the original bilingual data) to train a new phrase table.

Multilingual NMT We exploit the fact that NMT can readily be made multilingual by training a single model on all language directions at once.

5 Results

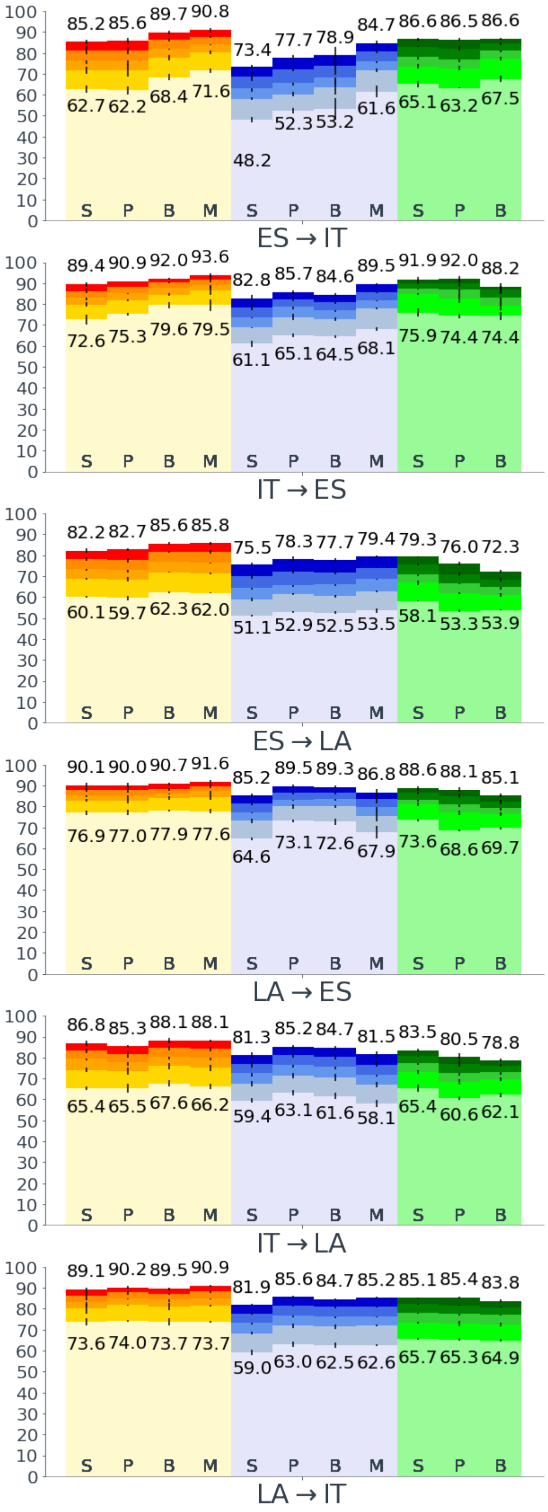

Figure 2: BLEU scores. Colours indicate the model type: RNNs in orange (col 1 to 4), Transformers in blue (col 5 to 8), SMT in green (col 9 to 11). Colour shades indicate the value of n in n-best predictions (1, 2, 3, 5 and 10 from bottom to top). The letters (x-axis) indicate the setup: S - standard/bilingual, P - with pretraining, B - with backtranslation, M - multilingual.

---

[9] For the multilingual model, this means that every encoder will see data from all languages, whereas each decoder will only see data from its specific language.

[10] This number of epochs is systematically big enough to reach convergence.

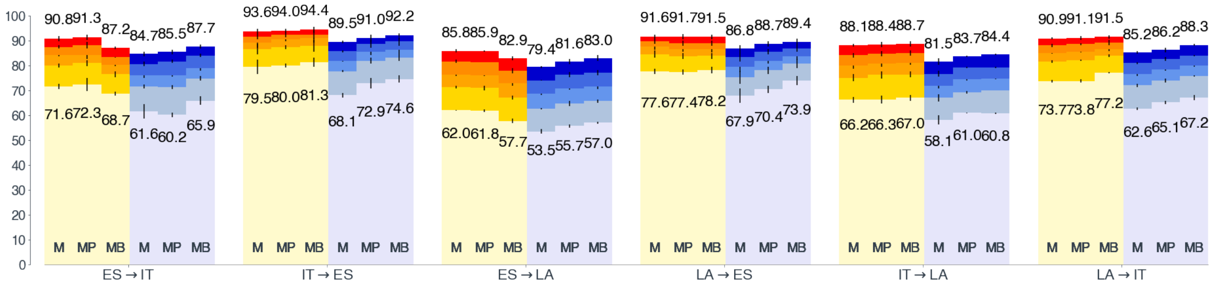

Figure 3: BLEU scores: RNNs in orange (col 1 to 3), Transformers in blue (col 4 to 6). Colour shades indicate the value of n in n-best predictions (1, 2, 3, 5 and 10 from bottom to top). On the x-axis, the letters indicate the setup: M - multilingual, MP - multilingual with pretraining, MB - multilingual with backtranslation.

5.1 Baseline: Bilingual setup

1-best Results At a first glance (Figure 2, "S" columns), SMT and RNN appear to have relatively similar results, varying between 58.1 and 76.9 BLEU depending on the language pair, outperforming the Transformer by 5 to 15 points on average. However, SMT performs better for IT↔ES (pair with the least data), and RNNs for the other pairs. This confirms results from the literature indicating that SMT outperforms NMT when data is too scarce, and seems to indicates that the data threshold at which NMT outperforms SMT (for our Romance cognates) is around 3,000 word pairs for RNNs, and has not been reached for Transformers.

n-best Results The BLEU scores for NMT and SMT increase by about the same amount for each new n ($n \leq 10$), reaching between 79.3 and 91.9 BLEU score at $n = 10$ for RNN and SMT. The Transformer, however, does not catch up.

5.2 Leveraging Extra Data

5.2.1 Pretraining, backtranslation

Both pretraining the models and using backtranslation (Figure 2, "P" and "B" columns) increase the results of the Transformer models by 1 to 9 points, though they are still below the RNN baseline. It is likely the added monolingual data mitigates the effect of too scarce bilingual sets. The impact on RNN performance is negligible for most language pairs, apart from the lowest resourced one (ES–IT), for which backtranslation increases results. Lastly, these methods seem to mostly decrease SMT performance, due to noisy data diluting the original (correct) bilingual data (cf. Section 3); this is less of a problem for NMT models, because they are then fine-tuned on the cognate task specifically.

5.2.2 Multilinguality

Data augmentation through a multilingual setup (Figure 2, "M" columns) seems to be the most successful data augmentation method for RNNs (increasing performance almost all the times), and allows them to finally outperform bilingual SMT for the least-resourced pair as well (ES↔IT). The Transformers benefit less from this technique than from adding extra monolingual data, apart for ES↔IT, most likely for the same reason as earlier: this dataset being the smallest, adding words in ES and IT from other language pairs helps to learn the translation and stabilises learning. This technique is not applicable to SMT.

Impact of the Translation Direction There are three relation types present in our experiments, each with their level of ambiguity (most for child-to-parent or child-to-child, least for parent-to-child, see Section 3). We observe that the SMT models, though bilingual, outperform multilingual NMT when going from ES or IT to LA (child to parent), and that multilingual NMT outperforms SMT in all other translation directions (ES↔IT, LA→ES, LA→IT: child-to-child and parent-to-child).

5.3 Combining data augmentation methods

We choose to combine the best performing data augmentation technique overall, multilinguality, with pretraining and backtranslation (Figure 3) for our NMT models.

Multilinguality + pretraining Combining multilinguality with pretraining has virtually no significant impact on the RNNs' results with respect to multilinguality only. For the Transformers, however, it increases the results by 2 to 3 BLEU on average.

Source context	Target context	Source	Target	SMT pred.	RNN pred.
(a) AMBIGUOUS SOUND CORRESPONDENCE NOT LEARNED WELL					
corvino ‘raven’	*corvino* ‘id.’	[kɔɾβino]	[korviːno]	[kɔrviːno]	[kɔrbiːno]
liebre ‘hare’	*lepre* ‘id.’	[lieβɾe]	[lɛːpre]	[liebrɛː]	[liɛːvre]
(b) MEANING AND/OR FORM OF THE COGNATES CHANGED TOO MUCH					
calaña ‘kind/sort’	*quale* ‘what/which’	[kalaɲa]	[kwaːle]	[kalaɲː]	[kalaɲː]
pie ‘foot’	*piede* ‘id.’	[pje]	[pjɛːde]	[pɛ]	[pɛːre]
(c) DATA ERROR					
suspirar ‘to sigh’	*squillan* ‘(it) rings’	[suspiɾaɾ]	[skwilːan]	[sospiraːre]	[sospiraːre]
frenesí ‘frenzy’	*frenetico* ‘frenetic’	[frenesi]	[frenɛtiko]	[freːnezi]	[fronɛsː]
(d) MODEL MISTAKE					
licencioso ‘licencious’	*licenciozo* ‘id’	[liθɛnθjoso]	[litʃentsioːzo]	[litʃɛntsioːzo]	[litʃɛntso]

Table 3: Prediction errors examples across ES→IT datasets for both SMT and RNN.

Multilinguality + backtranslation Combining multilinguality with backtranslation provides the best results overall for Transformers (both being the best performing methods for these models). For the RNNs, however, the performance increase is smaller for most languages, and we even observe a decrease in performance when translating from ES (which was not the case with bilingual models).

6 Discussion

We discuss the results of the best performing models for the best seed across all architectures (SMT, *multilingual* + *pretraining* RNN and *multilingual* + *backtranslation* Transformer) from ES→IT. More than a third of the predicted words are above 90 BLEU[11] (resp. 35.4/46.4/38.1% for SMT/RNN/Transformer), and for error analysis, we study the words below this threshold. The observations generalise to other language pairs.

6.1 Predictions

Close Results We observe a lot of inaccurate but very close translations (e.g. Spanish *conveniente* ‘convenient’, phonetised [kɔmbenjɛnte], was predicted as corresponding to Italian [konvenjɛnte] instead of [konveniɛnte], with only one phone different, and coherently so). Sometimes these translations have a very bad score: Spanish *pulpito* ‘pulpit’, phonetised [pulpito], was predicted as [pʊlpiːto] instead of [pulpito], two close pronunciations, for a sentence BLEU score of only 20.

Analysis of wrong results Wrongly predicted cognates correspond to four cases, as defined in Table 3.[12] We carried out a manual error analysis, and observed that their distribution was similar across models (resp. SMT/RNN/Transformer):

(a) 84.6/81.4/79.5% were cognates with an ambiguous sound correspondence (e.g. Spanish [β] to Italian [b/v/p]).

(b) 10.3/13.4/11.6% were cognates that had either evolved too far away from one another or contain rare sound correspondences, such as *pie* ‘foot’, phonetised [pje], predicted [pe] and [peːre] instead of [pjɛːde] *piede* ‘foot’.

(c) 0.9/0.9/0.9% corresponded to data errors, such as *suspirar* ‘to sigh’, phonetised as [suspiɾaɾ], which was predicted as [sospiraːre] *sospirare* ‘to sigh’, its actual cognate, instead of its erroneous counterpart in our database ([skwilːan] *squillan* ‘(it) rings’).

(d) 4.3/4.3/8.0% were model errors, such as “forgetting” part of a word during translation.

6.2 Usefulness of n-best results

The average position at which the best prediction (according to dev BLEU) occurs (in 10-best predictions) is between 1 and 3 (Table 7 in Appendix A.3). The lowest indices occur for Spanish (between 1 and 1.7) and Italian (between 1.6 and 2.2). The highest indices encountered occur when going for IT→LA or ES→LA (between 2 and 3). This illustrates the importance of n-best prediction when predicting cognates from child to parent languages, due to ambiguity. Standard deviations are between 2 and 3: for these languages, when studying cognate prediction, it is interesting to at least check the 5-best results.

---

[11] To study the BLEU of individual words, we use the sentenceBLEU function from `sacreBLEU` with its default parameters.

[12] Statistics are provided for the best models of the best seed, but examples are taken across seeds and models.

6.3 Language choice in a multilingual setup

To study the impact of the language pairs used in the multilingual setup, we train additional multilingual neural models on only 1000 pairs of ES–IT data (single set), complemented by either nothing (to act as baseline), an extra 600 pairs of ES–IT, or 600 pairs of ES–L and IT–L (L being either Latin, a parent language, French, a related language, or Portuguese, more closely related to Spanish than Italian). The rest of the data (Table 4) is split equally between dev and test.

Bilingual	FR–IT	FR–ES	PT–IT	PT–ES
#words	666	657	1,503	1,874
#phones	8,698	8,530	20,738	25,867
#Unique phones	40	43	36	41
Word length	6.53	6.49	6.90	6.90

Table 4: Supplementary bilingual lexicon statistics.

As we saw in Section 5.1, the Transformers' scores are far more affected by low resource settings than the RNNs. We therefore study the impact of adding extra languages with RNNs only.

Baseline	ES→IT	IT→ES
1000 pairs	53.9 ± 3.4	66.6 ± 4.2
Added data	ES→IT	IT→ES
Same language pair	62.5 ± 2.5	71.8 ± 1.7
Latin	57.1 ± 1.8	67.4 ± 3.3
French	58.5 ± 2.0	67.0 ± 2.8
Portuguese	58.8 ± 1.1	66.9 ± 2.9

Table 5: BLEU for different multilingual settings.

Results on our new low-resourced baseline are lower than the our previous baselines by around 10 points (Table 5), which is expected, since we use less data for training.

Adding 600 pairs of ES–IT words has more effect on ES–IT performance than adding any other pair of related languages, which indicates that, unsurprisingly, the best possible extra data to provide is in the language pair of interest. When adding a related extra language, the results are better than with the initial data only. From Spanish, the performance is best when adding Portuguese, its most closely related language, then French, then Latin. From Italian, we observe the opposite trend. Adding an extra language seems to help most to translate from, and not to, the language it is most closely related to. For very low-resource settings, where extra pairs of the languages of interest might not be available, it will probably be interesting to explore using extra languages related to the source language.

7 Conclusion

We examined the differences between cognate prediction and MT, in terms of data as well as underlying linguistic assumptions and aims. We then observed that, above a certain training data size, SMT and multilingual RNNs provide the best BLEU scores for the task, SMT still being unrivalled when it comes to smaller datasets (which coincides with previous work comparing SMT and NMT for low-resource settings).

When studying how to increase the amount of training data seen by our models, we found that exploiting the multilinguality of NMT architectures consistently provided better results than adding monolingual lexicons (through pretraining or back-translation), which contain noise for our task; combining the methods provided a significant amelioration for Transformers only. Adding multilingual data by training with extra languages also proved interesting, and we found the best possible extra data to add in a multilingual setting is, first, data from the languages at hand, followed by pairs between them and a parent language, then finally data from additional languages as close as possible to the source language.

We conclude that cognate prediction can benefit from certain conclusions drawn in standard low-resource MT, but that its specificities (intrinsic ambiguity which requires n-best prediction, reliance on cognate data only) must be systematically taken into account. Computational cognate prediction using MT techniques is a field in its infancy, and the work in this paper can be extended along several axes: working on less studied language families, or using the method in collaboration with linguists to better understand the etymology and history of languages.

A Appendix

A.1 Parameter Exploration Results

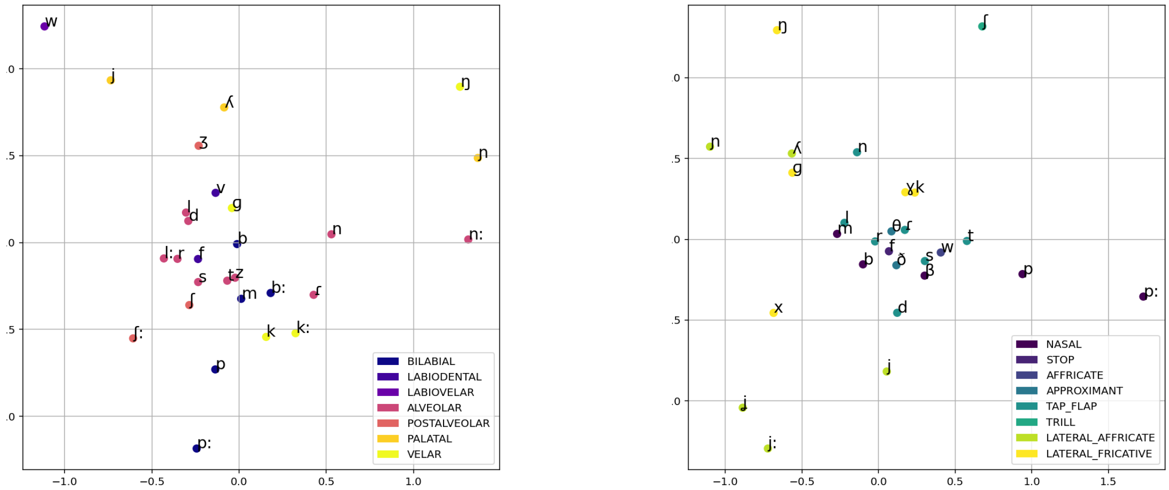
This section presents the hyperparameters which lead to the best dev BLEU across seeds, chosen during Section 4.2.3, and used for all subsequent experiments.

Model	Learning rate	Batch size	Embed. dim	Hidden dim	#layers	Model specific
RNN						Attention type
ES→IT	0.005	65	20	54	1	Luong-dot
IT→ES	0.005	65	20	72	1	Luong-dot
ES→LA	0.001	10	24	72	4	Luong-dot
LA→ES	0.005	100	20	72	1	Luong-dot
IT→LA	0.001	10	24	72	2	Bahdanau-dot
LA→IT	0.001	10	20	72	2	Luong-dot
Multilingual	0.001	10	24	72	2	Luong-general
Transformers						#heads
ES→IT	0.005	65	24	54	1	1
IT→ES	0.005	30	24	54	1	3
ES→LA	0.005	65	24	54	1	2
LA→ES	0.001	10	24	72	4	2
IT→LA	0.001	10	24	72	4	3
LA→IT	0.005	65	24	72	2	3
Multilingual	0.005	30	24	72	4	3

Luong-dot and Luong-general refer respectively to the dot and general attentions in (Luong et al., 2015), while Bahdanau-dot refers to our own implementation of the attention from (Bahdanau et al., 2015), simplified using the dot product to compute attention weights introduced in (Luong et al., 2015). See the code implementation with this paper for more detail.

Table 6: Results of parameter exploration experiments for RNN and Transformer models.

A.2 Learning Embeddings



(a) IT consonants, coloured according to the place of articulation.

(b) ES consonants, coloured according to manner of articulation

Figure 4: PCA of phonetic source embeddings for an ES–IT RNN model.

Our learned embeddings seem to contain relevant phonetic information: their respective principal component analyses (PCA), when coloured according to place or manner of articulation for the consonants, and backness or height for the vowels, are coherently divided. The following examples are provided for an ES–IT RNN model, but similar results have been observed for our other languages and architectures.

Figure 4(a) shows the PCA of the learned source phonetic embeddings of one RNN model, for IT consonant phones, coloured according to place of articulation. It is radially organised, with a smooth transition between labio-dentals from the centre [b] to the bottom [pː], and from centre alveolar to left post alveolar. Figure 4(b) shows a similar PCA, this time for learned source embeddings of ES consonant phones, coloured according to manner of articulation. It seems coherently divided, with a transition from nasal sounds on the bottom right to lateral affricates and fricatives on the top left.

A.3 Average position of the best result among the 10-best results.

We present here at which position the best prediction (according to sentenceBLEU, from `sacreBLEU`) occurs amongst the 10-best predictions. For example, when going from Spanish *terroso* ‘muddy’, phonetised [tɛroso], to Italian *terroso* ‘muddy’, phonetised [terɾoːzo], the RNN predicted [teroːzo], [terɔːzo], [tɛrɾoːzo], **[terɾoːzo]**, [tɛrɾosː], [tɛrɾɔːzo], [tɛrɾɔsː], [terɾɔːzo], [tɛrosː], and [tɛrosːo]: the correct result corresponds to the 4th position.

For all multilingual models, we computed the sentence BLEU score for each of the 10-best predictions and saved the position of the highest scoring prediction. We averaged these positions for all words in the test set and calculated the standard deviation. Table 7 contains the full results, analysed in Section 6.2.

	IT→ES	ES→IT	IT→LA	LA→IT	ES→LA	LA→ES
SMT	1.08 ± 1.93	2.12 ± 2.55	2.01 ± 2.50	1.67 ± 2.30	2.49 ± 2.68	1.30 ± 2.14
Multilingual RNN	1.04 ± 2.03	1.67 ± 2.42	2.20 ± 2.54	1.63 ± 2.38	2.51 ± 2.68	1.38 ± 2.30
Multilingual Transformer	1.34 ± 2.17	1.94 ± 2.34	2.42 ± 2.65	2.17 ± 2.57	2.78 ± 2.73	1.64 ± 2.31

Table 7: Average position of the closest prediction to the reference amongst the **10**-best predictions.

What if This Modified That?
Syntactic Interventions via Counterfactual Embeddings

Abstract

Neural language models exhibit impressive performance on a variety of tasks, but their internal reasoning may be difficult to understand. Prior art aims to uncover meaningful properties within model representations via probes, but it is unclear how faithfully such probes portray information that the models actually use. To overcome such limitations, we propose a technique, inspired by causal analysis, for generating counterfactual embeddings within models. In experiments testing our technique, we produce evidence that suggests some BERT-based models use a tree-distance-like representation of syntax in downstream prediction tasks.

1 Introduction

Large neural models like BERT and GPT-3 have established a new state of the art in a variety of challenging linguistic tasks (Devlin et al., 2019; Brown et al., 2020). These connectionist models, trained on large corpora in a largely unsupervised manner, learn to map words into numerical representations, or embeddings, that support language-reasoning tasks. Fine-tuning these models on tasks like extractive question answering specializes these generic models into performant, task-specific models (Wolf et al., 2019).

In conjunction with the rise of these powerful neural models, researchers have investigated what the models have learned. Probes, tools built to reveal properties of a trained model, are a favored approach (Hall Maudslay et al., 2020; Conneau et al., 2018). For example, Hewitt and Manning (2019) have uncovered compelling evidence that several models encode syntactic information in their embeddings. That is, by passing embeddings through a trained probe, one may recover information about a sentence's syntax.

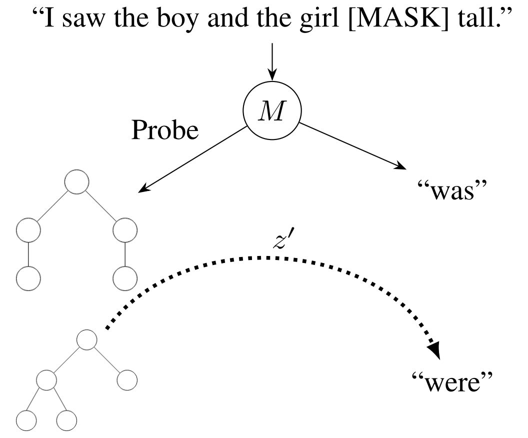

Figure 1: A language model, M, outputs predictions and a probe estimates properties from the model representation. We use probes to generate counterfactual representations, z', based on syntactic manipulations, revealing reasoning within the model.

Although these results are impressive, they fall short of clearly demonstrating what linguistic information the language models actually use. Syntactic information is present in sentences; that embeddings also encode syntax does not imply that a model uses syntactic knowledge.

In order to truly query a model's understanding, one must use causal analysis. Recently, several authors have done so by generating counterfactual data to test models (Kaushik et al., 2020; Goyal et al., 2019; Elazar et al., 2020). They either create new input data or ablate parts of embeddings and study how model outputs change. We extend this prior art via a new technique for generating counterfactual embeddings by using traditional probes to manipulate embeddings according to syntactic principles, as depicted in Figure 1. Because we conduct experiments with syntactically ambiguous inputs, we are able to measure how models respond to different valid parses of the same sentence instead of, for example, removing all syntactic information.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 862–875
August 1–6, 2021.

Thus, our technique uncovers not only what parts of its embeddings a model uses to represent syntax, but also how those parts influence downstream behavior.

Thus, in this work, we make two contributions. First, we develop a gradient-based algorithm to generate counterfactual embeddings, informed by trained probes. Second, in experiments using our technique, we find that the standard BERT model, trained on word-masking tasks, appears to leverage features of syntax in predicting masked words but that a BERT model fine-tuned for question-answering does not. In addition, these experiments yield new data to inform the ongoing debate on probe design.

2 Related Work

2.1 Neural Language Model Probes

Transformer-based models like GPT-3 and BERT have recently advanced the state of the art in numerous language-related problems (Brown et al., 2020; Devlin et al., 2019; Wolf et al., 2019). These large models appear to learn meaningful representations of words and sentences, enabling high performance when fine-tuned for a specific task.

In conjunction with these models, probes have been developed to uncover what principles models have learned. Such probes have been used in a wide variety of contexts, from image structure to syntax and semantics in language models (Alain and Bengio, 2018; Conneau et al., 2018; Hewitt and Manning, 2019; Coenen et al., 2019, among others). Our work uses two syntactic probes developed by Hewitt and Manning (2019) that map from model embeddings to predictions about word locations in a parse tree. These probes are simple by design – merely linear transformations – in order to prevent the probes themselves from doing parsing.

Recent work directly addresses the topic of probe simplicity. On the one hand, if probes are too expressive, they may reveal their own learning instead of a model's (Liu et al., 2019; Hewitt and Liang, 2019). On the other hand, Pimentel et al. (2020) argue from an information-theoretical perspective that more expressive probes are always preferable.

Our work differs from much prior art in probe design by leveraging causal analysis, which uses counterfactual data to test probes and models. This provides direct evidence of whether a model uses the same features as a probe, allowing us to experiment beyond linear probes (and indeed, we found that more complex probes offered an advantage in some cases).

2.2 Causal Analysis of Language Models

Motivated by the limitations of traditional, correlative probes, researchers have recently turned to causal analysis to better understand language models. Goyal et al. (2019) and Kaushik et al. (2020) generate counterfactual inputs to language models, while Vig et al. (2020) study individual neurons and attention heads to uncover gender biases in pre-trained networks.

Our work is most closely related to that of Elazar et al. (2020), who, as in this work, used probes to generate counterfactual embeddings within a network. Their amnesiac counterfactuals are generated by suppressing features in embeddings that a probe uses. In contrast, we use a continuous, gradient-based approach to generate counterfactuals, yielding insight into how features are used, as opposed to if they are used at all.

3 Technical Approach

3.1 Problem Formulation

We may characterize a transformer-based language model, M, trained on a specific task, as a function mapping from an input string, s, to an output y: $M(s) = y$. In order to reveal embeddings for analysis by probes, we may decompose M into two functions: M_{k-} and M_{k+}. M_{k-} represents the first k layers of the model; M_{k+} represents the layers of M after layer k; M is the composition of these functions: $M = M_{k+} \circ M_{k-}$. We label the embeddings output by M_{k-} as z_k. This decomposition of models to reveal internal embeddings mirrors the formulation for layer-specific probes (Hewitt and Manning, 2019). A probe may be defined as a function f_p that maps from an embedding, z_k, to a predicted property $\hat{p}$ about the input, s: $f_p(M_{k-}(s)) = \hat{p}$. (For the remainder of this paper, we focus on syntactic probes, but our reasoning may be extended to other linguistic properties.)

We may define two, potentially overlapping, subsets of the features of z_k by considering different uses of z_k. First, we may define z_p as the features of z_k that the probe uses in predicting $\hat{p}$ (for example, when using a linear probe, z_p is the projection of z_k onto the probe subspace). Assuming good syntactic probe performance, z_p is necessarily informative of the input's syntax. We likewise

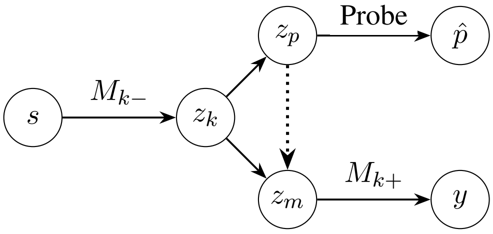

Figure 2: M_{k-} yields a representation, z_k. z_p and z_m are subsets of the features of z_k used by the probe and M_{k+}. We measured the causal link between z_p and z_m.

defined z_m as the features of z_k that M_{k+} uses in producing the model output. These two, potentially overlapping, representations of z_k are shown in Figure 2, inspired by causal diagrams by Pearl and Mackenzie (2018). We seek to discover if there is a causal link between z_p and z_m.

For some tasks, such a link should exist. For example, a question-answering model's response to "I shot the elephant wearing my pajamas. Who wore the pajamas?" should depend upon the inferred sentence syntax (e.g., if the probe predicts that "wearing my pajamas" modifies "the elephant," the model should output "the elephant"). Thus, the probe and model outputs should "agree" according to syntactic principles. Furthermore, if a causal link between z_p and z_m exists, changing z to produce a new prediction of syntax should change the model output to agree with the probe (e.g., if the probe predicts that "wearing my pajamas" now modifies "I," the model should now output "I"). In this work, therefore, we study whether a link between z_p and z_m exists and, if it does, to what extent it corresponds with linguistic principles.

3.2 Generating Counterfactual Embeddings via Gradient Descent

To study such a link, we must generate counterfactual embeddings, z', that modify probe outputs, starting from normal embeddings z_k. We borrow the term "counterfactual" from causal literature because z' represents what z_k would have been if z_p had been different (Pearl and Mackenzie, 2018). We were particularly interested in finding z' that changed both probe and model outputs; if z' only changed probe outputs, that could indicate that the probe was over-interpreting model embeddings (e.g., acting as a parser instead of a probe).[1]

We developed a gradient-based method to generate z' that changed the probe output. We assumed that, given the probe function, f_p, a loss, L, and the correct property value (e.g., parse), p, one could compute the gradient of the loss with respect to the probe inputs: $\nabla_{z'} L(f_p(z'), p)$. Neural network probes obey such differentiability assumptions.

Given z_k and p, we constructed a counterfactual embedding , z', by initializing z' as a z_k generated by the model and updating z' via gradient descent of the loss. Updating z' may be terminated based on various stopping criteria (e.g., local optimality, loss below a threshold, etc.), yielding the final counterfactual z'. Assuming non-zero gradients, this technique produces z's that, by design, change the probe outputs. In experiments, we studied how z's changed model outputs when passed through M_{k+}.

Although our technique bears some resemblance to gradient-based adversarial attacks (Szegedy et al., 2014), it may more broadly be thought of as guided search in a latent space. Adversarial images are often characterized by changes that are imperceptible to humans but change model behaviors to be incorrect. In contrast, we seek to find embeddings that change both probe and language model outputs. Furthermore, by design, we use syntactically ambiguous sentences in experiments and generate counterfactuals according to valid parses. Thus, unlike adversarial attacks on images that seek to switch model classification to an incorrect class, we merely guide embeddings among a set of valid interpretations. Lastly, even uncovering instances of embeddings that change probe outputs but not the model's is important, as it indicates a misalignment of probe and model reasoning.

4 Experiments

In the previous section, we proposed a technique for generating counterfactual embeddings; here, we detailed the experiments we conducted to measure the effect of using such embeddings. Inputs to our technique included the base language models, probes, test sentences, and different ground-truth parses to generate the counterfactual embeddings.

4.1 Model Tasks

We tested our technique on two BERT models trained on different tasks: masked word prediction and extractive question answering.

In the masked word prediction task, a model is given a sentence, S, comprising words $(s_0, s_1, \ldots$

---

[1] We did not study z' that only modified the model outputs, although this could be a promising avenue for future work.

Model	Corpus	Parse	Example Input
Mask	Coord.	Plur.	The woman saw (the boy and the dog) [MASK] falling.
		Sing.	(The woman saw the boy) and (the dog [MASK] falling.)
	NP/Z	Adv.	When the dog scratched (the vet [MASK] ran.)
		Noun	(When the dog scratched the vet) [MASK] ran.
QA	RC	Conj.	The ((smart women and rich men) who were desperate) bribed the judge.
		NP2	The (smart women) and (rich men who were desperate) bribed the judge.
	NP/VP	VP	The girl saw (the boy) with the telescope.
		NP2	The girl saw (the boy with the telescope.)

Table 1: Experiment design for different language models and test corpora, with illustrative sentences, decorated with auxiliary parentheses to reveal structure. The parentheses were not included in the actual corpora.

`[MASK]`, ..., s_n) and must predict the word at the location marked by `[MASK]`. For example, given a sentence, [‘The’, ‘children’, ‘went’, ‘out’, ‘to’, `[MASK]`, ‘.’], a correct answer might be ‘play.’ We used huggingface’s “bert-large-uncased-whole-word-masking” model, which was trained on masked word and next-sentence prediction, and referred to it as the “Mask” model (Wolf et al., 2019).

Extractive question answering is framed by Wolf et al. (2019) as follows: given a sentence, S, comprising word tokens $(s_0, s_1, ...s_n)$ and a question, identify the start and end tokens $(s_i, s_j; 0 \leq i \leq j \leq n)$ denoting a contiguous stretch of the sentence that answers the question. For example, given the sentence [‘I’, ‘ate’, ‘two’, ‘apples’, ‘.’] and the question “How many apples did I eat?,” a correct answer could be [2, 2] (“two”) or [2, 3] (“two apples”). We used huggingface’s “BertForQuestionAnswering,” already fine-tuned on the SQuAD dataset, and referred to the model as QA (Wolf et al., 2019; Rajpurkar et al., 2016).

4.2 Probes

Our technique for generating counterfactual embeddings depended on probes, so we used four different syntactic probes drawn from prior art and our own design.

The depth probe from Hewitt and Manning (2019) maps from embeddings to predictions over words’ depths in a sentence’s parse tree. The distance probe, given a pair of words, predicts the distance between the words in the parse tree (i.e., how many edges must be traversed). Both probes consist of a linear transformation from embedding to prediction.

We further implemented “deep” versions of the distance probe by creating two- and three-layer, non-linear probes trained on the distance task. These models used ReLU activations, with hidden dimension 1024, but otherwise used the same input and output format as the linear distance probe. (Experiments conducted with “deep” versions of the linear depth probe produced similar results to those of the normal depth probe and are therefore omitted.)

4.3 Evaluation Corpora

We used four corpora for evaluating the Mask and QA models, as summarized in Table 1.

4.3.1 Mask Test Corpora

For the Mask model, we used two test suites composed of sentences whose structural ambiguity was resolved by a masked word.

The first corpus, dubbed “Coordination,” comprised sentences that took the form “The NN1 VERB the NN2 and the NN3 [MASK] ADJ.” Such sentences may be interpreted in at least two ways by inserting either “was” or “were” in the masked location. The former reflects a conjunction of clauses (e.g., “The woman saw the boy and the dog was falling.”), whereas the latter reflects a conjunction of noun phrases (e.g., “The woman saw the boy and the dog were falling.”) Sentences were generated through combinations of NN1 [man, woman, child], VERB [saw, feared, heard], NN2 [boy, building, cat], NN3 [dog, girl, truck], and ADJ [tall, falling, orange], yielding 243 sentences, each with two parse trees dubbed “singular” or “plural,” depending on the grammatical verb type.

The second corpus, dubbed the NP/Z corpus, was inspired by classic psycholinguistic studies of the garden-pathing effect in online sentence processing (Frazier and Rayner, 1982; Tabor and Hutchins, 2004). Each sentence in the corpus took the form “When the NN1 VERB1 the NN2

[MASK] VERB2.” Without knowing the masked word, it is unclear if NN2 is the object of the subordinate clause or the subject of the main clause. For example, in the sentence “When the dog scratched the vet [MASK] ran,” either an adverb (e.g., “immediately”) or a noun (e.g., “she”) would be permitted but correspond to different parses. We created such parse trees and dubbed the first type “Adv.” and the second type “Noun.” We used the 24 sentences from Tabor and Hutchins (2004) that fit our template, and supplemented the dataset with 36 sentences of our own, generated by iterating over all combinations of NN1 [dog, child], NN2 [vet, boy, girl], VERB1 [scratched, bit], and VERB2 [ran, screamed, smiled]. (Augmenting the dataset was needed to increase the statistical analysis power, and plotting the 24 and 36 sentences separately established that they produced similar results.)

4.3.2 QA Test Corpora

For the QA model, we created two test suites. First, the “RC” corpus used sentences composed of a conjunction of nouns modified by a relative clause. All sentences took the form “The ADJ1 NN1 and ADJ2 NN2 who were ADJ3 VERB the NN3. Who was ADJ3?” For example, one sentence was “The smart women and rich men who were desperate bribed the judge. Who was desperate?” By construction, it was unclear if the relative clause modified the conjunction of the first and second noun phrases (The ADJ1 NN1 and ADJ2 NN2) or merely the second noun phrase (ADJ2 NN2). For each sentence, we generated two parses: “Conj. Parse” and “NP2 Parse,” corresponding to the former and latter. We generated sentences by iterating over all combinations of values for ADJ1 [smart, rich, tall, poor], NN1 [men, women], ADJ2 [smart, rich, tall, poor], NN2 [men, women], ADJ3 [corrupt, desperate], VERB [bribed, paid], and NN3 [politician, judge], excluding sentences in which NN1 and NN2 or ADJ1 and ADJ2 were the same. This produced 192 sentences, each with two parses.

Lastly, the “NP/VP” corpus used sentences with ambiguous prepositional phrase attachment. Inspired by sentences like “The girl saw the boy with the telescope,” we generated inputs with the template “The NN1 VERB the NN2 with the NN3. Who had the NN3?” We iterated through combinations of NN1 [man, woman, child], NN2 [man, woman, boy, girl, stranger, dog], and VERB-NN3 pairs [saw-telescope, poked-stick, thanked-letter, fought-knife, dressed-hat, indicated-ruler, kicked-shoe, welcomed-gift, buried-shovel], removing duplicate NN1 and NN2, yielding 144 inputs. Each input used two parses indicating the prepositional phrase modifying VP or NP2 (“the” and NN2).

4.4 Generating Embeddings

For all models, probes, and parses trees for each sentence, we generated counterfactual embeddings by initializing a counterfactual embedding, z', as the original model embedding for the input sentence, z_k, and running an Adam optimizer, with learning rate 0.0001, to minimize the probe loss (using a particular probe and parse tree) (Kingma and Ba, 2014). Recall that the optimizer updated z' rather than the probe parameters.

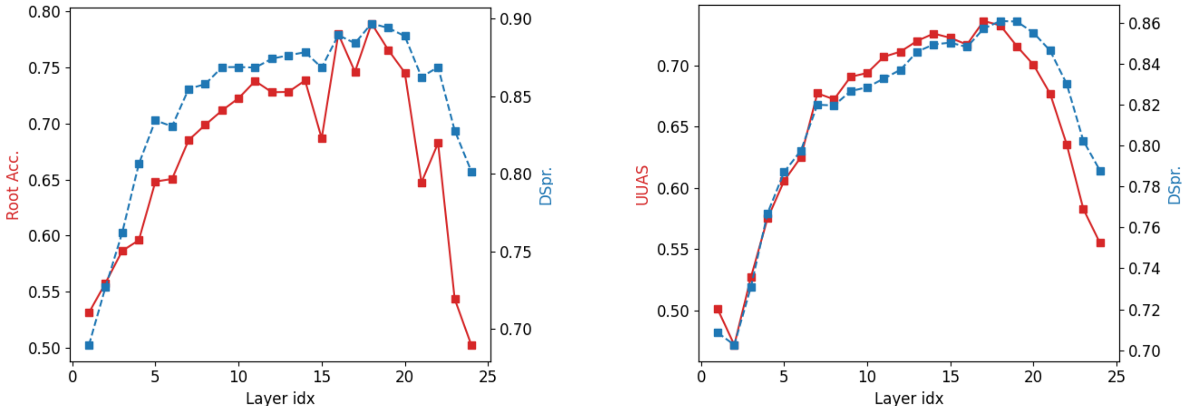
The optimizer used a patience value of 5000: it continued updating z' until the probe loss failed to improve for 5000 consecutive gradient updates. Using a patience-based termination condition (as opposed to setting a loss threshold or maximum number of updates, for example) was task-agnostic and seemed to be robust to a wide range of patience values. Brief experimentation with patience values from 50 to 5000 yielded similar results. On a Linux desktop with an Nvidia GEForce RTX 2080 graphics card, generating a single counterfactual took less than 1 minute, and the process was easily parallelized to batches of 80 embeddings, reducing the mean computation time to under one second.

