Sample encoder. We follow the same strategy to build a sample encoder. Given each sample $x = (I, tt)$, i.e., a candidate trigger word tt and its context I, we first utilize BERT to encode x and select the encoding of tt as the trigger representation $\mathbf{e}^*_{tt}$. As arguments are not explicitly given in x, we use an attention mechanism to aggregate the implicit argument information for current trigger tt, in which the *query* is $\mathbf{e}^*_{tt}$, *key* and *value* are both token encoding generate from I. We denote the argument encoding as $\mathbf{e}^*_a$.

Finally, we concatenate the trigger word encoding $\mathbf{e}^*_{tt}$ and the argument encoding $\mathbf{e}^*_a$, and use a feed forward network $f^{\mathcal{E}}$ to generate the sample encoding vector $\boldsymbol{\mathcal{E}}(x)$,

$$\boldsymbol{\mathcal{E}}(x) = f^{\mathcal{E}}\left([\mathbf{e}^*_a; \mathbf{e}^*_{tt}]\right). \tag{3}$$

4.2 Adaptive Knowledge-Enhanced Posterior

The posterior distribution can be factorized into a prior distribution (given the event knowledge) and a likelihood on the support set (Qu et al., 2020) as,

$$p(\mathbf{V}_{T_S}|X_S, Y_S, \mathscr{F}) \propto p(Y_S|X_S, \mathbf{V}_{T_S})p(\mathbf{V}_{T_S}|\mathscr{F}), \tag{4}$$

where $p(Y_S|X_S, \mathbf{V}_{T_S})$ is the likelihood on the support set, and $p(\mathbf{V}_{T_S}|\mathscr{F})$ is the adaptive knowledge-based prior for the prototype vectors. We describe the details of these two components as follows:

Adaptive Knowledge-based Prior. As we discussed in Section 1, an event type t may not have an exact/perfect match in the knowledge base $\mathscr{F}$. In such situations, we resort to finding the super-ordinate frame of t, which is semantically closest to t. As shown in Figures 1 and 2, where the event type t in the support set 'online-chat' is matched against the knowledge prior F_t 'Chatting' in FrameNet, a super-ordinate frame. In order to enable the knowledge encoding to accurately reflect the characteristics of the corresponding event type, we add a learnable *knowledge offset* to $\mathbf{h}_t$. We denote the knowledge offset between the event type t and its knowledge encoding $\mathbf{h}_t$ by $\Delta\mathbf{h}_t$. Recall that the knowledge in $\mathbf{h}_t$ is encoded from the exactly-matched frame or the super-ordinate frame. $\Delta\mathbf{h}_t$ is defined as follows:

$$\Delta\mathbf{h}_t = \boldsymbol{\lambda}_t \odot (\mathbf{m}_t - \mathbf{h}_t), \tag{5}$$

where $\odot$ is the element-wise product, and $\mathbf{m}_t$ is the mean of the encodings $\boldsymbol{\mathcal{E}}(x)$ of all the samples x in the support set. $\boldsymbol{\lambda}_t \in [0, 1]^{|\mathbf{h}_t|}$ is the adaptive weight (gate), which is obtained from the sample encoding $\mathbf{m}_t$ and the knowledge encoding $\mathbf{h}_t$:

$$\boldsymbol{\lambda}_t = \sigma(\mathbf{W}_\lambda\left[\mathbf{m}_t; \mathbf{m}_t - \mathbf{h}_t; \mathbf{h}_t\right] + \mathbf{b}_\lambda), \tag{6}$$

where σ is the nonlinear sigmoid function, and $\mathbf{W}_\lambda$ and $\mathbf{b}_\lambda$ are trainable parameters.

Putting it altogether, the knowledge prior distribution has the following form,

$$\begin{aligned} p(\mathbf{V}_{T_S}|\mathscr{F}) &= \prod_{t \in T_S} p(\mathbf{v}_t|\mathbf{h}_t, \Delta\mathbf{h}_t) \\ &= \prod_{t \in T_S} \mathcal{N}(\mathbf{v}_t|\mathbf{h}_t + \Delta\mathbf{h}_t, \boldsymbol{I}), \end{aligned} \tag{7}$$

where $\mathcal{N}(\mathbf{v}_t|\mathbf{h}_t + \Delta\mathbf{h}_t, \boldsymbol{I})$ is multivariate Gaussian with the mean $\mathbf{h}_t + \Delta\mathbf{h}_t$ and covariance $\boldsymbol{I}$ (the identity matrix). So, each prototype vector has a prior distribution containing knowledge from *FrameNet* adaptively adjusted according to the support set.

Likelihood. With the given prototype vectors $\mathbf{V}_{T_s}$ distributed according to $p(\mathbf{V}_{T_S}|X_S, Y_S, \mathscr{F})$, the likelihood for support samples is defined as,

$$\begin{aligned} p(Y_S|X_S,\mathbf{V}_{T_S}) &= \prod_{s\in S} p(y_s|x_s,\mathbf{V}_{T_S}) \qquad (8)\\ p(y_s=t|x_s,\mathbf{V}_{T_S}) &:= \frac{\exp(\boldsymbol{\mathcal{E}}(x_s)\cdot\mathbf{v}_t)}{\sum_{t'\in T_S}\exp(\boldsymbol{\mathcal{E}}(x_s)\cdot\mathbf{v}_{t'})}. \end{aligned}$$

The dot product of the sample encoding $\boldsymbol{\mathcal{E}}(x_q)$ and the event type prototype vector $\mathbf{v}_t$ estimates their similarity. We use $softmax$ to normalize the result to the probability of x_s belonging to event type t.

4.3 Optimization and Prediction

For prediction, the model computes and maximizes the log-probability $\log p(Y_Q|X_Q,X_S,Y_S,\mathscr{F})$. However, according to Eqn (1), the log-probability relies on the integration over prototype vectors, which is difficult to compute. Hence, we estimate it with Monte Carlo sampling (Qu et al., 2020),

$$\begin{aligned} &p(Y_Q|X_Q,X_S,Y_S,\mathscr{F})\\ &=\mathbb{E}_{p(\mathbf{V}_{T_S}|X_S,Y_S,\mathscr{F})}\left[p(Y_Q|X_Q,\mathbf{V}_{T_S})\right]\\ &\approx\frac{1}{N_s}\sum_{i=1}^{N_s}p(Y_Q|X_Q,\mathbf{V}_{T_S}^{(s)}) \qquad (9)\end{aligned}$$

where N_s is the number of samples, and $\mathbf{V}_{T_S}^{(s)}$ is a sample drawn from the posterior distribution, i.e. $\mathbf{V}_{T_S}^{(s)} \sim p(\mathbf{V}_{T_S}|X_S,Y_S,\mathscr{F})$. $p(Y_Q|X_Q,\mathbf{V}_{T_S}^{(s)})$ is the likelihood for query samples which has the same form as Eqn 8. To sample from the posterior, we use the stochastic gradient Langevin dynamics (Welling and Teh, 2011) with multiple stochastic updates. Formally, we initialize the sample $\hat{\mathbf{V}}_{T_S}$ and iteratively update the sample as,

$$\begin{aligned}\hat{\mathbf{V}}_{T_S}\leftarrow&\hat{\mathbf{V}}_{T_S}+\sqrt{\epsilon}\boldsymbol{z} \qquad (10)\\ &+\frac{\epsilon}{2}\nabla_{\hat{\mathbf{V}}_{T_S}}\log\ p(Y_S|X_S,\hat{\mathbf{V}}_{T_S})p(\hat{\mathbf{V}}_{T_S}|\mathscr{F}),\end{aligned}$$

where $\boldsymbol{z}\sim\mathcal{N}(\mathbf{0},\boldsymbol{I})$, and ϵ is a small real number representing the update step size. The gradient $\nabla_{\hat{\mathbf{V}}_{T_S}}\log\ p(Y_S|X_S,\hat{\mathbf{V}}_{T_S})p(\hat{\mathbf{V}}_{T_S}|\mathscr{F})$ in Eqn 10 balances the effect of the knowledge and the support set on the prototype vector. Please see Appendix B for derivation details and intuitive explanations of its influence.

The Langevin dynamics requires a burn-in period. To speed up the convergence, we follow the previous method (Qu et al., 2020) and initialize the sample as follows,

$$\begin{aligned}\hat{\mathbf{V}}_{T_S}&\leftarrow\{\hat{\mathbf{v}}_t\}_{t\in T_S}\\ \hat{\mathbf{v}}_t&\leftarrow\mathbf{m}_t+\mathbf{h}_t+\Delta\mathbf{h}_t-\mathbf{m},\end{aligned}\qquad(11)$$

where $\mathbf{m}$ is the mean encoding of all the samples in the support set.

Algorithm 1: Training Process

```
Input: Event type set $T$
Input: Event knowledge from FrameNet
while not convergence do
    Sample a subset $T_S$ from $T$ to build a FSED task
    Sample disjoint support and query sets for $T_S$
    Compute the sample encodings (Eq. 3)
    Compute the $\{\mathbf{m}_t\}_{t\in T_S}$ for each $t\in T_S$
    Compute knowledge encodings $\{\mathbf{h}_t\}_{t\in T_S}$ (Eq. 2)
    Compute knowledge offset $\{\Delta\mathbf{h}_t\}_{t\in T_S}$ (Eq. 5)
    Initialize prototype vectors $\{\mathbf{V}^s_{T_S}\}_{s=1}^{N_s}$ (Eq. 11)
    Update prototype vectors iteratively (Eq. 12)
    Compute and maximize log-likelihood (Eq. 9)
```

After obtaining prototype samples from the posterior, $\log p(Y_Q|X_Q,X_S,Y_S,\mathscr{F})$ is end-to-end approximated according to Eqn (9). During the training stage, we optimize the log-likelihood of the query set and update the model parameters by gradient descent. In the prediction stage, the log-likelihood will determine the probability that a query sample belongs to each event type. The training process is shown in Algorithm 1.

5 Experiments

We conduct evaluation with the following goals: (1) to compare our adaptive knowledge-enhanced Bayesian meta-learning method with existing few-shot event detection methods and few-shot learning baseline methods; (2) to assess the effectiveness of introducing external knowledge in different N-way-M-shot settings; and (3) to provide empirical evidence that our adaptive knowledge offset can flexibly adjust the impact of the support set and prior knowledge on event prototypes, making the model more accurate and generalizable.

5.1 Experimental Settings

We evaluate our method on an aggregated few-shot event detection dataset *FewEvent*[2] (Deng et al., 2020). *FewEvent* combines two currently widely-used event detection datasets, the ACE-2005 corpus[3] and the TAC-KBP-2017 Event Track Data[4], and adds external event types in specific domains including music, film, sports and education (Deng et al., 2020). As a result, *FewEvent* contains 70,852 samples for 19 event types that are further divided into 100 event subtypes.

In order to match the few-shot settings , we use

---

[2] `https://github.com/231sm/Low_Resource_KBP`

[3] `http://projects.ldc.upenn.edu/ace/`

[4] `https://tac.nist.gov/2017/KBP/Event/index.html`

88 event types covering a total of 15,681 samples to construct experimental data. 68 event types are selected for training, 10 for validation, and the rest 10 for testing. Note that there are no overlapping types between the training, validation and testing sets. In order to obtain a convincing result, we conducted 5 random divisions of training and testing for all event types, and the experimental results are averaged as the final result.

The comparisons with our AKE-BML are performed in two aspects, the *sample encoder* and the *few-shot learner*. We combine different encoders and few-shot learners to obtain different baseline models. We consider four sample encoders including CNN (Kim, 2014), Bi-LSTM (Huang et al., 2015), DMN (Kumar et al., 2016) and our trigger-attention-based sample encoder TA. For few-shot learners, we consider Matching Networks (MN) (Vinyals et al., 2016) and Prototypical Networks (PN) (Snell et al., 2017). We also compare to the SOTA few-shot event detection method DMN-MPN (Deng et al., 2020), which uses a dynamic memory network (DMN) as the sample encoder and a memory-based prototypical network as the few-shot learner. In addition, in order to verify the effectiveness of our proposed method, we perform an ablation study on our model, which evaluate the model without external knowledge and without dynamic knowledge adaptation.

As a result, the following methods are compared in our experiments:

- **AKE-BML**, our adaptive knowledge-enhanced Bayesian meta-learning method which uses TA encoder as the sample encoder.
- **KB-BML**, a variant of AKE-BML without dynamic knowledge adaption.
- **TA-BML**, a variant of AKE-BML using our TA encoder but without using external knowledge.
- **DMN-MPN**, dynamic-memory-based prototypical network (Deng et al., 2020).
- **Encoder+Learner**, combinations of various sample encoders and event type learners (e.g. CNN+MN and TA+PN).

We use stochastic gradient descent (Bottou, 2012) as the optimizer in training with the learning rate 1×10^{-5}. The sampling times N_s of Monte Carlo sampling and update step size ϵ are set to 10 and 0.01 respectively. The update times of stochastic gradient Langevin dynamics M is set to 5. We use dropout after the sample encoder and the knowledge encoder to avoid over-fitting; the dropout rate is set to 0.5. We evaluate the performance of event detection with F_1 and $Accuracy$ scores.

5.2 Main Results

As shown in Table 1, we compare methods on F_1 and $Accuracy$ scores. We observe the followings:

- Our full model AKE-BML outperforms all other methods on both $Accuracy$ and F_1 scores across all settings. Compared with the SOTA method DMN-MPN, AKE-BML achieves a substantial improvement of 15–23 absolute F_1 points in all N-way-M-shot settings. It shows our adaptive knowledge-enhanced Bayesian meta-learning method can effectively utilize external knowledge and adjust it according to the support set, thus build better prototypes of event types. Please see Appendix C and D for a detailed performance analysis over various N-way and M-shot settings.
- With the sample encoders (Bi-LSTM, CNN, DMN and TA) fixed, it can be observed that prototypical networks (PN) consistently outperforms matching networks (MN). DMN-MPN performs better than PN-based methods, because the dynamic memory network can extract key information from the support set through multiple iterations. However, DMN-MPN only considers the information of a few samples in each support set, hence suffering from insufficient sample diversity similar to PN- and MN-based methods.
- TA-BML performs similarly with DMN-MPN under the settings of N-way-5-shot and N-way-10-shot, but slightly worse under the N-way-15-shot setting. One possible explanation is that when the number of samples in the support set is larger, MPN can generate higher-quality prototypes. In addition, the performance of TA-BML is not as good as KB-BML, which shows the importance of introducing external knowledge.
- Compared with KB-BML, our full model AKE-BML can effectively solve the problem of deviation between knowledge and event types, and generate event prototypes with better generalization through knowledge. Compared with TA-BML, which does not incorporate external knowledge, AKE-BML achieves an even larger performance advantage, which further demonstrates the effectiveness of external knowledge.

5.3 Case Study

We present a case study on the dynamic knowledge adaptation between the support set and the

corresponding event knowledge to demonstrate our model's ability to learn robust event prototypes.

5.3.1 Predictions for Specific Cases

We select three event types as target categories to illustrate the contributions of each main component of our model. The event types are *Music.Compose*, *Music.Sing* and *Film.Film_Productution*. The sample contexts of *Music.Compose* and *Music.Sing* are similar, while *Music.Compose* and *Film.Film_Productution* share the same frame, which is *Behind_the_scenes*.

As shown in Table 2, only AKE-BML correctly predicts on all samples. TA-BML, the model without introducing knowledge, wrongly predicts the second sample of *Music.Compose* to be *Music.Sing*, due to their similar contexts. By introducing knowledge, both KB-BML and AKE-BML avoid this error, indicating that external knowledge can enrich event information based on the support set. For KB-BML, as *Music.Compose* and *Film.Film_Productution* share the same superordinate frame, the prototype of *Music.Compose* cannot distinguish between *Music.Compose* and *Film.Film_Productution*, so it wrongly classifies the third sample as *Music.Compose*. With our adaptive knowledge offset, AKE-BML can deal with sample similarity and knowledge deviation issues at the same time, thus it correctly classifies all samples.

5.3.2 Visualization of Prototypes

We use Latent Dirichlet Allocation (LDA) (Blei et al., 2003) to reduce the dimensionality of the prototypes, sample encodings and prior knowledge encodings. Figure 4 visualizes five event type prototypes (large solid shapes), their aligned frames (large solid shapes with circle outlines) in FrameNet and some corresponding samples (small solid shapes). Each event type and its samples are coded with the same color.

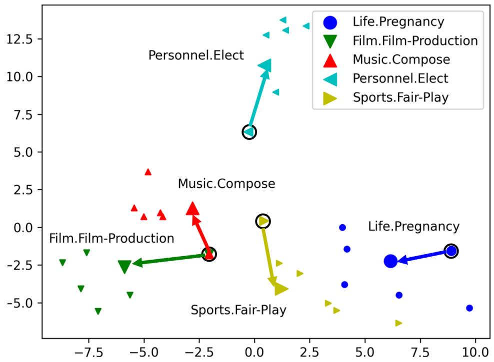

Figure 4: Visualization of event prototypes, prior knowledge, and event samples learned by AKE-BML in the 5-way-5-shot setting. The large, solid shapes denote event prototypes, the large shapes with circle outlines denote the prior knowledge, and the small shapes denote samples. Samples are marked by the color of their corresponding event types. The arrows indicate the adaption of prior knowledge to the prototype. Note that *Music.Compose* and *Film.Film-Production* share the same frame *Behind_the_scenes*.

In general, the samples and prototypes belonging to one event type are close in the space and different event types are far away from each other. Prior knowledge is distributed in different places in the space, which roughly determines the distribution of event prototypes. For example, the samples of *Life.Pregnancy* and *Sports.Fair-Play* are close to their respective event prototypes. Meanwhile, the distances between their prior knowledge is large, making their prototypes easily distinguishable.

It can also be seen that the event prototypes are closer to their samples than to the prior knowledge, which reflects the benefits of our proposed learnable knowledge offset. The visualization demonstrates the effectiveness of introducing external

Table 2: A case study of three event types. Words in bold indicate candidate trigger words.

Event Type	Explanation of Event Type	Examples in Support Set	λ_t	Corresponding Frame	Frame Definition
Contact.Letter-Communication	Communicate by writing letters.	(1)…*write* this letter to you… (2)…*sends* you this letter… (3)…the letter *passed* from…	0.228	Communication	A Communicator conveys a Message to an Addressee; the Topic and Medium of the communication also may be expressed.
Conflict.Attack	An assailant attacks a victim.	(1)He *shoot* them all with… (2)… *firing* at close… (3)Soldier hacked to death…	0.132	Attack	An Assailant physically attacks a Victim causing or intending to cause the Victim physical damage…
Film.Film-Production	The production process of the film.	(1)… *making* a film… (2)…*creating* the film… (3)…the action is *shot* as…	0.386	Behind_the_scenes	Artists work at various tasks that further the completion of a film, play, television show, or other similar Production
Music.Compose	Music creation process.	(1)…*composes* musical … (2)…*co-written* by him and… (3)… *create* musical sounds…	0.421		

Table 3: λ_t values corresponding to different event types. The larger the λ_t, the greater the dependence of the prototype vector on the support set.

knowledge and our adaptive knowledge offset's ability to balance the impact of the support set and prior knowledge on the event prototypes.

5.3.3 λ_t of Different Event Types

As shown in Formula (5), we use the learnable parameter λ_t to generate knowledge offsets. λ_t accounts for the deviation of the prior knowledge (i.e. a frame) from the event type it represents, and adaptively corrects this deviation using information of the support set. When the frame corresponding to the event type accurately expresses its semantics, the λ_t value should be small. When the knowledge is the super-ordinate frame of the event type (i.e., the frame cannot accurately describe the event semantics), the λ_t value should be large, so that the support set can be used to modify the prior knowledge to ensure that the prototype precisely represents the current event type.

Table 3 shows four different event types, their corresponding frames and λ_t values. The λ_t of *Conflict.Attack* is a small value 0.132, as the event type *Conflict.Attack* closely matches the frame *Attack*. The event type *Contact.Letter-Communication* matches the frame *Communication*. *Communication* does not contain the semantics of "by writing letters", but the core semantics is the same as *Contact.Letter-Communication*. Therefore, λ_t is small, at 0.228, which is still larger than the λ_t of *Conflict.Attack*. The event types *Film.Film-Production* and *Music.Compose* share the same super-ordinate frame *Behind_the_scenes* as prior knowledge, but the semantics of *Behind_the_scenes* is too abstract for *Film.Film-Production* and *Music.Compose*. Thus, it can be seen that the λ_t values corresponding to these two event types are relatively large: 0.386 for *Film.Film-Production* and 0.421 for *Music.Compose*.

The above cases demonstrate that our model is able to balance the influence of the support set and the knowledge on event prototypes through λ_t, and consequentially obtain highly accurate and generalizable prototypes.

6 Conclusion

In this paper, we proposed an Adaptive Knowledge-enhanced Bayesian Meta-Learning (AKE-BML) method for few-shot event detection. We alleviate the insufficient sample diversity problem in few-shot learning by leveraging the external knowledge base *FrameNet* to learn prototype representations for event types. We further tackle the uncertainty and incompleteness issues in knowledge coverage with a novel knowledge adaptation mechanism.

The comprehensive experimental results demonstrate that our proposed method substantially outperforms state-of-the-art methods, achieving a performance improvement of at least 15 absolute points of F_1. In the future, we plan to extend our proposed AKE-BML method to the few-shot event extraction task, which considers both event detection and argument extraction. We also plan to explore the zero-shot and incremental event extraction scenarios.

Appendix

A FrameNet

An important problem in the few-shot event detection task is the insufficient diversity of support set samples. There are only a few labeled samples in the support set, which results in the model unable to construct high-quality prototype features of event types. To address this problem, we introduce the *FrameNet* (Baker et al., 1998) as an external knowledge base of event types. *FrameNet* is a linguistic resource storing information about lexical and predicate-argument semantics. Each frame in *FrameNet* can be taken as a semantic frame of an event type (Liu et al., 2016), which can be used as background knowledge for event types to assist event detection (Liu et al., 2016; Fillmore et al., 2006). Figure 2 shows an example frame defining *Attack*. We can see the arguments involved in an *Attack* event and their roles. The linguistic units (LUs) of the frame *Attack* are the possible trigger words for the corresponding event. The frame is an important complementary source of knowledge to the support set. We match a frame in *FrameNet* to each event type, based on the event name, as its knowledge. In practice, *FrameNet* does not provide complete coverage of all event types, nor does every event type have an exact frame matched in *FrameNet*. For event types that cannot be exactly matched, we assign the frame corresponding to their super-ordinate event. For example, there is no corresponding frame for *Contact.Online-Chat*, so we assign it to the frame *Chatting*, which corresponds to the event type *Contact.Chat*.

B Gradient of posterior distribution

In order to show the change of the prototype vector after adding the knowledge shift, the gradient $\nabla_{\hat{\mathbf{V}}_{T_S}} \log\ p(Y_S|X_S, \hat{\mathbf{V}}_{T_S}) p(\hat{\mathbf{V}}_{T_S}|\mathscr{F})$ in iteration

$$\begin{aligned}\hat{\mathbf{V}}_{T_S} \quad &\leftarrow \hat{\mathbf{V}}_{T_S} + \sqrt{\epsilon}\boldsymbol{z} \\ &+ \frac{\epsilon}{2}\nabla_{\hat{\mathbf{V}}_{T_S}} \log\ p(Y_S|X_S, \hat{\mathbf{V}}_{T_S}) p(\hat{\mathbf{V}}_{T_S}|\mathscr{F}),\end{aligned} \tag{12}$$

is expanded. For ease of explanation, we only calculate the gradient of the prototype vector $\hat{\mathbf{v}}_t$. We denote the gradient of the original posterior distribution as $\mathbf{g}^o_{\hat{\mathbf{v}}_t}$, the gradient of the knowledge-shifted posterior distribution as $\mathbf{g}^s_{\hat{\mathbf{v}}_t}$. We first calculate $\mathbf{g}^o_{\hat{\mathbf{v}}_t}$:

$$\begin{aligned}\mathbf{g}^o_{\hat{\mathbf{v}}_t} =& \nabla_{\hat{\mathbf{v}}_t} \log\ p(Y_S|X_S, \hat{\mathbf{V}}_{T_S}) p^o(\hat{\mathbf{V}}_{T_S}|\mathscr{F}) \\ =& \nabla_{\hat{\mathbf{v}}_t} \log\ p(Y_S|X_S, \hat{\mathbf{V}}_{T_S}) + \log\ p^o(\hat{\mathbf{V}}_{T_S}|\mathscr{F}) \\ =& \nabla_{\hat{\mathbf{v}}_t} \log\ p(Y_S|X_S, \hat{\mathbf{V}}_{T_S}) + \\ & \nabla_{\hat{\mathbf{v}}_t} \log\ p^o(\hat{\mathbf{V}}_{T_S}|\mathscr{F}) \\ =& \nabla_{\hat{\mathbf{v}}_t} \log \prod_{s\in S, y_s=t} p(y_s|x_s, \hat{\mathbf{v}}_t) + \\ & \nabla_{\hat{\mathbf{v}}_t} \log\ p^o(\hat{\mathbf{v}}_t|\mathscr{F}) \\ =& \mathbf{g}^{o,l}_{\hat{\mathbf{v}}_t} + \mathbf{g}^{o,p}_{\hat{\mathbf{v}}_t},\end{aligned} \tag{13}$$

where $\mathbf{g}^{o,l}_{\hat{\mathbf{v}}_t} = \nabla_{\hat{\mathbf{v}}_t} \log \prod_{s\in S, y_s=t} p(y_s|x_s, \hat{\mathbf{v}}_t)$ and $\mathbf{g}^{o,p}_{\hat{\mathbf{v}}_t} = \nabla_{\hat{\mathbf{v}}_t} \log\ p^o(\hat{\mathbf{v}}_t|\mathscr{F})$. The prior distribution is

$$\begin{aligned}p^o(\hat{\mathbf{v}}_t|\mathscr{F}) &= \mathcal{N}(\mathbf{v}_t|\mathbf{h}_t, \boldsymbol{I}) \\ &= (2\pi)^{-\frac{d}{2}} e^{-\frac{1}{2}(\hat{\mathbf{v}}_t - \mathbf{h}_t)^2},\end{aligned} \tag{14}$$

the gradient of the logarithm of prior distribution to $\hat{\mathbf{v}}_t$ is:

$$\begin{aligned}\mathbf{g}^{o,p}_{\hat{\mathbf{v}}_t} &= \left(\log (2\pi)^{-\frac{d}{2}}\right)(\mathbf{h}_t - \hat{\mathbf{v}}_t) \\ &= C\left(\mathbf{h}_t - \hat{\mathbf{v}}_t\right),\end{aligned} \tag{15}$$

where $C = \log (2\pi)^{-\frac{d}{2}}$ is a constant, d is the dimension of prototype. The gradient of the log-likelihood on support set is

$$\begin{aligned}&\log \prod_{s\in S, y_s=t} p(y_s|x_s, \hat{\mathbf{v}}_t) \\ &= \log \prod_{s\in S, y_s=t} \frac{exp(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_t)}{\sum_{t'\in T_S} exp(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_{t'})} \\ &= \sum_{s\in S, y_s=t} \log \frac{exp(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_t)}{\sum_{t'\in T_S} exp(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_{t'})}.\end{aligned} \tag{16}$$

The gradient of the log-likelihood to $\hat{\mathbf{v}}_t$ is

$$\begin{aligned}\mathbf{g}^{o,l}_{\hat{\mathbf{v}}_t} =& \nabla_{\hat{\mathbf{v}}_t} \sum_{s\in S, y_s=t} \log \frac{exp\left(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_t\right)}{\sum_{t'\in T_S} exp\left(\left(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_{t'}\right)\right.} \\ =& \sum_{s\in S, y_s=t} \nabla_{\hat{\mathbf{v}}_t} \log \frac{exp(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_t)}{\sum_{t'\in T_S} exp(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_{t'})} \\ =& \sum_{s\in S, y_s=t} \nabla_{\hat{\mathbf{v}}_t}(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_t) \\ & - \nabla_{\hat{\mathbf{v}}_t} \log \sum_{t'\in T_S} exp(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_{t'}) \\ =& \sum_{s\in S, y_s=t} \boldsymbol{\mathcal{E}}(x_s) - \frac{\boldsymbol{\mathcal{E}}(x_s) exp(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_t)}{\sum_{t'\in T_S} exp(\boldsymbol{\mathcal{E}}(x_s)\cdot\hat{\mathbf{v}}_{t'})} \\ =& \sum_{s\in S, y_s=t} (1 - p^{(t)}_s)\boldsymbol{\mathcal{E}}(x_s),\end{aligned} \tag{17}$$

where $p_s^{(t)} = p(y_s|x_s, \hat{\mathbf{v}}_t)$ is the probability of correct classification of sample s in support set. Then we get

$$\mathbf{g}^o_{\hat{\mathbf{v}}_t} = \sum_{s\in S, y_s=t} (1-p_s^{(t)})\boldsymbol{\mathcal{E}}(x_s) + C(\mathbf{h}_t - \hat{\mathbf{v}}_t). \tag{18}$$

Then we calculate $\mathbf{g}^s_{\hat{\mathbf{v}}_t}$, The only difference between calculating $\mathbf{g}^s_{\hat{\mathbf{v}}_t}$ and $\mathbf{g}^o_{\hat{\mathbf{v}}_t}$ is $\mathbf{g}^s_{\hat{\mathbf{v}}_t}$ use the knowledge-shifted prior distribution

$$\begin{aligned} p(\hat{\mathbf{v}}_t|\mathscr{F}) &= \mathcal{N}(\mathbf{v}_t|\mathbf{h}_t + \Delta\mathbf{h}_t, \boldsymbol{I}) \\ &= (2\pi)^{-\frac{d}{2}}\, e^{-\frac{1}{2}(\hat{\mathbf{v}}_t - \mathbf{h}_t - \Delta\mathbf{h}_t)^2}. \end{aligned} \tag{19}$$

Same as the original posterior gradient, we have

$$\begin{aligned} \mathbf{g}^s_{\hat{\mathbf{v}}_t} =& \nabla_{\hat{\mathbf{v}}_t} \log \prod_{s\in S, y_s=t} p(y_s|x_s, \hat{\mathbf{v}}_t) \\ &+ \nabla_{\hat{\mathbf{v}}_t} \log\ p(\hat{\mathbf{v}}_t|\mathscr{F}) \\ =& \mathbf{g}^{s,l}_{\hat{\mathbf{v}}_t} + \mathbf{g}^{s,p}_{\hat{\mathbf{v}}_t}, \end{aligned} \tag{20}$$

where $\mathbf{g}^{s,l}_{\hat{\mathbf{v}}_t} = \mathbf{g}^{o,l}_{\hat{\mathbf{v}}_t} = \sum_{s\in S, y_s=t}(1-p_s^{(t)})\boldsymbol{\mathcal{E}}(x_s)$. The gradient of the logarithm of knowledge-shifted prior distribution to $\hat{\mathbf{v}}_t$ is:

$$\begin{aligned} \mathbf{g}^{s,p}_{\hat{\mathbf{v}}_t} &= \left(\log\,(2\pi)^{-\frac{d}{2}}\right)(\mathbf{h}_t + \Delta\mathbf{h}_t - \hat{\mathbf{v}}_t) \\ &= C\left(\mathbf{h}_t + \boldsymbol{\lambda}_t \odot (\mathbf{m}_t - \mathbf{h}_t) - \hat{\mathbf{v}}_t\right) \\ &= C\left((\mathbb{1} - \boldsymbol{\lambda}_t)\odot \mathbf{h}_t - \hat{\mathbf{v}}_t\right) + C\boldsymbol{\lambda}_t \odot \mathbf{m}_t, \end{aligned} \tag{21}$$

where $\mathbb{1}$ is a $|\mathbf{h}_t|$-dimensional vector, and each element of $\mathbb{1}$ is 1. then we get

$$\begin{aligned} \mathbf{g}^s_{\hat{\mathbf{v}}_t} =& \mathbf{g}^{s,l}_{\hat{\mathbf{v}}_t} + \mathbf{g}^{s,p}_{\hat{\mathbf{v}}_t} \\ =& \sum_{s\in S, y_s=t} (1-p_s^{(t)})\boldsymbol{\mathcal{E}}(x_s) \\ &+ C\left((\mathbb{1} - \boldsymbol{\lambda}_t)\odot \mathbf{h}_t - \hat{\mathbf{v}}_t\right) \\ &+ C\boldsymbol{\lambda}_t \odot \mathbf{m}_t, \end{aligned} \tag{22}$$

bring $\mathbf{m}_t = \frac{1}{M}\sum_{s\in S, y_s=t}\boldsymbol{\mathcal{E}}(x_s)$ into the above formula, we get

$$\begin{aligned} \mathbf{g}^s_{\hat{\mathbf{v}}_t} =& \sum_{s\in S, y_s=t}\left[(1-p_s^{(t)})\boldsymbol{\mathcal{E}}(x_s) + \frac{C\boldsymbol{\lambda}_t}{M}\odot \boldsymbol{\mathcal{E}}(x_s)\right] \\ &+ C\left((\mathbb{1} - \boldsymbol{\lambda}_t)\odot \mathbf{h}_t - \hat{\mathbf{v}}_t\right). \end{aligned} \tag{23}$$

Note that, when knowledge adaption is not used, the form of the prior knowledge distribution of the prototype is as follows,

$$p^o(\mathbf{V}_{T_S}|\mathscr{F}) = \prod_{t\in T_S} p^o(\mathbf{v}_t|\mathbf{h}_t) = \prod_{t\in T_S}\mathcal{N}(\mathbf{v}_t|\mathbf{h}_t, \boldsymbol{I}). \tag{24}$$

To intuitively show the influence of the knowledge-adapted posterior distribution on the prototype vector, we expand the gradient $\nabla_{\hat{\mathbf{V}}_{T_S}} \log\ p(Y_S|X_S, \hat{\mathbf{V}}_{T_S})p(\hat{\mathbf{V}}_{T_S}|\mathscr{F})$ in Eqn 12. For ease of explanation, we only calculate the gradient of the prototype vector $\hat{\mathbf{v}}_t$. Denote the gradient of the original posterior distribution without knowledge adaption as $\mathbf{g}^o_{\hat{\mathbf{v}}_t}$,

$$\mathbf{g}^o_{\hat{\mathbf{v}}_t} = \sum_{s\in S, y_s=t} (1-p_s^{(t)})\boldsymbol{\mathcal{E}}(x_s) + C(\mathbf{h}_t - \hat{\mathbf{v}}_t), \tag{25}$$

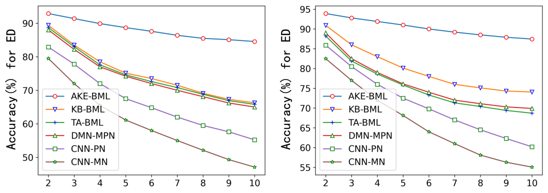
and the gradient of the knowledge-adapted posterior distribution as $\mathbf{g}^s_{\hat{\mathbf{v}}_t}$ from Eqn 23.

Comparing Eqn 23 and Eqn 25, it can be seen that the posterior distribution without knowledge adaption cannot dynamically balance the influence of the knowledge and the support set on the prototype vector, whereas the knowledge-adapted posterior distribution can adjust their contributions to the prototype vector through $\boldsymbol{\lambda}_t$. The parameters in Eqn 6 will be updated by the log-likelihood on the query set. This allows the model to reasonably choose the weight of the knowledge and the support set, and obtain prototype vectors with better generalization.

C M-shot Evaluation

In this section, we illustrate the effectiveness of adaptive knowledge-enhanced Bayesian meta-learning under different M-shot settings, such as N-way-5-shot, N-way-10-shot and N-way-15-shot. As shown in Table 1 in the main paper, as M increases, the performance of all models improves, which shows that increasing the number of samples in the support set can provide more pertinent event type-related features. At the same time, it can be seen that from 15-shot to 5-shot, the previous methods suffer a significantly larger performance degradation than AKE-BML. This observation shows our model's strong robustness against low sample diversity due to the incorporation of external knowledge.

The performance of KB-BML is close to that of DMN-MPN in the case of N-way-5-shot and N-way-10-shot, and the performance is better in the case of N-way-15-shot. This can be attributed to two factors: (1) the introduction of knowledge can improve the generalization of event prototypes; and (2) increasing the number of samples can reduce the impact of the deviation between knowledge and



(a) x-way-5-shot settings (b) x-way-15-shot settings

Figure 5: N-way ($N = 2, \ldots, 10$) evaluation and fixed shot numbers. (a) N-way-5-shot. (b) N-way-15-shot.

event types. When the support set is sufficiently large, the samples in the support set can compensate for the deviation between knowledge and event types, and the knowledge can also improve the generalization of the prototype vector. However, when M is small, the deviation between knowledge and event types will affect the quality of the prototype vectors.

AKE-BML can well balance the effects of samples and knowledge on the event type prototypes. It can be seen that when M is small, the performance of AKE-BML does not decline as quickly as other models, which also proves the effectiveness of knowledge in dealing with the problem of insufficient diversity of the support set. At the same time, compared with KB-BML, our adaptive knowledge offset can effectively use the information in the support set to correct the knowledge deviation.

D N-Way Evaluation

Figure 5 also illustrates model performance with respect to different way values (i.e. N), while fixing the shot values. It can be seen from the figure that when N increases, the performance of previous models decreases faster than AKE-BML, which shows that those models, only relying on the support set, cannot generate more recognizable event prototypes. The performance of KB-BML also declines significantly when N increases. This is because many event types can only be partially aligned in FrameNet, to its super-ordinate frame, which causes the event prototypes to be indistinguishable to similar event types.

On the contrary, the performance of AKE-BML does not decrease significantly when N increases, which shows that our adaptive knowledge-enhanced Bayesian meta-learning method can enhance the distinguishability of prototype vectors through the learnable knowledge offset. These results indicate that our adaptive knowledge-enhanced Bayesian meta-learning is more robust to the changes in the number of ways.

Stylized Story Generation with Style-Guided Planning

Abstract

Current storytelling systems focus more on generating stories with coherent plots regardless of the narration style, which is important for controllable text generation. Therefore, we propose a new task, stylized story generation, namely generating stories with specified style given a leading context. To tackle the problem, we propose a novel generation model that first plans the stylized keywords and then generates the whole story with the guidance of the keywords. Besides, we propose two automatic metrics to evaluate the consistency between the generated story and the specified style. Experiments demonstrates that our model can controllably generate *emotion*-driven or *event*-driven stories based on the ROCStories dataset (Mostafazadeh et al., 2016). Our study presents insights for stylized story generation in further research.

1 Introduction

Story generation is a challenging task in natural language generation (NLG), namely generating a reasonable story given a leading context. Recent work focuses on enhancing the coherence of generated stories (Fan et al., 2018; Yao et al., 2019) or introducing commonsense knowledge (Guan et al., 2020; Xu et al., 2020). However, it has not yet been investigated to generate stories with controllable styles, which is important since different styles serve different writing purposes. As exemplified in Figure 1, *emotion-driven* stories use emotional words (e.g., *"excited"*, *"enjoyed"*) to reveal the inner states of the characters and bring the readers closer to the characters. In comparison, *event-driven* stories usually contain a sequence of events with a clear temporal order (e.g., *"tearing"*→*"tried"*→*"found"*→*"hooked"*), which aims to narrate the story objectively.

Leading Context: Alice bought a new television.

Style	Story
Emotion-driven	She got **excited** to have it. It was **pretty** for the extra large screen. After using, she was very **satisfied** with the sound and design. She didn't **regret** buying this TV.
Event-driven	The picture on screen was **tearing**. Then she **tried** different adjustments. Eventually, she **found** out what was wrong. She got the wrong cable **hooked** up.

Figure 1: Example of stylized story generation given the same leading context. The stylized keywords are in bold.

In this paper, we formalize the task of stylized story generation, which requires generating a coherent story with a specified style given the first sentence as the leading context. *Style* has multiple interpretations, which can be seen as a unique voice of the author expressed through the use of certain stylistic devices (e.g. choices of words)(Mou and Vechtomova, 2020). In this work we focus on the choices of words and define the story styles based on the pattern of wording. Specifically, we focus on two story styles, including *emotion-driven* and *event-driven* stories. *Emotion-driven* stories contain abundant words with emotional inclination. We identify the emotional words using the off-the-shelf toolkit NRCLex (Mohammad, 2020), which supports retrieving the emotional effects of a word from a predefined lexicon. And *event-driven* stories tend to use serial actions as an event sequence. We use NLTK (Bird et al., 2009) to extract verbs in a story as the actions. Since no public datasets are available for learning to generate stylized stories, we regard the extracted words as stylistic keywords and then annotate the story styles for existing story datasets automatically based on the keyword distribution. Note that the story styles can be extended easily by defining new stylistic keywords.

In this work, we propose a generation model

for stylized story generation. Our model first predicts the distribution of stylistic keywords and then generates a story with the guidance of the distribution. Furthermore, we propose two new automatic metrics to evaluate the consistency between the generated stories and the specified styles: lexical style consistency (LSC) and semantic style consistency (SSC), which focus on the number of stylistic keywords and the overall semantics, respectively. Extensive experiments demonstrate that the stories generated by our model not only achieve better fluency and coherence than strong baselines but also have better consistency with the specified styles.[1]

2 Related Work

Story Generation Recently there have been significant advances for story generation with the encoder-decoder paradigm (Sutskever et al., 2014), the transformer-based architecture (Vaswani et al., 2017) and the large-scale pre-trained models (Radford et al., 2019; Lewis et al., 2020). Prior studies usually decomposed the generation into separate steps by first planning a sketch and then generating the whole story from the sketch. The sketch is usually a series of keywords (Yao et al., 2019), a learnable skeleton (Xu et al., 2018) or an action sequence (Fan et al., 2019; Goldfarb-Tarrant et al., 2020). Another line is to incorporate external knowledge into story generation (Guan et al., 2020; Xu et al., 2020). However, generating stories with controllable styles has hardly been investigated.

Stylized Generation Stylized generation aims to generate texts with controllable attributes. For example, recent studies in dialogue systems focused on controlling persona (Zhang et al., 2018; Boyd et al., 2020), sentence functions (Ke et al., 2018), politeness (Niu and Bansal, 2018), and topics (Tang et al., 2019). In story generation, Huang et al. (2019) and Xu et al. (2020) controlled the story topics and planned keywords, respectively. Besides, for general text generation, the authorship (Tikhonov and Yamshchikov, 2018), sentiment (Hu et al., 2017), and topics (Li et al., 2020) can also be controlled for different purposes. We introduce a new controllable attribute in story generation, i.e., the story style, which has been paid little attention to in prior studies.

3 Proposed Method

In this section, we first show the task formulation for stylized story generation (§3.1). Then we present the details of our two-step model: **style-guided keywords planning** (§3.2) and **generation with planned keywords** (§3.3).

3.1 Task Formulation

Input: The first sentence $\boldsymbol{x} = (x_1, x_2, \dots, x_n)$ of a story with length n, where x_i is the i-th word. A special token l to indicate the expected style of the generated story. $l \in \{\langle\texttt{emo}\rangle, \langle\texttt{eve}\rangle\}$, which refers to the *emotion-driven* and *event-driven* styles, respectively. Besides, in the training phase, we set $l = \langle\texttt{other}\rangle$ if the training example is neither emotion-driven nor event-driven to improve the data efficiency.
Output: A story $\boldsymbol{y} = (y_1, y_2, \dots, y_m)$ of length m with the style l, where y_i is i-th word.

3.2 Planning

We insert l at the beginning of $\boldsymbol{x}$ and encode them as follows:

$$[\boldsymbol{h}_0, \boldsymbol{h}_1, \dots, \boldsymbol{h}_n] = \texttt{Enc}(l, x_1, x_2, \dots, x_n), \quad (1)$$

where $\boldsymbol{h}_i$ $(1 \leqslant i \leqslant n)$ is the hidden state corresponding to x_i, $\boldsymbol{h}_0$ is the hidden state at the position of l, and $\texttt{Enc}$ is a bidirectional or unidirectional encoder. Then, we regard the stylistic keywords as bag-of-words (Kang and Hovy, 2020) and predict the keyword distribution $P_k(w|\boldsymbol{x}, l)$ over the whole vocabulary $\mathbb{V}$ as follows:

$$P_k(w|\boldsymbol{x}, l) = \text{softmax}(\mathbf{W}_k \boldsymbol{h}_c + \mathbf{b}_k), \quad (2)$$

where $\mathbf{W}_k$ and $\mathbf{b}_k$ are trainable parameters, and $\boldsymbol{h}_c$ is the context embedding to summarize the input information. We directly set $\boldsymbol{h}_c = \boldsymbol{h}_0$. The training objective in this stage is to minimize the cross-entropy loss $\mathcal{L}_k$ between the predicted keyword distribution $P_k(w|l, \boldsymbol{x})$ and the ground truth $\hat{P}_k(w|l, \boldsymbol{x})$ as follows:

$$\mathcal{L}_k = -\sum_{i=1}^{|\mathbb{V}|} \hat{P}_k(w_i|l, \boldsymbol{x}) \log P_k(w_i|l, \boldsymbol{x}), \quad (3)$$

where w_i denotes the i-th word in $\mathbb{V}$ and $\hat{P}_k(w|l, \boldsymbol{x})$ is an one-hot vector over $\mathbb{V}$. We do not decode a keyword sequence explicitly (Yao et al., 2019) but generate stories directly based on the keyword distribution $P_k(w|l, \boldsymbol{x})$ to avoid introducing extra exposure bias (He et al., 2019).

---

[1] Link to the code: `https://github.com/thu-coai/Stylized-Story-Generation-with-Style-Guided-Planning.git`

3.3 Generation

We employ a left-to-right decoder to generate a story conditioned upon the input and the predicted keyword distribution. The training objective in this stage is to minimize the negative log-likelihood $\mathcal{L}_{st}$ of the ground truth stories:

$$\mathcal{L}_{st} = -\sum_{t=1}^{m} \log P(y_t|l, \boldsymbol{x}, y_{<t}). \tag{4}$$

We derive $P(y_t|l, \boldsymbol{x}, y_{<t})$ by explicitly combining the stylistic keyword distribution into the decoding process as follows:

$$\begin{aligned} P(y_t|l, \boldsymbol{x}, y_{<t}) &= P_l(y_t|l, \boldsymbol{x}, y_{<t}) \cdot (1 - \boldsymbol{g}_t) \\ &\quad + P_k(y_t|l, \boldsymbol{x}) \cdot \boldsymbol{g}_t, & (5) \\ P_l(y_t|l, \boldsymbol{x}, y_{<t}) &= \text{softmax}(\mathbf{W}_s \boldsymbol{s}_t + \mathbf{b}_s), & (6) \\ \boldsymbol{s}_t &= \texttt{Dec}(y_{<t}, \{\boldsymbol{h}_i\}_{i=0}^{n}), & (7) \end{aligned}$$

where $\mathbf{W}_s$ and $\mathbf{b}_s$ are trainable parameters, P_l is a distribution over $\mathbb{V}$ without conditioning on the predicted keywords, and $\boldsymbol{g}_t \in \mathbb{R}^{|\mathbb{V}|}$ is a gate vector indicating the weight of the keyword distribution P_k. We compute $\boldsymbol{g}_t$ as follows:

$$\begin{aligned} \boldsymbol{g}_t &= \text{sigmoid}(\mathbf{W}_g[\boldsymbol{r}_t; \boldsymbol{s}_t] + \boldsymbol{b}_g), & (8) \\ \boldsymbol{r}_t &= \boldsymbol{W}_r P_k(y_t|l, \boldsymbol{x}) + \boldsymbol{b}_r, & (9) \end{aligned}$$

where $\boldsymbol{W}_g$, $\boldsymbol{b}_g$, $\boldsymbol{W}_r$ and $\boldsymbol{b}_r$ are trainable parameters. In summary, the final training objective $\mathcal{L}$ of our model is derived as follows:

$$\mathcal{L} = \mathcal{L}_{st} + \alpha \cdot \mathcal{L}_k. \tag{10}$$

where α is an adjustable scale factor.

4 Experimental Setup

4.1 Dataset

We conduct the experiments on the ROCStories corpus (Mostafazadeh et al., 2016), which contains 98,159 five-sentence stories. We randomly split ROCStories by 8:1:1 for training/validation/test, respectively. The average number of words in the input (the first sentence) and the output (the last four sentences) are 9.1 and 40.8, respectively. Besides, we follow Guan et al. (2020) to delexicalize stories in the dataset by masking all the male /female/neutral names with $\langle$`MALE`$\rangle$/ $\langle$`FEMALE`$\rangle$/ $\langle$`NEUTRAL`$\rangle$ to achieve better generalization.

4.2 Style Annotation

We extract stylistic keywords from stories in the dataset and assign a style label for each story according to the distribution of stylistic keywords.

Stylistic Keywords We use NRCLex and NLTK to extract stylistic keywords. NRCLex maps each word in a story to its underlying emotion labels according to a word-emotion lexicon (e.g., *"favorite"* → *"joy"*). We select the words with following emotion labels: *"fear"*, *"anger"*, *"surprise"*, *"sadness"*, *"disgust"* and *"joy"*, as the keywords for the emotion-driven style. Besides, we use NLTK to extract verbs as keywords for the event-driven style. We filter out the stop words and common verbs with bottom ten IDF[2] (e.g., *"is"*, *"have"*) from the extracted verbs. Intuitively, the more stylistic keywords of some style a story has, the more consistent it is with that style. Therefore, we propose to compare the numbers of keywords for different styles for style annotation.

Normalized Numbers of Keywords Let N_s denote the number of keywords for style s in a story. We assume N_s is a random variable, and follows a Gaussian distribution $\mathcal{N}(\mu_s, \sigma_s^2)$, where μ_s and σ_s are the mean and standard deviation computed on the training set. Given a story which contains n_s keywords for style s, we normalize n_s to $n'_s = P(N_s \leqslant n_s) \in [0, 1]$ for fair comparison between keywords for different styles.

Styles	Training	Validation	Test
Emotion-driven	17.7%	18.0%	17.9%
Event-driven	17.6%	17.0%	17.5%
Others	64.7%	65.0%	64.6%

Table 1: Distribution of stories annotated with different style for the training/validation/test set.

Annotation We annotate the style label l for a given story by comparing its n'_{emo} and n'_{eve}, which refer to the normalized numbers of keywords for emotion-driven and event-driven styles, respectively. We annotate the story with $\langle$`emo`$\rangle$ if n'_{emo} is higher than n'_{eve}, and $\langle$`eve`$\rangle$ otherwise. However, if both n'_{emo} and n'_{eve} are lower than τ_1, or $|n'_{\text{emo}} - n'_{\text{eve}}| < \tau_2$, we annotate the story with $\langle$`other`$\rangle$ since there is no significant tendency to any styles. τ_1 and τ_2 are hyper-parameters, which are set to 0.7 and 0.3, respectively. For stories labeled with $\langle$`other`$\rangle$, we select five words as the stylistic keywords from those keywords for emotion-driven and event-driven styles. Table 1 shows the stylistic distribution of the dataset.

---

[2] Inverse Document Frequency (IDF) is statistically analyzed on the stems of all the extracted keywords by NLTK.

4.3 Baselines and Experiment Settings

We compare our model with GPT-2 (Radford et al., 2019) and BART (Lewis et al., 2020) as baselines. We fine-tune the baselines on ROCStories with the style tokens and the beginnings as input.

We build our model based on BART. Our approach can easily adapt to other pre-trained models such as BERT. We set the scale factor in Equation 10 to 0.2. For all models, We generate stories using top-k sampling (Fan et al., 2018) with $k = 50$ and a softmax temperature of 0.8.

4.4 Automatic Evaluation

Evaluation Metrics We use the following metrics for automatic evaluation: **(1) Perplexity (PPL)**. Since the automatically annotated style labels may contain innate bias, we do not calculate the perplexity conditioned on the annotated styles for the stories in the test set. Instead, we calculate the perplexity of a model for each sample conditioned on two styles (emotion-driven and event-driven), respectively, and then get the perplexity on the entire test set by averaging the smaller perplexity for each sample.**(2) BLEU (B-n)** (Papineni et al., 2002)**:** The metric evaluates n-gram overlap ($n = 1, 2$). For each beginning in the test set, we generate two stories conditioned on two styles, respectively. Then we calculate the BLEU score on the test set by averaging the higher BLEU with the reference story for each sample.**(3) Distinct (D-n)** (Li et al., 2016)**:** The metric measures the generation diversity with the percentage of unique n-grams ($n = 1, 2$). **(4) Numbers of Stylistic Keywords (Number):** We use the average n' (described in §4.2) to evaluate how many consistent stylistic keywords the generated stories have. **(5) Lexical Style Consistency (LSC):** We calculate the percentage of the stories annotated with the consistent style in all generated stories using the annotation strategy described in §4.2. **(6) Semantic Style Consistency (SSC):** It is a learnable automatic metric (Guan and Huang, 2020). We fine-tune BERT$_{\text{BASE}}$ on the training set as a classifier to distinguish whether a story is emotion-driven, event-driven, or others with the automatic labels as the golden truth. For each style, we regard the average classification score on the style to measure the style consistency. Table 2 shows the accuracy and F1-Scores of the BERT model on the test set.