For both the QA and Mask models, we trained all probe types (depth, distance, 2-layer dist, and 3-layer dist) on each of the model’s 25 layers. We used 5000 entries from the Penn Treebank (PTB) for training, with the standard validation and test sets of nearly 4000 entries used for early stopping and evaluation, respectively (Marcus et al., 1993).

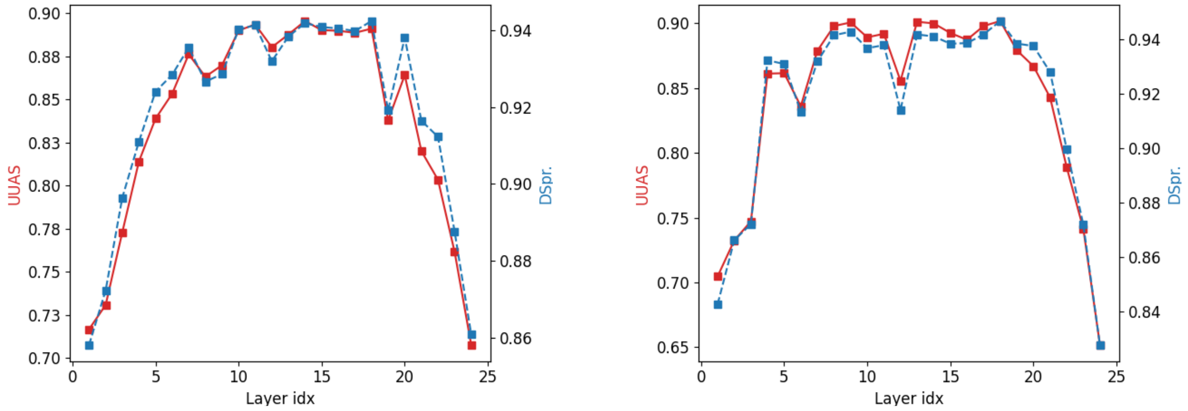
4.5 Metrics

We used two sets of metrics in our experiments. First, we measured probe performance using the Root Accuracy, UUAS, and Spearman Coefficient metrics used by Hewitt and Manning (2019) and refer to their work for details. Intuitively, these metrics captured how accurately the probes predicted aspects of syntactic structure from embeddings.

Second, we measured changes in model outputs when using counterfactual embeddings. The Mask model produced a probability distribution over more than 30,000 possible words for the masked location, but we restricted our attention to only a subset of those words, dubbed “candidates.” (We normalized predictions among the set of candidates,



(a) Depth Probe (b) Dist Probe



(c) 2-layer Dist Probe (d) 3-layer Dist Probe

Figure 3: All trained probes for the QA model exhibited high performance on the PTB corpus.

producing a proper probability distribution.) In the Coordination corpus, we used 5 candidates: [“was,” “is,” “were,” “are,” “as”]. In the NP/Z corpus, we generated the set of candidates by collecting the most likely predictions over the corpus, using both original and counterfactual embeddings. This set of 18 words is shown in the x-axis of Figure 6. For both corpora, we partitioned the candidates into two sets, depending upon which parse they implied, and measured the sum of the probabilities of words in each set. If counterfactual embeddings caused the models to change the type of word they predicted, we would expect to see a change in these sums.

For the QA model, we similarly measured changes in probabilities among sets of words, but in this case we focused on the predicted start location of the answer. Recall that the QA model produced two distributions over words, indicating its predictions over where the answer started and ended. Consider an example input, drawn from the RC corpus: “The smart women and rich men who were desperate bribed the politician. Who was desperate?” Two reasonable answers might be “The smart women and rich men” or “rich men,” corresponding to QA outputs with identical end words, but differing start words. We therefore created two partitions of starting words to consider: those belonging to the first noun phrase (“The smart women”) or the second noun phrase (“rich men”). We then measured the summed start probabilities of words in each partition. We did not normalize these probabilities, as the QA model rarely predicted start words outside these two partitions with more than 1% probability.

In all experiments, we employed one-sided Wilcox Signed-Rank tests, non-parametric tests for pairwise data, when determining the significance at $(p < 0.01)$. The parses were viewed as “treatments” for the same embedding. We compared the effect of using counterfactual instead of original embeddings, as well as the effect of using different parses to generate counterfactual embeddings.

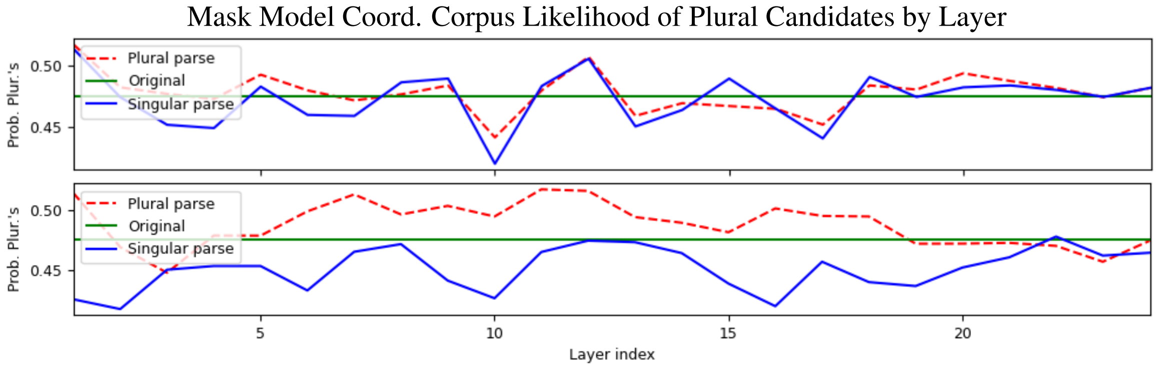


Figure 4: Mean probability of plural candidates using the depth probe (top) or the 3-layer dist probe (bottom), using original or counterfactual embeddings, in the Coordination corpus. Using a parse that implied plural words increased the probability of plural words when using the 3-layer dist probe.

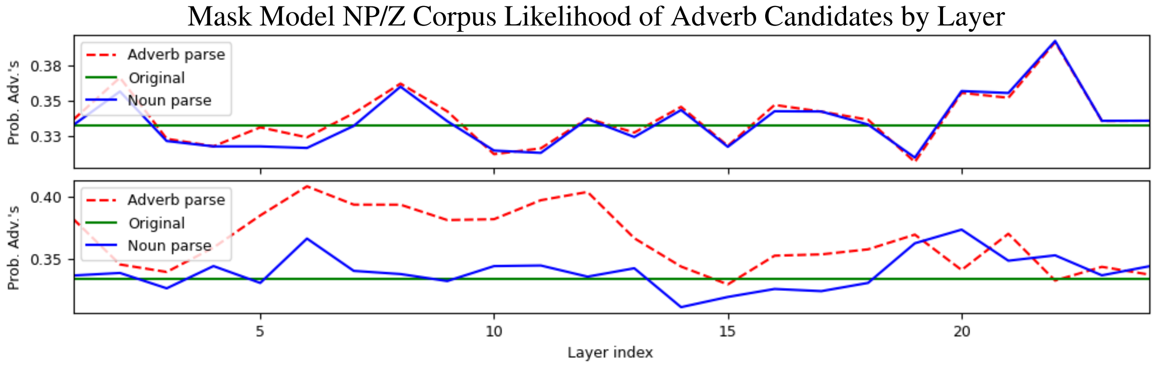

Figure 5: Mean probability of adverb candidates in the NP/Z corpus, using original and counterfactual embeddings generated by the depth (top) and 3-layer dist probes (bottom).

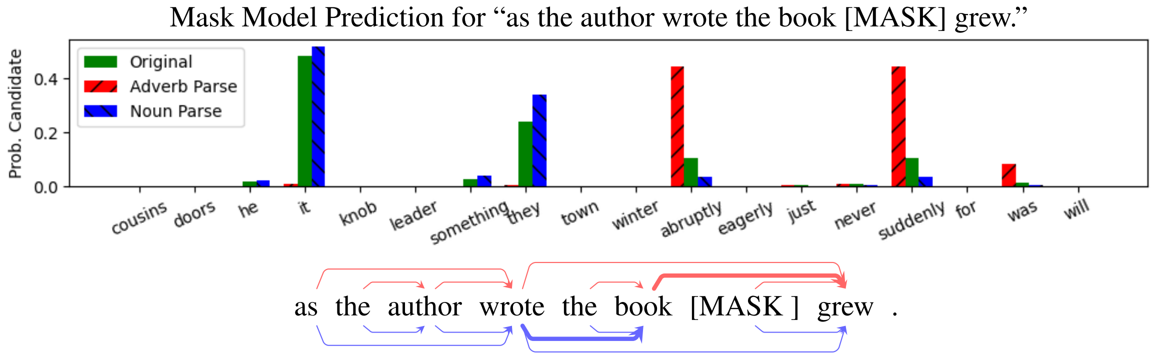

Figure 6: Given a sentence from the NP/Z corpus, the Mask model originally predicted "it" or "they," but using counterfactuals from the 5^{th} layer 3-layer dist probe changed predictions to favor nouns (cousins - winter) or adverbs (abruptly - suddenly). Visualizing the word dependencies revealed that the Adverb parse (top, red) and Noun parse (bottom, blue) induced different dependencies (differences in bold), as expected.

5 Results

Our results indicated that our probes performed well, as evaluated by performance metrics from prior art. However, we found that only some combinations of probe types and BERT models generated counterfactuals that altered the model's outputs according to syntactic principles.

5.1 Probe Performances

Measured on the PTB test set, the probe performance metrics confirmed that the probes predicted aspects of syntactic structure well (Marcus et al., 1993). Plots of performance, similar to those by Hewitt and Manning (2019), for probes trained on QA model embeddings are included in Figure 3.[2]

---

[2] All probe metrics are plotted in the appendix.

For both models and all probe types, we found that the probes were able to achieve high performance, indicating that both the Mask and QA models encoded syntactic information in their embeddings.

We also observed the unsurprising trend that multi-layered, non-linear distance probes outperformed the linear distance probe. This raised the question, if different probes exhibited different performance for the same model, which probe should be used to deduce model behavior? Injecting counterfactual embeddings generated by different probes helped us answer this question.

5.2 Mask Counterfactual Results

Next, we found that using the distance-based probes to generate counterfactual embeddings in the Mask model consistently produced the desired effect by shifting the model's prediction of the masked word according to syntactic principles, and that the multi-layer distance probes performed better than the linear probe.

We plotted the mean effect of counterfactual embeddings for the Coordination and NP/Z corpora in Figures 4 and 5, respectively.[3] Each plot depicts the mean prediction likelihood of one of the partitions of candidates (plural for Coord. corpus, adverbs for NP/Z), using original or counterfactual embeddings. Figure 4 shows results using the depth and 3-layer distance probes in the Coord. corpus: the depth probe failed to produced consistent changes in word probabilities, but embeddings generated by the 3-layer dist probe did exhibit the desired effect. The change in probability of plural words when using the plural parse was significantly positive for layers 6 through 14 (among others) and greater than the change when using the singular parse for layers for 4 through 21.

Similar results were observed using the 3-layer distance probe for the NP/Z corpus, as shown in Figure 5. The net increase in probability for adverbs when using the adverb parse was significantly greater than when using the NP2 parse for layers 5 through 19 and was positive for layers 4 through 13.

We examined an example sentence from the NP/Z corpus in Figure 6 in greater depth. The 18 words displayed along the x axis were the candidate words whose probabilities we calculated in the NP/Z corpus. As expected, using the Adv. parse increased the likelihood of adverbs like "suddenly," while using the Noun parse increased the likelihood of nouns like "it" or "they." Lastly, the bottom part of Figure 6 shows the dependency trees for the counterfactuals generated for each parse (see Hewitt and Manning (2019) for details on creating such trees). These trees reflected the dependencies of the parses that generated the counterfactuals, indicating that our technique changed embeddings in the way we intended.

Together, the results from both corpora, revealed that distance-, but not depth-, based probes elicited the desired response from the Mask model, which suggests that it leverages a distance-based representation of syntax in its reasoning.

5.3 QA Counterfactual Results

Lastly, we examined the effect of using counterfactual embeddings in the QA model. Compared to the Mask model, we found smaller and less consistent results, suggesting that the QA model may not use syntax.

Taking the mean across sentences in the corpus, we plotted the mean starting probabilities of words in each sentence's first noun phrase (as explained earlier in Section 4.5). These values reflect whether the model predicted NP1 should be included in the answer (e.g., "The smart women and rich men" instead of merely "rich men"). We plotted the results for the 3-layer dist probe, the best-performing probe for the Mask model, on both QA corpora in Figure 7. In both plots, the choice of layer in which counterfactuals were inserted had a greater effect than which parse was used to generate the counterfactuals – a sign of poor performance. Depth and other distance probes performed no better.

Visualizing dependency trees for QA embeddings revealed that the counterfactual embeddings induced the correct structure, indicating that the QA model simply did not use such structure in downstream predictions. Furthermore, given the success of our probes and technique with the Mask model, these poor results for the QA model suggest (but admittedly cannot definitely prove) that it may not have learned to use the syntactic information detected by the probes. This theory is consistent with prior art that finds that fine-tuning on specific tasks, as was done for the QA model, worsens the alignment between model and human representations of language (Gauthier and Levy, 2019).

---

[3] Plots for the effects of counterfactuals for all probes, models, and test corpora were included in the appendix.

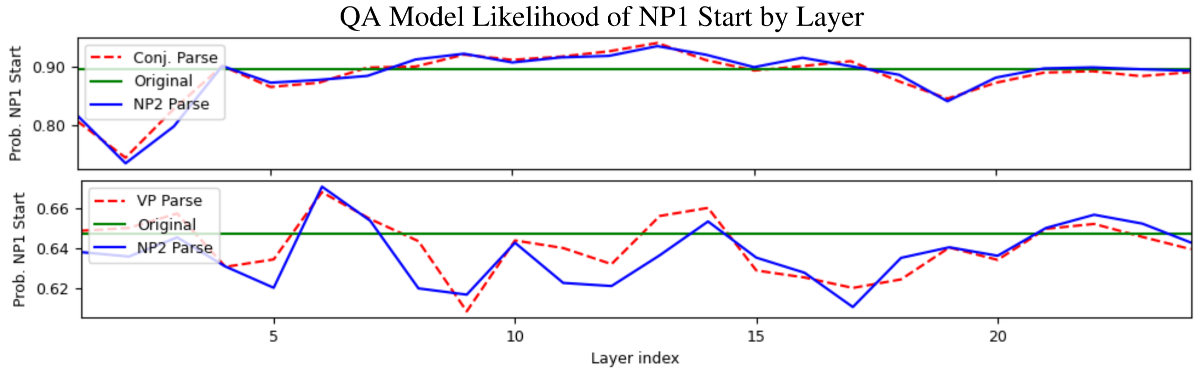

Figure 7: Mean effects of using counterfactual updates from the 3-layer dist probe on the QA model for the RC (top) and NP/VP (bottom) corpora.

6 Conclusion

In this work, we proposed and evaluated a new technique for producing counterfactual embeddings that tested syntactic understanding of models and probes. On the one hand, we uncovered clear evidence supporting a causal link between a distance-based representation of syntax and the outputs of a masked-word model. On the other hand, depth-based manipulations of embeddings had little effect, and we found no evidence that the BERT model finetuned on question-answering uses the syntactic information used by probes.

Our work is merely an initial step in the direction of causal analysis of language models. Developing new probes, backed by causal evidence, could increase our understanding of such models. In particular, our findings that multi-layered probes outperformed linear probes indicate that the prior guidance of simpler probes being preferable may be misleading. Furthermore, as the discrepancy between distance- and depth-based probes revealed, developing a large suite of probe types that focus on different features may be necessary to reveal a model's reasoning. In tandem with probe development, more sophisticated counterfactual generation techniques than our gradient-based method could produce more interesting counterfactuals for evaluation.

Acknowledgments

We thank the reviewers for their thoughtful comments, in particular regarding adversarial attacks. We thank Professors Julie Shah and Jacob Andreas for ongoing discussions and guidance. Lastly, we thank John Hewitt and Christopher Manning for releasing high-quality, reproducible code, enabling us to rapidly build upon their syntactic probe codebase.

RPL gratefully acknowledges support from the MIT–IBM Artificial Intelligence Laboratory and MIT's Quest for Intelligence.

Appendix: Complete Performance Plots

In this appendix, we included additional figures that we were unable to include within the main paper limits.

First, we depicted the probe performance characteristics for the 4 probes types we used in all our experiments: the depth, dist, 2-layer dist, and 3-layer dist probes. Each type of probe was trained for both the QA and Mask models. Evaluation of these probes was plotted in Figure 8.

Next, we reported the effect of counterfactual embeddings generated for each model, corpus, and probe type. Given the 4-page limit for the appendix, further plots breaking down the NP/Z corpus, for example, or depicting performance for multi-layered depth probes were not included. These plots merely confirmed trends already present in the data: that depth-based probes did not produce useful counterfactuals, and that the curated and automatically-generated sentences that formed the full NP/Z corpus yielded similar results.

In general, we observed small effects for counterfactuals in the QA Model (Figures 11 and 12), but consistent effects in the Mask Model (Figures 9 and 10). Within the Mask model results, we also observed that the distance probe (2^{nd} row) outperformed the depth probe (1^{st} row), and that the multi-layer distance probes (3^{rd} and 4^{th} rows) outperformed the linear distance probe.

Abstract

Modern text simplification (TS) heavily relies on the availability of gold standard data to build machine learning models. However, existing studies show that parallel TS corpora contain inaccurate simplifications and incorrect alignments. Additionally, evaluation is usually performed by using metrics such as BLEU or SARI to compare system output to the gold standard. A major limitation is that these metrics do not match human judgements and the performance on different datasets and linguistic phenomena vary greatly. Furthermore, our research shows that the test and training subsets of parallel datasets differ significantly. In this work, we investigate existing TS corpora, providing new insights that will motivate the improvement of existing state-of-the-art TS evaluation methods. Our contributions include the analysis of TS corpora based on existing modifications used for simplification and an empirical study on TS models performance by using better-distributed datasets. We demonstrate that by improving the distribution of TS datasets, we can build more robust TS models.

1 Introduction

Text Simplification transforms natural language from a complex to a simple format, with the aim to not only reach wider audiences (Rello et al., 2013; De Belder and Moens, 2010; Aluisio et al., 2010; Inui et al., 2003) but also as a preprocessing step in related tasks (Shardlow, 2014; Silveira and Branco, 2012).

Simplifications are achieved by using parallel datasets to train sequence-to-sequence text generation algorithms (Nisioi et al., 2017) to make complex sentences easier to understand. They are typically produced by crowdsourcing (Xu et al., 2016; Alva-Manchego et al., 2020a) or by alignment (Cao et al., 2020; Jiang et al., 2020). They are infamously noisy and models trained on these give poor results when evaluated by humans (Cooper and Shardlow, 2020). In this paper we add to the growing narrative around the evaluation of natural language generation (van der Lee et al., 2019; Caglayan et al., 2020; Pang, 2019), focusing on parallel text simplification datasets and how they can be improved.

Why do we need to re-evaluate TS resources? In the last decade, TS research has relied on Wikipedia-based datasets (Zhang and Lapata, 2017; Xu et al., 2016; Jiang et al., 2020), despite their known limitations (Xu et al., 2015; Alva-Manchego et al., 2020a) such as questionable sentence pairs alignments, inaccurate simplifications and a limited variety of simplification modifications. Apart from affecting the reliability of models trained on these datasets, their low quality influences the evaluation relying on automatic metrics that requires gold-standard simplifications, such as SARI (Xu et al., 2016) and BLEU (Papineni et al., 2001).

Hence, evaluation data resources must be further explored and improved to achieve reliable evaluation scenarios. There is a growing body of evidence (Xu et al., 2015) (including this work) to show that existing datasets do not contain accurate and well-constructed simplifications, significantly impeding the progress of the TS field.

Furthermore, well-known evaluation metrics such as BLEU are not suitable for simplification evaluation. According to previous research (Sulem et al., 2018) BLEU does not significantly correlate with simplicity (Xu et al., 2016), making it inappropriate for TS evaluation. Moreover, it does not correlate (or the correlation is low) with grammaticality and meaning preservation when performing syntactic simplification such as sentence splitting. Therefore in most recent TS research BLEU has not been considered as a reliable evaluation metric. We use SARI as the preferred method for TS eval-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 876–882
August 1–6, 2021.

uation, which has also been used as the standard evaluation metric in all the corpora analysed in this research.

Our contributions include 1) the analysis of the most common TS corpora based on quantifying modifications used for simplification, evidencing their limitations and 2) an empirical study on TS models performance by using better-distributed datasets. We demonstrate that by improving the distribution of TS datasets, we can build TS models that gain a higher SARI score in our evaluation setting.

2 Related Work

The exploration of neural networks in TS started with the work of Nisioi et al. (2017), using the largest parallel simplification resource available (Hwang et al., 2015). Neural-based work focused on state-of-the-art deep learning and MT-based methods, such as reinforcement learning (Zhang and Lapata, 2017), adversarial training (Surya et al., 2019), pointer-copy mechanism (Guo et al., 2018), neural semantic encoders (Vu et al., 2018) and transformers supported by paraphrasing rules (Zhao et al., 2018).

Other successful approaches include the usage of control tokens to tune the level of simplification expected (Alva-Manchego et al., 2020a; Scarton and Specia, 2018) and the prediction of operations using parallel corpora (Alva-Manchego et al., 2017; Dong et al., 2020). The neural methods are trained mostly on Wikipedia-based sets, varying in size and improvements in the quality of the alignments.

Xu et al. (2015) carried out a systematic study on Wikipedia-based simplification resources, claiming Wikipedia is not a quality resource, based on the observed alignments and the type of simplifications. Alva-Manchego et al. (2020a) proposed a new dataset, performing a detailed analysis including edit distance and proportion of words that are deleted, inserted and reordered, and evaluation metrics performance for their proposed corpus.

Chasing the state-of-the-art is rife in NLP (Hou et al., 2019), and no less so in TS, where a SARI score is too often considered the main quality indicator. However, recent work has shown that these metrics are unreliable (Caglayan et al., 2020) and gains in performance according to them may not deliver improvements in simplification performance when the text is presented to an end user.

3 Simplification Datasets: Exploration

3.1 Data and Methods

In the initial exploration of TS datasets, we investigated the training, test and validation subsets (when available) of the following: WikiSmall and WikiLarge (Zhang and Lapata, 2017), TurkCorpus (Xu et al., 2015), MSD dataset (Cao et al., 2020), ASSET (Alva-Manchego et al., 2020a) and WikiManual (Jiang et al., 2020). For the WikiManual dataset, we only considered sentences labelled as “aligned”.

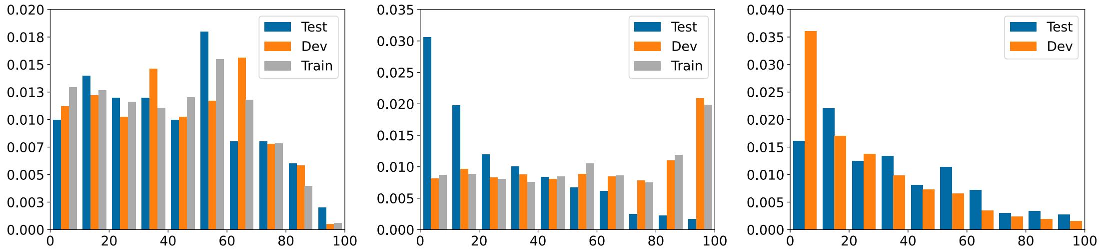
We computed the number of changes between the original and simplified sentences through the **token edit distance**. Traditionally, edit distance quantifies character-level changes from one character string to another (additions, deletions and replacements). In this work, we calculated the token-based edit distance by adapting the Wagner–Fischer algorithm (Wagner and Fischer, 1974) to determine changes at a token level. We preprocessed our sentences by changing them into lowercase prior to this analysis. To make the results comparable across sentences, we divide the number of changes by the length of the original sentence and obtain values between 0% (no changes) to 100% (completely different sentence).

In addition to toked-based edit operation experiments, we analysed the difference of sentence length between complex and simple variants, the quantity of edit operations type (INSERT, DELETE and REPLACE) and an analysis of redundant operations such as deletions and insertions in the same sentence over the same text piece (we define this as the MOVE operation). Based on our objective to show how different split configurations affect TS model performance, we have presented the percentage of edit operations as the more informative analysis performed on the most representative datasets.

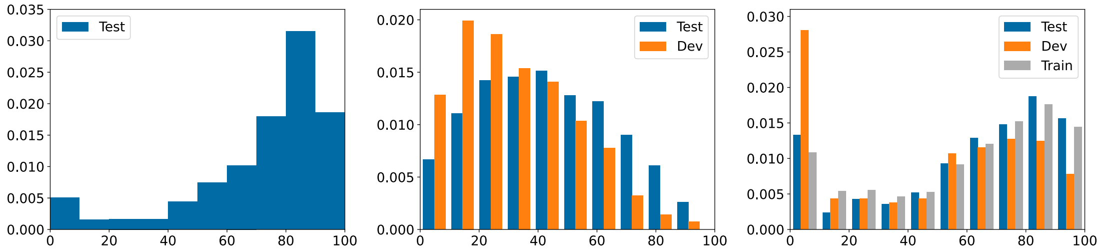
3.2 Edit Distance Distribution

Except for the recent work of Alva-Manchego et al. (2020b), there has been little work on new TS datasets. Most prior datasets are derived by aligning English and Simple English Wikipedia, for example **WikiSmall** and **WikiLarge** (Zhang and Lapata, 2017).

In Figure 1 we can see that the edit distance distribution of the splits in the selected datasets is not even. By comparing the test and development subsets in WikiSmall (Figure 1a) we can see differences in the number of modifications involved in simplification. Moreover, the WikiLarge dataset



(a) WikiSmall Test/Dev/Train (b) WikiLarge Test/Dev/Train (c) TurkCorpus Test



(d) MSD Test (e) ASSET Test (f) WikiManual Test/Dev/Train

Figure 1: Comparison of TS datasets with respect to the number of edit operations between the original and simplified sentences. X-axis: token edit distance normalised by sentence length, Y-axis: probability density for the change percentage between complex and simple sentence pairs.

(Figure 1b) shows a complete divergence of the test subset. Additionally, it is possible to notice a significant number of unaligned or noisy cases, between the 80% and 100% of change in the WikiLarge training and validation subsets (Figure 1b).

We manually checked a sample of these cases and confirmed they were poor-quality simplifications, including incorrect alignments. The simplification outputs (complex/simple pairs) were sorted by their edit distances and then manually checked to determine an approximate heuristic for noisy sentences detection. Since many of these alignments had really poor quality, it was easy to determine the number that removed a significant number of cases without actually reducing dramatically the size of the dataset.

Datasets such as **Turk Corpus** (Xu et al., 2015) are widely used for evaluation and their operations mostly consist of lexical simplification (Alva-Manchego et al., 2020a). We can see this behaviour in Figure 1c, where most edits involve a small percentage of the tokens. This can be noticed when a large proportion of the sample cases are between 0% (no change) to 40%.

In the search of better evaluation resources, TurkCorpus was improved with the development of **ASSET** (Alva-Manchego et al., 2020a) including more heterogeneous modification measures. As we can see in Figure 1e, the data are more evenly distributed than in Figure 1c.

Recently proposed datasets, such as **WikiManual** (Jiang et al., 2020), as shown in Figure 1f, have an approximately consistent distribution, and their simplifications are less conservative. Based on a visual inspection on the uppermost values of the distribution (≈80%), we can tell that often most of the information in the original sentence is removed or the target simplification does not express accurately the original meaning.

MSD dataset (Cao et al., 2020) is a domain-specific dataset, developed for style transfer in the health domain. In the style transfer setting, the simplifications are aggressive (i.e., not limited to individual words), to promote the detection of a difference between one style (expert language) and another (lay language). Figure 1d shows how their change-percentage distribution differs dramatically in comparison to the other datasets, placing most of the results at the right-side of the distribution.

Among TS datasets, it is important to mention that the raw text of the **Newsela** (Xu et al., 2015) dataset was produced by professional writers and is likely of higher quality than other TS datasets. Unfortunately, it is not aligned at the sentence level by default and its usage and distribution are limited by a restrictive data agreement. We have not included this dataset in our analysis due to the restrictive licence under which it is distributed.

Dataset	Split	KL-div	p-value
WikiSmall	Test/Dev	0.0696	0.51292
	Test/Tr	0.0580	0.83186
WikiLarge	Test/Dev	0.4623	<0.00001
	Test/Tr	0.4639	<0.00001
WikiManual	Test/Dev	0.1020	0.00003
	Test/Tr	0.0176	0.04184
TurkCorpus	Test/Dev	0.0071	0.00026
ASSET	Test/Dev	0.0491	<0.00001

Table 1: KL-divergence between testing (Test) and development (Dev) or training (Tr) subsets.

3.3 KL Divergence

In addition to edit distance measurements presented in Figure 1, we further analysed **KL divergence** (Kullback and Leibler, 1951) of those distributions to understand how much dataset subsets diverge. Specifically, we compared the distribution of the test set to the development and training sets for WikiSmall, WikiLarge, WikiManual, TurkCorpus and ASSET Corpus (when available). We did not include MSD dataset since it only has a testing set.

We performed **randomised permutation tests** (Morgan, 2006) to confirm the statistical significance of our results. Each dataset was joined together and split randomly for 100,000 iterations. We then computed the p-value as a percentage of random splits that result in the KL value equal to or higher than the one observed in the data. Based on the p-value, we can decide whether the null hypothesis (i.e. that the original splits are truly random) can be accepted. We reject the hypothesis for p-value lower than 0.05. In Table 1 we show the computed KL-divergence and p-values. The p-values below 0.05 for WikiManual and WikiLarge confirm that these datasets do not follow a truly random distribution.

4 Simplification Datasets: Experiments

We carried out the following experiments to evaluate the variability in performance of TS models caused by the issues described in Wiki-based data.

4.1 Data and Methods

For the proposed experiments, we used the EditNTS model, a Programmer-Interpreter Model (Dong et al., 2020). Although the original code was published, its implementation required minor modifications to run in our setting. The modifications performed, the experimental subsets as well as the source code are documented via GitHub[1]. We selected EditNTS model due to its competitive performance in both WikiSmall and WikiLarge datasets[2]. Hence, we consider this model as a suitable candidate for evaluating the different limitations of TS datasets. In future work, we will definitely consider testing our assumptions under additional metrics and models.

In relation to TS datasets, we trained our models on the training and development subsets from WikiLarge and WikiSmall, widely used in most of TS research. In addition, these datasets have a train, development and test set, which is essential for retraining and testing the model with new split configurations. The model was first trained with the original splits, and then with the following variations:

Randomised split: as explained in Section 3.3, the original WikiLarge split does not have an even distribution of edit-distance pairs between subsets. For this experiment, we resampled two of our datasets (WikiSmall and WikiLarge). For each dataset, we joined all subsets together and performed a new random split.

Refined and randomised split: we created subsets that minimise the impact of poor alignments. These alignments were selected by edit distance and then subsets were randomised as above. We presume that the high-distance cases correspond to noisy and misaligned sentences. For both WikiSmall and WikiLarge, we reran our experiments removing 5% and 2% of the worst alignments.

Finally, we evaluated the models by using the test subsets of external datasets, including: TurkCorpus, ASSET and WikiManual.

5 Discussion

Figure 2 shows the results for WikiSmall. We can see a minor decrease in SARI score with the random splits, which means that the noisy alignments were equivalently present in all the sets rather than using the best cases for training. On the other hand, when the noisy cases are removed from the datasets the increase in model performance is clear.

Likewise, we show WikiLarge results in Figure 3. When the data is randomly distributed, we obtain better performance than the original splits. This

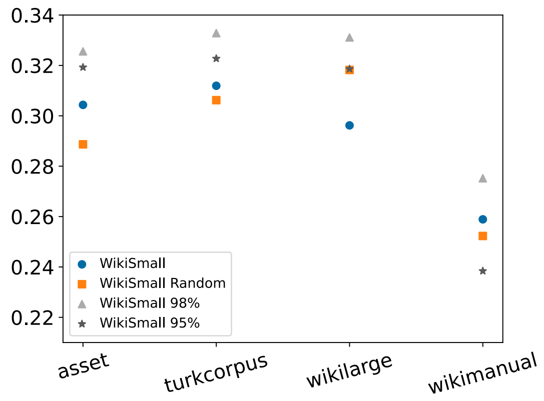

Figure 2: SARI scores for evaluating WikiSmall-based models on external test sets.

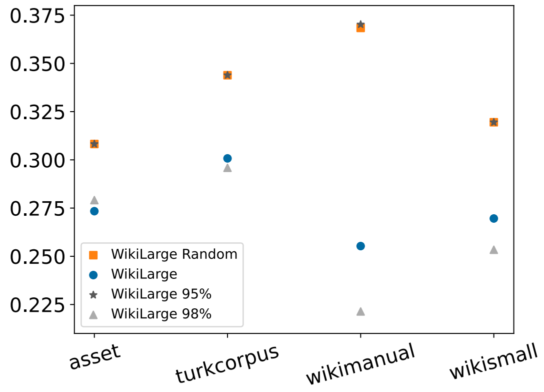

Figure 3: SARI scores for evaluating WikiLarge-based models on external test sets.

is consistent with WikiLarge having the largest discrepancy according to our KL-divergence measurements, as shown in Section 3.3. We also found that the 95% split gave a similar behaviour to WikiLarge Random. Meanwhile, the 98% dataset, gave a similar performance to the original splits for ASSET and TurkCorpus[3].

We can also note, that although there is a performance difference between WikiSmall Random and WikiSmall 95%, in WikiLarge the same splits have quite similar results. We believe these discrepancies are related to the size and distribution of the training sets. WikiLarge subset is three times bigger than WikiSmall in the number of simple/complex pairs. Also, WikiLarge has a higher KL-divergence (≈0.46) than WikiSmall (≈0.06), which means that WikiLarge could benefit more from a random distribution experiment than WikiSmall, resulting in higher performance on WikiLarge. Further differences may be caused by the procedures used to make the training/test splits in the original research, which were not described in the accompanying publications.

Using randomised permutation testing, we have confirmed that the SARI differences between the models based on the original split and our best alternative (95% refined) is statistically significant ($p < 0.05$) for each configuration discussed above.

In this study, we have shown the limitations of TS datasets and the variations in performance in different splits configurations. In contrast, existing evidence cannot determine which is the most suitable split, especially since this could depend on each specific scenario or target audience (e.g., model data similar to “real world” applications).

Also, we have measured our results using SARI, not only because it is the standard evaluation metric in TS but also because there is no better automatic alternatives to measure simplicity. We use SARI as a way to expose and quantify SOTA TS datasets limitations. The increase in SARI scores should be interpreted as the variability in the relative quality of the output simplifications. By relative we mean, that there is a change in simplicity gain but we cannot state the simplification is at its best quality since the metric itself has its own weaknesses.

6 Conclusions

In this paper, we have shown 1) the statistical limitations of TS datasets, and 2) the relevance of subset distribution for building more robust models. To our knowledge, distribution-based TS datasets analysis has not been considered before. We hope that the exposure of these limitations kicks off a discussion in the TS community on whether we are in the correct direction regarding evaluation resources in TS and more widely in NLG. The creation of new resources is expensive and complex, however, we have shown that current resources can be refined, motivating future studies in the field of TS.

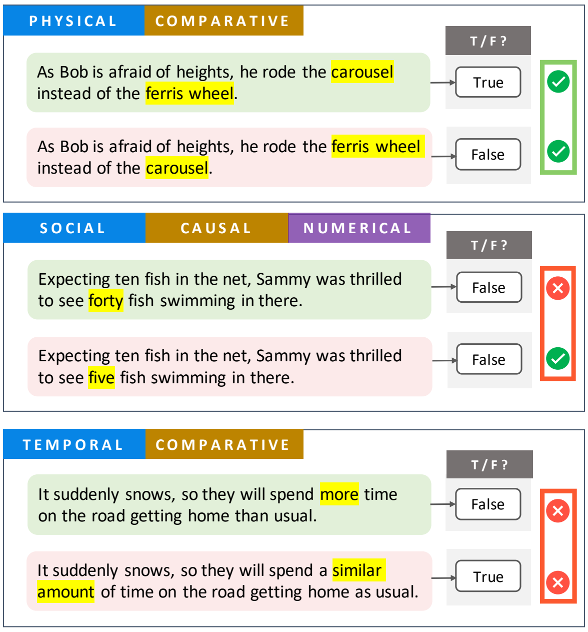
Abstract

Commonsense reasoning is intuitive for humans but has been a long-term challenge for artificial intelligence (AI). Recent advancements in pretrained language models have shown promising results on several commonsense benchmark datasets. However, the reliability and comprehensiveness of these benchmarks towards assessing model's commonsense reasoning ability remains unclear. To this end, we introduce a new commonsense reasoning benchmark dataset comprising natural language true/false statements, with each sample paired with its complementary counterpart, resulting in 4k sentence pairs. We propose a pairwise accuracy metric to reliably measure an agent's ability to perform commonsense reasoning over a given situation. The dataset is crowdsourced and enhanced with an adversarial model-in-the-loop setup to incentivize challenging samples. To facilitate a systematic analysis of commonsense capabilities, we design our dataset along the dimensions of knowledge domains, reasoning scenarios and numeracy. Experimental results demonstrate that our strongest baseline (UnifiedQA-3B), after fine-tuning, achieves ~71% standard accuracy and ~51% pairwise accuracy, well below human performance (~95% for both metrics). The dataset is available at `https://github.com/PlusLabNLP/Com2Sense`.

1 Introduction

The capability of acquiring and reasoning over commonsense knowledge plays a crucial role for artificial intelligence (AI) systems that interact with humans and accomplish tasks in the real world. For example, given a situation where *someone is asleep*, an agent should choose to *broom* instead of *vacuum* to clean the room, as the latter would be noisy. Likewise, a personal assistant should be able to infer that one is probably unavailable if they are *at work*. This ability to contextualize and draw upon implicit knowledge, and generalize to novel situations, requires commonsense reasoning.



As Bob is afraid of heights, he rode the carousel instead of the ferris wheel.

As Bob is afraid of heights, he rode the ferris wheel instead of the carousel.

Expecting ten fish in the net, Sammy was thrilled to see forty fish swimming in there.

Expecting ten fish in the net, Sammy was thrilled to see five fish swimming in there.

It suddenly snows, so they will spend more time on the road getting home than usual.

It suddenly snows, so they will spend a similar amount of time on the road getting home as usual.

Figure 1: Complementary sentence pair samples from COM2SENSE defined along knowledge domains (*e.g. physical*), reasoning scenarios (*e.g. comparative*) and numeracy attributes. Each sentence within a pair is either true (green boxes) or false (red boxes), followed by model predictions and annotations of whether the predictions are correct. A *standard* accuracy is computed by the percentage of correctly judged sentences (50% for these three pairs), while the *pairwise* accuracy requires both *individual* judgements to be correct in each pair (33% for these three pairs).

While humans are able to intuitively acquire commonsense knowledge from everyday experience and make sound inferences, whether current AI systems also possess such capabilities remains an open question. Recent advancements in natural language processing (NLP) has led to a surge in

new benchmark datasets towards evaluating commonsense reasoning. Specifically, existing benchmarks are formulated as natural language inference (NLI) (Bhagavatula et al., 2020), *multiple choice* (MC) question answering (Talmor et al., 2019a; Zellers et al., 2019; Bisk et al., 2020), and machine reading comprehension (Huang et al., 2019) tasks.

While recent state-of-the-art models (Liu et al., 2019; Raffel et al., 2020; Khashabi et al., 2020) have quantitatively demonstrated near human-level performance on these benchmarks, the exploitation of certain spurious patterns (Gururangan et al., 2018; Poliak et al., 2018; McCoy et al., 2019) in the datasets can be partly attributed to such achievements. Consider the examples in Figure 1, where each sentence is true/false, and is paired with a similar (with a few modifications) complementary counterpart such that the answer is flipped. Humans can infer each statement independently with confidence, but models on the other hand struggle to give consistent judgements for the complementary pairs. This indicates that models are able to *guess* the correct answer without a thorough understanding of the given input. If we formulate this as a multiple choice task, where *only the true* sentence needs to be *singled out* given the pairs, the models have higher chances to get it correct, as they are only required to select the *relatively better* option.