Results We show the evaluation results of PPL and BLEU in Table 3. Note that we do not provide PPL for GPT-2 since it does not adopt the same vocabulary used in BART. We can see that our model has lower perplexity and higher word overlap with the human-written stories than baselines.

Accuracy	**F1-Score**		
	Emotion-Driven	**Event-Driven**	**Other**
89.7%	0.863	0.838	0.922

Table 2: Accuracy and F1-Scores for each class of the BERT used in SSC.

Models	**PPL ↓**	**B-1 ↑**	**B-2 ↑**
GPT-2	N/A	32.8	16.1
BART	11.72	33.2	16.6
Ours	**11.29**	**33.8**	**17.1**

Table 3: Automatic evaluation results on the entire test set. The Best results are highlighted in **bold**. ↓/↑ indicates the lower/higher, the better.

We present the results of diversity and style consistency on the generated stories with different specified styles in Table 4. Our model achieves comparable diversity with baselines, generates more keywords of the specified styles, and outperforms baselines in both lexical and semantic style consistency by a large margin.

Models	**D-1 ↑**	**D-2 ↑**	**Number ↑**	**LSC↑**	**SSC ↑**
Emotion-driven Style					
GPT-2	0.679	0.924	0.454	0.243	0.201
BART	**0.701**	**0.952**	0.538	0.366	0.298
Ours	0.697	**0.952**	**0.623**	**0.474**	**0.371**
Event-driven Style					
GPT-2	0.675	0.925	0.375	0.107	0.088
BART	0.697	0.954	0.460	0.162	0.129
Ours	**0.698**	**0.955**	**0.591**	**0.309**	**0.293**

Table 4: Automatic evaluation results. The best results are highlighted in **bold**.

4.5 Manual Evaluation

We conduct a pairwise comparison between our model and baselines. We randomly generate 100 stories from the test set for each style and model. For each pair of stories (one by ours, and the other by a baseline), we hire three annotators to give a preference (*win*, *lose* and *tie*) in terms of fluency, coherence, and style consistency. We adopt majority voting to make the final decisions among the annotators. We resort to Amazon Mechanical Turk for manual annotation. As shown in Table 5, all the results show moderate ($0.4 \leqslant \kappa \leqslant 0.6$)

Styles	Models	Fluency				Coherence				Style Consistency			
		Win(%)	Lose(%)	Tie(%)	κ	Win(%)	Lose(%)	Tie(%)	κ	Win(%)	Lose(%)	Tie(%)	κ
Emotion-driven	**Ours** vs. **GPT-2**	37.0**	19.0	44.0	0.751	52.0**	25.0	23.0	0.803	39.0*	22.0	39.0	0.773
	Ours vs. **BART**	51.0**	22.0	27.0	0.672	52.0**	16.0	32.0	0.591	50.0*	31.0	19.0	0.640
Event-driven	**Ours** vs. **GPT-2**	40.0*	25.0	35.0	0.754	50.0*	30.0	20.0	0.735	54.0**	28.0	18.0	0.726
	Ours vs. **BART**	43.0*	25.0	32.0	0.644	45.0**	22.0	33.0	0.635	48.0*	33.0	19.0	0.612

Table 5: Manual evaluation results. The scores indicates the percentage of *win*, *lose* or *tie* when comparing our model with a baseline. κ denotes Fleiss' Kappa (Fleiss, 1971) to measure the inter-annotator agreement. * and ** mean p-value<0.05 and p-value<0.01 (Wilcoxon signed-rank test), respectively.

Leading Context: Bob has a girl friend.	
Emotion-driven Style	
GPT-2	She wants to **take** a trip to Hawaii. She **goes** on vacation. She is at the beach. It is a *pretty* day.
BART	One day, Bob **saw** a *cute* necklace on the sidewalk. Bob decided to **buy** it. After buying it, Bob *loves* it. Bob *likes* the necklace.
Ours	He is really *nervous* about her feeling around her. His girlfriend is very *protective* . Bob gets along *great* with her. Bob has a *wonderful* time with his girlfriend.
Event-driven Style	
GPT-2	She *likes* her hair. She **takes** a few pictures of her friend's hair. He **takes** a picture of her hair and **posts** it. She *likes* it very much and she is *happy* .
BART	He knew he was always going to be *mean* to her. After a while Bob **realized** that he was being *annoying* . He had to **leave** his job and **walk** . Now he has a new girlfriend and a new job.
Ours	He has been **talking** to her all day. She stopped **listening** to him now. One day, she **says** his name and **walked** away. He decided to **break** up with her in another place.

Table 6: Generated stories by different models with different specified styles. *Emotion-related* keywords and **event-related** keywords are highlighted in italic and bold, respectively.

or substantial (0.6 $\leqslant \kappa \leqslant$ 0.8) agreement, and our model outperforms baselines significantly in fluency, coherence, and style consistency.

5 Case Study

Table 6 shows several generated cases. We generate the stories using different models given the same leading context and specified style. For the *emotion-driven* style, our model can generate various emotional keywords (e.g., *"nervous"*, *"protective"*, *"great"*, and *"wonderful"*) and focus more on shaping the characters' personality. For the *event-driven* style, our model can generate fluent stories with a reasonable event sequence. In comparison, baselines tend to confuse the two styles. For example, the stories generated by the baselines for the event-driven style still contain many emotional keywords (e.g., *"likes"*, *"annoying"*). Besides, for the emotion-driven style, the baselines generate fewer and repetitive emotional keywords. Furthermore, the baselines may suffer from more severe repetition (e.g., "take a picture") than our model. And the baselines sometimes mix up or neglect some characters (e.g., GPT-2 and BART only cover one of *"Bob"* and *"his girlfriend"* but neglect the other one for the *emotion-driven* style). In summary, our model can generate more coherent stories with specified styles than the baselines.

6 Conclusion

We present a pilot study on a new task, stylized story generation. We define story *style* with respect to *emotion* and *event*, and propose a generation model which conditions on planned stylistic keywords. Comparative experiments with strong baselines show the promising results of the proposed model. Our work can inspire further research in this new direction.

Abstract

Chinese spelling check (CSC) is a task to detect and correct spelling errors in Chinese text. Most state-of-the-art works on the CSC task adopt a BERT-based non-autoregressive language model, which relies on the output independence assumption. The inappropriate independence assumption prevents BERT-based models from learning the dependencies among target tokens, resulting in an incoherent problem. To address the above issue, we propose a novel architecture named Dynamic Connected Networks (DCN), which generates the candidate Chinese characters via a Pinyin Enhanced Candidate Generator and then utilizes an attention-based network to model the dependencies between two adjacent Chinese characters. The experimental results show that our proposed method achieves a new state-of-the-art performance on three human-annotated datasets.

1 Introduction

Chinese spelling check (CSC) is an important task which can be utilized in many natural language applications such as optical character recognition (OCR) (Wang et al., 2018; Hong et al., 2019) and essay scoring. Meanwhile, CSC is a challenging task which requires human-level natural language understanding ability (Liu et al., 2010, 2013; Xin et al., 2014). Recently, BERT-based non-autoregressive language models have achieved state-of-the-art performance in the CSC task (Hong et al., 2019; Zhang et al., 2020; Cheng et al., 2020).

These works fine-tune BERT-based models using CSC training data. During the training phase, all the target Chinese characters will be involved as labels. In the inference stage, the models predict the most likely Chinese character from a candidate set at each position. When the most likely character is different from the input character, the input character will be considered as a spelling error and corrected to the most likely character. Based on the powerful generalization ability of BERT (Devlin et al., 2019), these works have achieved better performance than other models.

Wrong: 我忘记告诉你了，我真户秃。
Correct: 我忘记告诉你了，我真糊涂。 Translation: I forgot to tell you. I'm so confused.

Table 1: An example of Chinese spelling errors. Here, "户秃" should be corrected to "糊涂" (confused).

However, these works on the CSC task rely on the incorrect independence assumption, which may lead to an incoherent problem. Concretely, they assume that the predicted tokens are independent of each other, which generally does not hold in natural language (Yang et al., 2019; Gu and Kong, 2020). For the CSC task, one spelling error may have multiple corrections. Ignoring the corrected context may result in a correction conflict. As shown in Table 1, "户秃" may be corrected as "糊涂" (*confused*) or "尴尬" (*embarrassed*). Because of the independence of each token, the non-autoregressive language model may correct it as "尴涂" (*embafused*). This incoherent problem is also called a multi-modality problem in non-autoregressive machine translation (Gu et al., 2018).

To address the above problem, we propose a novel Dynamic Connected Networks (DCN) which can model the dependencies between two adjacent candidate Chinese characters. Specifically, we use the RoBERTa model (Liu et al., 2019; Cui et al., 2019) as our base model, which can also be replaced by other models. Firstly, we utilize RoBERTa with a Pinyin Enhanced Candidate Generator to incorporate phonological information and generate k candidate characters at each position. For each two adjacent candidates, DCN learns a

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2437–2446
August 1–6, 2021.

variable connection score to determine the strength of the dependency between them via a Dynamic Connected Scorer (DCScorer). The DCScorer calculates the connection scores by feeding the contextual representation and the candidate character embeddings of the current and the next position into an attention layer simultaneously. Eventually, the model generates k^n candidate paths, and we utilize the Viterbi algorithm (Rabiner, 1989) to quickly find the one with the highest score as our final correction result.

Conditional random fields (CRF) (Lafferty et al., 2001) can also model the dependencies of output labels, however it is not suitable for language modeling or the CSC task. The dependencies between Chinese characters are more related to the context and far more complicated than the label relations of other tasks such as NER. Thus, the capacity of a fixed transition matrix in CRF is inadequate. Moreover, the number of Chinese characters is usually more than 5K, making the transition matrix too large to learn. In contrast, output candidates (labels) and connection scores of DCN are dynamic and change according to the context. That empowers our model with a strong ability to learn the dependencies.

We conduct experiments on SIGHAN 2013, SIGHAN 2014, and SIGHAN 2015 benchmarks. Experimental results on the three human-annotated datasets demonstrate that the performance of our proposed method is significantly better than the state of the art models.

To summarize, our contributions are as follows:

- We propose a novel end-to-end dynamic connected networks (DCN) which can alleviate the incoherent problem of non-autoregressive language models in the CSC task.
- We propose a simple and effective Pinyin Enhanced Candidate Generator to incorporate phonological information and generate better candidate characters.
- Experimental results show that our proposed method achieves state-of-the-art performance on three human-annotated datasets.

For reproducibility, our code for this paper is available at https://github.com/destwang/DCN.

2 Related Work

Chinese spelling check (CSC) is a challenging task that requires human-level language understanding ability. With the development of deep learning techniques, the CSC task has recently made more progress. CSC is similar to the grammatical error correction (GEC) task (Dahlmeier and Ng, 2012). The difference between them is that CSC only focuses on Chinese spelling errors, while GEC also includes errors that need insertion and deletion.

Most models in the GEC task use an autoregressive Seq2Seq model to correct a sentence. Similarly, Seq2Seq models can also be used in the CSC task. Wang et al. (2019) propose an autoregressive pointer network which generates a Chinese character from the confusion set rather than the entire vocabulary. Although the autoregressive Seq2Seq model has the ability to correct the spelling errors, it is usually slow. The input and output are so similar that it would be "wasteful" to completely regenerate a sequence (Malmi et al., 2019).

Since the input and output have the same number of Chinese characters, and the correct and incorrect Chinese characters correspond to each other, it is more intuitive to use non-autoregressive language models such as BERT to directly correct the Chinese spelling errors. Hong et al. (2019) propose the FASPell model to predict candidate characters based on the BERT model and exploit the phonological and visual similarity information to select candidate characters. Zhang et al. (2020) propose a model named Soft-Masked BERT, which consists of a detection network and a correction network based on BERT. Cheng et al. (2020) propose to incorporate phonological and visual similarity knowledge into BERT via a specialized graph convolutional network. Bao et al. (2020) design a chunk-based framework and extend the traditional confusion sets with semantical candidates to cover different types of errors.

Although these non-autoregressive methods mentioned above have achieved state of the art in the CSC task so far, these methods still suffer from the incoherent problems that exist in non-autoregressive models (Gu et al., 2018; Gu and Kong, 2020). In this paper, we propose a novel model DCN which learns the dependencies between the adjacent Chinese characters and alleviates the incoherent problem.

3 Our approach

3.1 Problem

Given an input text sequence $X = \{x_1, x_2, ..., x_N\}$, the goal of the CSC task is

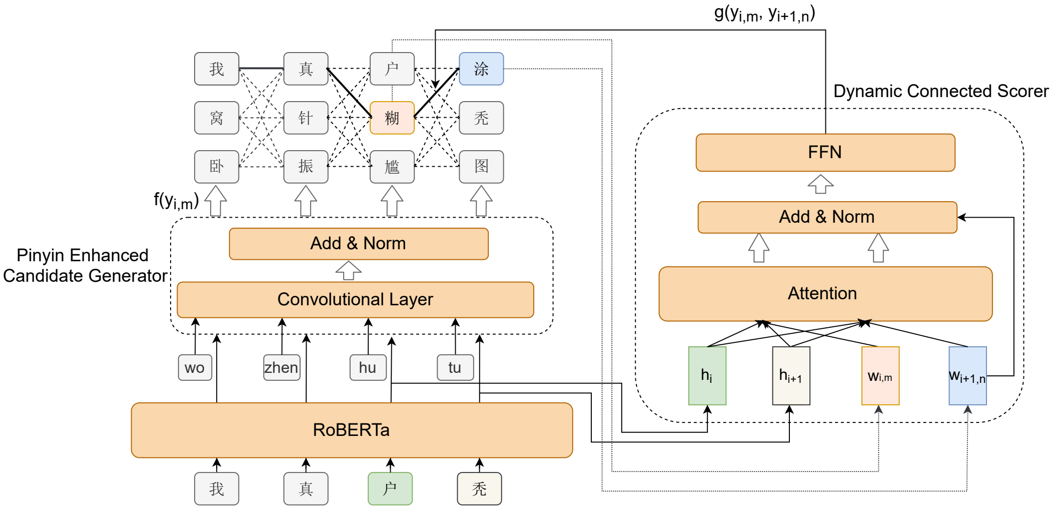

Figure 1: The architecture of DCN. Here, we only illustrate how to calculate one connection score between candidates “糊” and “涂” by the Dynamic Connected Scorer.

to automatically correct the incorrect part of the Chinese sentence and generate a correct target sequence $Y = \{y_1, y_2, ..., y_N\}$. Since the input sentence X and the output sentence Y have the same number of tokens (Chinese characters), pretrained non-autoregressive language models such as BERT are natural to be used in the CSC task. Given that non-autoregressive language models are based on the assumption of output independence, they will mismatch output Chinese characters and lead to the incoherent problem. This problem has also been mentioned in non-autoregressive machine translation (Gu et al., 2018, 2019; Gu and Kong, 2020) and pretrained language model (Yang et al., 2019).

3.2 Dynamic Connected Networks

To solve the above incoherence problem, we propose a novel model named Dynamic Connected Networks (DCN), which can learn the dependencies between output Chinese characters and alleviate the incoherence problem.

The model structure is illustrated in Figure 1. We use the RoBERTa (Liu et al., 2019; Cui et al., 2019) model as our base model. Firstly, RoBERTa with a Pinyin Enhanced Candidate Generator generates a series of candidate characters, and we sample k characters as candidates (the candidate generation method will be discussed in detail in the next subsection). For each two adjacent candidate characters, we learn the connection scores to determine the strength of the dependency between them by a dynamic connected scorer (DCScorer). The final correction score will be calculated by the joint prediction of connection scores and the prediction scores of the candidate generator at each position.

The DCScorer needs to consider the context information, the candidate characters of the current and next position simultaneously. Thus, we use the attention mechanism to learn the current candidate context representation p and next candidate context representation q. The strength of the dependency between two adjacent candidates is usually more related to the RoBERTa hidden representation of the current and next position, so the key and value in the attention mechanism contain only these two hidden representations. The DCScorer is formally defined as follows:

$$
\begin{aligned}
p_{i,m} &= \mathrm{Attention}(Q_{i,m}W^Q, K_iW^K, V_iW^V) \\
q_{i,n} &= \mathrm{Attention}(Q_{i+1,n}W^Q, K_iW^K, V_iW^V) \\
K_i = V_i &= \begin{bmatrix} h_i \\ h_{i+1} \end{bmatrix} \\
Q_{i,m} &= w_{i,m} \\
Q_{i+1,n} &= w_{i+1,n}
\end{aligned}
\tag{1}
$$

where i is the character position, m and n are the indices of candidates of current position and next position respectively. $\mathrm{Attention}$ denotes the attention mechanism, where the Q, K, V denote query, key and value, and W denote the parameters to be learned in the attention layer. h is the hidden representation of the last transformer block, w denotes the candidate token embedding.

We add the candidate token embedding to the candidate context representation. Then we feed the output into layer normalization and get two representations $p'_{i,m}$ and $q'_{i,n}$.

$$\begin{aligned} p'_{i,m} &= \text{LayerNorm}(p_{i,m} + w_{i,m}) \\ q'_{i,n} &= \text{LayerNorm}(q_{i,n} + w_{i+1,n}) \end{aligned} \tag{2}$$

We concatenate the two vectors and feed them into a feed-forward network (FFN) layer used by (Vaswani et al., 2017). Then we use a linear layer to calculate the connection score between the two candidates.

$$\begin{aligned} s &= \text{FFN}(\text{Concat}(p'_{i,m}, q'_{i,n})) \\ g(y_{i,m}, y_{i+1,n}) &= sv \end{aligned} \tag{3}$$

where v is a trainable weight vector and $g(y_{i,m}, y_{i+1,n})$ is the connection score between the mth candidate of ith position and nth candidate of $i + 1$th position.

Since we feed k^2 pairs of candidate combinations into DCScorer, we will generate k^2 scores at each position. Eventually, the model will generate k^n candidate paths, and the score of each path is calculated using the following equations:

$$\text{S}(X, Y) = \sum_{i=1}^{N} f(y_{i,m}) + \sum_{i=1}^{N-1} g(y_{i,m}, y_{i+1,n}) \tag{4}$$

where y is the candidate character, $f(y_{i,m})$ is the prediction score of Pinyin Enhanced Candidate Generator for mth candidate of ith position.

3.3 Candidate Generation

We generate the candidate Chinese characters via a Pinyin Enhanced Candidate Generator based on RoBERTa.

Pinyin Enhanced Candidate Generator According to statistics, more than 80% spelling errors are related to phonological similarity (Liu et al., 2010). Since phonological errors account for a large proportion of Chinese character errors, a suitable method of introducing phonological information would be of great help in generating the candidates and correcting spelling errors.

The conversion from a single Chinese Pinyin to the Chinese character has a large ambiguity. It is difficult to convert properly because one Pinyin usually corresponds to many Chinese characters. However, when there are multiple consecutive Pinyin, we will have more confidence to convert Pinyin into correct Chinese characters. For example, the Pinyin of Chinese characters “户” and “糊” is “hu”, and the Pinyin of “秃” and “涂” is “tu”. When “hu” and “tu” are together, it will have a high probability of being converted to “糊涂” which means “confused” in Chinese. This is also a basic assumption used in Chinese Pinyin input methods.

Based on this, we propose a Pinyin Enhanced Candidate Generator, which can effectively reduce the ambiguity and generate better Chinese characters. The architecture is shown in Figure 1. Concretely, we adopt a convolutional layer to encode consecutive Pinyin and add the output of convolutional layer, hidden representation of RoBERTa and character embedding together. Then we feed the sum to layer normalization and get the prediction score $f(y_{i,m})$ via a linear layer. The equations are as follows:

$$\begin{aligned} c_i &= \text{Conv}(p''_{i-1}, p''_i, p''_{i+1}) \\ o_i &= \text{LayerNorm}(c_i + w_i + h_i) \\ f(y_{i,m}) &= o_i v'_m \end{aligned} \tag{5}$$

where p'' is the Pinyin embedding, w_i is the Chinese character embedding, h_i is the last hidden representation of RoBERTa, v'_m is the trainable weight vector for mth candidate.

There are various ways to represent Pinyin, and we find that simply representing each Pinyin without tone as a separate embedding can achieve good performance. We also try to encode Pinyin by Multi-Layer Perceptron (MLP) and GRU (Chung et al., 2014) encoder, which treat each letter of Pinyin as an embedding vector. Since they cannot achieve better results, we simply represent each Pinyin as a separate embedding in our following experiments.

Candidate Sampling Method Given the large number of usual Chinese characters, we sample the candidate characters for learning. We try several sampling methods and find that selecting the characters with the top-k prediction scores from vocabulary performs best. This also shows that the more difficult candidates can be used as negative training examples to effectively improve the discriminatory ability of the model. Therefore, all the main experimental results are based on the top-k sampling.

3.4 Learning

Loss function The probability for the sequence Y can be approximated by the following equation

$$p(Y|X) = \frac{e^{\text{S}(X,Y)}}{\sum_{Y'_i} e^{\text{S}(X,Y'_i)}} \tag{6}$$

Training Sets	# Line	Avg. Length	# Erroneous Sent.
Wikipedia	7,756,725	47.0	-
(Wang et al., 2018)	271,329	44.4	271,329
SIGHAN 2013	700	49.2	350
SIGHAN 2014	3,435	49.7	3,432
SIGHAN 2015	2,339	30.0	2,339
Test Sets	**# Line**	**Avg. Length**	**# Erroneous Sent.**
SIGHAN 2013	1,000	74.1	996
SIGHAN 2014	1,062	50.1	529
SIGHAN 2015	1,100	30.5	550

Table 2: Statistics of datasets.

where Y_i' are the path generated by the candidate characters.

The loss function is the maximum likelihood of the probability distribution denoted as

$$Loss = \begin{cases} -\log(p(Y|X)) & \mathrm{S}(X,Y) < \mathrm{S}_{max}(X,Y') \\ 0 & \mathrm{S}(X,Y) \geq \mathrm{S}_{max}(X,Y') \end{cases} \quad (7)$$

The loss function is similar to the one used by LSTM-CRF (Huang et al., 2015). It learns only the sampled negative candidate characters and the dependencies between them, which will unduly degrade the ranking of potential candidates. This possibly makes more similar candidates have a lower ranking. In order to avoid the above problem, we make a restriction on the loss function by setting its loss to 0 when the gold score is higher than or equal to the max score of all the candidate paths.

Pretraining The dependencies between Chinese characters can be more sufficiently learned via a large scale training corpus. In this paper, we pretrain our proposed model using Chinese Wikipedia data shown in Table 2. We randomly replace 15% of the characters, including 70% MASK, 15% characters from the confusion set, and 15% random characters. We exploit the confusion set released from SIGHAN 2013 (Wu et al., 2013) which consist of pronunciation similarity and shape similarity characters. Based on the RoBERTa model, we freeze the main parameters and only fine-tune the Pinyin Enhanced Candidate Generator and the Dynamic Connected Scorer.

3.5 Predicting

In the predicting stage, the top-k candidate characters from vocabulary are generated by the Pinyin Enhanced Candidate Generator. Eventually, there are k^n paths. In order to quickly select the path with the highest score, we use the Viterbi algorithm (Rabiner, 1989) based on dynamic programming to decode the output sequence.

4 Experiments

4.1 Experimental Setup

Datasets We use the large automatically generated corpus (Wang et al., 2018)[1] as our training data. In addition, the training sets of SIGHAN 2013, SIGHAN 2014, and SIGHAN 2015 are also included. For the pre-training method, we use the Chinese Wikipedia texts which have been converted to simplified Chinese characters.

We evaluate our proposed model on the test sets from SIGHAN 2013, SIGHAN 2014, and SIGHAN 2015 benchmarks. Similar to the previous works, we convert the traditional characters to simplified characters by OpenCC[2].

In order to evaluate our model more reasonably, we take 500 sentences from the SIGHAN training sets and the corresponding corrected results of these 500 sentences together as the validation set. The statistic information of all the datasets is listed in Table 2.

Evaluation Metrics To compare with the state-of-the-art models, We use the widely adopted sentence-level precision, recall, and F1-score as our evaluation method, which has been used by Hong et al. (2019)[3] and Cheng et al. (2020).

Baseline Models We compare our model with several state-of-the-art models.

- FASPell (Hong et al., 2019): This model uses the phonological and visual similarity information to select candidate characters.
- Soft-Masked BERT (Zhang et al., 2020): This method combines a detection network and a correction network based on BERT.
- SpellGCN (Cheng et al., 2020): This model incorporates phonological and visual similarity knowledge into BERT via a specialized graph convolutional network.
- Chunk-based method (Bao et al., 2020): This method utilizes a chunk-based framework and extends the traditional confusion sets with semantical candidates to cover different types of errors.

Model Hyperparameters We use RoBERTa-wwm (Cui et al., 2019) as our base model in this

Table 3: Experimental results of sentence-level precision, recall, and F1-score (%). D, C denote the detection and correction respectively. Since "的", "地", "得" are rarely distinguished on SIGHAN 2013, we remove all the related correction results. To compare more fairly with SpellGCN, we rerun the released code of Cheng et al. (2020) and remove all the related correction results. The results are reported with SpellGCN*. The reported result of SpellGCN on SIGHAN 2015 is not correct, where the precision, recall and F-score don't match. If the precision and recall are correct, F-score should be 74.8.

paper. We utilize AdamW (Loshchilov and Hutter, 2019) optimizer with learning rate of 5e-5. The training batch size is set to 32, and we train 12 epochs for all the experiments. To better learn the dependencies between characters, we learn the DCN model with MASK token for the first 2 epochs the same with the pretraining method. The number of candidates k for training is set to 5 and the number for predicting is set to 8. The convolution window size of the Pinyin Enhanced Candidate Generator is set to 3. The dimensions of all the hidden representations are 768. We search learning rate from $\{2e\text{-}5, 3e\text{-}5, 5e\text{-}5\}$ and select the best model on the validation set.

4.2 Experimental Results

The experimental results are shown in Table 3. Our proposed RoBERTa-DCN model has the best detection and correction performance on the three SIGHAN test sets. Both FASPell and SpellGCN models use sophisticated techniques to incorporate the phonological and visual information and achieve a relatively good performance. Our DCN model is more focused on the incoherence problem and modeling the dependencies of the output tokens. Our proposed model exceeds FASPell and SpellGCN by simply using a Pinyin Enhanced Candidate Generator to model the phonological information, which also illustrates the effectiveness of DCN.

When we pre-train DCN using wiki data, the model gets further improvement in the effectiveness. This indicates that modeling the dependencies between output Chinese characters is important. DCN may achieve better performance if more data are used to learn the dependencies.

Soft-Masked BERT uses detection network and correction network simultaneously. In contrast, our DCN model predicts the target sequence directly, and the different tokens between the input sequence and the target sequence are regarded as the detection results. As shown in the experimental results, compared to Soft-Masked BERT, our method improves 5.5% and 9.9% on detection and correction respectively.

To compare with some other state-of-the-art works, we also evaluate our proposed model using the official evaluation toolkit[4] of SIGHAN 2015 in Table 4. The Chunk-based method, which uses a series of methods to construct the candidate set,

- DCScorer	87.4	88.4	87.9	86.8	87.8	87.3
- weighted loss	87.6	89.0	88.3	86.8	88.2	87.5
RoBERTa	86.1	89.2	87.6	85.5	88.6	87.0

Table 6: Ablation Study of DCN on validation set. PECGenerator is the Pinyin Enhanced Candidate Generator. Weighted loss refers to the condition of loss. When we remove the PECGenerator, the RoBERTa generates the candidates by predicting the candidate characters. When the DCScorer is removed, the model selects the top-1 predicted result as the correct character.

achieves good performance for precision. However, the recall of this method is relatively low, and the F-score of our method significantly outperforms the chunk-based method by more than 10%. Similarly, our model also achieves a better result than SpellGCN.

4.3 Effect of Candidate Generation

The performance of DCN varies with the candidate generation strategy and the number of sampled candidate characters. We compare the effects of four sampling methods for training, which are sampling top-k candidates from vocabulary, sampling top-k candidates from the confusion set, random sampling from the vocabulary and sampling from a multinomial distribution. For the multinomial distribution sampling, the probabilities are obtained from the Softmax output of the Pinyin Enhanced Candidate Generator. All the subsequent experiments are conducted on the validation set. The experimental results are shown in Table 5.

From Table 5, we can see that the top-k of vocabulary method has the best performance. The multinomial distribution sampling also has a good performance, while the random sampling and top-k of confusion set cannot achieve good performance. This means that sampling some difficult candidates is more beneficial to the model training to improve the model discriminative ability.

We also conduct experiments with the effect of the number of candidates. Figure 2(a) shows the change curve of the effect when the number of candidates for training increase. The effect gradually gets better as the number of candidates increases at the beginning, and the effect no longer has a significant improvement after the number of candidates for prediction exceeds 5. Figure 2(b) shows the performance when we fix the number of training candidates as 5 and increase the number of prediction candidates. The performance keeps improving as the number of prediction candidates increases.

4.4 Ablation Study

We conduct a series of experiments to determine which component in the DCN model plays a more important role. Table 6 shows the results of our experiments. When we remove the Pinyin Enhanced Candidate Generator, both the detection and correction F-scores decrease about 1.5%. This demonstrates that the phonological information plays an important role in candidates generation methods. When we remove the dynamic connected scorer, the detection F-score decreases nearly 2%, which indicates that the dependencies between Chinese characters are important for the CSC task. Similarly, the weighted loss also help our models improve the performance.

(b) Predicting stage.

Figure 2: The effect of the number of candidates.

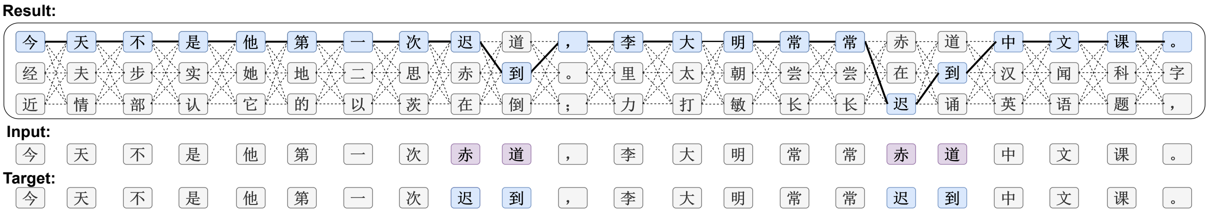

Figure 3: An example of Viterbi decoding. “赤道” in this sentence should be corrected to “迟到”. Translation of this example: *Today is not the first time he is late. Daming Li is often late to Chinese class.*

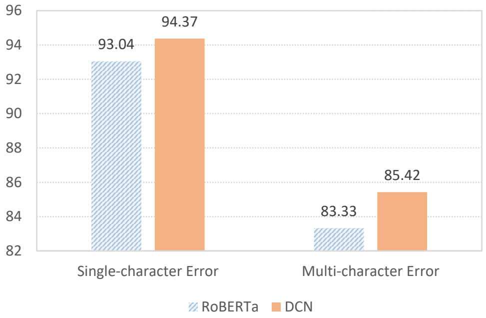

Figure 4: The comparison of detection F-score between RoBERTa and DCN on single-character error and multi-character error validation sets.

4.5 Case Study and Analysis

We find that the DCN model performs better than the vanilla RoBERTa model on consecutive errors. Figure 3 shows an example of consecutive errors. The vanilla RoBERTa model cannot detect it well and can only partially correct it because consecutive errors will influence each other. In contrast, DCN can correct it completely. The best path for this example is shown in this figure. The correct Chinese characters “迟到” did not rank first, but the path including “迟到” have the highest score because they are more fluent than other candidate combinations. This example also shows that our model can alleviate the incoherent problem.

Figure 4 shows the detection F-score of RoBERTa and DCN on single-character and multi-character error sets. DCN performs better than RoBERTa in both single-character and multi-character level cases. The effect of DCN is more obvious in the multi-character cases, which also shows that DCN has some advantages for multi-character type errors. At the same time, the performance of single-character error cases is much better than multi-character error cases, which indicates that DCN still has much room to improve for multi-character errors.

By comparing the results of RoBERTa and RoBERTa with the candidate generator. We find that 96.7% of the correct characters are in the top-5 candidates of RoBERTa. In contrast, 98.6% of the correct characters are in the top-5 candidates of RoBERTa with candidate generator. This result illustrates that the Pinyin Enhanced Candidate Generator can generate better candidates.

5 Conclusion

In this paper, we propose a novel model named DCN to solve the incoherent problem in the CSC task. To better incorporate the phonological information, we propose a simple and effective Pinyin Enhanced Candidate Generator. The experimental results show that our proposed model has achieved the state-of-the-art performance on three datasets. DCN may also be utilized on other tasks such as non-autoregressive machine translation. As for future work, how to make better use of phonological and visual information still needs to be discussed.

A Multi-Level Attention Model for Evidence-Based Fact Checking

Canasai Kruengkrai **Junichi Yamagishi** **Xin Wang**

Abstract

Evidence-based fact checking aims to verify the truthfulness of a claim against evidence extracted from textual sources. Learning a representation that effectively captures relations between a claim and evidence can be challenging. Recent state-of-the-art approaches have developed increasingly sophisticated models based on graph structures. We present a simple model that can be trained on sequence structures. Our model enables inter-sentence attentions at different levels and can benefit from joint training. Results on a large-scale dataset for Fact Extraction and VERification (FEVER) show that our model outperforms the graph-based approaches and yields 1.09% and 1.42% improvements in label accuracy and FEVER score, respectively, over the best published model.[1]

1 Introduction

False or misleading claims spread through online media faster and wider than the truth (Vosoughi et al., 2018). False claims can occur in many different forms, e.g., fake news, rumors, hoaxes, propaganda, etc. Identifying false claims that are likely to cause harm in the real world is important. Generally, claims can be categorized into two types: verifiable and unverifiable. Verifiable claims can be confirmed to be true or false as guided by evidence from credible sources, while unverifiable claims cannot be confirmed due to insufficient information.

Verifying the truthfulness of a claim with respect to evidence can be regarded as a special case of recognizing textual entailment (RTE) (Dagan et al., 2006) or natural language inference (NLI) (Bowman et al., 2015), where the premise (evidence) is not given. Thus, the task of claim verification is to first retrieve documents relevant to a given claim from textual sources, then select sentences likely to contain evidence, and finally assign a veracity relation label to support or refute the claim. For example, the false claim "*Rabies is a foodborne illness.*" can be refuted by the evidence "*Rabies is spread when an infected animal scratches or bites another animal or human.*" extracted from the Wikipedia article "*Rabies*". Figure 1 shows other examples that require multiple evidence sentences to support or refute claims. All of these claims are taken from a benchmark dataset for Fact Extraction and VERification (FEVER) (Thorne et al., 2018). A key challenge is to obtain a representation for claim and evidence sentences that can effectively capture relations among them.

ID: 8143
Claim: Moscovium is a transactinide element.
Label: SUPPORTED
Evidence: [*Moscovium*]
Moscovium is a superheavy synthetic element with symbol Mc and atomic number 115.^{0}
In the periodic table, it is a p-block transactinide element.^{7}
[*Transactinide_element*]
In chemistry, transactinide elements (also, transactinides, or super-heavy elements) are the chemical elements with atomic numbers from 104 to 120.^{0}

ID: 201459
Claim: A dynamic web page does not involve computer programming.
Label: REFUTED
Evidence: [*Web_page*]
A static web page is delivered exactly as stored, as web content in the web server's file system, while a dynamic web page is generated by a web application that is driven by server-side software or client-side scripting.^{14}
[*Dynamic_web_page*]
A dynamic web page is then reloaded by the user or by a computer program to change some variable content.^{9}

Figure 1: Examples from the FEVER dev set, where true evidence sentences are present in the selected sentences, and veracity relation labels are correctly predicted by our proposed model. Wikipedia article titles are in [*italics*]. Superscripts indicate the positions of the sentences in each article.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2447–2460
August 1–6, 2021.

Recent state-of-the-art approaches have attempted to meet this challenge by applying graph-based neural networks (Kipf and Welling, 2017; Velickovic et al., 2018). For example, Zhou et al. (2019) regard an evidence sentence as a graph node, while Liu et al. (2020) use a more fine-grained node representation based on token-level attention. Zhong et al. (2020) use semantic role labeling (SRL) to build a graph structure, where a node can be a word or a phrase depending on the SRL's outputs.

In this paper, we argue that such sophisticated graph-based approaches may be unnecessary for the claim verification task. We propose a simple model that can be trained on a sequence structure. We also observe mismatches between training and testing. At test time, the model predicts the veracity of a claim based on retrieved documents and selected sentences, which contain prediction errors, while at training time, only ground-truth documents and true evidence sentences are available. We empirically show that our model, trained with a method that helps reduce training-test discrepancies, outperforms the graph-based approaches.

In addition, we observe that most of the previous work neglects sentence-selection labels when training veracity prediction models. Thus, we propose leveraging those labels to further improve veracity relation prediction through joint training. Unlike previous work that jointly trains two models (Yin and Roth, 2018; Li et al., 2020; Hidey et al., 2020; Nie et al., 2020), our approach is still a pipeline process where only a subset of potential candidate sentences produced by *any* sentence selector can be used for joint training. This approach makes it possible to explore different sentence-selection models trained with different methods.

Our contributions are as follows. We develop a method for mitigating training-test discrepancies by using a mixture of predicted and true examples for training. We propose a multi-level attention (MLA) model that enables token- and sentence-level self-attentions and that benefits from joint training. Experiments on the FEVER dataset show that MLA outperforms all the published models, despite its simplicity.

2 Background and related work

2.1 Problem formulation

The input of our task is a claim and a collection of Wikipedia articles $\mathcal{D}$. The goal is to extract a set of evidence sentences from $\mathcal{D}$ and assign a veracity relation label $y \in \mathcal{Y} = \{\mathrm{S}, \mathrm{R}, \mathrm{N}\}$ to a claim with respect to the evidence set, where S = SUPPORTED, R = REFUTED, and N = NOTENOUGHINFO. The definition of our labels is identical to that of the FEVER Challenge (Thorne et al., 2018).

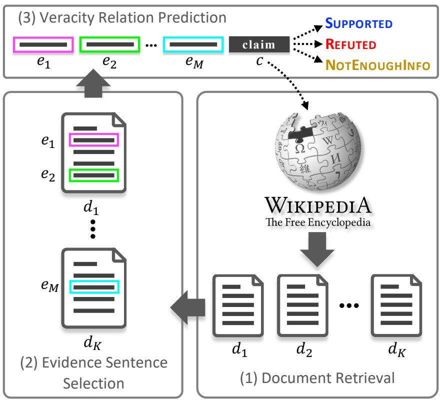

Figure 2: Process of evidence-based fact checking: retrieving documents relevant to a given claim from Wikipedia, selecting sentences likely to contain evidence, and predicting a veracity relation label based on selected sentences.

2.2 Overview of evidence-based fact checking

The process of evidence-based fact checking, shown in Figure 2, commonly involves the following three subtasks.

Document retrieval

Given a claim, the task is to retrieve the top K relevant documents from $\mathcal{D}$. Thorne et al. (2018) suggest using the document retriever from DrQA (Chen et al., 2017a), which ranks documents on the basis of the term frequency-inverse document frequency (TF-IDF) model with unigram-bigram hashing. Hanselowski et al. (2018) use a hybrid approach that combines search results from the MediaWiki API and the results of using exact matching on all Wikipedia article titles. In this paper, our main focus is to improve evidence sentence selection and veracity relation prediction, so we directly use the document retrieval results from Hanselowski et al. (2018). This allows us to fairly compare our model with a series of previous methods (Soleimani et al., 2019; Zhou et al., 2019; Liu et al., 2020; Ye et al., 2020) that also rely on Hanselowski et al. (2018)'s results.

Evidence sentence selection

The task is to select the top M sentences from the retrieved documents. Thorne et al. (2018) again use the TF-IDF model to rank sentences similar to a given claim. Nie et al. (2019a); Hanselowski et al. (2018) use the enhanced sequential inference model (ESIM) (Chen et al., 2017b) to encode and align a claim-sentence pair. Liu et al. (2020); Hanselowski et al. (2018) use a pairwise hinge loss to rank sentences, while Soleimani et al. (2019) explore both pointwise and pairwise losses and suggest selecting difficult negative examples for training. The pairwise hinge loss aims to maximize the margin between the scores of positive and negative examples, while the pointwise loss is a vanilla cross-entropy loss. Our model uses a pointwise loss trained with examples sampled from both ground-truth and predicted documents.

Veracity relation prediction

Given a claim and a set of M selected sentences, the task is to predict their veracity relation label y. Previous work on the FEVER Challenge modified existing RTE/NLI models to deal with multiple sentences (Nie et al., 2019a; Yoneda et al., 2018; Hanselowski et al., 2018; Thorne et al., 2018), used heuristic rules to combine predictions from individual claim-sentence pairs (Malon, 2018), or concatenated all sentences (Stammbach and Neumann, 2019). A line of recent work has applied graph-based neural networks (Zhou et al., 2019; Liu et al., 2020; Zhong et al., 2020). Our model is simply trained on linear sequences by using self- and cross-attention to learn inter-sentence interactions.

2.3 Pre-trained language models

A key to the success of state-of-the-art approaches is the use of pre-trained language models (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019; Lan et al., 2020). Here, we use BERT (Devlin et al., 2019), a bidirectional transformer (Vaswani et al., 2017), to obtain the vector representation of a token sequence. Each BERT layer transforms an input token sequence (one or two sentences) by using self-attention. The first hidden state vector of the final layer represents a special classification token (CLS), which can be used in downstream tasks. We denote the above process by $\mathrm{BERT}_{\mathrm{CLS}}(\cdot) \in \mathbb{R}^{d_h}$, where d_h means the dimensionality of BERT hidden state vectors.

3 Proposed method

In this section, we describe our contributions, including (1) our method for training the sentence-selection model and (2) our veracity prediction model that can be extended with inter-sentence attentions and joint training.

3.1 Learning to select sentences from mixed ground-truth and retrieved documents

Our goal is to select a subset of evidence sentences from all candidate sentences in the retrieved documents. We consider this task to be a binary classification problem that takes as input a pair of a claim c and a candidate sentence e_j and maps it to the output $z \in \mathcal{Z} = \{-1, +1\}$, where $+1$ indicates an evidence sentence and -1 otherwise. We train our sentence-selection model by minimizing the standard cross-entropy loss for each example:

$$\mathcal{L}_{e_j}(\phi) = -\sum_{z \in \mathcal{Z}} \mathbb{1}\{\hat{z} = z\} \mathrm{log} p_{\phi}(\hat{z}|c, e_j), \quad (1)$$

where $\mathbb{1}\{\cdot\}$ is the indicator function, and p_ϕ is the probability distribution of the two classes generated by our model. We compute p_ϕ by applying a multilayer perceptron (MLP) to the vector representation of e_j followed by a softmax function:

$$p_{\phi}(\hat{z}|c, e_j) = \mathrm{softmax}(\mathrm{MLP}(\mathbf{e}_j)), \quad (2)$$
$$\mathbf{e}_j = \mathrm{BERT}_{\mathrm{CLS}}(c, e_j).$$

The MLP contains two affine transformations that map $\mathbf{e}_j$ to the output space. Feeding the pair of c and e_j to BERT allows us to obtain hidden state vectors that capture interactions between c and e_j at the token level. This is due to the self-attention mechanism inside the BERT layers. We expect the final hidden state vector of the CLS token (i.e., $\mathbf{e}_j$) to encode useful information from e_j with respect to c. The parameters ϕ include those in MLP and BERT.

Training our model seems straightforward. However, two technical issues exist. First, each document typically contains one or two (or no) evidence sentences. Training with a few positive examples (i.e., evidence sentences) against all negative examples (i.e., non-evidence sentences) may be neither efficient nor effective. Soleimani et al. (2019) use hard negative mining (HNM) to repeatedly select a subset of difficult negative examples for training their sentence selector. Second, at test time, the model must examine all candidate sentences in the relevant documents returned by the document retriever. However, at training time, the model has no chance to learn the characteristics of non-evidence sentences in the irrelevant but highly ranked documents if only the ground-truth documents are used.

We propose to mitigate the aforementioned issues by using both the ground-truth and retrieved documents to create negative examples for a claim. First, we randomly choose r non-evidence sentences from each ground-truth document, where r is twice the number of true evidence sentences. Then, we sample two other non-evidence sentences from each retrieved document. For positive examples, we use the true evidence sentences in the ground-truth documents. Our scheme is more efficient than HNM of Soleimani et al. (2019). At test time, we select the top M sentences according to the probabilities assigned to the positive class.

3.2 Multi-level attention and joint training for veracity relation prediction

Training-test discrepancies also occur in veracity relation prediction. At test time, the model predicts the veracity of a claim on the basis of the predicted evidence sentences. At training time, only true evidence sentences are available for SUPPORTED and REFUTED, but not for NOTENOUGHINFO. In other words, we have no example sentences that more or less relate to a claim but may not be sufficient to support or refute the claim to train the model. Thorne et al. (2018) simulate training examples for NOTENOUGHINFO by sampling a sentence from the highest-ranked page returned by the document retriever.

We propose to reduce this discrepancy by using a mixture of true and predicted evidence sentences for training. First, we pair each claim with a list of the top M predicted sentences obtained through a sentence selector. At training time, we then prepend the true evidence sentences (if available) to the list and keep the number of all the sentences at most M.[2] At test time, we use the top M predicted sentences without requiring a predefined threshold to filter them. This is in contrast to previous work (Zhou et al., 2019; Nie et al., 2019b; Wadden et al., 2020) and helps reduce engineering effort. Our example sentences for NOTENOUGHINFO are from the sentence selector, not from the document retriever as in (Thorne et al., 2018). We expect our training examples to be similar to what our model may encounter at test time.

On the basis of the above scheme, each example is a pair of a claim c and a set of evidence sentences $\{e_j\}_{j=1}^{M}$. Our goal is to predict the veracity relation label $y \in \mathcal{Y} = \{\mathrm{S}, \mathrm{R}, \mathrm{N}\}$. We train our veracity prediction model by minimizing the class-weighted cross-entropy loss for each example:

$$\mathcal{L}_p(\boldsymbol{\theta}) = -\sum_{y \in \mathcal{Y}} \beta_y \mathbb{1}\{\hat{y} = y\} \log p_{\boldsymbol{\theta}}(\hat{y} | c, \{e_j\}_{j=1}^{M}), \tag{3}$$

where β_y is the class weight for dealing with the class imbalance problem (detailed in Section 4.2). Similar to Eq. (2), we compute the probability distribution $p_{\boldsymbol{\theta}}$ of veracity relation labels as:

$$p_{\boldsymbol{\theta}}(\hat{y} | c, \{e_j\}_{j=1}^{M}) = \mathrm{softmax}(\mathrm{MLP}(\mathbf{a})). \tag{4}$$

Here, $\mathbf{a}$ is the vector representation of aggregated evidence about a claim that is obtained through the multi-head attention (MHA) function:

$$\mathbf{a} = \mathrm{MHA}(\mathbf{Q} = \mathbf{c}, \mathbf{K} = \mathbf{E}, \mathbf{V} = \mathbf{E}), \tag{5}$$

where $\mathbf{c}$ is the claim vector, $\mathbf{E}$ is the set of evidence vectors $\{\mathbf{e}_j\}_{j=1}^{M}$, and $\mathbf{Q}$, $\mathbf{K}$, $\mathbf{V}$ denote the query, keys, and values, respectively. All the claim and evidence vectors are derived from BERT:

$$\mathbf{c} = \mathrm{BERT}_{\mathrm{CLS}}(c),$$
$$\mathbf{e}_j = \mathrm{BERT}_{\mathrm{CLS}}(c, e_j).$$

The parameters $\boldsymbol{\theta}$ are those in MLP, MHA, and BERT.

Now let us explain the MHA function, because we use and/or modify it in other components. The MHA function is based on the scaled dot-production attention (Vaswani et al., 2017):

$$\mathrm{attn}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \mathrm{softmax}\Big(\frac{\mathbf{Q}\mathbf{K}^{\top}}{\gamma}\Big)\mathbf{V}, \tag{6}$$

where $\gamma = \sqrt{d_h/n}$ is the scaling factor. The above function is the weighted sum of the values (i.e., the evidence vectors), where the weight assigned to each value is the result of applying a softmax function to the scaled dot products between the query (i.e., the claim vector) and the keys (i.e., the evidence vectors).

The MHA function contains a number of parallel heads (i.e., attention layers). We expect each head to capture different aspects of the input. We achieve this by linearly projecting $\mathbf{Q}$, $\mathbf{K}$, and $\mathbf{V}$ to new representations and feeding them to the scaled dot-product attention. Specifically, the MHA function is given by:

$$\mathrm{MHA}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = [\mathrm{head}_1, \ldots, \mathrm{head}_n]\mathbf{W}^{O}, \tag{7}$$

$$\mathrm{head}_i = \mathrm{attn}(\mathbf{Q}\mathbf{W}_i^{Q}, \mathbf{K}\mathbf{W}_i^{K}, \mathbf{V}\mathbf{W}_i^{V}), \tag{8}$$

---

[2] True evidence sentences may already exist in the list because the sentence selector can correctly identify them.

where n is the number of parallel heads, and $\mathbf{W}_i^Q, \mathbf{W}_i^K, \mathbf{W}_i^V \in \mathbb{R}^{d_h \times \frac{d_h}{n}}$; $\mathbf{W}^O \in \mathbb{R}^{d_h \times d_h}$ are the weight matrices of the linear projections.

Inter-sentence attentions

Although Eq. (5) helps aggregate the evidence from multiple selected sentences, our model still has no mechanism to learn interactions among these sentences. Unlike previous work that uses graph-based attention (Zhou et al., 2019; Liu et al., 2020; Zhong et al., 2020), our main tool is just the described MHA function.

Let $\mathbf{H}_j = [\mathbf{h}_{j,1}, ..., \mathbf{h}_{j,L}]$ be a sequence of the hidden state vectors of e_j generated by BERT, where L is the maximum sequence length. Let $\mathbf{H}$ be the concatenation of all the sequences $\{\mathbf{H}_j\}_{j=1}^{M}$. We obtain a new representation $\mathbf{G}$ of the concatenated sequence by applying a residual connection between $\mathbf{H}$ and token-level self-attention:

$$\mathbf{G} = \mathbf{H} + \mathrm{MHA}(\mathbf{H}), \tag{9}$$

where $\mathrm{MHA}(\cdot)$ is a simplified MHA function with one argument because $\mathbf{Q}$, $\mathbf{K}$, and $\mathbf{V}$ all come from the same $\mathbf{H}$.

In practice, we also add the static (sinusoid) positional encodings (PE) to the input of MHA.[3] We adopt this procedure from the original Transformer's sub-layer (Vaswani et al., 2017). The computation cost of Eq. (9) is not high. Concretely, let $L = 128$ and $M = 5$. The length of the concatenated sequence is thus 640 ($L \times M$), which is slightly longer than the maximum length of BERT's input sequence (i.e., 512 tokens).

Next, we perform sentence-level self-attention using a similar procedure. First, we split $\mathbf{G}$ back into individual sequences $\{\mathbf{G}_j\}_{j=1}^{M}$. Then, we pick the first hidden state vector from each $\mathbf{G}_j$, which corresponds to that of the CLS token. Let $\mathbf{F}$ be the concatenation of all the first hidden state vectors $\{\mathbf{g}_{j,1}\}_{j=1}^{M}$. We obtain the final representation $\mathbf{E}$ of the evidence sentences:

$$\mathbf{E} = \mathbf{F} + \mathrm{MHA}(\mathbf{F}). \tag{10}$$

We can use $\mathbf{E}$ as the keys and values in Eq. (5). Note that we do not share the parameters among the different MHA layers.