Furthermore, most existing commonsense benchmarks focus on the *factual* aspects of commonsense (Talmor et al., 2019a; Bisk et al., 2020), and generally do not explicitly concern with *reasoning* (Singer et al., 1992), *i.e.* the mental manipulation of factual knowledge, which we hypothesize is crucial for generalizing to novel situations. While some prior works investigate commonsense reasoning in the context of social intelligence and co-reference resolutions (Sap et al., 2019; Sakaguchi et al., 2020), the reasoning components are implicit. Existing benchmarks fail to provide a systematic and comprehensive means of analyzing different aspects of commonsense knowledge and reasoning.

To address these challenges, we introduce the **Com**plementary **Com**monsense (COM2SENSE) benchmark dataset which contains 4k complementary true/false sentence pairs. Each pair is constructed with minor perturbations to a sentence to derive its complement such that the corresponding label is inverted (see Figure 1). This *pairwise* formulation provides a more reliable evaluation metric, where a model is considered correct *only if it succeeds on both statements*. We employ an adversarial crowdsourcing framework to collect human created samples via a *gamified* machine-in-the-loop process: A strong pretrained model is setup to provide instant feedbacks, thereby incentivizing challenging samples that can *fool* the model.

Broadly inspired by the *Theory of Core Knowledge*, *i.e.* the ability to reason about objects, places, numbers and the social world (Spelke and Kinzler, 2007), we design our dataset along the following dimensions: **knowledge domains** (*physical*, *social*, *temporal*), and **reasoning scenarios** (*causal*, *comparative*). Additionally, concurrent to a recent work (Lin et al., 2020a) on studying numerical commonsense, we include a third dimension of **numeracy**, which extends the factual focus of Lin et al. (2020a) (*e.g.* *"Ants have* ***six*** *legs."*) to *numerical reasoning* (*e.g.* the *ten fish* versus *forty fish* in Figure 1). To the best of our knowledge, we are the first to explicitly introduce these dimensions in a commonsense benchmark dataset, thereby facilitating a more detailed and systematic probing of models' commonsense understanding.

Our experiments demonstrate that the best performing pretrained language models achieve ~71% standard and ~51% pairwise accuracy, well below human performance. Additionally, we provide ablation studies on effect of training size on model performance, and the transferrability across the reasoning scenarios. We summarize our contributions as follows: 1) We introduce a commonsense reasoning dataset which we position as a challenging *evaluation benchmark* (instead of a training resource) for NLP models. 2) We propose a pairwise evaluation metric featured by our complementary pair formulation for a more reliable assessment of commonsense reasoning abilities. 3) We benchmark state-of-the-art models that highlight significant gaps (>45%) between model and human performances.

2 Dataset

We introduce COM2SENSE, a dataset for benchmarking commonsense reasoning ability of NLP models. We use crowdsourcing to collect the dataset and supplemented with an adversarial *model-in-the-loop* approach. The key features of our development process are: 1) qualification quiz to filter and familiarize workers, 2) *gamified* creation tasks, and 3) quality check by experts. The details of dataset formulation and collection pro-

Domain	Scenario	Numeracy	Example	Complement
Physical	Comparative	No	*If we dropped* ***milk*** *on the floor, it is better to clean with a mop rather than a broom.*	*cereal*
Physical	Causal	No	*To* ***read books*** *at night, one should turn on the lights.*	*see stars*
Social	Comparative	No	*Sam robbed a store, while Tim jumped the lights. People will likely be more* ***forgiving*** *towards Tim.*	*chastising*
Social	Causal	Yes	*Given his $1500 monthly income and no savings, he can afford an apartment rent of* ***$500****.*	*$3000*
Temporal	Comparative	Yes	*Tim needs to return home in 2 hours, so he would prefer to* ***hit the gym*** *rather than* ***go hiking****.*	`swap`
Temporal	Causal	Yes	*If Leo earns $100 per day, then by working from Monday to* ***Friday*** *his weekly income will be $500.*	*Wednesday*

Table 1: Data samples from different categories in Com2Sense. Each example is labelled as true, while its complement (false) is generated by substituting or swapping the words in **bold** (in green or red font).

cedure, along with statistics are provided in the following sections.

2.1 Formulation

Com2Sense seeks to measure a comprehensive commonsense understanding of everyday events and entities. The task requires one to judge whether a given sentence is true or false. For each sentence in the dataset, we also compose its complementary counterpart by modifying a few words, such that the answer is inverted. The key advantages of using complementary pairs are two-folds: 1) it provides a more robust way of evaluating models' commonsense reasoning ability by requiring both sentences to be correctly judged, and 2) the complements naturally highlight the salient words which may be useful in probing model behaviors.

Furthermore, to facilitate a systematic study of commonsense, we design our dataset across the following three dimensions:

1. **Knowledge Domain:** We categorize commonsense knowledge into *physical*, *social* and *temporal* domains. The physical domain emphasizes on an intuitive understanding of physical properties (*e.g*. weight, shape, motion, space) and object affordances. The social domain encapsulates interactions (*e.g*. intent, emotion, reaction), activities, and societal norms. The temporal domain captures the notion of time, particularly attributes such as duration, frequency and order of events. While domains may not always be strictly exclusive (*e.g*. choice of transport and duration), our complementary pair setup naturally places emphasis on the intended domain.

2. **Reasoning Scenario:** We define two types of inferential reasoning scenarios: 1) The *causal* scenario requires the ability to infer whether a cause explanation or a subsequent event (cause-effect) is correct. 2) The *comparative* scenario requires the ability of determining the most plausible hypothesis between two or more competing ones.

3. **Numeracy:** Refers to the basic understanding of numbers, arithmetic, ratios, statistics, etc. With the objective of linking numeracy to commonsense, we particularly focus on "number sense" – an intuitive understanding of numbers, their magnitude and relationships, rather than computational and numerical precision.

Therefore, each sample in our dataset should fall into a category defined by a combination of the above dimensions, as exemplified in Table 1.

2.2 Dataset Creation

Com2Sense is developed through crowdsourcing on Amazon Mechanical Turk (MTurk) with the goal of collecting complementary sentence pairs. The creation tasks are constructed for each *category* defined by the combination of domain, scenario and numeracy attributes. An overview of the data collection workflow is illustrated in Figure 2. In order to participate, the workers are required to pass a **qualification quiz** designed to familiarize them with the key aspects of our dataset.

Creation: During the creation phase, to orient and aid workers' creativity, they are provided with five examples of complementary pairs that belong to a particular category as reference. We also share a list of verbs and topics pertinent to the current

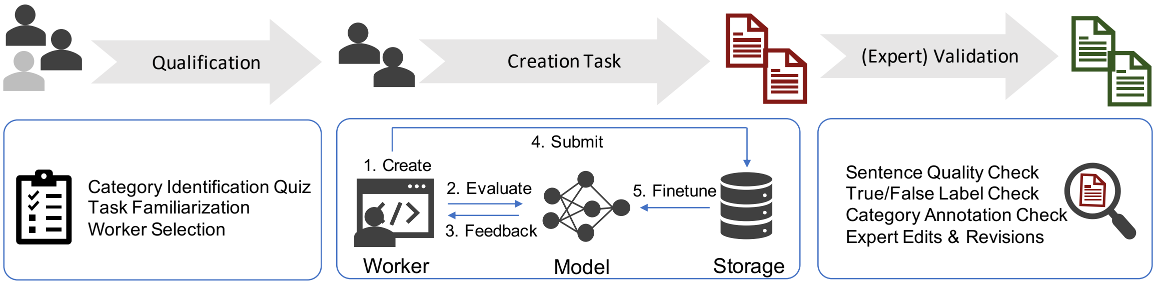

Figure 2: Data collection workflow: 1) qualification quiz to instruct the key aspects of our creation task and filter unqualified workers, 2) interactive *model-in-the-loop* creation process to incentivize challenging samples via model feedback, and 3) data validation according to our guidelines and category descriptions.

domain, as an optional resource. While our examples serve as a reference towards creating complementary pairs, the workers have the freedom to construct their sentences as they deem appropriate.

We employ an adversarial *model-in-the-loop* approach to provide workers with immediate feedback (*i.e.* model predictions) on each created sentence. After entering the inputs and labels, they may choose to evaluate and revise their inputs. If the sentence successfully fools our model to answer incorrectly, workers are awarded with an additional amount for each input[1].

To further incentivize worker creativity, we offer bonuses if the inputs are qualitatively regarded as creative during the validation stage. Such *gamified* process may continue for a few rounds until the workers are satisfied with their monetary rewards.

Model: We deploy a RoBERTa-large based model for binary sentence classification, finetuned on SemEval-2020 Task 4 (Wang et al., 2020) given its true/false format and broad coverage of commonsense knowledge. After the first phase of collection (2k pairs), the model weights are updated by finetuning on our dataset with 60% train, 20% dev and 20% test splits. This will naturally help diversify our dataset samples, as the model is unlikely to be fooled with repetitive knowledge and sentence structures.

Validation: To ensure high quality, the samples are validated by internal members to look for inconsistencies with regard to the category-type *i.e.* follows the domain, scenario and numeracy requirements, and inferential ambiguities that may arise due to insufficient context, specialized concepts, grammatical errors, etc. Furthermore, annotators may choose to revise the samples to fix any of the aforementioned issues. Each sample is validated by three annotators and the final outcome is decided through a majority vote. The inter-annotator agreement score is 0.989 measured using Fleiss' Kappa. Additionally, pairs in which neither input could fool the model are discarded during this stage.

The dataset is developed with the help of 173 workers. To ensure that workers are proficient in English, the demographic pool of the workers is initially limited to the United States. However, we removed this criteria to avoid cultural biases in the dataset. Additionally, to understand the utility of our adversarial model feedback setting, we analyze the data on number of revisions made by workers in order to successfully fool the model. We find that the average number of revisions is 1.36, while the median is zero. This suggests that for majority of samples, workers find our reference material sufficient and are also able to leverage model feedback to aid their creations. Additional details on dataset development are in Appendix Section A.

2.3 Dataset Statistics

Given that COM2SENSE is primarily a benchmark dataset, it is partitioned into train[2] (20%), development (10%), and test (70%) set, respectively. There are in total 4k of statement pairs in our dataset. Complementary statements from the same pair are distributed to the same partition. Table 2 gives the essential statistics of our dataset across different splits. Note that due to the complementary pair formulation, the type-token ratio is approximately reduced by a factor of two, and the dataset is naturally balanced along the true and false labels.

Table 3 gives the breakdown of percentage of samples from each category defined by a combination of the three dimensions. The distribution of most frequent nouns in the dataset is visualized

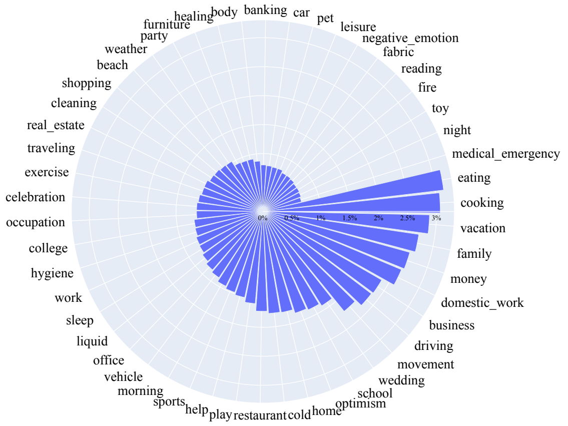

Figure 4: Top-50 frequent topics in the dataset.

in Figure 3. Likewise, the distribution of most frequent topics – lexical categories generated using the *Empath*[3]tool, is provided in Figure 4.

3 Experimental Setup

The experiments are designed to meet the following objectives: 1) benchmark state-of-the-art NLP models along the standard and pairwise formulation; 2) analyze the model performance across different categories of commonsense reasoning; 3) report the effect of training size on model performance; and 4) verify the role of reasoning types by measuring "cross-scenario" transferability.

Besides standard accuracy, we introduce a new metric called **pairwise accuracy** that evaluates as correct if both predictions within a pair are accurate.

Statistic	Train	Dev	Test
# complementary pairs	804	402	2779
Avg input length	21	21	21
Max input length	68	49	67
Min input length	6	7	6
# unique tokens	2306	1541	4407
# total tokens	21116	10520	72517

Table 2: Dataset statistics across different splits[4]

	Scenario	
Domain	Causal	Comparative
Physical	17.47% (24%)	18.92% (23%)
Social	14.68% (50%)	16.51% (22%)
Temporal	16.74% (57%)	15.68% (62%)

Table 3: Category-wise breakdown (percentage) of dataset samples. The quantities in parenthesis refer to the relative proportion of samples with numeracy, under the given combination of domain and scenario.

We benchmark several state-of-the-art NLP models, specifically the ones proven preeminent in existing commonsense benchmarks, and additionally include a Bi-LSTM model as a baseline to help check for potential spurious correlations in the dataset. We consider the following baselines:

BiLSTM+GloVe A bidirectional-LSTM model (Hochreiter and Schmidhuber, 1997) taking input word embeddings from GloVe (Pennington et al., 2014).

BERT The BERT-base (110M) model introduced in (Devlin et al., 2019).

RoBERTa-large A large variant (355M) of RoBERTa model (Liu et al., 2019) built upon BERT-large architecture.

DeBERTa-large Recently He et al. (2020) proposed a novel disentangled attention mechanism that improves upon BERT and RoBERTa models. We consider the large variant (390M) as a baseline.

T5-large Similarly, the large variant (770M) of the T5 model (Raffel et al., 2020). We follow the standard prefix-based text-to-text format, and adapt it for our binary classification setup.

UnifiedQA The UnifiedQA (Khashabi et al., 2020) was originally trained on numerous datasets including several commonsense reasoning benchmarks, and performed well under zero-shot setting. We consider the variants with T5-large and T5-3B as the architecture backbone.

Com2Sense$_{\text{pairwise}}$	25.00	33.28	41.84	95.00

Table 5: Test set accuracy for selected models (RoBERTa-large and T5-large), trained and evaluated on respective datasets.

4 Results and Analysis

Human Performance: To estimate a human upper bound for our dataset, we perform a separate run with ten top performing workers that had participated in our collection phase to examine a randomly selected subset of 200 samples (*i.e.* from 100 pairs). Each worker is assigned with a set of shuffled samples with his/her own creations deliberately filtered out. The answer is determined by majority vote from *three* workers. Human performances are 96.5% with standard accuracy and 95.0% with pairwise accuracy, respectively.

4.1 Results

Benchmark results: Table 4 summarizes the baseline performances on the test set. As the Bi-LSTM model performs close to random, we claim that improvements from stronger baselines should be attributed to the models and not annotation biases that they can exploit. Among the baseline models, the UnifiedQA-3B achieves the best performance on both the standard and pairwise metric. Note that the number of learnable parameters in UnifiedQA-3B is much larger than those in the second and third best models, which are DeBERTa-large (390M) and UnifiedQA-large (770M). Our Com2Sense benchmark remains quite challenging, as there are significant gaps between the model and the human performances.

Dataset comparisons: In order to contrast the difficulty of Com2Sense with other related benchmarks, we report the performances of two well performing models on the following: CommonsenseQA (CQA) (Talmor et al., 2019b), SWAG (Zellers et al., 2018), SocialIQA (Sap et al., 2019), PhysicalIQA (PIQA) (Bisk et al., 2020) and WinoGrande (Sakaguchi et al., 2020).

The results in Table 5 indicate that models clearly struggle more to perform well on Com2Sense than other datasets.

Performance across domains and scenarios: In Figure 5 we present the in-depth breakdown results for T5-large and DeBERTa-large across combinations of domain, scenario and numeracy. We observe that models consistently perform worse in categories involving numeracy, highlighting the limitations of current language models. For physical domain, both models perform worse in causal than in comparative scenario. We hypothesize that while the models may possess the required physi-

Setting	Test	Dev
Multiple-Choice	70.63	77.61
Standard (T/F)	63.53	66.29

Table 6: Performance (accuracy) of DeBERTa-large on the MC formulation of our dataset compared to the standard true/false setting. The model performs relatively worse on the latter.

	Model$_{\text{metric}}$			
Train set	DeBERTa$_{\text{std}}$	T5$_{\text{std}}$	DeBERTa$_{\text{pair}}$	T5$_{\text{pair}}$
20%	63.92	60.65	41.51	34.29
40%	67.74	62.60	48.04	38.11
60%	68.46	63.96	48.47	40.66

Table 7: Performance across different training set sizes (20% / 40% / 60% of the entire dataset) for DeBERTa-large and T5-large. `"std"` and `"pair"` stand for standard and pairwise accuracy correspondingly.

cal knowledge, they fail to generalize to a logical reasoning over known facts or grasp the implicit changes of physical properties, which is generally unseen in the pretraining corpora for NLP models. Opposite trends are observed in both social and temporal domains, where similar hypothesis can be made that causal statements are more frequent patterns in the corpora when social activities or senses of time are the subjects. Furthermore since model feedback was part of our dataset construction, we also report the category-wise difficulty in fooling the model (number of trials) during sample creation in Section A.4 for a reference.

True/False versus multiple choice setup: We further conduct an experiment with DeBERTa-large model on the same data splits with the input formulated as an **MC task** in Table 6. Under this setting, the model is provided with the sentence pair and is required to select the true sentence among the two choices, for the response to be correct. The performance is significantly higher compared to both standard (>7%) and pairwise accuracy (>25%) presented in Table 4. This result supports our intuition that it is easier for models to exploit spurious correlations in the surface patterns under the *multiple choice* question answering setup.

4.2 Analysis

The Effect of Training Data Size: To study the effect of training size on model performance, we design an experiment by varying the sample size in the training set, with fixed dev (10%) and test (30%) sets to **ensure consistency** in evaluation. We consider DeBERTa-large and T5-large models for this ablation study, and report our findings in Table 7. The results indicate a plateau in performance with increase in training samples.

Setting	Standard	Pairwise
Train-C$_{\text{exclude}}$	56.52	19.00
Train-C$_{\text{include}}$	63.54	40.49

Table 8: Test set performance of DeBERTa-large on two different setups with respect to the complementary pairs. Both setups have the same training set size, but in Train-C$_{\text{exclude}}$ only one sentence of each pair is present in the training set, while in Train-C$_{\text{include}}$ both samples in a pair are included. The results indicate the effectiveness of training the models with our formulated complementary pairs.

Role of Complementary Pairs: In previous experiments, we measure the model generalizations by distributing data samples into train and evaluation sets **by complementary pair**. This ensures the similarly constructed sentences within the same pair is not *leaked* into different data splits, and thus an "inter-pair" generalization is measured. To investigate the effectiveness of our complementary pair formulation on training models to acquire commonsense reasoning ability, we first sample a subset with identical size (20% data, 800 pairs) to that of the original train set, and then construct the following two variants (using the same subset):

- **Train-C$_{\text{exclude}}$:** One of the complementary samples (in each pair) is *excluded*, *i.e.* no two samples belong to the same pair in this train set. It comprises 800 samples from 800 pairs, with balanced true/false labels.
- **Train-C$_{\text{include}}$:** We retain half of the data samples where both sentences from a pair are *included*, which leads to 800 samples from 400 pairs in this train set.

The remaining samples from the dataset (without the excluded ones in the two settings) are then split into dev (10%) and test (70%) sets. We compare the performance of DeBERTa-large in the above two different settings in Table 8. The results show a significant decrease in performance when complementary sentences are not provided. We hypothesize that the worse performances are due to the models' tendency to pick up surface patterns and memorize the labels in the training set without really understanding the scenario. Also, model

Train	Evaluate			
	Causal$_{\text{std}}$	Comp.$_{\text{std}}$	Causal$_{\text{pair}}$	Comp.$_{\text{pair}}$
Causal	**63.64**	59.36	**35.46**	28.25
Comp.	58.47	**64.50**	26.43	**43.86**

Table 9: Performance of DeBERTa-large trained on X and evaluated on Y, where X and Y are partitions created as per a reasoning scenario *(causal, comparative)*.

generalization benefits from having complementary samples within the training set.

Cross-Scenario Generalizability: Given that knowledge domain and numeracy attributes of our dataset are intuitively distinct, we intend to quantitatively investigate if the same holds for reasoning scenarios. Our "cross-scenario" experiments with DeBERTa-large, *i.e.* trained on *causal*, evaluated on *comparative* and vice versa, indicate a poor generalization across both standard and pairwise accuracy metrics (see Table 9), underscoring the significance of having reasoning types.

5 Related Works

Commonsense Resources: As commonsense is a crucial component to the actualization of AI, there has been a surge in creating relevant benchmarks, notable ones include evaluating machines' commonsense abilities in the format of pronoun resolution (Levesque et al., 2012; Sakaguchi et al., 2020), multiple choice (Zellers et al., 2018; Talmor et al., 2019a), natural language generations (Lin et al., 2020b), story understanding (Mostafazadeh et al., 2016), and reading comprehensions (Zhang et al., 2018; Huang et al., 2019; Ning et al., 2020). Our work puts forth to create a commonsense benchmark in the format of true/false complementary pairs, where a more robust pairwise accuracy is adopted. Note that although natural language inference (NLI) can be tasked similarly to the true/false formulation, the existing commonsense NLI benchmark either is not crowdsourced with high quality (Zhang et al., 2017), or still resorts to a multiple choice setting (Bhagavatula et al., 2020). There are also benchmarks that specifically concern a type of commonsense knowledge, such as physical (Bisk et al., 2020) and social (Sap et al., 2019) intelligence, as well as temporal understanding (Zhou et al., 2019). The ability to understand and induce numerical knowledge in texts has been studied in several recent works (Dua et al., 2019; Ravichander et al., 2019), including numerical commonsense (Lin et al., 2020a). Our work differs to these works in the focus on less factual and arithmetic-precise numerical knowledge, but more on the intuitive sense of numbers, in conjunction with our defined knowledge domains and the scenarios.

It is worth noting that some prior works (Wu et al., 2017; Clark et al., 2019) also investigate the effectiveness in the binary true/false (yes/no) formulation to construct a question answering dataset, while COM2SENSE is the first to focus on commonsense reasoning.

Dataset Biases: It is a widely perceived issue that spurious statistical patterns in datasets can often be exploited by machine learning models, which can potentially lead to overoptimistic judgements on the model improvements. Particularly in NLP domain, prior works have shown that hypothesis-only baselines or syntactic heuristics perform surprisingly well in the NLI task (Gururangan et al., 2018; Glockner et al., 2018; Tsuchiya, 2018; Poliak et al., 2018; McCoy et al., 2019). Model exploiting biases or failing on simple adversarial patterns, can also be seen in sentence classification (Wieting and Kiela, 2019) and question answering (Jia and Liang, 2017; Kaushik and Lipton, 2018; Geva et al., 2019) tasks. We put forth to reduce the potential sentence-level biases by requiring the models to perform equally well on both directions in a complementary true/false pair.

Adversarial Data Collection: Removing representation biases in a dataset by adversarially filtering undesired data samples, has been frequently practiced to collect datasets more challenging to the models. Recent work *AFLite* (Sakaguchi et al., 2020; Le Bras et al., 2020), built upon the adversarial filtering (AF) method in (Zellers et al., 2018, 2019), adopted an iteratively improving model-in-the-loop approach to collect challenging commonsense benchmarks (Sakaguchi et al., 2020; Bisk et al., 2020). *Gamified* (Yang et al., 2018) or interactive (Wallace et al., 2019) approaches leverage human-in-the-loop to increase the difficulty of datasets and hence more robust model training. Counterfactual editing of data samples with human annotators (Kaushik et al., 2020; Gardner et al., 2020) is also closely related to our complementary pair construction that seeks to *invert* the model predictions for a more reliable evaluation.

Recently, several works have attempted to exploit the merits in involving both models and humans in the data creation cycle, *i.e.* human-and-model-in-the-loop, to construct data samples that are both *new* and challenging to the models (Chen et al., 2019; Nie et al., 2020; Bartolo et al., 2020). To our best knowledge, we are the first to employ such an approach in constructing commonsense reasoning benchmark, specifically, our complementary pair formulation makes it more sophisticated as the annotators are required to not only *fool* the model but also pay attention to the salient concepts of their creations in both directions.

6 Conclusion

We present a new challenging commonsense reasoning benchmark, COM2SENSE, developed via an adversarial *gamified* model-in-the-loop approach. COM2SENSE comprises 4k *manually created* complementary true/false statement pairs, designed along three dimensions: knowledge domain, reasoning scenario, and numeracy. We propose a robust pairwise metric to evaluate models' commonsense reasoning ability based on the complementary pair formulation, and benchmark the dataset with several state-of-the-art NLP models, highlighting significant gaps well below human performances ($>$ 45% gap).

On top of providing a new commonsense reasoning benchmark, we demonstrate studies on transferrability among defined commonsense aspects, with an objective to spur future research on a more systematic probing of models' grasp of commonsense. As a potential future work drawn from these insights, we hope to inspire future model developments, specifically in two directions: 1) the ability to reason over known facts (*i.e*. reasoning scenario), and 2) acquiring the implicit knowledge that is commonsensible to humans (*i.e*. knowledge domain). Furthermore, we hope our investigation in the formulations of question answering task (*i.e*. MC setting versus our true/false complementary setting) can shed light on future explorations in identifying potential artifacts in NLP datasets.

7 Acknowledgements

We thank the anonymous reviewers for their feedback, and all the workers who have participated in the dataset creation on Amazon Mechanical Turk. We give special thanks to Peifeng Wang, Xiangci Li, and Gleb Satyukov for their great help in the early stage of annotation pipeline construction as well as providing valuable feedback in composing the guidline instructions. This work is supported by the Machine Common Sense (MCS) program under Cooperative Agreement N66001-19-2-4032 with the US Defense Advanced Research Projects Agency (DARPA). The views and the conclusions of this paper are those of the authors and do not reflect the official policy or position of DARPA.

8 Ethics and Broader Impacts

We hereby acknowledge that all of the co-authors of this work are aware of the provided *ACM Code of Ethics* and honor the code of conduct. This work is mainly about the creation of a challenging commonsense benchmark dataset. The followings give the aspects of both our ethical considerations and our potential impacts to the community.

Dataset We collect an English dataset of commonsense complementary sentence pairs via Amazon Mechanical Turk (MTurk) and ensure that all the personal information of the workers involved (e.g., usernames, emails, urls, demographic information, etc.) is discarded in our dataset. This research has been reviewed by the **IRB board** and granted the status of an **IRB exempt**. The detailed annotation process (pay per amount of work, guidelines) is included in the appendix; and overall, we ensure our pay per task is above the the annotator's local minimum wage (~$12 USD/HR). Although commonsense can vary from different demographic areas, we primarily consider English speaking regions for the first round, and include more annotators from non English-spoken countries to diversify the dataset. Future work can include collecting a more diverse dataset across more demographics regions to incorporate more regional-dependent commonsense, while using some post editing to ensure English proficiency of the constructed data.

Techniques We benchmark the created dataset with the state-of-the-art large-scale pretrained language models, with minimum adaptation to the formulation of this dataset (*i.e*. true/false formulation). As commonsense is of our main focus, we do not anticipate production of harmful outputs, especially towards vulnerable populations, after training NLP models on our dataset.

A Additional Details of COM2SENSE

A.1 Collection with MTurk

Qualification Quiz To familiarize the workers with our collection task, we design a quiz with the following types of questions: 1) examine if a given statement can be correctly judged with only commonsense or it requires specialized knowledge, 2) infer the true/false label of a given statement, and 3) select the most suitable domain and scenario where a given statement belongs to.

Human Intelligence Tasks (HITs) The general instructions of our HIT page include: **Task Overview**, **Task Payment** and **Overall Task Procedure** for each category, to engage more workers. At the end of the HIT instruction page, a link is provided to redirect the workers to the data creation page, where more detailed instructions and useful resources for the creation tasks are provided. Besides passing our qualification quiz, the workers are also required to have a *HIT Approval Rate* greater than 98% and the *Number of HITs Approved* greater than 5000. In each HIT assignment, workers are required to submit three complementary pairs. In the first phase of data collection, the base pay is \$0.6 for each assignment and workers will receive a \$0.5 bonus per sentence if it follows our instructions and fools the model; for the second phase, the base payment for each assignment is \$0.3 but we change the bonus to: \$0.5 (for either high-quality sentence or successful fooling) or \$0.9 (if both requirements are met, similar to those for the \$0.5 bonus in the first phase) to encourage workers to create higher quality data.

A.2 Details of the Creation

Tool Interface Screenshots of our creation interface are as shown in Figure 6 and Figure 7. We name our deployed model (RoBERTa-large) *Carl* to help emphasize the interactive and gamified creation set-up.

Guidelines To inspire workers and collect from more diverse topics of commonsense, we further provide: 1) some hints for having higher chances fooling the model, such as exploiting contradictory physical concepts, negations, swapping entities, etc., 2) topics pertinent to the domains, and (3) examples of low quality along with their reasons.

A.3 Details of Validation

To ensure data quality, our internal members have helped checking each pair with the validation tool we implement. For each pair received from the workers, both labels for the statements and their intended domains and scenarios are carefully verified. For statements which are ambiguous even for humans, if they can be easily fixed by adding more context or better word choices, another round of editing is conducted.

A.4 Adversarial Setting

The total number of collected complementary pairs is around 4.8k, where around .8k are discarded for not having sufficiently high quality, *e.g.* "*Frank traded a stock an hour late and lost 80 million dollars.*" and "*Frank traded a stock a second late and lost 80 million dollars.*" Among all the data we collected, the overall fooling rate is 48.55% per sentence and 78.7% per pair. For category-specific fooling rates, please refer to Figure 10.

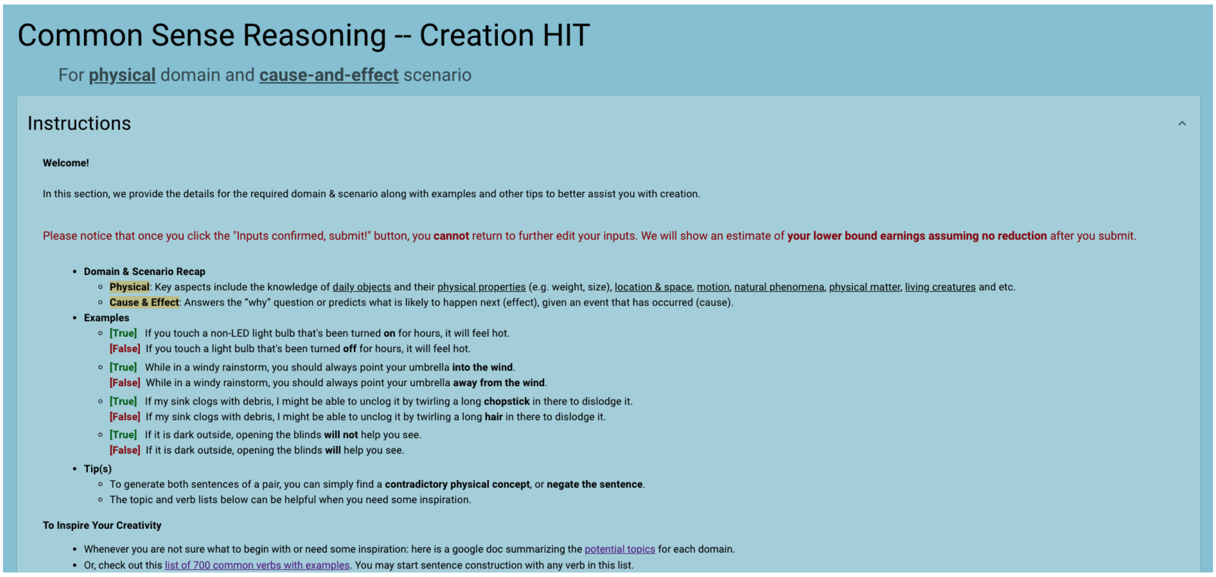
For sentences that successfully fool the model, we report the mean time of fooling one sentence to be 3.40, the standard deviation (std) as 2.48, and the median as 2.57 (all in minutes). Please notice that the total time is directly retrieved from MTurk and is likely to be overestimated due to worker inactivity. The mean of the number of revisions per fooling sentence is 1.36 with a std as 3.95, and a median as 0 (fooling without re-attempts, requiring no revision). Noticeably, 63% of the fooling sentences are submitted with no revision.

For any potential interests, Figure 8 shows the mean and median of required time of fooling per sentence across categories, and similarly Figure 9 for the mean and median of the number of attempts which equals to the number of revisions $+1$.

Figure 11 shows the distribution of ratings during the exit survey from a total of 699 valid responses. The survey questions include: 1) how helpful is our instruction? and 2): how challenging is our task? For question 1, the mean rating is 4.66 ± 0.59 and median is 5; for question 2, the mean rating is 4.23 ± 0.92 and the median is 4, where 1-5 is from low-to-high rating.

A.5 Statistics of Workers

173 workers participated in our task, and Figure 12 shows the worker counts for the different numbers of assignments attempted by each of the workers, and Figure 13 shows the worker counts for the time



Common Sense Reasoning -- Creation HIT

For **physical** domain and **cause-and-effect** scenario

Instructions

Welcome!

In this section, we provide the details for the required domain & scenario along with examples and other tips to better assist you with creation.

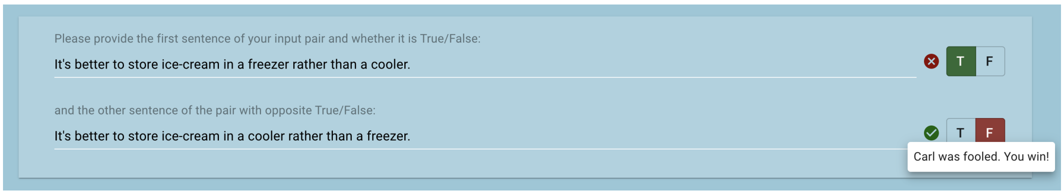
Please notice that once you click the "Inputs confirmed, submit!" button, you **cannot** return to further edit your inputs. We will show an estimate of **your lower bound earnings assuming no reduction** after you submit.

- **Domain & Scenario Recap**
  - **Physical**: Key aspects include the knowledge of daily objects and their physical properties (e.g. weight, size), location & space, motion, natural phenomena, physical matter, living creatures and etc.
  - **Cause & Effect**: Answers the "why" question or predicts what is likely to happen next (effect), given an event that has occurred (cause).
- **Examples**
  - **[True]** If you touch a non-LED light bulb that's been turned **on** for hours, it will feel hot.
    [False] If you touch a light bulb that's been turned **off** for hours, it will feel hot.
  - **[True]** While in a windy rainstorm, you should always point your umbrella **into the wind**.
    [False] While in a windy rainstorm, you should always point your umbrella **away from the wind**.
  - **[True]** If my sink clogs with debris, I might be able to unclog it by twirling a long **chopstick** in there to dislodge it.
    [False] If my sink clogs with debris, I might be able to unclog it by twirling a long **hair** in there to dislodge it.
  - **[True]** If it is dark outside, opening the blinds **will not** help you see.
    [False] If it is dark outside, opening the blinds **will** help you see.
- **Tip(s)**
  - To generate both sentences of a pair, you can simply find a **contradictory physical concept**, or **negate the sentence**.
  - The topic and verb lists below can be helpful when you need some inspiration.

To Inspire Your Creativity

- Whenever you are not sure what to begin with or need some inspiration: here is a google doc summarizing the potential topics for each domain.
- Or, check out this list of 700 common verbs with examples. You may start sentence construction with any verb in this list.

Figure 6: Screenshot of the creation interface (instruction section).



Please provide the first sentence of your input pair and whether it is True/False:

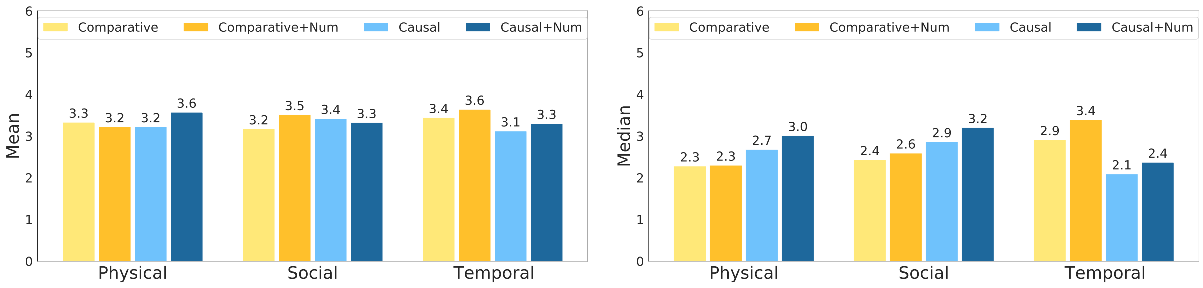
It's better to store ice-cream in a freezer rather than a cooler.

and the other sentence of the pair with opposite True/False:

It's better to store ice-cream in a cooler rather than a freezer.

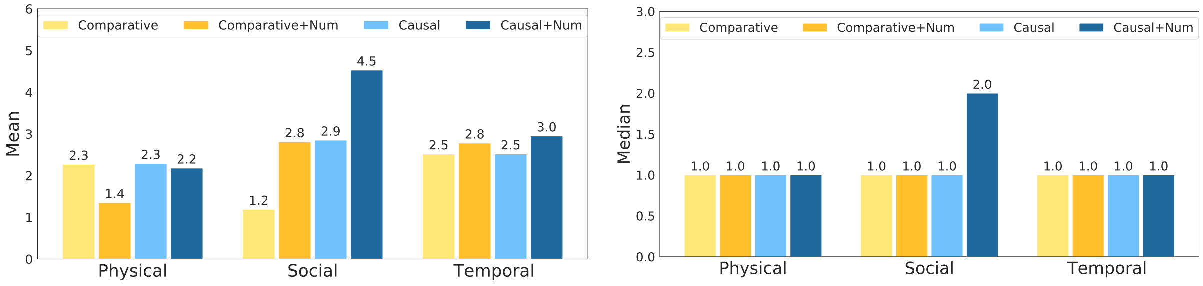
Carl was fooled. You win!

Figure 7: Screenshot of the creation interface (1/3 input section).



(a) Mean (b) Median

Figure 8: Mean and median of the time needed (in minutes) to fool a sentence for all categories, "`+Num`" denotes numeracy involved.



(a) Mean (b) Median

Figure 9: Number of attempts (*i.e.* # revisions + 1) per sentence for all categories, "`+Num`" denotes numeracy involved.

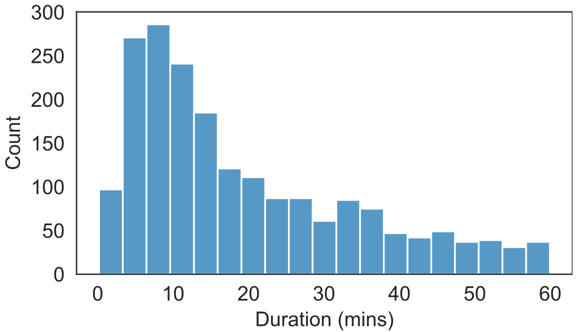

Figure 13: Worker counts over different assignment duration (in minutes).

(duration, in minutes) each worker spent on one assignment.

B Additional Details on Baseline Models

We include several essential implementation details of the benchmark models in the following:

Bi-LSTM+GloVe Our Bi-LSTM model (Hochreiter and Schmidhuber, 1997) is one-layered with a 512-dimensional hidden layer, which takes input word embeddings from 300-dimensional GloVe word embeddings (Pennington et al., 2014). We train all LSTM layers from scratch.

BERT-base Models For BERT-style architectures we employ a multi-layer-perceptron (MLP) on top of the [CLS] special token for binary prediction.

T5-large To adopt T5-large's text-to-text format to our dataset, we use the prefix *com2sense sentence:* and the labels *True* and *False* as model output.

UnifiedQA Models We use two UnifiedQA Models. One with the T5-large backbone and one with the T5-3b backbone. For these models, we use *Is the following sentence correct?* as the prefix, to create a question. Then as the answer we use *Yes* / *No*.

C More Details on the Experiments

C.1 Hyperparameters

All the essential hyperparameters used throughout this work can be referred to in Table 10. We also include the search bounds as well as the number of trials in searching for our manually-tuned hyperparameter search procedures in Table 10.

Model	# Params	Batch-Size	LR	Training Iterations	Gradient Accumulation Steps	Max. Token Length
BiLSTM+GloVe	3.5M	64	1×10^{-5}	100	4	80
BERT-base	109.5M	64	1×10^{-5}	100	4	80
RoBERTa-large	355.4M	32	1×10^{-5}	100	4	80
DeBERTa-large	405.2M	32	1×10^{-5}	100	4	80
T5-large	737.5M	8	1×10^{-5}	100	4	80
UnifiedQA-t5-large	737.5M	8	1×10^{-5}	100	4	80
UnifiedQA-t5-3b	3000M	2	1×10^{-5}	100	8	64
Bound (lower-upper)		1-64	5×10^{-5}–1×10^{-6}	10-100	1-10	
Number of trials		2-3	2-3	2-3	2-3	

Table 10: Hyperparameters used for each model during finetuning on COM2SENSE along with the search bounds for them: *LR* denotes the learning rate that does not change during the training process. All the models are trained with Adam optimizers (Kingma and Ba, 2015). We include number of parameters of each model in the first column, denoted as *# params*.

C.2 Validation Set Results

We validate all trained models on a 402-pair validation set and tune the hyperparameters accordingly. The performances on the validation set are reported in Table 11.

Model	Standard	Pairwise
Random	50.00	25.00
BiLSTM+GloVe	52.80	27.50
BERT-base	57.07	23.11
RoBERTa-large	62.81	38.30
T5-large	62.81	35.82
UnifiedQA-large	63.43	37.31
DeBERTa-large	66.29	43.03
UnifiedQA-3b	**75.12**	**56.22**

Table 11: Validation-set accuracy for selected models, trained and evaluated on respective datasets.

C.3 Performance Across Input Lengths

Although the sentence length in our dataset varies, we find no obvious relation between the length of the sentences and the difficulty for the model to comprehend, in terms of accuracy. As depicted in Figure 14, we therefore conclude that sentence length would not have significant influence on fooling models including DeBERTa-large.

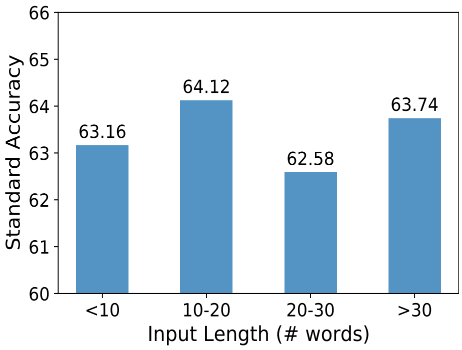

Figure 14: Standard accuracy of the DeBERTa-large model measured on subsets of data with different input lengths.

C.4 Software, Hardware, & Other Details

Transformer-based models are implemented via the HuggingFace PyTorch API (Wolf et al., 2020). All the benchmarked models, except for UnifiedQA-T5-3b are trained on Nvidia GeForce 2080Ti GPUs[5] on a CentOS 7 operating system. The UnifiedQA-T5-3b is trained on NVIDIA Tesla V100 GPUs [6] on an Ubuntu 18 operating system. The T5-large and UnifiedQA-T5-large are trained using the model parallelism approach on two GPUs. The UnifiedQA-T5-3b is trained using model parallelism on 8 GPUS.

The maximum training time is approximately 6 hours for all the models, with the BERT-style models on the lower end of the range and the T5-style models on the higher end.

[2]University of Trento, Italy

`ychung@fbk.eu, tekiroglu@fbk.eu, guerini@fbk.eu`

Abstract

Tackling online hatred using informed textual responses – called counter narratives – has been brought under the spotlight recently. Accordingly, a research line has emerged to automatically generate counter narratives in order to facilitate the direct intervention in the hate discussion and to prevent hate content from further spreading. Still, current neural approaches tend to produce generic/repetitive responses and lack grounded and up-to-date evidence such as facts, statistics, or examples. Moreover, these models can create plausible but not necessarily true arguments. In this paper we present the first complete knowledge-bound counter narrative generation pipeline, grounded in an external knowledge repository that can provide more informative content to fight online hatred. Together with our approach, we present a series of experiments that show its feasibility to produce suitable and informative counter narratives in in-domain and cross-domain settings.

1 Introduction

Standard approaches for online hate mitigation generally rely on content moderation, ranging from deletion of hate content and suspension of user accounts to shadow banning. However, these approaches may draw limits on free speech and diverse opinions. An alternative approach is to directly intervene in the conversation with counter narratives. A Counter Narrative (`CN`) is a non-negative response to a Hate Speech (`HS`), targeting and contradicting extreme statements with fact-bound arguments or alternative viewpoints (Benesch, 2014; Schieb and Preuss, 2016). Such strategy seeks to de-escalate the conversation, disengage from hateful sentiment and encourage mutual understanding through exchange of opinions. Many Non-Governmental Organizations (NGOs) specialized in hate countering are already adopting this approach by training operators to compose counter narratives. According to NGO guidelines[1], proper `CN`s should also include credible evidence.

HS: *The world would be a better place without Muslims. They are only killing and raping our children.*
CN1: *Evidence for this? This is not true. How can you say this about an entire faith?*
CN2: *On the contrary, most children abuse is operated by people they know: a relative, family friends, sports coach, someone in a position of trust and authority. Besides, Muslims help people - A Muslim woman rushed to help the victims of a triple stabbing in Manchester on New Year's Eve.*
CN3: *You are truly one stupid backwards thinking idiot to comment on Muslims like that.*

Table 1: An example hate speech with appropriate counter narratives (`CN1` and `CN2`) and an inappropriate one (`CN3`) containing abusive language.

In Table 1, we present an `HS` along with several `CN`s. Although `CN1` and `CN2` are both appropriate responses, not all appropriate `CN`s are equally effective (Silverman et al., 2016; Tuck and Silverman, 2016). `CN2` is expected to be more effective as it is tailored to the `HS` and demonstrates contextualized and persuasive statements with supporting facts, knowledge, and logical reasoning (Habernal and Gurevych, 2016) rather than a simple generic request for evidence as in `CN1`. Conversely, `CN3` is considered as a natural but inappropriate and aggressive response.

In this context, scaling manual response to massive amounts of online hatred is an undeniably challenging task for NGO operators. Recently, studies have started to focus on data and strategies for the automatic generation of counter narratives in an end-to-end fashion (Chung et al., 2019; Qian et al., 2019; Tekiroğlu et al., 2020; Chung et al., 2020). However, the seminal studies, based on training

---

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 899–914
August 1–6, 2021. ©2021 Association for Computational Linguistics

models using only the `HS`-`CN` data samples, do not directly address the required properties for proper and effective `CN`s such as providing credible evidence and knowledge with facts, statistics or examples. While such models possess knowledge to a certain extent through utilizing existing generative language models (LMs) such as GPT-2 (Radford et al., 2019), this knowledge (e.g., events or news) will get out-dated over time. Furthermore, such models are able to create plausible but not necessarily true arguments - a problem known as content hallucination - (Zellers et al., 2019; Solaiman et al., 2019). A hallucinated example of a fact-bound `CN`, generated by GPT-2 model fine-tuned as done by Tekiroğlu et al. (2020), is provided in Table 2. Therefore, in this paper we investigate the generation of knowledge-bound counter narratives, which had never been studied yet to the best of our knowledge. We hypothesized that knowledge infusion can not only leverage generating informative `CN`s but also handling hate speech from unseen domains (i.e. hate targets) without further training (e.g., train on Islamophobia and test on Antisemitism).

HS: *Muslims are invading our country*
CN: *Actually, there were 16,938,000 Muslims in the UK in 2016, so if you exclude London, that is actually increasing by 2%, which doesn't seem very significant.*

Table 2: Hallucinated `CN` generated by GPT-2 that is fluent and credible (according to Office for National Statistics, the Muslim population is just above 3M).

To this end, we explore methodologies to generate informative `CN`s using external knowledge. In particular, we propose an extension of knowledge-grounded generation approaches by adopting an intermediate step where we generate keyphrases for retrieving needed knowledge. So, we first train a counter narrative keyphrase generator, then the generated keyphrases are employed for selecting relevant knowledge sentences. Finally, pre-trained LMs are fine-tuned on the relevant knowledge sentences, together with the `HS` input, to produce knowledge-augmented `CN`s. Our extensive experiments on `CN` generation, including both automatic and expert evaluation, demonstrate that the presented approach produces more specific and tailored responses both for in-domain and zero-shot cross-domain configurations as compared to other approaches, such as standard LMs, that are simply fine-tuned for the task without the use of external knowledge.

As our main contribution, we show that: (i) external knowledge can boost informative `CN` generation, (ii) keyphrase generation improves the quality of retrieved documents, (iii) silver knowledge is utilizable for the task when no gold knowledge is available, (iv) knowledge-bound models are advantageous while tackling zero-shot cross-domain generation especially if (v) using injection of knowledge in large pre-trained LMs.

2 Related Work

In this section we review three main research topics that are relevant for fighting hatred online: (i) studies on `CN` effectiveness in hate countering, (ii) counter-argument generation and (iii) knowledge-guided generation.

Hate countering. Employing counter narratives has shown to be an effective strategy in hatred intervention on social media platforms. Studies have focused on identifying successful counter narratives (Benesch et al., 2016a,b), evaluating their efficacy (Schieb and Preuss, 2016; Silverman et al., 2016; Ernst et al., 2017; Munger, 2017), and analyzing counter speaker accounts characteristics (Mathew et al., 2018). In particular, by analyzing conversations from Twitter, Wright et al. (2017) show that some arguments among strangers induce favorable changes in discourse and attitudes.

Counter-argument generation shares similar objectives as `CN` generation, i.e., to produce the opposite or alternate stance of a statement, but the latter faces peculiar difficulties such as the absence in `HS` of explicit or well-structured 'arguments' (e.g., "*Islam is a disease*") and the limited amount of data available for training. Studies usually focus on domains with large discussions, e.g., politics (Hua and Wang, 2018) and economy (Le et al., 2018). The closest work to ours is counter-argument generation with external knowledge augmentation by Hua et al. (2019). Our approach differs from theirs in three aspects: (i) we explore generating queries to extract knowledge for grounding `CN` with, (ii) pre-trained generative models are utilized for leveraging the knowledge present, (iii) our approach requires less manipulation over knowledge.

Knowledge-guided generation. There is a growing interest in exploiting external knowledge to generate informative responses for applications such as dialog systems (He et al., 2017; Young et al., 2018) and question answering (Das et al., 2017; Saha et al., 2019). Previous approaches inject knowledge through topic phrases (Fan et al., 2019), structured knowledge graphs (Zhou et al., 2018) and unstructured texts (Dinan et al., 2019; Hua et al., 2019).

3 HS-CN Dataset

To the best of our knowledge, there is no high-quality hate speech - counter narrative dataset available yet where `CN`s are explicitly paired with relevant knowledge. Since constructing such dataset with a decent-size would be too costly and out of the scope of the present paper[2], we resort to a "reverse-engineering" strategy such that we automatically paired relevant knowledge with an already existing high quality `CN` dataset. We chose `CONAN` (Chung et al., 2019), which is a dataset niche-sourced to expert NGO operators offering high quality `CN`s, and the best and most diverse material among the other `CN` datasets (Tekiroğlu et al., 2020). `CONAN` consists of 6645 English pairs of `HS-CN` including: 1288 original pairs, 2576 pairs where two paraphrases of the original `HS` are paired with the original `CN`, and 2781 translated pairs from French and Italian. The English data is split into 4069/1288/1288 samples for train/dev/test.

4 Architecture

Our architecture, illustrated in Figure 1, consists of a knowledge retrieval module that retrieves sentence-level relevant knowledge, and a generation module that generates a counter narrative. Specifically, the knowledge retrieval module first prepares variants of a query Q for a given hate speech `HS` using two strategies: query extraction (Q_{hs}) and automatic query generation (Q_{gen}). Then, the obtained queries are employed to search for relevant knowledge articles via a search engine. Finally, it uses a sentence selector to filter and rank the most relevant sentences as the relevant knowledge (`KN`) from the retrieved articles. For the counter narrative generation module, we fine-tuned several LMs that take a `HS` and the ranked knowledge sentences `KN` as input and output a corresponding counter narrative.

5 Knowledge Retrieval Module

The knowledge retrieval module in the architecture incorporates a knowledge repository, query construction sub-module, and a knowledge sentence selection sub-module.

5.1 Knowledge Repository

Previous approaches on introducing external knowledge for dialog generation have exploited unstructured and structured knowledge. Since no structured knowledge is available for the hate speech domain, we rely on unstructured textual knowledge in the format of articles, which allows for updating the knowledge repository easily. Considering that the proliferation of `HS` is also triggered with target-related events (e.g., terrorist attacks), being able to update the knowledge, such as news articles, would let us produce proper `CN`s that contain the latest statistics or evidence from the current events.

We include `Newsroom` (Grusky et al., 2018) and `WikiText-103` (Merity et al., 2017) to our knowledge repository. `WikiText-103` is a large collection of 28,595 full Wikipedia articles covering over 103 million words. `Newsroom` consists of 1.3 million articles extracted from major news publications between 1998 and 2017, featuring over 6.9 million words.

5.2 Query Construction

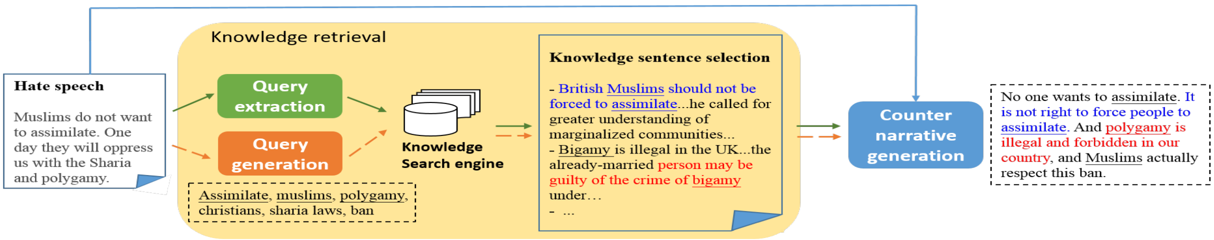
To construct comprehensive and proper queries to search for relevant knowledge for the data pairs, we applied two strategies: (i) query extraction and (ii) query generation. In both strategies, the query is composed of keyphrases that can be defined as the important and topical phrases from a text (Turney, 2000).

Query extraction. We extracted keyphrases from `CONAN` dataset using Keyphrase Digger (Moretti et al., 2015), a multilingual keyphrase extraction system that uses statistical measures and linguistic information, and is proven to be one of the best systems for unsupervised settings[3]. Following the knowledge retrieval strategy using input argument by Hua et al. (2019) for counter argument generation, we first obtained the `HS` keyphrases to construct the initial query Q_{hs}. However, `HS`s from `CONAN` mostly contain hateful and simplistic

---

[2] Obtaining access to a pool of trained NGO operators is very complicated, furthermore keeping track of their search activity and the material they used during `CN` production would require long and complex data collection sessions that might span several months.

[3] Keyphrase Digger is a new implementation of KX (Pianta and Tonelli, 2010) with several improvements, and it was ranked the best performing unsupervised system on task 5 of SemEval 2010 evaluation campaign (Moretti et al., 2015).



Muslims do not want to assimilate. One day they will oppress us with the Sharia and polygamy.

Assimilate, muslims, polygamy, christians, sharia laws, ban

- British Muslims should not be forced to assimilate...he called for greater understanding of marginalized communities...
- Bigamy is illegal in the UK...the already-married person may be guilty of the crime of bigamy under…
- ...

No one wants to assimilate. It is not right to force people to assimilate. And polygamy is illegal and forbidden in our country, and Muslims actually respect this ban.

Figure 1: Architecture of knowledge grounded generation with extracted (green solid arrow) and generative (dotted arrow) queries (topical phrases) that are exploited to retrieve relevant knowledge. The knowledge sentences extracted together with input HS are fed to CN generation. We give the example of generative approach.

phrases in comparison to the input arguments used by Hua et al. (2019) that can be rich in content[4]. Therefore, in the HS-CN scenario, we hypothesize that the keyphrases from Q_{hs} alone would not be sufficient for relevant knowledge search especially for mapping the knowledge onto training data.

To this end, we also extracted keyphrases from CN together with HS to increase the possibility that the retrieved knowledge sentences contain pieces of information found in the ground truth. Hence, the second query $Q_{hs\cup cn}$ contains CN keyphrases for the relevancy to the target CN and HS keyphrases for preserving the hate context. We investigated the effects of various keyphrase query configurations in terms of HS relevancy and $Q_{hs\cup cn}$ is proven to be the best configuration (See Appendix A.1 for more details.).

Query generation. Since the best query configuration $Q_{hs\cup cn}$ cannot be available at test time, we need a way to obtain keyphrases that serve as CN cues for searching knowledge sentences during the CN generation. To this end, we built a query generation model that takes HS as input and outputs a comma-separated list of CN keyphrases, which is then used as Q_{gen}. Our aim is to obtain an approximation of $Q_{hs\cup cn}$ via $Q_{hs\cup gen}$ at the test time.

The model is trained using Transformer (Vaswani et al., 2017) architecture as it has obtained state-of-the-art performances for generation tasks (Dinan et al., 2019; Ghazvininejad et al., 2018). For the training data, we used CONAN dataset and discarded the CNs that are less than 10 words, since they are usually generic, poor in terms of argumentative content and cannot provide a meaningful search (e.g., "*No they are not - prove this?*", "*What does that even mean?*", "*Any evidence?*"). Accordingly, we kept 4038/1257/1257 instances for train/dev/test set. The train set includes the pairs marked as original in the dataset, and all translated pairs from French and Italian; the dev set consists of one paraphrase of each original HS and its CNs; and the test set contains the rest of the paraphrased HSs. The training inputs are represented as HS $[HS\_end\_token]$ KP $[KP\_end\_token]$, where KP is the list of keyphrases extracted from the gold CN.

The model has been trained following the configuration of the base model in (Vaswani et al., 2017): with 6 transformer layers, 8 transformer heads, embedding size of 512, hidden size of 2048, dropout rate of 0.1, batch size of 64 for 100 epochs. The training time lasted around 7 hours. All experiments in this paper have been conducted on a Nvidia Tesla V100 GPU. For decoding, we used nucleus sampling (Holtzman et al., 2020) with a p value of 0.9.

We report keyphrase generation results in terms of BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) against the keyphrases extracted from gold test CNs. We obtained a score of 0.162 for BLEU-2 and a score of 0.353 for ROUGE-L. Although both scores can be considered as low, this is due to the open ended nature of the set of possible CN keyphrases for a given HS. Example queries for a single pair, extracted from its HS, its CN, and generated with the keyphrase generation model are shown in Table 3.

5.3 Knowledge Sentence Selection

We use Solr[5] to index the articles and retrieve those relevant to a given query based on the similarity between the articles and the query using BM25 (Robertson et al., 1995). Once the queries have been obtained either through extraction or generation, they are presented to Solr for retrieving

---

[4] e.g., an argument "*A universal basic income will help the labor market adapt to inevitable disruptions caused by advancements in automation and artificial intelligence.*" vs. HS "*Islam is a disease*".

[5] https://lucene.apache.org/solr/

HS	CN	Query	Knowledge sentences (KN)
Islam is a disease.	Like Christianity or any other, islam is a religion of tolerance. Disease does not discriminate on religious grounds.	Q_{hs}: islam, disease	(i) Do Muslims want to heal from the disease...? (ii) Being infected by religious extremism is like being infected by a disease...
		Q_{gen}: islamic law, god, christians	(i) Islamic law is to create an environment...submission to God. (ii) Certain areas of the Muslim world have always been home to large populations of Christians...
		Q_{cn}: tolerance, christianity, discriminating	(i) Islam is a 1400-year-old religion that preaches tolerance...like Christianity and... (ii) Disease does not discriminate...on religious grounds...

Table 3: Examples of KN retrieved using queries extracted from HS (Q_{hs}), generated (Q_{gen}) and created from both HS and CN keyphrases (Q_{cn}).

the 25 top-ranked articles. Next, we used spaCy sentence segmentation[6] to split an article into sentences. Similar to Zhang et al. (2020), given a query Q we score each sentence x_i in the set of articles D independently, using ROUGEL-F1 (Lin, 2004) as in Equation 1.

$$s_i = rouge(x_i, Q), \forall i \in D \qquad (1)$$

In the final step, we distilled the knowledge by keeping the top 5 knowledge sentences that have the highest scores among 25 top-ranked articles. Instead of a more stringent filtering, such setting has been applied to grant a better variety of source articles and corresponding distilled sentences. We refer to such automatically associated sentences as “silver knowledge”.

6 Counter Narrative Generation Module

Large pretrained LMs require less amount of high-quality data to be fine-tuned on downstream tasks while providing strong performances and they already store large amount of factual and commonsense knowledge from their training data (Petroni et al., 2019). To this respect, we built the following models: (1) **GPT-2$_{KN}$**, obtained by fine-tuning GPT-2 on CONAN data paired with KN; (2) **GPT-2$_{KN,MT}$**, by fine-tuning GPT-2$_{KN}$ in a multi-task learning fashion for learning to distinguish CNs from HS as next utterances; (3) **XNLG** (Chi et al., 2020) for its ability to copy information to the output (in our case the retrieved KN to be copied to the CN). We expect all three models to attend over the HS and retrieve KN and look for the relevant snippets to be recovered while generating a CN.

6.1 Models

The training HS-CN pairs are represented as $HS\ [HS\_end\_token]\ KN\ [KN\_end\_token]\ CN\ [CN\_end\_token]$. Each model is trained with $Q_{hs \cup cn}$ and then tested on Q_{hs}, Q_{gen}, and $Q_{hs \cup gen}$. We also tested the models with $Q_{hs \cup cn}$ to define an oracle scenario with an upperbound performance when the data can only be paired with silver knowledge.

GPT-2$_{KN}$. We fine-tuned the GPT-2[7] medium model for 3 epochs with a batch size of 2048 tokens. We used Adam optimizer with a learning rate of 5e-5. At inference time, responses were generated employing nucleus sampling with a p value of 0.9, conditioned on HSs and corresponding KN.

GPT-2$_{KN,MT}$. Since we noticed that GPT-2 occasionally produces responses that contain fragments of abusive language, we combined the language modeling objective with a next-sentence prediction objective for fine-tuning GPT-2 in a multi-task setting, inspired by Wolf et al. (2018). Next-sentence prediction adopts a linear classification layer added to the last layer of the transformer language model and then applies a cross-entropy loss to classify a proper next response to the input HS from 2 distractors randomly selected from HS. We used Adam optimizer with a learning rate of 5e-5 and empirically fine-tuned it for 1 epoch and the same sampling strategy as GPT-2$_{KN}$ has been applied.

XNLG is a pre-trained Transformer-based language model trained on Wikipedia dumps with two relevant objectives for our task: to obtain contextual representations and to recover a given input. We fine-tuned XNLG[8] for generating counter narratives on all layers with a batch size of 10 for 100 epochs. We used Adam optimizer with a learning rate of 1e-4. We tokenized and removed accent from the entire dataset and applied the same BPE

[8] https://github.com/CZWin32768/XNLG

codes used by Chi et al. (2020). For `KN` and `CN` we kept the first 256 tokens, while setting the `HS` to 70 tokens, which is the maximum length of hate speech in the dataset. We experimented with various decoding methods and adopted beam search with a beam-width of 3 for the best performing setting (details in Appendix A.2).

Baselines used for comparison are: (1) non-pretrained **Transformer** without knowledge using the same hyper-parameters as keyphrase generation model; (2) **GPT-2** without knowledge following the same configuration as GPT-2_{KN}; (3) **Candela** (Hua et al., 2019), an LSTM-based state-of-the-art knowledge-driven architecture for argument generation. Since `CONAN` is relatively small, we hypothesize that a pre-training procedure[9] on data from a similar task (argument generation) can be beneficial for generalization and porting knowledge. Thus, we first pre-trained Candela architecture on argument generation dataset (Hua et al., 2019), following the configuration described in the paper. We then fine-tuned the model for 20 epochs on `CONAN` with `KN` using Q_{hs} as it is done in the original setting of Candela.

6.2 Results for the Silver Knowledge Test Set

We report BLEU-2 (B-2) and ROUGE-L (R-L) scores for all proposed models and baselines in Table 4 on the test split of `CONAN` that we automatically paired with silver knowledge using various queries. We also measure the capability of each model to produce *novel* responses with respect to the training data by Jaccard similarity (Wang, 2018), and *diverse* responses for the given input by repetition rate (RR) (Cettolo et al., 2014).

Among our models, GPT-2_{KN} yields the highest B-2 and XNLG the highest novelty, diversity, and R-L. The notably improved novelty achieved by knowledge-grounded models indicates the benefits of adding knowledge on producing `CN`s, in comparison to the baselines - particularly Transformer `TRF`. On the other hand, the quantitative performance of XNLG does not reflect its true performance in terms of quality. A quick glance at the output `CN`s showed that XNLG model copies almost everything from `KN` to the output instead of a proper `CN` generation, increasing the novelty and diversity scores. The issue can easily be observed from the average numbers of words and sentences in the XNLG output in comparison to the outputs of the other models presented in Table 4. GPT-$2_{KN,MT}$ falls behind among our models in terms of RR, B-2, and R-L, still providing a competitive novelty. Regarding Candela, while it obtained similar performances to our models in terms of R-L and B-2, the generation is repetitive and less novel.

As for the testing with different query types, $Q_{hs \cup gen}$ induces more novel responses than $Q_{hs \cup cn}$ and Q_{hs}. While XNLG yields the highest novelty with Q_{hs} (0.824), it can be explained again with the problem of copying the whole `KN`, which is more varied due to the less restrictive search using only `HS`.

The oracle query $Q_{hs \cup cn}$, in which we deliberately provide the best knowledge possible through the keyphrases containing also from the gold `CN`, yields the best R-L scores among the query variations of knowledge-grounded models. Among all the models, $Q_{hs \cup cn}$ also leads to the best B-2 through GPT-2_{KN}, and the best R-L through XNLG, as we have anticipated. Finally, $Q_{hs \cup gen}$ outperforms Q_{hs} and Q_{gen} over most metrics, hinting at the advantages of using generated queries together with hate context for silver-knowledge retrieval.

We have also conducted complementary experiments by taking into consideration the design choices and the various phenomena in our study. Since in our test set, in line with `CONAN`, a `HS` can be paired with more than one `CN`, Q_{hs} would retrieve the same `KN` for all the target `CN`s of the same input `HS`. Contrarily, we obtain a different set of `KN` using queries Q_{gen}, $Q_{hs \cup gen}$ and $Q_{hs \cup cn}$ for each target `CN`. Therefore, we also report an evaluation on unique `HS`-`CN` pairs, where a single target `CN` has been randomly chosen for each `HS`, among all query types in Appendix A.4. Finally, to simulate Candela configuration (that uses only Q_{hs}) also with the other models, we run an additional set of experiments where we used Q_{hs} for retrieving the knowledge for training samples. The results are reported in Appendix A.3.

6.3 Results for the Gold Knowledge Test Set

To isolate the effect of the knowledge retrieval strategies from the knowledge-grounded generation performances, we conducted a second evaluation on a newly crafted test set paired with gold standard knowledge. In this evaluation, in addition to stereotypical islamophobic in-domain (i.e.

---

[9] We also trained Candela from scratch on `CONAN` but decided not to proceed with this setting for the poor performance.

Table 5: Results of `CN` generation with gold knowledge in-target and cross-target test sets.

in-target) scenario, we also explore the effect of knowledge infusion on cross-domain (i.e. cross-target) `CN` generation under zero-shot setting. We hypothesize that having a system trained to make use of substandard silver knowledge to generate proper `CN`s for a given context, could be robust to cross-domain zero-shot conditions. Therefore, we organized a data collection session with an expert operator in writing `CN`s. In this session, 50 islamophobic `HS`s randomly sampled from `CONAN` and 144 new cross-target `HS`s (covering misogyny, antisemitism, racism, and homophobia) are provided along with the knowledge retrieved by $Q_{hs\cup cn}$ queries. The expert is tasked with composing a suitable `CN` using the corresponding knowledge as much as possible. Thus, we could obtain a gold test set[10]. in which the input knowledge can certainly be found in the `CN`s.

We tested all models with gold knowledge in-domain and cross-domain test cases. Results are given in Table 5. For in-domain scenario, as we have anticipated, knowledge grounded models yield better performances in B-2 and R-L in comparison to the silver knowledge test setting. Especially with the striking jump in the performance of GPT-2$_{KN}$, we can confirm the proper infusion of the given knowledge to the generated `CN`s. As for cross-domain tests, GPT-2$_{KN}$ still yields better performance than baselines while the performance for all models (except for XNLG) drops due to unseen events during training. All GPT-2 variations present better diversity performances on the cross-domain setting as compared to both in-domain and silver-knowledge settings. Regardless of domains, XNLG yields fallaciously high scores due to its extensive copying. A cross-target generation from the models can be seen in Table 7. More examples in-/cross-domain generations from all the models are provided in Appendix A.6.

Human evaluation. We further resort to human evaluation to assess the final generation quality of

---

[10] We release the gold test set at `https://github.com/marcoguerini/CONAN`.

each model. For this reason we perform human evaluation of generation using gold knowledge, to rule out the effect of possible noise in the knowledge that may result from the retrieval process.

Our models were evaluated by 3 expert operators from the NGO Stop Hate UK. The annotators are already experienced, and specifically trained, in reading hateful content and writing `CN`s for online hate countering[11]. The annotators are instructed to assess all generated pairs in gold knowledge test sets in terms of *suitableness* to the `HS`, *informativeness*, and *intra-coherence* of `CN` regardless of `HS`. Each score is on a scale of 1 (the least) to 5 (the most). To avoid possible bias and hints towards models, we normalized the pairs (e.g., lowercase and space between words and punctuation) and divided them into 3 partitions of randomized files for experts (See Appendix A.5 for annotation instruction). Each expert was given 388 pairs, resulting in a total of 1164 pairs for evaluation. To avoid excessive workload annotators were allowed to complete the task over multiple sessions at their preference.

Results are reported in Table 6. We also computed Kendall's Tau-b (Kendall, 1938) to measure the annotators' agreement towards the model ranking for each aspect. The high correlations indicate a strong concordance among the annotators (threshold tau-b > 0.35). Regardless of domains, annotators consider XNLG generations as the most informative and GPT-2$_{KN}$ generations as the most suitable. TRF yields a reasonable suitableness and coherence since it tends to memorize the training `CN`s, almost behaving like a retrieval system on human responses. However, such behavior can be fatal in cross-domain settings. Candela fails to generate suitable cross-domain `CN`s despite preserving the intra-`CN` coherence. While GPT-2 and GPT-2$_{KN}$ generations are found almost equally coherent, the lower suitableness and informativeness of GPT-2 output (2.26 and 1.92) for cross-domain as compared to GPT-2$_{KN}$ (2.51 and 2.29) encourages the grounding `CN`s in knowledge.

7 Discussion

Our findings suggest that a large pre-trained LM with knowledge injection is preferred to alleviate the demand for gold data and improves in-/cross-domain generations. GPT-2$_{KN}$ outperforming GPT-2, which becomes more clear with every increase in the quality of provided `KN` (i.e., from silver Q_{gen} to silver $Q_{hs \cup gen}$ to gold in-domain), indicates that our model trained on silver knowledge learns to grasp relevant `KN` to the given `HS` instead of random copying. As for GPT-2$_{KN,MT}$, since the model is trained to distinguish `CN` from `HS`, certain typical counter responses are prone to appear. Through a manual analysis, we confirmed that its responses tend to be simpler (e.g., negation: "*terrorism is **not** a religion.*", "*It's **not** true...*") than the responses of other GPT-2 variant models. Future work can explore alternative multitask learning frameworks to improve the generation.

Table 6: Human evaluation results of `CN` generation.

From a practical perspective, we can conclude that fine-tuning a pretrained language model for conditional generation, utilizing silver-knowledge sentences retrieved through a query generation model is the most promising approach for knowledge-bound `CN` generation. In fact, (i) among various models we tried, GPT-2 with knowledge infusion is shown to produce the most informative and suitable output. (ii) At deployment time, using input context together with generated keyphrases becomes prominent with more novel and diverse `CN`s and (iii) for new hate-targets in a zero-shot scenario, the generation model can produce coherent and suitable `CN`s without retraining if a reasonable set of input knowledge is provided. Moreover, this approach can be applied to other scenarios, such as dialogue response generation, since it does not require any extra data collection or annotation.

8 Conclusion

Online hate speech intervention is a challenging problem and research on counter narrative generation is still in its infancy. In this work, we have proposed methods for improving counter narrative generation to fight hatred online, incorporating external knowledge retrieved through extracted and generated keyphrases. To this end, a dataset of hate-speech/counter-narrative pairs was augmented with relevant knowledge to train systems that are able to

---

[11] The compensation for annotation work met with EU regulations.

HS: Jews are different from non-Jews not because of their beliefs, but because of their physical nature. “Jewishness” and malevolence is inherited through blood.

Human: Today one of the biggest concerns is the reinvention of clinical concepts of race, based on inaccurate generalizations. The notion that the superiority of the white race was part of the natural order was deviously reinforced by the rise of modern ”scientific” racism in the late 19th century. Despite the strong objections of many of our contemporaries, this idea of a ”jewish race” is still going around.

GPT-2: Muslims are not different from non-Muslims because of their faith.

GPT-2$_{KN}$: I think that the notion of race is a generalization based on ignorance.

GPT-2$_{KN,MT}$: All that is wrong is that we cannot accept that violence is necessary.

XNLG: today , one of the biggest concerns is the reinvention of clinical concepts of race , based on inaccurate generalizations about the prejudice to certain physical characteristics and civilizations . despite the strong objections of many contemporary contemporaries , the notion of fixed ” race ” - packages of physical and behavioral characteristics

Table 7: Samples of cross-domain generation.

produce suitable and informative arguments. Our experiments on in-/cross- domain generation indicate that the generated responses can meet these desiderata. As future work we plan to test other query generation approaches (e.g., exploit human-crafted queries in an interactive setup or the use of pre-trained LMs) to improve knowledge selection and to test other architectures for the final generation step.

Acknowledgments

This work was partly supported by the HATEMETER project within the EU Rights, Equality and Citizenship Programme 2014-2020. We are deeply grateful to Stop Hate UK and its volunteers for their help and effort in evaluating the output of our systems.

Ethical Considerations

While we believe that counter narratives are a better tool than content moderation in fighting hate speech (e.g. they do not hinder freedom of speech), still the automatic generation of CNs should be taken with care. Since this work aims at presenting a methodology for knowledge-bound counter narrative production through neural approach, several ethical consequences should be considered.

First, neural models may still produce substandard counter narratives containing abusive language or negative content. To mitigate this issue, possible solutions include (1) integrating in the pipeline a classifier or a human reviewer for validation and possible post-editing (Tekiroğlu et al., 2020), (2) detoxification techniques for controllable generation methods (Gehman et al., 2020), and (3) discarding undesirable content from the corpora used for training (Raffel et al., 2020), even if the appropriate criteria for such purpose are still investigated.

Second, while our approach reduces the risks of content hallucination, an additional step, where the accuracy of the generated text is checked against the provided knowledge (Nie et al., 2019; Dušek and Kasner, 2020), would provide further robustness to the system.

Third, natural language generation models may still induce unintended social biases. This issue can be moderated by measuring/promoting fairness in models and data employed (Blodgett et al., 2020), and designing bias triggers (Sheng et al., 2020) or regularization methods (Bordia and Bowman, 2019; Corbett-Davies et al., 2017) for controllable bias.

To sum up, while some additional automated techniques may help in maintaining generation quality, human evaluation should always be considered as the foremost solution, at least for delicate tasks such as ‘real’ hate countering on social media platforms. For this reason we advocate that generation systems should be used as a suggestion tool for NGO operators, to make their countering work more effective. In this way there is always a “human moderator” taking the final decision (Chung et al., 2019).

A Appendices

A.1 Analysis on Keyphrase Extraction Configurations

We conducted a preliminary manual analysis to investigate the effects of various keyphrase extraction configurations. We randomly sampled 48 hate speech and counter-narrative pairs from `CONAN` dataset and extracted the keyphrases. Then, we retrieved the `KN` (see Section 5.3) with the queries Q_{hs} and $Q_{hs \cup cn}$. On the other hand, we also wanted to inspect the condition with the keyphrases only from `CN`, i.e., Q_{cn}. For each sample and condition, annotators have assigned a score for relevance to the hate speech in the scale of 1 to 5; 1 meaning no-relevance, and 5 perfect relevance. As a result, we have noticed that Q_{cn} is the worst condition, i.e., non-optimal, having an average score of 2.30. The analysis shows that it causes the loss of context related to `HS`, bringing information mostly from whole another topic. For instance, especially when `CNs` are rather generic, often, no lexical hint can be found related to the topic of Islamophobia (e.g., "*Do you have any proof?*"). Indeed, Q_{hs} provides an apparently better average score (3.46) since it provides a better context to search for. However, as expected, the best score (3.77) has been obtained through $Q_{hs \cup cn}$, i.e, optimal, verifying our hypothesis of utilizing both `HS` and `CN` keyphrases for training.

A.2 Preliminary Analysis on Decoding Methods for XNLG

To find a suitable decoding method for our task, we generated `CNs` with 3 candidate settings: beam search with a beam-width of 3 and top-k sampling with a k value of 8 and 10. For each setting we utilized `KN` retrieved with both non-optimal (Q_{cn}) and optimal ($Q_{hs \cup cn}$) queries. Then we sampled 120 `HS`-`CN` pairs and served them to three experts in `CN` writing for evaluating the generation on a scale of 1 (the worst) to 5 (the best) in terms of suitableness and informativeness. Suitableness measures if the generated `CN` is relevant to the `HS` and informativeness evaluates the amount of information (e.g. statistics and facts) enclosed in the `CN`.

The results reported in Table 8 reveal a clear difference between beam search and top-k sampling regardless of `KN` being optimal or non-optimal. In a manual investigation, we observed that the generation using both beam search and top-k sampling generally can copy some pieces of information from the given `KN`, while top-k seems to replace part of the text with slightly relevant and uncommon words. Hence, copying the right knowledge pieces through the decoding strategy is a key factor instead of diverging from the knowledge solely for the sake of lexical diversity. Therefore, based on the results, we adopt beam search with a beam-width of 3, which is shown to be the most suitable and informative, for decoding method in our experiments.

Decoding methods	Suit.	Info.
Non-optimal knowl.		
Beam-3	1.950	2.325
Topk-8	1.275	1.775
Topk-10	1.625	2.100
Optimal knowl.		
Beam-3	2.325	2.450
Topk-8	1.975	2.175
Topk-10	2.050	2.325

Table 8: Human evaluation on `CN` generation using various decoding methods.

A.3 CN Generation with Q_{hs}

In this section we report the `CN` generation results of our knowledge-bound models trained and tested with Q_{hs}. We applied the same hyperparameter configurations as the models trained with $Q_{hs \cup cn}$ described in Section 6.1.

The results are given in Table 9. In contrast to the baselines (i.e., models without knowledge and Candela), all models obtained higher novelty with Q_{hs}. The repetition rate, on the other hand, is not improved since the models exploit the same knowledge for multiple test samples due to the repeated `HSs` with different `CNs` in the test set.

We also observed that for GPT-2_{KN} and GPT-$2_{KN,MT}$ the generation with Q_{hs} is more repetitive and less novel compared to the generation applying queries $Q_{hs \cup gen}$ (as shown in Table 4). This result demonstrates the viability and necessity of using generated queries, as potential `CN` prompts, along with `HS` context.

A.4 Unique HS Test Set Analysis

Concerning that one `HS` can be paired with different `CNs` in the test, we further conducted an evaluation on a unique set by keeping each unique `HS` and one randomly selected `CN` among its `CNs`. The unique `HS` set lets us perform a fairer comparison among query configurations especially for Q_{hs}

							`KN` overlap (ngram)		
Models	Nov.	RR	B-2	R-L	#Word	#Sent.	1	2	3
GPT-2$_{KN}$	0.700	8.66	0.082	0.098	14.87	1.32	0.235	0.019	0.003

w/ Q_{gen}	0.819/0.821	6.88/**4.03**
w/ $Q_{hs\cup gen}$	0.812/0.817	6.98/5.19
w/ $Q_{hs\cup cn}$	0.819/0.816	**5.69**/4.64

Table 10: Results of unique `HS` test set (U) for novelty and diversity. For comparison, we keep the results of whole test set (W).

with models employing beam search (i.e. XNLG and Candela). The results are given in Table 10.