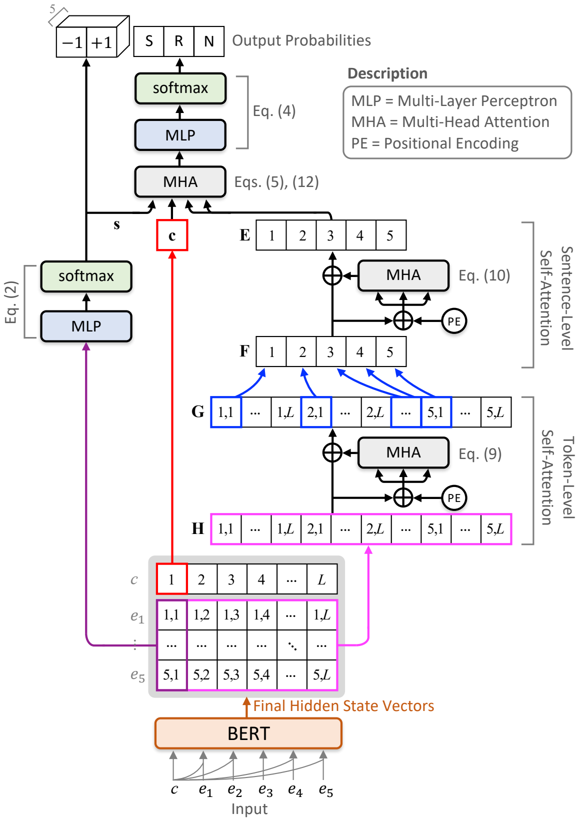

Figure 3: Architecture of our multi-level attention (MLA) model. The model takes as input a claim together with five evidence sentences. These sentences can be derived from any sentence selector. BERT encodes each sentence into a sequence of hidden state vectors, each of which is denoted by a squared box. The first hidden state vector (corresponding to the CLS token) is used for classification. MLA applies token- and sentence-level self-attentions and combines all the hidden state vectors as well as the sentence-selection scores at the final attention layer.

Joint training

Since the sentence-selection label assigned to each evidence sentence is available at training time, we can use it to guide our veracity prediction model. We apply the idea of multi-task learning (MTL) (Caruana, 1993; Ruder, 2017), in which we consider veracity relation prediction to be our main task and evidence sentence selection to be our auxiliary task. Our goal is to leverage training signals from our auxiliary task to improve the performance of our main task. Note that the sentence-selection component here is independent of the stand-alone model (i.e., our model in Section 3.1 or an alternative model in Section 4.3).

Let $\mathbf{s} = [s_1, \ldots, s_M]$ be the vector of sentence-selection scores, where s_m denotes the probability distribution of the positive class returned by our

---

[3] During development, we tried the other basic components, i.e., layer normalization and position-wise feed-forward, but found it yielded no improvements in our task.

sentence-selection component. We propose using $\mathbf{s}$ as a gate vector to determine how much of the values should be maintained before applying a residual connection followed by a linear projection. Thus, we modify Eq. (8) with:

$$\mathrm{head}_i = \mathrm{attn}(\mathbf{Q}\mathbf{W}_i^Q, \mathbf{K}\mathbf{W}_i^K, \widetilde{\mathbf{V}}\mathbf{W}_i^V), \quad (11)$$

$$\widetilde{\mathbf{V}} = \mathbf{V} + \mathbf{s} \odot \mathbf{V}, \quad (12)$$

where $\odot$ means the element-wise multiplication.

Our modification is close to Shaw et al. (2018)'s method in which extra vectors are added to the keys and the values after applying the linear projections. During development, we found that their method does not work well in our task. We compare different strategies in Section 4.4, including applying the gate vector to the keys or both the keys and the values.

Finally, we combine Eqs. (1) and (3) to get our composite loss function:

$$\min_{\boldsymbol{\theta},\boldsymbol{\phi}} \mathcal{L} = \mathcal{L}_p + \lambda \sum_{j=1}^{M} \mathcal{L}_{e_j}, \quad (13)$$

where λ is the weighting factor of the sentence-selection component.

To summarize, our model, shown in Figure 3, contains token-level attention over a claim-evidence pair through BERT, token- and sentence-level self-attentions across an evidence set, and claim-evidence cross-attention incorporating the sentence-selection scores through joint training. Hence, we call it the multi-level attention (MLA) model.

4 Experiments

4.1 Dataset and evaluation metrics

Table 1 shows the statistics of the FEVER dataset. We used the corpus of the June 2017 Wikipedia dump, which contains 5,416,537 articles preprocessed by Thorne et al. (2018). We used the document retrieval results given by Hanselowski et al. (2018), containing the predicted Wikipedia article titles (i.e., document IDs) for all the claims in the training/dev/test sets. Following (Stammbach and Neumann, 2019; Soleimani et al., 2019; Liu et al., 2020), we prefixed the Wikipedia article titles to the candidate sentences to alleviate the co-reference resolution problem.

We evaluated performance by using the label accuracy (LA) and FEVER score. LA measures the 3-way classification accuracy of veracity relation prediction. The FEVER score reflects the performance of both evidence sentence selection and veracity relation prediction, where a complete set of true evidence sentences is present in the selected sentences, and the claim is correctly labeled. We used the official FEVER scorer during development.[4] We limited the number of the selected sentences to five (M = 5) according to the FEVER scorer. The performance on the blind test set was evaluated through the FEVER Challenge site.

Split	SUPPORTED	REFUTED	NOTENOUGHINFO
Training	80,035	29,775	35,659
Dev	6,666	6,666	6,666
Test	6,666	6,666	6,666

Table 1: Statistics of the FEVER dataset. Veracity relation labels and evidence sentences of the test set are not publicly available.

4.2 Training details

We implemented our model on top of HuggingFace's Transformer (Wolf et al., 2020). The dimension of hidden state vectors d_h and the number of heads n varied according to those of the pre-trained models. We used BERT-base (d_h = 786; n = 12) for our stand-alone sentence-selection model and tried various BERT-style models for MLA.

We trained all models using Adafactor (Shazeer and Stern, 2018) with a batch size of 256, a linear learning rate decay, a warmup ratio of 0.06, and a gradient clipping of 1.0. Following the default configuration of HuggingFace's Transformer, we initialized all parameters by sampling from $\mathcal{N}(0, 0.02)$ and setting the biases to 0, except for the pre-trained models. We set λ in Eq. (13) to 1. We trained each model for 2 epochs with a learning rate of 5e-5, unless otherwise specified.

For regularization, we applied dropout (Hinton et al., 2012) with a probability of 0.1 to the MHA layers, MLP layers, and gated values in Eq. (12). We computed the class weight β_y in Eq. (3) by:

$$\beta_y = \frac{\hat{\beta}_y}{\sum_{y \in \mathcal{Y}} \hat{\beta}_y}, \quad \hat{\beta}_y = \frac{N}{|\mathcal{Y}| \times N_y},$$

where $\hat{\beta}_y$ is the balanced heuristic used in scikit-learn (Pedregosa et al., 2011) and β_y is normalized to sum to 1. In our case, N = 145,469 is the total

---

[4] `https://github.com/sheffieldnlp/fever-scorer`

number of training examples, $|\mathcal{Y}| = 3$ is the number of classes, and N_y is the number of training examples in y (i.e., the first row in Table 1). We interpreted $\hat{\beta}_y$ as the ratio of the balanced class distribution ($N/|\mathcal{Y}|$) to the observed one (N_y). Here, we wanted to penalize the less-observed classes, like REFUTED and NOTENOUGHINFO, more.

4.3 Results

Baselines

The use of different pre-trained and pipeline models in the previous work makes a fair comparison difficult. For this reason, we chose baseline models that use BERT-base for pre-training and Hanselowski et al. (2018)'s document retrieval results. We designed two sets of experiments.

First, we required that all the models use the same sentence-selection model, which is Hanselowski et al. (2018)'s ESIM.[5] For the veracity relation prediction, Hanselowski et al. (2018) incorporate ESIM with attention and pooling operations to get a representation of a claim and top five selected sentences. Soleimani et al. (2019) make five independent predictions for each claim-evidence pair and use a heuristic (Malon, 2018) to get a final prediction. GEAR (Zhou et al., 2019) is a graph-based model for evidence aggregating and reasoning. KGAT (Liu et al., 2020) is a kernel graph attention model. Second, we allowed different sentence-selection models. Soleimani et al. (2019) use HNM to select negative examples with the highest loss values, while our negative examples are sampled once from both the ground-truth and retrieved documents, as described in Section 3.1.

Table 2 shows the results of the two settings on the dev set. MLA outperforms the other baselines in both settings. Table 3 shows the sentence-selection results returned by the FEVER scorer. The precision, recall@5, and F1 are consistent across the three models. Hanselowski et al. (2018) use ESIM with a pairwise hinge loss, while Soleimani et al. (2019) use a pointwise loss with HNM. Our model is also a pointwise approach but simpler to train. Without sampling non-evidence sentences from the retrieved documents, all the scores drop by around 2%, indicating that our technique is useful. In the following sections, we will refer to our BERT-base sentence-selection results with MLA.

Model	LA	FEVER
Sentence selection with ESIM		
Hanselowski et al. (2018)	68.49	64.74
Soleimani et al. (2019)	71.70	69.79
GEAR† (Zhou et al., 2019)	74.84	70.69
KGAT† (Liu et al., 2020)	75.51	71.61
MLA (Ours)	**76.30**	**72.83**
Sentence selection with BERT-base		
Soleimani et al. (2019)‡	73.54	71.33
MLA (Ours)	**76.92**	**73.78**

Table 2: LA and FEVER score results on the dev set. All the models use the document retrieval results from Hanselowski et al. (2018). Results marked with † indicate using ESIM with a threshold filter, and ‡ indicates using BERT-base with HNM.

Model	Prec	Rec@5	F1
ESIM (Hanselowski et al., 2018)	24.08	86.72	37.69
BERT-base‡ (Soleimani et al., 2019)	25.13	88.29	39.13
BERT-base (Ours)	**25.63**	**88.64**	**39.76**
w/o sampling from retrieved docs.	23.59	87.18	37.13

Table 3: Sentence selection results on the dev set. Result marked with ‡ indicates using HNM.

Effect of pre-trained models

The next set of experiments examined the benefits of using different pre-trained models. ALBERT (Lan et al., 2020) is a lite BERT training approach that uses cross-layer parameter sharing and replaces next sentence prediction with sentence ordering. RoBERTa (Liu et al., 2019) is a robustly optimized BERT approach that introduces better training schemes, including dynamic masking, larger batch size, and other techniques. We chose these two BERT-style models because they can be easily plugged into our implementation without much modification.

Table 4 shows the results of the different pre-trained models on the dev set. For all the large pre-trained models, we decreased the learning rate to 2e-5 and trained them for 3 epochs. Additional results including training times can be found in Appendix A. As shown in the table, BERT and ALBERT perform similarly, while ALBERT has fewer parameters. RoBERTa offers consistent improvements over the other two models and achieves the best performance with its large model. Therefore,

---

[5] We used the sentence-selection results reproduced by Zhou et al. (2019).

Pre-trained model	# Params	LA	FEVER
BERT-base	117M	76.92	73.78
BERT-large	349M	77.27	74.10
ALBERT-base	20M	76.58	73.83
ALBERT-large	33M	76.94	74.24
RoBERTa-base	132M	77.54	74.41
RoBERTa-large	370M	**79.31**	**75.96**

Table 4: LA and FEVER score results of MLA on the dev set using different pre-trained models. The second column shows the number of parameters, including those from the pre-trained model and our task-specific layers (i.e., MHA and MLP layers).

Model	LA	FEVER
Hanselowski et al. (2018)	65.46	61.58
Yoneda et al. (2018)	67.62	62.52
Nie et al. (2019a)	68.21	64.21
GEAR† (Zhou et al., 2019)	71.60	67.10
SR-MRS† (Nie et al., 2019b)	72.56	67.26
BERT‡ (Soleimani et al., 2019)	71.86	69.66

we applied MLA with RoBERTa-large to the blind test set.

Comparison with state-of-the-art methods

Table 5 shows the results on the blind test set.[6] The results are divided into two groups. The first group represents the top scores of the FEVER shared task, including those of Hanselowski et al. (2018); Yoneda et al. (2018); Nie et al. (2019a). The second group contains recently published results after the shared task. GEAR (Zhou et al., 2019), KGAT (Liu et al., 2020), and DREAM (Zhong et al., 2020) are graph-based models. SR-MRS (Nie et al., 2019b) uses a semantic retrieval module for selecting evidence sentences. HESM (Subramanian and Lee, 2020) uses a multi-hop evidence retriever and a hierarchical evidence aggregation model. CorefRoBERTa (Ye et al., 2020) trains KGAT by using a pre-trained model that combines a coreference prediction loss. Their pre-trained model is initialized with RoBERTa-large's parameters and further trained on Wikipedia. MLA outperforms all the published models and yields 1.09% and 1.42% improvements in LA and FEVER score, respectively, over CorefRoBERTa. Additional sentence-selection results can be found in Appendix B.

Model	LA	FEVER
MLA (full)	**76.92**	**73.78**
w/o token-level self-attention	76.30	73.20
w/o sentence-level self-attention	76.50	73.41
w/o class weighting	76.44	73.14
w/o joint training	76.65	73.22

Table 6: Ablation studies of the proposed components on the dev set with BERT-base.

Model	LA	FEVER
MLA (w/ value)	**76.92**	**73.78**
w/ key	76.74	73.65
w/ key & value	76.82	73.60
w/ dot-product	76.70	73.51
w/o using s	76.64	73.47

Table 7: Ablation studies of different strategies for using the sentence-selection scores s on the dev set with BERT-base.

4.4 Ablation study

We conducted two sets of ablation studies on the dev set using MLA with BERT-base. First, we examined the effect of our proposed components. Table 6 shows that all the components contribute to the final results. Without class weighting, Eq. (3) falls back to the standard cross-entropy loss. Without joint training, MLA is a stand-alone veracity prediction model. These results suggest that token-level self-attention and class weighting are the two most important components of our model.

Second, we explored a number of strategies for exploiting the sentence-selection scores s. MLA basically uses s as a gate vector and only applies it to the values, as described in Eq. (12). We can apply the same calculation to the keys or both the keys and the values. In addition, we can use s as a bias vector and add it to the scaled dot-product term, as done by Yang et al. (2018). Table 7 shows the results of the aforementioned strategies. These results indicate that applying s to the values produces the best results.

[6] The results can also be found on the FEVER leaderboard: `https://competitions.codalab.org/competitions/18814#results`

ID: 35237
Claim: Philomena is a film nominated for seven awards.
Evidence: [*Philomena_(film)*] It was also nominated for four BAFTA Awards and three Golden Globe Awards.^{9}
Annotated label: SUPPORTED
Predicted label: REFUTED

(a)

ID: 33547
Claim: Mick Thomson was born in Ohio.
Evidence: [*Mick_Thomson*] Born in Des Moines, Iowa, he is best known as one of two guitarists in Slipknot, in which he is designated #7.^{1}
Annotated label: SUPPORTED
Predicted label: REFUTED

(b)

ID: 73443
Claim: Heavy Metal music was developed in the United Kingdom.
Evidence: [*Heavy_metal_music*] Heavy metal (or simply metal) is a genre of rock music that developed in the late 1960s and early 1970s, largely in the United Kingdom and the United States.^{0}
Annotated label: REFUTED
Predicted label: SUPPORTED

(c)

ID: 212780
Claim: Harvard University is the first University in the U.S.
Evidence: [*Harvard_University*] Established originally by the Massachusetts legislature and soon thereafter named for John Harvard (its first benefactor), Harvard is the United States' oldest institution of higher learning ...^{3}
Annotated label: SUPPORTED
Predicted label: NOTENOUGHINFO

(d)

Table 8: Examples where the models disagree with the annotated labels.

4.5 Error analysis

To better understand the limitations of our method, we manually inspected 100 prediction errors on the dev set, where the true evidence sentences are present in the predicted sentences but MLA failed to predict the veracity relation labels. Here, we required that both BERT-base and RoBERTa-large MLA models produce the same errors.

Table 8(a) shows a prediction error requiring complex reasoning that our models are unable to deal with. The claim "*Philomena is a film nominated for **seven** awards.*" is supported by the evidence "*It was also nominated for **four** BAFTA Awards and **three** Golden Globe Awards.*". In this case, the models must understand that four plus three equals seven.

Table 8(b) shows a possible annotation error. The claim "*Mick Thomson was born in **Ohio**.*" is annotated as SUPPORTED, while the evidence "*Born in Des Moines, **Iowa**, he is best known as ...*" refutes the claim. Our models also predict REFUTED.

Table 8(c) shows the half-true claim "*Heavy Metal music was developed in **the United Kingdom**.*", which is annotated as REFUTED. However, the evidence "*Heavy metal (or simply metal) is ... developed ... in **the United Kingdom and the United States**.*" would indicate that the claim is partly true. The half-true label is defined in some previous smaller datasets (Vlachos and Riedel, 2014; Wang, 2017), but not in the FEVER dataset.

Table 8(d) shows the questionable claim "*Harvard University is **the first University** in the U.S.*", which is annotated as SUPPORTED by the evidence "*... Harvard is the United States' **oldest institution** of higher learning ...*". However, this evidence does not directly support the claim.[7] Our models predict NOTENOUGHINFO. Our analysis results suggest that probing disagreements between an ensemble of models and annotators may help improve annotation consistency. Additional results on error analysis are given in Appendix C.

5 Conclusion

We have presented a multi-level attention model that operates on linear sequences. We find that, when trained properly, the model outperforms its graph-based counterparts. Our results suggest that a sequence model is sufficient and can serve as a strong baseline. Using better upstream components (i.e., a better document retriever or sentence selector) or larger pre-trained models would further improve the performance of our model. Training models that are robust to adversarial examples while maintaining high performance for normal ones is an important direction for our future work.

Acknowledgments

We thank Erica Cooper (NII) for providing valuable feedback on an earlier draft of this paper. This work is supported by JST CREST Grants (JPMJCR18A6 and JPMJCR20D3) and MEXT KAKENHI Grants (21H04906), Japan.

A Additional results on different pre-trained models

Table 9 shows the results of different pre-trained models in detail. All the pre-trained models used in our experiments also come from HuggingFace.[8] We conducted each experiment on a single NVIDIA Tesla A100 GPU with 40 GB RAM. We used a batch size of 256 with gradient accumulation to control memory.

B Additional sentence-selection results

Table 10 shows the results of various sentence-selection models on the test set. Not all published models report precision and recall. Our precision, recall@5, and F1 scores are slightly better than those of Liu et al. (2020). Our sentence-selection model took 1 hour and 10 minutes to train. We find that getting high recall in evidence sentence selection is necessary to achieve good results in veracity relation prediction.

C Additional error analysis

Here, we provide additional examples of errors, including complex reasoning errors (Table 11), possible annotation errors (Table 12), half-true claims (Table 13), and questionable claims (Table 14).

RealTranS: End-to-End Simultaneous Speech Translation with Convolutional Weighted-Shrinking Transformer

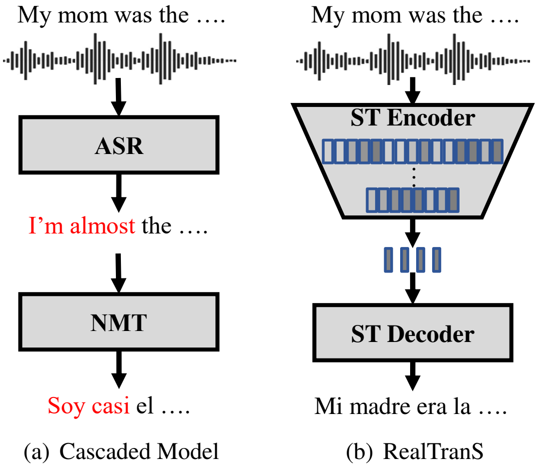
Xingshan Zeng, Liangyou Li, Qun Liu
Huawei Noah's Ark Lab
`{zeng.xingshan,liliangyou,qun.liu}@huawei.com`

Abstract

End-to-end simultaneous speech translation (SST), which directly translates speech in one language into text in another language in real-time, is useful in many scenarios but has not been fully investigated. In this work, we propose RealTranS, an end-to-end model for SST. To bridge the modality gap between speech and text, RealTranS gradually downsamples the input speech with interleaved convolution and unidirectional Transformer layers for acoustic modeling, and then maps speech features into text space with a weighted-shrinking operation and a semantic encoder. Besides, to improve the model performance in simultaneous scenarios, we propose a blank penalty to enhance the shrinking quality and a Wait-K-Stride-N strategy to allow local reranking during decoding. Experiments on public and widely-used datasets show that RealTranS with the Wait-K-Stride-N strategy outperforms prior end-to-end models as well as cascaded models in diverse latency settings.

1 Introduction

Simultaneous speech translation (SST) (Fügen et al., 2007; Oda et al., 2014; Ren et al., 2020) aims to translate speech in one language into text in another language concurrently. It is useful in many scenarios, like synchronous interpretation in international conferences, automatic caption for live videos, etc. However, prior studies either focus on full sentence speech translation (ST) (Berard et al., 2016; Weiss et al., 2017; Liu et al., 2019) or simultaneous text-to-text machine translation (STT) (Cho and Esipova, 2016; Gu et al., 2017; Dalvi et al., 2018) which takes a segmented output from an automatic speech recognition (ASR) system as input. Such two-stage models (i.e., cascaded models) inevitably introduce error propagation and also increase translation latency (see Figure 1). Ren et al. (2020) propose an end-to-end SST system called SimulSpeech, but they ignore the modality gap between speech and text, which is important for improving translation quality (Liu et al., 2020).



(a) Cascaded Model (b) RealTranS

Figure 1: An example for a cascaded model and our RealTranS. The ASR part in the cascaded model wrongly recognizes "My mom was" as "I'm almost". The error is propagated to NMT and leads to a wrong translation. RealTranS avoids such errors and translates accurately.

In this paper, we propose RealTranS model for SST. To relieve the burden of our encoder (Wang et al., 2020c; Liu et al., 2020), we decouple it into three parts: acoustic encoder, weighted-shrinking operation, and semantic encoder. We apply Conv-Transformer (Huang et al., 2020) as our acoustic encoder, which gradually downsamples the input speech and learns acoustic information with interleaved convolution and Transformer layers. The weighted-shrinking operation bridges the length gap between speech and text, by weighted summing up the frames in one detected segment based on the posterior probabilities generated by a CTC module (Graves et al., 2006). Finally, we use a semantic encoder to extract semantic features and deliver them to the decoder for translation.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2461–2474
August 1–6, 2021.

To enable simultaneous decoding, unidirectional Transformer is applied in our encoder. This inevitably affects the performance of the CTC module and the following shrinking operation. To alleviate this, we introduce a blank-limited CTC loss, which adds a blank penalty to the traditional CTC loss to encourage the model to produce non-blank labels, given the observation that CTC tends to produce peaky distribution as a kind of overfitting (Liu et al., 2018) by over predicting blank labels. Accordingly, the shrinking quality can be improved. Furthermore, we propose a new simultaneous strategy Wait-K-Stride-N which allows local reranking during decoding. This strategy can resolve the inherent drawback of the conventional Wait-K strategy (Ma et al., 2019), which cannot apply vanilla beam search efficiently (Zheng et al., 2019c).

Experiments on Augmented LibriSpeech En–Fr, MUST-C En–Es and En–De datasets demonstrate the effectiveness of the Wait-K-Stride-N strategy, and show that RealTranS achieves better performance than the prior end-to-end model SimulSpeech (Ren et al., 2020) as well as the cascaded models. Further analysis and ablation study reveal the effects of our proposed modules in RealTranS. We also compare RealTranS with other methods on full sentence ST. Results show that RealTranS achieves competitive or even better results, indicating its superiority.

In summary, the contributions of this work include the following aspects:

- We propose RealTranS for SST, which can gradually bridge the modality gap between speech and text with the help of gradual downsampling and weighted shrinking.
- We introduce a blank penalty and the Wait-K-Stride-N strategy to improve the performance in simultaneous translation scenarios.
- Extensive experiments on public and widely-used datasets show the superiority of our RealTranS model and our Wait-K-Stride-N strategy in diverse latency settings.

2 Related Work

Speech Translation. Speech translation (ST) has recently attracted intensive attention from the AI community. Earlier works are mostly based on cascaded models, which perform NMT on the outputs of ASR systems (Ney, 1999; Mathias and Byrne, 2006; Sperber et al., 2017; Bahar et al., 2021). Cascaded models inevitably introduce error propagation from ASR (Weiss et al., 2017). To avoid this problem and for better efficiency, end-to-end ST models are proposed and become popular in recent years (Berard et al., 2016, 2018; Bansal et al., 2018; Gangi et al., 2019). To alleviate the data scarcity problem of end-to-end ST models, various techniques are utilized, including pre-training (Bansal et al., 2019), multi-task learning (Anastasopoulos and Chiang, 2018), knowledge distillation (Liu et al., 2019; Ren et al., 2020), data synthesis (Jia et al., 2019), self-supervised learning (Chen et al., 2020) and speech augmentation techniques like SpecAugment (Bahar et al., 2019) or speed perturbation (Stoian et al., 2020).

Some studies focus on how to bridge the gap between different modalities (speech and text) or different modules (acoustic and semantic modeling). Wang et al. (2020b,c) propose a TCEN model and a curriculum pre-training technique to make sure the modules learn desired information, respectively. Salesky and Black (2020) explore phone features as intermediate representations to improve performance, while Dong et al. (2020b) use pre-trained BERT to guide the model to learn semantic knowledge. Modality Agnostic Meta-Leaning is also exploited for ST in Indurthi et al. (2019). To bridge the length gap, Zhang et al. (2020) propose adaptive feature selection, while Dong et al. (2020a) and Liu et al. (2020) exploit the CTC-based (Graves et al., 2006) shrinking mechanism. Nevertheless, they do not explore in simultaneous scenarios, where encoding quality inevitably suffers because of lacking future information in unidirectional encoders.

Simultaneous Translation. Previous studies on simultaneous translation focus on text-to-text scenarios (STT) (Cho and Esipova, 2016; Gu et al., 2017; Dalvi et al., 2018), where fixed policies (Ma et al., 2019) and adaptive policies (Arivazhagan et al., 2019; Zheng et al., 2019a,b) are proposed to decide when to read and write tokens. (Ma et al., 2019) proposed a simple yet effective strategy, Wait-K, based on a prefix-to-prefix framework. It first waits for the first k tokens, and then start to generate target tokens concurrently with the source stream. It achieves competitive performance in simultaneous translation (Zheng et al., 2019a, 2020).

Traditional simultaneous speech-to-text translation (SST) mainly depends on the ASR segmentation and then performs NMT based on the stream-

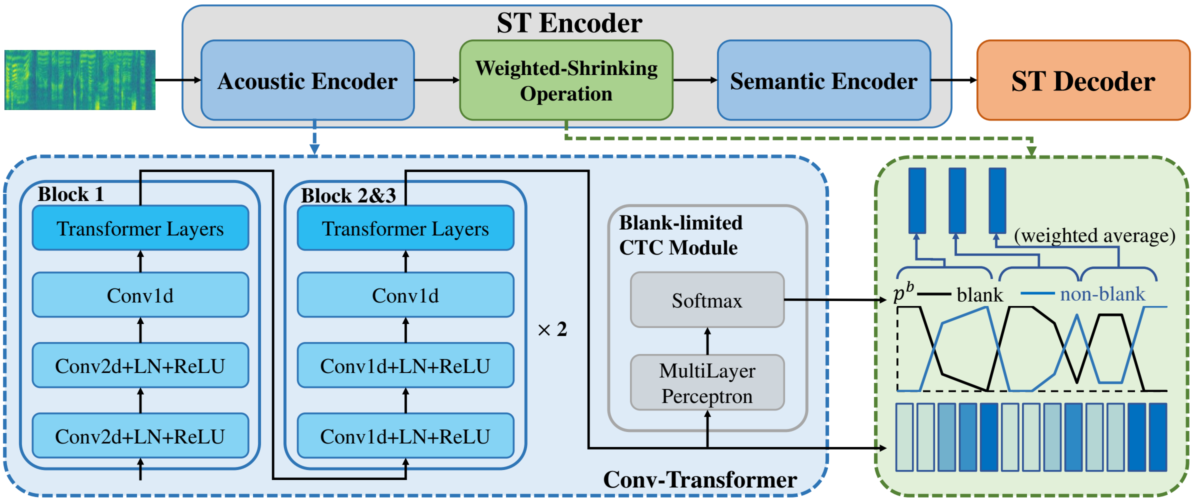


Figure 2: Overall structure of the proposed RealTranS model.

ing segmented chunks (Oda et al., 2014; Iranzo-Sánchez et al., 2020). There is little attention on end-to-end SST. Ren et al. (2020), to our knowledge, first propose an end-to-end model called SimulSpeech with multi-task learning and knowledge distillation, and apply the Wait-K strategy to perform simultaneous translation. Ma et al. (2020a) explore how to define a "token" in source speech, and then adapt methods from STT to SST. And Ma et al. (2020b) introduce a memory-augmented Transformer to tackle the streaming speech input. However, none of them investigate the modality gap between speech and text.

3 The RealTranS Model

Our RealTranS follows the sequence-to-sequence architecture, which consists of an ST encoder and an ST decoder. The ST encoder is decoupled into three parts, an acoustic encoder, a weighted shrinking operation, and a semantic encoder, to gradually map speech inputs into semantic representation space of text. Figure 2 shows the architecture.

3.1 Problem Formulation

Speech translation corpora usually contain triples of speech, transcription and translation, denoted as $\mathcal{D}_{ST} = \{(\boldsymbol{x}, \boldsymbol{z}, \boldsymbol{y})\}$. Specifically, $\boldsymbol{x} = (x_1, x_2, ..., x_{T_x})$ is a sequence of speech features extracted from speech signals, e.g., filterbanks. $\boldsymbol{z} = (z_1, z_2, ..., z_{T_z})$ and $\boldsymbol{y} = (y_1, y_2, ..., y_{T_y})$ are the corresponding transcription in source language and translation in target language. T_x, T_z, and T_y are the lengths of speech, transcription and translation, respectively, where usually $T_x \gg T_z$ and $T_x \gg T_y$. A typical end-to-end model only makes use of $\boldsymbol{x}$ and $\boldsymbol{y}$, while $\boldsymbol{z}$ can be used as multi-task training for other objectives, like CTC loss.

3.2 Acoustic Encoder

Acoustic encoder mainly encodes speech features $\boldsymbol{x}$ into a hidden space to learn acoustic knowledge. We apply Conv-Transformer (Huang et al., 2020) to extract the desired features. It contains three blocks, each of which is composed of three convolution layers followed by unidirectional Transformer layers (see lower left in Figure 2) to prevent from leveraging future context in SST. Similar to Huang et al. (2020), we make the model aware of limited future frames with a look-ahead window in the convolution layers, to help improve acoustic modeling. At the same time, we gradually downsample the long speech features by setting the stride size to 2 in the second convolution layer in each block. In this way, the speech features are gradually reduced and approach the length of the corresponding text.

To predict the word boundaries[1] in the speech input and further improve the learned acoustic features, we adopt the Connectionist Temporal Classification (CTC) (Graves et al., 2006) module on top of the acoustic encoder. This module contains a Multilayer Perceptron (MLP) followed by a Softmax operator. CTC predicts a path $\boldsymbol{\pi} = (\pi_1, \pi_2, ..., \pi_{T'_x})$, where T'_x is the length of hidden states after the Conv-Transformer. And $\pi_t \in \mathcal{V} \cup \{\phi\}$ can be either a token in the source

---

[1] For ease of understanding, we use word boundaries here. Same methods can be applied to boundaries between phones, chars, subwords, etc., depending on the the granularity of the CTC loss units. We use subword units in our experiments.

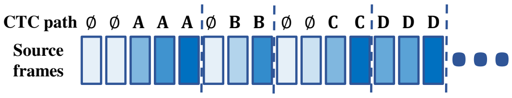

Figure 3: An example of how to define the word boundaries. The dash lines are the boundaries.

vocabulary $\mathcal{V}$ or the blank symbol ϕ. CTC paths have the many-to-one mapping to output sequences by removing blank symbols and consecutively repeated labels, denoted as operation $\mathcal{B}$. Therefore, CTC loss is defined as follows:

$$\mathcal{L}_{CTC} = -\sum_{(\boldsymbol{x},\boldsymbol{z})\in\mathcal{D}} \sum_{\boldsymbol{\pi}\in\mathcal{B}^{-1}(\boldsymbol{z})} p(\boldsymbol{\pi}|\boldsymbol{x}) \qquad (1)$$

where $\mathcal{B}^{-1}(\boldsymbol{z})$ denotes all possible CTC paths that can be mapped to the transcription $\boldsymbol{z}$. With the CTC module, we can define a word boundary between two frames where the first frame has a non-blank label while the second frame has a different label from the first one. Figure 3 shows an example of word boundaries.

Due to the data scarcity problem in ST and CTC's inherent characteristics (Liu et al., 2018), the detected word boundaries are usually not accurate enough. The module will overly predict the occurrence of blank labels (as a kind of overfitting), resulting in a large gap between the number of detected boundaries and the number of tokens in transcription, especially when unidirectional Transformer is applied (see Table 3). To alleviate the problem, we add a blank penalty to encourage the module to produce non-blank labels. It is called blank-limited CTC loss and defined as follows:

$$\mathcal{L}'_{CTC} = \mathcal{L}_{CTC} + \lambda \sum_{\boldsymbol{x}\in\mathcal{D}} \sum_{\pi_t\in\boldsymbol{\pi}(\boldsymbol{x})} p(\pi_t = \phi|\boldsymbol{x}) \qquad (2)$$

where $\boldsymbol{\pi}(\boldsymbol{x})$ means the argmax results of CTC softmax outputs. λ controls the effect of blank penalty.

3.3 Weighted-Shrinking Operation

The length gap between acoustic features and the corresponding transcription and translation is still large after the gradual downsampling in Section 3.2. Inspired by previous studies (Dong et al., 2020a; Liu et al., 2020), we adopt a shrinking operation to bridge the gap based on CTC predictions. Prior works usually either remove blank frames and then average repeated frames (Dong et al., 2020a) or select a single representative frame (Liu et al., 2020) in a detected segment (i.e., frames between two word boundaries). However, there might be useful information in the detected blank or repeated frames, especially when the boundary detection is not accurate enough (see Section 3.2).

We propose a weighted-shrinking mechanism to tackle the problem. We assume that the probability of a frame to be labeled as "blank" represents the confidence that the model "thinks" it is not important. Therefore, for the frames in one segment, their weights are decided by the probabilities to be blank labels. The representation of the segment will be the weighted average of the corresponding frames. The specific operation is shown as follows:

$$\boldsymbol{h}_{t'} = \sum_{t\in seg\, t'} \boldsymbol{h}_t \frac{\exp(\mu(1-p_t^b))}{\sum_{s\in seg_{t'}} \exp(\mu(1-p_s^b))} \qquad (3)$$

where p_t^b denotes the probability of the frame t to be blank, and $\boldsymbol{h}_t$ represents the hidden state of the frame t in our acoustic encoder. $\mu \geq 0$ controls the temperature of the distribution (i.e., Softmax function). When $\mu = 0$, it means that we simply average the frames; and when $\mu \to \infty$ it degenerates to the general shrinking mechanism where only the representative frames with the highest confidence are selected.

3.4 Semantic Encoder

The shrinking operation only bridges the length gap between speech and text, but the shrunk representations still lack semantic information. Therefore, we apply a semantic encoder on top of the shrunk representations (Liu et al., 2020). It first applies a positional embedding layer, and then follows several Transformer layers (also unidirectional to mask future context), to extract semantic representations.

3.5 ST Decoder

A similar decoder as the basic Transformer architecture in NMT is adopted, where several Transformer decoder layers are stacked on top of target embeddings. To simulate simultaneous translation, we follow the prefix-to-prefix framework (Ma et al., 2019) and mask certain future context in cross attention to ensure that the model predicts the current token based on only part of the input from the ST encoder. How much context the model can see depends on the simultaneous strategy that is applied. For example, a Wait-K (Ma et al., 2019) based decoder predicts the t-th token based on the first $t+k-1$ hidden states produced by the ST encoder.

Wait-K-Stride-N. There is one drawback in the conventional Wait-K strategy – it cannot perform vanilla beam search while decoding except for the

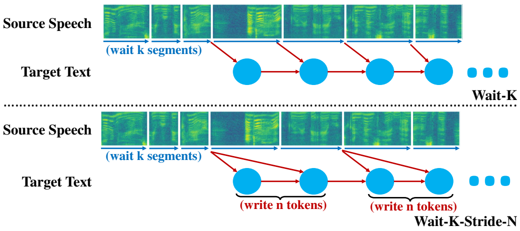

Figure 4: Wait-K vs. Wait-K-Stride-N (in this example, we set $k = 3$ and $n = 2$).

long-tail scenario (Ma et al., 2019; Zheng et al., 2019c), though beam search has been proven very effective in improving translation quality. Based on the prefix-to-prefix framework and STATIC-RW strategy proposed in Dalvi et al. (2018), we propose the Wait-K-Stride-N strategy to allow using beam search for local reranking during simultaneous decoding. Similar to the Wait-K strategy, our strategy first reads k input units (tokens in MT or segments in ST). Then, the model repeatedly performs n write and read operations until the end of the sentence (see Figure 4). In this way, the translation latency is close to Wait-K, but we can perform beam search during the n write operations. The objective with such a strategy is hence defined as follows:

$$\mathcal{L}_{ST} = -\sum_{(\boldsymbol{x},\boldsymbol{y})\in\mathcal{D}} \prod_{t=1}^{T_y} p(y_t|y_{<t}, x_{\leq n\lfloor (t-1)/n \rfloor + k}) \quad (4)$$

where $y_{<t}$ represents the target tokens before y_t, T_y is the length of the target sentence, and $x_{\leq t}$ represents the first t detected source segments.

3.6 Training Procedure

The total objective of our model will be the sum of the CTC part and the ST part:

$$\mathcal{L} = \mathcal{L}_{ST} + \alpha \mathcal{L}'_{CTC} \quad (5)$$

where α controls the influence of the CTC part.

To enhance the CTC quality, we also apply a pre-training procedure (Stoian et al., 2020). We only use CTC loss to pre-train the acoustic encoder[2]. In this way, we can prevent the training waste (Wang et al., 2020b), and focus on improving the alignment results, which are essential for shrinking operations (see Table 3). The whole model is then fine-tuned with the whole ST corpus.

Corpus	Train	Dev	Test
En–Fr	47,271×2 (100h)	1,071 (2.0h)	2,048 (4.0h)
En–Es	265,625 (496h)	1,316 (2.5h)	2,502 (4.0h)
En–De	229,703 (400h)	1,423 (2.5h)	2,641 (4.0h)

Table 1: The number of sentences and the duration of audios for Augmented LibriSpeech En–Fr, MuST-C En–Es and En–De datasets.

4 Experimental Setup

4.1 Datasets

We conduct experiments on three publicly available datasets: Augmented LibriSpeech English-French (En–Fr) corpus (Kocabiyikoglu et al., 2018), and MUST-C English-Spanish (En–Es) and English-German (En–De) corpus (Di Gangi et al., 2019). All the datasets include source audios with the corresponding transcriptions in source language and translations in target language. For the Augmented Librispeech En–Fr corpus, we follow previous work (Wang et al., 2020c) and use the 100-hour clean training set with aligned references and provided Google translations, resulting in double size of training pairs. For MUST-C datasets, We use the official data splits for train and development and tst-COMMON set for test. The statistics for these three datasets are listed in Table 1.

4.2 Experimental Settings

We use 80-dimensional log-mel filterbanks as acoustic features, which are calculated with 25ms window size and 10ms step size and normalized by utterance-level Cepstral Mean and Variance Normalization (CMVN). For transcriptions and translations, SentencePiece[3] (Kudo and Richardson, 2018) is used to generate subword vocabularies with the sizes of 4k and 8k respectively. We remove the punctuation in transcriptions.

Our acoustic encoder follows the settings of the original Conv-Transformer (Huang et al., 2020), except that the channel number in convolution layers and hidden size and head number in Transformer layers are half values of theirs. This means the output dimension of the acoustic encoder is 256. We use 6 Transformer layers in the semantic encoder and 4 in the ST decoder. The hyper-parameters λ (Eq. 2), μ (Eq. 3) and α (Eq. 5) in our model are set to 0.5, 1.0 and 1.0, respectively.

---

[2] We do not pre-train the decoder for simplicity though it might further improve our performance.

[3] `https://github.com/google/sentencepiece`

Our model is trained with 8 NVIDIA Tesla V100 GPUs, batched with an approximate 40000-frame features. We use Adam optimizer (Kingma and Ba, 2015) with a 0.002 learning rate and 10000 warm-up steps followed by the inverse square root scheduler. Dropout strategy is used with a rate of 0.1. We save checkpoints every epoch and average the last 10 checkpoints for evaluation with a beam size of 5. For simplicity, we use the same K and N values as those of training for inference. We implement our model based on Fairseq S2T[4] (Wang et al., 2020a).

4.3 Evaluation Metrics

We apply SacreBLEU[5] for translation quality evaluation unless otherwise stated. For the metrics of latency, we adapt Average Proportion (AP) (Cho and Esipova, 2016) and Average Lagging (AL) (Ma et al., 2019) to ST settings, following previous studies (Ren et al., 2020; Ma et al., 2020a).

Average Proportion. AP calculates the mean absolute latency cost by each target token, where we replace the steps of source tokens with the time spent. It can be calculated as follows:

$$AP(\boldsymbol{x},\boldsymbol{y}) = \frac{1}{|\boldsymbol{x}||\boldsymbol{y}|}\sum_{i=1}^{|\boldsymbol{y}|} d(y_i) \qquad (6)$$

where $d(y_i)$ is the speech duration that has been listened when producing the target token y_i.

Average Lagging. AL evaluates the degree of that the user is out of sync with the speaker, in terms of the number of source tokens (Ma et al., 2019). Following Ma et al. (2020a), we also extend it to the basis of time duration rather than source tokens, which is defined as follows:

$$AL(\boldsymbol{x},\boldsymbol{y}) = \frac{1}{\tau(|\boldsymbol{x}|)}\sum_{i=1}^{\tau(|\boldsymbol{x}|)}\left[d(y_i) - \frac{|\boldsymbol{x}|}{|\boldsymbol{y}^*|}T_s(i-1)\right] \qquad (7)$$

where $|\boldsymbol{y}^*|$ is the length of the reference translation, and $\tau(|\boldsymbol{x}|)$ denotes the index of the corresponding target token when our model has read the entire source speech. T_s represents that the speech features are extracted every T_s ms (decided by the step size in the feature extraction and downsampling rates in convolution layers), which will be 80ms in our model. What's more, our Conv-Transformer module introduces a 140ms look-ahead window (Huang et al., 2020), so we add 140 to the final AL scores to be fairly compared with other models.

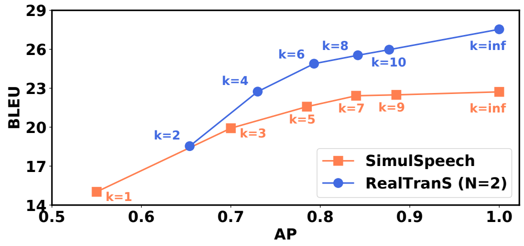
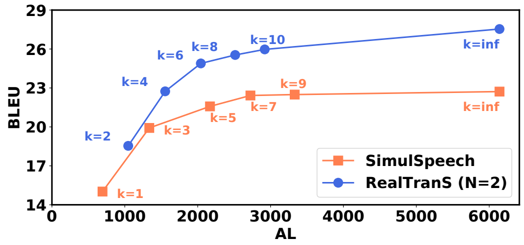
[5] `https://github.com/mjpost/sacreBLEU`



(a) Translation quality vs. latency in terms of AP



(b) Translation quality vs. latency in terms of AL

Figure 6: Translation quality (BLEU) vs. latency (AP and AL) comparison on MUST-C En-Es dataset.

most of the compared results. Their corresponding numeric results can be found in Appendix A.

5.1 Translation Quality vs. Latency

We first evaluate our RealTranS model with our Wait-K-Stride-N simultaneous strategy on the three datasets. We select three values 1, 2 and 3 for N to compare (it becomes conventional Wait-K when N=1). The results are displayed in Figure 5.

Results show that RealTranS achieves higher BLEU scores as the K value increases, with sacrfice of translation delay, consistent with prior works (Ren et al., 2020; Ma et al., 2020a).

Compared to the conventional Wait-K (N=1), our model with N=2 can achieve better BLEU scores under the same latency requirements, which demonstrates the effectiveness of our proposed Wait-K-Stride-N strategy. When N=3, the latency becomes higher. And it only achieves similar gains in BLEU scores compared to N=2 on MUST-C En–Es and En–De datasets. Therefore, we will use N=2 as our simultaneous strategy in later experiments unless otherwise stated.

5.2 Comparison with SimulSpeech

We compare with SimulSpeech (Ren et al., 2020), the state-of-the-art end-to-end model for SST. Figure 6 shows the performance comparison on the MUST-C En-Es dataset (we report tokenized case-sensitive BLEU scores following their settings). Since they only report segment-based AL, we transfer it to our time-based AL proportionally based on the latency when K=inf.

Model	K=2	K=4	K=6	K=8	K=10	K=inf
Cascaded	14.92	19.22	22.11	23.33	24.47	26.79
RealTranS	**18.45**	**22.65**	**24.79**	**25.41**	**25.82**	**27.40**

Table 2: Comparison with the cascaded model using Wait-K-Stride-N strategy when N=2 in terms of BLEU scores. The same K value means similar latency.

We find that our RealTranS model outperforms SimulSpeech almost in all latency settings, with an average of about 3 higher BLEU scores. Although SimulSpeech achieves relatively lower latency (e.g. less than 1000 ms AL when K=1), the performance inevitably suffers. What's more, SimulSpeech has leveraged multi-task learning and knowledge distillation to enhance their performance, which can be also applied to further improve the performance of our RealTranS model.

5.3 Comparison with Cascaded Model

We implement a cascaded model to compare with RealTranS under the same latency. Specifically, we combine our acoustic encoder (Section 3.2) and a Transformer decoder as our ASR model and use the conventional Transformer encoder-decoder architecture as our NMT model. Their configuration is similar to RealTranS (e.g. the same hidden dimension and the same number of Transformer layers). And we train the ASR and NMT model with the same corpus. The conventional Wait-K strategy is used in the ASR model since the alignment between speech and transcription is monotonic, while Wait-K-Stride-N is applied in the NMT model. Since several combinations of the ASR and NMT models may be under the same latency, we report the best BLEU score among them.

Table 2 shows the comparison results on MUST-C En–Es dataset. We have the following observations: 1) our RealTranS model outperforms the cascaded model in all latency settings, which demonstrates the superiority of RealTranS. 2) The improvement over the cascaded model becomes larger when the value of K is smaller. This observation is consistent with Ren et al. (2020). We attribute this to the advantage of end-to-end models over cascaded models, where the impact of error propagation in cascaded models may be amplified when the latency is low.

Model	Diff≤2	Diff≤4	Diff≤6	BLEU
Full Model	**52%**	**74%**	**85%**	**27.40**
- CTC PT	48%	70%	82%	26.63
- BP	35%	53%	67%	25.76
+ Bi-Enc	42%	59%	72%	26.58

Table 3: Shrinking quality of RealTranS. "CTC PT" indicates that the acoustic encoder is pre-trained with CTC. "BP" represents blank penalty, and "Bi-Enc" means that using bidirectional Transformer encoders. "Diff $\leq n$" means the difference between the length of shrunk representations and that of the ground-truth transcription is less than or equal to n. We report the percentage of the cases on the MUST-C En–Es test set. The BLEU scores displayed are results when K=inf.

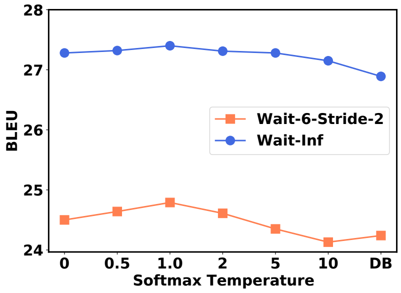
5.4 Effects of Blank Penalty and Weighted Shrinking Operation

In this subsection, we examine the effects of our proposed methods, including blank penalty (Eq. 2) and weighted-shrinking operation (Eq. 3).

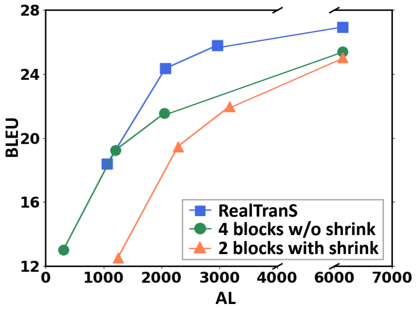
Blank Penalty. We propose a blank penalty to alleviate the inaccuracy of alignments between speech features and transcriptions when applying unidirectional encoders for SST (Section 3.2). To examine the effect, we evaluate the shrinking quality, i.e., the differences between the length of representations after the shrinking operation and that of the ground-truth transcription, on MUST-C En–Es dataset, and display the statistics in Table 3. We can see that the performance, as well as the shrinking quality, drops when removing CTC pre-training. It further decreases when removing the blank penalty, which shows its effectiveness. Also, we can see that the performance loss partly comes from using unidirectional encoders rather than bidirectional for simultaneous purposes (the 4th row), which can be compensated by the blank penalty.

Weighted-Shrinking. To validate our weighted-shrinking operation, we first investigate the effects of various values for the shrinking temperature μ in Eq. 3 and display the results in Figure 7(a). The results show that our weighted-shrinking mechanism ($\mu = 1.0$) performs better than both simply averaging all the frames ($\mu = 0$) and dropping blank frames ("DB").

We also try to replace our weighted-shrinking module with another Conv-Transformer block (see Section 3.2), resulting in a model with 240ms downsample rate in total (denoted as "4 blocks w/o shrink"). Figure 7(b) shows comparison results, together with a model with only 2 blocks (40ms downsample rate, denoted as "2 blocks with shrink"). We can find that downsampling only with convolution layers performs worse than RealTranS, while less downsample rate also affects the performance. This implies that there is an upper-bound for downsampling with only convolution layers while maintaining performance, and our weighted-shrinking operation can be used as an addition to further improve the performance.



(a) Different shrinking methods



(b) Different downsampling methods

Figure 7: Upper: the BLEU scores for different shrinking methods, where "DB" means simply dropping blank frames. Lower: BLEU-AL tendency for different downsampling methods, where "n blocks" represents using n Conv-Transformer blocks in the acoustic encoder.

5.5 Ablation Study

We evaluate the contributions of different modules in RealTranS. Each module is evaluated in four kinds of latency settings: Wait-2-Stride-2, Wait-6-Stride-2, Wait-10-Stride-2, and also Wait-Inf (full sentence translation). The results are shown in Figure 8, where "-CTC PT" means we do not pre-train the encoder with CTC loss and "-BP" indicates we further remove the blank penalty. "-shrink" means removing the weighted-shrinking operation and the semantic encoder, while "-GD" denotes disabling the gradual downsampling by moving the Transformer layers in block 1 & 2 to block 3 (see Fig-

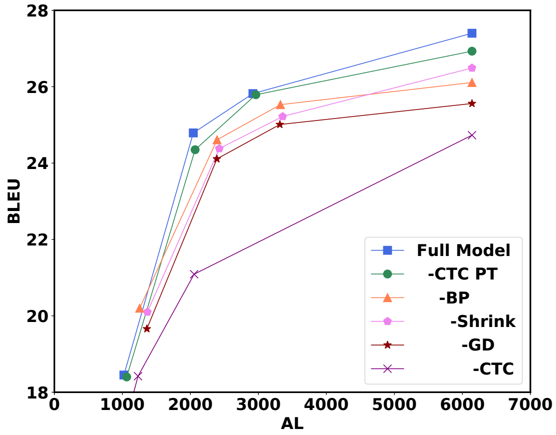


Figure 8: Ablation study for RealTranS. We choose the results of 3 latency settings and full sentence translation for each ablation. “GD” means gradual downsampling.

ure 2) to perform downsampling at the beginning layers of the acoustic encoder. Finally, “-CTC” indicates that CTC objective is removed.

Figure 8 shows that all modules play a role in RealTranS. Specifically, we have the following observations: 1) The CTC module is important for improving translation quality, and it can be further improved by pre-training. 2) The blank penalty is useful in reducing latency while maintaining translation quality. 3) The blank penalty is essential for the shrinking operation since on full sentence translation the shrinking operation degrades the performance without the blank penalty (“-BP” vs “-Shrink”). 4) Gradual downsampling also contributes to the performance, because directly downsampling to a large rate may make it difficult to learn acoustic features.

5.6 Comparison in Full Sentence Translation

Although focusing on SST, RealTranS can also be applied in full sentence ST. For fair comparison, we replace the unidirectional Transformer layers in RealTranS with bidirectional ones and report both case-insensitive and case-sensitive BLEU scores following prior works. Table 4 displays the BLEU scores compared with existing methods (we only compare with end-to-end models trained with the same data for fair comparison) on Augmented LibriSpeech En–Fr and MUST-C En–De dataset. RealTranS yields competitive (En–Fr) or even better (En–De) results, even though most of these prior methods depend on some extra techniques like pre-training decoders or using SpecAugment (Park et al., 2019). This validates the superiority of our proposed architecture.