For XNLG and GPT-2$_{KN,MT}$, we observed an increase in the novelty and diversity with Q_{hs} and Q_{gen} on the unique `HS` set over the whole test set. As for GPT-2$_{KN}$, while diversity improves for all query configurations, we did not observe an increase in novelty through Q_{hs}. For Candela, while novelty also increases, the diversity does not improve.

A.5 Human Evaluation Instruction

Three experts are tasked with `CN` generation evaluation. We briefed the annotators the aim of the evaluation, and then we explained common and appropriate `CN`s along with 10 examples of `HS`-`CN` pairs. The annotators are instructed to evaluate the generation with intuition. The generation is evaluated in terms of 3 aspects: (i) **suitableness:** How suitable the counter narrative is under evaluation for its hate speech, i.e. coherence and relevance of a counter narrative with regard to the hate speech. (ii) **informativeness:** How informative/specific the counter narrative is as a response for its hate speech. (iii) **intra-coherence:** How coherent the counter narrative is under evaluation as a response, i.e. internal coherence of a counter narrative regardless of its hate speech. In Table 11 we give the annotation examples with the score explanations provided to the annotators.

HS: Muslims do not want to assimilate. They demand that everyone shows respect for Islam, but they don't respect our laws. One day they will oppress us with the Sharia and polygamy.
CN: Do you really believe that they are a problem? I have a job. **evaluation**: suit.: 3, info.: 1, cohe.: 1 **Note**: The first sentence is relevant but not the second one. There is no coherence between 2 sentences.
CN: As far as they do not force us to follow sharia laws, we should not be concerned with them following their laws. **evaluation**: suit.: 5, info.: 3, cohe.: 5 **Note**: The `CN` is an appropriate and coherent response, but not providing a substantial amount of information or facts.
CN: Muslims should not be forced to assimilate, since it is not right and no one wants that. And polygamy is illegal and forbidden in UK and Muslims actually respect this ban. **evaluation**: suit.: 5, info.: 5, cohe.: 5 **Note**: The whole `CN` is perfectly suitable for the given `HS`. It is highly informative with the facts and internally coherent.

Table 11: Annotation examples with score explanations.

A.6 Generation Examples

HS: Jews are Christ Killers.
Human: While the Catholic Church has for decades taught that Jews weren’t collectively responsible, the argument laid out by the Pope Benedict XVI was a landmark statement. In his book, he not only confirms church teaching refuting the decide charge, he also explains biblically and theologically why there is no basis in Scripture for the argument that the Jewish people as a whole were responsible for Jesus’ death.
TRF: Why do you consider muslims like beasts? Did they do something wrong? If you take into consideration the crimes committed by muslims, why do you distinguish the muslim criminals from the non muslim? They are all criminals and all of them are punished.
GPT-2: I know many Muslims who are peaceful and respectful and do not kill.
Candela: Do you have proof? Where did you get this information from? I do not see the link between islamism and the news of the muslim community.
GPT-2$_{KN}$: No, the crucifixion of Jesus Christ is not a source for anti-Semitism. The Jewish people were not responsible for the death of Jesus.
GPT-2$_{KN,MT}$: On the basis of christianity, as christianity is not a religion, jews are not responsible for their own death.
XNLG: In ”jesus of nazareth-part ii” excerpts the church’s teaching that refuted the deicide charge of the jewish people, as well as theologically explains one of the most controversial issues in christianity.
KN: Pope Benedict XVI has made a sweeping exoneration of the Jewish people for the death of Jesus Christ. While the Catholic Church has for five decades taught that Jews weren’t collectively responsible, Jewish scholars said... would help fight anti-Semitism today. In ”Jesus of Nazareth-Part II” excerpts released Wednesday, Benedict explains biblically and theologically why there is no basis in Scripture for the argument that the Jewish people as a whole were responsible for Jesus’ death.

Table 12: Sample cross-domain `CN` generation from different models.

HS: Why gays do not try to heal?
Human: Contrary to some insinuations, sexual orientation is not like a disease.
TRF: Type imam boussena and we ll see who the scum is.
GPT-2: So they’re the ones who are trying to make us hate them.
Candela: You see more and more attacks on muslims as a result of the controversies? Do you really want to believe in a ‘caliphate’?
GPT-2$_{KN}$: We know that homosexuality is not a disease.
GPT-2$_{KN,MT}$: The genetics of homosexuality have been studied, but it seems to me that the human race is not suited to do that.
XNLG: And , contrary to the insinuation , sexual orientation is not like a disease . more recent studies have identified other potential links between homosexuality and genetics , and scientists have offered explanations on how same sex attraction can advance procreation , suggesting that the same twin is more likely to be gay , but finding the biological origins of the same
KN: Contrary to Perry’s insinuation, sexual orientation is not like a disease. More recent studies have identified other potential links between homosexuality and genetics, and scientists have offered explanations on how same-sex attraction could advance procreation. Studies of identical twins, who share the same genes, have shown that, if one twin is gay, the other is more likely to be gay, suggesting sexual orientation is influenced by genetics. Scientific studies have demonstrated that biology plays a role in one’s sexual orientation.

Table 13: Samples of cross-domain `CN` generation from different models.

HS: It seems that I cannot define Islam as a cult which promote wars and conquers host nations and legitimate this by its scriptures. Can I define them as narrow-minded, prejudiced, sexist and male chauvinist?
Human: Everyone has the right of free speech, while it does not mean anyone can use it to hurt people. Plus, based on what you critisize Islam? I recommend you to read something about true Islam and Muslims. You would find that they are no difference from us.
TRF: Islam is all about the religions and tolerance insert quote from koran. Migrants is not evil?
GPT-2: It seems to me that this is the antithesis of what Islam teaches.
KN Q_{hs}: Hakim al-Mutairi, secretary-general of the emirate's Umma (Islamic Nation) party, urged the pope to apologise immediately "to the Muslim world for his calumnies against the Prophet Muhammad and Islam".... Instead of bringing Islam and Christianity closer, he is straining relations between the two religions". In the present political atmosphere such views can be exploited by those who are trying to malign Muslims and Islam. **Candela:** I have no accountability. I have no problem with those who claim to belong to, but i do not have the right to practice whatever religion. **GPT-2$_{KN}$:** The Qur'an clearly teaches peace, love and tolerance towards everyone, including the non-Muslims. The only thing that Islam does not have is a message of conquest and war. **GPT-2$_{KN,MT}$:** Islam is a religion founded on the principle that you must believe in the good will of all people. **XNLG:** Extremist muslim national party secretary, hamid al mutairi, urged the pope to define immediately to the muslim world for his calumies against the prophet muhammad and islam. Pope benedict xvi was full of hostility and hatred against muslims and islam. In the present political atmosphere such views can be exploited by those who bring
KN $Q_{hs\cup gen}$: Islam, as practiced by the vast majority of people, is a peaceful religion, a religion that respects others. "The large majority of Muslims tinker," said Franck Fregosi, a sociologist who has written extensively on Islam in Europe.... **GPT-2$_{KN}$:** Hi, I do not understand the problem you have. The vast majority of Muslims do not advocate wars and conquer the world. They practice a peaceful religion that respects others. **GPT-2$_{KN,MT}$:** It seems that i have just come across the iota of muslims who have been insulted, persecuted, killed, raped, harassed, murdered, killed by the muslims in europe. **XNLG:** It seems that islam, as practiced by the vast majority of people, is a peaceful religion, a religion that respects others. The large majority of muslims tinker, as franck fregosi, who has written extensively on islam in europe. It seems that it does not define islam as an inclusion and respect for all of the religion
KN $Q_{hs\cup cn}$: No doubt, it is the legitimate right of Muslims to build a community center near Ground Zero. So please stop conflating criticism of Islam with discrimination of Muslims. As a nation of free people, we can never defeat Islam but we can make war against terrorists and governments that support them. a "moderate Islamic countries" when all unanimously reject the Universal Declaration of Human Rights and support The Cairo Declaration of Human Rights in Islam. **GPT-2$_{KN}$:** The Islamic countries do not promote wars and conquer host nations. Islam is not a cult but a peaceful religion which respects all peoples. **GPT-2$_{KN,MT}$:** The vast majority of men in the world are not able to articulate the spiritual values of islam. **XNLG:** It seems that it is the legitimate right of muslims to build a community center near zero ground, so please confine criticism of islam with discrimination against muslims. As a nation of free people, we can never defeat islam, but we can make war against terrorists and governments that support them. My comment gives a lot of information about what islam and muslims

Abstract

The widespread use of offensive content in social media has led to an abundance of research in detecting language such as hate speech, cyberbullying, and cyber-aggression. Recent work presented the *OLID* dataset, which follows a taxonomy for offensive language identification that provides meaningful information for understanding the type and the target of offensive messages. However, it is limited in size and it might be biased towards offensive language as it was collected using keywords. In this work, we present *SOLID*, an expanded dataset, where the tweets were collected in a more principled manner. *SOLID* contains over nine million English tweets labeled in a semi-supervised fashion. We demonstrate that using *SOLID* along with *OLID* yields sizable performance gains on the *OLID* test set for two different models, especially for the lower levels of the taxonomy.

1 Introduction

Offensive language in social media has become a concern for governments, online communities, and social media platforms. Free speech is an important right, but moderation is needed in order to avoid unexpected serious repercussions. In fact, this is so serious that many countries have passed or are planning legislation that makes platforms responsible for their content, e.g., the *Online Harm Bill* (HM Government, 2019) in the UK and the *Digital Services Act* (European Commission, 2020) in the EU. Even in the United States, content moderation or the lack thereof can have significant impact on business (e.g., Parler was denied server space), government (U.S. Capitol Riots), and individuals (hate speech is linked to self-harm). Explainability is needed to indicate in detail why content has been deleted or flagged as inappropriate. Moreover, users can be educated by such feedback to avoid future biases.

There have been several areas of work in the detection of offensive language (Basile et al., 2019; Fortuna and Nunes, 2018; Ranasinghe and Zampieri, 2020), covering overlapping characteristics such as toxicity, hate speech, cyberbullying, and cyber-aggression. Further, using a hierarchical approach to analyze different aspects of the offensive content, such as the type and the target of the offense, helps provide explainability. The Offensive Language Identification Dataset, or *OLID*, (Zampieri et al., 2019a) is one such example, and it has been widely used in research. *OLID* contains 14,100 English tweets, which were manually annotated using a three-level taxonomy:

A: Offensive Language Detection
B: Categorization of Offensive Language
C: Offensive Language Target Identification

The taxonomy proposed in *OLID* makes it possible to represent different kinds of offensive content as a function of the *type* and the *target* of a post. For example, offensive messages targeting a group are likely hate speech, whereas offensive messages targeting an individual are likely cyberbullying. *OLID* has been used to annotate datasets in languages such as Arabic (Mubarak et al., 2021), and Greek (Pitenis et al., 2020), allowing for multilingual learning and analysis.

An inherent feature of the hierarchical annotation is that the lower levels of the taxonomy contain a subset of the instances in the higher levels, and thus there are fewer instances in the categories in each subsequent level. This makes it very difficult to train robust deep learning models on such datasets. Moreover, due to the natural infrequency of offensive language (e.g., less than 3% of the tweets are offensive when selected at random), obtaining offensive content is

---

WARNING: This paper contains tweet examples and words that are offensive in nature.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 915–928
August 1–6, 2021. ©2021 Association for Computational Linguistics

a costly and time-consuming effort. In this paper, we address these limitations by proposing a new dataset: **S**emi-Supervised **O**ffensive **L**anguage **I**dentification **D**atatset (*SOLID*)[1]. Our contributions are as follows:

1. We are the first to apply a semi-supervised method for collecting new offensive data using *OLID* as a seed dataset, thus avoiding the need for time-consuming annotation.
2. We create and publicly release *SOLID*, a training dataset containing 9 million English tweets for offensive language identification, the largest dataset for this task. *SOLID* is the official dataset of the SemEval shared task OffensEval 2020 (Zampieri et al., 2020).
3. We demonstrate sizeable improvements over prior work on the mid and lower levels of the taxonomy, where gold training data is scarce when training on *SOLID* and testing on *OLID*.
4. We provide a new larger test set and a comprehensive analysis of *EASY* (i.e., simple explicit tweets such as using curse words) and *HARD* (i.e., more implicit tweets that use underhanded comments or racial slurs) examples of offensive tweets.

The remainder of this paper is organized as follows: Section 2 presents related studies in aggression identification, bullying detection, and other related tasks. Section 3 describes the *OLID* dataset and annotation taxonomy. Section 4 introduces the computational models used in this study. Section 5 presents the *SOLID* dataset. Section 6 discusses the experimental results and Section 6.3 offers additional discussion and analysis. Finally, Section 7 concludes and discusses possible directions for future work.

2 Related Work

There have been several recent studies on offensive language detection and related tasks such as hate speech, cyberbulling, aggression, and toxic comment detection.

Hate speech identification is by far the most studied abusive language detection task (Ousidhoum et al., 2019; Chung et al., 2019; Mathew et al., 2021). One of the most widely used datasets is the one by Davidson et al. (2017), which contains over 24,000 English tweets labeled as non-offensive, hate speech, and profanity. A recent shared task on the topic is HatEval (Basile et al., 2019).

In cyberbullying detection, Xu et al. (2012) used sentiment analysis and topic models to identify relevant topics. Dadvar et al. (2013) and Safi Samghabadi et al. (2020) studied the use of the conversational context for detecting cyberbullying. In particular, Dadvar et al. (2013) used user-related features such as the frequency of profanity in previous messages. More recent work has addressed the issues of scalable and timely detection of cyberbullying in online social networks. To this end, Rafiq et al. (2018) employed a dynamic priority scheduler, and Yao et al. (2019) proposed a sequential hypothesis testing. Safi Samghabadi et al. (2020) constructed a dataset of cyberbullying episodes from the semi-anonymous social network ask.fm.

There were two editions of the TRAC shared task on Aggression Identification (Kumar et al., 2018, 2020) which provided participants with datasets containing annotated Facebook posts and comments in English and Hindi for training and validation. Facebook and Twitter datasets were used for testing. The goal was to discriminate between three classes: non-aggressive, covertly aggressive, and overly aggressive. Two other shared tasks addressed toxic language. The Toxic Comment Classification Challenge[2] at Kaggle provided participants with comments from Wikipedia annotated using six labels: toxic, severe toxic, obscene, threat, insult, and identity hate. The recent SemEval-2021 Toxic Spans Detection shared task addressed the identification of the token spans that made a post toxic (Pavlopoulos et al., 2021).

There were several shared tasks that have focused specifically on offensive language identification. For example, GermEval 2018 (Wiegand et al., 2018) which focused on offensive language identification in German tweets, HASOC 2019 (Mandl et al., 2019), and TRAC 2018 (Fortuna et al., 2018).

In this paper, we extend the prior work of the *OLID* dataset (Zampieri et al., 2019a). *OLID* is annotated using a hierarchical annotation schema as in (Basile et al., 2019; Mandl et al., 2019). In contrast to prior approaches, it takes both the target and the type of offensive content into account. This allows multiple types of offensive content (e.g., hate speech and cyberbullying) to be repre-

---

[1] Available at: `https://sites.google.com/site/offensevalsharedtask/solid`

[2] `http://kaggle.com/c/jigsaw-toxic-comment-classification-challenge`

sented in *OLID*'s taxonomy. We create a large-scale semi-supervised dataset using the same annotation taxonomy as in *OLID*.

3 The OLID Dataset

The *OLID* (Zampieri et al., 2019a) dataset tackles the challenge of detecting offensive language using a labeling schema that classifies each example using the following three-level hierarchy:

Level A: ***Offensive Language Detection*** Is the text offensive?
OFF Inappropriate language, insults, or threats.
NOT Neither offensive, nor profane.

Level B: ***Categorization of Offensive Language*** Is the offensive text targeted?
TIN Targeted insult or threat towards a group or individual.
UNT Untargeted profanity or swearing.

Level C: ***Offensive Language Target Identification*** What is the target of the offense?
IND The target is an individual explicitly or implicitly mentioned in the conversation;
GRP Hate speech, targeting a group of people based on ethnicity, gender, sexual orientation, religion, or other common characteristic.
OTH Targets that do not fall into the previous categories (e.g., organizations, events, and issues.)

The taxonomy was successfully adopted for several languages (Mubarak et al., 2021; Pitenis et al., 2020; Sigurbergsson and Derczynski, 2020; Çöltekin, 2020), and it was used in a series of shared tasks (Zampieri et al., 2019b; Mandl et al., 2019). Tweets from the *OLID* dataset labeled with the taxonomy are shown in Table 1. The *OLID* dataset consists of 13,241 training and 860 test tweets.

Table 2 presents detailed statistics about the distribution of the labels. There is a substantial class imbalance on each level of annotation, especially at Level B. Furthermore, there is a sizable difference in the total number of annotations between the levels due to the schema (e.g., Level C is 1/3 smaller than Level A), and the data sizes for B and C are rather small. These drawbacks indicate the need to create a larger dataset.

4 Models

In this section, we describe the models used for semi-supervised annotation and for evaluating the contribution of *SOLID* for offensive language identification. We use a suite of heterogeneous machine learning models: PMI (Turney and Littman, 2003), FastText (Joulin et al., 2017), LSTM (Hochreiter and Schmidhuber, 1997), and BERT (Devlin et al., 2019). They have diverse inductive biases, which is an essential prerequisite for our semi-supervised setup (see Section 4.5). We assume that an ensemble of models with different inductive biases decreases each individual model's bias.

Tweet	**A**	**B**	**C**
@USER Anyone care what that dirtbag says?	OFF	TIN	IND
Poor sad liberals. No hope for them.	OFF	TIN	GRP
LMAO....YOU SUCK NFL	OFF	TIN	OTH
@USER What insanely ridiculous bullshit.	OFF	UNT	-
@USER you are also the king of taste	NOT	-	-

Table 1: Examples from the *OLID* dataset.

4.1 PMI

We use a PMI-based model that computes the n-gram-based similarity of a tweet to the tweets of a particular class c in the training dataset. The model is considered naïve as it accounts only for the n-gram frequencies in the discrete token space and only in the context of n neighboring tokens. We compute the PMI score (Turney and Littman, 2003) of each n-gram in the training set w.r.t. each class:

$$PMI(w_i, c_j) = log_2\left(\frac{p(w_i, c_j)}{p(w_i) * p(c_j)}\right) \quad (1)$$

where $p(w_i, c_j)$ is the frequency of n-gram w_i in instances of class c_j, $p(w_i)$ is the frequency of n-gram w_i in instances from the entire training dataset, and $p(c_j)$ is the frequency of class c_j. Additionally, we find that semantically oriented PMI scores (Turney and Littman, 2003) improve the performance of this naïve method:

$$PMI - SO(w_i, c_j) = log_2(\frac{p(w_i, c_j) * p(C \setminus \{c_j\})}{p(w_i, C \setminus \{c_j\}) * p(c_j)}) \quad (2)$$

where $C \setminus \{c_j\}$ is the set of all classes except c_j. At training time, we collect the frequencies of the n-grams on the training set. At inference time, we use the frequencies to calculate PMI and PMI-SO scores for each unigram and bigram in each instance and then average PMI and PMI-SO to a single score for each instance and class. Finally, we select the class with the highest score. If the instance contains no words with associated scores, we choose NOT for Level A, UNT for Level B –

Level	Label	*OLID* Train	*OLID* Test	*SOLID* Train	*SOLID* Test
A	OFF	4,640	240	1,448,861	3,002
	NOT	9,460	620	7,640,279	2,991
B	TIN	4,089	213	149,550	1,546
	UNT	551	27	39,424	1,451
C	IND	2,507	100	120,330	1,055
	GRP	1,152	78	22,176	349
	OTH	430	35	7,043	140

Table 2: Train and Test data distribution for the *OLID* and the *SOLID* datasets.

the classes most likely to contain neutral orientation, and the majority class IND for Level C. We remove words appearing less than five times in the training set and add a smoothing factor of 0.01 to all frequencies.

4.2 FastText

A suitable extension to the word-based model is to use subword representations to overcome the naturally noisy structure of tweets. FastText (FT) (Joulin et al., 2017) is a strong subword model which has shown strong performance on various tasks without the need for extensive hyperparameter tuning. It uses a shallow neural model for text classification similar to the continuous bag-of-words model (Mikolov et al., 2013). Instead of predicting the word based on its neighbors, it predicts the target label based on the sample's words. FT provides a valuable, diverse modeling representation to the ensemble due to its differences with the simple PMI model and the heavy-lifting LSTM and BERT models. We train FT with bigrams and a learning rate of 0.01 for Levels A and B and with trigrams and a learning rate of 0.09 for Level C. All tasks use a window size five and a hierarchical softmax loss.

4.3 LSTM

In contrast to the prior models, the LSTM model (Hochreiter and Schmidhuber, 1997; Vaswani et al., 2017) can account for long-distance relations between words. First is an embedding layer initialized with a concatenation of the GloVe 300-dimensional (Pennington et al., 2014) and FastText's Common Crawl 300-dimensional embeddings (Grave et al., 2018). It is followed by a dropout and a bi-directional LSTM layer with an attention mechanism on top of it. We concatenate the attention mechanism's output with averaged and maximum global poolings on the outputs of the LSTM model. The final prediction is produced by a sigmoid layer for Levels A and B, where we have a binary classification, and a softmax layer for Level C, where we have three classes. We train the LSTM model using early stopping with patience for no improvements over the validation loss of up to five epochs. Level A uses a hidden size of 128, a dropout rate of 0.3, a batch size of 256, and a learning rate of 0.0002. Levels B and C use a hidden size of 50, a dropout rate of 0.1, a batch size of 32, and a learning rate of 0.0001. The Adam optimizer is used for training.

4.4 BERT

The Transformer architecture (Vaswani et al., 2017) has achieved (nearly) state-of-the-art performance for several NLP tasks. It displays both high representational power and robustness across tasks. We exploit the benefits of transfer learning in a low-resource setup by using the pre-trained BERT model (Devlin et al., 2019) and fine-tune it to our task. We use the base uncased model implementation from HuggingFace (Wolf et al., 2020), which has 12 layers, a hidden size of 768, and 12 attention heads, amounting to 110 million parameters. We fine-tune the BERT model for each task, starting from the pre-trained base model. We fine-tune BERT for 2, 3, and 3 epochs for Level A, B, and C, respectively. We use learning rates of 0.00002 for Levels A and B, and 0.00004 for Level C. We apply per-class weights to cope with the data imbalance in Level C as follows: IND=1, GRP=2, OTH=10. We use the Adam optimizer and a linear warm-up schedule with a 0.05 warm-up ratio.

4.5 Democratic Co-training

Democratic co-training (Zhou and Goldman, 2004) is a semi-supervised technique used to create large datasets with noisy labels when provided with a set of diverse models trained in a supervised way. This approach has been successfully applied in tasks like time series prediction with missing data (Mohamed et al., 2007), early prognosis of academic performance (Kostopoulos et al., 2019), and in the health domain (Longstaff et al., 2010). Using models with diverse inductive biases to label the target tweet can help ameliorate the individual model biases and produce predictions with a lower degree of noise.

In our work, we employ democratic co-training to create semi-supervised labels for all three levels of *SOLID* using *OLID* as our seed dataset. Distant supervision is conducted by the ensemble of models with different inductive biases as follows:

1. Train N *diverse* supervised models $\{M_j(X)\}$, where $j \in [1, N]$ on a labeled dataset $X = \{(x_i, y_i)\}$, where $i \in [1, |X|]$
2. For each example x'_i in the unannotated dataset $X' = \{(x'_i)\}, |i \in [1, |X'|])$ and each model M_j, predict the confidence p'^j_i for the positive class.

5 The *SOLID* Dataset

In this section, we describe the process of collecting a large dataset of over 12 million tweets All of the data was labeled using the democratic co-training approach described in the previous section. The statistics for the dataset are shown in Table 2.

5.1 A Large-Scale Dataset of Tweets

We collected our data from Twitter using the Twitter streaming API[3] via Twython[4] in 2019. We search the API using the 20 most common English stopwords (e.g. *the*, *of*, *and*, *to*) to ensure truly random tweets and avoid rate limits. Using stopwords ensures that we are more likely to obtain English tweets as well as a diverse set of random tweets. We kept the stream running the entire time and continuously choose a stopword at random based on its frequency in Project Gutenberg, a sizeable monolingual corpus. We collected 1,000 tweets for each stopword. Thus, tweets, including more frequent stopwords, are collected more frequently. A full list of the stopwords and their frequency is shown in Appendix A.1. We used this approach to help mitigate biases found in *OLID*. *OLID* was collected using a predefined list of keywords that were more likely to retrieve offensive tweets. This caused offensive tweets in *OLID* to be explicit and easier to classify. In contrast, the tweets collected in *SOLID* contain implicit and explicit offensive text. This allows us to study the performance of models in hard classification cases.

We used the `langdetect` tool[5] to select English tweets and discarded tweets with less than 18 characters or less than two words. We substituted all user mentions with `@USER` for anonymization purposes. We also ignored tweets with URLs as those don't tend to be offensive and might be less self-contained, e.g., they could have a link to an article, image, video, etc. Understanding such tweets would require going beyond their purely textual content. In total, we collected over 12 million tweets. We kept 9 million as training data, and we created a new test dataset from a portion of the remaining 3 million tweets.

Model	Level A	Level B	Level C
Majority Baseline	0.419	0.470	0.214
BERT	0.816	0.705	0.568
PMI	0.684	0.498	0.461
LSTM	0.681	0.657	0.585
FastText	0.662	0.470	0.590

Table 3: Macro-F1 score of the models in the democratic co-training ensemble on the *OLID* test set.

5.2 Semi-Supervised Training Dataset

We used the democratic co-training setup described in Subsection 4.5 to create the semi-supervised dataset. We first trained each model on the *OLID* dataset using 10% of the training dataset for validation. The performance of the individual models on the *OLID* dataset is shown in Table 3. BERT is the best model for Level A. The PMI model performs almost on par with the LSTM model. We expect this is due to the size of the dataset and the fact that a simple lexicon of curse words would be highly predictive of the offensive content present in a tweet. The performance of the FastText model is the lowest by 2 points. BERT performs best for Level B, followed by the LSTM model. The task is more challenging at this level for the frequency and n-gram-based approaches of PMI and FastText.

Finally, the overall performance of the models at Level C decreases further. This is expected as the size of the dataset becomes smaller, and the task is a three-way classification, whereas Levels A and B are two-way. BERT and LSTM outperform FastText and PMI, with BERT being the best model. The decrease in the performance in the final level can lead to increased noise in the semi-supervised labels, but we use an ensemble of four models, and we provide the average and the standard deviation of the confidence across the models on each instance to mitigate this. As we show later, these scores can be successfully used to filter out a large amount of noise in the semi-supervised dataset, thus yielding performance improvements.

We compute the aggregated single prediction based on the average and the standard deviation of the confidences predicted by each of the models:

	Getting these niggas tatted is a overstatement are ya dead serious	0.700	0.691	0.770	0.491	0.663	0.104	GRP	H

Table 4: Training data aggregation examples. Columns 3-6 show the confidence of each of the models with respect to the positive class in Levels A and B (OFF, UNT) and only for the corresponding class in C (one example for each of the classes: TIN, GRP, OTH). The label column shows manual annotations, and the last column shows whether the tweet is considered Easy (E) or Hard (H) based on its AVG confidence.

$SOLID = \{(x'_i, p'_i)|i \in [1, |SOLID|])\}$, where p'_i = avg$(\{p'^{j}_i | j \in [1, N]\})$, std$(\{p'^{j}_i | j \in [1, N]\})$. In particular, we compute the scores based on the confidences for the positive class at Levels A and B and the confidences for the IND, GRP, and OTH classes at Level C. We performed the above aggregation step instead of just using the scores of each model to avoid over-fitting to any particular model in the ensemble. This helps to prevent biases on individual models in future uses of the dataset. Further, the standard deviation and the average scores can be used to filter instances that the models disagree on, thus reducing potential noise in the semi-supervised annotations.

The dataset is labeled using the semi-supervised manner by assigning a Level A label to all the tweets. Then, we select the subset of tweets that are likely to be offensive for all models (BERT and LSTM $\geq .5$, PMI and FT=OFF) as instances that should be assigned a label for Level B. We chose the tweets likely to be TIN at Level B with a standard deviation lower than 0.25 for Level C. Thus, only the instances that are most likely to be offensive are considered at Levels B and C, and only those that are most likely to be offensive and targeted are considered at Level C. The size and the label distribution across the datasets can be found in Table 2 and examples of tweets along with models' prediction confidences can be found in Table 4.

5.3 *SOLID* Test Dataset

The *OLID* test set is very small, particularly for Levels B and C. Therefore, we also annotated a portion of our held-out 3 million tweets to create a new *SOLID* test set to obtain more stable results and to analyze the performance in more detail.

First, all co-authors of this paper (five annotators) annotated 48 tweets that were predicted to be OFF in order to measure inter-annotator agreement (IAA) using $P_0 = \frac{agreement\_per\_annotation}{total\_annotations*num\_annotators}$. We found IAA to be *0.988* for Level A; an almost perfect agreement for OFF/NOT. The IAA for Level B was *0.818*, indicating a good agreement on whether the offensive tweet was TIN/UNT. Finally, for Level C, the IAA was *0.630*, which is lower but still considered reasonable as Level C is more complicated due to its 3-way annotation schema: IND/GRP/OTH. In addition, a tweet may address targets of different types (e.g., both an individual and a group), but only one label can be chosen.

After having observed high IAA, we annotated additional offensive tweets with a single annotation per instance. We divided our Level A data into four portions based on model confidence:

- *if* BERT $\geq .8 \wedge$ PMI = OFF $\wedge$ FT = OFF $\wedge$ LSTM $\geq .8$ *then* ***Easy*** **OFF** [2380 tweets]
- *else if* BERT $\geq .5 \wedge$ PMI = OFF $\wedge$ FT = OFF $\wedge$ LSTM $\geq .5$ *then* ***Hard*** **OFF** [835 tweets]
- *else if* BERT $\leq .2 \wedge$ PMI = NOT $\wedge$ FT = NOT $\wedge$ LSTM $\leq .8$ *then* ***Easy*** **NOT** [2500 tweets]
- *else if* BERT $< .5 \wedge$ PMI = NOT $\wedge$ FT = NOT $\wedge$ LSTM $< .5$ *then* ***Hard*** **NOT** [278 tweets]

Note, PMI = OFF and FT = OFF designates that the model's probability is higher for the OFF class than for the NOT class. We selected the rest of the thresholds after a manual examination of the confidence scores for each model. We chose the threshold where the model is confident and mostly correct.

We annotated 3,493 tweets for Level A. The

#	Type	Prediction	Tweet	Gold Label
1	Easy	OFF	this job got me all the way fucked up real shit	OFF UNT
2	Easy	OFF	@USER It's such a pain in the ass	OFF UNT
3	Easy	OFF	wtf ari her ass tooo big	OFF TIN IND
4	Easy	NOT	This account owner asks for people to think rationally.	NOT
5	Hard	OFF	It sucks feeling so alone in a world full of people	NOT
6	Hard	OFF	@USER We are a country of morons	OFF TIN GRP
7	Hard	NOT	Hate the sin not the sinner...	NOT
8	Hard	NOT	Somebody come get her she's dancing like a stripper	OFF TIN IND

Table 5: Example tweets from the *SOLID Test* dataset and its four subsets. Shown are the difficulty of each subset (Type), the ensemble model prediction for the examples in each subset (Prediction), an example tweet's text, and the manually annotated gold label.

Type	Model Prediction	Gold Label OFF	Gold Label NOT	Total
easy	OFF	2,187	193	2,380
easy	NOT	0	2,500	2,500
hard	OFF	670	165	835
hard	NOT	145	133	278
Total		**3,002**	**2,991**	**5,993**

Table 6: Statistics of the *SOLID Test* dataset grouped by difficulty (Type) and model prediction.

number of annotations at each level is shown above in square brackets. Furthermore, to create a complete test dataset for Level A (where we only labeled offensive tweets), we also took a random set of 2,500 *Easy* NOT tweets. The resulting test sizes are shown in Table 2. Of the 3,493 annotated tweets, 491 were determined to be NOT. In total, there are 5,993 tweets in our test set. In all cases, all three levels were annotated, but the decision of whether a tweet in Level B/C is *Easy* or *Hard* is still based on its Level A confidence.

Table 5 shows some tweets and whether they are *Easy* OFF/NOT (lines 1-4) or *Hard* OFF/NOT (lines 5-8), and Table 6 shows statistics regarding the Easy and Hard examples in the test dataset. Note that determining the labels for the *Hard* examples is not simple and the model does make incorrect predictions such as in lines 5 and 8 of Table 5. In fact, 25% of the *Hard* OFF tweets that we annotated were NOT. In contrast, 8% of the *Easy* OFF tweets were judged to be NOT.

6 Experiments and Evaluation

In this section we describe our experiments and results when training with *OLID* + *SOLID* data compared to just *OLID* on the *OLID* test set.

6.1 Experimental Setup

We used the BERT and FastText models from the semi-supervised annotation set up to estimate the performance improvements when training on the supervised dataset *OLID* together with the semi-supervised *SOLID*. The models in all sets of experiments were fine-tuned on a 10% validation split of the training set used during co-training. We explored different schemes to combine *OLID* and *SOLID*, as well as different thresholds for the confidence of the instances in *SOLID*. We achieved improvements for Levels B and C by upsampling the underrepresented classes: we sampled K instances of each class, where K is the number of instances for the most frequent class. We also removed the warm-up in Levels B and C, which improved the results further.

FastText. The FastText model used an external command-line tool without control over the training. Therefore, we merged the training splits of *OLID* and *SOLID*, randomly shuffled them, and trained models with the combined dataset. The FastText model has the same parameters used above in co-training.

BERT. Due to the computational requirements of BERT, we subsampled 20,000 tweets from *SOLID* in Level A and B for BERT. Including more semi-supervised instances did not improve the performance. During training, we used *SOLID* in the first epoch and *OLID* in the following two epochs for Level A. Using *SOLID* after training with *OLID* yielded worse results. We assume this can be explained by the fact that the semi-supervised dataset by construction contains labels that are not golden truth. It can be used as an initial step to guide the model towards a better local minimum. On the other hand, we conjecture that the supervised

Level	Baseline	BERT		FastText	
		OLID	*+SOLID*	*OLID*	*+SOLID*
A	0.419	**0.816**	0.809	0.662	**0.720**
B	0.470	0.687	**0.729**	0.470	**0.591**
C	0.214	0.589	**0.643**	**0.590**	0.515

Table 7: Macro-F1 score on the *OLID* test set for BERT and FastText with and without training on *SOLID* compared to the majority class baseline.

	Model	Baseline	BERT		FastText	
			OLID	*+SOLID*	*OLID*	*+SOLID*
A	Full	0.338	0.922	**0.923**	0.856	**0.860**
	Easy	0.400	0.983	**0.983**	0.936	**0.940**
	Hard	0.444	0.557	**0.570**	0.525	**0.536**
B	Full	0.236	0.559	**0.666**	0.355	**0.493**
	Easy	0.232	0.569	**0.677**	0.349	**0.509**
	Hard	0.234	0.542	**0.649**	0.363	**0.467**
C	Full	0.203	0.627	**0.645**	0.387	**0.504**
	Easy	0.201	0.635	**0.644**	0.378	**0.504**
	Hard	0.205	0.616	**0.649**	0.397	**0.505**

Table 8: Experimental results (macro-F1 scores) on the *SOLID Test* dataset, and on its Easy and Hard subsets, compared to the majority class baseline.

dataset is better suited for fine-tuning the model towards the local minimum with the gold data, particularly in Level A, where the training split of *OLID* is already sufficient for training BERT. For Levels B and C, we trained for two epochs with the training split of *OLID* and then for one epoch with *SOLID*. At Levels B and C, we observed that training with *SOLID* in the first epochs and then fine-tuning with *OLID* did not improve the performance. Furthermore, training with *OLID* and then using *SOLID* for the final epochs yielded substantial performance improvements. We assume this is due to the small training size of *OLID* which can cause the model to overfit to a suboptimal local minimum when used in the final training epochs.

Selecting *SOLID* Instances. We filter the training instances from *SOLID* to be the most confident examples based on the average probability score provided in *SOLID* when training with FastText and BERT. We choose the threshold for the average confidence score based on the validation dataset as follows:

Level A: $avg(\text{OFF}) < 0.20 \cup avg(\text{OFF}) > 0.70$
Level B: $avg(\text{UNT}) < 0.35 \cup avg(\text{UNT}) > 0.65$
Level C: $avg(\text{IND}) > 0.80 \cup avg(\text{GRP}) > 0.70 \cup avg(\text{OTH}) > 0.65$

To select a label for each instance, we choose: NOT when $avg(\text{OFF}) < 0.20$, otherwise OFF in Level A; UNT when $avg(\text{UNT}) > 0.65$, otherwise TIN in Level B; the class with the highest probability in Level C.

6.2 *OLID* Results

In this section we describe our results on the *OLID* test set using just *OLID* and adding *SOLID*. The results are shown in Table 7.

The results for Level A are improved only with FastText, which is a weaker model (see Table 3). It leverages a large performance improvement when trained with *OLID+SOLID*. On the other hand, the BERT model already achieves high performance without augmenting *OLID* with *SOLID* because *OLID* is large enough for Level A. As a result, including semi-supervised data did not improve the performance. Our findings are in line with the study of Longstaff et al. (2010), who observed that democratic co-training performs well when the initial classifier's accuracy was low.

The *OLID* training dataset is smaller for Level B, and the task is more complex. Moreover, the FastText model here performs on par with the majority class baseline. Augmenting *OLID* with *SOLID* yields performance improvements for both models. We achieve an improvement of 0.042 points for BERT and a large margin of improvement of 0.121 points for FastText.

Finally, in Level C, the supervised *OLID* data is even smaller, and the complexity of the subtask is more pronounced, mainly due to it having three possible labels. Interestingly, using *SOLID* for FastText does not yield better results. This might be due to the model already achieving high performance on par with BERT (see Table 3), while democratic co-training performs well when the initial classifier's performance is low. Additionally, this may be due to the instability of the test set for Level C, which is very small. On the other hand, the *SOLID* data helps the BERT model by a large margin of 0.054 points.

6.3 *SOLID* Results

In the previous section, we showed noticeable improvements on the *OLID* dataset using *SOLID*. However, *OLID* is small (particularly for Levels B and C). Showcasing the performance on a larger test set, *SOLID* test, is important for estimating the models' stability. We also focus on *Easy* vs. *Hard* examples (based on the confidence computed during co-training) to gain better insight into why some tweets are easier to predict as offensive than others. Results are shown in Table 8 and significantly beat the majority baselines.

The overall Level A results on *SOLID* test are 92.3% and 86.0% macro-F1 for BERT and FastText, respectively, with a small improvement when *OLID* is augmented with *SOLID* for FastText only. This is consistent with what we found on the *OLID* test set. Note that the full results for Level A are much better than on the OLID dataset in Table 7. We expect that this is partially due to our selection of tweets for the new test set, indicating that there are more *Easy* tweets in it. Similar findings to the full test set occur with the *Easy* tweets, but the scores are even higher. On the other hand, for the *Hard* tweets, the results are much lower at 57% and 53.6% for BERT and FastText, respectively. Using *SOLID* yields a nice improvement for both models on the *Hard* tweets, which was not evident in the *OLID* test set in Table 7.

To provide further insight into why the results are so high for *Easy* OFF tweets in Level A, we implemented a curse word baseline using the absence or presence of 22 curse words like *fuck*, *bitch*, and *nigga*. A full list of the curse words used in the baseline can be found in Appendix A.1. We found that most *Easy* tweets were classified correctly with this baseline with 93.6% F1-score. In contrast, the curse word baseline was not effective on the hard examples, just like the BERT and FastText models. It achieved a macro-F1 score of 58%, which is one point higher than the BERT result. The BERT and FastText models are clearly overfitting to the curse words. The *hard* tweets are offensive due to other language use such as negative biases rather than the appearance of a curse word such as examples 6 and 8 in Table 5. Classifying these tweets successfully remains an open challenge.

The difference between *Easy* OFF/NOT and *Hard* OFF/NOT tweets is less pronounced for Levels B and C. The curse word imbalance may have a small impact on the lower levels as UNT tweets are more likely to contain curse words. In all cases, including *SOLID* with *OLID* for Levels B and C yields a nice improvement, indicating that the larger test set can better showcase the improvements, leading to more stability. The results for Levels B and C vary greatly for the two models compared to those on the *OLID* test set in Table 7, which points to the challenges of having a very small test set.

7 Conclusion and Future Work

We presented *SOLID*, a large-scale semi-supervised training dataset for offensive language identification, which we created using an ensemble of four different models. To the best of our knowledge, *SOLID* is the largest dataset of its kind, containing nine million English tweets. We have shown that using *SOLID* yields noticeable performance improvements for Levels B and C of the OLID annotation schema, as measured on the *OLID* test set. Furthermore, in contrast to using keywords, our approach allows us to distinguish between *Hard* and *Easy* offensive tweets. The latter enables us to have a deeper understanding of offensive language identification and indicates that detecting *Hard* offensive tweets is still an open challenge. Our work encourages safe and positive places on the web that are free of offensive content, especially non-obvious cases (i.e., *Hard*). *SOLID* is the official dataset of the SemEval shared task OffensEval 2020 (Zampieri et al., 2020). In the future, we would like to provide insights and methods for categorizing *Hard* tweets.

Acknowledgements

We would like to thank the anonymous reviewers who provided us with constructive and insightful feedback to further improve the quality of the paper. PA has received funding from the European Union's Horizon 2020 research and innovation programme under the Marie Skłodowska-Curie grant agreement No 801199. This work is also part of the Tanbih mega-project, developed at the Qatar Computing Research Institute, HBKU, which aims to limit the impact of "fake news," propaganda, and media bias by making users aware of what they are reading.

Ethics Statement

Dataset Collection The *OLID* and the *SOLID* datasets were collected using the Twitter API[6]. The *OLID* dataset was collected using keywords that would be more likely to be accompanied with offensive tweets (Zampieri et al., 2019a). The *SOLID* dataset was collected using frequent stop words (See Section 5) intending to aid in detecting offensive tweets in English only, We follow the terms of use outlined by Twitter[7]. Specifically, we only

---

[6] `http://developer.twitter.com/en/docs`

[7] `http://developer.twitter.com/en/developer-terms/agreement-and-policy`

download public tweets and we provide only the user ids of the tweets to ensure that deleted tweets will no longer be available in our dataset. Further, in all our examples in this paper, we anonymize the user names in the tweets. Since no private information is stored, IRB approval is not required. All annotations were performed internally by the authors of the paper.

Biases *SOLID* is a large-scale semi-supervised dataset for offensive language detection We note that determining whether a piece of text is offensive can be subjective, and thus it is inevitable that there would be biases in our gold-labeled data. It is expected that these biases will, therefore, also be present in the semi-supervised dataset we generated from such tweets.

While we cannot ensure that no biases occur in the gold data, we address these concerns by following a well-defined schema, which sets explicit definitions for offensive content during annotation. Our high inter-annotator agreement makes us confident that the assignment of the schema to the data is correct most of the time.

Using semi-supervised techniques to create a large dataset, *SOLID*, can cause the biases found in the gold data to be expanded further. We mitigate this in two ways. First, we gather tweets based on the most frequent words in English to ensure a random set of initial tweets. Next, we construct an ensemble of models with diverse inductive biases to label the target tweet, which can help to ameliorate the individual model biases and to produce predictions with a lower degree of noise. At test time, we aim to have a meaningful ratio of offensive and non-offensive tweets based on a random collection of tweets. We also label all test offensive tweets manually. The aim of these steps was to help reduce the potential biases. Please refer to Section A.2 of the Appendix for some analysis that indicates the diversity of the models.

We acknowledge that current semi-supervised techniques do not address the problem of the bias inherent in the semi-supervised data coming from the supervised source model(s), which can also be studied in future work. Further, we acknowledge that biases can still exist in the ratio of offensive/non-offensive tweets. The size of the data and the method of collection for the SOLID dataset mean that biases are hard to avoid.

In addition, offensive language can vary depending on demographics, such as the gender of the targeted individual and the target can even be a particular gender group. Such biases that are present in natural language data (Olteanu et al., 2019) is an attractive future study.

Misuse Potential Most datasets compiled from social media present some risk of misuse. We therefore ask researchers to be aware that the *SOLID* dataset can be maliciously used to unfairly moderate text (e.g., a tweet) that may not be offensive based on biases that may or may not be related to demographics and other information within the text. Intervention with human moderation would be required in order to ensure this does not occur.

Intended Use We present *SOLID* to encourage research in automatically detecting and stopping offensive content from being disseminated on the web. Such systems can be used to alleviate the burden for media moderators, which can suffer from psychological disorders due to the exposure of extremely offensive content. Improving the performance of offensive content detection systems can decrease the amount of work for moderators, but human supervision is required for more intricate cases and to ensure that the system is not causing harm. With the possible ramifications of a highly subjective dataset, we distribute *SOLID* for research purposes only, without a license for commercial use. Any biases found in the dataset are unintentional, and we do not intend to cause harm to any group or individual.

We believe that this dataset is a useful resource when used in the appropriate manner with great potential to improve the performance of current offensive content detection systems.

A Appendices

A.1 Data Collection and Analysis

Section 5.1 we described our method for collecting tweets. We collect tweets using the most frequent English words based on the large monolingual Project Gutenberg corpus.[8] Table 9 shows the top-20 most frequent words in the corpus and their frequency which we used to collect tweets. The normalized value is the percentage of the total frequency for all top 20 words. We randomly pick a number between 0 and 1, and choose the word based on the normalized value. For example, .45 would be "and".

In Section 6.3, we discussed the simple curse word baseline used to analyze the *Easy* OFF/NOT tweets. Table 10 lists the 22 curse words used in the baseline.

A.2 Implementation Details

The fine-tuning of the models was performed on a 10% split from the *OLID* dataset. All models were trained on an NVIDIA Titan X GPU with 8GB of RAM.

Table 10: The 22 common offensive terms used in the curse word baseline.

The evaluation metric used for all experiments is macro F1 from scikit-learn.[9]. The performance of the models in the ensemble used for semi-supervised labelling is provided in Table 11.

Model	**A**	**B**	**C**
BERT	0.788	0.610	0.577
PMI	0.772	0.595	0.536
LSTM	0.599	0.599	0.579
FastText	0.672	0.489	0.456

Table 11: F1 score performance of each model used in the ensemble on the validation dataset of Levels A, B, and C.

In Table 12 we show the agreement of the models for the task prediction. For Levels A and B, it is more common that all four models agree, while in Level C, there are more cases when at least one model disagrees with the rest models. Furthermore, in Level A, there are almost no cases when the decision is tied with two models disagreeing with the other two. Finally, as in Level C, the performance of the models is lower, the disagreement between the models in the ensemble is the largest and it is least common for all four models to agree on

RealFormer: Transformer Likes Residual Attention

Ruining He, Anirudh Ravula, Bhargav Kanagal, Joshua Ainslie
Google Research
{ruininghe,braineater,bhargav,jainslie}@google.com

Abstract

Transformer is the backbone of modern NLP models. In this paper, we propose **RealFormer**, a simple and generic technique to create **Re**sidual **A**ttention **L**ayer Trans**former** networks that significantly outperform the canonical Transformer and its variants (BERT, ETC, etc.) on a wide spectrum of tasks including Masked Language Modeling, GLUE, SQuAD, Neural Machine Translation, WikiHop, HotpotQA, Natural Questions, and OpenKP. We also observe empirically that RealFormer stabilizes training and leads to models with *sparser* attention. Source code and pre-trained checkpoints for RealFormer can be found at `https://github.com/google-research/google-research/tree/master/realformer`.

1 Introduction

Transformer (Vaswani et al., 2017) architectures are the backbone of numerous state-of-the-art NLP models such as BERT (Devlin et al., 2019), GPT (Radford et al., 2019), and Meena (Adiwardana et al., 2020), and have seen wide success across both academia and industry. Typically, a Transformer network consists of a stack of residual layers. The original design follows a "Post-LN" structure which adds Layer Norm (LN) as a "post-processing" step for each sub-layer, as shown in Figure 1 (a). It has been adopted by various state-of-the-art models including BERT, XLNet (Yang et al., 2019), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2019), Transformer-XL (Dai et al., 2019), and ETC (Ainslie et al., 2020). Another notable design is to reorganize the order of modules to create a "direct"/clean path to propagate embeddings of tokens in the input sequence through the whole network, as shown in Figure 1 (b).[1] This design adds LN as a "pre-processing" step for each sub-layer, and is often referred to as "Pre-LN" and used by some well-known extra large models such as GPT-2 (Radford et al., 2019) and Megatron (Shoeybi et al., 2019). In some respect, Post-LN and Pre-LN are analogous to ResNet v1 (He et al., 2016a) and ResNet v2 (He et al., 2016b) respectively in the Computer Vision literature. Although ResNet v2 is usually preferable to v1 for Computer Vision, it does not appear to be the case for Pre-LN Transformer in the NLP literature. It is likely that the particularities of self-attention modules and Transformer architectures potentially favor (at least slightly) different designs compared to traditional convolutional neural networks.

In this paper, we propose a simple and generic technique to show that it is beneficial to create a "direct" path to propagate raw attention scores through Transformer-based networks. Our technique is called ***Re**sidual **A**ttention **L**ayer Trans**former***, or ***RealFormer*** in short. We also use *RealFormer* to denote the resulting Transformer networks whenever no confusion may arise. Without losing generality, taking the standard Transformer encoder as an example, each RealFormer layer takes the raw attention scores of all attention heads from the previous layer and adds "residual scores" (computed the same way as attention scores in regular Transformers) on top, as shown in Figure 1 (c). The sum of the two scores is then used to compute attention probabilities via softmax.

In other words, RealFormer can be seen as adding simple skip connections to a backbone Transformer. Since it does not add expensive multiplication ops, performance is expected to be comparable.[2] Note that our technique can also be applied straightforwardly for different Transformer varia-

---

[1] Note that a final LN module is usually added at the very top of the whole network.

[2] In certain settings, we find it helpful for RealFormer to use running *mean* of attention scores instead of running *sum*, though it adds some negligible amount of multiplications.

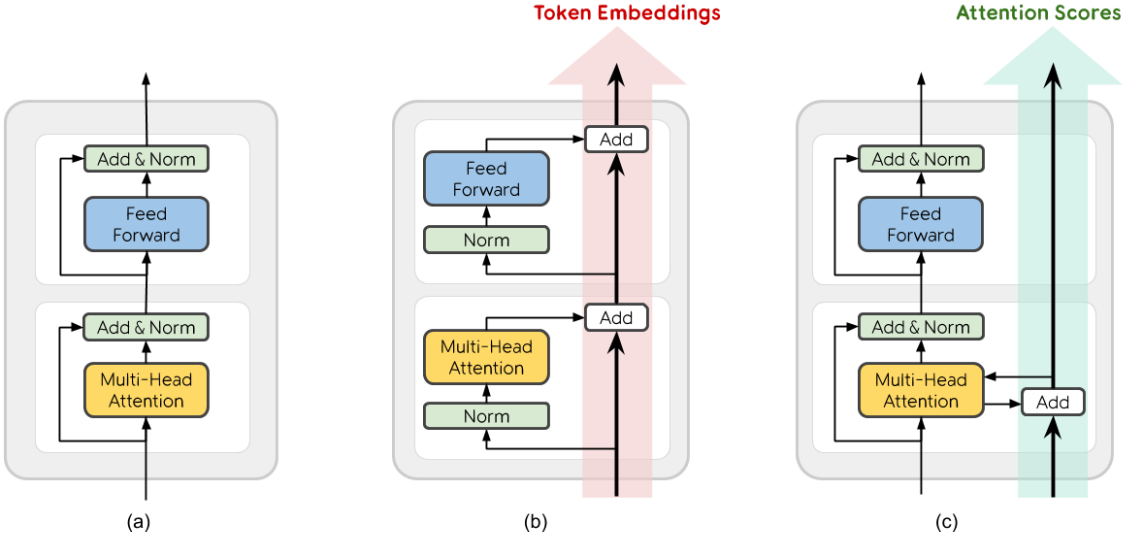

Figure 1: Comparison of different styles of Transformer layers: (a) The prevalent Post-LN layer used by (*e.g.*) BERT; (b) Pre-LN layer used by (*e.g.*) GPT-2 that creates a "direct" path to propagate token embeddings; (c) Our RealFormer layer that creates a "direct" path to propagate attention scores (by adding a simple skip edge on top of (a)). Note that here we are showing Transformer encoder for demonstration purposes only; RealFormer can be applied straightforwardly for different Transformer variations (*e.g.*, when decoders are involved).

tions and even when decoders are involved.

Specifically, our main contributions include:

- We present RealFormer, a simple, generic, and cheap technique to improve Transformer-based networks. It adds no parameters or hyper-parameters, and usually takes no more than a few lines of code changes to implement.

- We show that RealFormer can be used as a drop-in replacement of Transformer in BERT, outperforming both Post-LN and Pre-LN Transformers across a wide spectrum of model sizes for pre-training. In terms of fine-tuning, it even achieves competitive downstream results when pre-trained with only half the number of epochs of the baselines.

- We further demonstrate the genericity of RealFormer by using it as a drop-in replacement of two recent state-of-the-art Transformer variation models: ADMIN (Liu et al., 2020) from the Neural Machine Translation (NMT) domain, and ETC (Ainslie et al., 2020) that extends Transformer to handle long and structured inputs. We show that RealFormer can improve these models significantly on various tasks and lead to new state-of-the-art results.

- Qualitatively, we observe that attention in RealFormer tends to be *sparser* and more correlated across layers compared to baselines, which we believe may have some regularization effects that could stabilize training and benefit fine-tuning.

2 Related Work

Vaswani et al. (2017) proposed Transformer initially for NMT and it has profoundly changed the NLP field ever since.

Radford et al. (2018) demonstrated that generative pre-training of a Transformer-based language model (GPT) on a diverse corpus of unlabeled text can give large gains to downstream NLP tasks that suffer from scarce labeled data. Following this thread, Devlin et al. (2019) proposed to pre-train a *bidirectional* Transformer encoder (BERT) with a novel Masked Language Modeling as the main optimization objective. Since then, advances on many NLP tasks have been dominated by the self-supervised general-purpose pre-training, task-specific fine-tuning paradigm. Following BERT, there has been a large stream of work that explores better self-supervision objectives (*e.g.*, Yang et al. (2019); Clark et al. (2020)), larger pre-training data and better hyper-parameters (*e.g.*, Liu et al. (2019)), model parameter sharing (*e.g.*, Lan et al. (2019)), multi-task pre-training (*e.g.*, Sun et al. (2020); Raffel et al. (2020)). These efforts typically employ a Post-LN Transformer at their core. In this paper we adopt BERT to test different Transformer architectures because it is widely used and representative of this body of work.

Another notable thread of work focuses on improving the efficiency/scalability of Transformer. Typically, they try to reduce the *quadratic* complexity of the self-attention mechanism with respect to sequence length via low-rank methods (*e.g.*, Wang et al. (2020)), fixed strided attention patterns (*e.g.*, Child et al. (2019)), learnable attention patterns (*e.g.*, Kitaev et al. (2020); Roy et al. (2020)), memory-based global & local attention (*e.g.*, Ainslie et al. (2020); Beltagy et al. (2020); Zaheer et al. (2020)), and so on. These methods are particularly useful when dealing with long documents that go beyond the capacity of standard Transformer models. We would refer the reader to Tay et al. (2020) for a detailed survey. RealFormer is orthogonal to these methods as it focuses on improving various Transformer networks with an universal technique which can apply to these models as well. In this paper, we will use RealFormer to improve a state-of-the-art model, ETC (Ainslie et al., 2020), from this line of work to demonstrate the universality of RealFormer.

Some recent work (*e.g.*, Wang et al. (2019b); Xiong et al. (2020); Zhang et al. (2018); Huang et al. (2020); Zhang et al. (2019)) has studied normalization and parameter initialization schemes for Transformers, though most evaluations focus only on NMT to the best of our knowledge. In this strand, Liu et al. (2020) recently proposed ADMIN, which achieved state-of-the-art results on multiple popular NMT benchmarks. In this paper, we will take ADMIN as an example to (1) evaluate RealFormer in settings involving decoders, and (2) show that it is possible to apply RealFormer on top of this line of work.

3 RealFormer

3.1 Standard Transformer

There is an encoder and a decoder in Transformer (Vaswani et al., 2017). Since they work in a similar way, here we only introduce the encoder and refer the reader to the original paper for complete details.

There are two sub-layers inside each layer of a Transformer encoder. The first sub-layer contains a Multi-Head Attention module that computes output embeddings of a set of queries (Q) by aggregating the embeddings (V) of a set of keys (K):

$$\begin{aligned}\text{MultiHead}\,(Q, K, V) = \\ \text{Concat}\,(head_1, ..., head_h)\, W^O,\end{aligned}$$

where $head_i = \text{Attention}\,(QW_i^Q, KW_i^K, VW_i^V)$. Q and K are matrices with dimension d_k and V is a matrix with dimension d_v. W_i^Q, W_i^K, and W_i^V are matrices that linearly project queries, keys, and values into the "attention space" of the i-th head. W^O is a matrix that linearly transforms the concatenation of the outputs of all heads.

The attention function is typically implemented with a Scaled Dot-Product Attention module (Vaswani et al., 2017) which computes a weighted sum of the values:

$$\text{Attention}\,(Q', K', V') = \text{Softmax}\,(\frac{Q'K'^T}{\sqrt{d_k}})\, V',$$

where matrix $\frac{Q'K'^T}{\sqrt{d_k}}$ contains the raw attention scores for each (query, key) pair. These scores are normalized via the Softmax function for each query and then act as weights for the corresponding vectors in V'.

The second sub-layer contains a fully-connected Feed-Forward Network (FFN) module with one hidden layer:

$$\text{FFN}\,(x) = \sigma\,(x\,W_1 + b_1)\,W_2 + b_2,$$

where σ is an activation function usually implemented with ReLU or GELU (*e.g.*, Devlin et al. (2019)). FFN is applied to each position in the sequence separately and identically. Finally, there are Layer Norm (LN) modules inserted into the above two sub-layers to stabilize training.

As shown in Figure 1, there are two canonical designs of the Transformer network which only differ in the ways they organize the modules. Post-LN is the original architecture proposed by Vaswani et al. (2017) which normalizes the outputs at the end of each sub-layer. In contrast, Pre-LN normalizes sub-layer inputs instead and creates a direct path (without LN in the way) to propagate embeddings of the tokens in the sequence.

3.2 Residual Attention Layer Transformer

RealFormer uses a Post-LN style Transformer[3] as backbone and adds skip edges to connect

---

[3] Potentially we could also use Pre-LN, but Post-LN tends to outperform Pre-LN, as we will show in Section 4.

Multi-Head Attention modules in adjacent layers, as shown in Figure 1 (c). More formally, it adds $Prev$, the pre-softmax attention scores from the previous layer with shape $(\#heads, from\_seq\_len, to\_seq\_len)$,[4] as one additional input to the Multi-Head Attention module in the current layer:

$$\begin{aligned}&\text{ResidualMultiHead}\left(Q, K, V, Prev\right) = \\ &\qquad \text{Concat}\left(head_1, ..., head_h\right) W^O,\end{aligned}$$

where $head_i = \text{ResidualAttention}\left(QW_i^Q, KW_i^K, VW_i^V, Prev_i\right)$ and $Prev_i$ is the slice of $Prev$ with shape $(from\_seq\_len, to\_seq\_len)$ corresponding to $head_i$. ResidualAttention adds "residual scores" on top of $Prev_i$ and then computes the weighted sum as usual:

$$\begin{aligned}&\text{ResidualAttention}\left(Q', K', V', Prev'\right) = \\ &\qquad \text{Softmax}\left(\frac{Q'K'^T}{\sqrt{d_k}} + Prev'\right) V'.\end{aligned} \tag{1}$$

Finally, new attention scores $\frac{Q'K'^T}{\sqrt{d_k}} + Prev'$ are passed over to the next layer.

Implementing RealFormer takes no more than adding a few lines of code to the backbone Transformer. Note that the RealFormer technique can be straightforwardly applied for Transformer variations and even when there are more than one type of attention modules in the network. For example, there are encoder self-attention, encoder-decoder attention, and decoder self-attention modules for machine translation. In such cases, RealFormer simply adds skip edges to create *multiple* direct paths, one for each type of attention module.

Discussion. Adding skip edges is equivalent to using a softmax over the running sum of the attention scores (to get attention probabilities). This might be sub-optimal for very deep networks due to the linear scaling nature of sum. Empirically, we find it helpful to use running *mean* instead in such cases, which can be viewed as adding a temperature (*i.e.*, #traversed layers) to the softmax function in Eq. 1 of each RealFormer layer.

4 Experiments

To demonstrate that RealFormer is general-purpose, we conduct comprehensive empirical studies on a variety of tasks including (masked) language modeling, machine translation, and long document modeling, based on corresponding state-of-the-art models: BERT, ADMIN, and ETC. To evaluate its robustness, we only do minimal (if at all) hyper-parameter tuning for RealFormer and initialize all parameters the same way as the backbone Transformers. More aggressive hyper-parameter tuning or better initialization might further improve RealFormer, though we leave them for future work. Details of our experiments are included in Appendix.

4.1 BERT

BERT (Devlin et al., 2019) has been the standard way of transferring knowledge from large unlabeled text corpora by pre-training a bidirectional Transformer encoder. Numerous downstream NLP tasks suffering from scarcity of supervised data have benefited considerably by fine-tuning a pre-trained BERT model. This drives us to adopt BERT as the main evaluation setup for RealFormer.

Experiment setup. Our experiments are based on the official BERT repository[5]. We follow the standard pre-training setup (dataset: Wikipedia + BookCorpus, vocab: uncased 30K, max sequence length: 512[6], dropout: 10%, learning rate: 1e-4, learning rate schedule: warm up and then linearly decay to 0, weight decay: 0.01, optimizer: AdamW, objective: Masked Language Modeling + Next Sentence Prediction, etc.) to compare three Transformer models: Post-LN, Pre-LN, and RealFormer. We experiment with Transformer architectures with a wide spectrum of sizes as detailed in Table 1. For simplicity, all models are pre-trained 1M steps with a mini-batch size of 512 (except that xLarge uses 256 to avoid TPU OOM). Note that we use a larger mini-batch size than Devlin et al. (2019), *i.e.*, doubling the amount of pre-training epochs, to show more complete behavior of different models.

We use exactly the same setup for all three Transformer architectures except that for the Pre-LN Transformer we follow the initialization strategy suggested by Radford et al. (2019) and Child et al. (2019).[7] Note that for simplicity RealFormer reuses all hyper-parameter setups from Post-LN Transformer unless otherwise specified. We use running sum of attention scores for all RealFormer

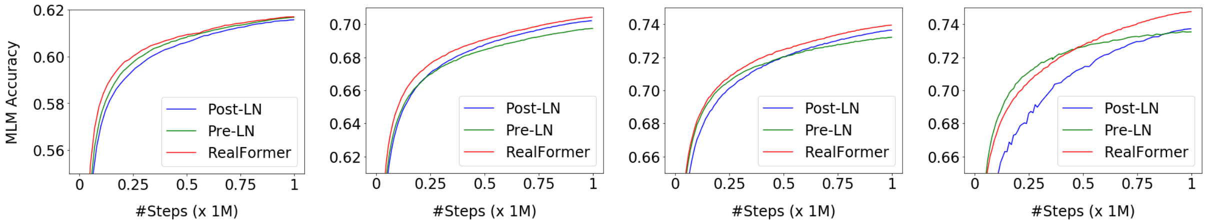
---

[4] Batch dimension is omitted for ease of discussion.

[5] `https://github.com/google-research/bert`

[6] Unlike BERT which uses a reduced sequence length for the first 90% of steps, we always use 512 for simplicity.

[7] We also tried BERT-style initialization in our pilot experiments but without success.



(a) BERT-Small (b) BERT-Base (c) BERT-Large (d) BERT-xLarge

Figure 2: Development set MLM accuracy (best viewed in color). Improvement gap of RealFormer over the best baseline tends to increase with model size. Note that these are without hyper-parameter tuning for RealFormer. (As we will show later, RealFormer can benefit from larger learning rates and even double the gap size over Post-LN.)

Model	**L**	**H**	**A**	**I**	**P**
BERT-Small	4	512	8	2,048	30M

BERT-Small	61.57%	61.67%	**61.70%**
BERT-Base	70.20%	69.74%	**70.42%**
BERT-Large	73.64%	73.21%	**73.94%**
BERT-xLarge	73.72%	73.53%	**74.76%**

Table 2: Development set MLM accuracy after pre-training 1M steps. RealFormer outperforms baselines more as model size increases.

models except xLarge (for which we use running mean for reasons discussed in Section 3.2).

All experiments are performed on 128 or 256 TPU v3 cores depending on model sizes (see Appendix A.1 for details).

4.1.1 Pre-training Results

To evaluate pre-trained models, we report Masked Language Modeling (MLM) accuracy[8] on a randomly held-out development set. As shown in Table 2, RealFormer outperforms the two baseline Transformers considerably with the gap increasing with model size. Our hypothesis is that larger models are inherently harder to train (*e.g.*, we observe that BERT with Post-LN is unstable and sometimes even diverges for xLarge) and RealFormer can help regularize the model and stabilize training.

We also report the pre-training curves in Figure 2. One interesting finding is that the Pre-LN Transformer seems to favor the combination of extra large models and a small number of steps, though it is consistently outperformed by the other two in "regular-sized" settings or given enough pre-training budget.

4.1.2 Downstream Results

To evaluate downstream performance, we fine-tune the above pre-trained BERT-Large models on both sentence-level (*i.e.*, GLUE) and token-level (*i.e.*, SQuAD) NLP tasks.

GLUE. General Language Understanding Evaluation (GLUE) is a canonical benchmark proposed by Wang et al. (2019a) for evaluating models across a diverse set of NLU tasks. Following the fine-tuning recipe in Devlin et al. (2019), we use a mini-batch size of 32 for all models on all tasks. For each (task, model) pair, we select number of fine-tuning epochs in {2, 3, 4} and learning rate in {6e-6, 8e-6, 1e-5, 2e-5, 3e-5, 4e-5, 5e-5}.[9] For each setup, we run the experiment five times and report the best median performance and the corresponding standard deviation on the development set.

Results are tabulated in Table 3. We exclude the problematic WNLI task following Devlin et al. (2019). For each task, we report metric(s) suggested by Wang et al. (2019a). RealFormer achieves the best overall performance and outperforms both baselines on most tasks, testifying its strength at tackling sentence-level tasks.

SQuAD. The Stanford Question Answering Dataset (SQuAD v1.1) is a reading comprehension dataset consisting of 100K crowd-sourced question-answer pairs, where the answer to each question is

---

[8] All methods achieved similar (and great) results on Next Sentence Prediction presumably because it is much easier.

[9] We use a slightly wider range than Devlin et al. (2019) to better accommodate all three models.

4.1.3 Research Questions

How well does RealFormer perform with half the pre-training budget? Although RealFormer has outperformed both Post-LN and Pre-LN considerably when pre-training 1M steps, we are also interested in investigating its potential when the pre-training budget is more limited. For this purpose, we experiment with BERT-Large models. In particular, we take the 500K step checkpoint of the pre-trained RealFormer in Table 2 and fine-tune it on GLUE and SQuAD datasets using exactly the same procedure as described above. Comparison results against the strongest baseline, Post-LN Transformer pre-trained 500K (checkpoint) and 1M steps respectively, are collected in Table 5. We can see that RealFormer with merely half the amount of pre-training epochs can beat Post-LN (1M) on GLUE with a significant margin, and almost match its performance on SQuAD.

Does a larger learning rate help? As suggested by some recent work (*e.g.*, Xiong et al. (2020)), Pre-LN Transformer may benefit from using larger learning rates. To this end, we follow the pre-training procedure detailed earlier and switch to a larger learning rate, 2e-4, to pre-train BERT-Large with the three Transformer models. Development set MLM accuracy with training steps can be found in Figure 3. We find that both Pre-LN and RealFormer can reap some benefits of using larger learning rates with RealFormer seeming to benefit slightly more in this case (73.94% → 74.31%) compared to Pre-LN (73.21% → 73.46%). Post-LN diverges with the learning rate of 2e-4. Note that it also means that RealFormer can outperform Post-LN, the strongest baseline, actually with a

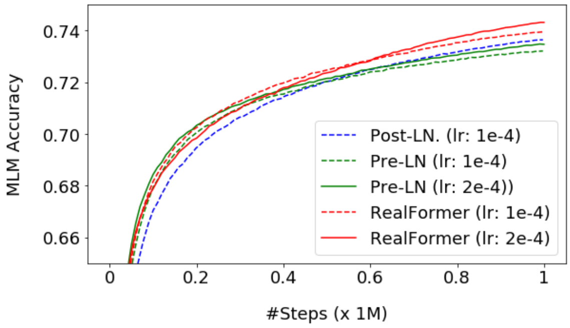

Figure 3: Development set MLM accuracy of BERT-Large with different learning rates (best viewed in color). RealFormer seems to benefit slightly more from using a larger, non-default learning rate compared to Pre-LN, while Post-LN diverges with 2e-4.

prominent gap, 0.67% (*i.e.*, 74.31% - 73.64%), for pre-training, though with only minimal learning rate tuning.

Is attention sparser in RealFormer? We conduct one empirical study to observe the qualitative differences between RealFormer and Post-/Pre-LN Transformers. We randomly sample 8,192 examples from the held-out development set and visualize the distribution of attention probabilities of each token in these examples across heads in all layers. In particular, for each (token, layer, head) triplet, we compute the entropy of the attention probabilities as the "sparsity measure" of attention. Intuitively, as entropy gets lower, the attention weight distribution becomes more skewed and therefore attention is sparser.

In a similar fashion to Ramsauer et al. (2020), we use violin plots to show the entropy distributions of the pre-trained BERT-Base model with RealFormer from Table 2 (see Figure 4). Plots for the two baseline Transformers in Table 2 are included in Appendix A.4. Each row is a layer in BERT-Base and each column is an attention head.

We find that attention tends to get sparser for later (upper) layers for all three Transformers. However, RealFormer differs from the two baselines in the following ways:

- RealFormer has *significantly sparser* attention for top layers (layer 9-11);
- RealFormer tends to have lower variance across all layers, which means that attention density is less input-dependent.

We hypothesize that the above two properties might be a sign of stableness and benefit fine-tuning.

Dropout	Post-LN	Pre-LN	RealFormer
0%[10]	71.16%	69.80%	**71.30%**
10%	73.64%	73.21%	**73.94%**
20%	73.21%	72.97%	**73.66%**

Table 6: Development set MLM accuracy of BERT-Large with different dropout rates.

Do attention heads in layer L resemble those in layer $L-1$? Since RealFormer uses a residual attention scheme, it is interesting to show to what extent an attention head is "relying on" the corresponding head in the previous layer. To this end, we take each of the three pre-trained BERT-Base models in Table 2 and compute the Jensen-Shannon Divergence (JSD) between attention probabilities in each pair of *vertically* adjacent heads, *i.e.*, JSD $(\text{head}_i^L, \text{head}_i^{L-1})$, for $1 \leq L < 12$ and $0 \leq i < 12$.

Appendix A.5 demonstrates detailed JSD distributions of Post-LN and RealFormer respectively based on 8,192 held-out examples. We observe that RealFormer tends to have *significantly lower* JSD values (*i.e.*, indicating more "similar" attention across layers), especially for heads in middle layers. This might mean that RealFormer has some regularization advantages and provides one hypothesis for why it tends to outperform Post-LN more for larger models. Note that head_i^L can still be useful even if it has exactly the same attention probabilities with head_i^{L-1} because of the existence of the FFN sublayer and the potential differences in value matrices (*i.e.*, V' in Eq. 1).

Is residual attention really necessary? One may wonder whether increasing dropout rate can already regularize large models well so that residual attention is redundant. To this end, we experiment with different dropout rates for pre-training BERT-Large with different Transformers (following the procedures in Section 4.1.1). Results are collected in Table 6, from which we can see that (1) RealFormer outperforms the two baselines across all dropout settings, and (2) simply increasing dropout rate can not regularize Transformer models as well as what residual attention appears to be doing.

4.2 ADMIN

To evaluate the genericity of RealFormer, here we try it on top of ADMIN (Liu et al., 2020), a state-of-

---

[10] When dropout rate is 0%, we use early stopping for all models due to overfitting.

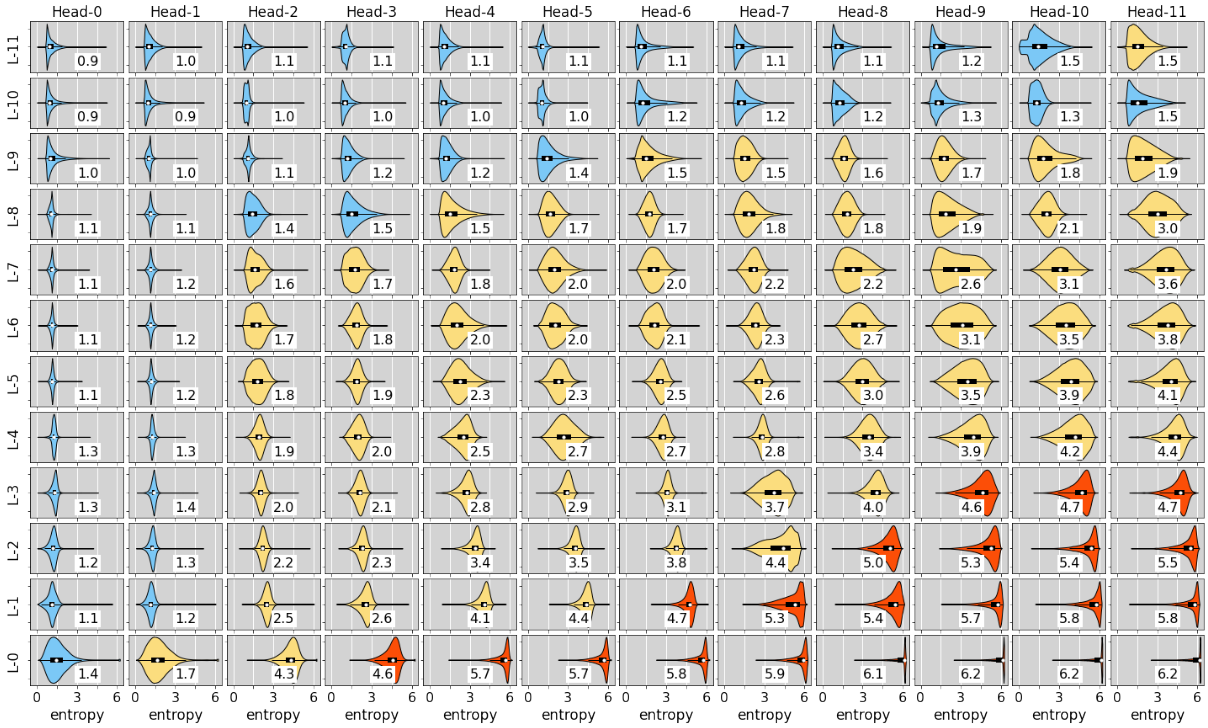

Figure 4: Distribution of entropies of the attention probabilities of the tokens of 8,192 held-out examples using the pre-trained BERT-Base with **RealFormer** (see Section 4.1.1). For better legibility, (1) attention heads in each layer are ordered by their medians of entropies, and (2) distributions are color-coded based on the median of entropies: RED (median > 4.5), YELLOW ($1.5 \leq$ median ≤ 4.5), BLUE (median < 1.5), *i.e.*, colder colors mean sparser attention. There is a clear trend that higher layers tend to have *sparser* attention.

the-art NMT model without using either additional data or data augmentation. ADMIN adopts Post-LN as the backbone, which we simply replace with RealFormer. In particular, we add three types of skip edges for encoder-encoder, encoder-decoder, and decoder-decoder attention respectively to the Post-LN Transformer. Empirically, RealFormer with running mean of attention scores tends to outperform running sum for our experiments, therefore here we use the former exclusively for brevity.

We use two popular NMT benchmarks, WMT'14 En-De and WMT'14 En-Fr, and follow Liu et al. (2020) for all training setups on both benchmarks except that in all cases (1) we select the peak learning rate from {5e-4, 1e-3, 1.2e-3} and use a linear learning rate decay schedule (instead of inverse sqrt);[11] (2) we train RealFormer only 50 epochs (in contrast, ADMIN trains 100 epochs on En-De and 50 epochs on En-Fr); and (3) we average across the last 25 checkpoints (while ADMIN uses the last 10). More checkpoints are helpful for us (especially for large models) presumably because the last few are not "diverse" enough as learning rate decays to 0.

Our experiments are performed on NVIDIA A100 GPUs, based on the official ADMIN repository[12]. We follow Liu et al. (2020) to configure the amount of GPUs to use for different setups.

BLEU scores on test sets are collected in Table 7. For fair comparisons, we also run ADMIN using our above setups and report results in the same table. Following Liu et al. (2020), all networks (including both encoders and decoders) share the same width setup (hidden size 512, intermediate size 2048, 8 heads) and only vary in depth. RealFormer outperforms all baselines across all depths considerably with a new state-of-the-art BLEU score (43.97) on En-Fr for models not using additional data or data augmentation to the best of our knowledge. One interesting observation here is that RealFormer does not always lead to larger improvement gaps for larger models, which might be due to the checkpoint averaging mechanism (which potentially regularizes large models reasonably well).

---

[11] With inverse sqrt decay, we find that RealFormer tends to favor larger peak learning rates than what Liu et al. (2020) uses, and we have also seen improvements in most cases.

Ours	**28.17**	**29.06**	**29.35**	**41.92**	**43.97**

Table 7: Test set BLEU scores on two WMT'14 benchmarks using different sizes of models. xL-yL: #Encoder layers-#Decoder layers. First three rows are from Liu et al. (2020). Ours is switching the backbone of ADMIN from Post-LN to RealFormer. †Our run of ADMIN using the same setups as RealFormer.

4.3 ETC

Extended Transformer Construction (ETC) is a recent sparse attention mechanism proposed by Ainslie et al. (2020) and Zaheer et al. (2020) to handle long context. It has achieved state-of-the-art results on four natural language benchmarks requiring long and/or structured inputs. Here we evaluate RealFormer on top of ETC models on these benchmarks including WikiHop (Welbl et al., 2018), HotpotQA (Yang et al., 2018), Natural Questions (Kwiatkowski et al., 2019), and OpenKP (Xiong et al., 2019). They vary significantly in terms of dataset size, context length, and structure in text inputs. Please refer to Ainslie et al. (2020) for more details.

Our experiments are based on the official ETC repository[13]. We take the ETC-Large model (24 layers, 1024 hidden size, 16 heads), add residual attention edges (*i.e.*, using running sum), and follow all the pre-training and fine-tuning recipes as well as hardware setups detailed in Ainslie et al. (2020). For each fine-tuning setup, we run the experiment five times and report the best median performance and the corresponding standard deviation on the development set in Table 8. RealFormer can improve ETC consistently across all four benchmarks.

As of June 2021, we are ranked the first on the WikiHop leaderboard[14] with a test accuracy of 84.4% (2.1% absolute improvement over the previous best result).

Task	Metric	ETC	Ours
WikiHop	Accuracy	78.92$_{\pm 0.14}$	**79.21**$_{\pm 0.38}$
HotpotQA	Ans. F1	80.38$_{\pm 0.13}$	**80.86**$_{\pm 0.16}$
	Sup. F1	89.07$_{\pm 0.06}$	**89.21**$_{\pm 0.12}$
	Joint F1	73.12$_{\pm 0.19}$	**73.57**$_{\pm 0.19}$
Natural Questions	Long Ans. F1	77.70$_{\pm 0.15}$	**77.93**$_{\pm 0.31}$
	Short Ans. F1	58.54$_{\pm 0.41}$	**59.10**$_{\pm 0.81}$
	Average F1	68.07$_{\pm 0.17}$	**68.51**$_{\pm 0.56}$
OpenKP	F1@3	44.06$_{\pm 0.08}$	**44.27**$_{\pm 0.08}$

Table 8: Development set results of ETC-Large. Ours is adding residual attention edges to ETC. Numbers in smaller font are standard deviations. All numbers are scaled by 100.