Dataset	Method	BLEU
En-Fr	Transformer+KD (Liu et al., 2019)	17.02
	TCEN-LSTM (Wang et al., 2020b)	17.05
	Curriculum PT (Wang et al., 2020c)	17.66
	LUT (Dong et al., 2020b)	17.75
	STAST (Liu et al., 2020)	17.81
	COSTT (Dong et al., 2020a)	17.83
	Transformer+AFS (Zhang et al., 2020)	18.56*
	RealTranS (ours)	18.97 18.30*
En-De	Transformer+MAM (Chen et al., 2020)	21.87*
	Transformer+ML (Indurthi et al., 2019)	22.11*
	Transformer+AFS (Zhang et al., 2020)	22.38*
	Fairseq S2T (Wang et al., 2020a)	22.70*
	Espnet ST (Inaguma et al., 2020)	22.91*
	STAST (Liu et al., 2020)	23.06
	RealTranS (ours)	23.53 22.99*

Table 4: Full sentence translation results on Augmented LibriSpeech En–Fr and MUST-C En–De datasets. Results marked with * are case-sensitive BLEU scores, while the others are case-insensitive.

6 Conclusion

This work proposes a new end-to-end model RealTranS and a new strategy Wait-K-Stride-N for SST. RealTranS gradually bridges the modality gap between speech and text, and achieves new state-of-the-art results for SST. Empirical studies have shown the proposed blank penalty for CTC loss helps on the alignment with transcription, which reduces latency while maintaining translation quality. Our weighted-shrinking operation, as well as Wait-K-Stride-N simultaneous strategy, further improves the performance. We also compare RealTranS with other methods for full sentence translation, where RealTranS still exhibits competitive results, showing its superiority.

Acknowledgment

We thank MindSpore, a new deep learning computing framework, for the partial support of this work. Given the superior performance of Huawei Ascend AI Processor and MindSpore framework, our code will be released based on MindSpore at (`https://gitee.com/mindspore/mindspore/tree/master/model_zoo/research/nlp/realtrans`).

Abstract

Pre-trained text encoders such as BERT and its variants have recently achieved state-of-the-art performances on many NLP tasks. While being effective, these pre-training methods typically demand massive computation resources. To accelerate pre-training, ELECTRA trains a discriminator that predicts whether each input token is replaced by a generator. However, this new task, as a binary classification, is less semantically informative. In this study, we present a new text encoder pre-training method that improves ELECTRA based on multi-task learning. Specifically, we train the discriminator to simultaneously detect replaced tokens and select original tokens from candidate sets. We further develop two techniques to effectively combine all pre-training tasks: (1) using attention-based networks for task-specific heads, and (2) sharing bottom layers of the generator and the discriminator. Extensive experiments on GLUE and SQuAD datasets demonstrate both the effectiveness and the efficiency of our proposed method.

1 Introduction

Contextualized representations from pre-trained text encoders have shown great power for improving many NLP tasks (Rajpurkar et al., 2016; Wang et al., 2019b,a; Liu and Lapata, 2019). Most pre-trained encoders, despite their variety, follow BERT (Devlin et al., 2019) and adopt the masked language modeling (MLM) pre-training task which trains the model to recover the identities of a small subset of masked tokens. Although being more effective than conventional left-to-right language model pre-training (Peters et al., 2018; Radford et al., 2018) due to capturing bidirectional information, MLM-based approaches (Liu et al., 2019b; Joshi et al., 2019) can only learn from those masked tokens which are typically just 15% of all tokens in the input sentences.

To address the low sample efficiency issue, ELECTRA (Clark et al., 2020a) proposes a new pre-training task. Specifically, it corrupts a sentence by replacing some tokens with plausible alternatives sampled from a generator and trains a discriminator to predict whether each token in the corrupted sentence is replaced or not. After pre-training ends, it throws away the generator and exports the discriminator for down-stream applications. As the discriminator can learn from all input tokens, ELECTRA is more sample efficient than previous MLM-based methods. However, follow-up studies (Xu et al., 2020; Aroca-Ouellette and Rudzicz, 2020) find this new replaced token detection task, as a binary classification, is often too simple to learn. As a result, the discriminator output representations are insufficiently trained and encode inadequate semantic information.

In this work, we propose a novel text encoder pre-training method **TEAMS** which stands for "Training ELECTRA Augmented with Multi-word Selection". Compared with ELECTRA, our method also consists of a generator and a discriminator but they are equipped with different pre-training tasks. For each masked position in the input sentence, the generator replaces the original token with an alternative token and samples a candidate set that consists of the original token and other K non-original ones. Then, we train the discriminator to simultaneously perform two tasks: (1) a *multi-word selection* task in which the discriminator learns to select the original token from the sampled candidate set, and (2) a *replaced token detection* task similarly defined in ELECTRA. The first task, as a $(K+1)-$way classification on the masked positions, pushes the discriminator to differentiate ground truth tokens from other negative non-original ones. At the same time, the second task, with reduced task complex-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2475–2486

ity, keeps the discriminator to achieve the same sample efficiency as ELECTRA.

To further improve the performance and efficiency of our method, we introduce two techniques. The first one is using attention-based task-specific heads for discriminator multi-task pre-training. Different from previous studies (Liu et al., 2019a; Sun et al., 2020) that pass the last encoder layer outputs to different task heads, our method directly incorporates task-specific attention layers into the discriminator encoder. Such a design offers higher flexibility in capturing task-specific token dependencies in sequence and leads to significant performance boost. The second technique is to share the bottom layers of the generator and the discriminator. This technique reduces the number of parameters, saves computes, and serves as a form of regularization that stabilizes the training and helps the generalization.

Combining above novelties all together, we train our models of various sizes and test their performance on the GLUE natural language understanding benchmark (Wang et al., 2019b) and SQuAD question answering benchmark (Rajpurkar et al., 2016). We show that TEAMS substantially outperforms previous MLM-based methods and ELECTRA, given the same model size and pre-training data. For example, our base-sized model, achieving 84.51 SQuAD 2.0 F1 score, outperforms BERT and ELECTRA by 8.34 and 2.99, respectively. Moreover, TEAMS-Base can outperform ELECTRA-Base++ using a fraction of computes.

Contributions. The major contributions of this paper are summarized as follows: (1) We propose a new text encoder pre-training method TEAMS that simultaneously learns a generator and a discriminator using multi-task learning. (2) We develop two techniques, attention-based task-specific head and partial layer sharing, to further improve TEAMS performance. (3) We conduct extensive experiments to verify the effectiveness of TEAMS on GLUE and SQuAD benchmarks[1].

2 Background

In this section, we first discuss some related studies on pre-training text encoders. Then, we introduce our notations and describe ELECTRA in details.

2.1 Text Encoder Pre-training

Current state-of-the-art natural language processing systems often rely on a text encoder to generate contextualized representations. This text encoder is commonly pre-trained on massive unlabeled corpora using different self-supervised tasks. Peters et al. (2018) and Radford et al. (2018) pre-train either a LSTM or a Transformer (Vaswani et al., 2017) using the standard language modeling task. To further improve pre-trained models, more effective pre-training objectives have been developed, including masked language modeling and next sentence prediction in BERT (Devlin et al., 2019), permutation language modeling in XLNet (Yang et al., 2019), masked span prediction in SpanBERT (Joshi et al., 2019), sentence order prediction in StructBERT (Wang et al., 2020), and more.

Most pre-training methods demand massive amounts of computes, which limits their accessibilities and raises concerns about their environmental costs. To alleviate such issue, Gong et al. (2019) and Yang et al. (2020) propose to accelerate BERT training by progressively stacking a shallow model to a deep model. Gu et al. (2020) extend this idea by growing a low-cost model in different dimensions. Along another line of work, Clark et al. (2020a) propose a new pre-training task, named replaced token detection, that learns a text encoder to distinguish real input tokens from synthetically generated replacements. Compared to BERT-style MLM pre-training in which only 15% of tokens are utilized, ELECTRA can leverage *all tokens* in input sentences and thus achieves better sample efficiency. Following this idea, Xu et al. (2020) propose a new pre-training task based on the multi-choice cloze test with a rejection option, and Clark et al. (2020b) connect ELECTRA with cloze modeling and pre-train the text encoder as an energy-based cloze model. As our method is built upon ELECTRA, we discuss it in more detail below.

2.2 ELECTRA

ELECTRA jointly trains two models, a generator G and a discriminator D. Both models adopt the Transformer architecture as their backbones and map a sentence of n tokens $\mathbf{x} = [x_1, \ldots, x_n]$ to their corresponding contextualized representations $h(\mathbf{x}) = [h(\mathbf{x})_1, \ldots, h(\mathbf{x})_n]$.

The generator G is trained using the masked language modeling (MLM) task. Specifically, given an input sequence $\mathbf{x}$, it first randomly selects a few

---

[1] Code and pre-trained model weights are available at `https://github.com/tensorflow/models/tree/master/official/nlp/projects/teams`.

masked positions and replaces tokens at these positions with a special mask symbol `[MASK]`. We denote this masked sequence as $\mathbf{x}^M$. Then, the generator learns to predict the original identities of those masked-out tokens by minimizing the below MLM loss:

$$\mathcal{L}_{\text{MLM}}(\mathbf{x}; G) = \mathbb{E}\left(\sum_{i:x_i^M=\texttt{[MASK]}} -\log P_G(x_i|\mathbf{x}^M)\right), \tag{1}$$

where $P_G(x_i|\mathbf{x}^M)$ is the probability that G predicts token x_i appears in the masked position i in $\mathbf{x}^M$, and the expectation is taken over the random draw of masked positions. More specifically, the generator calculates $P_G(x_i|\mathbf{x}^M)$ by passing contextualized representations $h_G(\mathbf{x}^M)$ into a softmax layer as follows:

$$P_G(x_i|\mathbf{x}^M) = \frac{\exp(e(x_i)^T h_G(\mathbf{x}^M)_i)}{\sum_{x'_i \in V} \exp(e(x'_i)^T h_G(\mathbf{x}^M)_i)}, \tag{2}$$

where $e(x_i)$ is the embedding of token x_i and V denotes the vocabulary of all tokens. Finally, for each masked position i, the generator samples one token $\hat{x}_i \sim P_G(\cdot|\mathbf{x}^M)$ and replaces the original token x_i with $\hat{x}_i$. We use $\mathbf{x}^R$ to denote this corrupted sentence with replaced tokens.

The discriminator D learns to perform the replaced token detection (RTD) task that requires a model to predict whether each token in $\mathbf{x}^R$ is replaced or not. In particular, ELECTRA adopts a sigmoid layer, on top of the discriminator output contextualized representations $h_D(\mathbf{x}^R)$, to decide the probability that token x_i^R matches the original token x_i as follows:

$$P_D(x_i^R = x_i) = \text{sigmoid}(w^T h_D(\mathbf{x}^R)_i), \tag{3}$$

where w is a learnable parameter. The loss on D is then defined as follows:

$$\mathcal{L}_{\text{RTD}}(\mathbf{x}, \mathbf{x}^R; D) = \mathbb{E}\Big(\sum_{i:x_i^R=x_i} -\log P_D(x_i^R = x_i) + \sum_{i:x_i^R \neq x_i} -\log(1 - P_D(x_i^R = x_i))\Big). \tag{4}$$

Finally, the generator and discriminator are jointly learned based on losses in Eq. (1) and Eq. (4). After pre-training, ELECTRA throws out the generator and keeps only the discriminator for fine-tuning on downstream tasks.

3 The TEAMS Method

In this section, we first introduce a new pre-training task named "multi-word selection". Then, we present our TEAMS method with two techniques for performance improvements.

3.1 Multi-word Selection Task

To train a model on an input sequence $\mathbf{x} = [x_1, \ldots, x_n]$ using the multi-world selection task, we first choose a random set of positions in this sequence, denoted as $\{i_1, \ldots, i_m\}$ where m is an integer between 1 and n. Then, for each chosen position $i_j, j \in \{1, \ldots, m\}$, we replace token x_{i_j} with another token $\hat{x}_{i_j}$ and create a *candidate set* S_{i_j} that includes the original token x_{i_j} and K non-original ones. Following ELECTRA, we use $\mathbf{x}^R$ to denote the corrupted sentence with all tokens in chosen positions replaced. Finally, the model inputs the corrupted sentence and outputs a probability for selecting the original token x_{i_j} from the candidate set S_{i_j} as follows:

$$P(x_{i_j}|\mathbf{x}^R, S_{i_j}) = \frac{\exp(e(x_{i_j})^T h(\mathbf{x}^R)_{i_j})}{\sum_{x'_{i_j} \in S_{i_j}} \exp(e(x'_{i_j})^T h(\mathbf{x}^R)_{i_j})}, \tag{5}$$

where $h(\mathbf{x}^R)_{i_j}$ is the contextualized representation of token $\hat{x}_{i_j}$ from the model outputs.

Figure 1 shows a concrete example wherein a sequence of 6 tokens is given and its 2^{nd}, 4^{th}, and 6^{th} positions are chosen to be masked. Take the 2^{nd} position as an example, the generator replaces the original token x_{i_1}="*famous*" with another token $\hat{x}_{i_1}$="*old*" and generates the candidate set S_{i_1}={"*top*", "*young*", "*french*", "*famous*"} which includes the original token x_{i_1} and $K = 3$ non-original alternatives.

We may view the multi-word selection task as a simplification of masked language modeling and a generalization of replaced token detection. Asking the model to select the correct word from a candidate set rather than from the entire vocabulary, we can save more computes. At the same time, being essentially a $(K + 1)-$way classification problem, the multi-word selection task is more challenging than the replaced token detection task (which is a binary classification problem) and thus pushes the model to learn more semantic representations. We describe how to generate the candidate set and present our entire method below.

3.2 Multi-task Learning in TEAMS

In TEAMS, we jointly train two transformer encoders, one as the generator network G and the other as the discriminator network D. Given a masked sequence $\mathbf{x}^M$, we use the generator G to perform two tasks for each masked position i_j in this sequence. First, similar to ELECTRA, we sample one token $\hat{x}_{i_j} \sim P_G(\cdot|\mathbf{x}^M)$ (c.f. Eq. (2)) and

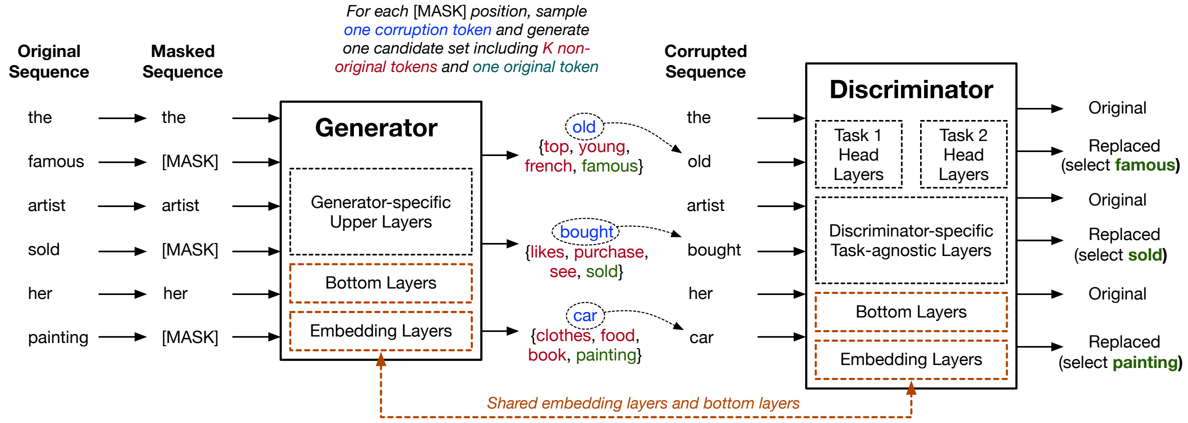

Figure 1: The overview framework of TEAMS. For each masked position, the generator replaces its original token with a new one and outputs a candidate set consisting of the original token and another K possible alternatives. The discriminator inputs the corrupted sentence and learns to (1) predict for every token whether it is replaced or not and (2) select the original token from the candidate set for each masked position.

obtain the corrupted sequence $\mathbf{x}^R$. Second, we draw K non-original tokens $\{x^1_{i_j}, \ldots, x^K_{i_j}\}$ from $P_G(\cdot|\mathbf{x}^M)$ without replacement[2] and construct the candidate set $S_{i_j} = \{x_{i_j}, x^1_{i_j}, \ldots, x^K_{i_j}\}$. Finally, we learn the generator G using the standard masked language modeling task (c.f. Eq. (1)).

On the discriminator side, we train the discriminator network D using two tasks — replaced token detection (RTD) task and multi-word selection (MWS) task. Given a corrupted sentence $\mathbf{x}^R$ of length n, the discriminator will generate two sets of contextualized representations $\{h^{\text{RTD}}_D(\mathbf{x}^R)_i\}|^n_{i=1}$ and $\{h^{\text{MWS}}_D(\mathbf{x}^R)_i\}|^n_{i=1}$, one for each pre-training task. For each position $i \in \{1, \ldots, n\}$, we use $h^{\text{RTD}}_D(\mathbf{x}^R)_i$ to calculate the probability that the token $\mathbf{x}^R_i$ is replaced as follows:

$$P_D(\mathbf{x}^R_i = \mathbf{x}_i) = \text{sigmoid}(w^T h^{\text{RTD}}_D(\mathbf{x}^R)_i), \qquad (6)$$

and optimize the same RTD loss defined in Eq. (4). For each masked position $i_j, j \in \{1, \ldots, m\}$, we obtain the candidate set S_{i_j} from generator outputs and use $h^{\text{MWS}}_D(\mathbf{x}^R)_{i_j}$ to compute the probability of selecting the correct original token x_{i_j} from this candidate set as follows:

$$P_D(x_{i_j}|\mathbf{x}^R, S_{i_j}) = \frac{\exp(e(x_{i_j})^T h^{\text{MWS}}_D(\mathbf{x}^R)_{i_j})}{\sum_{x'_{i_j} \in S_{i_j}} \exp(e(x'_{i_j})^T h^{\text{MWS}}_D(\mathbf{x}^R)_{i_j})}. \qquad (7)$$

As the multi-word selection task is a multi-class classification problem, we define its loss function as follows:

$$\mathcal{L}_{\text{MWS}}(\mathbf{x}, \mathbf{x}^R; D, \mathbb{S}) = \mathbb{E}\left(\sum_{j=1}^{m} -\log P_D(x_{i_j}|\mathbf{x}^R, S_{i_j})\right), \qquad (8)$$

where $\mathbb{S} = \{S_{i_j}\}|^m_{j=1}$ is the collection of candidate sets at all masked positions. Finally, we learn TEAMS by optimizing a combined loss as follows:

$$\min_{G,D} \Big(\mathcal{L}_{\text{MLM}}(\mathbf{x}; G) + \lambda_1 \mathcal{L}_{\text{RTD}}(\mathbf{x}, \mathbf{x}^R; D) + \lambda_2 \mathcal{L}_{\text{MWS}}(\mathbf{x}, \mathbf{x}^R; D, \mathbb{S})\Big), \qquad (9)$$

where λ_1 and λ_2 are two loss balancing hyper-parameters. For the example sequence in Figure 1, the discriminator needs to predict the tokens in 1^{st}, 3^{rd}, 5^{th} positions are not replaced, the tokens in 2^{nd}, 4^{th}, 6^{th} positions are replaced, and select tokens "*famous*", "*sold*", and "*painting*" in 2^{nd}, 4^{th}, 6^{th} positions, respectively.

After pre-training, we keep the discriminator network and fine-tune it for downstream applications[3].

Attention-based Task-specific Heads. One remaining question is how to generate two sets of *task-specific* representations on the discriminator side. Previous studies (Liu et al., 2019a; Sun et al., 2020; Aroca-Ouellette and Rudzicz, 2020) achieve this goal by adding task-specific layers on top of each individual token, as shown in Figure 2 (Left). However, this approach does not model token dependencies within the task-specific layers.

In this work, we propose to use attention-based task-specific heads to capture global dependen-

---

[2] More discussions on other possible negative sampling strategies are presented in experiment section.

[3] Empirically, we find that using the contextualized representations for the MWS task (i.e., $\{h^{\text{MWS}}_D(\mathbf{x}^R)_i\}|^n_{i=1}$) can achieve better fine-tuning performance.

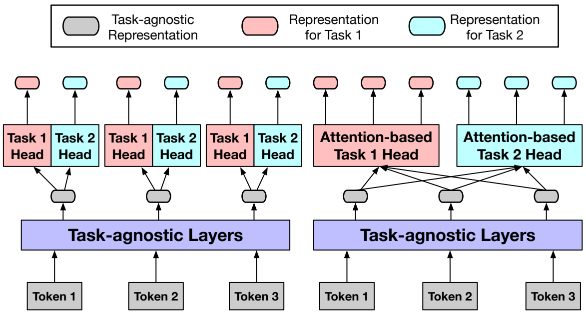

Figure 2: Architectures for transforming task-agnostic representations to task-specific representations. (Left) Adding task-specific heads on each token separately. (Right) Using task-specific attention heads capture all token information holistically.

cies in sequences. Particularly, we design this attention head to be one transformer layer (i.e., a self-attention block followed by a fully connected network with one hidden layer). Since our discriminator also uses a transformer model to obtain each token's task-agnostic representation, we can merge one task head into the discriminator backbone. From this perspective, we can generate different sets of *task-specific* representations as follows. First, we input the sequence to a transformer with L layers and retrieve the final layer output representations for one task. Then, we feed the output of an intermediate layer (*e.g.*, the $(L-1)^{th}$ layer) into another transformer layer to obtain token representations for the second task.

Partial Layer Sharing. ELECTRA has shown that tying the embedding layers of the generator and the discriminator can help improve the pre-training effectiveness. Our study confirms this observation and finds that sharing some transformer layers of the generator and discriminator and can further boost the model performance. More specifically, we design the generator to have the same "width" (i.e., hidden size, intermediate size and number of heads) as the discriminator and share the bottom half of all transformer layers between the generator and the discriminator.

4 Experiments

4.1 Experiment Setups

Pre-training Datasets. We use two datasets for model pre-training: (1) **WikiBooks**, which consists 3.3 Billion tokens from English Wikipedia and BooksCorpus (Zhu et al., 2015). This is the same dataset used in BERT (Devlin et al., 2019). (2) **WikiBooks++**, which extends WikiBooks dataset to 33 Billion tokens by including data from Gigaword (Parker et al., 2011), ClueWeb (Callan et al., 2009), and CommonCrawl (Crawl, 2019). The same dataset is used in XLNet (Yang et al., 2019) and ELECTRA (Clark et al., 2020a).

Evaluation Datasets and Metrics. We evaluate all pre-trained models on the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019b) and Stanford Question Answering (SQuAD) dataset (Rajpurkar et al., 2016). GLUE benchmark includes various tasks formatted as either single sentence classification (SST, CoLA) or sentence pair classification (*e.g.*, RTE, MNLI, QNLI, MRPC, QQP, STS). More details of each task are available in the Appendix Section A. SQuAD dataset requires models to select a text span from a given passage that answers a question. In SQuAD v1.1, the answers can always be located in the passage, while SQuAD v2.0 contains some questions unanswerable by the given passage.

We compute Spearman correlation for STS, Matthews correlation for CoLA, accuracy for all other GLUE tasks, and report the GLUE score as the average of all 8 tasks. For SQuAD, we use the standard evaluation metrics of Exact Match (EM) and F1 scores. Since different random seeds may significantly affect fine-tuned model performances, we report the median of 15 fine-tuning runs from the same pre-trained model checkpoint for each result. Unless stated otherwise, results are on the GLUE and SQuAD development sets.

Model Hyper-parameters. We follow and evaluate TEAMS with different model sizes. For *small-sized* model, we set model hidden dimension to 256 and reduce token embedding dimension to 128. The transformer in the discriminator network has 12 layers and each layer consists of 4 attention heads with the intermediate layer size 1024. For *base-sized* model, we adopt the commonly used BERT-base configuration with 768 hidden dimension, 12 layers with 12 attention heads, and 3072 intermediate layer size. For *large-sized* model, we use BERT-large configuration with 1024 hidden dimension, 24 layers with 16 attention heads, and 4096 intermediate layer size. Following (Clark et al., 2020a), we design the generator network size to be 1/2 of the discriminator network size for models of all sizes. For TEAMS, we set the loss balancing parameter $\lambda_1 = 5$, $\lambda_2 = 2$ (c.f., Eq. (9)), and the number of sampled non-original tokens $K = 5$ (c.f., Section 3.1).

Table 1: Comparison results of TEAMS and baseline methods on GLUE and SQuAD datasets. All results are the medians of 15 fine-tuning runs with different initial random seeds. As ELECTRA original paper only releases the public checkpoints for Small++, Base++, and Large models, we can only report results for these three variants.

During pre-training, we set the batch size to be 256 and the input sequence length to be 512 for both small-sized and base-sized models. We update small-sized models for 500K steps and base-sized models for 1M steps on the WikiBooks dataset. Moreover, we test the performance of each model when it is pre-trained for longer time with larger batch size using the WikiBooks++ dataset. We use the suffix "*small*++" to denote a small-sized model pre-trained for 2M steps with batch size 256, and the suffix "*base*++" to denote a base-sized model pre-trained for 1M steps with batch size 1024. Finally, for large-sized models, we use batch size 2048 and pre-train the model for 1.76M steps. All large-sized models and models with suffix "++" are trained using the WikiBooks++ dataset. More pre-training and fine-tuning details are included in the Appendix Section B and C.

Model Implementations. For fair comparison, we implement all compared methods in TensorFlow 2 and evaluate their performances using the official pipeline in TensorFlow Model Garden[4]. In addition to our own implementations, we also report the performance of ELECTRA publicly released checkpoints[5]. All models are trained on TPU v3.

4.2 Experiment Results

We validate the advantages of our proposed TEAMS method by comparing it with BERT (Devlin et al., 2019) and ELECTRA (Clark et al., 2020a). Table 1 shows the comparison results on GLUE and SQuAD datasets. We find that TEAMS can consistently outperform baseline models of the same size. For example, compared to ELECTRA-Base, our TEAMS-Base improves SQuAD 2.0 performance from 78.59 to 81.59 and from 81.52 to 84.51 in terms of EM and F1 score, respectively.

To further verify the performance improvements do not come from consuming more computations, we draw the learning curves of TEAMS-Small/Base and ELECTRA-Small/Base in Figure 3. We observe that for both small-sized and base-sized models, our method can consistently outperform ELECTRA when trained for the some amount of time. Moreover, on SQuAD datasets, TEAMS-Base can even outperform the ELECTRA-Base++ model that requires much more computation.

4.3 Ablation Studies

We continue to evaluate the design of each component within TEAMS and test its sensitivity to some critical hyper-parameters.

Effectiveness of Pre-training Tasks. We report the results of small-sized models learned using dif-

---

Table 2: Effectiveness of multi-task pre-training for *small*++ models. “MLM”, “RTD”, and “MWS” stand for “masked language modeling”, “replaced token detection”, and “multi-word selection”, respectively.

ferent pre-training tasks in Table 2. First, we can see that the model trained with multi-word selection (MWS) task can outperform the one learned using masked language modeling (MLM) task. Second, on SQuAD datasets, we find that pre-training on only 15% of masked tokens using MWS task is comparable with pre-training on all tokens using replaced token detection (RTD) task. These observations demonstrate the effectiveness of our proposed MWS task. Finally, we show that a text encoder pre-trained using both MWS and RTD tasks can outperform those learned using only single task.

Task-specific Layer Designs. In TEAMS, we pre-train the discriminator network using multi-task learning and introduce the attention-based task-specific heads. To verify the effectiveness of these attention-based task-specific heads, we train another model that uses the traditional feed forward network (FFN) as the task-specific head. Table 3 shows the results. We can see that our model achieves better performances because the attention-based heads can effectively model the token dependencies in sequences.

We continue to study where to add these task-specific heads. Currently, given a transformer with 12 layers, we treat its last layer output for one task and feed the 11^{th} layer output to a separate transformer layer to obtain representations for the second task[6]. An alternative design is to add two separate transformer layers (as two task-specific heads) directly on top of the last layer (i.e., the 12^{th} layer). As shown in Table 3, we find the latter design can slightly improve the model performance on SQuAD datasets but leads to a larger discriminator network with effectively 13 transformer layers and thus requires more computation during both pre-training and fine-tuning stages.

Method	**GLUE**	**SQuAD 1.1**		**SQuAD 2.0**

ELECTRA-Small++	81.71	77.45	85.32	70.07	72.91
TEAMS-Small++	81.99	78.94	86.65	72.11	75.11
Use FFN task heads	81.49	78.18	86.35	72.00	74.90
Add task head on 12^{th} layer	81.29	79.08	86.66	72.47	75.31
Use RTD task head outputs	81.83	77.72	85.80	69.56	72.57

Table 3: Analysis of task-specific layers and exported representations for *small*++ models. Please refer to Section 4.3 for detailed descriptions of each method.

Finally, as our discriminator network will output two sets of contextualized representations, one for MWS task and the other for RTD task, we need to decide which set of representations to use in the fine-tuning stage. Empirically, we find the representations for MWS task has better fine-tuning performance than the ones for RTD task, especially on the SQuAD datasets (c.f. Table 3). This observation also confirms the effectiveness of our proposed MWS task as it produces representations capturing more fine-grained semantic information compared to the RTD task.

Partial Layer Sharing. Table 4 reports the results of our models with different levels of parameter sharing between the generator and the discriminator. First, we can see that tying all generator layers with discriminator layers results in significant performance drops, as such a binding restricts the model representation power. Second, we find that compared to no weight sharing, our design of partial layer tying can improve the model performance. One possible explanation is that such layer tying serves as an implicit form of regularization and forces the shared transformer layers to capture useful information for both generator pre-training task (i.e., MLM) and discriminator pre-training tasks (i.e., RTD and MWS).

---

[6] We can interpret the first 11 layers as *task-agnostic* layers and view the 12^{th} layer and the newly introduced separate layers as two *task-specific* heads.

Method	GLUE	SQuAD 1.1		SQuAD 2.0	
		EM	F1	EM	F1
ELECTRA-Small++	81.71	77.45	85.32	70.07	72.91
TEAMS-Small++	**81.99**	**78.94**	**86.65**	72.11	75.11
Full Tie	80.57	77.75	85.76	69.93	72.82
No Tie	81.65	78.42	86.32	**72.73**	**75.73**

No Tie	86.63	85.51	91.98	80.72	83.60

Table 4: Effect of sharing generator and discriminator bottom layers for *small*++ and *base*++ models. "Full Tie" and "No Tie" stand for tying all or none of generator layers with the discriminator, respectively.

Sampling Strategy and Negative Sample Size. To use the multi-world selection task for pre-training, we need to first obtain a set of negative samples (i.e., non-original tokens) for each masked position in a sequence. In this study, we test two strategies to generate K negative samples for each masked position. Given the generator output probability distribution for a target position, we can either sample from this distribution K times without replacement or directly select K non-original tokens with the highest probabilities. We denote these two approaches as "Sampled" and "Hardest", respectively, and report the results in Figure 5. First, we can see that performing repeated sampling is a better strategy than always selecting those hardest samples. One possible reason is that the "Sampled" strategy can generate more diverse negative samples and thus helps model to generalize[7]. Second, we notice that increasing K over 5 will somewhat hurt the model performance. One reason is that a larger K causes a higher probability of including false negative examples. Finally, we find that for a wide range of K from 3 to 50, our method can outperform ELECTRA, which further demonstrates the effectiveness of multi-word selection task.

Generator Size. We test how the size of generator affects the model performance by varying the number of transformer layers in the generator. For all tested models, we tie the bottom half of generator with the discriminator. Figure 4 reports the results. We find that the performance first increases as the generator size increases until it reaches about half of the discriminator size and then starts to decrease when we further increase the generator size. The same results also hold for base-sized models.

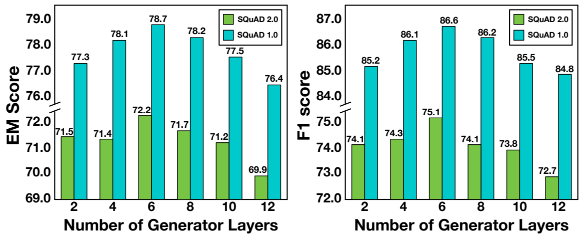

Figure 4: Analysis of the number of generator layers in TEAMS-small++ models.

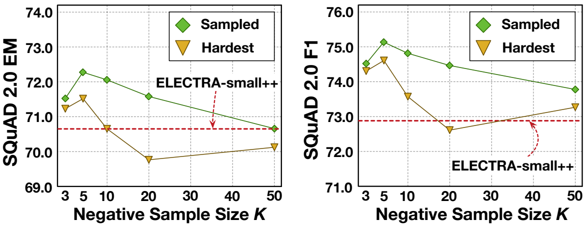

Figure 5: Analysis of negative sampling strategies and negative sample sizes for *small*++ models. Based on the generator output distribution, we either perform weighted sampling without replacement K times ("Sampled") or select K most likely non-original tokens ("Hardest") for each masked position.

5 Related Work

Besides the general language pre-training work we discussed in Section 2.1, this study is particularly related to methods that apply multi-task learning (Caruana, 1997; Ruder, 2017; Shen et al., 2018) to language representation learning. An early study (Liu et al., 2019a) proposes to simultaneously fine-tune a pre-trained BERT model to perform multiple natural language understanding tasks and achieves promising results on the GLUE dataset. Sun et al. (2020) continue this line of work and propose to push the multi-task learning to the model pre-training stage. Specifically, they use a continual multi-task learning framework that incrementally builds and inserts seven auxiliary tasks (*e.g.*, masked entity prediction, sentence distance prediction, *etc.*.) to the text encoder. More recently, Aroca-Ouellette and Rudzicz (2020) extend this idea to incorporate fourteen auxiliary tasks and identify six tasks are particularly useful. While achieving inspiring performance, these studies all assume the MLM pre-training task must present and just combine MLM with additional tasks. In this paper, we relax this assumption and combine our new multi-word selection task with the replace token detection task for effective pre-training.

---

[7] A similar result is also witnessed in (Shen et al., 2019) and thus we adopt the "Sampled" approach in this study.

6 Conclusions and Future Work

This work presents a new text encoder pre-training method that simultaneously learns a generator and a discriminator using multi-task learning. We propose a new pre-training task, multi-word selection, and combine it with previous pre-training tasks for efficient encoder pre-training. We also develop two techniques, attention-based task-specific heads and partial layer sharing, to further improve pre-training effectiveness. Extensive experiments on GLUE and SQuAD datasets demonstrate our TEAMS method can consistently outperform previous state-of-the-arts methods. In the future, we plan to explore how other auxiliary pre-training tasks can be integrated into our framework. Moreover, we consider extending our pre-training method to text encoders with other architectures such as those based on dynamic convolution and sparse attention. Finally, being orthogonal to this study, distillation techniques could be applied to further compress our pre-trained encoders into smaller models for faster inference speeds.

Broader Impact Statement

Recent years have witnessed the great success of pre-trained text encoders in lots of NLP applications such as text classification, question answering, text retrieval, dialogue system, etc. This paper presents a new pre-training method TEAMS that learns a text encoder with better performance using lower training cost. Therefore, on the positive side, our work has the potentials to benefit all downstream applications that leverage a pre-trained text encoder, especially those applications with limited computation resources. On the negative side, TEAMS, as one specific pre-training method, could still face the generic issues for all language pre-training work. For example, the pre-training large corpora, collected from the internet, may include abusive language usages and fail to capture the cultures that have smaller linguistic footprints online.

A GLUE Details

The original GLUE benchmark (Wang et al., 2019b) contains 9 natural language understanding datasets. We describe them below:

- **MNLI:** The Multi-genre Natural Language Inference Corpus (Williams et al., 2018) contains 393K training sentence pairs with textual entailment annotations. Given a premise sentence and a hypothesis sentence, a model needs to predict whether the premise entails the hypothesis, contradicts the hypothesis, or neither.

- **RTE:** Recognizing Textual Entailment (Giampiccolo et al., 2007) dataset is similar to MNLI and contains 2.5K sentence pairs with binary entailment annotations (entailment or contradiction).

- **QNLI:** Question Natural Language Inference dataset is a binary sentence pair classification dataset constructed from SQuAD (Rajpurkar et al., 2016). It contains 108K training sentence pairs and requires a model to predict whether a context sentence contains the answer to a question sentence.

- **CoLA:** Corpus of Linguistic Acceptability (Warstadt et al., 2018). This dataset includes 8.5K training sentences annotated with whether it is a grammatical English sentence.

- **SST:** Stanford Sentiment Treebank (Socher et al., 2013) dataset contains 67K sentences from movie reviews and their corresponding binary sentiment annotations.

- **MRPC:** Microsoft Research Paraphrase Corpus (Dolan and Brockett, 2005) includes 3.7K sentence pairs from online news sources. The task is to predict whether two sentences are semantically equivalent or not.

- **STS:** Semantic Textual Similarity (Cer et al., 2017) benchmark contains 5.8K training sentence pairs. The task is to predict the similarity score of two sentences from 1 to 5.

- **QQP:** Quora Question Pairs (Iyer et al., 2017) dataset includes 364K question pairs sampled from the community question-answering website Quora. Models are trained to predict whether a pair of questions are semantically equivalent.

- **WNLI:** Winograd NLI (Levesque et al., 2011) is a small natural language inference dataset. However, as GLUE official website[8] indicates there are some issues during its construction process, we follow previous studies (Clark et al., 2020a; Jiang et al., 2020) and exclude this dataset for fair comparisons.

B Pre-training Details

For the pre-training architecture configurations, we mostly use the same hyper-parameters as BERT and ELECTRA. To generate masked positions, we follow BERT and duplicate training data 40 times so each sequence is masked in 40 different ways. We find this static masking strategy performs similar to the dynamic masking strategy in ELECTRA, while being easier to implement and has less computation overhead. Besides, we notice a mask percentage of 15 works well for all models and thus do not increase it to 25 for large-size models as suggested in ELECTRA. We set λ_1 and λ_2, the loss balancing parameters to 5 and 2, respectively, to ensure different loss terms are of the same scale. For small-size and base-size models, we search for the learning rate out of {1e-4, 2e-4, 3e-4, 5e-4}, batch size from {128, 256, 512, 1024}, and training steps from {500K, 1M, 1.5M, 2M}. For large-size models, we search for the learning rate out of {1e-4, 2e-4, 3e-4, 5e-4} and batch size from {1024, 2048}. Also, we select the generator size out of {1/4, 1/3, 1/2} in early experiments. The best configurations are reported in the main text and we perform no other hyper-parameter tuning. The full set of hyper-parameters are listed in Table 5.

C Fine-tuning Details

For fair comparisons, we fine-tune all pre-trained checkpoints using the official pipeline in TensorFlow Model Garden[9] and report the median of 15 fine-tuning runs. We do not include layer-wise learning-rate decay. We search for the learning rate from {1e-5, 3e-5, 5e-5, 8e-5, 1e-4}, batch size from {32, 48}, and training epoch from {2, 3, 5}. For GLUE tasks, best evaluation scores during fine-tuning are reported. For SQuAD, scores at the end of fine-tuning are reported. The full set of hyper-parameters are listed in Table 6.

Abstract

The lack of reliable automatic evaluation metrics is a major impediment to the development of open-domain dialogue systems. Various reference-based metrics have been proposed to calculate a score between a predicted response and a small set of references. However, these metrics show unsatisfactory correlations with human judgments. For a reference-based metric, its reliability mainly depends on two factors: its ability to measure the similarity between the predicted response and the reference response, as well as the reliability of the given reference set. Yet, there are few discussions on the latter. Our work attempts to fill this vacancy. We first clarify an assumption on reference-based metrics that, if more high-quality references are added into the reference set, the reliability of the metric will increase. Next, we present **REAM♯**: an enhancement approach to **R**eference-based **E**v**A**luation **M**etrics[1] for open-domain dialogue systems. A prediction model is designed to estimate the reliability of the given reference set. We show how its predicted results can be helpful to augment the reference set, and thus improve the reliability of the metric. Experiments validate both the effectiveness of our prediction model and that the reliability of reference-based metrics improves with the augmented reference sets.

1 Introduction

The lack of reliable automatic evaluation metrics is a major impediment to the development of open-domain dialogue systems (Li and Jurafsky, 2016; Gao et al., 2019; Li et al., 2020a). The underlying difficulty in evaluation lies in the diversity of the possible outcomings. Existing evaluation metrics for open-domain dialogue systems can be roughly divided into reference-based and reference-free metrics. Reference-based metrics usually measure how similar a generated response is to the reference responses. Reference-free metrics, on the other hand, measure the quality of a response without any reference and usually focus on specific aspects of the responses. For example, much work often computes the perplexity of a generated response as a measure of fluency (Li et al., 2020b), and adopts Dist-1/2 (Li et al., 2016b) to measure the diversity of the response. In this work, we focus on reference-based metrics.

BLEU (Papineni et al., 2002), originally for machine translation, is now a popular reference-based metric to evaluate open-domain dialog systems automatically. However, it has been shown that BLEU and other word-overlap metrics such as METEOR (Banerjee and Lavie, 2005) and ROUGE (Lin, 2004), rely on surface-form similarities only without considering the semantic diversity, thus fail to correlate well with human judgements (Liu et al., 2016). Instead, embedding-based metrics are adopted to consider the semantic meaning of a word defined by a distributed representation. For example, Zhang et al. (2020) introduce an embedding-based metric BERTScore that computes the similarity between the generated response and reference responses using contextual embeddings obtained from BERT (Devlin et al., 2019).

Intuitively, the reliability of a referenced-based metric depends on two factors: (1) the ability of the metric to measure the similarity between the generated response and the reference response and (2) the reliability of the reference set for evaluating each generated response. As can be seen from above, most current work falls into improving the former factor, while few considers the latter. However, without a high-quality reference set, the results obtained by all these metrics will have a poor correlation with human judgments.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2487–2500
August 1–6, 2021.

Unlike most previous studies that propose new evaluation metrics, the focus of our study is on improving the reliability of the reference set. We first clarify an assumption on reference-based metrics that, if more high-quality responses are added into the reference set, the correlation of reference-based metrics with human judgments will increase. We perform experiments to demonstrate that the standard BLEU (Papineni et al., 2002) does not hold this assumption, but two existing metrics can. One is a modified BLEU metric (Freitag et al., 2020) that compares the generated response with each reference response within the set using single-reference BLEU. We refer this modified BLEU as BLEU*. The other is the BERTScore (Zhang et al., 2020), which can also be used to evaluate responses with multiple references.

In this work, we propose **REAM♯**: an enhancement approach to **R**eference-based **E**v**A**luation **M**etrics for open-domain dialogue systems. Our approach, which can enhance a reference-based metric that satisfies our assumption (such as BLEU* and BERTScore), consists of two parts: (1) reliability prediction and (2) high-quality references augmentation. In the first part, we devise a reliability prediction model to estimate the reliability of the reference set. Given a query and its reference set, the model will predict a reliability score to reflect how reliable a metric is used to evaluate the results of the query using the given reference set. In the second part, we aim to augment high-quality references with the help of the reliability prediction model. We introduce two ways to handle reference candidates with different qualities. If the acquired reference candidates are considered reliable, we can adopt automatic annotation. If we are not certain about the relevance of the reference candidates, human annotators are needed for an interactive annotation. Experimental results show that our proposed approach can effectively enhance the reliability of the reference set and improve the correlation of the reference-based metrics BLEU* and BERTScore.

The rest of this paper is organized as follows. In Section 2, we introduce our assumption on the reference-based metrics, and conduct a series of preliminary experiments to validate this assumption on existing metrics. We also provides details about data collection and metric evaluation in this section. Section 3 describes our reliability prediction model and Section 4 presents how to augment high-quality references with the help of the proposed reliability prediction model. Section 5 shows our experimental results about the proposed reliability prediction model as well as different strategies to augment the reference set. Section 6 describes related work. Finally, we conclude our work and discuss some future work in Section 7.

2 Research Questions and Settings

We first make an assumption on reference-based metrics for open-domain dialog system that if more high-quality reference responses are added to the reference set, a reference-based metric will show a higher correlation with human judgments. We want to draw such an assumption due to two considerations. First, by considering the nature of open-domain dialog, a query is possible to be relevant to multiple diverse responses. Including more relevant responses in the reference set can naturally help alleviate the assessment difficulty associated with linguistic variation. Second, if a low-quality response, e.g. a general response "I don't know" is added to the reference set, the reference-based metric will assign a very high score for the same low-quality predicted response, resulting in a low correlation. Therefore, only by ensuring that the responses in the reference set are of high-quality can we avoid the metric assigning high scores to low-quality responses.

We validate this assumption on three existing metrics: the original multi-reference BLEU (Papineni et al., 2002), BLEU* (Freitag et al., 2020) and BERTScore (Zhang et al., 2020). The original BLEU uses a modified form of precision to compare a generated response against multiple reference responses. For BLEU* and BERTScore, the multi-reference score of a response y can be computed as:

$$score(y, R) = \max_{r \in R} d(y, r) \tag{1}$$

where d is the given metric, $R = \{r_1, r_2, \cdots, r_n\}$ is the given reference set.

We examine the assumption by answering the following questions:

1. *Will the correlation of the reference-based metric improve when more high-quality responses are added to the reference set?*
2. *How will the low-quality responses included in the reference set affect the correlation of the reference-based metric?*

Raw Dataset	
# Training Samples	4,000
# Validation Samples	500
# Test Samples	500
Each Sample	
# Model Responses	14
# Reference Responses	≤ 200

Table 1: Our dataset statistics. Each sample is in the form (query, model responses, reference responses).

Before presenting the details of the preliminary experiments, we first describe the data collection used in the experiments and how we estimate the reliability of a metric.

2.1 Data Collection and Metric Evaluation

To evaluate the correlation of reference-based metrics with human judgments, we collect a dataset as follows. We first crawled 5,000 queries from some Chinese social websites and the largest reference set for the obtained queries has 200 responses. Then, we generated 14 responses obtained from several widely used response generation models (described in Appendix A). We asked 5 annotators to assign each generated response with a score ranging from 1 to 5 respectively, and the final score of each response was obtained by averaging the five scores. Table 1 shows the data statistics. See Appendix A for a detailed description of our dataset.

To evaluate the performance of a metric, we leverage the Pearson Correlation. Given a sample consisting of a query $\boldsymbol{q}$, 14 generated responses $\boldsymbol{\mathcal{Y}} = \{\boldsymbol{y}_1, \cdots, \boldsymbol{y}_{\mathbf{14}}\}$ with their human annotated scores $\hat{\boldsymbol{S}} = \{\hat{\boldsymbol{s}}_1, \cdots, \hat{\boldsymbol{s}}_{14}\}$ and a set of reference responses $\boldsymbol{\mathcal{R}} = \{\boldsymbol{r}_1, \cdots, \boldsymbol{r}_n\}$ ($n \leq 200$), we first score each model response $\boldsymbol{y} \in \boldsymbol{\mathcal{Y}}$ with a certain metric, yielding a sequence of automatic evaluated scores $\boldsymbol{S} = \{s_1, \cdots, s_{14}\}$. With the automatic evaluated scores $\boldsymbol{S}$ and human annotated scores $\hat{\boldsymbol{S}}$ for the 14 generated responses, we can obtain the reliability score c for each sample using the Pearson Correlation:

$$c = \mathrm{Pearson}(\boldsymbol{S}, \hat{\boldsymbol{S}}). \tag{2}$$

2.2 Preliminary Experiments

Next, we conduct our preliminary experiments using the 500 samples in the test set and present our empirical observations regarding the two questions in beginning of Section 2. In the experiments in this section, the correlation of a certain metric is obtained by averaging the reliability scores over all 500 samples.

First, we would like to see how it affects the correlation of the metrics when high-quality responses are continuously added to the reference set. To ensure that each added reference response is of high quality, we also have human annotators assign a quality score to each crawled reference response, and then randomly select 10 high-quality reference responses (quality score over 4) for each sample in the test set. We sequentially add the 10 high-quality reference responses to the reference set initialized with an empty set. Each time a new reference response is added to the set, we calculate a reliability score of a certain metric using the updated set. Figure 1 shows the evaluation results of the original BLEU, BLEU* and BERTScore. Noticeably, the correlation of the original BLEU does not improve as the number of high-quality sentences increases. The reason may be that the original BLEU is defined at the corpus-level and the n-gram precisions are sums over all corpus sentences, which means the newly added reference will cause the value to fluctuate. We, however, find that BLEU* and BERTScore are consistent with our assumption that the correlation of the metric improves as the number of high-quality responses in the set increases. Therefore, not all metrics meet our assumption, and we use BLEU* and the BERTScore for our following experiments.

Second, we test how low-quality responses would affect the correlation of the metric by adding noise into the reference set. In the noisy reference set, the first 5 responses in the reference set are added with the same high-quality responses as above, while the later 5 added responses are replaced with negative samples which are responses sampled from other queries. As shown in Figure 1, "BLEU*-noisy" and "BERTScore-noisy" denote the results of BLEU* and BERTScore using the noisy reference sets, respectively. As the number of negative samples in the set increases, the performance of the metrics starts to degrade. This further confirms our assumption that only adding more high-quality responses to the reference set will help the metric.

Based on the above analysis, we can see that for reference-based metrics satisfying our assumption, we can enhance its reliability by augmenting high-quality references to calculate the metric. Next,

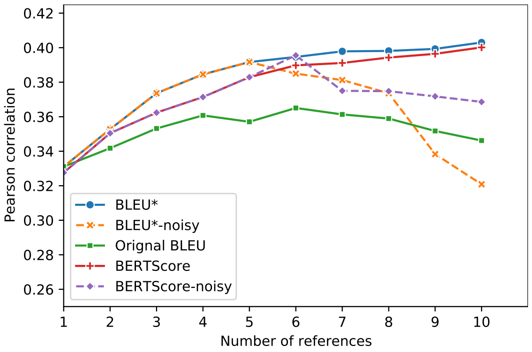

Figure 1: Pearson correlations of BLEU, BLEU* and BERTScore with human judgements obtained using different numbers of reference responses.

a key question arises, how can we augment high-quality references? In the following, we propose a reliability prediction model to estimate the reliability of the reference set (Section 3) and provide effective approaches to augment high-quality references with the help of the reliability prediction model (Section 4).

3 The Reliability Prediction Model

In this section, we aim to estimate the reliability of a metric, when we use it to compute a performance score of an output response based on a given gold response set. We formulate this task as a regression problem. Formally, given a query sentence $\boldsymbol{q} = \{q_1, \dots, q_M\}$ of length M, and a reference set $\mathcal{R} = \{\boldsymbol{r}_i\}_{i=1}^{N}$ with N gold responses of the query, our goal is to learn a function $\boldsymbol{f} : (\boldsymbol{q}, \mathcal{R}) \rightarrow c$ that predicts a reliability score c that represents how reliable a metric is used to evaluate results of the input query using this reference set. In this work, we consider using Pearson correlation (c) in Eq. 2 between the human evaluation results and the metric scores from the given $\mathcal{R}$ as the reliability score of each $(\boldsymbol{q}, \mathcal{R})$. We introduce the reliability prediction model in this section, and discuss efficient methods to augment high-quality responses based on the trained prediction model in the next section.

Our learning framework is shown in Figure 2, which contains two parts. We first design a prediction model to predict a reliability score for each $(\boldsymbol{q}, \mathcal{R})$. Then, we construct negative samples and use contrastive learning to train the proposed prediction model.

3.1 Model Structure

Input Representation For a query $\boldsymbol{q}$ and each response $\boldsymbol{r}$ in the reference response set $\mathcal{R}$, we first concatenate them into one sequence. Then we can obtain N query-response pairs. We leverage BERT (Devlin et al., 2019) that learns contextualized representations of the query-response pairs:

$$[\boldsymbol{v}_c, \boldsymbol{v}_{q_1}, \cdots, \boldsymbol{v}_{r_1}, \cdots, \boldsymbol{v}_{r_m}] = \text{BERT}([\boldsymbol{q}, \boldsymbol{r}]) \quad (3)$$

where $\boldsymbol{v}_c$ is the representation for the special token [CLS] in the BERT and we use its contextualized representation for each query-response pair. Then, we get N query-response representations.

Graph Encoder: In order to transform the dialogue context features into higher-level features that consider the intrinsic variance between reference responses in the reference set, we represent all query-response pairs in a fully-connected graph and each query-response pair is a node in the graph. Then we adopt a graph attention layer (Velickovic et al., 2018) to obtain a better representation of each query-response pair:

$$[\hat{\boldsymbol{v}}_{c_1}, \dots, \hat{\boldsymbol{v}}_{c_n}] = \text{GAT}([\boldsymbol{v}_{c_1}, \dots, \boldsymbol{v}_{c_n}]). \quad (4)$$

The final representation $\boldsymbol{v}_g$ of the graph is computed using the max-pooling strategy.