5 Conclusions

We propose RealFormer, a simple, generic, and cheap technique based on the novel idea of residual attention to improve Transformer-based networks. Quantitatively, we show that RealFormer can improve a diverse set of state-of-the-art Transformer-based models considerably for tasks like Masked Language Modeling, Neural Machine Translation, and long document modeling. Qualitatively, we show that RealFormer tends to have comparatively *sparser* attention, both within heads and across heads in adjacent layers.

A Appendices

A.1 Training Details: BERT

All our experiments are conducted on TPUs based on `https://github.com/google-research/bert`, the official BERT repository in TensorFlow (Abadi et al., 2016).

Pre-training. We use 128 TPU v3 cores (*i.e.*, 64 chips) for BERT-Small/Base/Large and 256 TPU v3 cores (*i.e.*, 128 chips) for BERT-xLarge. Table 9 demonstrates the time used to pre-train each model 1M steps. We can see that there is 10%-15% performance drop when adding residual attention edges for all sizes except xLarge. Our suspicion is that additions are not as optimized as other ops like matrix multiplications on TPU v3 cores. There is a much smaller performance drop for xLarge though, which might indicate that addition scales nicely compared to other ops on TPU v3 cores. As we will show later in Appendix A.2, performance drop on GPUs is almost negligible across different Transformer sizes, suggesting that it is hardware-dependent.

Fine-tuning. We use 8 TPU v2 cores (*i.e.*, 4 chips) to fine-tune each model. Best hyper-parameter configurations for BERT-Large with RealFormer on GLUE and SQuAD are collected in Table 10. We include RealFormer pre-trained both 1M and 500K steps, corresponding to the results in Table 3, 4, and 5.

A.2 Training Details: ADMIN

All our NMT experiments are conducted on NVIDIA A100 GPUs based on `https://github.com/LiyuanLucasLiu/Transformer-Clinic`, the official ADMIN repository implemented via fairseq (Ott et al., 2019). We use the same scripts to collect and process data and evaluate all models.

Following Liu et al. (2020), we use different number of GPUs for different setups, as detailed in Table 11. For our runs of ADMIN and RealFormer (*i.e.*, the last two rows in Table 7), learning rate is set to 5e-4 on WMT’14 En-De and 1.2e-3 on WMT’14 En-Fr across different model sizes. We train all models 50 epochs across the two benchmarks and average across the last 25 checkpoints (corresponding to the last 25 epochs).

Training time comparison of ADMIN and our model using the same setups is shown in Table 11. Adding residual attention edges and using running mean of attention scores do not incur significant performance drop on GPUs across different model sizes.

A.3 Training Details: ETC

All our experiments are conducted on TPU v3 cores based on the official ETC repository in TensorFlow: `https://github.com/google-research/google-research/tree/master/etcmodel`.

Pre-training. As is the case with ETC-Large (Ainslie et al., 2020), we find that pre-training ETC-Large with RealFormer can also benefit sig-

Task	Instance Statistics				Hyper-parameter		
	#Training	Median Length	95%tile Length	Max Length	BS	LR	EP
WikiHop	43,738	1,541	3,994	20,337	32	4e-5	15
HotpotQA	90,447	1,227	1,810	3,560	32	4e-5	5
Natural Questions	307,373	4,004	17,137	156,551	64	3e-5	2
OpenKP	133,724	761	4,546	89,183	64	3e-5	2

Table 12: Statistics of benchmarks and the hyper-parameter configurations for best-performing ETC-Large with RealFormer. BS: mini-batch size, LR: learning rate, EP: #fine-tuning epochs.

nificantly from lifting weights from RoBERTa (Liu et al., 2019). Note however that we lift from the same RoBERTa checkpoint as our ETC-Large baseline, which could be disadvantageous to our model since RoBERTa is pre-trained *without* residual attention.

Fine-tuning. Statistics of the four benchmarks and the corresponding best hyper-parameter configurations for ETC-Large with RealFormer are collected in Table 12. On Natural Questions and OpenKP, we simply reuse the best configurations for our ETC-Large baselines as reported in Ainslie et al. (2020). On WikiHop and HotpotQA, we follow the hyper-parameters search space specified in Ainslie et al. (2020) for ETC-Large.[15] In addition, on WikiHop we found it to be slightly better (development set accuracy 79.21 vs 78.96) to turn off RealFormer during fine-tuning (*i.e.*, adding no residual attention but still loading from our pre-trained RealFormer checkpoint); therefore we adopted this setup for WikiHop in Table 8 and our leaderboard submission.

A.4 Entropy Distribution of Pre-trained Baseline Transformer Models

Violin plots demonstrating the entropy distributions of the pre-trained BERT-Base models with Post-LN and Pre-LN Transformers from Table 2 are included in Figure 5.

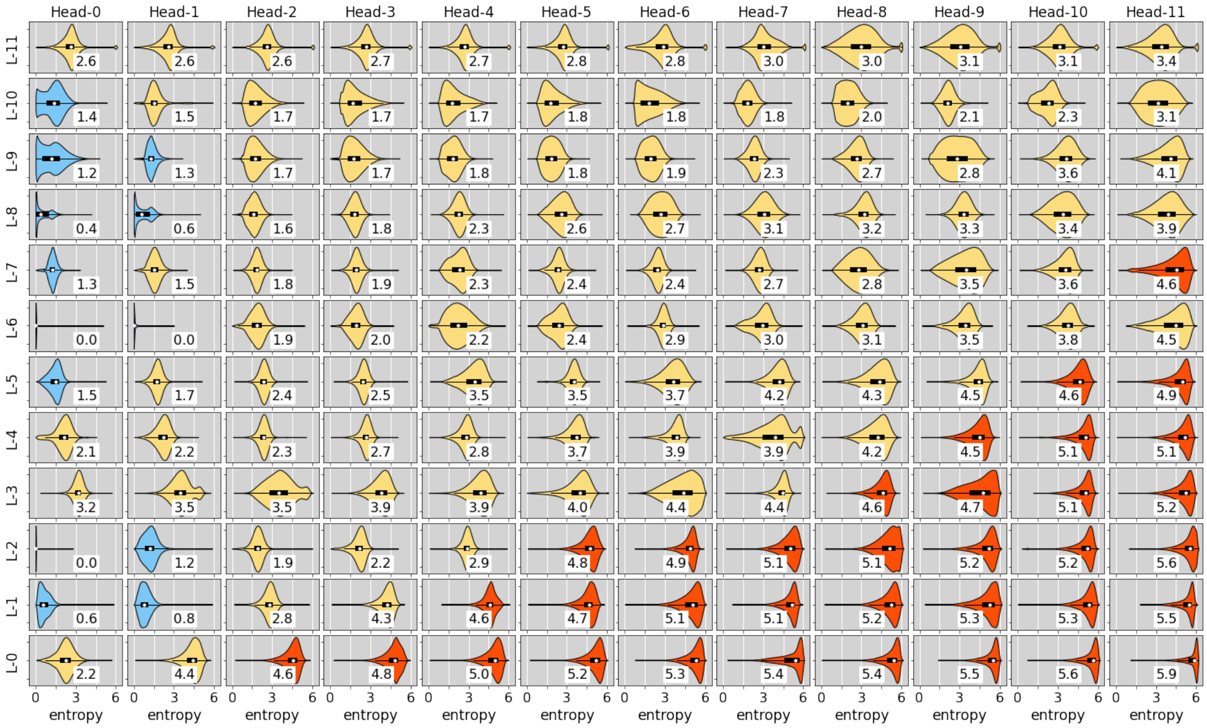
A.5 Jensen-Shannon Divergence of Different Pre-trained Transformers

We use violin plots to show the Jensen-Shannon Divergence distributions of the pre-trained BERT-Base models with Post-LN and RealFormer from Table 2 respectively (see Figure 6). Each row is a pair of adjacent layers in BERT-Base and each column is an attention head. Instead of computing one scalar value for each head pair, we show the full distribution based on the tokens in 8,192 held-out examples, *i.e.*, each data point is the JSD between the attention probabilities of a token at these two heads. For better legibility, we color code these plots to help distinguish head pairs with relatively "similar" attention (BLUE: median < 0.25) and relatively "distinct" attention (RED: median > 0.75) from the rest (YELLOW: $0.25 \leq$ median ≤ 0.75).

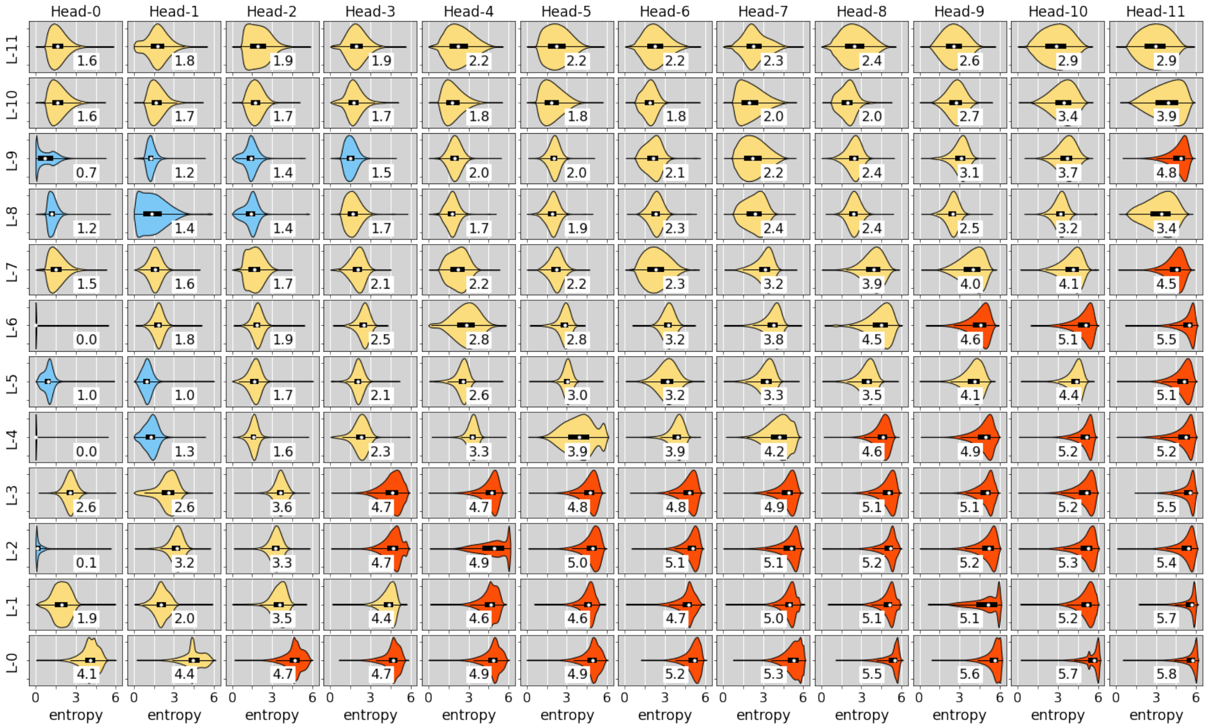
Note that JSD results from Post-LN are used only as a reference; we expect them to be "random" because there is no correspondence between heads in adjacent layers for Post-/Pre-LN. Proof: An equivalent Post-/Pre-LN can be constructed by permuting the order of attention heads in a layer (and the corresponding variables).

---

[15] On WikiHop, number of fine-tuning epochs is selected from {5, 10, 15} instead of {5, 10} for both ETC-Large and our model. We added 15 here following the official ETC repository.

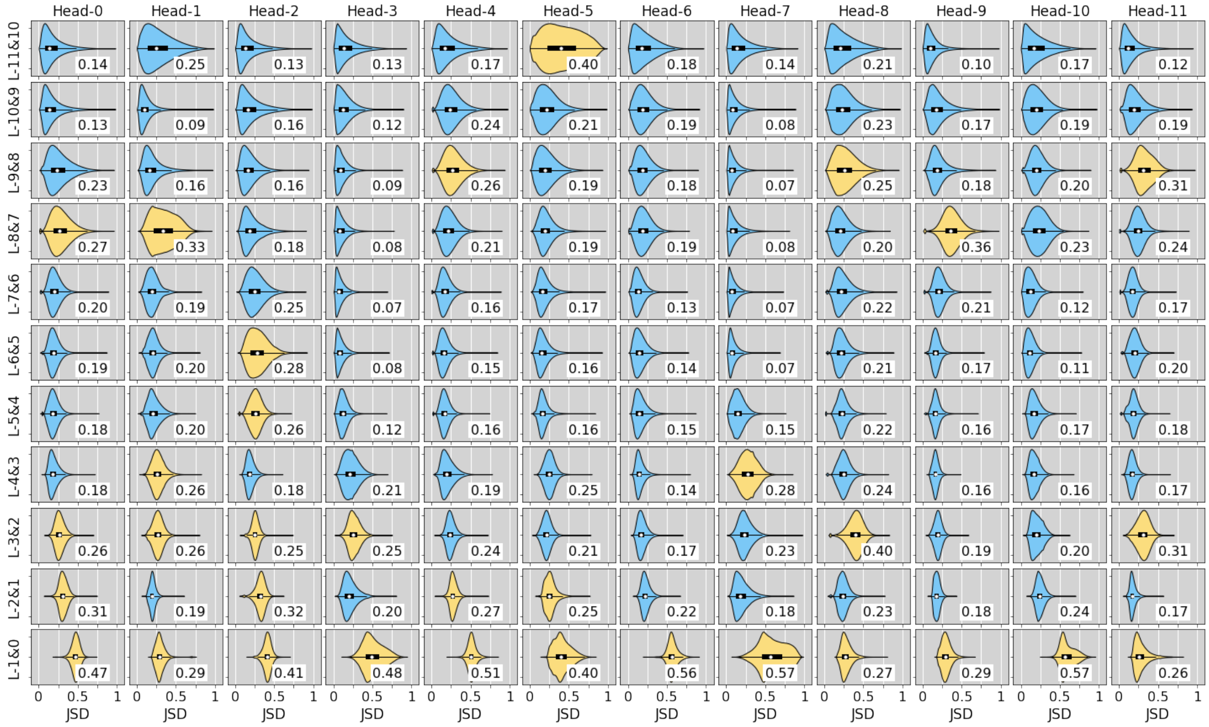


(a) Post-LN

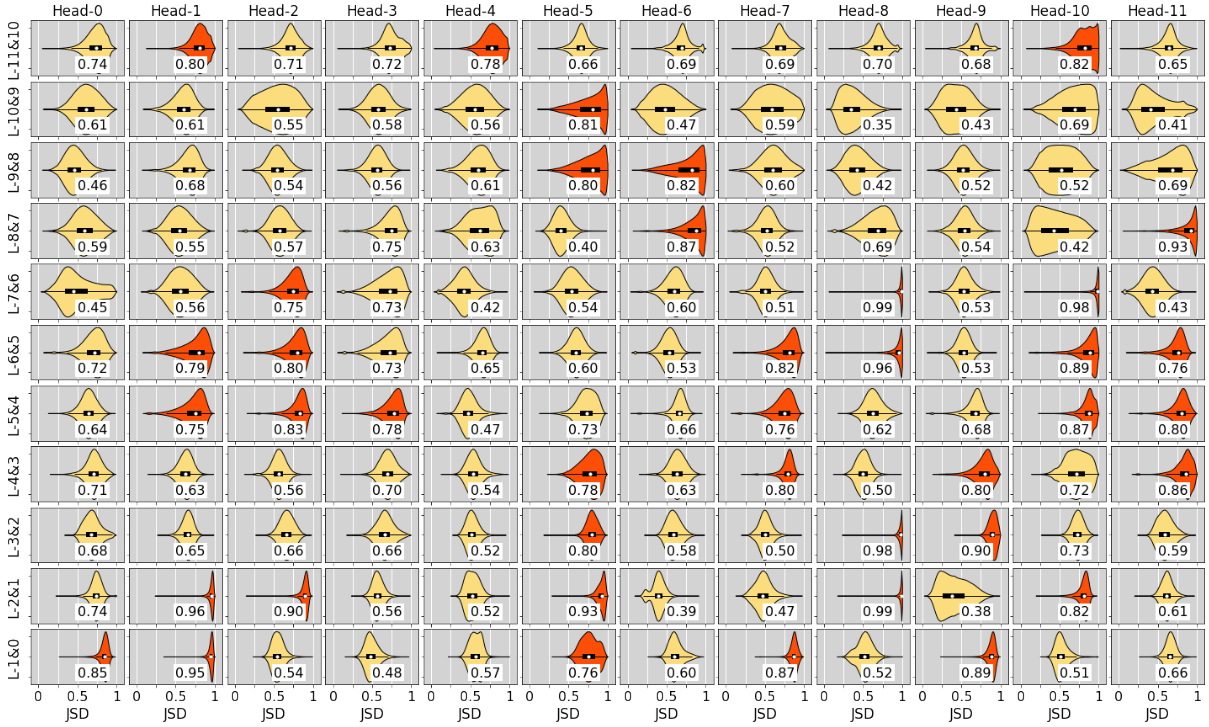


(b) Pre-LN

Figure 5: Distribution of entropies of the attention probabilities of the tokens of 8,192 held-out examples using the pre-trained BERT-Base with **Post-LN** and **Pre-LN** Transformer respectively (see Section 4.1.1). For better legibility, (1) attention heads in each layer are ordered by their medians of entropies, and (2) distributions are color-coded based on the median of entropies: RED (median > 4.5), YELLOW ($1.5 \leq$ median ≤ 4.5), BLUE (median < 1.5), *i.e.*, colder colors mean sparser attention. Note that here top layers (layer 9-11) tend to have larger entropies compared to RealFormer, which means that attention is relatively *denser*.



(a) RealFormer



(b) Post-LN

Figure 6: Distribution of Jensen-Shannon Divergence (JSD) of attention probabilities in (vertically) adjacent attention heads, *i.e.*, $\mathrm{JSD}(\mathrm{head}_i^L, \mathrm{head}_i^{L-1})$. Based on 8,192 held-out examples using the pre-trained BERT-Base with **RealFormer** and **Post-LN** Transformer respectively (see Section 4.1.1). Distributions are color-coded based on the median of JSDs: RED (median > 0.75), YELLOW ($0.25 \leq$ median ≤ 0.75), BLUE (median < 0.25). *I.e.*, colder color means more “similar” attention heads across adjacent layers.

Promoting Graph Awareness in Linearized Graph-to-Text Generation

Abstract

Generating text from structured inputs, such as meaning representations or RDF triples, has often involved the use of specialized graph-encoding neural networks. However, recent applications of pretrained transformers to linearizations of graph inputs have yielded state-of-the-art generation results on graph-to-text tasks. Here, we explore the ability of these linearized models to encode local graph structures, in particular their invariance to the graph linearization strategy and their ability to reconstruct corrupted inputs. Our findings motivate solutions to enrich the quality of models' implicit graph encodings via scaffolding. Namely, we use graph-denoising objectives implemented in a multi-task text-to-text framework. We find that these *denoising scaffolds* lead to substantial improvements in downstream generation in low-resource settings.

1 Introduction

Parameter-rich pretrained transformer language models succeed at generating text that is prima facie fluent, but that closer inspection will often reveal to be semantically transgressive (Bisk et al., 2020). Indeed, there is limited practical use for unconditional text generation: we expect language to relate to some identifiable, extrinsic meaning. When a system communicates information to an individual in natural language, it will typically rely on a structured representation of that information. Consequently, generating text that faithfully conveys structured data is an important goal in NLP, where inputs can take the form of tables (ToTTo, Parikh et al., 2020), RDF triples (e.g., WebNLG, Gardent et al., 2017), or Abstract Meaning Representations (AMR, Flanigan et al., 2016). NLP datasets in this domain consists of pairs of structured data (e.g., `<henri_matisse, hasOccupation, artist>`) and a representation of that data in text ("Matisse is an artist.").

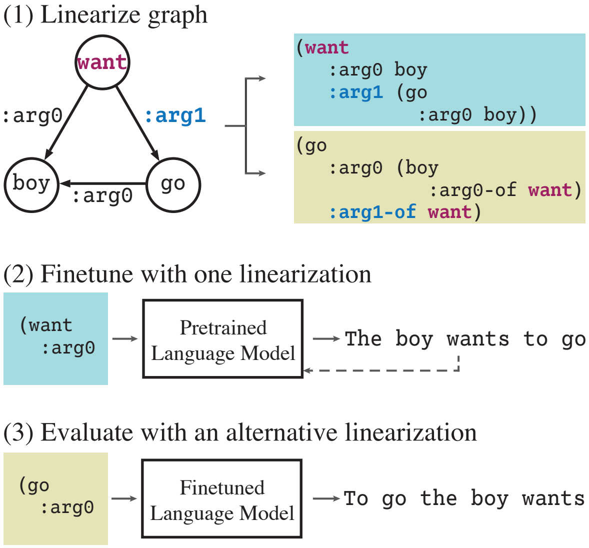

Figure 1: Diagram of our adversarial evaluation procedure for graph-to-text generation using pretrained language models (§3.2). (1) A graph can admit multiple possible linearizations. (2) Following standard practice, we train with a single linearization. (3) At evaluation time, we present the model with a meaning-preserving alternative.

Importantly, these types of inputs can be encoded as *graphs*. Accordingly, advances in neural architectures designed to explicitly encode graphs, such as graph neural networks (GNNs, Kipf and Welling, 2017) and graph transformers, have been used in these graph-to-text settings (Zhu et al., 2019; Zhao et al., 2020; Wang et al., 2020, to name a few). But graphs can also be represented as text (see top portion of Fig. 1). Hence, as an alternative to constraining a model architecture with a graph structure, it is also possible to simply *linearize* a graph into a string and train a sequence-to-sequence model from scratch (Pourdamghani et al., 2016; Konstas et al., 2017; Vinyals et al., 2015). Graph-

Note that the **bolded** relation in the graph, `(resemble-01 :ARG1 and)`, is represented differently depending on the linearization.

based encoders were introduced because they outperformed these sequence-to-sequence models. Recently, however, there has been a stark reversal: graph-encoder generation performance has been *far surpassed* by pretrained transformer language models (LMs) finetuned on pairs of linearized graphs and their corresponding surface realizations (Mager et al., 2020; Kale and Rastogi, 2020; Harkous et al., 2020; Ribeiro et al., 2020, henceforth termed *pretrained linearized models*). Moreover, both automated and human assessments indicate that text generated with LMs retains meaning at least as well as graph-encoding baselines (Mager et al., 2020).

This is not the sole product of pretrained models' general language knowledge: Mager et al. (2020), using a GPT-2-based (Radford et al., 2019) model, report that ablating structural graph information (e.g., edges) in the linearized representation notably degrades generation performance, particularly in AMR-to-text tasks. The remarkable performance of pretrained linearized models is intriguing: explicit representation of the input graph by way of the model architecture appears to be well-substituted by simply writing the graph as a linear sequence.

In this work, we further investigate the extent to which pretrained models can leverage linearized graph inputs. Focusing on AMR graphs and sets of RDF triples in English-language datasets, we structure our investigation by first testing whether models' encodings are invariant to the linearization strategy—the way in which a graph is traversed and encoded when producing the linearized representation (see Figure 1). We discover that generation suffers under random permutations of the linearization, and embrace a simple-but-effective training strategy to mitigate this problem: adversarial training (Goodfellow et al., 2015). Motivated by this finding, we encourage more faithful encodings of graph structure via denoising objectives in the more complex AMR setting. This multi-task *scaffolding* (Swayamdipta et al., 2018) reveals that straightforward masking of the graph input is sufficient to improve generation quality in low resource settings.[1]

Moreover, when treating this denoising performance as a proxy for the quality of models' implicit graph encoding, we find that it correlates with the semantic fidelity of the resulting generation better than reasonable alternatives, suggesting possibilities for future evaluation metrics.

We organize our investigation around two research questions:

RQ1 To what extent are pretrained linearized models invariant to graph linearization strategy? (§3)

RQ2 Does encouraging pretrained linearized models' implicit graph representation lead to better generation? (§4)

2 Background: Graph-to-Text Generation

In a graph-to-text setting, we transduce graph inputs g to their corresponding surface realization $y = \langle y_1, \ldots, y_N \rangle$ via a parameterized probabilistic model $p_\theta(\cdot)$. In linearized models specifically, the graph g is first mapped to text by way of a (usually deterministic) linearization function $x = l(g)$, where $p_\theta(\cdot)$ is an off-the-shelf sequence-to-sequence model. This leads to the likelihood objective: $p_\theta(y \mid g) = \prod_{i=1}^{N} p_\theta(y_i \mid x, y_{1:i-1})$. When $p_\theta(\cdot)$ is an autoregressive pretrained transformer, generation quality far exceeds architectures with encoders specifically engineered to encode graphs (Mager et al., 2020; Kale and Rastogi, 2020; Harkous et al., 2020; Ribeiro et al., 2020).

Table 1: Dataset statistics. Perplexity estimated on the development set with GPT-2 (Radford et al., 2019) fine-tuned on the training data using default hyperparameters in the `transformers` library (`gpt-2` model, Wolf et al., 2020).

Graph-to-Text Generation Datasets We explore two datasets for generation from a graph structure to English text.

Abstract Meaning Representation (AMR, Banarescu et al., 2013) is a formalism intended to represent the propositional meaning of utterances—"who is doing what to whom"—using graphs that have minimal dependence on the surface form. AMR graphs are directed and acyclic with a single "top" node (Goodman, 2020). They can be represented as either a graph, a tree, or sets of triples (van Noord and Bos, 2017). For our data, we use the AMR 2.0 release (LDC2017T10),[2] both because it spans a varied set of domains and styles, and because of its extensive use in prior work.

A simpler graph-to-text problem involves converting a set of RDF triples to natural text realizations of the information contained in the set, exemplified by the WebNLG dataset (Gardent et al., 2017). WebNLG pulls information from an existing knowledge base (DBPedia, Mendes et al., 2012) for a specific subset of 15 categories (e.g., "astronaut"). To generate the paired sentences, crowdworkers verbalize individual triples. Then, for examples consisting of multiple triples, they merge already-annotated sentences and apply minimal changes (leading to reduced sentence complexity relative to AMR; see perplexity scores in Table 1). There can be multiple surface realizations per input.

Models To study pretrained linearized models' invariance to graph linearization, we use T5 (Raffel et al., 2020), an *encoder-decoder* transformer (Vaswani et al., 2017) that has led to state-of-the-art generation on AMR (specifically, LDC2017T10) and WebNLG (Kale and Rastogi, 2020; Ribeiro et al., 2020).

We modify the T5 implementation from the `transformers` library (Wolf et al., 2020).[3] We use the Adafactor optimizer (Shazeer and Stern, 2018) with a learning rate of 0.0001, selected from the set $\{0.001, 0.0001, 3 \times 10^{-5}, 1 \times 10^{-5}, 1 \times 10^{-6}\}$ after tuning on 1000 training examples across five random seeds.[4] We train until development set BLEU has not improved for 10 epochs. See Appendix A.1 for further details.

Evaluation Measures As a primary metric, we evaluate generated text using BLEU (Papineni et al., 2002), calculated with `SacreBLEU` (Post, 2018). Despite its limitations in generation settings, BLEU still generally accords with rankings of models, either by human evaluations or by alternate metrics (Manning et al., 2020). We also evaluate our scaffolding models (§4) using BertScore (Zhang et al., 2020), which measures token similarity with contextual embeddings, permitting a more nuanced measure of semantic similarity. Lastly, we use the $\mathcal{M}$ portion of the $\mathcal{MF}$-score (Opitz and Frank, 2020), which measures how well the source AMR graph can be reconstructed from the generated target sentence using an off-the-shelf parser. Unlike BLEU, which applies corpus-wide, this metric provides a best-guess at sentence-level accuracy.

3 RQ1: Robustness to Permutation of Graph Linearization

In this section, we explore the extent to which pretrained linearized models are invariant to the particular method used to linearize the input graph. Motivated by the strong graph-to-text performance of these models, we ask: do they implicitly develop a robust internal encoding of the input graph? Whereas a GNN-based model has an architecture designed for graph representation (e.g., information flows between adjacent nodes in a message-passing update), a linearized model must infer how connections are specified in a sequence during training.

If linearized models do form a representation, then their estimates of the target sentence should be invariant to an alternative linearization of the same graph, so long as the original linearization is in principle recoverable from this alternative. If a model meets this criterion, we call it **linearization-invariant**.

---

[2] `catalog.ldc.upenn.edu/LDC2017T10`

[3] We use T5-Base for WebNLG and T5-Large for AMR, finding that the larger model did not benefit the WebNLG task.

[4] Less extensive experiments with the full dataset indicated the same optimal setting, although in general it is relatively robust to learning rate.

3.1 Experimental Setup

To better understand models' graph-encoding behavior, we experiment with adversarial linearization strategies in two graph-to-text settings.[5]

Permutations of AMR-Graph Linearizations Standard AMR corpora are linearized as spanning trees over the graphs in PENMAN notation (Matthiessen and Bateman 1991, see Fig. 2a). In the present work, we also linearize graphs using PENMAN, doing so for several reasons: (1) it is sufficiently flexible to accommodate significant changes to the linearization, discussed below; (2) it is more concise than sets of directed triples, both reducing training time and ensuring that inputs fit in the transformer context window; (3) the format leads to superior generation over reasonable alternatives, e.g., DFS traversal paths (Mager et al., 2020).

We will refer to the human-created linearizations in AMR corpora as CANONICAL, since annotators follow a standardized process. There is evidence that this format, in particular the relative ordering of edge types, leaks information about the associated sentence order (Konstas et al., 2017). We speculate that overparametrized models may overfit to such correlations rather than develop robust implicit graph encodings, since it has been repeatedly reported that large models use dataset shortcuts (Jia and Liang, 2017; Gururangan et al., 2018; Geva et al., 2019, among others).

As an alternative linearization, Goodman (2020) defines the RECONFIGURE operation as creating a tree from an AMR graph, where order information from the canonical linearization is ignored, except for the top node (e.g., `and` in Figs. 2a and 2b). Although it is not a labeled element in the graph, the top node conveys structural information about the sentence—for instance, it is often the main verb. Reconfiguration can include reversals of edge labels (e.g., `ARG0` to `ARG0-of`), therefore constituting a substantive change to the linearization.

We also experiment with a more drastic restructuring of the graph, where we construct a tree from a RANDOMIZED triple set alone, disregarding all order information from the canonical format (Fig. 2c). Since it remains a valid traversal of the graph, in principle a model should be able to use this information to construct the surface sentence.

We parse, reconfigure, and randomize graphs using the `Penman` library (Goodman, 2020),[6] then replace variable names with their references and remove word sense information, following Ribeiro et al. (2019).

Permutations of RDF-Triple Linearizations We follow the procedure of Ribeiro et al. (2020) to form our standard linearization: we prepend a special token to each element of the triple, and separate triples with another dedicated token. For the output sentence "Ned is the father of Rod and Todd," we would have:

In: (Ned *fatherOf* Rod), (Ned *fatherOf* Todd)
Out: `<rel> <S> Ned <V> father of <O> Rod`
`<rel> <S> Ned <V> father of <O> Todd`

For our adversarial permutation, we RANDOMIZE the ordering of the triples.

Encouraging Robustness to Linearization We train additional models with the goal of encouraging an agnosticism to graph linearization strategy. We adopt an adversarial training approach (Goodfellow et al., 2015), and alter the graph linearization presented to the model at each epoch. We argue that this scheme ought to reduce any model dependence on the human-derived annotation.

3.2 Robustness Results

For both tasks, we train the model on the canonical linearization, then evaluate on the various linearizations described in Section 3.1.

Impact of Adversarial Linearizations The CANONICAL columns of Table 2 show results for models trained on that linearization, then evaluated on permuted graph linearizations. We note a strong negative impact in models' generation capacity for both tasks, with a starker decrease for the AMR data. These results suggest that pretrained linearized models are not linearization-invariant, failing to learn robust implicit graph representations, even in the case of the much simpler WebNLG data.

The remaining columns of Table 2 show that our straightforward adversarial training technique improves robustness, with only minor cost to generation performance. This is the case even with the more drastic RANDOMIZED AMR linearization. Moreover, it only incurs a minor training time cost—for AMR, the CANONICAL, RECONFIGURE,

---

[5] Although "adversarial" can imply inputs specifically designed to break a model, here we use it to mean that inputs are merely *likely* to cause issues by diverging from the training order. In addition, we intend to draw parallels to adversarial training (Goodfellow et al., 2015).

Table 2: BLEU under different linearizations, using T5-LARGE (AMR, development set) and T5-BASE (WebNLG, for both "seen" and "unseen" test sets). Percentages represent the decrease from the CANONICAL representation following the adversarial evaluation (i.e., they should be read columnwise).

and RANDOMIZE variants attain 40 BLEU at 2, 3, and 5 epochs, respectively.

Given that elements of canonical annotations are known to correlate with the target sentence order (Konstas et al., 2017), we do not find it surprising that the models trained *and* evaluated on the permuted linearizations show decreased performance. However, it is meaningful that the canonical linearization at evaluation time still leads to the best results, even for models trained with the randomized inputs—these models did not learn to associate the canonical ordering signal with the input graph. One possible explanation is that the earlier pretraining induces a sensitivity to input token order that persists despite the adversarial fine-tuning, but the behavior merits further exploration.

In addition, note that the canonical order does not have an explicit formal definition, and may require heuristic reverse engineering; in a real-world system, recreating a canonical graph linearization (e.g., from a knowledge-base query) for a subsequent graph-to-text model may not be straightforward. These results show it is possible to inoculate models to accommodate this sort of use case.

4 RQ2: Better Implicit Graph Encodings with Text-to-Text Scaffolding

The positive results of our adversarial training procedure (§3.2) suggest that pretrained linearized models can form a robust internal graph representation, even though they rely on linearized inputs. Under substantively different linearizations, models retain the ability to generate accurately (even the RANDOMIZE model outperforms best-in-class graph transformers; Wang et al. 2020).

Prior work, involving both GNNs and pretrained linearized models, has explored various ways of improving models' sensitivity to the structure of the input graph. To better maintain fidelity to the graph, previous graph-to-text methods incorporate additional loss terms, specialized architectures, or generation-time ranking to influence the semantic accuracy of generation: ranking outputs by the correctness of the AMR parse (Mager et al., 2020; Harkous et al., 2020), jointly "back-parsing" graphs when decoding (Bai et al., 2020), or using distinct components to model different graph traversals (Ribeiro et al., 2019).

These efforts suggest that explicitly accounting for graph structure can assist generation. Can we expand on this idea, and improve generation quality by inducing more robust internal graph representations? To answer this question, we propose secondary objectives designed to promote graph "awareness." In addition to the above graph-to-text approaches, we also draw inspiration from *denoising* methods used in language model pretraining (Raffel et al., 2020; Lewis et al., 2020), as well as syntactic *scaffolds* that support semantic tasks with an auxiliary syntax-dependent loss (Swayamdipta et al., 2018). Intermediate auxiliary pretraining has been repeatedly shown to be successful in other contexts (Phang et al., 2018; Li et al., 2019; Gururangan et al., 2020).

4.1 Experimental Setup

In particular, we propose unsupervised graph-denoising tasks that we train alongside AMR-to-text generation, following the multi-task setup of Raffel et al. (2020). For each batch, we either optimize the likelihood in Section 2 or one of the objectives described below.[7]

---

[7] Per-task batches proved marginally better than mixing within a batch. The scaffolding task probability is a hyperparameter, which we set to 0.5.

Masked Graph Modeling When training transformers to have wide-ranging natural language capabilities, unsupervised denoising objectives like masked language modeling have proven extremely successful (Devlin et al., 2019; Raffel et al., 2020). We argue that a similar principle ought to apply to graph understanding, and therefore apply masking directly to linearized graphs.

In masked language modeling, each word token is masked with probability 15%. Here, we mask different sets of tokens, depending on the experimental condition, always setting the probability such that 15% of *all* tokens will be masked. Specifically, we mask: all tokens in the linearized graph, the graph components alone (edge labels and parentheses), and the semantic nodes. We also experiment with standard masking of the surface sentence, which mirrors the unsupervised domain-adapted pretraining employed by Ribeiro et al. (2020).[8] For example, when masking components alone:

```
orig ( stupefy :ARG1 ( we )   )
  in ( stupefy <M>   ( we <M> )
 out original text
```

Graph masking can also be performed on any of the linearization variants defined in Section 3.1.[9]

Graph Reordering Building on our findings from Section 3.2, we introduce a *reordering* objective. Specifically, we provide the model with a RECONFIGURED or RANDOMIZED linearization, then task the model with reconstructing the canonical version. We suspect that learning this mapping requires that the model captures the graph structure better, leading to superior graph-to-text generation. Unlike the joint re-generation approach of Mager et al. (2020), where the input graph is copied alongside the target text, our method both requires a nontrivial encoding of the graph and has the effect of augmenting the data (due to the nondeterministic reconfiguration).[10]

4.2 Scaffolding Results

We find that, overall, denoising objectives drive substantial improvements over the baseline when training on the reduced $n = 1000$ dataset (Table 3). In fact, using less than 3% of the full data produces results that exceed that of state-of-the-art GNN models from less than two years prior to this writing (BLEU 27.37, Ribeiro et al., 2019). Moreover, the results suggest that focusing on the graph representation itself is most important: standard sentence masking (i.e., MLM-style) is less beneficial than graph masking, although it still outperforms the baseline. Surprisingly, the various graph-masking objectives perform similarly to one another—there is little benefit to more complex strategies that specifically account for the graph structure.

	BLEU	BS	$\mathcal{M}$
Bai et al. (2020)	34.19	-	-
Ribeiro et al. (2020)	45.80	-	-
Baseline	44.51 (0.48)	77.40 (0.36)	76.53 (0.19)
Scaffolding			
Mask nodes	45.14 (0.23)	77.75 (0.13)	76.52 (0.14)
RECON., mask all	44.89 (0.39)	77.56 (0.26)	76.54 (0.20)
Reorder from RECON.	44.86 (0.19)	77.62 (0.16)	76.34 (0.17)

Table 4: Test-set results of scaffolding objectives and baselines trained on the *full* AMR dataset (LDC2017T10). Bai et al. (2020) is a state-of-the-art graph transformer. Ribeiro et al. (2020) finetunes T5-LARGE, which we re-implement as our baseline model. BS is BertScore (Zhang et al., 2020), and $\mathcal{M}$ is the meaning component of the $\mathcal{MF}$-score (Opitz and Frank, 2020). Mean (s.d.) over 5 seeds.

While the increased generation quality from the graph-denoising methods is not drastic relative to the MLM case, we contextualize our gains by noting that other ways of promoting greater graph awareness yield similar improvements in absolute terms—and come at the cost of greater model

---

[8] We use MASS-style masking (Song et al., 2019) for the tokens, rather than the span-replacing of T5, as it performed somewhat better.

[9] We restrict ourselves to the RECONFIGURE setting given that early results showed little difference from RANDOMIZE.

[10] Simultaneously generating the surface text and reordering to the canonical linearization did not improve results.

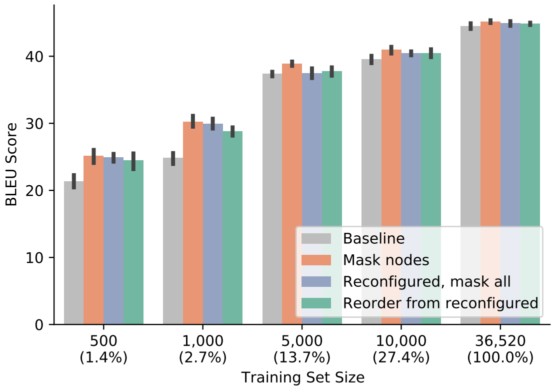

Figure 3: Test set BLEU on the AMR dataset (LDC2017T10) under different amounts of training data for selected scaffolding objectives (over 5 seeds). In low-data regimes, the scaffolding objectives substantially improve BLEU score over the baseline.