Reliability Score Prediction: The reliability score is computed using a single-layer feedforward network coupled with a tanh activation function:

$$f(\boldsymbol{q}, \mathcal{R}) = \tanh(\mathbf{W} \cdot \boldsymbol{v}_g + \mathbf{b}) \quad (5)$$

where $\mathbf{W}$ and $\mathbf{b}$ are trainable parameters. The model is trained to minimize the squared error between the model prediction and the gold correlation coefficient c with L2-regularization:

$$\mathcal{L}_r = (f(\boldsymbol{q}, \mathcal{R}) - c)^2 + \gamma \|\theta\|_2 \quad (6)$$

where γ is a hyper-parameter and θ denotes the parameters of the model.

3.2 Data Augmentation

To address the problem of limited data, we adopt the data augmentation method to improve the generalization of our models. Our input sample consists of a query $\boldsymbol{q}$ and a set of reference responses $\mathcal{R}$. We can expand the training data by using different combinations of reference responses, generating more different reference sets for each query. Since the number of all combinations is huge, we randomly sample some various combinations for each query. Given a set of reference responses $\boldsymbol{\mathcal{R}} = \{\boldsymbol{r}_1, \cdots, \boldsymbol{r}_n\}$ of n elements ($n \leq 200$), the set of k-combinations are denoted as $\boldsymbol{\mathcal{C}}_n^k$, where

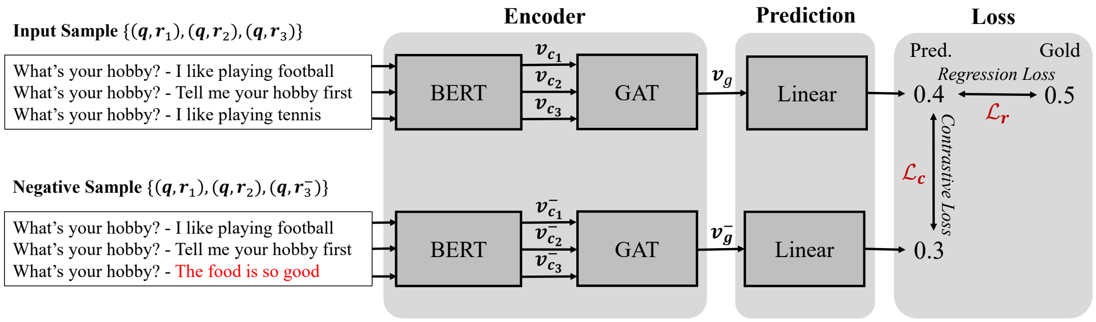

Figure 2: Our proposed prediction model. For each training sample $(\boldsymbol{q}, \{\boldsymbol{r}\})$, we construct negative samples $(\boldsymbol{q}, \{\boldsymbol{r}\}^-)$ according to our assumption and compute the contrastive loss. The model is trained with the combination of regression loss and contrastive loss.

each combination has k different elements. In our work, we use $k \in \{3, 5, 7, 10\}$ and randomly sample 25 different combinations from each set $\mathcal{C}_n^k$ ($k \in \{3, 5, 7, 10\}$). We then expand the validation set in the same way.

To evaluate the generalization performance of the model, the test set should be used not only to verify the effectiveness of the model on samples with $k \leq 10$, but also to test the performance of the model on samples with $k > 10$. Therefore, we use $k \in \{3, 5, 10, 20, 30, 40\}$ to augment the test set. For each set $\mathcal{C}_n^k$ ($k \in \{3, 5, 10, 20, 30, 40\}$), we only randomly sample one combination. Finally, applying data augmentation as described above gives us a total of 400,000/4,000/3,000 augmented training/validation/test samples.

3.3 Contrastive Learning

Optimizing the simple regression objective above with the augmented training samples may not yield a robust performance. To make the model capable to capture the differences between different reference set for the same query, we construct multiple negative samples for each training sample $(\boldsymbol{q}, \{\boldsymbol{r}\})$, and use contrastive learning to train the prediction model. Given a training sample $(\boldsymbol{q}, \{\boldsymbol{r}\})$ we design three kinds of negative samples $(\boldsymbol{q}, \{\boldsymbol{r}\}^-)$:

- Remove one response r from the existing reference set $\{\boldsymbol{r}\}$. This is based on the understanding in Section 2 that a set of gold responses generally does not yield a higher correlation than a super set of it. We note that all samples with deteriorated correlation here, are treated as negative samples.
- Randomly select a response of any other query to add to the existing set. This is based on the understanding in Section 2 that a noise response included in a gold reference set should deteriorate the correlation.
- Randomly select a response of any other query to replace a response in the existing set. The intuition is the same as the above one.

The contrastive loss function $\mathcal{L}_c$ with T negative samples constructed is computed as:

$$\mathcal{L}_c = \frac{1}{T}\sum_t \max\{0, \Delta - f(\boldsymbol{q}, \{\boldsymbol{r}\}) + f(\boldsymbol{q}, \{\boldsymbol{r}\}_t^-)\}, \tag{7}$$

where Δ is a margin. The final loss can be computed as:

$$\mathcal{L} = \mathcal{L}_r + \mathcal{L}_c. \tag{8}$$

4 Augmenting High-quality References

In this section, we describe how we can augment high-quality references based on the current gold reference set for a given query with the help of the proposed reliability prediction model. Suppose a large set of reference candidates can be easily obtained. For example, more conversation data can be assessed to build a retrieval system to search for more references for the given query. We introduce two ways to handle reference candidates with different qualities. If the acquired reference candidates are considered reliable, we can adopt automatic annotation. If we are not certain about the relevance of the reference candidates, human annotators are needed for an interactive annotation.

4.1 Automatic Annotation

We assume the response candidates are all relevant to the given query. However, there may exist uninformative responses, such as the generic responses or those similar to the gold references. We now introduce how to use the predicted scores to automatically select out high-quality responses from the candidate set. Each time a response is randomly picked to tentatively add into the gold reference set, the model will predict a reliability score for the augmented reference set. If the reliability score of the augmented reference set improves, this picked response can be considered as a high-quality one and now confirmed to add to the gold reference set. Otherwise, we remove it from the gold reference set. We continue this process until all response candidates have been picked once, and return the final augmented gold reference set.

4.2 Interactive Annotation

If the response candidates are of uneven relevance to the query, we need to hire annotators to manually check and edit the response candidates. We design an interactive annotation strategy to allow the model to assist annotators. For each selected response candidate, the annotator mainly executes the following three steps:

1. If he/she considers the response candidate is relevant to the given query and the reliability score of the set improves with the current candidate response, he/she can retain this response directly;
2. If he/she considers the response candidate is not relevant enough to the given query but the reliability score of the set shows improvement with the current candidate response, he/she needs to edit this response and check whether the reliability score of the set increases with the edited response;
3. If the reliability score of the set does not improve with the current candidate response, no matter whether the candidate response is relevant or not, he/she still needs to edit this response and check whether the reliability score of the set increases with the edited response;

In both Step2 and Step3, we allow the interactive annotation with a maximum number of attempts. Otherwise, we abandon this response and continue to the next response candidate. This process can help annotators avoid writing responses with unsatisfactory quality.

5 Experiments

5.1 Setup

In our experiments, we use the quality scores obtained by BLEU* and BERTScore to compute the Person correlations with human judgments respectively. The reliability models introduced in Section 3 trained with BLEU and BERTScore are referred as **REAM♯(BLEU*)** and **REAM♯(BS)** respectively. The augmented dataset mentioned in Section 3.2 is used for the corresponding model training and testing. To show its effectiveness on automatic annotation and interactive annotation, we use the 500 test samples in the raw dataset introduced in Section 2.1. See Appendix B for implementation and training details.

# Refs	MSE	Pred.	Gold
REAM♯(BLEU*)

Table 2: Results of the **REAM♯(BLEU*)** model and the **REAM♯(BS)** model on multiple test sets consisting of different number of reference responses.

5.2 Results on Reliability Prediction Models

In Table 2, we report MSE, the averaged predicted reliability scores and averaged gold reliability scores. Standard deviations are also provided. We can see that the MSE of both prediction models are kept at a low level on different test sets. The difference between the average predicted reliability score and the average gold scores is at most 0.014. Also, the models have good stability and rarely show extreme cases, as shown by their standard deviations of less than 0.01. Our proposed models also have good generalization performance in terms of different sizes of the reference set. The number of references of training samples in the training set is at most 10, but the two models still have a small test error on the test set with more than 10 references, which is comparable to the test set with less than 10 references.

5.3 Results on Automatic Annotation

Once we have a reliable model, the next is to use the model to help us collect high-quality references. When enough candidate responses are available, we can directly use the model to identify which

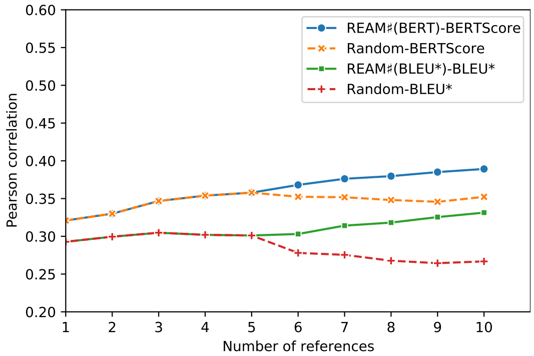

Figure 3: Pearson correlations of BLEU* and BERTScore on multiple reference sets obtained by different strategies. "REAM♯(BS)-BERTScore" means using the **REAM♯(BS)** to augment the reference set and testing it with **BERTScore**. "REAM(BLEU*)-BLEU*" means using the **REAM♯(BLEU*)** to augment the reference set and testing it with **BLEU***. We also add a random strategy for comparison.

responses are helpful to improve the reliability of the set. The experiment on automatic annotation is conducted with the raw test set introduced in Section 2.1. For each sample in the test set, we initialize the reference set with a randomly sampled crawled reference response, then add the remaining reference responses (as mentioned before, each sample has at most 200 reference responses) to its reference set one by one. Each time a new response is added, the model predicts a reliability score. The augmentation method follows the strategy mentioned in Sec. 4.1. We selected 10 responses for each sample.

Figure 3 shows the Pearson correlations of BLEU* and BERTScore on multiple reference sets obtained by different strategies. "REAM♯(BS)-BERTScore" means using the **REAM♯(BS)** model to augment the reference set and testing it with **BERTScore**. Similarly, "REAM(BLEU*)-BLEU*" means using the **REAM♯(BLEU*)** model to augment the reference set and testing it with **BLEU***. We also use a random strategy for comparison (orange and red), where the first 5 responses are the same as those previously selected using the models, and the last 5 responses are obtained by randomly sampling. As shown in the figure, the reliability of the reference sets constructed using our proposed method tends to increase steadily as more selected responses are added to the set, while the reliability of the reference sets constructed using the random strategy appears to be unstable. We also test the transferability of the model and find that the model trained with one metric also yields reliable performance when tested with other metrics. The results are shown in Appendix E.

The final results are shown in Table 3 which reports Pearson and Kendall correlations of BLEU* and BERTScore calculated using three reference sets. "Raw" denotes the initial reference set containing the first selected reference response. The remaining 9 selected responses for each sample are then used to augment the "Raw" set. "Aug-REAM♯(BS)" and "Aug-REAM♯(BLEU*)" are the reference sets augmented using the **REAM♯(BS)** and **REAM♯(BLEU*)**, respectively. "Mix" is the union of the two sets. As can be seen, the performances of the two metrics both improve using the augmented reference set. When combining the two augmented reference sets, both Pearson and Kendall correlations of BERTScore improve, while for BLEU*, the Pearson and the Kendall correlations dropped slightly. This indicates that BERTScore is better at capturing semantics than BLEU* and is able to select the most adequate reference response from multiple augmented sets for evaluation.

5.4 Results on Interactive Annotation

In the following, we perform experiments to augment high-quality references of 30 queries randomly selected in the test set in Section 2.1 using interactive annotation introduced in Section 5.4. For each test query, we first use ElasticSearch [2] to retrieve 100 candidate responses from a database with 200 million (query, response) pairs with Jaccard similarity for each query, and display them to each annotator. We recruit six annotators and divide them into two groups. The reliability scores predicted by the **REAM♯(BERT)** model will reveal to annotators in the first group ("Human-REAM♯(BS)") for interactive annotation but not annotators in the second group ("Human"). Annotators in "Human" perform non-interactive annotations. They are required to rewrite their considered unsuitable responses directly without the predicted scores as a reference. For each round of annotation, we pick one identical candidate response to all annotators.

Figure 4 shows the Pearson correlations of human evaluation results and BERTScore with the

augmented reference sets after each round of annotation by one annotator in "Human-REAM♯(BS)" and another annotator in "Human". See Appendix D for the results of all six annotators. We can see that using the augmented response set from annotators in the first group has already reached a relatively high Pearson correlation with only a few annotation rounds. When the number of responses increases to a certain level, the reliability score of the metric hits a bottleneck and rises more slowly. However, the correlation results using the augmented response set from annotators in the second group are not stable. Though the overall trend is increasing, the final obtained reference set has even worse correlations than a much small augmented set from the first group. This shows that our interactive annotation strategy is effective to help annotators avoid writing responses with unsatisfactory quality.

6 Related Work

Automatic evaluation is crucial to the research of open-domain dialog systems (Li and Jurafsky, 2016; Li et al., 2017; Gao et al., 2019; Venkatesh et al., 2018; Chan et al., 2021; Xiang et al., 2021). Existing metrics can be broadly categorized into reference-based and reference-free metrics (Chen et al., 2021). In this work, we focus on reference-based metrics, which usually measure how similar a generated response is to the reference response.

The most commonly used reference-based metrics for dialog systems were originally proposed for machine translation. They typically count the amount of word-overlap between the generated response and the reference response. BLEU (Papineni et al., 2002) is the most widely used metric in machine translation that calculates the geometric mean of the precision for n-gram. Other related word-overlap metrics such as NIST (Lin and Och, 2004), METEOR (Banerjee and Lavie, 2005) and ROUGE (Lin, 2004) also have been used for dialogue evaluation.

Instead of using word-overlap based metrics, embedding-based metrics are adopted to consider the semantic meaning of a word as defined by a distributed representation. They typically compute the similarity between the generated response and reference response using approximated sentence-level representations. The most commonly used word embedding based metrics use a heuristic to combine the vector representation of the individual word in the sentence. For example, Embedding Average (Foltz et al., 1998; Mitchell and Lapata, 2008), Vector Extrema (Forgues and Pineau, 2014), and Greedy Matching (Rus and Lintean, 2012). Zhang et al. (2020) introduce a better embedding-based metric BERTScore that computes token similarity using contextual embeddings that capture the specific use of a word in a sentence.

A few reference-based metrics for dialog systems are learnable functions. ADEM (Lowe et al., 2017) which is based on neural networks is trained to predict a score of a response given its query and a reference response. RUBER (Tao et al., 2018) evaluates responses with a blending of scores from the referenced and unreferenced metrics. RUBER is learnable, but its training does not require human annotation scores.

As discussed from the very beginning of our work, all the above work focus on designing a better metric. However, the reliability of the reference set is also a key to improve the correlation of reference-based metrics, but not investigated in detail in previous work. Therefore, we believe our work can fill this vacancy and provide a new direction to improve reference-based metrics for open-domain dialogue generation.

7 Conclusions and Future Work

In this paper, we first clarify an assumption on existing reference-based metrics that if more high-quality reference responses are added to the reference set, it should have a higher correlation with human judgment. For metrics satisfying this assumption, we present **REAM♯**, an enhancement approach to improve their reliability. In our approach, a reliability prediction model is trained to estimate the reliability of the reference set and we explore both automatic and interactive ways to augment high-quality references with the help of the reliability prediction model. Experiments show that our approach can efficiently help augment high-quality references and the correlations of reference-based metrics improve when using the augmented reference sets to evaluate dialog responses. Our work currently focuses on open-domain dialog systems as a starting point. However, the **REAM♯** framework can be extended naturally to other open-ended text generation tasks such as story generation and question generation.

8 Ethical Considerations

The dataset used in our work are crawled from several Chinese social media websites, BaiduTieba, Douban, Weibo and Zhihu. We purposefully avoid deanonymization techniques based on exploiting software vulnerabilities and our approach that involves human participation in rewriting responses gives us no access to any personally identifiable information.

A Dataset

The dataset used in our work are crawled from several Chinese social media websites, BaiduTieba, Douban, Weibo and Zhihu. We purposefully avoid deanonymization techniques based on exploiting software vulnerabilities and our approach that involves human participation in rewriting responses gives us no access to any personally identifiable information. We crawled 5,000 queries and each query has at most 200 ref-erence responses. Then, we collected 14 machine-generated responses obtained from several widely used responses generation models:

- LSTM-S2S-BS: a LSTM Seq2Seq model that generates responses with beam search.
- LSTM-S2S-Sampling: a LSTM Seq2Seq model that generates responses with top k sampling.
- LSTM-S2S-MMI: a LSTM Seq2Seq model with a Maximum Mutual Information-based decoding strategy.
- Fconv-S2S-BS: a convolutional Seq2Seq model (Gehring et al., 2017) that generates responses with beam search.
- Fconv-S2S-Sampling: a convolutional Seq2Seq model (Gehring et al., 2017) that generates responses with top k sampling.
- Fconv-S2S-DBS: a convolutional Seq2Seq model (Gehring et al., 2017) that generates responses with diverse beam search (Li et al., 2016a).
- Transformer-S2S-BS: a Transformer Seq2Seq model that generates responses with beam search.
- Transformer-S2S-Sampling: a Transformer Seq2Seq model that generates responses with top k sampling.
- Transformer-S2S-DBS: a Transformer Seq2Seq model that generates responses with diverse beam search (Li et al., 2016a).
- GPT2-BS: a GPT2 (Radford et al., 2019) model that generates responses with beam search.
- GPT2-TopK Sampling (k=20): a GPT2 (Radford et al., 2019) model that generates responses with top 20 sampling.
- GPT2-TopK Sampling (k=10): a GPT2 (Radford et al., 2019) model that generates responses with top 10 sampling.

The GPT2 model are trained on a 200 million chinese dataset crawled also from the Chinese social media websites (BaiduTieba, Douban, Weibo and Zhihu). The LSTM-S2S, Fconv-S2S and Transformer-S2S models are trained on a benchmark dataset with 7M query-response pairs proposed by Liu et al. (2018).

B Implementation and Training Details

We leverage "bert-as-service" (`https://github.com/hanxiao/bert-as-service`), an open-source system that uses BERT as a sentence encoder and hosts it as a service to map sentences into fixed-length representations. In our work, we use the character-level BERT pre-trained in Chinese. Our reliability prediction model is implemented using "PyTorch Geometric" which is a geometric deep learning extension library for PyTorch. We use one layer. For graph encoding, we employ a one-layer graph attention network with an input size of 768. The input size of the prediction linear layer also is 768. The model is trained using Adam optimizer with a learning rate of 0.0005. The batch size is 128.

For computing BLEU, we use the Python NLTK library. For computing BERTScore, we use the implementation provided by Zhang et al. (2020) at `https://github.com/Tiiiger/bert_score`.

C Case Study

Figure 6 shows two examples of using our **REAM♯(BS)** model to predict reliability scores for reference sets. Given a query and a reference set consisting of four reference responses, we first predict a reliability score for this set (e.g 0.312 and 0.275). We prepared four different candidate responses for each sample. The sentences with blue text are high-quality and diverse responses. Sentences without color are responses that are similar in meaning to the responses already in the set. Red sentences are responses that are completely irrelevant to the queries. We add each of the four candidate responses to the set and predict the reliability score for the new set. As shown in the figure, when the high-quality responses are added to the set, the model predicts a higher reliability score than the original reliability score. When responses with repeated semantics are added to the set, the model predicts a slightly lower reliability score compared to the original one. When poor quality responses are added to the set, the reliability scores predicted by the model drop sharply. It can be seen that our model can effectively evaluate the impact of responses with different qualities on the reference set.

D More Results on Interactive Annotation

Figure 5 shows the results of all six annotators. We can see that using the augmented response set from annotators in the first group has already reached a relatively high Pearson correlation with only a few annotation rounds. When the number of responses increases to a certain level, the reliability score of the metric hits a bottleneck and rises more slowly. However, the correlation results using the augmented response set from annotators in the second group are not stable. Though the overall trend is increasing, the final obtained reference set has even worse correlations than a much small augmented set from the first group. This shows that our interactive annotation strategy is effective to help annotators avoid writing responses with unsatisfactory quality.

E Transferbility

We would like to see if the model trained with one metric also yields reliable performance when tested with other metrics. Figure 7 shows the Pearson correlations of the two models, **REAM♯(BS)** and **REAM♯(BLEU*)** tested using BLEU* and BERTScore, respectively. From the figure, we can see that whether tested with BLEU* or BERTScore, the difference in performance between **REAM♯(BS)** and **REAM♯(BLEU*)** is very small. We also notice that the difference in performance tested with BLEU* between the two models is somewhat larger than that tested with BERTScore when the number of references is large. This may be because BLEU* does not utilize the semantic information compared to BERTScore, which leads to some high-quality responses in the reference set being ignored. Therefore, our enhancement approach is more effective as the metric's ability to capture semantic similarity increases.

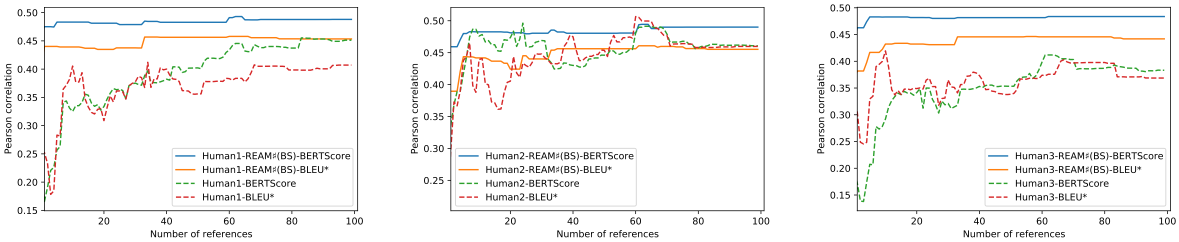

Figure 5: Pearson correlations of the reference sets constructed with and without the **REAM♯(BS)** model, respectively. "Human-REAM♯(BS)" denotes the annotator with the model assistance and "Human" is the annotator without the model assistance.

Abstract

Relation extraction is an important task in information extraction and retrieval that aims to extract relations among the given entities from running texts. To achieve a good performance for this task, previous studies have shown that a good modeling of the contextual information is required, where the dependency tree of the input sentence can be a beneficial source among different types of contextual information. However, most of these studies focus on the dependency connections between words with limited attention paid to exploiting dependency types. In addition, they often treat different dependency connections equally in modeling so that suffer from the noise (inaccurate dependency parses) in the auto-generated dependency tree. In this paper, we propose a neural approach for relation extraction, with type-aware map memories (TaMM) for encoding dependency types obtained from an off-the-shelf dependency parser for the input sentence. Specifically, for each word in an entity, TaMM maps all associated words along with the dependencies among them to memory slots and then assigns a weight to each slot according to its contribution to relation extraction. Our approach not only leverages dependency connections and types between words, but also distinguishes reliable dependency information from noisy ones and appropriately model them. The effectiveness of our approach is demonstrated by the experiments on two English benchmark datasets, where our approach achieves state-of-the-art performance on both datasets.[1]

1 Introduction

Relation extraction is an important natural language processing (NLP) task that facilitates information extraction, whose results is beneficial to downstream tasks such as schema induction (Nimishakavi et al., 2016), knowledge graph construction (Yu et al., 2017), and question answering (Xu et al., 2016). Normally, relation extraction aims to predict the relation between each pair of entities in a given sentence. For example, in the sentence "*the [bone marrow]*$_{e_1}$ *produces [stem cells]*$_{e_2}$" with the entity terms "*bone marrow*" and "*stem cells*", the relation between the two entities is "*Product-Producer*". Therefore, the ability of modeling the context from the input is of great importance to guarantee the performance of relation extraction. To this end, approaches based on neural networks have achieved promising success for the task in the past decade (Socher et al., 2012; Zeng et al., 2014; Zhang and Wang, 2015; Xu et al., 2015; dos Santos et al., 2015; Zhang et al., 2015; Wang et al., 2016; Zhou et al., 2016; Zhang et al., 2017; Wu and He, 2019; Soares et al., 2019; Fu et al., 2019; Aydar et al., 2020; Tian et al., 2021c) because of their effectiveness in capturing contextual information by powerful encoders.

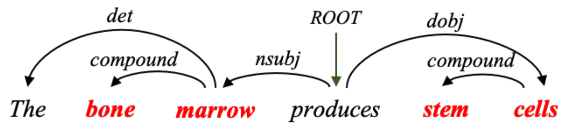

Figure 1: An illustration of an example sentence (including the entity terms "*bone marrow*" and "*stem cells*") with its dependency parsing result.

In addition, previous studies try to improve relation extraction performance by incorporating extra knowledge into their models. Among all such knowledge, syntactic information from the auto-generated dependency parse of the input sentence indicates its helpfulness to improve model performance for the reason that word dependencies provide long distance contextual information (Xu et al., 2015). However, in previous studies, the main focus is the dependencies among words, with little attention paid to dependency types, which are also

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2501–2512
August 1–6, 2021.

essential to help the relation extraction task. For example, Figure 1 shows the dependency tree of a sentence where the entities (i.e., "*bone marrow*" and "*stem cells*") are highlighted in red; the dependency type "*nsubj*" (nominal subject) between "*bone marrow*" and "*produces*" as well as the type "*dobj*" (direct object) between "*stem cells*" and "*produces*" indicates the first (i.e., "*bone marrow*") and the second entity (i.e., "*stem cells*") are the subject and object of "*produces*", which provide important cues to predict the relation between the two entities. Moreover, previous studies also suffer from the noise in the auto-generated dependency tree, in which cases all the dependencies are modeled equally without identifying their contributions to the task.[2] Therefore, it is important to design an appropriate approach to leverage the dependency information to improve the relation extraction task.

In this paper, we propose a neural approach for relation extraction, with a type-aware map memory (TaMM) module to encode dependency information obtained from an off-the-shelf dependency parser. Specifically, for each word in an entity, we firstly extracts the dependency information associated with it, where two types of dependency information are considered: the first is "*in-entity*" dependency suggested by the governor and dependents of that word; the second is "*cross-entity*" dependency obtained from the dependency path between entities. Then, TaMM is applied to map the associated words along with the dependency types between them to memory slots and then assign a weight to each slot to distinguish its contribution to the relation extraction task. Compared with other approaches, such as graph neural networks (GCN), to leverage dependency information, our approach not only leverages the dependency type information, but also distinguish reliable dependency information from noisy ones and model them accordingly. The evaluation of different models is performed on two English benchmark datasets, i.e., ACE2005 and SemEval 2010 Task 8 (Hendrickx et al., 2010), where our approach outperforms all baselines and previous studies by achieving the state-of-the-art performance on both datasets.

2 Preliminaries

Relation extraction is conventionally regarded as a text classification task, where an input sentence $\mathcal{X} = x_1 \cdots x_l$ has l words and two entities, i.e., E_1 and E_2, in it are mapped to a particular relation class (denoted by $\widehat{y}$).[3] In most cases the contextual information is of great importance to make a correct prediction for relations. Therefore, it is straightforward to consider integrating extra features to enhance contextual modeling. Of all such features, the syntactic information suggested by the dependency tree of the input sentence has been demonstrated to be useful for relation extraction in many studies (Xu et al., 2015; Zhang et al., 2018; Guo et al., 2019). However, most models to leverage the dependency information are not naturally appropriate to model the dependency types among words. It is required to find an appropriate approach to leverage the dependency type information.

Of all choices, key-value memory networks (KVMN) (Miller et al., 2016) is an effective solution in modeling pair-wisely organized information to improve many NLP tasks (Tapaswi et al., 2016; Das et al., 2017; Mino et al., 2017; Xu et al., 2019; Nie et al., 2020; Song et al., 2020; Tian et al., 2020a,d, 2021b). Specifically, KVMN maps the information instances into a list of memory slots $s_i = (k_i, v_i)$ (i is the index of the memory slot s_i) with k_i referring to the key and v_i the value, respectively. The KVMN addresses the memory slot s_i by assigning a weight p_i to the value v_i by comparing the input (denoted by x) to the key k_i:

$$p_i = \text{softmax}\left(\mathbf{A}\Phi_X(x) \cdot \mathbf{A}\Phi_K(k_i)\right) \tag{1}$$

where $\Phi_\cdot$ are functions that map the input features into their embeddings and $\mathbf{A}$ is a matrix that maps the embeddings into another vector space. After addressing all memory slots, KVMN reads the values by computing the weighted sum of the value vectors (i.e., $\mathbf{A}\Phi_V(v_i)$) using the resulting probability weights (i.e., p_i), which is expressed by

$$\mathbf{a} = \sum_j p_i \cdot \mathbf{A}\Phi_V(v_i) \tag{2}$$

Then, $\mathbf{a}$ is incorporated into the input representation by an element-wise summation:

$$\mathbf{o} = \mathbf{A}\Phi_X(x) + \mathbf{a} \tag{3}$$

Thus, the resulting vector $\mathbf{o}$ contains the weighted information from all values in the memory slots and is finally used to predict the output.

---

[2] For example, in Figure 1, the dependency between "*the*" and "*marrow*" contributes less than the dependency between "*marrow*" and "*produces*" to relation extraction.

[3] E_1 and E_2 are actually sub-strings of $\mathcal{X}$ and we assume E_1 is on the left side of E_2.

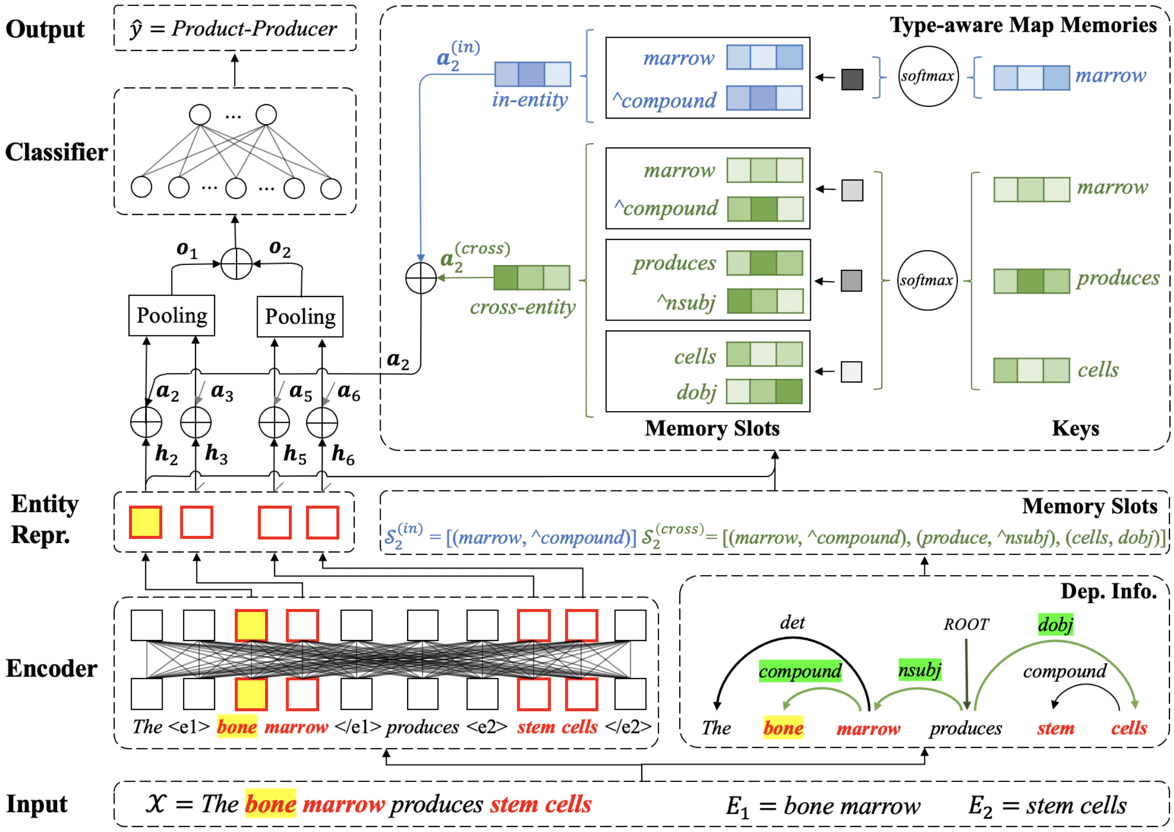

Figure 2: The architecture of our approach with an example sentence where entities are highlighted in red color. The left part illustrates the backbone classification model; the right part shows the process to leverage the in-entity and cross-entity memory slots associated with "*bone*" (highlighted in yellow) through the proposed type-aware map memories (TaMM). In entity and cross-entity memory slots are written in blue and green color respectively.

3 The Proposed Approach

Although KVMN can be used to leverage extra information for relation extraction, it loses the information of keys by using it as a weighting component as stated previously. Therefore, we propose type-aware map memories (TaMM) to leverage both context words (keys) and dependency types (values) to improve relation extraction, where two types of dependency information, i.e., "*in-entity*" and "*cross-entity*" dependencies are considered.

Figure 2 illustrates the architecture of our approach, in which the entities in the input $\mathcal{X}$ is highlighted in red; the left part illustrates the backbone classification model; the right part shows the process of constructing in-entity ($\mathcal{S}^{(in)}$) and cross-entity ($\mathcal{S}^{(cross)}$) memory slots from the dependency tree of the input and the process of incorporating them into the backbone model through TaMM. To summarize, our approach can be formalized as

$$\widehat{y} = \underset{y \in \mathcal{T}}{\arg\max}\, p\left(y|\mathcal{X}, E_1, E_2, \text{TaMM}\left(\mathcal{S}\right)\right) \quad (4)$$

where $\mathcal{T}$ is the set of entity relation types and $\mathcal{S} = (\mathcal{S}^{(in)}, \mathcal{S}^{(cross)})$ is the memory slots for TaMM.

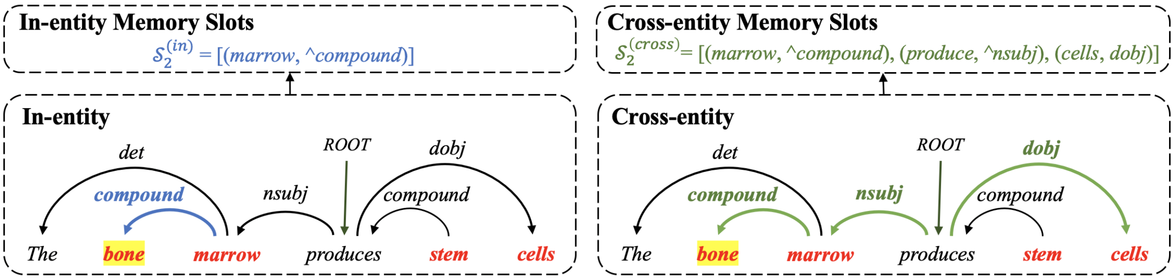
The following texts illustrates the details of our proposed appraoch, including how we construct the memory slots and the computation of TaMM, with its application in relation extraction.

3.1 Memory Slot Construction

In order to construct the memory slots used in our approach, we firstly use an off-the-shelf toolkit to generate the dependency parsing results of the input $\mathcal{X}$. In the parse tree, every word in $\mathcal{X}$ is connected with its governor and its dependents with labeled dependency connections; for any two words in $\mathcal{X}$, there is exactly one path between them[4]. For each word in an entity, e.g., the word x_{i_u} in E_u (i_u is the index of x_{i_u} in $\mathcal{X}$ and $u \in \{1, 2\}$), we consider two types of dependency information suggested by the obtained dependency tree of $\mathcal{X}$ and construct their corresponding memory slots. The first one is "*in-entity*" memory slots constructed upon all the governor and dependents of x_{i_u} (i.e., first-order dependencies). The second is "*cross-entity*" memory

---

[4] The dependency parsing results actually build a graph (tree) of the input $\mathcal{X}$, where words in $\mathcal{X}$ represent the graph nodes, and the dependency connections are the graph edges.



(a) (b)

Figure 3: An illustration of the construction process for two types of memory slots (i.e., in-entity memory slots (a) and cross-entity memory slots (b)) for "*bone*" (with yellow background). Entities are presented in red color.

slots constructed upon the words and dependency arcs along the dependency path between x_{i_u} and the words in the other entity[5]. Figure 3 shows the process to construct the two types of memory slots from the dependency tree of a sentence, where the entities in it are highlighted in red. In the following text, we illustrate the way to extract the in-entity and the cross-entity memory slots for x_{i_u}.

In-entity Memory Slots In-entity memory slots focus on the contextual information from the words connecting to x_{i_u} by dependency parses. To construct them, we firstly locate the governor and all dependents of x_{i_u} in $\mathcal{X}$ from the dependency tree. Then we regard the governor and dependents as the keys in the memory slots and their dependency relations with x_{i_u} as their corresponding values. Therefore, we obtain a list of memory slots with the j-th of them denoted as $s_{i_u,j}^{(in)} = (k_{i_u,j}^{(in)}, v_{i_u,j}^{(in)})$, where $k_{i_u,j}^{(in)}$ is the word connected with x_{i_u} by a dependency connection and $v_{i_u,j}^{(in)}$ the dependency relation type between them. For example, in Figure 3(a), for the word "*bone*" (highlighted with yellow background) in the first entity "*bone marrow*", we find its dependent "*marrow*" and the dependency relation type *compound* between them (the dependency with its type is highlighted in blue) and obtain the dependency slot $\mathcal{S}_2^{(in)}$ =[(*morrow*, ˆ*compound*)].[6] In this case, there is only one word (i.e., "*marrow*") associated with "*bone*". Similarly, if the word we focus on is "*marrow*", the in-entity memory slots for it should be $\mathcal{S}_3^{(in)}$ = [(*The*, *det*), (*bone*, *compound*), (*produces*, ˆ*nsubj*)].

Cross-entity Memory Slots Cross-entity memory slots aim to incorporate the contextual information along the dependency path in between the two entities. To construct cross-entity memory slots, for each x_{i_u} in E_u (we denote the other entity as $E_{\widetilde{u}}$), we firstly find the dependency path from x_{i_u} to the last word of $E_{\widetilde{u}}$. The motivation of using the last word is that noun phrases in English (entities are always noun phrases) tend to be head-final[7]. Then, similar to the process of constructing in-entity memory slots, we extract all words along that path (including the last word of $E_{\widetilde{u}}$) as well as the corresponding dependency relation types. Finally, we regard the words as keys and the dependency relation types as values in the memory slots and denote the j-th memory slot as $s_{i_u,j}^{(cross)} = (k_{i_u,j}^{(cross)}, v_{i_u,j}^{(cross)})$. As illustrated in Figure 3(b), for "*bone*" (highlighted with yellow background) in the first entity "*bone marrow*", we locate the dependency path between "*bone*" and the last word "*cells*" of the second entity "*stem cells*": "*bone – marrow – produces – cells*", as well as the dependency relation types along that path: "*compound*" for "*bone – marrow*", "*nsubj*" for "*marrow – produces*", and "*dobj*" for "*produces – cells*" (highlighted in green). Therefore, the cross-entity memory slots for "*bone*" are $\mathcal{S}_2^{(cross)}$ = [(*marrow*, ˆ*compound*), (*produces*, ˆ*nsubj*), (*cells*, *dobj*)].

In summary, for x_{i_u} in in E_u, we obtain the in-entity memory slot list $\mathcal{S}_{i_u}^{(in)}$ and the cross-entity memory slot list $\mathcal{S}_{i_u}^{(cross)}$, which are fed into the TaMM module as illustrated in Figure 2.

3.2 Type-aware Map Memories

There are previous approaches for relation extraction that leverage dependency information and focus on dependencies among words without considering their dependency types. With learning from such information, there is a nonnegligible challenge that there are noises in the auto-generated depen-

---

[5] "*The other entity*" means E_2 if x_{i_u} is a word in E_1.

[6] We add a ˆ mark before the dependency type to illustrate the directional information of the dependency type.

[7] For example, the head of "*bone marrow*" is "*marrow*" and the head of "*stem cells*" is "*cells*".

dency results, which may hurt model performance since they provide misleading contextual information. One straightforward way to address this issue is to weight different dependencies according to their contribution to the relation extraction task. As discussed in the previous section, although KVMN provides a way to selectively model dependency information it is limited in omitting the contextual information carried by the keys in the final output from the memories.

To address the aforementioned limitations in KVMN, we propose type-aware map memories (TaMM) to incorporate the dependency information carried by both the keys and values (i.e., the memory slots), where the architecture of TaMM is illustrated on the top right of Figure 2. Specifically, for each word in an entity, e.g., the word x_{i_u} in E_u (i_u is the index of x_{i_u} in $\mathcal{X}$ and $u \in \{1, 2\}$), we consider two types of dependency information, i.e., "*in-entity*" and "*cross-entity*" dependency information, and construct their corresponding memory slots. We denote the j-th in-entity and cross-entity memory slots as $s^{(in)}_{i_u,j} = (k^{(in)}_{i_u,j}, v^{(in)}_{i_u,j})$ and $s^{(cross)}_{i_u,j} = (k^{(cross)}_{i_u,j}, v^{(cross)}_{i_u,j})$, respectively, and use the same process to model them.

Taking the in-entity memory slots as an example, we firstly use two matrices to map the keys $k^{(in)}_{i_u,j}$ and values $v^{(in)}_{i_u,j}$ in the memory slots into their embeddings, which are denoted by $\mathbf{e}^{k,(in)}_{i_u,j}$ and $\mathbf{e}^{v,(in)}_{i_u,j}$, respectively. Next, we compute the weight $p_{i_u,j}$ assigned for each value through the inner production between the key embedding $\mathbf{e}^{k,(in)}_{i_u,j}$ and the hidden vector of x_{i_u} (which is denoted as $\mathbf{h}_{i_u}$) obtained from the encoder in the backbone model:

$$p_{i_u,j} = \frac{\exp\left(\mathbf{h}_{i_u} \cdot \mathbf{e}^{k,(in)}_{i_u,j}\right)}{\sum_{j=1}^{m^{(in)}_{i_u}} \exp\left(\mathbf{h}_{i_u} \cdot \mathbf{e}^{k,(in)}_{i_u,j}\right)} \qquad (5)$$

where $m^{(in)}_{i_u}$ is the number of in-entity memory slots associated with x_{i_u}. Then, we apply the weights to the corresponding memory slots and obtain the weighted sum (denoted as $\mathbf{a}^{(in)}_{i_u}$) of both keys and values through

$$\mathbf{a}^{(in)}_{i_u} = \sum_{j=1}^{m^{(in)}_{i_u}} p_{i_u,j}(\mathbf{e}^{k,(in)}_{i_u,j} + \mathbf{e}^{v,(in)}_{i_u,j}) \qquad (6)$$

where "+" refers to element-wise sum of vectors. Therefore, compared to KVMN, our approach is able to leverage both context words and dependency types associated with x_{i_u}.

		ACE2005	SemEval
# Instances	Train	48,198	8,000
	Dev	11,854	-
	Test	10,097	2,717
# Relation Types		7	19

Table 1: The statistics (number of instances and relation types) of the two benchmark datasets.

With the same process for in-entity memory slots, we deal with the cross-entity ones and obtain the weighted sum $\mathbf{a}^{(cross)}_{i_u}$. Finally, we concatenate the two resulting vectors by $\mathbf{a}_{i_u} = \mathbf{a}^{(in)}_{i_u} \oplus \mathbf{a}^{(cross)}_{i_u}$ with $\mathbf{a}_{i_u}$ denoting the output of TaMM and containing the weighted dependency information to enhance the backbone model.

3.3 Relation Extraction with TaMM

Once the TaMM is built, it is straightforward to apply it to relation extraction through a backbone classifier. In our approach, we use BERT (Devlin et al., 2019) as the classifier to encode the input $\mathcal{X}$ and obtain the hidden vectors for all words. Note that we only use the hidden vectors of the words in the two entities to predict their relations. Therefore, for each word x_{i_u} in the entity E_u, we feed $\mathbf{h}_{i_u}$ into TaMM and obtain the corresponding output $\mathbf{a}_{i_u}$. Then, we concatenate $\mathbf{h}_{i_u}$ and $\mathbf{a}_{i_u}$, and for each entity E_u, use the max pooling strategy to obtain the vectorized representation $\mathbf{o}_u$ by

$$\mathbf{o}_u = \text{MaxPooling}(\mathbf{h}_{i_u} \oplus \mathbf{a}_{i_u}) \qquad (7)$$

Afterwards, we concatenate the representation of the two entities (i.e. $\mathbf{o}_1$ for E_1 and $\mathbf{o}_2$ for E_2) and pass the resulting vector through a fully connected layer (a classifer) to obtain the final prediction $\widehat{y}$ by

$$\widehat{y} = \mathbf{W} \cdot (\mathbf{o}_1 \oplus \mathbf{o}_2) + \mathbf{b} \qquad (8)$$

where $\mathbf{W}$ and $\mathbf{b}$ are the trainable weight matrix and bias vector for the fully connected layer.

4 Experimental Settings

4.1 Datasets

Two English benchmark datasets, i.e., ACE2005EN (ACE2005)[8] and SemEval 2010 Task 8 (SemEval)[9] (Hendrickx et al., 2010) are used in the experiments to evaluate our approach. For ACE2005, we follow the same preprocess as that in Christopoulou

Table 2: The hyper-parameters tested in tuning our models. The best ones used in our final experiments are highlighted in boldface.

et al. (2018); Ye et al. (2019), by removing the two small subsets: cts and un, and splitting the remaining 511 documents into three parts: 351 for training, 80 for development and the rest 80 for test[10]. For SemEval, we follow previous studies (Hendrickx et al., 2010; Zeng et al., 2014; Zhang and Wang, 2015; Xu et al., 2015; dos Santos et al., 2015; Zhang et al., 2015; Wang et al., 2016; Zhou et al., 2016; Zhang et al., 2017; Soares et al., 2019) to use its official train/test split. The statistics of the two datasets are summarized in Table 1.

4.2 Implementation

In our experiments, we use Standard CoreNLP Toolkits (SCT)[11] to obtain the dependency tree for each input sentence. Since the quality of text representation plays an important role in the performance of NLP models (Komninos and Manandhar, 2016; Song et al., 2017, 2018; Liu and Lapata, 2018; Song and Shi, 2018; Song et al., 2021), we use BERT[12] (Devlin et al., 2019), which is a pre-trained language model that achieves state-of-the-art in many NLP tasks (Wu and He, 2019; Soares et al., 2019; Tian et al., 2020b,c, 2021a), as the encoder in our model. Specifically, we use the uncased version of BERT with its default settings (e.g., for BERT-base, we use 12 layers of multi-head attentions with 768 dimensional hidden vectors; for BERT-large, we use 24 layers of multi-head attentions with 1024 dimensional hidden vectors) and fine-tune its all trainable parameters in the training stage. For TaMM, we randomly initialize the embeddings of all keys and values with their dimensions matching that of the hidden vectors from BERT. For evaluation, we follow previous studies to use the standard micro-F1 scores[13] for ACE2005 and use the macro-averaged F1 scores[14] for SemEval. For other hyper-parameter settings (i.e., learning rate, warmup rate, dropout rate, and batch size) to train our model, we report them Table 2, where we test all combinations of them for each model and use the one achieving the highest F1 score in our final experiments (the best combination of them is illustrated in boldface).

Models	ACE2005	SemEval
BERT-base	75.31	87.87
+ GCN	75.59	88.19
+ GAT	76.01	88.39
+ KVMN (In)	76.40	88.73
+ TaMM (In)	76.80	88.91
+ KVMN (Cross)	76.45	88.61
+ TaMM (Cross)	76.61	88.74
+ KVMN (Both)	76.83	88.98
+ TaMM (Both)	**77.07**	**89.18**
BERT-large	76.79	89.02
+ GCN	77.17	89.43
+ GAT	77.23	89.39
+ KVMN (In)	77.32	89.42
+ TaMM (In)	77.76	89.72
+ KVMN (Cross)	77.21	89.37
+ TaMM (Cross)	77.66	89.58
+ KVMN (Both)	77.96	89.88
+ TaMM (Both)	**78.98**	**90.06**

Table 3: F1 scores of our TaMM and baselines (i.e., BERT, standard GCN, standard GAT, and KVMN) on the test sets of ACE2005 and SemEval, where BERT-base and BERT-large encoders are used. For KVMN and TaMM, different combinations of in-entity and cross-entity dependency information (i.e., in-entity only, cross-entity only, and both of them) are tried.

5 Results and Analyses

5.1 Overall Performance

In the main experiments, we run our models using BERT-base and BERT-large encoders with and without TaMM and try different combinations of in-entity and cross-entity dependency information (i.e., in-entity dependency information only, cross-entity dependency information only, and both of them). We also run the baselines using standard graph convolutional networks (GCN), standard graph attention networks (GAT), and KVMN to leverage the dependency information. Table 3 shows the results (F1 scores) of different models.[15]

---

[10] We use the dataset split from `https://github.com/tticoin/LSTM-ER/tree/master/data/ace2005/split`.

[11] We use SCT under version 3.9.2 from `https://stanfordnlp.github.io/CoreNLP/`.

[12] We download different BERT models from `https://github.com/huggingface/transformers`.

[13] We use the evaluation script from *sklearn* framework.

[14] We use the official evaluation script downloaded from `http://semeval2.fbk.eu/scorers/task08/SemEval2010_task8_scorer-v1.2.zip`.

[15] For the same group of models, we report the F1 scores on the development sets in Appendix A and the mean and standard deviation of their test set results in Appendix B.

*†TaMM (Both) (BERT-large)	**78.98**	**90.06**

Table 4: The comparison between our models (the ones using TaMM (Both)) and previous studies on ACE2005 and SemEval. Models with dependency features and BERT-large are marked by "†" and "*", respectively.

There are several observations. First, TaMM works well with both BERT base and large, where consistent improvement is observed over the BERT-base and BERT-large baselines across all datasets, although they have already achieved very good performance. Second, TaMM outperforms standard GCN and GAT models, which can be attributed to our modeling of dependency type information in TaMM. Third, under all the three settings to incorporate different types of dependency information (i.e., in-entity, cross-entity, and both), our models with TaMM outperforms the BERT baseline and the highest F1 score is achieved when both in-entity and cross-entity dependency information are used (i.e., + TaMM (Both)). This observation confirms the individual contribution of in-entity and cross-entity dependency information as well as the effectiveness of our approach to leverage them together to improve model performance. Fourth, compared with our TaMM models using cross-entity dependency information only (i.e., + TaMM (Cross)), the models using in-entity dependency information only (i.e., + TaMM (In)) achieves higher results in most cases. One possible explanation could be the following. There are overlaps between in-entity dependencies and cross-entity dependencies. For example, the dependency between "*bone*" and "*marrow*" is shared by both in-entity dependencies and cross-entity dependencies in Figure 3. Therefore, with in-entity dependency only, TaMM not only leverages the contextual words directly associated with the entities themselves, but also can still partially benefit from the contextual information along the dependency path, whereas TaMM with cross-entity dependency only fails to leverage the contextual words directly associated with the entities, which leads TaMM (In) to achieve better performance than TaMM (Cross). Fifth, for all the settings, our model with TaMM consistently outperforms the baselines with KVMN, which demonstrates the effectiveness of our approach to improve relation extraction. The explanation is that TaMM is able to leverage both context words (keys) and dependency types (values) at the same time, while KVMN fails to incorporate the context information carried by keys, which leads KVMN to omit some important features and thus get inferior results.

Models	Order	ACE2005	SemEval
Baseline	N/A	76.79	89.02
TaMM (In)	1st	77.76	89.72
	2nd	77.53	89.59
	3rd	78.05	89.79
TaMM (Both)	1st	**78.98**	**90.06**
	2nd	78.27	89.95
	3rd	78.41	89.91

Table 5: F1 scores of models using BERT-large and TaMM (In/Both) to leverage 1st-, 2nd-, and 3rd-order dependencies. "N/A" refers to no order can be applied.

Moreover, we compare our model under the best setting (i.e., the ones using TaMM to leverage both in-entity and cross-entity dependency relation) with previous studies and report the results (F1 scores) in Table 4. It is found that our model with BERT-large encoder outperforms all previous studies (including the ones also using BERT-large encoder).

5.2 The Effect of Dependency Information

To analyze the effect of using dependency information, we perform three investigations on models using BERT-large encoder.

The first investigation is to examine different orders of dependencies used in TaMM. Previous experiments showed the effectiveness of our model with TaMM on first-order word dependencies. We also try second- and third-order dependencies via the model (i.e., large BERT) with TaMM (Both). The results (with scores from the first-order dependencies) are reported on table 5, where the corresponding results from the models with TaMM (In) as well as the BERT-large baseline are also reported. The observations are drawn as follows. First, models with TaMM under all settings outperforms the BERT-large baseline, which is confirmed by all results on both datasets. Second, models with TaMM (Both) consistently outperform the ones with TaMM (in) under the same setting, which indicates the cross-entity dependencies are able to bring greater improvements. Third, for models

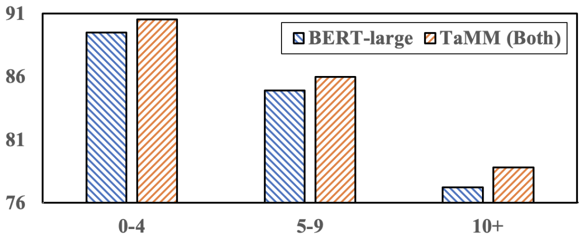

Figure 4: The performance of BERT-large baseline and our TaMM (both) on test instances from SemEval grouped by the entities' distance (i.e., the number of words between two entities).

with TaMM (Both), using higher order dependencies often results in inferior results; while the trend is on the opposite for models with TaMM (in). One possible explanation is that for TaMM (both), most essential word dependencies in between the two entities have already been encoded, higher order dependencies sometimes introduce noise other than useful information; while for TaMM (In), leveraging higher order dependencies allows the model to cover more contextual information along the dependency path between two entities.

The second is to explore the performance of our model on different test instances grouped by their entity distance (i.e., the number of words between the two entities), to see whether our approach can capture long-distance word-word dependencies and help with relatin extraction. In doing so, we split the test set of SemEval into three groups according to the entity distance (i.e., from 0 to 4, from 5 to 9, and higher than 10) and perform our best TaMM model and the BERT baseline on them. Figure 4 illustrates the performance of TaMM (i.e., the orange bar) and BERT (i.e., the blue bar). It can be found that our TaMM outperforms the BERT-baseline on all three groups of test instances, where bigger gaps can be observed when the entities' distance goes higher. This observation demonstrates the effectiveness of our approach to encode dependency information to improve relation extraction.

The third investigation is to explore the effect of TaMM using different dependency parsers. Specifically, in addition to the Stanford CoreNLP Toolkits (SCT) used in the main experiments, we also try spaCy[16] to obtain the dependency trees and report the results (with BERT-large encoder) in Table 6. It is found that models with different dependency parsers consistently outperform the BERT-large baseline, which indicates the robustness of our model design in improving relation extraction.

Models	**Parser**	**ACE2005**	**SemEval**
Baseline	N/A	76.79	89.02
TaMM (In)	SCT	77.76	89.72
	spaCy	77.74	89.78
TaMM (Cross)	SCT	77.66	89.58
	spaCy	77.60	89.61
TaMM (Both)	SCT	**78.98**	**90.06**
	spaCy	78.92	90.01

Table 6: F1 scores of models using BERT-large and TaMM (In/Cross/Both) to leverage dependency information from different parsers (i.e., SCT and spaCy).

5.3 Case Study

To examine how TaMM leverages dependency information to improve model performance, in Figure 5, we show an example input where our approach successfully predicts the relation in between the two entities (in red colors) to be "*Entity-Destination*", while the BERT-large baseline fails to do so ("*Component-Whole*"). In the figure, the dependencies between words are highlighted in different colors to represent the total weights assigned to their corresponding in-entity and cross-entity memory slots, where darker color refers to higher weight. Overall, we find that the most emphasized dependencies are along the dependency path connecting the two entities, where the memory slots for those dependencies receive the highest weights. For the first entity "*treadmill*", the dependency type *ˆnsubj: pass* (passive nominal subject) in the highlighted memory slot (*installed*, *ˆnsubj: pass*) suggests the first entity is the patient of the action *install*; similarly, for the second entity "*space station*", the highlighted dependency type *ˆobj* (object) suggests this entity is the location of the action *install* given the fact that the input is a passive sentence. Therefore, our approach is able to leverage these cues learned from word dependencies and their dependency types so as to predict the correct relation for the two entities: "*Entity-Destination*".

6 Related Work

Relation extraction is an important task in NLP, which significantly relies on a good modeling of the contextual information to achieve outstanding model performance. To improve the capability of context modeling for relation extraction, studies in the past decade leverage neural networks, such as using CNN (Zeng et al., 2014; Wang et al., 2016), RNN (Socher et al., 2012; Xu et al., 2015; Zhou et al., 2016) and BERT encoders (Wu and He, 2019; Soares et al., 2019; Wang et al., 2019). To further

---

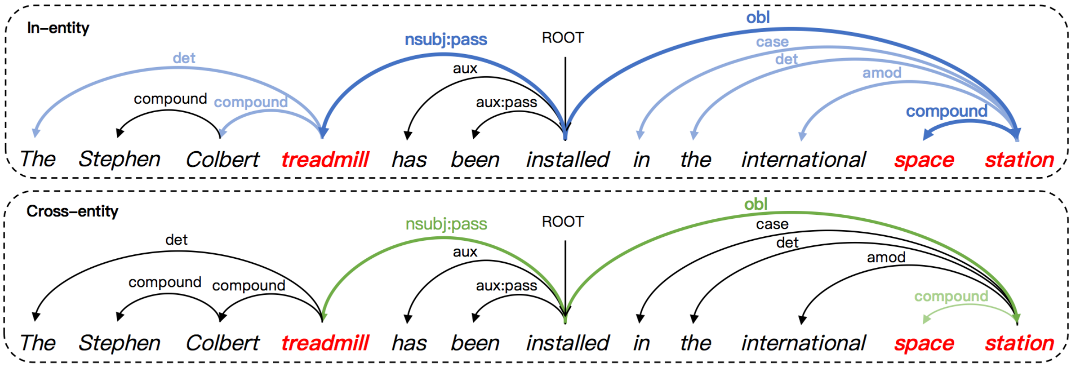

Figure 5: An example input fed into our model with TaMM (Both) and its correctly predicted relation between the two entities marked in red. Word dependencies are highlighted in different colors to visualize the total weights assigned to their corresponding in-entity and cross-entity memory slots, where darker color refers to higher weight.

enhance the models for this task, incorporating extra knowledge into the models has been proved as an effective method, where normally three types of extra knowledge are used: lexical, syntactic and semantic knowledge, and syntactic knowledge has been proved to be useful for this task (Xu et al., 2015). With this finding, there are studies also using advanced neural architecture, such as graph convolutional networks, to incorporate syntactic knowledge from auto-generated dependency parse of the input sentence (Zhang et al., 2018; Guo et al., 2019; Sun et al., 2020; Yu et al., 2020; Mandya et al., 2020). Compared to the aforementioned studies, TaMM offers a simple yet effective non-graph-based approach to leverage dependencies for relation extraction. TaMM provides the ability not only incorporate both word dependencies and their types into the model to help improve relation extraction performance, but also discriminatively leverage the dependencies by assigning different weights to them, which can address the potential noise in the auto-generated dependencies and thus further improve model performance.

7 Conclusion

In this paper, we proposed an effective method for relation extraction with word dependencies encoded by TaMM, whose keys and values are built upon the dependency tree of the input sentence obtained from off-the-shelf toolkits. Particularly, for each entity in the sentence, we extract words associated with it according to the dependency parse of the input sentence and their corresponding dependency relation types. Then, we use TaMM to encode and weight such information and integrate it into the relation extraction task. The novelty of this work lies in the modeling of contextual information through dependencies and their relation types encoded in TaMM. Experimental results on two public English benchmark datasets illustrate the effectiveness of our approach with state-of-the-art performance achieved on all datasets.

Appendix A. Experimental Results on the Development Set

Table 7 reports the F1 scores of different models on the development set of ACE2005.[17]

Models	**BERT-base**	**BERT-Large**
BERT	75.03	76.51
+ GCN	75.33	76.82
+ GAT	75.77	76.89
+ KVMN (In)	76.28	77.10
+ TaMM (In)	76.61	77.52
+ KVMN (Cross)	76.25	77.06
+ TaMM (Cross)	76.54	77.44
+ KVMN (Both)	76.49	77.48
+ TaMM (Both)	76.86	78.13

Table 7: F1 scores of models with different configurations (i.e., the ones using base or large BERT with KVMN or TaMM and different combinations of in-entity and cross-entity dependency information) on the development set of ACE2005 for relation extraction.

Appendix B. Mean and Deviation of the Results

In the experiments, we test models with different configurations. For each model, we train it with the best hyper-parameter setting using five different random seeds. We report the mean (μ) and standard deviation (σ) of the F1 scores on the test set of ACE2005 and SemEval in Table 8.

Models	**ACE2005**		**SemEval**	
	μ	σ	μ	σ
BERT-base	74.86	0.42	87.48	0.38
+ GCN	75.15	0.31	88.02	0.16
+ GAT	75.70	0.29	88.01	0.36
+ KVMN (In)	76.15	0.24	88.62	0.10
+ TaMM (In)	76.61	0.18	88.76	0.14
+ KVMN (Cross)	75.99	0.42	88.43	0.16
+ TaMM (Cross)	76.43	0.14	88.49	0.24
+ KVMN (Both)	76.44	0.34	88.59	0.36
+ TaMM (Both)	**76.59**	0.46	**88.96**	0.19
BERT-large	76.28	0.47	88.66	0.34

Abstract

To build a high-quality open-domain chatbot, we introduce the effective training process of PLATO-2 via curriculum learning. There are two stages involved in the learning process. In the first stage, a coarse-grained generation model is trained to learn response generation under the simplified framework of one-to-one mapping. In the second stage, a fine-grained generative model augmented with latent variables and an evaluation model are further trained to generate diverse responses and to select the best response, respectively. PLATO-2 was trained on both Chinese and English data, whose effectiveness and superiority are verified through comprehensive evaluations, achieving new state-of-the-art results.

1 Introduction

Recently, task agnostic pre-training with large-scale transformer models has achieved great success in natural language processing (Devlin et al., 2019), especially open-domain dialogue generation. For instance, based on the general language model GPT-2 (Radford et al., 2019), DialoGPT (Zhang et al., 2020) is further trained for response generation using Reddit comments. To obtain a human-like open-domain chatbot, Meena (Adiwardana et al., 2020) scales up the network parameters to 2.6B and employs more social media conversations in the training process, leading to significant improvement on response quality. To mitigate undesirable toxic or bias traits of large corpora, Blender (Roller et al., 2021) fine-tunes the pre-trained model with human annotated datasets and emphasizes desirable conversational skills of engagingness, knowledge, empathy and personality.

In addition to the attempts from model scale and data selection, PLATO (Bao et al., 2020) aims to tackle the inherent one-to-many mapping problem to improve response quality. The one-to-many mapping refers to that one dialogue context might correspond to multiple appropriate responses. It is widely recognized that the capability of modeling one-to-many relationship is crucial for open-domain dialogue generation (Zhao et al., 2017; Chen et al., 2019). PLATO explicitly models this one-to-many relationship via discrete latent variables, aiming to boost the quality of dialogue generation. PLATO has a modest scale of 132M network parameters and trained with 8M samples, achieving relatively good performance among conversation models on a similar scale. However, scaling up PLATO directly encounters training instability and efficiency issues, which might result from the difficulty to capture the one-to-many semantic relationship from scratch.

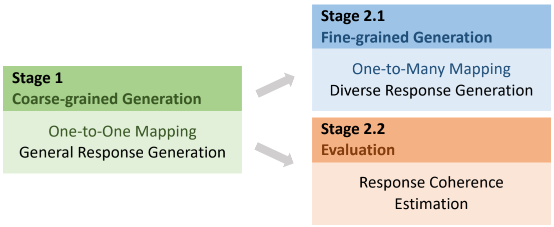

Figure 1: Curriculum learning process in PLATO-2.

In this work, we try to scale up PLATO to PLATO-2 and introduce an effective training schema via curriculum learning (Bengio et al., 2009). There are two stages involved in the whole learning process, as shown in Figure 1. In the first stage, under the simplified one-to-one mapping modeling, a **coarse-grained** generation model is trained for response generation under different conversation contexts. This model tends to capture typical patterns of diversified responses, sometimes resulting in general and dull responses during inference. Despite the problem of safe responses,

Context: How's your vacation?

Amazing! I had a wonderful trip to Hawaii.

Quite boring, how's yours?

I went hiking with my family.

Response: Amazing! I had a wonderful trip to Hawaii.

Figure 2: PLATO-2 illustration. Left: training phase via curriculum learning, model parameters in the second stage are warm started by those trained well in the first stage. Right: toy example to illustrate inference phase.

this coarse-grained model is still highly effective in learning general concepts of response generation.

The curriculum learning continues to the second stage, which contains the training of a **fine-grained** generation model and an evaluation model. The fine-grained generation model explicitly models the one-to-many mapping relationship via latent variables for diverse response generation. To select the most appropriate response, an evaluation model is trained to estimate the bi-directional coherence between the dialogue context and responses. Distinct with multi-task PLATO, the separate design of fine-grained generation and evaluation enables the model to concentrate more on its corresponding task, getting exempt from multi-task disturbance (Standley et al., 2020).

As compared with PLATO, PLATO-2 leverages curriculum learning to learn response generation gradually, from the general concept of one-to-one mapping to the complex concept of one-to-many mapping. With curriculum learning, we successfully scale the model up to billions of parameters, achieving new state-of-the-art results. Besides open-domain chitchat, the models learned in these two stages can also benefit task-oriented conversation and knowledge grounded dialogue respectively, whose effectiveness is verified thoroughly in DSTC9 (Gunasekara et al., 2020).

To sum up, we trained PLATO-2 with different model sizes: 1.6B, 314M and 93M parameters. In addition to the English models, we also trained Chinese models with massive social media conversations. Comprehensive experiments on both English and Chinese datasets demonstrate that PLATO-2 outperforms Meena, Blender and other state-of-the-art models. We have released our English models and source codes at GitHub, hoping to facilitate the research in open-domain dialogue generation.[1]

2 Methodology

The backbone of PLATO-2 is consisted of transformer blocks with pre-normalization (Radford et al., 2019). Distinct with conventional Seq2Seq, there are no separate encoder and decoder networks in our infrastructure. PLATO-2 keeps the unified network for bi-directional context encoding and uni-directional response generation through flexible attention mechanism (Dong et al., 2019).

2.1 Curriculum Learning

In this work, we carry out effective training of PLATO-2 via curriculum learning. As shown in Figure 2, there are two stages involved in the learning process: during stage 1, a coarse-grained baseline model is trained for general response generation under the simplified one-to-one mapping relationship; during stage 2, two models of fine-grained generation and evaluation are further trained for diverse response generation and response coherence estimation respectively.

---

[1] `https://github.com/PaddlePaddle/Knover/tree/develop/projects/PLATO-2`

2.1.1 General Response Generation

It is well known that there exists a one-to-many relationship in open-domain conversations, where a piece of context may have multiple appropriate responses. Since conventional approaches try to fit the one-to-one mapping, they tend to generate generic and dull responses. Whereas, it is still an efficient way to capture the general characteristics of response generation. As such, we first train a coarse-grained baseline model to learn general response generation under the simplified relationship of one-to-one mapping. Given one training sample of context and response (c, r), we need to minimize the following negative log-likelihood (NLL) loss:

$$\begin{aligned}\mathcal{L}_{NLL}^{\text{Baseline}} &= -\mathbb{E}\ \log p(r|c) \\ &= -\mathbb{E}\ \sum\nolimits_{t=1}^{T}\ \log p(r_t|c, r_{<t})\ ,\end{aligned} \tag{1}$$

where T is the length of the target response r and $r_{<t}$ denotes previously generated words. Since the response generation is a uni-directional decoding process, each token in the response only attends to those before it, shown as dashed orange lines in Figure 2. As for the context, bi-directional attention is enabled for better natural language understanding, shown as blue lines in Figure 2.

2.1.2 Diverse Response Generation

Based upon the coarse-grained baseline model, diverse response generation is warm started and further trained under the relationship of one-to-many mapping. Following the previous work PLATO, the discrete latent variable z is introduced for the one-to-many relationship modeling. z is one K-way categorical variable, with each value corresponding to a particular latent speech act in the response. The model will first estimate the latent act distribution of the training sample $p(\mathbf{z}|c, r)$ and then generate the response with the sampled latent variable $p(r|c, z)$. It is notable that these two tasks of response generation and latent act recognition are trained jointly within the shared network. The NLL loss of diverse response generation is defined as:

$$\begin{aligned}\mathcal{L}_{NLL}^{\text{Generation}} &= -\mathbb{E}_{z\sim p(\mathbf{z}|c,r)}\ \log p(r|c, z) \\ &= -\mathbb{E}_{z\sim p(\mathbf{z}|c,r)} \sum_{t=1}^{T}\ \log p(r_t|c, z, r_{<t})\ ,\end{aligned} \tag{2}$$

where z is the latent act sampled from $p(\mathbf{z}|c, r)$. As sampling is not differentiable, we approximate it with Gumbel-Softmax (Jang et al., 2017). The posterior distribution over latent values is estimated through the task of latent act recognition:

$$p(\mathbf{z}|c, r) = \text{softmax}(W_1 h_{[M]} + b_1) \in \mathbb{R}^K\ , \tag{3}$$

where $h_{[M]} \in \mathbb{R}^D$ is the final hidden state of the special mask token [M], $W_1 \in \mathbb{R}^{K\times D}$ and $b_1 \in \mathbb{R}^K$ denote the weight matrices of one fully-connected layer.

To facilitate the training process of discrete latent variables, the bag-of-words (BOW) loss (Zhao et al., 2017) is also employed:

$$\begin{aligned}\mathcal{L}_{BOW}^{\text{Generation}} &= -\mathbb{E}_{z\sim p(\mathbf{z}|c,r)} \sum\nolimits_{t=1}^{T}\ \log p(r_t|c, z) \\ &= -\mathbb{E}_{z\sim p(\mathbf{z}|c,r)} \sum\nolimits_{t=1}^{T}\ \log \frac{e^{f_{r_t}}}{\sum_{v\in V} e^{f_v}}\ ,\end{aligned} \tag{4}$$

where V refers to the whole vocabulary. The function f tries to predict the words within the target response in a non-autoregressive way:

$$f = W_2 h_z + b_2 \in \mathbb{R}^{|V|}\ , \tag{5}$$

where h_z is the final hidden state of the latent variable. f_{r_t} denotes the estimated probability of word r_t. As compared with NLL loss, the BOW loss discards word orders and forces the latent variable to capture the global information of target response.

To sum up, the objective of the fine-grained generation model is to minimize the following integrated loss:

$$\mathcal{L}^{\text{Generation}} = \mathcal{L}_{NLL}^{\text{Generation}} + \mathcal{L}_{BOW}^{\text{Generation}} \tag{6}$$

2.1.3 Response Coherence Estimation

By assigning distinct values to the latent variable, the fine-grained generation model is able to produce multiple high-quality and diverse responses. To select the most appropriate response from these candidates, one straightforward way is to rank them according to $p(z|c)p(r|c, z)$. However, it is widely recognized that the prior distribution $p(\mathbf{z}|c)$ is difficult to estimate and the uniform distribution is not an effective approximation. To this end, we adopt an alternative approach to train an evaluation model in the second stage, estimating the coherence between each response and the given dialogue context. The loss of response coherence estimation (RCE) is defined as follows:

$$\begin{aligned}\mathcal{L}_{RCE}^{\text{Evaluation}} = &- \log p(l_r = 1|c, r) \\ &- \log p(l_{r^-} = 0|c, r^-)\end{aligned} \tag{7}$$

The positive training samples come from the dialogue context and corresponding target response (c, r), with coherence label $l_r = 1$. And the negative samples are created by randomly selecting responses from the corpus (c, r^-), with coherence label $l_{r^-} = 0$.

In addition to our coherence evaluation function $p(l_r|c, r)$, there are two other functions widely used for response selection. One is the length-average log-likelihood (Adiwardana et al., 2020), which considers the forward response generation probability $p(r|c)$. The other one is the maximum mutual information (Zhang et al., 2020), which considers the backward context recovery probability $p(c|r)$. However, the forward score favors safe and generic responses due to the property of maximum likelihood, while the backward score tends to select the response with a high overlap with the context, resulting in repetitive conversations. By contrast, the discriminative function $p(l_r|c, r)$ considers the bi-directional information flow between the dialogue context and response. Our coherence evaluation is able to ameliorate the aforementioned problems, whose effectiveness is verified in the experiments.

To maintain the capacity of distributed representation, the task of masked language model (MLM) (Devlin et al., 2019) is also included in the evaluation network. Within this task, 15% of the input tokens will be masked at random and the network needs to recover the masked ones. The MLM loss is defined as:

$$\mathcal{L}^{\text{Evaluation}}_{MLM} = -\mathbb{E} \sum\nolimits_{m \in M} \log p(x_m | x_{\backslash M}), \quad (8)$$

where x refers to the input tokens of context and response. $\{x_m\}_{m \in M}$ stands for masked tokens and $x_{\backslash M}$ denotes the rest unmasked ones.

To sum up, the objective of the evaluation model is to minimize the following integrated loss:

$$\mathcal{L}^{\text{Evaluation}} = \mathcal{L}^{\text{Evaluation}}_{RCE} + \mathcal{L}^{\text{Evaluation}}_{MLM} \quad (9)$$

2.2 Inference

For open-domain chitchat, the inference is carried out with the second stage's models as follows.

1) Diverse response generation. Conditioned on each latent value $z \in \{1, \cdots, K\}$, its corresponding candidate response r_z is produced by the fine-grained generation model $p(r_z|c, z)$.
2) Response coherence estimation. The evaluation model will preform ranking and select the one with highest coherence value as the final response $r^* = \text{argmax}_{r_z}\, p(l_{r_z} = 1|c, r_z)$.

3 Experiments

3.1 Training Data

PLATO-2 has English and Chinese models, with training data extracted from open-domain social media conversations. The English training data is extracted from Reddit comments, which are collected by a third party and made publicly available on pushshift.io (Baumgartner et al., 2020). To improve the generation quality, we carry out elaborate data cleaning, as discussed in the Appendix. After filtering, the data is split into training and validation sets in chronological order. The training set contains 684M (context, response) samples, ranging from December 2005 to July 2019. For the validation set, 0.2M samples are selected from the rest data after July 2019. The English vocabulary contains 8K BPE tokens (Sennrich et al., 2016), constructed with the SentencePiece library.

The Chinese training data is collected from public domain social medias. After filtering, there are 1.2B (context, response) samples in the training set, 0.1M samples in the validation set, and 0.1M samples in the test set. As for the Chinese vocabulary, it contains 30K BPE tokens.

3.2 Training Details

PLATO-2 has three model sizes: a standard version of 1.6B parameters, a small version of 314M parameters, and a tiny version of 93M parameters. Detailed network and training configurations are summarized in the Appendix. The main hyper-parameters used in the training process are listed as follows. The maximum sequence lengths of context and response are all set to 128. K is set to 20 for the discrete latent variable (Bao et al., 2020; Chen et al., 2019). We use Adam (Kingma and Ba, 2015) as the optimizer, with a learning rate scheduler including a linear warmup and an invsqrt decay (Vaswani et al., 2017). To train the large-scale model with a relatively large batch size, we employ gradient checkpointing (Chen et al., 2016) to trade computation for memory. The training was carried out on 64 Nvidia Tesla V100 32G GPU cards. It takes about 3 weeks for 1.6B parameter model to accomplish curriculum learning process.

3.3 Evaluation Settings

3.3.1 Compared Methods

The following methods have been compared in the experiments.

- PLATO (Bao et al., 2020) is trained on the basis of $\text{BERT}_{\text{BASE}}$ using 8.3M Twitter and Reddit conversations (Cho et al., 2014; Zhou et al., 2018; Galley et al., 2019). There are 132M network parameters in this model.
- DialoGPT (Zhang et al., 2020) is trained on the basis of GPT-2 (Radford et al., 2019) using Reddit comments. There are three model sizes: 117M, 345M and 762M. Since the 345M parameter model obtains the best performance in their evaluations, we compare with this version.
- Blender (Roller et al., 2021) is first trained using Reddit comments and then fine-tuned with human annotated conversations – BST (Smith et al., 2020), to help emphasize desirable conversational skills of engagingness, knowledge, empathy and personality. Blender has three model sizes: 90M, 2.7B and 9.4B. Since the 2.7B parameter model obtains the best performance in their evaluations, we compare with this version.
- Meena (Adiwardana et al., 2020) is an open-domain chatbot trained with social media conversations. There are 2.6B network parameters in Meena. Since Meena has not released the model or provided a service interface, it is difficult to perform comprehensive comparison. In the experiments, we include the provided samples in their paper for static evaluation.
- Microsoft XiaoIce (Zhou et al., 2020) is a popular social chatbot in Chinese. The official Weibo platform is used in the evaluation.

For the sake of comprehensive and fair comparisons, different versions of PLATO-2 are included in the experiments.

- PLATO-2 1.6B parameter model is the standard version in English, which is first trained using Reddit comments and then fine-tuned with BST conversations. To measure the effectiveness of PLATO-2, this model will be compared to the state-of-the-art open-domain chatbot Blender.
- PLATO-2 314M parameter model is a small version in English, which is trained with Reddit comments. This model will be compared to DialoGPT, as they have similar model scales.
- PLATO-2 93M parameter model is a tiny version in English, which is trained with Reddit comments. As it is difficult to scale up PLATO, we use this version to compare with PLATO.
- PLATO-2 336M parameter Chinese model[2] will be compared to XiaoIce in the experiments.

3.3.2 Evaluation Metrics

We carry out both automatic and human evaluations in the experiments. In automatic evaluation, to assess the model's capacity on lexical diversity, we use the corpus-level metric of distinct-1/2 (Li et al., 2016a), which is defined as the number of distinct uni- or bi-grams divided by the total number of generated words.

In human evaluation, we employ four utterance-level and dialogue-level metrics, including coherence, informativeness, engagingness and humanness. Three crowd-sourcing workers are asked to score the response/dialogue quality on a scale of [0, 1, 2], with the final score determined through majority voting. The higher score, the better. These criteria are discussed as follows, with scoring details provided in the Appendix.

- Coherence is an utterance-level metric, measuring whether the response is relevant and consistent with the context.
- Informativeness is also an utterance-level metric, evaluating whether the response is informative or not given the context.
- Engagingness is a dialogue-level metric, assessing whether the annotator would like to talk with the speaker for a long conversation.
- Humanness is also a dialogue-level metric, judging whether the speaker is a human being or not.

3.4 Experimental Results

In the experiments, we include both static and interactive evaluations.

3.4.1 Self-Chat Evaluation

Self-chats have been widely used in the evaluation of dialogue systems (Li et al., 2016b; Bao et al., 2019; Roller et al., 2021), where a model plays the role of both partners in the conversation. As compared with human-bot conversations, self-chat logs can be collected efficiently at a cheaper price. As reported in Li et al. (2019), self-chat evaluations exhibit high agreement with the human-bot chat evaluations. In the experiments, we ask the bot to perform self-chats and then invite crowd-sourcing workers to evaluate the dialogue quality.

The way to start the interactive conversation needs special attention. As pointed out by Roller et al. (2021), if starting with 'Hi!', partners tend

---

[2] This model has 24 transformer blocks and 16 attention heads, with the embedding dimension of 1024. As the Chinese vocabulary contains 30K BPE tokens, this model has 22.5M more parameters than the English small model.

Model	Human Evaluation				Automatic Evaluation		Average Length
	Coherence	Informativeness	Engagingness	Humanness	Distinct-1	Distinct-2	
PLATO	0.568	0.564	0.340	0.280	0.042	0.255	34.961
PLATO-2 93M	0.688	0.672	0.640	0.560	0.047	0.276	18.292
DialoGPT	0.720	0.712	0.340	0.100	0.150	0.508	9.335
PLATO-2 314M	1.572	1.620	1.300	1.160	0.065	0.435	22.732
Blender	1.856	1.816	1.820	1.540	0.117	0.385	16.873
PLATO-2 1.6B	**1.920**	**1.892**	**1.840**	**1.740**	**0.169**	**0.613**	15.736

Table 1: Self-chat evaluation results, with best value written in bold.

Model	Human Evaluation				Automatic Evaluation		Average Length
	Coherence	Informativeness	Engagingness	Humanness	Distinct-1	Distinct-2	
Microsoft XiaoIce	0.869	0.822	0.560	0.260	**0.289**	**0.764**	6.979
PLATO-2 336M Chinese	**1.737**	**1.683**	**1.600**	**1.480**	0.212	0.713	6.641

Table 2: Chinese interactive evaluation results, with best value written in bold.

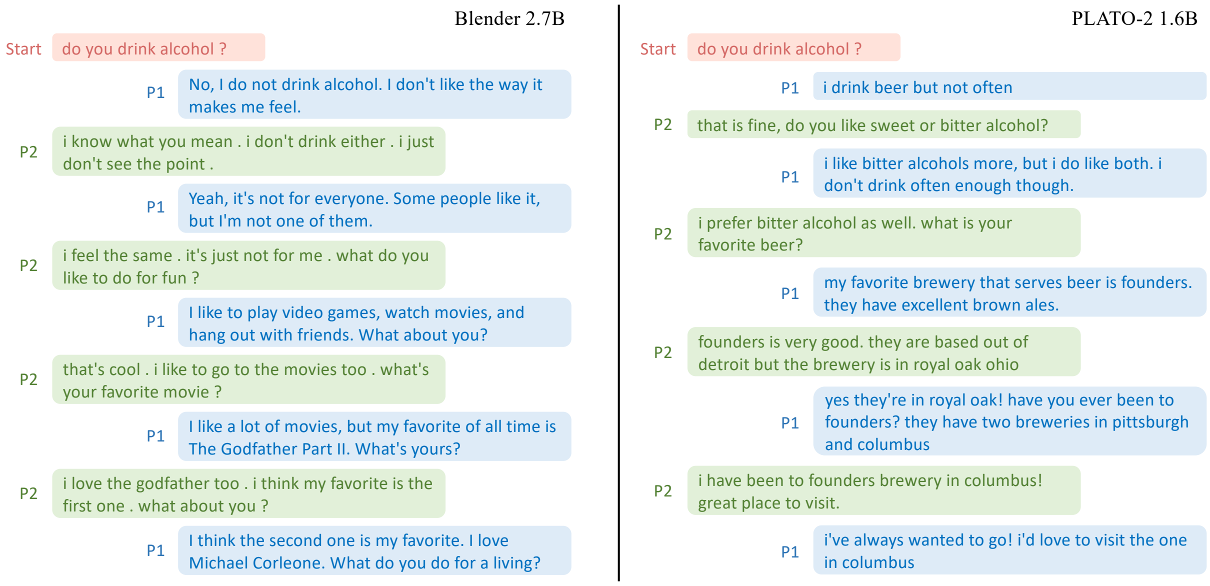
to greet with each other and only cover some shallow topics in the short conversation. Therefore, to expose the model's weaknesses and explore the model's limits, we choose to start the interactive conversation with pre-selected topics. We use the classical 200 questions as the start topic (Vinyals and Le, 2015) and ask the bot to performance self-chats given the context. There are 10 utterances in each dialogue, including the input start utterance. We carry out automatic evaluation on the 200 self-chat logs and randomly select 50 conversations for human evaluation.

The compared models are divided into three groups. The first group includes PLATO 132M model and PLATO-2 93M model. Both of them have similar model scales. The second group includes DialoGPT 345M model and PLATO-2 310M model. Both of them are trained using Reddit comments and have similar model scales. The third group includes Blender 2.7B model and PLATO-2 1.6B model. Both of them are first trained using Reddit comments and further fine-tuned with BST conversations. In human evaluation, two self-chat logs, which are from the same group and have the same start topic, will be displayed to three annotators. One example is given in Figure 3. As suggested in ACUTE-Eval (Li et al., 2019), we ask crowd-sourcing workers to pay attention to only one speaker within a dialogue. In the evaluation, they need to give scores on coherence and informativeness for each P1's utterance, and assess P1's overall quality on engagingness and humanness.

The self-chat evaluation results are summarized in Table 1. These results indicate that PLATO-2 1.6B model obtains the best performance across human and automatic evaluations. In the first group, PLATO-2 achieves better performance than PLATO on a similar model scale, which might mainly result from the stable curriculum learning and large-scale conversation data. In the second group, DialoGPT tends to generate repetitive conversations due to the backward scoring function, resulting in poor performance in interactive evaluation. In the third group, PLATO-2 outperforms the state-of-the-art open-domain chatbot Blender. The gap of Blender and PLATO-2 on the corpus-level metric distinct-1/2 suggests that PLATO-2 has a better capacity on lexical diversity. In addition, the difference among these three groups suggests that enlarging model scales and exploiting human annotated conversations help improve the dialogue quality.

3.4.2 Human-Bot Chat Evaluation

In the Chinese evaluation, it is difficult to carry out self-chats for Microsoft XiaoIce, as there is no public available API. Therefore, we collect human-bot conversations through their official Weibo platform. The interactive conversation also starts with a pre-selected topic and continues for 7-14 rounds. 50 diverse topics are extracted from the high-frequency topics of a commercial chatbot, including travel, movie, hobby and so on. The collected human-bot conversations are distributed to crowd-sourcing



Blender 2.7B

Start: do you drink alcohol ?

P1: No, I do not drink alcohol. I don't like the way it makes me feel.

P2: i know what you mean . i don't drink either . i just don't see the point .

P1: Yeah, it's not for everyone. Some people like it, but I'm not one of them.

P2: i feel the same . it's just not for me . what do you like to do for fun ?

P1: I like to play video games, watch movies, and hang out with friends. What about you?

P2: that's cool . i like to go to the movies too . what's your favorite movie ?

P1: I like a lot of movies, but my favorite of all time is The Godfather Part II. What's yours?

P2: i love the godfather too . i think my favorite is the first one . what about you ?

P1: I think the second one is my favorite. I love Michael Corleone. What do you do for a living?

PLATO-2 1.6B

Start: do you drink alcohol ?

P1: i drink beer but not often

P2: that is fine, do you like sweet or bitter alcohol?

P1: i like bitter alcohols more, but i do like both. i don't drink often enough though.

P2: i prefer bitter alcohol as well. what is your favorite beer?

P1: my favorite brewery that serves beer is founders. they have excellent brown ales.

P2: founders is very good. they are based out of detroit but the brewery is in royal oak ohio

P1: yes they're in royal oak! have you ever been to founders? they have two breweries in pittsburgh and columbus

P2: i have been to founders brewery in columbus! great place to visit.

P1: i've always wanted to go! i'd love to visit the one in columbus

Figure 3: Self-chat examples by Blender and PLATO-2.

workers for evaluation. The human and automatic evaluation results are summarized in Table 2. XiaoIce obtains higher distinct values, which may use a retrieval-based strategy in response generation. The human evaluations indicate that our PLATO-2 model achieves significant improvements over XiaoIce across all the human evaluation metrics.

3.4.3 Static Evaluation

Besides the interactive evaluation, we also employ static evaluation to analyze the model's performance. In static evaluation, each model will produce a response towards the given multi-turn context. Those powerful models are involved in the evaluation: Meena, Blender, DialoGPT and PLATO-2 1.6B. To compare with Meena, we include their provided 60 static samples in the Appendix of the paper and generate corresponding responses with other models. We also include 60 test samples about daily life from Daily Dialog (Li et al., 2017) and 60 test samples about in-depth discussion from Reddit. Given that the measurement of humanness usually needs multi-turn interaction, this metric is excluded from static evaluation. The evaluation results are summarized in Table 3. It can be observed that PLATO-2 is able to produce coherent, informative and engaging responses across different chat scenarios. The average Fleiss's kappa (Fleiss, 1971) of human evaluation is 0.466, indicating annotators have reached moderate agreement.

Model	Meena Samples		
	Coherence	Informativeness	Engagingness

3.5 Discussions

3.5.1 Case Analysis

To further analyze the models' features, two self-chat examples of Blender and PLATO-2 are provided in Figure 3. Although both models are able to produce high-quality engaging conversations, they exhibit distinct discourse styles. Blender tends to switch topics quickly in the short conversation, including alcohol, hobbies, movies and work. The emergence of this style might be related with BST

	Blender Win	Tie	PLATO-2 Win
In-depth Discussion	8	18	**24**

Table 4: In-depth discussion w.r.t. the start topic.

	PLATO-2 Stage-1 Win	Tie	PLATO-2 Stage-2 Win
Engagingness	3	31	**16**
Humanness	6	29	**15**

Table 5: Comparison of the models in PLATO-2.

fine-tuning data. For instance, persona chat in BST is about the exchange of personal information between two partners, where topics need to switch quickly to know more about each other. Due to the task settings of data collection, some human annotated conversations might be a little unnatural. Nevertheless, fine-tuning with BST conversations is essential to mitigate undesirable toxic traits of large corpora and emphasize desirable skills of human conversations.

Distinct with Blender, PLATO-2 can stick to the start topic and conduct in-depth discussions. The reasons might be two-fold. First, our model is able to generate diverse and informative responses with the accurate modeling of one-to-many relationship. Second, the evaluation model helps select the coherent response and stick to current topic. We asked crowd-sourcing workers to annotate which model's in-depth discussion is better w.r.t. the start topic. The comparison result is shown in Table 4, which also verifies our above analysis on discourse styles.

3.5.2 Why PLATO-2 Performs Better?

Why PLATO-2 achieves better performance as compared with Meena, Blender and other state-of-the-art models? As analyzed above, major reasons might come from two aspects: fine-grained generation and evaluation. First, PLATO-2 employs discrete latent variable for the one-to-many relationship modeling, which is able to generate high-quality and diverse responses. Second, the evaluation model in PLATO-2 is effective at selecting the most appropriate response from the candidates.

In fact, these two aspects are associated with the curriculum learning in the second stage, modeling the one-to-many relationship for open-domain conversations. By contrast, Meena and Blender are learned under the one-to-one mapping relationship, similar to the first stage in PLATO-2. To dissect the effects of these two stage models, we further ask crowd-sourcing workers to evaluate the models' self-chat logs on the dialogue-level metrics. The comparison results are summarized in Table 5. These results verify the effectiveness of curriculum learning in PLATO-2.

3.5.3 Further Exploration of PLATO-2

In addition to open-domain chitchat, there are two other kinds of dialogues in conversational AI (Gao et al., 2018): knowledge grounded dialogue, and task-oriented conversation. Similar to open-domain conversation, the one-to-many mapping relationship also exists in knowledge grounded dialogue (Kim et al., 2020): given a dialogue context, multiple pieces of knowledge might be applicable for the response generation. Therefore, the one-to-many mapping models of the second stage can also be adapted for knowledge grounded dialogue. By expanding the network input with the knowledge segment, the background knowledge is encoded and grounded for response generation. Distinct from the open-domain conversation and knowledge grounded dialogue, task-oriented conversations usually need to accomplish a specific goal. Accordingly, the conversation flow would become less diverse and concentrated on task completion. Therefore, the one-to-one mapping generation model of the first stage can be used for the end-to-end task-oriented conversation.

For the exploration of PLATO-2 two-stage framework, we participated in several tasks of DSTC9 (Gunasekara et al., 2020), including interactive evaluation of open-domain conversation (Track3-task2), static evaluation of knowledge grounded dialogue (Track3-task1), and end-to-end task-oriented conversation (Track2-task1). PLATO-2 has achieved the first place in all three tasks (Bao et al., 2021). To sum up, the benefits brought by the two-stage curriculum learning in PLATO-2 are two-fold. Firstly, given the difficulties to scale up PLATO, the two-stage curriculum learning is an essential ingredient for the successful training of 1.6B parameter PLATO-2. Secondly, the two-stage PLATO-2 adapts well to multiple conversational tasks, indicating its potentials as a unified pre-training framework for conversational AI.

4 Related Work

Related works include large-scale language models and open-domain dialogue generation.

Large-scale Language Models. Pre-trained large-scale language models have brought many breakthroughs on various NLP tasks. GPT (Radford et al., 2018) and BERT (Devlin et al., 2019) are representative uni-directional and bi-directional language models, trained on general text corpora. By introducing pre-normalization and modifying weight initialization, GPT-2 (Radford et al., 2019) successfully extends the model scale from 117M to 1.5B parameters. To cope with memory constraints, Megatron-LM (Shoeybi et al., 2019) exploits model parallelism to train an 8.3B parameter model on 512 GPUs. GPT-3 (Brown et al., 2020) further trains an 175B parameter autoregressive language model, demonstrating strong performance on many NLP tasks. The development of large-scale language models is also beneficial to the task of dialogue generation.

Open-domain Dialogue Generation. On the basis of GPT-2, DialoGPT (Zhang et al., 2020) is trained for response generation using Reddit comments. To obtain a human-like open-domain chatbot, Meena (Adiwardana et al., 2020) scales up the network parameters to 2.6B and utilizes more social media conversations in the training process. To emphasize desirable conversational skills of engagingness, knowledge, empathy and personality, Blender (Roller et al., 2021) further fine-tunes the pre-trained model with human annotated conversations. In addition to the attempts on model scale and data selection, PLATO introduces discrete latent variable to tackle the inherent one-to-many mapping problem to improve response quality. In this work, we explore the effective training of PLATO-2 via curriculum learning.

5 Conclusion

In this work, we discuss the effective training of open-domain chatbot PLATO-2 via curriculum learning, where two stages are involved. In the first stage, one coarse-grained model is trained for general response generation. In the second stage, two models of fine-grained generation and evaluation are trained for diverse response generation and response coherence estimation. Experimental results demonstrate that PLATO-2 achieves substantial improvements over the state-of-the-art methods in both Chinese and English evaluations.

A Data Cleaning Process

PLATO-2 has English and Chinese models, with training data extracted from open-domain social media conversations. As the comments are formatted in message trees, any conversation path from the root to a tree node can be treated as one training sample, with the node as response and its former turns as context. To improve the generation quality, we carry out elaborate data cleaning. A message node and its sub-trees will be removed if any of the following conditions is met.

1) The number of BPE tokens is more than 128 or less than 2.
2) Any word has more than 30 characters or the message has more than 1024 characters.
3) The percentage of alphabetic characters is less than 70%.
4) The message contains URL.
5) The message contains special strings, such as r/, u/, &amp.
6) The message has a high overlap with the parent's text.
7) The message is repeated more than 100 times.
8) The message contains offensive words.
9) The subreddit is quarantined.
10) The author is a known bot.

After data cleaning, the English training data contains 684M (context, response) samples and the Chinese training data contains 1.2B (context, response) samples. Each English/Chinese sample has 2.78/2.82 utterances and each utterance has 26.29/22.20 tokens on average.

B Training Configurations

PLATO-2 has three model sizes: a standard version of 1.6B parameters, a small version of 314M parameters, and a tiny version of 93M parameters. The 1.6B parameter model has 32 transformer blocks and 32 attention heads, with the embedding dimension of 2048. The 314M parameter model has 24 transformer blocks and 16 attention heads, with the embedding dimension of 1024. The 93M parameter model has 12 transformer blocks and 12 attention heads, with the embedding dimension of 768. The training configurations of PLATO-2 1.6B are provided in Table 6. The training was carried out on 64 Nvidia Tesla V100 32G GPU cards. It takes about 3 weeks for the 1.6B parameter model to accomplish the curriculum learning process.

C Chinese Case Analysis

We also provide two human-bot chat examples of XiaoIce and PLATO-2 in Figure 4, with original interactive logs shown on the left and translated logs on the right. It can be observed that some responses produced by XiaoIce are not coherent with the contexts and there are some abrupt changes of topics. By contrast, the interaction with PLATO-2 is more coherent and engaging.

D Scoring Criteria in Human Evaluation

The criteria used in human evaluation are provided in Table 7.

Model	Stage	Batch Size	Learning Rate	Warmup Steps	Training Steps
PLATO-2 1.6B Parameter	1. Coarse-grained Generation	524,288	5e-4	3125	20w
	2.1. Fine-grained Generation	65,536	1e-5	3125	10w
	2.2. Evaluation	524,288	5e-5	3125	10w

Table 6: Training configurations of PLATO-2.

Human All right.
Bot Bring yourself as well, lol

Figure 4: Human-bot chat examples by Microsoft XiaoIce and PLATO-2.

Score	Coherence
0	• The response is not related with the context. • The response simply repeats the context. • The response has obvious conflicts with the context. • There are serious logic conflicts within the response.
1	• The response has minor conflicts with the context. • There are some minor logic conflicts in the response.
2	• The response is coherent with the context.

Score	Informativeness
0	• The response doesn't contain any information. • This response just repeats the context and fails to bring any additional information. • The information is invalid, as the coherence score is 0.
1	• The information has conflicts with common sense. • There are factual errors in the response.
2	• The response has appropriate and correct information.

Score	Engagingness
0	• I don't want to talk with this speaker.
1	• It is kind of boring, but it is still ok to talk with this speaker.
2	• I would like to talk with this speaker for a long conversation.

Score	Humanness
0	• This speaker seems like a bot.
1	• This speaker gives unnatural responses occasionally and seems not that human-like.
2	• This speaker seems like a human being.

Table 7: Score details of four metrics in human evaluation.

E Response Selection Comparison

We carry out more experiments to compare the performance of distinct scoring functions in response selection. Firstly, one Chinese response selection dataset is constructed: 100 dialogue contexts are selected from the test set and 10 candidate responses are retrieved for each context with a commercial chatbot. Secondly, we ask crowd-sourcing workers to annotate the label whether the candidate response is coherent with the context. Thirdly, we train three 336M parameter models as the scoring function, including the forward response generation probability $p(r|c)$, the backward context recover probability $p(c|r)$ and the bi-directional coherence probability $p(l_r|c,r)$. Their results on the annotated response selection dataset are summarized in Table 8. The metrics of mean average precision (MAP), mean reciprocal rank (MRR) and precision at position 1 (P@1) are employed. These results indicate that PLATO-2's evaluation model is better at selecting appropriate responses.

Score Function	MAP	MRR	P@1
$p(r\|c)$	0.705	0.790	0.700
$p(c\|r)$	0.672	0.737	0.610
$p(l_r\|c,r)$	**0.754**	**0.819**	**0.750**

Table 8: Comparison of different score functions in response selection, with best value written in bold.

JointGT: Graph-Text Joint Representation Learning for Text Generation from Knowledge Graphs

Abstract

Existing pre-trained models for knowledge-graph-to-text (KG-to-text) generation simply fine-tune text-to-text pre-trained models such as BART or T5 on KG-to-text datasets, which largely ignore the graph structure during encoding and lack elaborate pre-training tasks to explicitly model graph-text alignments. To tackle these problems, we propose a graph-text joint representation learning model called JointGT. During encoding, we devise a structure-aware semantic aggregation module which is plugged into each Transformer layer to preserve the graph structure. Furthermore, we propose three new pre-training tasks to explicitly enhance the graph-text alignment including respective text / graph reconstruction, and graph-text alignment in the embedding space via Optimal Transport. Experiments show that JointGT obtains new state-of-the-art performance on various KG-to-text datasets[1].

1 Introduction

Knowledge-graph-to-text (KG-to-text) generation aims to generate high-quality texts which are consistent with input graphs (Gardent et al., 2017). This task requires to simultaneously encode the graph structure and the content, and effectively leverage the input graphs in the decoding process (Zhao et al., 2020). As a major natural language generation (NLG) task that connects knowledge graphs and texts, this task can further promote the applicability of knowledge graphs in more realistic NLG scenarios, such as knowledge-grounded dialogue generation (Zhou et al., 2018a) and story generation (Guan et al., 2019; Ji et al., 2020).

Due to the limited amount of graph-text parallel data, it's hard for typical neural text generation models to learn the alignments between source entities / relations and target tokens from scratch (Guo et al., 2020; Fu et al., 2020). Recent work resorts to constructing general-purpose pre-trained language models for KG-to-text generation. The most common and simple way is to linearize input graphs into text sequences, and directly fine-tune text-to-text Transformer-based pre-trained models like GPT (Radford et al., 2018, 2019), BART (Lewis et al., 2020) or T5 (Raffel et al., 2020) on KG-to-text datasets (Ribeiro et al., 2020a; Kale and Rastogi, 2020). Benefiting from self-supervised pre-training on large-scale unlabelled text corpora, pre-trained language models can generate high-quality texts via simply fine-tuning, and outperform other models with sophisticated structures.

Despite the superior performance of fine-tuning pre-trained models on KG-to-text datasets, we argue that building pre-trained models for KG-to-text generation still faces two major challenges: 1) **Structural information loss during encoding**. Most of the existing pre-trained models capture contextual information via bidirectional Transformers (Devlin et al., 2019), which include full attention connections. This model structure may neglect the structural information when encoding knowledge graphs since the relation between each pair of input entities is not explicitly considered (Zhu et al., 2019). 2) **Absence of explicit graph-text alignments**. Existing work on pre-trained models for text generation commonly adopts auto-encoding or auto-regressive text reconstruction to learn text-text alignments, which encodes the corrupted text sequence and decodes the original sequence (Lewis et al., 2020; Raffel et al., 2020). Since knowledge graphs may possess more complex structures than text sequences, it's hard to explicitly learn graph-text alignments by directly using the pre-training tasks based on text reconstruction.

Thus, we propose a graph-text joint represen-

tation learning framework called *JointGT* to deal with the above challenges. **Firstly**, to alleviate the structural information loss during encoding, we devise a simple structure-aware semantic aggregation module at each Transformer layer to aggregate contextual information following the graph structure. **Secondly**, we propose three pre-training tasks including graph enhanced text reconstruction, text enhanced graph reconstruction, and graph-text embedding alignment to explicitly build the connection between knowledge graphs and text sequences. The first two tasks are expected to enhance the graph-text alignment in the discrete vocabulary space, where our model is required to predict the masked information of graphs / texts based on the observed information of texts / graphs. And the third task is designed to model the graph-text alignment in the continuous embedding space via Optimal Transport (Peyré and Cuturi, 2019) to match the hidden representations of graphs and texts. Our contributions are as follows:

- We propose a novel pre-trained model called JointGT for KG-to-text generation tasks. This model adopts a structure-aware semantic aggregation module to model the structure of an input graph at each Transformer layer, and utilizes three pre-training tasks to explicitly learn graph-text alignments in the discrete and continuous spaces.
- We conduct experiments on the datasets of KG-to-text generation including WebNLG, WebQuestions and PathQuestions. Results show that JointGT achieves new state-of-the-art performance on KG-to-text generation.

2 Related Work

KG-to-Text Generation

Recent studies on KG-to-text generation tasks mainly fall into three aspects: 1) *Encoder modification*: To alleviate the structural information loss of sequence encoders with the input of linearized graphs (Gardent et al., 2017; Trisedya et al., 2018; Moryossef et al., 2019), researchers focus on more complex encoder structures for better graph representations, such as graph neural networks (Marcheggiani and Perez-Beltrachini, 2018; Ribeiro et al., 2020b) and graph Transformers (Koncel-Kedziorski et al., 2019; Schmitt et al., 2020a). 2) *Unsupervised training*: researchers devise unsupervised training objectives to jointly learn the tasks of graph-to-text and text-to-graph conversion with non-parallel graph-text data (Schmitt et al., 2020b; Guo et al., 2020; Jin et al., 2020). 3) *Building pre-trained models*: With the development of pre-trained NLG models such as GPT (Radford et al., 2018, 2019), BART (Lewis et al., 2020) and T5 (Raffel et al., 2020), recent work directly fine-tunes these models on graph-to-text datasets and reports impressive performance (Ribeiro et al., 2020a; Kale and Rastogi, 2020; Chen et al., 2020b; Mager et al., 2020).

Compared with the existing work on pre-trained models for KG-to-text generation, our model utilizes pre-training methods to explicitly learn graph-text alignments instead of directly fine-tuning text-to-text pre-trained models on KG-to-text datasets.

KG-Enhanced Pre-Trained Models

Another line of related studies is pre-trained models enhanced by knowledge graphs for natural language understanding (NLU). The motivation of these models is to incorporate knowledge graphs into pre-trained models to facilitate the understanding of entities and relations in natural language. Early work including ERNIE (Zhang et al., 2019) and KnowBERT (Peters et al., 2019) directly uses fixed entity embeddings based on TransE (Bordes et al., 2013) or word vectors (Mikolov et al., 2013) during pre-training. Recent work like KEPLER (Wang et al., 2021) and JAKET (Yu et al., 2020) resorts to jointly pre-training graph-text representations. Specifically, they encode the textual descriptions of entities with pre-trained language models as entity embeddings and jointly optimize the knowledge embedding objective and the masked language modeling objective.

In comparison, our model focuses on joint pre-training methods on knowledge graph encoding and sequence decoding in KG-to-text generation tasks, rather than considering graph-text joint encoding methods in NLU tasks.

3 Method

3.1 Task Definition and Model Overview

Given a knowledge graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V} = \{e_1, e_2, \cdots, e_{|\mathcal{V}|}\}$ denotes the entity set and $\mathcal{E} = (r_{ij})_{|\mathcal{V}|\times|\mathcal{V}|}$ indicates the relations connecting the entities, and its linearized version $\mathcal{G}_{linear} = (w_1, w_2, \cdots, w_m)$ which consists of m tokens, our goal is to generate a text sequence $X = (x_1, x_2, \cdots, x_n)$ which is consistent with the input graph.