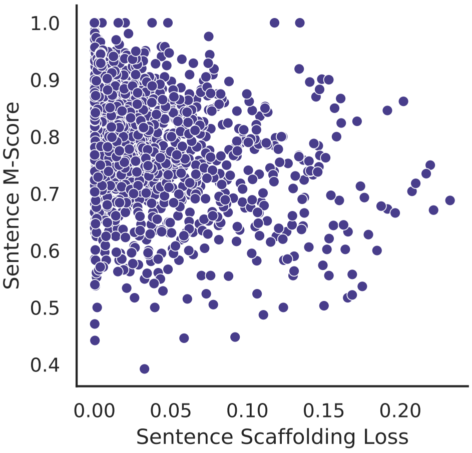

Figure 4: Sentence-level scaffolding loss and $\mathcal{M}$-score on the validation set, using a model trained with the *reordering-from-reconfigured* scaffold. $\mathcal{M}$-score is a measure of the generated sentence's semantic fidelity, and the scaffolding loss is a proxy for the graph encoding accuracy.

complexity or generation time. For instance, the use of two graph representations in Ribeiro et al. (2019) achieve a roughly 1-BLEU increase over the use of one alone.

Based on the findings from the $n = 1000$ setting (Table 3), we select three of the best-performing scaffolding objectives—*mask nodes*, *reconfigure & mask all tokens*, and *reorder from reconfigured*—and train them at $n \in \{500, 1000, 5000, 10000, N\}$. Results are shown in Fig. 3. At $n = 5000$, representing 14% of the data, the impact of scaffolding is no longer strong across all objectives. When evaluating on the full dataset, the difference is minor (Table 4). For both BLEU and BertScore, we observe slight improvement over the baseline on average for the *mask nodes* case, but it is within a standard deviation of the baseline (estimated over 5 seeds). $\mathcal{M}$-score does not vary between models, but it is also not yet established for fine-grained model selection. It appears that the increased size of the data supplants the need for scaffolding losses: the diversity of the source graphs encourages a graph-reasoning ability sufficient to generate accurate sentences. Of course, in a realistic application, hundreds or thousands of training examples are more attainable than tens of thousands. That such straightforward methods can yield strong gains is promising for future work in low-resource graph-to-text generation.

Manual Annotations In a manual analysis of 100 random model predictions, we generally observe broad agreement between the model trained with the *reordering-from-reconfigured* scaffold and the baseline (73% agreement in fidelity), both trained with the full dataset. However, in three cases, the baseline model fails to capture the order of arguments (e.g., "from y to x" when "from x to y" is correct), whereas the scaffolded model remains true to the graph (see Table 5; we did not observe instances of the reverse case). While we fail to observe "hallucinations"—material information that is not contained in the graph input—both models occasionally drop modifiers (e.g., adjectives or adverbs). Both models exhibit word-sense confusion (see the third row in Tab. 5, where "long [in length]" is substituted with "long [in duration]"). We presume this is due to the removal of word-sense suffixes during preprocessing to avoid sparsity issues (`long-03` → `long`).

4.3 Encoding Graphs and Generation Performance

The results of Section 4.2 show that the denoising scaffolds impact generation performance. If we consider the sentence-level scaffolding loss as a proxy for the quality of its implicit graph encoding, can it help explain generation fidelity? In order to determine this relationship, we quantify generation accuracy using the $\mathcal{M}$ component of the $\mathcal{MF}$-score (Opitz and Frank, 2020). It is calculated by first using an off-the-shelf parser to create an AMR graph from the generated target sentence, then by measuring the overlap with the gold source AMR (from 0 to 1)—this is equivalent to the "smatch"

Target	*Both Norway and Sweden have been spared violent terror acts but authorities in both countries have voiced concern about terrorists or terror financiers operating out of Scandinavia.*

Table 5: Selected predictions from the baseline and a model using the *reordering-from-reconfigured* scaffold (trained on the full data). **Colored text** denotes a semantically incorrect generation.

rescoring metric (Cai and Knight, 2013). As seen in Fig. 4, there is a substantial negative relationship (Pearson's $\rho = -0.35^*$) between these two variables, measured using outputs from the model trained with the *reordering-from-reconfigured* scaffold on the full data.

To fully operationalize the above question, we estimate a linear regression on the $\mathcal{M}$ score of predicted sentences from the validation set. In this scenario, the linear regression can quantify how much variation in predicted sentences' semantic fidelity (measured by the $\mathcal{M}$-score) can be explained by model components and target sentence characteristics. If the coefficient for the sentence-wise scaffolding loss is significant (and negative), then this would suggest that there is a relationship between the scaffolding objective and the predicted sentence's semantic fidelity.

As covariates, we include the above (logged) scaffolding loss, in addition to other metrics that have a significant independent correlation with generation quality. In particular, we use sentence-BLEU, the number of edges in the graph, graph re-entrancies, words in the target sentence, and the (also logged) sentence generation loss.[11]

We use the Bayesian information criterion (BIC) to select the model from all possible combinations of the above covariates. We find that the preferred model with p covariates, $p \in \{1, \ldots, 6\}$, includes the reordering loss in all but one case ($p = 2$), suggesting its validity as an indicator of graph fidelity above and beyond other alternatives. As seen in Table 6, it has a significant negative relationship with the $\mathcal{M}$ score, larger than that of the comparably-scaled generation loss. These results indicate that the reordering loss captures important information about the quality of the graph encoding.

X	β
Intercept	0.7590*
Scaffolding loss (log)	-0.0094*

BIC	-2378
Adj. R^2	0.267

Table 6: OLS regression results on validation sentence $\mathcal{M}$-score, a measure of semantic fidelity that relies on the gold AMR graph. These results indicate that the scaffolding loss explains a significant amount of the variation in the semantic fidelity of the generated sentence to the gold target. Model trained with the *reordering-from-reconfigured* scaffold. *Significance at $p < 0.001$.

5 Related Work

Pretrained Transformers for Graph-to-Text Generation Mager et al. (2020) condition GPT-2 (Radford et al., 2019) on a linearized AMR graph, then fine-tune on the corresponding surface representation text. Later work using transformers has also found success on both AMR-to-text and data-to-text tasks (Kale and Rastogi, 2020; Harkous et al., 2020; Ribeiro et al., 2020). To our knowl-

---

[11] We eliminate outliers consisting of the bottom 0.5% of target lengths and $\mathcal{M}$-scores and the top 0.5% of the losses.

edge, across a diverse set of tasks and automated[12] metrics, a pretrained transformer of sufficient capacity will always outperform a specialized GNN, often by a large margin. Ribeiro et al. (2020), following Gururangan et al. (2020), further pretrain on additional in-domain data, using both supervised (silver AMR parses to text) and unsupervised (denoising target text) objectives.

Graph-Dependent Losses Mager et al. (2020) use various heuristics to improve fidelity. During training, they regenerate the input graph, and in inference, they parse generations and rank their consistency with the original graph. Harkous et al. (2020) instead rank with a trained classifier, and introduce additional "state embeddings" to help indicate the ordering of graph components. The encoder-decoder methods cited in the previous paragraph eschew these approaches and nonetheless perform better. In preliminary replications of the Mager et al. experiments with T5, we find that joint re-generation leads to no improvement (moreover, the longer output sequences increase training time). Experimenting with other graph-sensitive embeddings is a valuable direction for future work.

Graph Linearization Other work also studies linearizations for AMR-to-text settings. As opposed to our efforts, the focus is not on enriching or measuring models' graph encoding, but instead on determining what elements of linearization (e.g., edge labels) are necessary for generation.

Closest to our work is Konstas et al. (2017), who experiment with alternative graph traversals by randomizing the edge type order (less drastic than either RECONFIGURE or RANDOMIZE) with an LSTM-based model. Rather than randomizing at each epoch, as in our approach, they employ a *consistent* random ordering for each example during training, and do not evaluate models across different linearizations. The results help establish that LSTMs can be made agnostic to ordering, but fail to measure the extent to which models overfit to the training order (Section 3.2).

Ribeiro et al. (2020) report paired training and evaluation shuffling results (as in Table 2), but they ignore parentheses, only reodering node labels. Hence, their results cannot establish models' graph-encoding ability, instead revealing that node order is informative of word order, corroborating findings in Konstas et al. (2017). Both works, along with Mager et al. (2020), run ablations by removing parenthetical markers, finding that graph structure is necessary for strong generation.

Finally, Kedzie and McKeown (2020), appearing contemporaneously to our work, seek to control the output generation by manipulating the input linearization order, using a randomization similar to ours as an "uncontrolled" baseline. Given their focus on task-oriented dialogue planning, which uses simpler meaning representations and sentences than the AMR dataset used here (i.e., shallower graphs and limited domains), we view their work as complementary to our own.

6 Conclusion

In this work, we explore the graph-encoding ability of pretrained transformers through the lens of graph-to-text generation that relies on linearized graph inputs. First, we determine the extent to which these models are invariant to the method by which graphs are linearized, finding that models trained on the fixed, canonical linearizations fail to generalize to meaning-preserving alternatives. We rectify this shortcoming by training models on linearizations corresponding to alternative random traversals of the graph. Following prior work that has used graph-aware losses to improve generation quality, we then explore ways of improving models' sensitivity to the input graphs. Motivated by the success of denoising objectives in other text-to-text settings, we encourage robust internal graph encodings through additional scaffolding losses. Although scaffolding leads to tepid improvements in generation quality when training data is plentiful, it yields substantial gains in low-resource settings. Finally, while pretrained transformers may not learn the entirety of a graph's structure via scaffolding, our text-to-text methods take a step in the direction of increasing graph sensitivity.

7 Acknowledgments

We thank AI2 AllenNLP team members for advice throughout the project, and anonymous reviewers for their insightful comments. We also thank Leonardo Ribeiro for his publicly available implementations and assistance.

Table 7: OLS regression results on validation sentence $\mathcal{M}$-score, a measure of semantic fidelity that relies on the gold AMR graph. These results indicate that the scaffolding loss explains a significant amount of the variation in the semantic fidelity of the generated sentence to the gold target. Model trained with the *reordering-from-reconfigured* scaffold using 1000 training examples. *Significance at $p < 0.001$. † Significance at $p < 0.01$.

A Appendix

A.1 Hyperparameters, Computing Infrastructure, and Data Processing

We set the batch size to 32 for WebNLG, and 6 for AMR. During decoding, we use a beam size of 10 for WebNLG and 5 for AMR, following Ribeiro et al. (2020). All models were trained with a NVIDIA Quadro RTX 8000 GPU.

To maintain a reasonable batch size, long AMR inputs are truncated to 354 tokens (affecting less than 1% of examples); this step is not necessary for WebNLG. Finally, during preprocessing of the LDC2017T10 data, we differ from Ribeiro et al. (2019) and remove the `:wiki` attribute from the graph[13] both because they are not a standard component of all AMR graphs and because they increase the length of the inputs. We suspect that this change is the reason our baseline achieves slightly different results than Ribeiro et al. (2020) (Table 4).

A.2 Regression Results at $n = 1000$

In Table 7, we show OLS regression results analogous to those in Table 6 for one run of the $n = 1000$ case. While the fit is lower (a lower R^2), the scaffolding loss still has an explanatory effect.

Abstract

Languages vary in their placement of multiple adjectives before, after, or surrounding the noun, but they typically exhibit strong intra-language tendencies on the relative order of those adjectives (e.g., the preference for 'big blue box' in English, 'grande boîte bleue' in French, and 'alṣundūq al'azraq alkabīr' in Arabic). We advance a new quantitative account of adjective order across typologically-distinct languages based on maximizing information gain. Our model addresses the left-right asymmetry of French-type ANA sequences with the same approach as AAN and NAA orderings, without appeal to other mechanisms. We find that, across 32 languages, the preferred order of adjectives mirrors an efficient algorithm of maximizing information gain.

1 Introduction

Languages that allow multiple sequential adjective modifiers tend to exhibit strong tendencies on the relative order of adjectives, as in 'big blue box' vs. 'blue big box' in English (Dixon, 1982). To date, most of the research on adjective ordering has focused on preferences in pre-nominal languages like English where adjectives precede the modified noun (Futrell et al., 2020a), or in post-nominal languages like Arabic where adjectives follow the noun (Kachakeche and Scontras, 2020). This research usually posits a metric, such as information locality (Futrell et al., 2020b) or subjectivity (Scontras et al., 2017), which governs the preferred distance between a noun and its adjectives. Because these theories predict only the relative linear *distance* between noun and adjective, they cannot be straightforwardly applied to mixed languages like French, where adjectives regularly appear both before and after the modified noun, at least not without added assumptions about hierarchical distance (Cinque, 1994). Instead, these mixed languages are often modeled with constraints on which adjective classes or functions can appear before or after a noun (Cinque, 2010; Fox and Thuilier, 2012).

Traditional accounts of adjective ordering in the linguistics literature often assume a **tree structure** in which the target measure is the hierarchical distance from noun (N) to adjective (A). According to syntactic accounts, ordering regularities are predicted by a universal hierarchy of lexical semantic classes (e.g., color adjectives are hierarchically closer to the modified noun than size adjectives; Cinque, 1994; Scott, 2002). Alternative accounts use aspects of adjective meaning to predict adjective order, making appeal to notions like 'inherentness' (Whorf, 1945) or 'definiteness of denotation' (Martin, 1969). Recently, Scontras et al. (2017) provide experimental evidence that their synthesis of semantic predictors into a continuum based on subjectivity reliably predicts ordering preference in English; followup studies have found subjectivity to be a reliable predictor in other languages as well (Tagalog: Samonte and Scontras, 2019; Mandarin: Shi and Scontras, 2020; Arabic: Kachakeche and Scontras, 2020; Spanish: Rosales Jr. and Scontras, 2019; Scontras et al., 2020). Explanations for the role of subjectivity in adjective ordering show how subjectivity-based orderings are more **efficient** than alternative orderings, thereby maximizing communicative success (Simonič, 2018; Hahn et al., 2018; Franke et al., 2019; Scontras et al., 2019).

Other efficiency-based approaches to adjective order quantify efficiency with information-theoretic measures of word distributions such as surprisal or entropy (Cover and Thomas, 2006; Levy, 2008). Models in this vein have a long conceptual history in the field, originating with the idea that semantic closeness between words is reflected in syntactic closeness in a surface realization (Sweet, 1900; Jespersen, 1922; Behaghel,

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 957–967
August 1–6, 2021. ©2021 Association for Computational Linguistics

1932). Modern quantitative incarnations include integration cost (Dyer, 2017) and information locality (Futrell et al., 2020b), both generalizations of the widely-accepted principle of dependency distance minimization (Liu et al., 2017; Temperley and Gildea, 2018).

Crucially, while previous approaches are able to model symmetrical structures within the noun phrase, as in the mirror-image $A_1 A_2 N$ orders of English and the $N A_2 A_1$ orders of Arabic, a hierarchical approach cannot model the **left–right asymmetry** of Romance $A_1 N A_2$ without an appeal to other, usually syntactic, mechanisms (Cinque, 2009, 2010).

We advance an information-theoretic factor that predicts adjective ordering across the three typological 'templates' of adjective order—pre (AAN), mixed (ANA), and post (NAA)—based on **information gain** (IG), a measure of the reduction in uncertainty attained by transforming a dataset. IG is used in machine learning for ordering the nodes of a decision tree (Quinlan, 1986; Norouzi et al., 2015), where nodes are most often ordered in a greedy fashion such that the information gain of each node is maximized. By analogy, we view the noun phrase as a decision tree for reducing a listener's uncertainty about a speaker's intended meaning. Each word acts as a node in the decision tree; preferred adjective orders thus reflect an efficient ordering of nodes.

2 Empirical background

Empirical investigations of adjective ordering have focused on the cross-linguistic stability of these preferences across a host of unrelated languages (e.g., Dixon, 1982; Hetzron, 1978; Sproat and Shih, 1991). For example, where English speakers prefer 'big blue box' to 'blue big box', Mandarin speakers similarly prefer *dà-de lán-de xiāng-zi* 'big blue box' to *lán-de dà-de xiāng-zi* 'blue big box' (Shi and Scontras, 2020). In post-nominal languages, we find the mirror-image of the English pattern, such that adjectives that are preferred closer to the noun in pre-nominal languages are also preferred closer to the noun in post-nominal languages.[1] For example, speakers of Arabic prefer *alṣundūq al'azraq alkabīr* 'the box blue big' to *alṣundūq alkabīr al'azraq* 'the box big blue'.

In support of the cross-linguistic stability of adjective ordering preferences, Leung et al. (2020) present a latent-variable model capable of accurately predicting adjective order in 24 languages from seven different language families, achieving a mean accuracy of 78.9% on an average of 1335 sequences per language. Importantly, the model succeeds even when the training and testing languages are different, thus demonstrating that different languages rely on similar preferences. However, Leung et al.'s study was limited to AAN and NAA templates. There has been very little corpus-based empirical work on ordering preferences in the mixed ANA template, where adjectives both precede and follow the modified noun.[2]

While Leung et al. (2020) learn adjective order by training on observed adjective pairs, an alternate strategy is to posit one or more a priori metrics as an underlying motivation for adjective order (e.g., Malouf, 2000, in part). This approach allows for the study of why adjective orders might have come about. To that end, Futrell et al. (2020a) report an accuracy of 72.3% for English triples based on a combination of subjectivity and information-theoretic measures derived from the distribution of adjectives and nouns.

One of the information-theoretic measures analyzed by Futrell et al. (2020a) is an implementation of information gain based on the partitioning an adjective performs on the space of possible noun referents. However, it is unclear how this formulation of information gain could be implemented for post-nominal adjectives, in which the noun has presumably already been identified. Instead, the current study implements information gain based on feature vectors, as outlined in §3.

To our knowledge, the current study is the first attempt at predicting adjective order across all three templates, with an eye not only to raw accuracy, but in hopes of illuminating the functional pressures which might contribute to word ordering preferences in general. While we acknowledge that multiple factors are likely involved in adjective order preferences, our contribution here is a single quantitative factor capable of predicting adjective order across typologically distinct languages.

---

[1] Celtic languages have been claimed to be an exception to this trend (Sproat and Shih, 1991), though our own investigations into Irish suggest that it behaves like other post-nominal languages, at least with respect to information gain.

[2] We note three empirical studies that have examined the placement of a single adjective or adjective phrase before or after the noun in Romance languages: Thuilier (2014), Gulordava et al. (2015) and Gulordava and Merlo (2015). However, these studies do not tackle the question of order preferences among ANA triples.

3 Information gain

3.1 Picture of communication

We assume that a speaker is trying to communicate a **meaning** to a listener, with a meaning represented as a binary vector, where each dimension of the vector corresponds to a feature. Multiple features can be true simultaneously. For example, a speaker might have in mind a vector like $m_1 = [111\ldots0]$ in Figure 1, where the vector has value 1 in the dimensions for 'is-big' (f_0), 'is-grey' (f_1), and 'is-elephant' (f_2), and 0 for all other features. A meaning of this sort would be conveyed by the noun phrase 'big grey elephant'. We call m a **feature vector** and the set of feature vectors M.

The listener does not know which meaning m the speaker has in mind; the listener's state of uncertainty can be represented as a probability distribution over all possible feature vectors, $P(m)$, corresponding to the prior probability of encountering a given feature vector. We call this distribution the **listener distribution** L.

By conveying information, each word in a sequence causes a change in the listener's prior distribution. Suppose as in Figure 1 that a listener starts with probability distribution L, then hears a word w conveying a feature (f_2), resulting in the new distribution L'. The amount of change from L to L' is properly measured using the Kullback–Leibler (KL) divergence $D_{\text{KL}}[L'||L]$ (Cover and Thomas, 2006). Therefore, the divergence $D_{\text{KL}}[L'||L]$ measures the amount of information about meaning conveyed by the word.

Another measure of the change induced by a word is the information gain, an extension of KL divergence to include the notion of negative evidence. Let $\bar{L}'$ represent the listener's probability distribution over feature vectors conditional on the negation of w. By taking a weighted sum of the positive and negative KL divergence, we recover **information gain** (Quinlan, 1986):

$$\text{IG} = \frac{|L'|}{|L|} D_{\text{KL}}[L'||L] + \frac{|\bar{L}'|}{|L|} D_{\text{KL}}[\bar{L}'||L], \quad (1)$$

where $|L|$ indicates the number of elements in the support of L with non-zero probability. Information gain represents the information conveyed by a word and also the information conveyed by its negation.

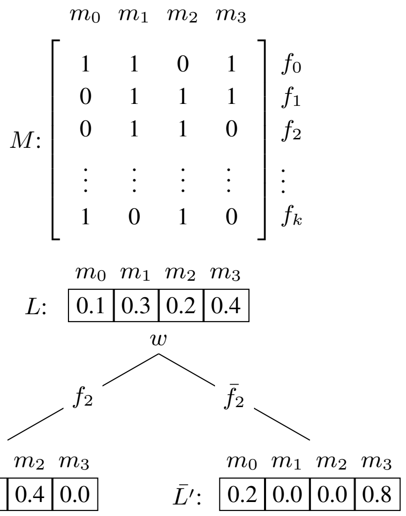

Figure 1: A toy universe composed of four feature vectors m defined by k binary features f and an associated probability distribution L. Partitioning L on f_2 yields L', the probability distribution of the feature vectors containing a 1 for f_2, viz. m_1 and m_2, as well as $\bar{L}'$, the distribution of feature vectors containing a 0 for f_2, or $\bar{f}_2$.

3.2 Relationship to other quantities

Our IG quantity in Eq. 1 is drawn from the ID3 algorithm for generating decision trees (Quinlan, 1986). The goal of ID3 is to produce a classifier for some random variable (call it L) which works by successively evaluating some set of binary features in some order. The optimal order of these features is given by greedily maximizing information gain, where information gain for a feature f is a measure of how much the entropy of L is decreased by partitioning the dataset into positive and negative subsets based on whether f is present or absent. Our application of information gain to word order comes from treating each word as a binary indicator for the presence or absence of the associated feature, and then applying the ID3 algorithm to determine the optimal order of these features.

The first term of Eq. 1, the divergence $D_{\text{KL}}[L'||L]$, measures the amount of information about L conveyed by the word w and has been the subject of a great deal of study in psycholinguistics. In particular, Levy (2008) shows that if the word w and the context c can be reconstructed perfectly from the updated belief state L', then the amount of information conveyed by w reduces to the **surprisal** of word w in context c:

$$D_{\text{KL}}[L'||L] = -\log p(w|c). \quad (2)$$

Importantly for our purposes, the positive evidence term $D_{\mathrm{KL}}[L'||L]$ in Eq. 1 alone is unlikely to make useful predictions about cross-linguistic ordering preferences, because surprisal is invariant to reversal of word order across a language as a whole (Levy, 2005; Futrell, 2019): the same surprisal values would be measured for any given language and a language with all the same sentences in reverse order. As such, these metrics are unable to predict any a priori asymmetries in word-order preferences between pre- and post-nominal positions.

3.3 Negative evidence

The new feature of information gain, which has not been presented in previous information-theoretic models of language, is the negative evidence term in $D_{\mathrm{KL}}[\bar{L}'||L]$, indicating the change in the listener's belief about L given the negation of the features indicated by word w, a quantity related to extropy (Lad et al., 2015). For example, consider *académie*/NOUN *militaire*/ADJ 'military/ADJ academy/NOUN' in French. Let L represent a listener's belief state after having heard the noun *académie* 'academy'. Upon hearing the adjective *militaire* 'military', L is partitioned into L'—the portion of L in which *militaire* is a feature—and $\bar{L}'$, the portion of L in which *militaire* is not a feature. Put another way, $\bar{L}'$ is the probability distribution over non-military academies.

The negative evidence portion of information gain is of primary interest to us because it breaks the symmetry to word-order reversal that we would have if we used the positive evidence term alone. That is, because the sum of surprisals of words w_1 and w_2 in the context of w_1 is the log joint probability of a sequence:

$$-\log p(w_1) - \log p(w_2|w_1) = -\log p(w_1, w_2), \tag{3}$$

the sum of w_2 and w_1 in the context of w_2 necessarily yields the same quantity. Conversely, IG's negative-evidence value is related to the log probability of w_2 conditional on the event of *not* observing w_1, and as such the sum of negative evidence values is not equivalent to the joint surprisal.

Information gain can therefore predict left–right asymmetrical word-order preferences such as the order of adjectives in ANA templates. Further, it maps onto a well-known decision rule for the ordering of trees.

3.4 An efficient algorithm

The goal of algorithms such as ID3 is to produce a decision tree which divides a dataset into equal-sized and mutually-exclusive partitions, thereby creating a shallow tree (Quinlan, 1986). While finding the smallest possible binary decision tree is NP-complete (Hyafil and Rivest, 1976), ID3's locally-optimal approach has proven quite effective at producing shallow trees capable of accurate classification (Dobkin et al., 1996).

By analogy, the ordering of adjectives in a noun phrase by maximizing information gain likewise produces a tree with balanced positive and negative partitions at each node. Specifically, adjectives that minimize the entropy of both the positive and negative evidence are placed before adjectives which are less 'decisive' at partitioning feature vectors.

4 Methodology

4.1 Data

Our study relies on two types of source data, both extracted from the CoNLL 2017 Shared Task: Multilingual Parsing from Raw Text to Universal Dependencies (Ginter et al., 2017; Zeman et al., 2017): a set of Common Crawl and Wikipedia text data from a variety of languages, automatically parsed according to the Universal Dependencies scheme with UDPipe (Straka and Straková, 2017). First, we extract **noun phrases** (NPs) containing at least one adjective to populate feature vectors (§4.3). Second, we extract **triples**, instances of a noun and two dependent adjectives, where the three words are sequential in the surface order and neither the noun nor the adjectives have other dependents.

We restrict triples in this way to minimize the effect that other dependents might have on order preferences. For example, while single-word adjectives tend to precede the noun in English, as in 'the *nice* people', adjectives in larger right-branching phrases often follow: 'the people *nice to us*' (Matthews, 2014), a trend also seen in Romance (Gulordava et al., 2015; Gulordava and Merlo, 2015). Similarly, conjunctions have been shown to weaken or neutralize preferences (Fox and Thuilier, 2012; Rosales Jr. and Scontras, 2019; Scontras et al., 2020).

NPs and triples extracted from the Wikipedia dumps are used to generate feature vectors and to train our regression (§4.4). We use triples from the Common Crawl dumps to perform hold-out accuracy testing.

4.2 Normalization

Because our source data are extracted from dumps of automatically-parsed text, they contain a large amount of noise, such as incorrectly assigned syntactic categories, HTML, nonstandard orthography, and so on. To combat this noise, we extract all lemmas with UPOS marked as ADJ and NOUN in all Universal Dependencies (UD) v2.7 corpora (Zeman et al., 2020) for a given language—the idea being that the UD corpora are of higher quality—and include only NPs and triples in which the adjectives and nouns are in the UD lists. All characters are case-normalized, where applicable.

4.3 Feature vectors

Each NP attested in the Wikipedia corpus for a given language corresponds to a feature vector with value 1 in the dimension associated with each adjective or noun lemma. For example, an NP such as "the best room available" generates a vector containing 1 for 'is-available', 'is-best', and 'is-room'.

The relative count of each NP in the Wikipedia corpus yields a probability distribution on feature vectors. It is this distribution which is transformed by partitioning on each lemma in a triple.

4.4 Evaluation

For a given typological template (AAN, ANA, or NAA) there are two competing variants; our tasks are to (i) predict which of the variants will be attested in a corpus and (ii) show a cross-linguistic consistency in how that prediction comes about.

Because we are limiting our study to the two competing variants within each template, the position of the noun is invariant, leaving only the relative order of the two adjectives to determine the order of a triple. Our problem thus reduces to whether the information gain of the first linear adjective is greater than that of the second.

In the case of AAN and ANA triples, the IG of each adjective is calculated by partitioning the entire set of feature vectors L on each of the two adjectives. In the case of NAA triples, however, IG is calculated by partitioning only those feature vectors which 'survive' the initial partition by the noun, and are therefore part of L'. Thus we calculate $\text{IG}(L, a)$ before the noun and $\text{IG}(L', a)$ after.

Rather than simply implement the ID3 algorithm and choose adjectives based on their raw information gain, we train a logistic regression to predict surface orders based on the *difference* of IG between the attested first and second adjective, a method previously used by Morgan and Levy (2016) and Futrell et al. (2020a). The benefits of this approach are two-fold: we are able to account for bias in the distribution of adjectival IGs, and we can more easily deconstruct how strong information gain is as a predictor of adjective order.

Within each template, for each attested triple τ, let π_1 be the lexicographically-sorted first permutation of τ and π_2 be the second, with α_1 being the first linear adjective in π_1 and α_2 being the first linear adjective in π_2. Our independent variable p is whether π_1 is attested in the corpus, and our dependent variable is the difference between the information gain of α_1 and α_2. We train the coefficients β_0 and β_1 in a logistic regression of the form

$$\begin{aligned} p &= \begin{cases} 1, & \text{if } \pi_1 \text{ is attested} \\ 0, & \text{if } \pi_2 \text{ is attested} \end{cases} \\ \log \frac{p}{1-p} &\sim \beta_0 + \beta_1[\text{IG}(\alpha_1) - \text{IG}(\alpha_2)]. \end{aligned} \tag{4}$$

A positive value for β_1 tells us that permutations in which the larger-IG adjective is placed first tend to be attested. The value of β_0 tells us whether there is a generalized bias towards a positive or negative $\text{IG}(\pi_1) - \text{IG}(\pi_2)$. The accuracy we achieve by running the logistic regression on held-out testing data tells us the effectiveness of an IG-based algorithm at predicting adjective order.

4.5 Reporting results

We report results for languages from which at least 5k triples could be analyzed, and for templates representing at least 10% of a language's triples in UD corpora. The count of analyzable triples for each language is a product of those available in the 2017 CoNLL Shared Task, those with sufficiently large UD v2.7 corpora, and those that meet our extraction requirements (§4.1).

Because we are interested in exploring a cross-linguistic predictor of adjective order, we report macro-average accuracies and β_1 coefficients. That is, each language's accuracy and coefficient are calculated independently and are then averaged. We report both type- and token-accuracy, using the latter in our analysis based on the intuition that the preference for the order of a commonly-occurring triple is stronger than a more rare one.

Table 1: Results by template and language: n triples analyzed, regression coefficient β_1 and P-value, and test accuracies. Means with 95% confidence intervals shown for each template.

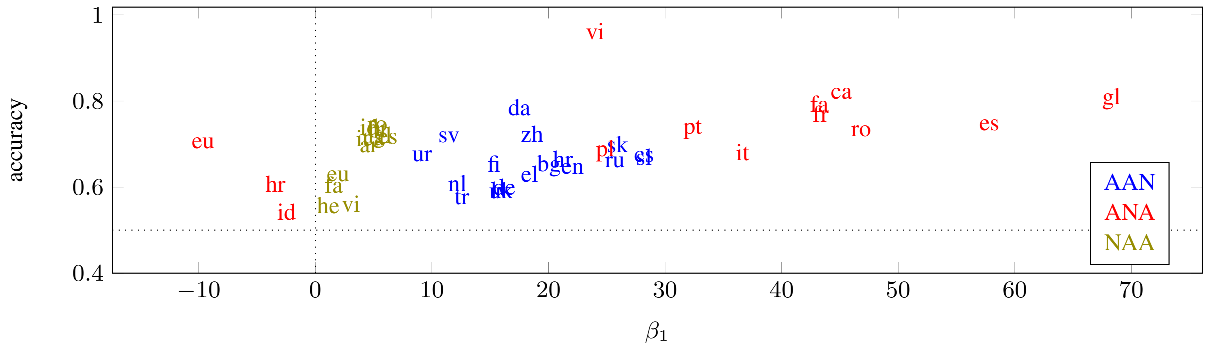

Figure 2: Plot of accuracy and β_1 coefficient, categorized by template type.

5 Results

We extracted and analyzed at least 5k triples from 32 languages across a variety of families.[3] Because some languages contain triples in two typological templates, we report results for 44 sets of triples. Table 1 reports language-specific results and means for each template, including n triples analyzed, regression coefficient β_1 and P-value, token and type accuracy, and 95% confidence intervals. Figure 2 shows a plot of accuracy and β_1 coefficient for each language, categorized by template.

As reported in Table 1, we find above-chance ($> 50\%$) accuracy for all languages tested. We accurately predict 65.6% of AAN triples, 73.7% of ANA triples, and 68.0% of NAA triples, for a comprehensive accuracy across all languages of 68.7%. Overlapping 95% confidence intervals across template suggest that IG-based prediction performs equally well across templates.

The high performance on Vietnamese ANA triples (96.2%) is largely due to the algorithm correctly predicting that the highly-frequent adjective *nhiều* ‘many’ should be placed before the noun, while most other adjectives are placed after.[4]

Though we cannot make a direct comparison to other studies due to a lack of shared data, Table 2 shows that our cross-linguistic accuracy of 68.7% bests any single predictor applied to a similar set of English AAN triples by Futrell et al. (2020a).

	n	accuracy	confidence interval
IG-FV	44	**0.687**	[0.686, 0.688]
Subj.	1	0.661	[0.657, 0.666]
PMI	1	0.659	[0.654, 0.664]
IG-NR	1	0.650	[0.645, 0.654]
IC	1	0.642	[0.634, 0.646]

Table 2: Comparison across n languages of the current metric, IG of feature vectors (IG-FV), and subjectivity, PMI, IG of noun referents (IG-NR), and integration cost (IC) (Futrell et al., 2020a)

The learned β_1 coefficient is not significantly different between AAN (18.591) and ANA (31.313) triples, though that of NAA (4.140) triples is significantly smaller than the other two. More generally, of the 44 datasets tested, β_1 is positive in 41 (93.2%), suggesting that there is a strong preference to maximize information gain. Further, of the three instances of a negative β_1, two (Croatian and Indonesian ANA) do not reach significance, perhaps due to a paucity of data. The sole significant negative β_1 is from Basque ANA triples.

6 Discussion

6.1 β_1 coefficient

Our results show a strong tendency across typological templates and across languages for the adjective which yields a larger information gain to be placed before the other, as evidenced by a positive β_1. However, the absolute value of β_1 is difficult to interpret without understanding the relative magnitudes of the underlying IG scores, magnitudes that vary across datasets and word distributions.

In general, we observe that a larger value of β_1 indicates that IG is a more reliable predictor within a dataset. More specifically, a value of $\beta_1 = 1$ indicates that if the IG difference between orders is equal to one bit, then the log odds of the order with larger IG increases by one.

---

[3] `https://github.com/wmdyer/infogain`

[4] One might worry about the classification of ‘many’ as an adjective. While widely extant across languages, the class of adjectives is not entirely homogeneous. As such, the equivalent of a word like ‘many’ in some languages might be marked as an adjective, determiner, or other syntactic category. For the current study, we simply follow the UD annotation scheme.

	n	rate	confidence interval
AAN	18	0.017	[0.012, 0.022]
ANA	13	**0.007**	[0.002, 0.011]
NAA	13	0.022	[0.013, 0.032]
all	44	0.016	[0.012, 0.020]

Table 3: Macro-average rate of adjectives attested in both possible orders within each template, showing n languages, rate of attestation, and 95% confidence intervals.

6.2 Asymmetries

The preference for one variant of an ANA triple over the other is an asymmetry without a straightforward explanation in a distance-based model; there is no clear mapping from ANA onto the other templates, which means that an adjective's relative distance to the noun is not informative. Our algorithm is novel in that the placement of the adjectives is governed by greedy IG, not distance to the noun—an innovation that allows us to break the symmetry between the adjectives in ANA triples. Similarly, IG makes no a priori prediction as to whether a mirror- or same-order will emerge between AAN and NAA triples: both pre- and post-nominal behavior is a product of ordering adjectives such that information gain is maximized, and IG itself is fundamentally derived from the distribution of adjectives and nouns that populate a language's possible feature vectors for conveying meaning.

Another left–right asymmetry that has been posited in the linguistics literature holds that dependents placed before the head in a surface realization (e.g., the adjectives in an AAN triple) follow a more rigid ordering than those placed after (e.g., the adjectives in a NAA triple; Hawkins, 1983). Both noun modifiers in general and adjectives specifically have been reported to follow this pattern, with a largely-universal pre-nominal ordering and a mirror, same, or 'free' post-nominal order (Hetzron, 1978). There is as yet no large-scale empirical evidence for this claim, though Trainin and Shetreet (2021) suggest that Hebrew NAA order preferences may be weaker than English AAN for a restricted set of adjective classes.

In an effort to empirically assess the claim that post-nominal orderings are more flexible compared to orderings pre-nominally across languages, Table 3 reports the average prevalence of adjective pairs attested in both possible orders (e.g., A_1A_2N and A_2A_1N, where N can be any noun) within each template in our dataset. At 95% confidence the difference between AAN and NAA does not reach significance, though the rate for ANA is significantly lower than the other two. More generally, the mean rate of just 1.6% across templates reinforces the notion that ordering preferences are quite robust regardless of template, at least for our normalized triples from the languages analyzed here.

6.3 Ablation

Equation 1 defines information gain as the conditioned sum of two elements, the positive evidence $D_{\text{KL}}[L'||L]$ and the negative evidence $D_{\text{KL}}[\bar{L}'||L]$. The positive evidence alone is akin to surprisal, a well-studied quantity in psycholinguistics (§3.2), while the negative evidence is related to extropy (§3.3). By ablating the IG formulation into the two terms discretely, we can show empirically that the proportionally-combined positive and negative evidence yield more accurate and consistent results than either of the two constituent terms alone.

Table 4 shows the mean accuracy and polarity proportion of the β_1 coefficient across languages and templates. The polarity of β_1 tells us whether maximizing IG (positive) or minimizing IG (negative) is the better strategy. Thus a polarity percentage close to 0 or 1 indicates more consistent behavior across templates.

For example, while the accuracy of using only positive evidence, $D_{\text{KL}}[L'||L]$, for AAN triples is 0.565, that accuracy is realized due to a 0.000 rate of positive β_1 coefficient—that is, the 56.5% accuracy is achieved by minimizing IG, placing the adjective with the lower IG first. On the other hand, while using only positive evidence to predict NAA triples yields the same accuracy, 0.565, the coefficient polarity proportion of 0.769 means that, in most NAA cases, IG should be maximized. The three templates together reflect a modest accuracy (0.566) and an inconsistent coefficient polarity proportion (0.273).

Using only negative evidence, $D_{\text{KL}}[\bar{L}'||L]$, yields even worse accuracies and similarly inconsistent coefficients as positive only. The accuracy across templates is little better than chance at 0.535, and the average coefficient polarity proportion of 0.273 likewise demonstrates that using negative evidence alone does not produce consistent behavior across templates.

	accuracy				proportion of positive β_1			
	AAN	ANA	NAA	all	AAN	ANA	NAA	all
$D_{\mathrm{KL}}[L'\|\|L]$	0.565	0.567	0.565	0.566	0.000	0.154	0.769	0.273
$D_{\mathrm{KL}}[\bar{L}'\|\|L]$	0.533	0.548	0.526	0.535	0.167	0.231	0.462	0.273
IG	**0.657**	**0.737**	**0.680**	**0.687**	**1.000**	**0.769**	**1.000**	**0.932**

Table 4: Ablation on accuracy and the proportion of positive coefficients for positive evidence ($D_{\mathrm{KL}}[L'||L]$) alone, negative evidence ($D_{\mathrm{KL}}[\bar{L}'||L]$) alone, and proportionally combined terms (IG). Boldfaced values indicate the highest accuracy or coefficient polarity proportion in each column.

The full IG calculation, including both positive and negative evidence, yields the highest accuracy across templates (0.687), as well as the highest for each template—AAN (0.657), ANA (0.737) and NAA (0.680). IG also demonstrates the most consistent behavior across languages and templates: at a rate of 0.932, maximizing IG yields the highest accuracy, regardless of whether adjectives precede or follow the noun.

7 Summary

We have taken a novel approach to the problem of predicting the surface order of adjectives across languages, casting it as a decision tree operating on a probability distribution over binary feature vectors. As each adjective is uttered, probability mass is partitioned into positive and negative subsets: those vectors that contain the feature and those that do not. The information gained by this partition can be used to order adjectives in a greedy manner, similarly to well-known algorithms for ordering nodes in a decision tree.

An IG-based approach allows us to provide the first quantitative information-theoretic account predicting the order of ANA triples. Further, with this approach we need not stipulate mirror- or same-orders for AAN and NAA triples. Because IG is not a distance metric between adjective and noun, and because IG incorporates negative evidence, both ANA and pre- or post-nominal asymmetries are able to emerge within an IG framework, without appeal to other mechanisms.

Our results show that information gain is a good predictor of adjective order across languages. Importantly, IG-based prediction follows a consistent pattern across the three typological templates, namely that adjectives that maximize information gain tend to be placed first.