Our model is built on pre-trained encoder-decoder models like BART (Lewis et al., 2020) and T5 (Raffel et al., 2020). First of all, we follow the existing work (Chen et al., 2020b) to linearize knowledge graphs in the form of triple lists (as shown in Figure 1), and devise a simple structure-aware semantic aggregation module which is plugged into each Transformer layer of the encoder to preserve the structural information of input graphs (§3.2). Then, we propose three pre-training tasks including graph / text reconstruction in the discrete vocabulary space and graph-text matching in the continuous embedding space, which enable our model to jointly learn the representations of knowledge graphs and texts (§3.3).

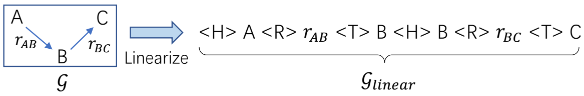

Figure 1: Illustration of linearizing knowledge graphs into text sequences. The special tokens <H>, <R> and <T> mean the head entity, relation and tail entity in the knowledge triples, respectively.

3.2 Model Structure

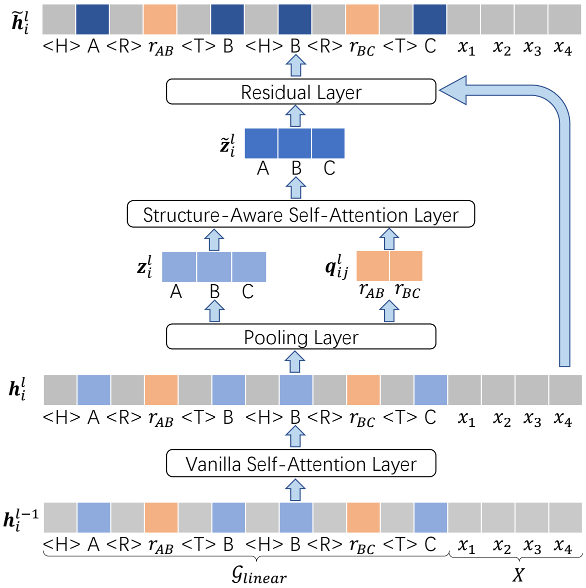

Figure 2: Structure-aware semantic aggregation module at each layer of the Transformer encoder. This module contains a pooling layer to obtain the contextual semantic representations of entities (z_i^l) and relations (q_{ij}^l) from the output of the vanilla self-attention layer (h_i^l), a structure-aware self-attention layer to aggregate the entity representations ($\tilde{z}_i^l$) based on the graph structure, and a residual layer to fuse the contextual and structural representations ($\tilde{h}_i^l$).

To simultaneously leverage the contextual representation from pre-trained models and preserve the structural information, we devise a structure-aware semantic aggregation module in the Transformer encoder. Assume that the input of our encoder during pre-training is the linearized graph $\mathcal{G}_{linear}$ and the corresponding text sequence X (which may be corrupted or empty in some pre-training tasks), the self-attention layer in the l-th Transformer layer can be formulated as follows[2]:

$$\begin{aligned} \boldsymbol{h}_i^l &= \sum_{j=1}^{m+n} \alpha_{ij}^l (\boldsymbol{h}_j^{l-1} \boldsymbol{W}^V) \\ \alpha_{ij}^l &= \frac{\exp(t_{ij}^l)}{\sum_{p=1}^{m+n} \exp(t_{ip}^l)} \\ t_{ij}^l &= \frac{\left(\boldsymbol{h}_i^{l-1} \boldsymbol{W}^Q\right) \left(\boldsymbol{h}_j^{l-1} \boldsymbol{W}^K\right)^\top}{\sqrt{d_k}} \\ & i = 1, 2, \cdots, m+n \end{aligned} \tag{1}$$

where $\boldsymbol{W}^Q, \boldsymbol{W}^K, \boldsymbol{W}^V$ are the model parameters and d_k denotes the dimension of query / key / value vectors. The fully-connected attention captures rich contextual semantic relationship among the entities, relations and the tokens of text sequences, but is not sufficient to encode the structural information of input graphs. Thus, we devise a structure-aware semantic aggregation module on top of vanilla self-attention, as shown in Figure 2. First of all, we utilize a mean pooling layer[3] to obtain the representation of each entity and relation from the output of the vanilla self-attention layer:

$$\begin{aligned} \boldsymbol{z}_i^l &= \text{pooling}(\{\boldsymbol{h}_p^l | p \in \mathcal{P}(e_i), 1 \leq p \leq m\}) \\ \boldsymbol{q}_{ij}^l &= \text{pooling}(\{\boldsymbol{h}_p^l | p \in \mathcal{P}(r_{ij}), 1 \leq p \leq m\}) \\ & i = 1, \cdots, |\mathcal{V}|; \quad j = 1, \cdots, |\mathcal{V}| \end{aligned} \tag{2}$$

where $\mathcal{P}(e_i)/\mathcal{P}(r_{ij})$ means the set of positions occupied by e_i / r_{ij} in the linearized graph. Note that $\boldsymbol{q}_{ij}^l$ will be set to an all-zero vector if there is no relation between e_i and e_j. Then we update entity representations with a structure-aware self-

---

[2] We take a single attention head as an example in this section. In practice, we use our proposed method in the multi-head attention.

[3] We find that there is no significant difference in the model performance between mean pooling and other aggregation functions like max pooling.

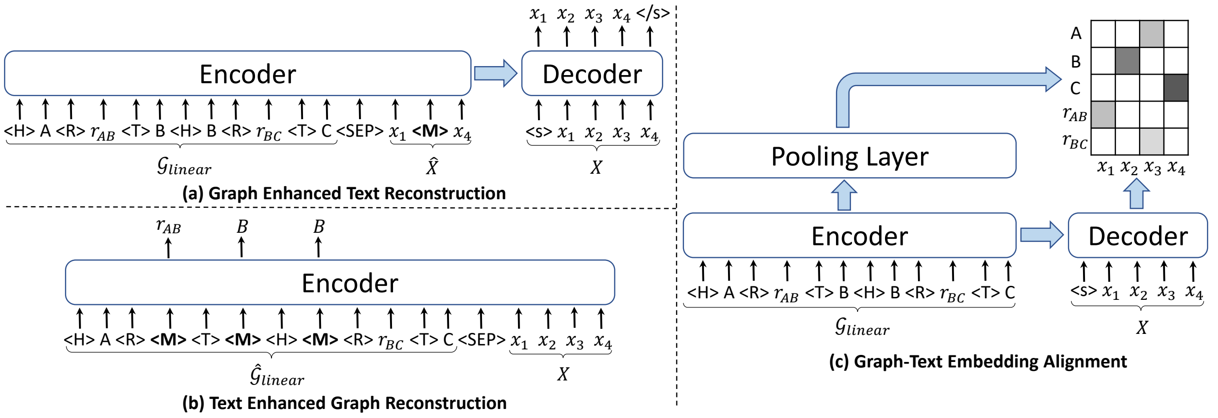

Figure 3: Overview of our proposed pre-training tasks: (a) Graph enhanced text reconstruction: reconstructing the text sequence given the complete graph. (b) Text enhanced graph reconstruction: predicting the masked entities and relations of the corrupted graph conditioned on the complete text. (c) Graph-text embedding alignment: matching the embedding vectors of the knowledge graph and the text via Optimal Transport. The special token <SEP> is to separate the linearized graph and the text, while <M> denotes the placeholder for masked tokens.

attention layer (Shaw et al., 2018):

$$\begin{aligned}\tilde{\boldsymbol{z}}_i^l &= \sum_{j=1}^{|\mathcal{V}|} \beta_{ij}^l (\boldsymbol{z}_j^l \boldsymbol{W}^{VS} + \boldsymbol{q}_{ij}^l \boldsymbol{W}^{VR}) \\ \beta_{ij}^l &= \frac{\exp(u_{ij}^l)}{\sum_{p=1}^{|\mathcal{V}|} \exp(u_{ip}^l)} \qquad (3)\end{aligned}$$

$$u_{ij}^l = \frac{\left(\boldsymbol{z}_i^l \boldsymbol{W}^{QS}\right)\left(\boldsymbol{z}_j^l \boldsymbol{W}^{KS} + \boldsymbol{q}_{ij}^l \boldsymbol{W}^{KR}\right)^\top}{\sqrt{d_k}}$$
$$i = 1, 2, \cdots, |\mathcal{V}|$$

where $\boldsymbol{W}^{QS}, \boldsymbol{W}^{KS}, \boldsymbol{W}^{VS}, \boldsymbol{W}^{KR}, \boldsymbol{W}^{VR}$ are the weight matrices in the structure-aware self-attention. This layer integrates the contextual semantic representation of entities and relations based on the graph structure, thereby injecting the structural information into the vanilla Transformer layer. Finally, we use a residual layer to fuse semantic and structural representations of entities, and obtain the hidden states for the following computation:

$$\tilde{\boldsymbol{h}}_i^l = \begin{cases} \boldsymbol{h}_i^l + \tilde{\boldsymbol{z}}_j^l, & i \in \mathcal{P}(e_j) \\ \boldsymbol{h}_i^l, & otherwise. \end{cases} \qquad (4)$$
$$i = 1, \cdots, m+n; \quad j = 1, \cdots, |\mathcal{V}|$$

Compared with existing structure-aware Transformer encoders (Zhu et al., 2019; Song et al., 2020) that either use the entity and relation embeddings from an external knowledge embedding model or directly learn them as model parameters, our encoder obtains the entity and relation embeddings via contextual semantic representations. This design fully employs the effective contextual representations from the existing pre-trained models while preserving the structural information, and enables our model to generalize to new entities and relations better when fine-tuned to the datasets with a different knowledge graph.

3.3 Pre-Training Task

Given the input graph $\mathcal{G}$ and its corresponding text sequence X, the goal of our pre-training task is to jointly learn the graph encoder and sequence decoder to enhance graph-text alignments, which can benefit the downstream tasks of KG-to-text generation. We devise three pre-training tasks to explicitly learn graph-text alignments in both discrete and continuous spaces.

3.3.1 Graph Enhanced Text Reconstruction

The purpose of graph enhanced text reconstruction is to recover the masked text sequence based on the complete knowledge graph, as shown in Figure 3. Assume that $\hat{X}$ denotes the masked text sequence, we can formulate the loss function of this pre-training task as follows:

$$\begin{aligned}\mathcal{L}_{text} &= -\log P(X|\mathcal{G}, \hat{X}) \\ &= -\sum_{i=1}^{n} \log P(x_i|\mathcal{G}, \hat{X}, x_{<i}) \qquad (5)\end{aligned}$$

To construct $\hat{X}$, we masked the entity words with a probability of 40% and other words with 20% since entity words are more important in the task of KG-to-text generation. We also follow the existing work (Lewis et al., 2020) to merge the consecutive mask tokens into one mask token to increase the difficulty of text reconstruction. This task enables our model to utilize the knowledge graph to reconstruct the corrupted text sequence, which explores the connection between them in the discrete vocabulary space.

3.3.2 Text Enhanced Graph Reconstruction

As shown in Figure 3, this pre-training task aims to recover the corrupted graph according to the information of the text sequence. Given the corrupted knowledge graph $\hat{\mathcal{G}}$ with masked entities and relations, and the complete text sequence X, the loss function is to recover the masked entities and relations in the linearized knowledge graph:

$$\begin{aligned}\mathcal{L}_{graph} &= -\log P(\mathcal{G}|\hat{\mathcal{G}}, X)\\ &= -\sum_{i=1}^{m} M_i \log P(w_i|\hat{\mathcal{G}}, X) \qquad (6)\end{aligned}$$

where M_i denotes an indicator function and equals 1 if and only if w_i is masked. We empirically set the masking probability of entities / relations as 40% / 20%. This task explicitly exerts the impact of the text on the graph reconstruction, thereby guiding the encoder to focus more on the entities and relations that may appear in the text.

3.3.3 Graph-Text Embedding Alignment

This pre-training task is devised to encourage the graph-text alignment in the embedding space. We use Optimal Transport (OT), which is commonly used in the cross-domain alignment (Chen et al., 2020a), to calculate the minimum cost of transporting the graph representation from the encoder to the text representation from the decoder (and vice versa). As shown in Figure 3, the input of the encoder is the linearized knowledge graph $\mathcal{G}_{linear}$ while the input of the decoder is the text sequence X. Assume that $\boldsymbol{H}^L = (\boldsymbol{h}_1^L, \boldsymbol{h}_2^L, \cdots, \boldsymbol{h}_m^L)$ indicates the final hidden states of the encoder, we can similarly acquire the entity and relation representations via mean pooling:

$$\begin{aligned}\boldsymbol{z}_i^L &= \text{pooling}(\{\boldsymbol{h}_p^L | p \in \mathcal{P}(e_i), 1 \leq p \leq m\})\\ \boldsymbol{q}_{ij}^L &= \text{pooling}(\{\boldsymbol{h}_p^L | p \in \mathcal{P}(r_{ij}), 1 \leq p \leq m\})\\ & i = 1, \cdots, |\mathcal{V}|; \quad j = 1, \cdots, |\mathcal{V}| \qquad (7)\end{aligned}$$

Let $\mathcal{G}_{seq} = \mathcal{V} \cup \mathcal{E} = (g_1, g_2, \cdots, g_{|\mathcal{V}|+|\mathcal{E}|})$ denotes the sequence of all the entities and relations in $\mathcal{G}$, we can directly obtain the contextual embedding vectors $\boldsymbol{H}^{\mathcal{G}} = (\boldsymbol{h}_1^{\mathcal{G}}, \cdots, \boldsymbol{h}_{|\mathcal{V}|+|\mathcal{E}|}^{\mathcal{G}})$ for each entity and relation from Equation 7. We can also acquire the embedding vectors of X from the decoder's final hidden states, which is denoted by $\boldsymbol{S} = (\boldsymbol{s}_1, \boldsymbol{s}_2, \cdots, \boldsymbol{s}_n)$.

To model the alignment between graphs and texts in the embedding space, we regard $\mathcal{G}_{seq}$ as a discrete distribution $\boldsymbol{\mu} = \sum_{i=1}^{|\mathcal{V}|+|\mathcal{E}|} \boldsymbol{a}_i \delta_{g_i}$ and X as $\boldsymbol{v} = \sum_{j=1}^{n} \boldsymbol{b}_j \delta_{x_j}$, where $\boldsymbol{a} = \{\boldsymbol{a}_i\}_{i=1}^{|\mathcal{V}|+|\mathcal{E}|}$ and $\boldsymbol{b} = \{\boldsymbol{b}_j\}_{j=1}^{n}$ satisfy $\sum_{i=1}^{|\mathcal{V}|+|\mathcal{E}|} \boldsymbol{a}_i = \sum_{j=1}^{n} \boldsymbol{b}_j = 1$, and δ_{g_i} / δ_{x_j} indicates the Dirac function centered on g_i / x_j. Then, we utilize the OT distance between $\boldsymbol{\mu}$ and $\boldsymbol{v}$ as the loss function, which is defined as the solution of the following problem:

$$\mathcal{L}_{OT} = \min_{\boldsymbol{T} \in \Pi(\boldsymbol{a}, \boldsymbol{b})} \sum_{i=1}^{|\mathcal{V}|+|\mathcal{E}|} \sum_{j=1}^{n} \boldsymbol{T}_{ij} \cdot d(g_i, x_j) \qquad (8)$$

$$\begin{aligned}\Pi(\boldsymbol{a}, \boldsymbol{b}) = \{\boldsymbol{T} \in \mathbb{R}_+^{(|\mathcal{V}|+|\mathcal{E}|) \times n} | \boldsymbol{T} \cdot \mathbf{1}_n = \boldsymbol{a},\\ \boldsymbol{T}^\top \cdot \mathbf{1}_{|\mathcal{V}|+|\mathcal{E}|} = \boldsymbol{b}\}\end{aligned}$$

where $\boldsymbol{T}$ denotes a transport plan, $\mathbf{1}_{|\mathcal{V}|+|\mathcal{E}|}$ / $\mathbf{1}_n$ indicates the $(|\mathcal{V}| + |\mathcal{E}|)$ / n -dimensional all-one vector respectively, and $d(g_i, x_j)$ is the cost function of transporting g_i to x_j. We follow the existing work (Chen et al., 2020c) to adopt the cosine distance between the contextual embedding vectors of g_i and x_j as the cost function, which is defined as $d(g_i, x_j) = 1 - \frac{\boldsymbol{h}_i^{\mathcal{G}} \boldsymbol{s}_j}{\|\boldsymbol{h}_i^{\mathcal{G}}\|_2 \|\boldsymbol{s}_j\|_2}$. Since the exact minimization over $\boldsymbol{T}$ is computationally intractable, we utilize IPOT algorithm (Xie et al., 2019) to approximate the OT distance and iteratively obtain the solution of $\boldsymbol{T}$ (more details are provided in the Appendix A). After solving $\boldsymbol{T}$, $\mathcal{L}_{OT}$ can serve as an alignment loss to optimize the model parameters. This task builds the connection between the contextual embedding vectors of knowledge graphs and texts, and explicitly promotes the graph-text alignment in the continuous space.

4 Experiment

4.1 Pre-training Dataset and Implementation

We used KGTEXT (Chen et al., 2020b) as our pre-training dataset. This dataset contains 7M graph-text data pairs, where texts are crawled from English Wikidump[4] and the corresponding knowledge graphs are acquired by querying WikiData with the

Table 2: Statistics of pre-training and fine-tuning datasets, including the total number of entities and relations, the data split, the average number of triples, and the average length of texts.

Since our model can adapt to Transformer-based pre-trained models with the encoder-decoder framework, we chose BART (Lewis et al., 2020) and T5 (Raffel et al., 2020) as the base model in this paper, which are denoted by JointGT (BART) and JointGT (T5), respectively. The hyper-parameters of the Transformer blocks were the same as BART-base and T5-base because of the limited computational resources. We initialized our model parameters with the pre-trained checkpoint of BART-base / T5-base except for the structure-aware semantic aggregation module, which was randomly initialized. We followed BART / T5 to use Byte-Pair Encoding (BPE) vocabulary (Radford et al., 2019) with the size of 50,265 / WordPiece vocabulary (Kudo and Richardson, 2018) with the size of 32,000. The batch size was 42 / 32 for JointGT (BART) / JointGT (T5). The maximum length of linearized input graphs was 600, while the maximum length of text sequences was 64. We adopted Adam (Kingma and Ba, 2015) as the optimizer and set the learning rate to be 3e-5. The warmup ratio was 0.1. JointGT was pre-trained on KGTEXT for 1 epoch with the proposed pre-training tasks. It took 44 / 69 hours for JointGT (BART) / JointGT (T5) on 3 NVIDIA Quadro RTX 6000 GPUs.

4.2 Fine-Tuning Settings

We adopted WebNLG, WebQuestions and Path Questions as the benchmark datasets during fine-tuning, and provided the statistics in Table 2.

WebNLG: This dataset aims to convert RDF triples into a textual description. We followed the existing work (Chen et al., 2020b) to use the version of 2.0 (Shimorina and Gardent, 2018). This dataset contains two official data splits: the traditional split (Unconstrained) which guarantees that there is no overlap of input graphs among train / validation / test sets, and a more challenging split (Constrained) where the non-overlap constraint is applied to the triples of input graphs. We denoted these two data splits as *WebNLG(U)* and *WebNLG(C)* in our paper. We followed the preprocessing steps of the existing work (Chen et al., 2020b) to replace the underlines in the entities and relations with spaces, and split the entities and relations in a camel case into multiple words.

WebQuestions: This dataset (Yih et al., 2016; Talmor and Berant, 2018) is the benchmark for question generation over knowledge bases (KBQG), whose purpose is to generate natural language questions about the corresponding knowledge graphs (Serban et al., 2016). It is constructed from two question answering datasets, i.e., WebQuestionsSP (Yih et al., 2016) and ComplexWebQuestions (Talmor and Berant, 2018). These two datasets contain natural language questions, SPARQL queries and answer entities. We converted the SPARQL query to return a subgraph, and used the same preprocessing steps and data splits as the existing work (Kumar et al., 2019; Chen et al., 2020d).

PathQuestions: Similar to WebQuestions, the PathQuestions dataset is also the benchmark for KBQG, which is constructed from a question answering dataset (Zhou et al., 2018b). The main

Model	Fluency			κ	Adequacy			κ
	Win (%)	Lose (%)	Tie (%)		Win (%)	Lose (%)	Tie (%)	
JointGT (BART) vs. BART	29.0*	19.7	51.3	0.413	26.3**	16.0	57.7	0.517
JointGT (T5) vs. T5	23.7	18.7	57.6	0.405	22.7*	16.3	61.0	0.424

Table 3: Human evaluation on WebNLG(U). The scores indicate the percentages of win, lose and tie when JointGT is compared with other baselines. κ is Fleiss' Kappa (all indicate moderate agreement). The scores marked with * mean $p < 0.05$ while ** means $p < 0.01$ in sign test.

difference is that the knowledge graph in PathQuestions is a 2-hop / 3-hop path between two entities. We used the same preprocessing steps and data splits as the existing work (Kumar et al., 2019; Chen et al., 2020d).

More detailed fine-tuning settings including the search space and the best assignment of hyperparameters on the downstream datasets are reported in the Appendix B.

4.3 Baselines

We chose the following two categories of models as our baselines:

Pre-Trained Models: We adopted KGPT (Chen et al., 2020b), BART (Lewis et al., 2020) and T5 (Raffel et al., 2020) as the pre-trained baselines. KGPT is a pre-trained model for KG-to-text generation, which utilizes the same pre-training dataset as our model and directly uses KG-to-text generation as the pre-training task. BART and T5, as the state-of-the-art pre-trained models for text generation, can be applied to KG-to-text generation with the input of linearized knowledge graphs and the output of text sequences (Ribeiro et al., 2020a).

Task-Specific Models without Pre-Training: We also chose the state-of-the-art task-specific models without pre-training for each dataset as our baselines, including Seq2Seq with copying or delexicalisation (Shimorina and Gardent, 2018) for WebNLG v2.0, and G2S (Chen et al., 2020d) for WebQuestions and PathQuestions.

We directly re-printed the results of baselines if they use the same datasets as ours. Otherwise, we implemented the baselines based on the codes and model parameters released by the original papers. We reported all the results of our implemented models with the mean values over 5 runs.

4.4 Automatic Evaluation

We followed the existing work (Shimorina and Gardent, 2018; Chen et al., 2020d) to use BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005) and ROUGE-L (Lin, 2004) as our automatic metrics. The main results on WebNLG, WebQuestions and PathQuestions are shown in Table 1. We can observe that JointGT based on BART / T5 can outperform vanilla BART / T5 on most of the metrics, respectively, and obtain the state-of-the-art performance on all the datasets. This indicates that our method can promote graph-text alignments and further enhance the performance of the state-of-the-art pre-trained models on KG-to-text datasets.

4.5 Human Evaluation

To further evaluate the quality of generated results, we conducted human evaluation on the WebNLG(U) dataset. We followed the existing work (Ferreira et al., 2019; Ribeiro et al., 2020b) to select two criteria: *fluency* (whether a sentence is grammatically fluent) and *adequacy* (whether a sentence clearly describes the knowledge graph). We randomly sampled 100 knowledge graphs from the test set, and collected the generated results from our models and the most competitive baseline models (i.e., BART and T5). We used the pairwise comparison between BART / T5 and JointGT (BART) / JointGT (T5). Specifically, for each pair of generated texts (one from JointGT and the other from the corresponding baseline, given the same input knowledge graph), three annotators were hired to label which text is better (i.e., win, lose or tie) in terms of the metrics mentioned above. Note that the two metrics were evaluated independently.

Results in Table 3 show that JointGT can beat the corresponding baselines in both fluency and adequacy. Especially for adequacy, our model can significantly outperform BART / T5, which indicates that our model equipped with the structure-aware encoder and well-designed pre-training tasks can generate high-quality texts to describe knowledge graphs more clearly. To evaluate the agreement among different annotators, we calculated Fleiss' Kappa (Fleiss, 1971) for each pairwise comparison, where the results in Table 3 show moderate agreement ($0.4 \leq \kappa \leq 0.6$).

4.6 Ablation Study

4.6.1 Encoder Structure

To investigate the effect of our proposed structure-aware semantic aggregation module, we fixed the pre-training tasks and compared our encoder with two Transformer-based encoders commonly used in the existing work:

SeqEnc: This sequence encoder takes linearized graphs as input and ignores structural information (Ribeiro et al., 2020a; Kale and Rastogi, 2020).

RelEnc: This relation-aware encoder regards the entity sequence as input and leverages the relation embedding into the self-attention layer. Both the entity and relation embedding vectors are directly learned as model parameters (Shaw et al., 2018; Zhu et al., 2019; Song et al., 2020).

Model	#Param	BLEU	METEOR	ROUGE
JointGT (BART)	160M	**65.92**	**47.15**	**76.10**
w/ SeqEnc	140M	64.82	46.87	75.37
w/ RelEnc	160M	65.17	47.07	75.69

Table 4: Ablation test of different encoder structures on WebNLG(U), including our encoder, sequence encoder (SeqEnc) and relation-aware encoder (RelEnc).

Note that we only chose the encoder structures that can directly adapt to BART / T5 for fair comparison[5]. Results in Table 4 show that our encoder structure can perform better than the other baselines. Compared with the relation-aware encoder which can also capture the structural information of knowledge graphs, our model fully utilizes the effective contextual semantic representation to initialize the entity / relation representation at each Transformer layer instead of directly using the learnable entity / relation embedding vectors. This design equips JointGT with better generalization ability during fine-tuning, thereby enhancing our performance on downstream datasets.

Model	#Triples	
	1-3	4-7
JointGT (BART)	**71.24**	**61.36**
w/ SeqEnc	70.83 (-0.41)	60.11 (-1.25)
w/ RelEnc	70.98 (-0.26)	60.58 (-0.78)

Table 5: BLEU scores of three encoders on the test set of WebNLG(U) with different numbers of input triples.

To further demonstrate the effectiveness of our encoder, we divided the test set of WebNLG(U) into two subsets according to the number of triples in knowledge graphs, and compared the performance of three encoders. Results in Table 5 show that the improvement margin between our encoder and other encoders is more evident when the number of input triples is large, which indicates that our model can facilitate the encoding of knowledge graphs with more complex structures.

4.6.2 Pre-Training Task

Model	BLEU	METEOR	ROUGE
JointGT (BART)	**65.92**	**47.15**	**76.10**
w/o TextRecon	64.22	46.56	74.96
w/o GraphRecon	65.37	47.09	75.97
w/o OT	65.03	47.09	75.83
w/ BARTPretrain	64.60	46.78	75.74
w/ KGPTPretrain	65.14	46.94	75.72

Table 6: Ablation test of three pre-training tasks on WebNLG(U), including text / graph reconstruction and graph-text alignments via OT. BARTPretrain / KGPT-Pretrain means using the pre-training tasks of BART / KGPT instead of our tasks on KGTEXT.

To study the effect of three pre-training tasks, we maintained the encoder structure and removed each task respectively to test the performance. We also replaced all our pre-training tasks with the tasks of the existing work for comparison:

BARTPretrain: The pre-training tasks of BART including text infilling and sentence permutation (Lewis et al., 2020). Since these tasks cannot be applied to graph data, we only used these tasks on the text data of the pre-training dataset.

KGPTPretrain: The pre-training task of KGPT, i.e., KG-to-text generation on the pre-training dataset (Chen et al., 2020b).

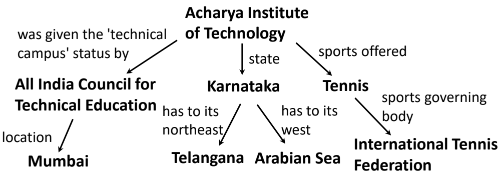
Results in Table 6 show that each of our pre-training tasks contributes to the model performance. Compared with the other two tasks, graph enhanced text reconstruction plays a more important role in the task of KG-to-text generation, which directly supervises the decoder with the conditional generation loss. We also observe an apparent performance drop if we replace our pre-training tasks with those proposed by the existing work, thereby indicating the effectiveness of our pre-training tasks to promote KG-to-text generation.

4.7 Few-Shot Learning

To further analyze whether our pre-training tasks can learn a good graph-text joint representation that benefits the downstream KG-to-text generation tasks, we considered the few-shot setting where

---

[5] We observed a significant performance drop if we used the encoders which are incompatible with BART / T5 (such as graph neural networks) because we had to randomly initialize the parameters of them during pre-training.



BART: The Acharya Institute of Technology is located in the state of Karnataka which has Telangana to its northeast and the Arabian Sea to its west . The Institute was given the 'Technical Campus ' status by the All India Council for Technical Education in Mumbai . The International Tennis Federation governs tennis . **[sports offered]**

T5: The Acharya Institute of Technology is located in Karnataka , India . It was given the 'Technical Campus ' status by the All India Council for Technical Education in Mumbai . The Institute is affiliated with the International Tennis Federation . The Arabian Sea is to the west of Karnataka and Telangana is northeast of the state . Tennis is one of the sports offered by the Institute . **[sports governing body]**

JointGT (BART): The Acharya Institute of Technology is located in the state of Karnataka which has Telangana to its northeast and the Arabian Sea to its west . The Institute was given the 'Technical Campus ' status by the All India Council for Technical Education in Mumbai . One of the sports offered at the Institute is tennis which is governed by the International Tennis Federation .

JointGT (T5): The Acharya Institute of Technology is located in the state of Karnataka . Karnataka has Telangana to its northeast and the Arabian Sea to its west . The Institute was given the 'Technical Campus ' status by the All India Council for Technical Education in Mumbai . The Institute offers tennis which is governed by the International Tennis Federation .

Figure 4: Generated results on WebNLG(U). We highlight the missing and unfaithful parts of each text in red and blue, respectively.

Model	Data Proportion			
	0.5%	1%	5%	10%
BART	33.92	39.08	52.24	56.58
JointGT (BART)	**37.18**	**42.26**	**54.41**	**57.73**
w/ BARTPretrain	32.63	37.11	52.91	56.81
w/ KGPTPretrain	35.33	40.72	53.08	57.18

Table 7: BLEU scores of the models with correponding pre-training tasks trained on different proportions of WebNLG(U).

only a few training instances were used during fine-tuning. We still fixed our model structure and compared our pre-training tasks with the tasks of BART and KGPT mentioned in §4.6.2.

Results in Table 7 show that our pre-training tasks can perform better than other tasks, especially when the amount of training data is small. This indicates that our proposed tasks can capture the graph-text alignments during pre-training, thereby making our model generalizable to the downstream KG-to-text datasets better with only a few training samples.

4.8 Case Study

To intuitively show the generation quality of our model, we provided some generated cases in Figure 4. We observe that JointGT can generate high-quality texts that describe the knowledge graph more completely and faithfully. For example, in the generated case on WebNLG(U), both BART and T5 fail to cover all the input triples, where BART misses the triple *(Acharya Institute of Technology, sports offer, Tennis)* and T5 misses *(Tennis, sports governing body, International Tennis Federation)*. Also, T5 generates non-existing facts that are unfaithful to the knowledge graph. Equipped with the structure-aware Transformer encoder and the well-designed pre-training tasks to learn graph-text alignments, JointGT (BART) and JointGT (T5) can generate descriptions which include all the input triples and express the relation between each pair of entities more faithfully.

5 Conclusion

We propose a novel graph-text joint representation learning model called JointGT for KG-to-text generation. This model plugs a simple structure-aware semantic aggregation module into the vanilla Transformer layer to preserve the structure of input graphs, and utilizes three pre-training tasks to learn graph-text alignments in the discrete vocabulary space and continuous embedding space. Experiments show that JointGT can outperform state-of-the-art pre-trained NLG models on various datasets of KG-to-text generation.

A IPOT Algorithm

Inexact Proximal point method for Optimal Transport (IPOT) is an effective iterative method to approximate OT distance and compute the transport plan $\boldsymbol{T}$ (Xie et al., 2019). Given the sequence of entities and relations in the knowledge graph $\mathcal{G}_{seq} = (g_1, \cdots, g_{|\mathcal{V}|+|\mathcal{E}|})$ with its corresponding embedding vectors $\boldsymbol{H}^{\mathcal{G}} = (\boldsymbol{h}_1^{\mathcal{G}}, \cdots, \boldsymbol{h}_{|\mathcal{V}|+|\mathcal{E}|}^{\mathcal{G}})$, and the text sequence $X = (x_1, \cdots, x_n)$ with its embedding vectors $\boldsymbol{S} = (\boldsymbol{s}_1, \cdots, \boldsymbol{s}_n)$, the implementation of IPOT algorithm to calculate $\boldsymbol{T}$ is shown in Algorithm 1.

Algorithm 1 IPOT Algorithm

```
Require:
    $\mathcal{G}_{seq} = \{g_i\}_{i=1}^{|\mathcal{V}|+|\mathcal{E}|}$, $X = \{x_j\}_{j=1}^{n}$, and their embedding vectors $\boldsymbol{H}^{\mathcal{G}} = \{\boldsymbol{h}_i^{\mathcal{G}}\}_{i=1}^{|\mathcal{V}|+|\mathcal{E}|}$, $\boldsymbol{S} = \{\boldsymbol{s}_j\}_{j=1}^{n}$
    Generalized stepsize: $1/\beta$
$\boldsymbol{\sigma} = \frac{1}{n}\mathbf{1}_n, \boldsymbol{T}^{(1)} = \mathbf{1}_{|\mathcal{V}|+|\mathcal{E}|}\mathbf{1}_n^{\top}$
$\boldsymbol{C}_{ij} = d(g_i, x_j) = 1 - \frac{\boldsymbol{h}_i^{\mathcal{G}}\boldsymbol{s_j}}{\|\boldsymbol{h}_i^{\mathcal{G}}\|_2\|\boldsymbol{s}_j\|_2}$
$\boldsymbol{A}_{ij} = e^{-\frac{\boldsymbol{C}_{ij}}{\beta}}$
for $t = 1$ to $N$ do
    $\boldsymbol{Q} = \boldsymbol{A} \odot \boldsymbol{T}^{(t)}$
    for $k = 1$ to $K$ do
        $\boldsymbol{\delta} = \frac{1}{(|\mathcal{V}|+|\mathcal{E}|)\boldsymbol{Q}\boldsymbol{\sigma}}, \boldsymbol{\sigma} = \frac{1}{n\boldsymbol{Q}^{\top}\boldsymbol{\delta}}$
    end for
    $\boldsymbol{T}^{(t+1)} = \mathrm{diag}(\boldsymbol{\delta})\boldsymbol{Q}\mathrm{diag}(\boldsymbol{\sigma})$
end for
return $\boldsymbol{T}$
```

In the algorithm of IPOT, $\odot$ denotes Hadamard product. β, K and N are all hyper-parameters. We followed the existing work (Chen et al., 2020a) to set $\beta = 1.0$, $K = 1$ and $N = 10$.

B Hyper-Parameter Setting

Hyper-parameter	Search Space
Masking Probability (entity / relation / word)	*choice*[20%,30%,40%]
Learning Rate	*choice*[2e-5,3e-5,5e-5]
Training Epoch	*choice*[1,2]
Warmup Ratio	*choice*[0,0.1]
Batch Size	*choice*[32,36,42]
Input Length	600
Output Length	64
Maximum Gradient Norm	1.0
Optimizer	Adam
Epsilon (for Adam)	1e-8

Table 8: Hyper-parameter search space of JointGT during pre-training. *choice* indicates that the listed numbers will be chosen with the same probability.

We provided the detailed settings of hyper-parameters during pre-training and fine-tuning. The settings include hyper-parameter search space and best assignments. Note that we used Huggingface's Transformers[6] to implement our models.

---

[6] `https://github.com/huggingface/transformers`

Hyper-parameter	Search Space
Learning Rate	*choice*[2e-5,3e-5,5e-5,1e-4]
Training Epoch	*choice*[20,30,40]
Warmup Step	*uniform-integer*[0,total_step*0.2]
Batch Size	*choice*[24,32]
Input Length	*choice*[128,256]
Output Length	*choice*[64,128]
Beam Size	*choice*[2,3,5]
Length Penalty	*choice*[1.0,3.0,5.0]
Maximum Gradient Norm	1.0
Optimizer	Adam
Epsilon (for Adam)	1e-8

Table 9: Hyper-parameter search space of JointGT during fine-tuning. *uniform-integer* means the integers in the interval can be selected uniformly. In the search space of warmup step, total_step denotes the total training steps on the corresponding datasets.

Thus all the hyper-parameters reported in our paper were consistent with the codes of Huggingface's Transformers.

Table 10: Best assignments of hyper-parameters on the downstream datasets.

We presented the hyper-parameter search space during pre-training in Table 8. The number of hyper-parameter search trials was 10. Manual search was adopted to select hyper-parameters, and the selection criterion was BLEU on the validation set when we fine-tuned the pre-trained model on WebNLG(U). The best assignment of pre-training was described in our main content.

We also provided the detailed settings of hyper-parameters during fine-tuning on the downstream datasets, including the hyper-parameter search space in Table 9 and the best assignments in Table 10. The number of hyper-parameter search trials was 20. BLEU was adopted as our criterion in the manual search on all the downstream tasks.

AdaST: Dynamically Adapting Encoder States in the Decoder for End-to-End Speech-to-Text Translation

Wuwei Huang, Dexin Wang, Deyi Xiong *
College of Intelligence and Computing, Tianjin University, Tianjin, China
{wwhuang, 2019218007, dyxiong}@tju.edu.cn

Abstract

In end-to-end speech translation, acoustic representations learned by the encoder are usually fixed and static, from the perspective of the decoder, which is not desirable for dealing with the cross-modal and cross-lingual challenge in speech translation. In this paper, we show the benefits of varying acoustic states according to decoder hidden states and propose an adaptive speech-to-text translation model that is able to dynamically adapt acoustic states in the decoder. We concatenate the acoustic state and target word embedding sequence and feed the concatenated sequence into subsequent blocks in the decoder. In order to model the deep interaction between acoustic states and target hidden states, a speech-text mixed attention sublayer is introduced to replace the conventional cross-attention network. Experiment results on two widely-used datasets show that the proposed method significantly outperforms state-of-the-art neural speech translation models.

1 Introduction

Speech-to-text translation (ST) aims at translating the source language speech into the text of the target language. Approaches to ST can be roughly divided into two categories: end-to-end ST and cascaded ST. Early research on ST is primarily using a cascaded model that combines a speech recognition (ASR) module with a machine translation component, both usually trained independently on speech and parallel corpora (Ney, 1999; Matusov et al., 2005). In contrast, end-to-end ST, which directly translates the speech of the source language into text of the target language (Berard et al., 2016), not only avoids error propagation in the ASR-MT pipeline, but also greatly reduces inference latency.

However, despite these advantages, end-to-end ST is confronted with its own challenging problems: performing cross-modal translation and cross-lingual conversion in one shot. On the one hand, compared with text-to-text translation, end-to-end ST has to deal with acoustic inputs which are typically longer than their corresponding text inputs. This makes the cross-modal source-target dependencies more complicated. On the other hand, compared with monotonic ASR, end-to-end speech translation usually handles non-monotonic cross-lingual conversion.

Generally, end-to-end ST uses the seq2seq encoder-decoder framework (Sutskever et al., 2014) as the backbone for training and inference, where the encoder computes hidden states layer by layer according to speech inputs. The decoder yields target translations word by word by attending to the fixed-after-computing hidden states of the encoder. Since the hidden states are static in the encoder, information only flows one direction: from the encoder to the decoder. Given the cross-modal and cross-lingual challenge in end-to-end ST, we argue that more sophisticated interaction between the encoder and decoder would be desirable.

In this paper, we propose an adaptive ST (AdaST) model that incorporates acoustic states into the decoder for modeling the deep interaction between the encoder and decoder for end-to-end ST. We enable AdaST to dynamically adapt encoder states in the decoder when target hidden states are updated layer by layer. It also learns to represent speech and text in one shared space in the decoder for mitigating the cross-modal issue.

Our contributions can be summarized as follows:

- We present AdaST, a new architecture for end-to-end ST, which learns representations of two modalities (textual and audio) in one shared space in the decoder.
- We conduct experiments to validate the effectiveness of AdaST. Our experiments and

Berard et al. (2016) demonstrate the potential of end-to-end neural ST and Weiss et al. (2017) achieve good performance by using an end-to-end neural architecture, which trigger more research interests in end-to-end ST. Both Bansal et al. (2019) and Stoian et al. (2020) train a speech recognition model first and then use the encoder of ASR to initialize the encoder of speech translation. Jia et al. (2019) synthesize training data for end-to-end speech translation from MT and ASR dataset. Gangi et al. (2019); Inaguma et al. (2019) adapt the idea of multilingual machine translation to speech translation. In addition to these methods, Bahar et al. (2019) use phoneme-level representations instead of speech frame-level representations as input, greatly reducing the length of acoustic sequences. Knowledge distillation (Liu et al., 2019), meta-learning (Indurthi et al., 2019), curriculum learning (Wang et al., 2020b), and two-pass decoding (Sung et al., 2019), have also been studied in end-to-end speech translation.

To solve the cross-modal and cross-lingual challenges of end-to-end speech translation, Wang et al. (2020a) and Dong et al. (2020) propose to use submodules to separately analyze cross-modal and cross-lingual problems in end-to-end ST. Each module introduced solves one problem. Unfortunately, they introduce a large number of extra parameters and rely on a large amount of external data to pre-train each submodule. In contrast, we do not introduce any additional submodules and therefore we do not need external data for pretraining.

3 The AdaST Model

In this section, we first introduce the widely-used CNN + Transformer structure as the strong baseline for end-to-end ST. After that we elaborate the proposed AdaST model.

3.1 Baseline ST Model

The CNN + Transformer end-to-end ST model consists of a speech encoder and a translation decoder. The basic building unit of Transformer (Vaswani et al., 2017) is the self-attention mechanism, which can be formulated as follows:

$$\mathrm{Attention}(Q, K, V) = \mathrm{softmax}(\frac{QK^T}{\sqrt{d_k}})V \quad (1)$$

The speech encoder is composed of N_c CNN layers for encoding acoustic signals and Ne Transformer encoder layers stacked over CNN layers. The translation decoder consists of N_d Transformer decoder layers.

The CNN module subsamples acoustic features to fit them into the subsequent Transformer encoder layers. The Transformer encoder layers then learn encoder states from the output of the CNN module, which are fixed during decoding. That is to say, the Transformer decoder layers attend to static Transformer encoder hidden states for yielding target words.

3.2 AdaST

As shown in Figure 1, our proposed AdaST uses the same speech encoder as the baseline ST model. The significant difference lies in the decoder. In order to make acoustic states dynamically adaptive to decoder states in each layer, we concatenate the hidden acoustic state sequence generated from the last layer of the speech encoder with the target word embedding sequence and feed the concatenated sequence into the subsequent decoder blocks. The concatenated input sequence is combined with positional encoding, similar to the vanilla Transformer decoder. In addition to positional encoding, we also adapts modality embeddings, which are defined in a embedding matrix with size of $2 \times c$ (c is the dimension of attention) adding to the input sequence to distinguish the target textual tokens from the source acoustic features. Modality embeddings has also been used in other cross-modal tasks, e.g., Vilbert for vision-text multimodal pretraining. Our experiments show that using modality embeddings in our model can slightly improve translation quality.

In the decoder, each block consists of a multi-head speech-text mixed attention sublayer and a feedforward sublayer. The multi-head speech-text mixed attention (STMA) is calculated as follows:

$$\text{STMA}(Q, K, V) = \text{softmax}(\frac{QK^T}{\sqrt{d_k}} + Mask)V \tag{2}$$

$$Q = \text{Concat}(src, tgt)W^Q \tag{3}$$

$$K = \text{Concat}(src, tgt)W^K \tag{4}$$

$$V = \text{Concat}(src, tgt)W^V \tag{5}$$

where src and tgt represent the sequence of acoustic hidden states and target word embeddings respectively, and $Mask$ is a predefined matrix which serves as indicators controlling which positions of the acoustic and target sequence are visible to attention heads, similar to the look ahead mask matrix used in Transformer to prevent the decoder from attending future tokens.

In each decoder layer of the proposed AdaST, we divide the $Mask$ matrix into four parts:

$$Mask = \begin{bmatrix} M_{SS} & M_{ST} \\ M_{TS} & M_{TT} \end{bmatrix}$$

M_{SS} represents the self-attention mask matrix of the acoustic state, which is the same as used in the encoder. M_{ST} is the mask matrix for the attention from acoustic states to target hidden states. During parallel training, as source acoustic states are not visible to target hidden states, we set all values of M_{ST} to minus infinity to forbid such attention. M_{TS} denotes the mask matrix for attention from target hidden states to acoustic states. Values in M_{TS} are the same as the mask matrix used for the cross-attention in Baseline ST. M_{TT} is the mask matrix for self-attention over target hidden states, which is the same as the mask matrix used for self-attention on the Baseline ST decoder.

The proposed AdaST benefits from the following features. First, the acoustic states and decoder hidden states are unified into a shared semantic space. Second, the acoustic states at each decoder layer change accordingly after the calculations at the current layer are performed. Third, instead of calculating softmax for self-attention and then calculating softmax for cross-attention in the baseline ST, the neural representations in the AdaST decoder are updated by calculating a single softmax over both acoustic states and hidden states for target words. With these changes, we hope to mitigate the cross-modal and cross-lingual challenges in end-to-end ST.

4 Experiments

We conducted experiments to examine the proposed AdaST model.

4.1 Datasets

We used two datasets that are widely adopted to evaluate end-to-end ST: IWSLT18 En-De and Augmented Librispeech En-Fr (Berard et al., 2018).

Augmented Librispeech English-French. The corpus provides triples for each instance: English speech signal, English transcription, French text translation from the aligned e-books. Following Wang et al. (2020b), we only used the 100 hours clean data for training, with 2 hours data as the development set and 4 hours as the test set, which corresponds to 47,271, 1071 and 2048 utterances respectively. To be consistent with their settings, we also doubled the training data by concatenating the aligned references with pseudo translations by the Google Translate.

IWSLT18 English-German. The IWSLT18 speech translation dataset is from TED Talks, which contains 271 hour speech with 171K corresponding English transcripts and German translations. As there is no validation set in this dataset, we randomly sampled 2000 samples from the training data as our validation set. Following Wang et al.

(2020b), we used tst2013 as the test set.

4.2 Settings

We built our model based on the Espnet toolkit (Inaguma et al., 2020). On the two datasets, we extracted 80-dimensional Fbank features from audio files, setting the step size as 10ms and the window size as 25ms. We deleted sentences with frame size larger than 3000 and sentences with poor alignments. Following Wang et al. (2020a), we adopted speed perturbation with factors 0.9 and 1.1. To further reduce overfitting, we used SpecAugment strategy (Bahar et al., 2019). In Librispeech, we used subword level decoding, which was performed via SentencePiece with a size of 1K tokens. In IWSLT18, we performed character level decoding. As the tst2013 of IWSLT2018 is not aligned, we employed Espnets default LIUM SpkDiarization tool to segment each audio sequence. We used RWTH toolkit (Bender et al., 2004) to calculate BLEU scores (Papineni et al., 2002).

A two-layer CNN was taken in the speech encoder. The step size was set to 2. The size of the convolution kernel was 2 × 2. The dimension of the attention was set to 256. We used 12-layer encoder. The number of decoder layers in both the baseline and AdaST was set to 10. We used the Adam optimizer (Kingma and Ba, 2015) and run our models on four P100 GPUs.

4.3 Main Results

In order to make each layer of the decoder to interact with acoustic states, our model requires additional computational overhead. However, the conventional source-to-target attention network in Transformer is subsumed in the decoder, which helps AdaST to use fewer parameters than Transformer, hence partially offsetting the additional cost. Overall, the number of parameters in AdaST is 0.65 million fewer than that of the standard CNN+Transformer structure. On the augmented dataset, AdaST increased the training time by 11.7% and the inference time by 15.7%. We compared our work against previous state-of-the-art models and the ASR pretraining + MT fine-tuning method. Table 1 shows the results on the two datasets. We observe that the proposed AdaST is able to achieve improvements of +0.83 BLEU and +1.18 BLEU over the best baseline results on En-Fr and En-De translation, respectively. This demonstrates that our proposed method benefits end-to-end ST at both the character and subword level. We have also carried out experiments to compare against a standard CNN+Transformer model with deeper encoder and decoder. Experiment results show that simply deepening either encoder or decoder of the standard structure is not helpful for speech-to-text translation.

	Method	BLEU
En-Fr	LSTM ST (Berard et al., 2018)	12.90
	Transformer+ASR pre-train (Inaguma et al., 2020)	15.53

5 Analysis

We conducted further experiments and analyses to take a deep look into our proposed method.

5.1 Only Cross-modal or Cross-lingual Challenge

In order to investigate whether our proposed architecture is helpful for a task with only cross-modal or cross-lingual challenge, we also conducted experiments for automatic speech recognition (ASR) and machine translation (MT) tasks with the proposed method on the Agmented Librispeech dataset. Experimental results in Table 2 show that the performance of ASR task drops, while the performance of MT task is improved slightly. This suggests that the proposed architecture is more appropriate for dealing with cross-lingual and cross-modal challenges at the same time.

5.2 Adaptive vs. Static Acoustic States

We assume that dynamically adaptive representations of acoustic states in accord with hidden decoder states at each decoder layer will be of great

Structure	BLEU
Transformer+ASR pre-train	15.21
Transformer+Additional Self-Att	16.08
AdaST	**16.39**

Method	ACC
Transformer+ASR pre-train	74.2
AdaST	96.7

Table 4: Classification accuracy (%) on speaker verification.

help to end-to-end ST. In order to examine this hypothesis, we add an additional self-attention at each encoder layer in the baseline ST, which forces acoustic states at the corresponding encoder layer to adapt to decoder hidden states. The results on the IWSLT18 dataset, as displayed in Table 3, validate this assumption. However, the added additional self-attention substantially increase the number of parameters at each layer. By contrast, our AdaST does not introduce additional parameters at each layer to learn adaptive acoustic states on the one hand and achieves better performance on the other.

5.3 Probing the Speech Encoder

We further compared the trained speech encoder of our AdaST against that of the baseline ST by evaluating speaker verification accuracy on the Fluent Speech Commands dataset (Lugosch et al., 2019) to investigate the change of the semantic information learned by the encoder. Generally, the more semantic information the encoder contains, the less audio information it learns and hence the lower classification accuracy it will obtain. We froze parameters of these two speech encoders, and added a linear classification layer on the top of the encoder . Only the added classification layer is trained on the dataset mentioned above. Table 4 shows the classification accuracy results, where the baseline encoder achieves 74.2% while our encoder 96.7%, substantially higher than the baseline encoder. This indicates that our encoder focuses on modeling the audio modality and passes the major task of modeling semantic information in speech inputs to the decoder. In contrast, the baseline encoder has to model both semantic and modality information of speech inputs, which weakens its modeling capacity for modality and therefore makes it have a much lower performance on speaker verification.

6 Conclusions

In this paper, we have presented AdaST, a neural model dynamically adapting acoustic states in the decoder, which is able to mitigate the cross-lingual and cross-modal challenge for end-to-end speech translation. Experiments demonstrate that AdaST achieves an improvement of 1.18 BLEU points over state-of-the-art neural speech translation models.

OKGIT: Open Knowledge Graph Link Prediction with Implicit Types

Chandrahas

ppt@iisc.ac.in

Abstract

Open Knowledge Graphs (OpenKG) refer to a set of (head noun phrase, relation phrase, tail noun phrase) triples such as (tesla, return to, new york) extracted from a corpus using OpenIE tools. While OpenKGs are easy to bootstrap for a domain, they are very sparse and far from being directly usable in an end task. Therefore, the task of predicting new facts, i.e., link prediction, becomes an important step while using these graphs in downstream tasks such as text comprehension, question answering, and web search query recommendation. Learning embeddings for OpenKGs is one approach for link prediction that has received some attention lately. However, on careful examination, we found that current OpenKG link prediction algorithms often predict noun phrases (NPs) with incompatible types for given noun and relation phrases. We address this problem in this work and propose OKGIT that improves OpenKG link prediction using novel type compatibility score and type regularization. With extensive experiments on multiple datasets, we show that the proposed method achieves state-of-the-art performance while producing type compatible NPs in the link prediction task.

1 Introduction

An Open Knowledge Graph (OpenKG) is a set of factual triples extracted from a text corpus using Open Information Extraction (OpenIE) tools such as TEXTRUNNER (Banko et al., 2007) and ReVerb (Fader et al., 2011). These triples are of the form (noun phrase, relation phrase, noun phrase), e.g., (*tesla*, *return to*, *new york*). An OpenKG can be viewed as a multi-relational graph where the noun phrases (NPs) are the nodes, and the relation phrases (RPs) are the labeled edges between pairs of nodes. It is easy to bootstrap OpenKGs from a domain-specific corpus, making them suitable for newer domains. However, they are extremely sparse and may not be directly usable for an end task. Therefore, tasks such as NP canonicalization (merging mentions of the same entity) and link prediction (predicting new facts) become an important step in downstream applications. Some example applications are text comprehension (Mausam, 2016), relation schema induction (Nimishakavi et al., 2016), canonicalization (Vashishth et al., 2018), question answering (Yao and Van Durme, 2014), and web search query recommendation (Huang et al., 2016). In this work, we focus on improving OpenKG link prediction.

Table 1: Some sample tail NP predictions by CaRE, BERT, and OKGIT. The true tail NP is underlined. As we can see, both CaRE and BERT fail to predict the correct tail NP. However, BERT predictions are type compatible with the query. OKGIT predicts the correct NP while improving the type compatibility with the query.

Although OpenKGs are structurally similar to Ontological KGs, they come with a different set of challenges. They are extremely sparse, NPs and RPs are not canonicalized, and no type information is present for NPs. There has been much work on learning embeddings for Ontological KGs in the past years. However, this task has not received much attention in the context of OpenKGs. CaRE (Gupta et al., 2019) is a recent method which addresses this problem. It learns embeddings for NPs and RPs in an OpenKG while incorporating NP canonicalization information. However, even after incorporating canonicalization, we find that CaRE struggles to predict NPs whose types are compati-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2546–2559

ble with given head NP and RP.

As observed by Petroni et al. (2019), modern pretrained language representation models like BERT can store factual knowledge and can be used to perform link prediction in KGs. However, in our explorations with OpenKGs, we found that even though BERT may not predict the correct NP on the top, it predicts type compatible NPs (Table 1). A similar observation was also made in the context of entity linking (Chen et al., 2020). As OpenKGs do not have any underlying ontology and obtaining type information can be expensive, BERT predictions can help improve OpenKG link prediction.

Motivated by this, we employ BERT for improving OpenKG link prediction, using novel type compatibility score (Section 4.2) and type regularizer term (Section 4.4). We propose OKGIT, a method for OpenKG link prediction with improved type compatibility. We test our model on multiple datasets and show that it achieves state-of-the-art performance on all of these datasets.

We make the following contributions:

- We address the problem of OpenKG link prediction, focusing on improving type compatibility of predictions. To the best of our knowledge, this is the first work that addresses this problem.
- We propose OKGIT, a method for OpenKG link prediction with novel type compatibility score and type regularization. OKGIT can utilize NP canonicalization information while improving the type compatibility of predictions.
- We evaluate OKGIT on the link prediction across multiple datasets and observe that it outperforms the baseline methods. We also demonstrate that the learned model generates more type compatible predictions.

Source code for the proposed model and the experiments from this paper is available at https://github.com/Chandrahasd/OKGIT.

2 Related Work

OpenKG Embeddings: Learning embeddings for OpenKGs has been a relatively under-explored area of research. Previous work using OpenKG embeddings has primarily focused on canonicalization. CESI (Vashishth et al., 2018) uses KG embedding models for the canonicalization of noun phrases in OpenKGs. The problem of incorporating canonicalization information into OpenKG embeddings was addressed by Gupta et al. (2019). Their method for OpenKG embeddings (i.e., CaRE) performs better than Ontological KG embedding baselines in terms of link prediction performance. The challenges in the link prediction for OpenKGs were discussed in Broscheit et al. (2020), and methods similar to CaRE were proposed. In spirit, CaRE (Gupta et al., 2019) comes closest to our model; however, they do not address the problem of type compatibility in the link prediction task.

Entity Type: Entity typing is a popular problem where given a sentence and an entity mention, the goal is to predict *explicit* types of the entity. It has been an active area of research, and many models and datasets, such as (Mai et al., 2018), (Hovy et al., 2006), and (Choi et al., 2018), have been proposed. However, unlike this task, we aim to incorporate unsupervised **implicit** type information present in the pre-trained BERT model into OpenKG embeddings, rather than predicting *explicit* entity types present in ontologies or corpora.

For unsupervised cases, the problem of type compatibility in link prediction was addressed in (Jain et al., 2018). They employ a type compatibility score by learning a type vector for each NP and two type vectors (head and tail) for each relation. This score is multiplied with the triple score function, and the type vectors are trained jointly with embedding vectors. Although their method addresses the type compatibility issue, it is based on Ontological KG embedding models and shares the same limitations. In another work (Xie et al., 2016), hierarchical type information available in the dataset is incorporated while learning embeddings. However, their model is suitable only for Ontological KGs where the type information is readily available.

BERT in KG Embedding: BERT architecture has been used for scoring KG triples (Yao et al., 2019; Wang et al., 2019). However, their methods work on Ontological KGs without any explicit attention to NP types. In other work (Petroni et al., 2019), pre-trained BERT models are used for predicting links in KG. However, their focus was to evaluate knowledge present in the pre-trained BERT models instead of improving the existing link prediction model. BERT embeddings were also used for extracting entity type information (Chen et al., 2020). However, it was used for Entity Linking compared to OpenKG link prediction in our case.

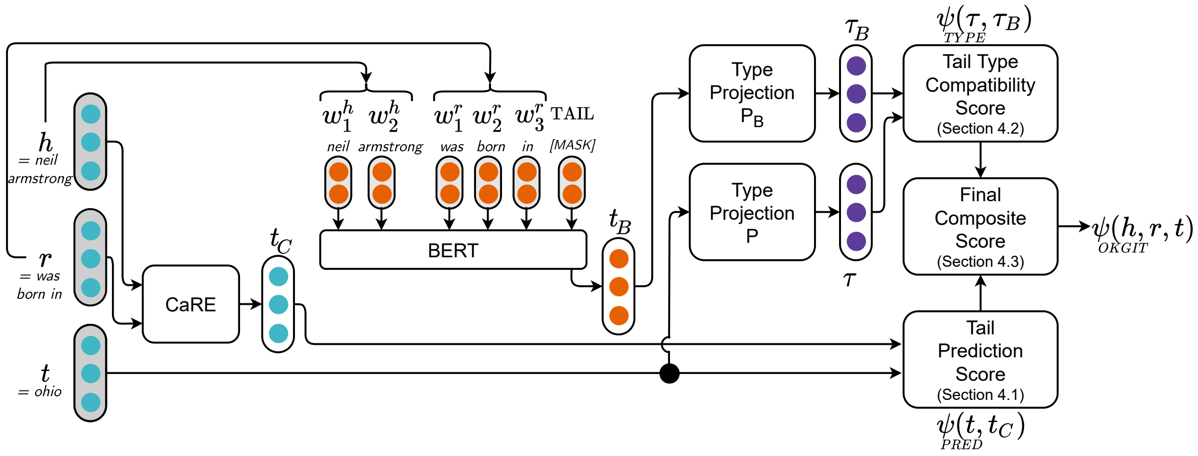

Figure 1: OKGIT Architecture. OKGIT learns embeddings for Noun Phrases (NP) and Relation Phrases (RP) present in an OpenKG by augmenting a standard tail prediction loss with type compatibility loss. Guidance for the tail type is obtained through type projection out of BERT's tail embedding prediction. In the figure, h, r, and t are the head NP, relation (RP), and tail NP. $h = w_1^h \dots w_{k_h}^h$ and $r = w_1^r \dots w_{k_r}^r$ are tokens in the head NP and relation, respectively. t_C and t_B are the tail NP vectors predicted by CaRE and BERT models (Please see Section 3 for background on these two models). Vectors τ_B and τ are the type vectors obtained using type projections P_B and P, respectively. ψ_{PRED} represents tail prediction score (Section 4.1) while ψ_{TYPE} represents type compatibility score (Section 4.2). ψ_{OKGIT} is the combined score generated by OKGIT for the input triple (h, r, t) (Section 4.3). Please refer to Section 4 for more details.

3 Background

We first introduce the notation used in this paper, followed by brief descriptions of BERT and CaRE.

Notation: An Open Knowledge Graph OpenKG = ($\mathcal{N}$, $\mathcal{R}$, $\mathcal{T}$) contains a set of noun phrases (NPs) $\mathcal{N}$, a set of relation phrases (RPs) $\mathcal{R}$ and a set of triples $(h, r, t) \in \mathcal{T}$ where $h, t \in \mathcal{N}$ and $r \in \mathcal{R}$. Here, h and t are called the head and tail NPs, and r is the RP between them. Each of them contains tokens from a vocabulary $\mathcal{V}$, specifically, $h = (w_1^h, w_2^h, \dots, w_{k_h}^h)$, $t = (w_1^t, w_2^t, \dots, w_{k_t}^t)$ and $r = (w_1^r, w_2^r, \dots, w_{k_r}^r)$. Here, k_h, k_r, and k_t are the numbers of tokens in the head NP, the relation, and the tail NP. OpenKG embedding methods learn vector representations for NPs and RPs. Specifically, vectors for an NP $e \in \mathcal{N}$ and an RP $r \in \mathcal{R}$ are represented by boldface letters $\mathbf{e} \in \mathbb{R}^{d_e}$ and $\mathbf{r} \in \mathbb{R}^{d_r}$. Here, d_e and d_r are dimensions of NP and RP vectors. Usually, $d_e = d_r$. A score function $\psi(h, r, t)$ represents the plausibility of a triple. Similarly, BERT represents tokens by d_B-dimensional vectors. A type projection matrix P takes the vectors to a common d_τ-dimensional type space $\mathbb{R}^{d_\tau}$. The vectors in the type space are denoted by τ.

BERT (Devlin et al., 2019): BERT is a bi-directional language representation model based on the transformer architecture (Vaswani et al., 2017), which has shown performance improvements across multiple NLP tasks. It is pre-trained on two tasks, (1) Masked Language Modeling (MLM), where the model is trained to predict randomly masked tokens from the input sentences, and (2) Next Sentence Prediction (NSP), where the model is trained to predict whether an input pair of sentences occurs in a sequence or not. In our case, we use a pre-trained BERT model (without fine-tuning) for predicting a masked tail NP in a triple.

CaRE (Gupta et al., 2019): CaRE is an OpenKG embedding method that can incorporate NP canonicalization information while learning the embeddings. NP canonicalization is the problem of grouping all surface forms of a given entity in one cluster, e.g., inferring that *Barack Obama*, *Barack H. Obama*, and *President Obama* all refer to the same underlying entity. CaRE consists of three components: (1) a canonicalization cluster encoder (CN), which generates NP embeddings by aggregating embeddings of canonical NPs from the corresponding cluster, (2) a bi-directional GRU based phrase encoder (PN), which encodes the tokens in RPs to generate RP embeddings, and (3) a base model, which is an Ontological KG embedding method like ConvE (Dettmers et al., 2018). It uses NP and

RP embeddings for scoring triples. These triple scores are then fed to a loss function (e.g., pairwise ranking loss with negative sampling (Bordes et al., 2013) or binary cross-entropy loss (BCE) (Dettmers et al., 2018)). In this paper, we use CaRE with ConvE as the base model. This model generates a candidate tail NP vector for a given NP h and RP r, denoted by CaRE($\mathbf{h}$, $\mathbf{r}$).

4 OKGIT: Our Proposed Method

Motivation: As illustrated in Table 1, top NPs predicted by CaRE may not always be type compatible with the input query. On the other hand, BERT's top predictions are usually type compatible (Chen et al., 2020), although they may not be factually correct. Thus, we hypothesize that a combination of these two models can produce correct as well as type compatible predictions. Motivated by this, we develop OKGIT, which combines the best of both of these models. The complete architecture of the proposed model can be found in Figure 1. In the following section, we present various components of the proposed model.

4.1 ψ_{PRED}: Tail Prediction Score

The correctness of tail prediction in a triple is measured by the triple score function ψ_{PRED}. Given a triple (h, r, t), it uses the corresponding vectors ($\mathbf{h}$, $\mathbf{r}$, $\mathbf{t}$) and assigns high scores to correct triples and low scores to incorrect triples. We follow CaRE (Gupta et al., 2019) for scoring triples, which internally uses ConvE (Dettmers et al., 2018) as the base model. For a given triple (h, r, t), the CaRE model first predicts a tail NP vector $\mathbf{t_C}$ as

$$\mathbf{t_C} = \text{CaRE}(\mathbf{h}, \mathbf{r}) \tag{1}$$

The predicted tail NP vector $\mathbf{t_C}$ is then matched against the given tail NP vector $\mathbf{t}$ using dot product to generate the triple score ψ_{PRED}.

$$\psi_{\text{PRED}}(\mathbf{t}, \mathbf{t_C}) = \mathbf{t_C}^\top \mathbf{t}. \tag{2}$$

The score ψ_{PRED} represents tail prediction correctness, and CaRE model uses only this score.

4.2 ψ_{TYPE}: Tail Type Compatibility Score

The type compatibility between a given (head NP, RP) pair and a tail NP is measured by the type compatibility score function ψ_{TYPE}. It assigns a high score when an NP t has suitable types as candidate tail NP for given head NP h and RP r. We employ a Masked Language Model (MLM) for measuring type compatibility, specifically BERT (Devlin et al., 2019). Following (Petroni et al., 2019), we can generate a candidate tail NP vector using BERT. Specifically, given a triple (h, r, t), we replace the head NP h and RP r with their tokens and tail NP t with a special MASK token. The resulting sentence $(w_1^h, \ldots, w_{k_h}^h, w_1^r, \ldots, w_{k_r}^r, \text{MASK})$ is sent as input to the BERT model. We denote the output vector from BERT corresponding to the MASK tail token as $\mathbf{t_B}$.

$$\mathbf{t_B} = \text{BERT}(h, r, \text{MASK}) \tag{3}$$

We can predict tail NPs for a given (h, r) by finding the nearest neighbors of $\mathbf{t_B}$ from the BERT vocabulary (Appendix D). These predicted NPs may not be the correct tail NP present in KG; however, they tend to be type compatible with the given (h, r) pair.

Motivated by this, we extract the implicit NP type information from this vector using a type projector $P_B \in \mathbb{R}^{d_\tau \times d_B}$. The output vector from BERT t_B is high-dimensional and can be used as a proxy for NP's type (Chen et al., 2020). Therefore, P_B projects the $\mathbf{t_B}$ vector to a lower dimensional space such that only relevant information is retained. We do a similar operation on tail NP embedding $\mathbf{t}$ and use a type projector $P \in \mathbb{R}^{d_\tau \times d_e}$ to extract type information. Both P_B and P are trained jointly with the model. Thus, the type vectors are given by

$$\boldsymbol{\tau_B} = P_B \mathbf{t_B} \quad \text{and} \quad \boldsymbol{\tau} = P\mathbf{t} \tag{4}$$

for BERT and CaRE, respectively. Here, both $\boldsymbol{\tau_B}, \boldsymbol{\tau} \in \mathbb{R}^{d_\tau}$. Then, the type compatibility score between these can be measured by negative of Euclidean distance, i.e.,

$$\psi_{\text{TYPE}}(\boldsymbol{\tau}, \boldsymbol{\tau_B}) = -||\boldsymbol{\tau_B} - \boldsymbol{\tau}||_2^2.$$

We also experimented with a dot product version of the type score, $\psi_{\text{TYPE}}^{\text{Dot}}(\boldsymbol{\tau}, \boldsymbol{\tau_B}) = \boldsymbol{\tau_B}^\top \boldsymbol{\tau}$, and found its performance to be comparable to the Euclidean distance version. Therefore, we use the Euclidean distance version for all our experiments.

4.3 ψ_{OKGIT}: Final Composite Score

The score functions ψ_{PRED} and ψ_{TYPE} may contain complementary information. Therefore, we use a combination of triple and type compatibility scores as final score for a given triple.

$$\psi_{\text{OKGIT}}(h, r, t) = \psi_{\text{PRED}}(\mathbf{t}, \mathbf{t_C}) + \gamma \times \psi_{\text{TYPE}}(\boldsymbol{\tau}, \boldsymbol{\tau_B}). \tag{5}$$

Dataset	#NPs	#RPs	#Gold Clusters	#Average NPs Per Cluster

ReVerb45KF	14,775	1,781	2,650

Table 2: Dataset Statistics. Please refer to Section 5 for more details.

Please recall that $\mathbf{t_C}$ and $\boldsymbol{\tau_B}$ are in turn dependent on h and r ((1) and (3)), while $\boldsymbol{\tau}$ is dependent on t (4). Here, γ controls the relative weights given to individual scores. This final score takes care of both, i.e., triple correctness as well as type compatibility. For training, we feed the sigmoid of this score function to the Binary Cross Entropy (BCE) loss function following (Dettmers et al., 2018).

4.4 Learning with Type Regularization

Let $\mathcal{X} = \{(h_i, r_i) | (h_i, r_i, t_i) \in \mathcal{T} \text{for some } t_i \in \mathcal{N}\}$ be the set of all head NPs and RPs which appear in the OpenKG. Let y_i be the label for the triple (h_i, r_i, t_i) which is 1 if $(h_i, r_i, t_i) \in \mathcal{T}$ and 0 otherwise. We apply the logistic sigmoid function σ on score ψ_{OKGIT} to get the predicted label

$$\hat{y}_i = \sigma(\psi_{\text{OKGIT}}(h_i, r_i, t_i))$$

Finally, we use the following binary cross-entropy (BCE) loss for triple correctness.

$$\text{TripleLoss}(h_i, r_i, t_i) = y_i \cdot \log(\hat{y}_i) + (1 - y_i) \cdot \log(1 - \hat{y}_i)$$

To further reinforce the type compatibility in the model, we include an additional loss term which forces the type vectors of correct triples to be closer in the type space. Similar to TripleLoss, we use the binary cross-entropy loss for type regularization as well. The type regularization term is shown below.

$$\text{TypeLoss}(h_i, r_i, t_i) = y_i \cdot \log(\hat{p}_i) + (1 - y_i) \cdot \log(1 - \hat{p}_i)$$

where $\hat{p} = \sigma(\psi_{\text{TYPE}}(\boldsymbol{\tau}, \boldsymbol{\tau_B}))$. The cumulative loss function is then given as below.

$$\sum_{i=1}^{n} \text{TripleLoss}(h_i, r_i, t_i) + \lambda \times \text{TypeLoss}(h_i, r_i, t_i) \tag{6}$$

where n is the number of training instances. We consider $\mathcal{X} \times \mathcal{N}$ as our training data where triples present in $\mathcal{T}$ have label 1 and rest have label 0.

5 Experiments

Datasets: Following (Gupta et al., 2019), we use two subsets of English OpenKGs created using ReVerb (Fader et al., 2011), namely ReVerb20K and ReVerb45K. We follow the same train-validation-test split for these datasets. As noted in (Petroni et al., 2019), predicting multi-token NPs using BERT could be challenging and it might require special pre-training (Joshi et al., 2020). To understand this difference, we create filtered subsets of these datasets such that they contain only single token NPs [1]. Specifically, we create ReVerb20KF (ReVerb20K-Filtered) and ReVerb45KF (ReVerb45K-Filtered) which contain only single token NPs. More details about these datasets can be found in Table 2.

Setup and hyperparameters: We use $d_e = d_r$ = 300 for NP and RP vectors. For other hyperparameters, we use grid-search and select the model based on MRR on validation split. For type vectors, we select d_τ from {100, 300, 500}. The weight for type regularization term λ is selected from the range $\{10^{-3}, 10^{-2} \ldots, 10^{1}\} \cup \{0\}$. Type composition weight γ is selected from {0.25, 0.5, 1.0, 2.0, 5.0}. For the language model, we try both BERT-base as well as BERT-large. The optimal values for hyperparameters are shown in Table 3. The experiments run for 1.5 hours (for filtered subsets) and 9 hours (for full datasets) on GeForce GTX 1080 Ti GPU.

6 Results

We evaluate the proposed model on the link prediction task. We follow the same evaluation process as in (Gupta et al., 2019). From our experiments, we try to answer the following questions:

1. Is OKGIT effective in the link prediction task? (Section 6.1)

---

[1] Please note that the single-token limitation is only valid for BERT, not for OKGIT (Appendix D).

Table 4: Results of link prediction task. Here ↑ indicates higher values are better while ↓ indicates lower values are better. We can see that the OKGIT model outperforms the baseline models on all the datasets (Section 6.1).

2. Does OKGIT generate more type compatible NPs in link prediction? (Section 6.2)

3. Is the Type Projector effective in extracting type vectors from embeddings? (Section 6.3)

6.1 Effectiveness of OKGIT Embeddings in Link Prediction

We evaluate our model on the link prediction task. Given a held-out triple (h_i, r_i, t_i), all the NPs $e \in \mathcal{N}$ in the KG are ranked as candidate tail NP based on their score $\psi_{\text{OKGIT}}(h_i, r_i, e)$. Let the rank of the correct tail NP t be denoted by $rank_i^t$. Similarly, ranks are also calculated for predicting head NPs instead of tail NPs using inverse relations (Dettmers et al., 2018; Gupta et al., 2019); let it be denoted by $rank_i^h$. These ranks are then used to find Mean Reciprocal Rank (MRR), Mean Rank (MR) and Hit@k (k=1,3,10) as follows.

$$\text{MRR} = \frac{1}{2 \times n_{test}} \sum_{i=1}^{n_{test}} \left(\frac{1}{rank_i^h} + \frac{1}{rank_i^t} \right),$$

$$\text{MR} = \frac{1}{2 \times n_{test}} \sum_{i=1}^{n_{test}} \left(rank_i^h + rank_i^t \right), \text{ and}$$

$$\text{Hits@k} = \sum_{i=1}^{n_{test}} \frac{\mathbb{1}(rank_i^h \leq k) + \mathbb{1}(rank_i^t \leq k)}{2 \times n_{test}}.$$

Here, n_{test} is the number of test triples and $\mathbb{1}$ is the indicator function. As noted in (Gupta et al., 2019), ranking individual NPs is not suitable for OpenKGs due to the lack of canonicalization. Hence, following their approach, we rank gold canonicalization clusters instead of individual NPs. The gold canonicalization partitions the NPs into clusters such that NPs mentioning the same entity belong to the same cluster. For ranking these clusters, we first find ranks of all NPs $e \in \mathcal{N}$. Then for each cluster, we keep the NP with minimum rank as representative and discard others. The representative NPs are then ranked again and the new ranks are assigned to the corresponding clusters. The rank of the cluster containing the true NP is then used for evaluating the performance. For better readability, the MRR and Hits@k metrics have been multiplied by 100.

We compare OKGIT with BERT (MLM), ConvE (Ontological KGE) and CaRE (OpenKGE). We also compare against a version of CaRE where phrase embeddings have been initialized with BERT (CaRE [BERT initialization]). As we can see from the results in Table 4, the proposed model OKGIT outperforms baseline methods in link prediction task across all datasets. This suggests that the implicit type scores from BERT help in improving ranks of correct NPs. Moreover, OKGIT outperforms CaRE with BERT initialization, suggesting the importance of type projectors [2].

The performance gain is higher for ReVerb20K and ReVerb20KF (+5.3 MRR) than ReVerb45K and ReVerb45KF (+1.2 and +3.1 MRR) datasets. As we can see from Table 2, the number of NPs are very close to the number of gold clusters in the 20K

---

[2] Please refer to Appendix A for a detailed comparison.

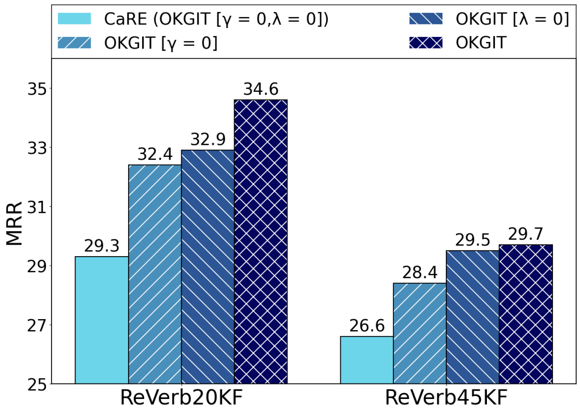

Figure 2: Effect of type compatibility score and type regularization on link prediction performance. While the type compatibility score with $\lambda = 0$ gives better gains in MRR (11%-12%) than type regularization term with $\gamma = 0$ (7%-11%), the combined model performs the best, achieving 12%-18% gains in MRR (Section 6.1).

Dataset	CaRE	OKGIT
ReVerb20KF	0.23	**0.30**
ReVerb20K	0.35	**0.36**
ReVerb45KF	0.22	**0.31**
ReVerb45K	0.34	**0.35**

Table 5: Results of type evaluation in CaRE and OKGIT predictions. We find that OKGIT performs better than CaRE in all datasets in terms of F1-score. Also, the results are statistically significant for all the datasets (Section 6.2).

datasets. Thus, the canonicalization information is slightly weaker in the 20K datasets than the 45K datasets. Due to this, CaRE achieved better gains in the ReVerb45K dataset as noted in (Gupta et al., 2019). This leaves more scope of improvements in the 20K datasets. By including the type information from BERT, OKGIT is able to fill this gap. It achieves better gains in the 20K datasets and is able to alleviate the lack of canonicalization information. Moreover, OKGIT is able to improve ranks of correct NPs ranked lower by CaRE. This can be seen by significant improvements in the MR.

Other Language Models: Using RoBERTa instead of BERT results in similar performance improvements (Appendix B). However, our primary focus is to understand the impact of *implicit type information* present in pre-trained MLMs, such as BERT, and *not* to compare multiple MLMs themselves.

Ablations: We perform ablation experiments to compare the relative importance of type compatibility score ψ_{TYPE} and type regularization term. We evaluate OKGIT with disabled type compatibility score (i.e., $\gamma = 0$ in Equation (5)) and disabled type regularization term (i.e., $\lambda = 0$ in Equation (6)) separately. Please note that CaRE model is equivalent to OKGIT with $\gamma = 0$ and $\lambda = 0$. The results of this experiment are shown in Figure 2. We find that while type compatibility score gives more performance gain (11%-12% gain in MRR) than type regularization (7%-11% gain in MRR), the combined model achieves the best performance (12%-18% gain in MRR). It suggests that both the components are important. Please refer to the Appendices A, B, C for more ablation experiments.

6.2 Type Compatibility in Predicted NPs

As noted in (Chen et al., 2020), BERT vectors contain NP type information[3]. OKGIT utilizes this type information for improving OpenKG link prediction. In this section, we evaluate whether OKGIT improves upon CaRE in predicting type compatible NPs. For such an evaluation, we require type annotations for the NPs in the OpenKGs. However, OpenKGs do not have an underlying ontology or explicit gold NP type annotations, making a direct evaluation impossible. Therefore, we employ a pre-trained entity typing model UFET (Choi et al., 2018). Given a sentence and an entity mention, the entity typing model predicts the mentioned entity's types. Using this model, we obtain types for true as well as predicted NPs by CaRE and OKGIT and use it for the evaluation. Please note that this evaluation is limited to the coverage and quality of the UFET model.

Evaluation Protocol: The type vocabulary in UFET model contains $10,331$ types including 9 general, 121 fine-grained, and $10,201$ ultra-fine types. The model takes a sentence $(w^h_1, \ldots, w^h_{k_h}, w^r_1, \ldots, w^r_{k_r}, w^t_1, \ldots, w^t_{k_t})$ formed from a triple (h, r, t) along with an entity mention (either t or h) as inputs and outputs a distribution over types. We use the top five predicted types for our experiments[4]. For a triple (h, r, t), we consider the types predicted for the true tail NP t as true types $\Gamma(t)$. Let $\hat{t}_{CaRE}$ and $\hat{t}_{OKGIT}$ be the top predicted tail NP by CaRE and OKGIT for the (h, r) pair. Then the types $\Gamma(\hat{t}_{CaRE})$ predicted for $\hat{t}_{CaRE}$

---

[3] We also verify this using Freebase, an ontological KG. Please refer to the Appendix G for more details.

[4] We observe similar behaviour with top one and three types.

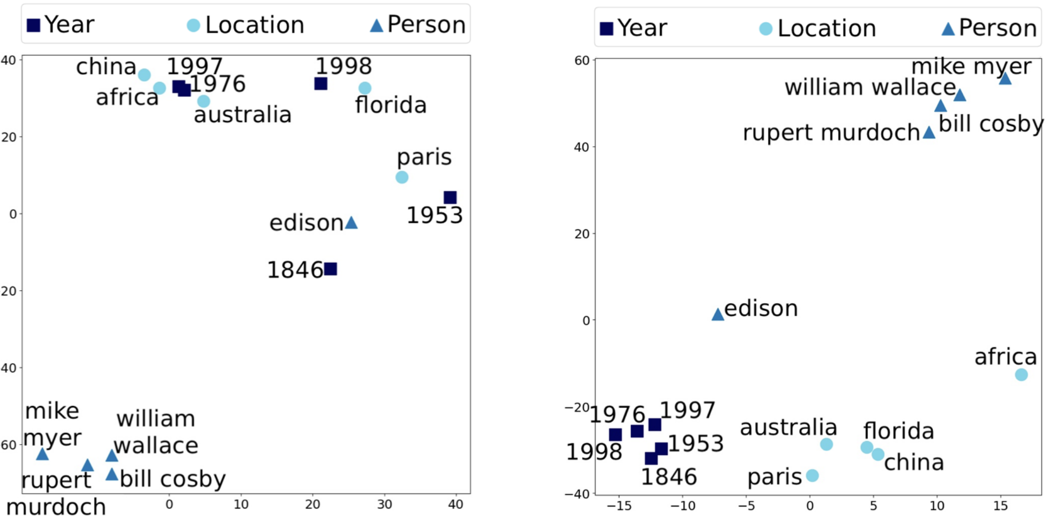

Figure 3: t-SNE projections of tail NP embeddings (left) and type vectors (right) extracted by the Type Projector from tail NP embeddings (Section 4.2) in the ReVerb20K dataset. We find that the Type Projector is able to extract informative type vectors from the tail embeddings. This is evident from the fact that the tail embeddings corresponding to person, location, and dates were inter-mixed in the left plot, while they have been separated into type specific clusters in the right plot. Please see Section 6.3 for details.

in the triple $(h, r, \hat{t}_{CaRE})$ is used as predicted types for CaRE. Similarly the types $\Gamma(\hat{t}_{OKGIT})$ predicted for $\hat{t}_{OKGIT}$ in the triple $(h, r, \hat{t}_{OKGIT})$ are used as predicted types for OKGIT. For evaluation, we calculate the mean F1-score as follows [5]

$$\text{F1} = \frac{2}{n_{test}} \sum_{i=1}^{n_{test}} \frac{|\Gamma(t_i) \cap \Gamma(\hat{t}_i)|}{|\Gamma(\hat{t}_i)| + |\Gamma(t_i)|}.$$

Here, $|\Gamma(t)|$ denotes the number of types present in $\Gamma(t)$ and $\hat{t}$ represents $\hat{t}_{CaRE}$ or $\hat{t}_{OKGIT}$. We can obtain the F1-scores for head NP similarly. We evaluate the mean F1-scores across head and tail NP prediction tasks on the test data and compare CaRE with OKGIT.

As we can see from the results in Table 5, OKGIT performs better than CaRE, suggesting that OKGIT generates more type compatible NPs than CaRE in the link prediction task. OKGIT achieves higher gains in the single-token datasets (i.e., ReVerb20KF and ReVerb45KF) than multi-token dataset (i.e., ReVerb20K and ReVerb45K). Upon investigation, we found that the types obtained using the entity typing model (true as well as predicted) for the multi-tokens datasets often contain common noisy types, leading to the small difference between CaRE and OKGIT. Following Dror et al. (2018), we also check the results for statistical significance using Permutation, Wilcoxon, and t-test with $\alpha = 0.05$, and found it to be significant for all the datasets.

6.3 Effectiveness of Type Projector

To better understand the effect of type projection, we visualize the vectors in NP-space from CaRE and Type-space (i.e., after type projection) from OKGIT. For this experiment, we randomly select 5 NPs from 3 categories, namely Person, Location and Year. More details about this selection process can be found in the Appendix E. We project the NP vectors (i.e., $\mathbf{t}$) corresponding to these NPs to a 2-dimensional NP-space using t-SNE (Maaten and Hinton, 2008)[6]. Similarly, we also project the corresponding type vectors (i.e., τ) to 2-dimensional Type-space. We plot the resulting vectors, color and shape coded by their respective categories, in Figure 3.

We can see that the vectors from different categories in the NP-space are mixed. However, after the type projection, the vectors in the Type-space are clustered together based on their categories.

6.4 Qualitative Evaluations

In this section, we present some examples of predictions made by CaRE and OKGIT methods. The result is shown in Table 6. As we see in Triple-1, both CaRE and OKGIT predict the correct NP (i.e.,

---

[5] Since we use a fixed number of types for ground truth and predictions, precision, recall, and F1-score have the same values. Therefore, we only report the F1-score.

[6] We run t-SNE for 2000 iterations with 15 perplexity.

	Triples	CaRE	OKGIT
1.	(*bach*, *moved to*, *?*)	*leipzig* *mobile* *vladimir h. horowitz* *yo yo*	*leipzig* *vienna* *stockholm* *sweden* *turin*
2.	(*clinton*, *lead by*, *?*)	*purchase* *sale* *video* *movie* *discount*	*1500* *260* *80* *99* *hire*

Table 6: Few example predictions made by CaRE and OKGIT models. We observe that the OKGIT predictions are more type compatible with the query. Please refer to Section 6.4 for more details.

leipzig) on top. However, more predictions from OKGIT are type compatible (i.e., all are locations) to the input query. On the other hand, CaRE predictions have mixed types (i.e., location, person, etc.). Also, CaRE makes an incorrect prediction, *vladimir horowitz*, possibly due to the presence of a training triple (*vladimir horowitz*, *had a great affinity for*, *bach*).

We see similar patterns in Triple-2, where the correct tail NP should be of type *number* indicating the count of votes. OKGIT is able to predict numbers in top predictions for Triple-2, while CaRE has mixed types in top predictions.

7 Conclusion

The task of link prediction for Open Knowledge Graphs (OpenKG) has been a relatively underexplored research area. Previous work on OpenKG embeddings has primarily focussed on improving or incorporating NP canonicalization information. While there are few methods for OpenKG link prediction, they often predict noun phrases with types incompatible with the query noun and relation phrases. Therefore, we use implicit type information from BERT to improve OpenKG link prediction and propose OKGIT. With the help of novel type compatibility score and type regularization term, OKGIT achieves significant performance improvement on the link prediction task across multiple datasets. We also find that OKGIT produces more type compatible predictions than CaRE, evaluated using an external entity typing model.

Acknowledgments

We thank the anonymous reviewers for their constructive comments. This work is supported by the Ministry of Human Resource Development (Government of India).

Broader Impact

OKGIT is the first attempt towards incorporating implicit type information in OpenKG link prediction without human intervention. It will greatly benefit densification and applications of OpenKGs where no underlying ontologies are available.

However, OKGIT predictions depend on various datasets, i.e., the corpus used for training the masked language model (e.g., BERT) and the corpus from which the OpenKG triples were extracted. A potential, possibly undesirable, bias may be introduced in the predictions by manipulating these corpora or adding a large number of malicious triples in the OpenKG.

We have tested OKGIT in English datasets. While the overall model architecture is independent of the language, the model's effectiveness might vary depending upon the quality of the masked language model, and it needs to be tested.

Appendices

A BERT Initialization vs Type Projectors

Here, we demonstrate the importance of type projectors by comparing OKGIT with multiple BERT-augmented versions of CaRE. Specifically, we initialize the phrase and word embeddings in CaRE with a pre-trained BERT model. The phrase (word) is passed as input to BERT and the output corresponding to the $[CLS]$ token is then used for initializing phrase (word) embedding for CaRE model. This modified CaRE model is trained similar to the base CaRE model. Based on different initialization methods, we experiment with following baselines.

CaRE [BERT NP]: NP embeddings are initialized using BERT and the rest of the model is same as CaRE. This model uses 768 (for BERT-base) or 1024 (for BERT-large) dimensional vectors.

CaRE [BERT NP+PROJ]: Since CaRE [BERT NP] uses higher dimensional vectors (768 or 1024) compared to other methods (300), the comparison may not be fair. To address this issue, we project BERT embeddings to 300 dimension. The projection is trained with the rest of the model.

CaRE [BERT NP+RP]: We initialize NP embeddings as well as the word embeddings in RP encoder using BERT embeddings. This method also uses 768 or 1024 dimensional vectors[7].

In all the methods, including OKGIT, we never fine-tune BERT, as our goal is to evaluate the type information already present in pre-trained BERT model. We experiment with both, BERT-base and BERT-large, and report the best performing model.

As we can see from the results in Table 7, OKGIT outperforms these baselines. Although BERT initialization improves the performance of CaRE model, the usage of explicit type-score and type regularization leads to significant performance improvements, suggesting their importance.

B Replacing BERT with other operations

In this section, we evaluate whether BERT module in OKGIT can be replaced by simple operations such as vector addition and concatenation. Specifically, we modify $\mathbf{t_B}$ in Equation (3) by replacing BERT with these operations leading to the following variants of OKGIT.

OKGIT-C: BERT is replaced by concatenation of head NP vector $\mathbf{h}$ and relation phrase vector $\mathbf{r}$

$$\mathbf{t_B} = [\mathbf{h}; \mathbf{r}].$$

OKGIT-A: BERT is replaced by vector addition

$$\mathbf{t_B} = \mathbf{h} + \mathbf{r}.$$

OKGIT-R: We also experiment with another masked language model RoBERTa in place of BERT.

$$\mathbf{t_B} = \text{RoBERTa}(h, r, \text{MASK}).$$

For this experiment, we use the ReVerb20KF and ReVerb45KF datasets as representatives. We perform grid-search with similar hyper-parameters as in Section 5 of the main paper and select the best model based on the MRR on the validation split. The results are reported in Table 8.

As we can see from the results, the OKGIT-C and OKGIT-A perform very similar to CaRE on both datasets. This suggests that the performance gains for OKGIT come from the BERT module. This observation is further reinforced because OKGIT-R results in similar improvements compared to CaRE as OKGIT. However, in all cases, we find that OKGIT with BERT outperforms other model variants.

C CaRE with Entity Typing

Entity typing is the task of predicting explicit types of an entity given a sentence and its mention. As we are interested in improving type compatibility of predictions in the link prediction task, we can also incorporate the output from an entity typing model. In this section, we explore this setting by replacing the BERT module in OKGIT with an entity typing model UFET from (Choi et al., 2018). Specifically, we replace the vector t_B in Equation (3) with the output of UFET representing the predicted probability distribution over types.

OKGIT(UFET) Model: The UFET model takes a sentence and an entity mention as input and produces a distribution over explicit set of types. In our case, the sentence is formed by concatenating the subject NP, relation phrase, and object NP, while the object NP is used as mention. The output distribution from UFET is used as t_B in our model. We call this version of the model as OKGIT(UFET) and compare it CaRE and OKGIT.

We run a grid-search for finding the best hyper-parameter similar to Section 5 and report the results

---

[7] we also tried using pre-trained BERT as RP encoder in CaRE, however, it performed poorly due to fixed RP encoder.

Table 9: Comparison of OKGIT with OKGIT(UFET). We can see that including UFET model in the system hurts the performance of the model (Appendix C).

on ReVerb20KF and ReVerb45KF datasets. The results are presented in the Table 9. As we can see from the results, OKGIT(UFET) performs poorly, even when compared to CaRE. It suggests that explicit type vectors from UFET model does not help in the link prediction task.

D BERT as Link Prediction Model

As mentioned in Section 4.2, t_B from Equation (3) can be used for predicting tail NPs by finding nearest neighbors in BERT vocabulary. However, this approach has a limitation. This model can only predict NPs that are single token and present in BERT vocabulary, restricting its applicability.

This limitation, however, is not valid for OKGIT. In OKGIT, the vector t_B is used for computing tail type compatibility score, instead of predicting tail NPs. Therefore, it is not restricted to BERT vocabulary or single-token NPs. As shown in Table 4, OKGIT is equally effective for single-token

datasets (e.g., ReVerb20KF and ReVerb45KF) and multi-token datasets (e.g., ReVerb20K and ReVerb45K).

E Selection of NPs for t-SNE

The OpenKGs do not have type annotations for the NPs. Therefore, we manually annotated a set of NPs and visualized a random subset. For this process, we first list all the NPs and shuffle them. Then we scan this list and note the first fifteen person names, locations, and years. Later, we select five NPs from each of these categories randomly and use them for the evaluation.

F Link Prediction Performance on Validation Split

The performance of CaRE and OKGIT on validation data on the link prediction task can be found in Table 10. These performance corresponds to the respective models which were used to report results in Table 4 of the main paper.

G Type Information in BERT Predictions

Our proposed OKGIT model is based on the hypothesis that BERT vectors (i.e., $\mathbf{t_B}$ in Equation (3) in Section 4.2) contain implicit type information. In this section, we evaluate this hypothesis that BERT vectors contain type information. It should be noted that evaluating OKGIT model for predicting NP types is not the goal here. We are interested in understanding whether pre-trained BERT vectors have sufficient type information, measured with respect to some existing anchors.

Evaluation Method: For this experiment, we use Freebase (Bollacker et al., 2008) which contains explicit gold type information for entities. Specifically, we use FB15K dataset (Bordes et al., 2013). We use the data from (Yao et al., 2019) for converting symbolic names in FB15k to textual descriptions. We only consider the subset of triples in FB15k which has single token in the tail node as BERT can only predict single token NPs.[8] This results in $n_T = 95,782$ triples. For type information, we use the data from (Xie et al., 2016). It contains 61 primary types (e.g., */award*). Please note that each node in FB15k can have multiple types. For a triple (h, r, t), we consider the types associated with the true tail NP t as true types $\Gamma(t)$. We then pass tokenized head NP and RP to BERT and find the top prediction $\hat{t} = \text{BERT}(h, r, \text{MASK})$ for tail position. The set of types associated with the predicted NP $\hat{t}$, denoted by $\Gamma(\hat{t})$, is then used as the predicted types. For evaluation, we calculate the following metrics

$$\text{Precision} = \frac{1}{n_T}\sum_{i=1}^{n_T}\frac{|\Gamma(t_i) \cap \Gamma(\hat{t}_i)|}{|\Gamma(\hat{t}_i)|},$$

$$\text{Recall} = \frac{1}{n_T}\sum_{i=1}^{n_T}\frac{|\Gamma(t_i) \cap \Gamma(\hat{t}_i)|}{|\Gamma(t_i)|}, and$$

$$\text{F1} = \frac{2}{n_T}\sum_{i=1}^{n_T}\frac{|\Gamma(t_i) \cap \Gamma(\hat{t}_i)|}{|\Gamma(\hat{t}_i)| + |\Gamma(t_i)|}.$$

Here, $|\Gamma(t)|$ and $|\Gamma(\hat{t})|$ denotes the number of types present in $\Gamma(t)$ and $\Gamma(\hat{t})$ respectively. [9] For comparison, we use the following baseline methods to assign types to a given (h, r, t).

---

[8] Please note that this limitation is only valid for BERT, not for OKGIT.

[9] Please note that, since we have gold type annotations available for Freebase, the number of true and predicted types need not be the same. Therefore, we evaluate precision and recall along with F1-scores.

Model	Precision	Recall	F1
Random	0.13	0.10	0.10
MFT	0.45	0.30	0.31
BERT	0.44	**0.40**	**0.36**
Human	**0.87**	0.18	0.27

Table 11: Results of the experiment to test whether BERT embeddings are rich with type information. As we can see, BERT outperforms other methods in terms of F1 score, suggesting that it contains relevant type information. Please refer to Appendix G for more details.

Random: assign $|\Gamma(\hat{t})|$ randomly selected types.
Most Frequent Types (MFT): assign $|\Gamma(\hat{t})|$ most frequent types.
Human: We also evaluate the type annotations provided by human annotators on randomly selected 100 triples. Each triple is exposed to three annotators and they are asked to provide types to the tail NP. Since most of the annotations contain one type for each triple, we take the union of the types provided by different annotators to compensate for Recall. For 69% of the triples, the annotators agreed on the same type.

To be fair with the automated baselines, we use the same number of predicted types as BERT (i.e., $|\Gamma(\hat{t})|$). A comparison with a pre-trained explicit entity typing methods, such as (Choi et al., 2018), is not applicable here as their type vocabulary is different. As we can see from the results in Table 11, BERT achieves best F1 score, suggesting that it contains type information. The Recall for Human is low since most of the annotations contained only one type, resulting in lower F1 score.

Multimodal Fusion with Co-Attention Networks for Fake News Detection

Abstract

Fake news with textual and visual contents has a better story-telling ability than text-only contents, and can be spread quickly with social media. People can be easily deceived by such fake news, and traditional expert identification is labor-intensive. Therefore, automatic detection of multimodal fake news has become a new hot-spot issue. A shortcoming of existing approaches is their inability to fuse multimodality features effectively. They simply concatenate unimodal features without considering inter-modality relations. Inspired by the way people read news with image and text, we propose a novel Multimodal Co-Attention Networks (MCAN) to better fuse textual and visual features for fake news detection. Extensive experiments conducted on two real-world datasets demonstrate that MCAN can learn inter-dependencies among multimodal features and outperforms state-of-the-art methods.

1 Introduction

The rapid growth of social media has created fertile soil for the emergence and fast spread of fake news (Zhao et al., 2015), resulting in serious consequences. For example, during the U.S. 2016 presidential election, the most popular fake news was more widely spread than the most popular authentic news on Facebook, which confused people and broke the authenticity balance of the news ecosystem (Shu et al., 2017). To mitigate the negative effects caused by fake news, it is crucial to detect fake news on social media automatically.

Tweets with images are getting popular on social media recently, which have richer information and attract more viewers than tweets with only texts (Jin et al., 2017). Fake news also makes full use of this advantage to draw and mislead readers. Figure 1 shows three examples of fake news from Twitter.

Sharks in the mall! After the hurricane sandy!

Lenticular Clouds over Mount Fuji.

Woman, 36, gives birth to 14 children from 14 different fathers.

Figure 1: Some fake news from Twitter.

In the left example, both text and image indicate it is likely to be fake. The text of the middle one provides little evidence that it is fake news, but the image is obviously forged. In the right example, the image seems normal, while the textual contents indicate that it is probably fake. A hypothesis drawn from these examples is that combining text and the attached image is more conducive to detecting fake news.

Recent works have a growing interest in using multimodal (text + image) information to detect fake news. Jin et al.(2017) utilize local attention mechanisms to fuse features of image, text, and social context. Some studies explore to learn the joint representations of text and image, based on auxiliary adversarial networks (Wang et al., 2018) and variational autoencoders (Khattar et al., 2019). Nevertheless, they are not fine-grained enough in feature extraction and feature fusion. First, some studies require labor-intensive extra information, such as social context (Jin et al., 2017) and event category (Wang et al., 2018), to help detect fake news, which increases the cost of the detection. Second, except for texts in tweets, the methods mentioned above all focus on characteristics of images at the semantic level (e.g., emotional provocations), which can be reflected in the spatial domain. However, these methods ignore the individual information of fake images at the physical level, e.g., re-compression artifacts, which is reflected in the frequency domain (Qi et al., 2019). Third, some

August 1–6, 2021.

models (Wang et al., 2018; Khattar et al., 2019) obtain fused representations by simply concatenating multi-modality features. Although leverages local attention mechanism, the attention values of att-RNN (Jin et al., 2017) are only obtained from joint textual-social representations, which cannot reflect the similarity between textual-social representations and visual representations. Intuitively, when people judge news credibility with text and image, they often observe image first and then read text (Wang et al., 2020). This process may be repeated several times. In this process, people understand image according to the textual information, and understand text according to the associated image information. So the information of one modality is conditionally fused with that of another modality for once or multiple times. Intuitively, there are inter-modality attention relations between image and text. However, existing state-of-the-art methods are weak to fuse multimodal features due to their neglect of inter-modality interactions.

To address the aforementioned challenges, we propose the Multimodal Co-Attention Networks (MCAN) for fake news detection by considering multimodal features. In our proposed model, we first extract spatial-domain features and frequency-domain features from image, as well as textual features from text. Then we develop a novel fusion approach with multiple co-attention layers to learn inter-modality relations, which fuses visual features first, and then the textual features. The fused representation obtained from the last co-attention layer is used for fake news detection.

The contributions of this paper can be summarized as follows: (1) We propose a novel end-to-end approach to detect fake news on social media only using the text and the attached image, without any extra information and auxiliary tasks. (2) The proposed MCAN model stacks multiple co-attention layers to fuse the multimodal features, which can learn inter-dependencies among them. (3) Our MCAN model is a general framework for fake news detection, and the components of MCAN are flexible. The sub-networks used to extract multimodal features can be replaced by different models. Moreover, the modular fusion process of MCAN allows our model to handle more modalities conveniently. (4) We evaluate MCAN on two large scale real-world datasets. The results demonstrate that our model outperforms the state-of-the-art models.

The rest of the paper is organized as follows: In Section 2, we summary previous related work on fake news detection. In Section 3, we detail our proposed model. The datasets, baselines, and experiment results are presented in Section 4. We conclude the study in Section 5.

2 Related Work

Following the previous work (Ruchansky et al., 2017; Shu et al., 2017), we specify that **fake news is the news that is intentionally fabricated and can be verified as false**. Existing methods for fake news detection can be divided into unimodal approaches and multimodal approaches.

2.1 Unimodal Fake News Detection.

Textual features are extracted from text content, including statistical features, such as the number of paragraphs in the text (Volkova et al., 2017), the percentage of negative words (Potthast et al., 2017; Bond et al., 2017), the number of punctuation and emojis (Castillo et al., 2011), and semantic features, such as writing styles (Chen et al., 2015) and language styles (Feng et al., 2012). However, these features are hand-designed, bringing bias and design difficulty. To address this problem, many studies use deep learning technologies, such as RNN (Ma et al., 2016), CNN (Yu et al., 2017), and GAN (Ma et al., 2019), to identify fake news. Their results show that deep learning methods perform better.

Visual features are important for news verification (Jin et al., 2016; Shu et al., 2017), such as clarity score (Jin et al., 2016), the number of images (Wu et al., 2015; Jin et al., 2016). However, these features are manually crafted and just learn simple patterns, hardly applying to real images. Qi et al. (2019) design a CNN-based model to capture image patterns, but their model only works in the case of large samples. So the applicable scope is very limited.

Social context features are born in the social connection between users and tweets, such as user profile and the number of posts. Liu et al. (2018) use user profiles on the news propagation path to determine the truth of the news. Some other works model propagation patterns as tree structures based on kernel methods (Wu et al., 2015; Ma et al., 2017). However, social context features are handcrafted, incomplete, and unstructured.

The above work embodies the limitations of unimodal features in detecting fake news. In this paper,

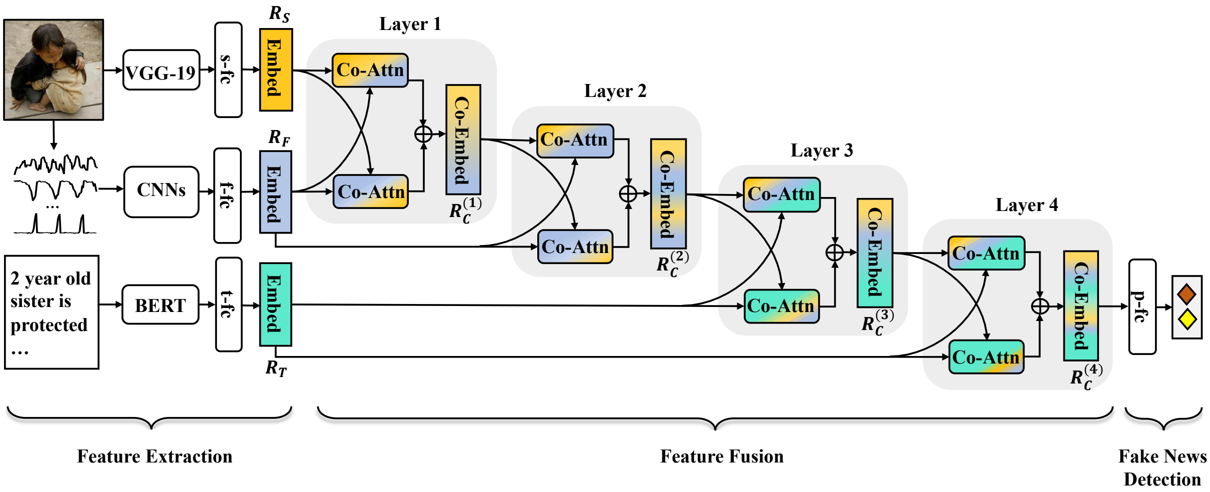

Figure 2: The architecture of our MCAN model.

we consider multiple modalities simultaneously when detecting fake news.

2.2 Multimodal Fake News Detection.

Recent works explore to fuse multimodal features. Jin et al. (2017) use local attention mechanism to fuse textual, visual, and social context features. Wang et al. (2018) learn event-invariant features by an aided adversarial network. Khattar et al. (2019) utilize autoencoders coupled with a detector to learn the shared representation of the text and the attached image. However, they ignore the characteristics of fake images at physical level (e.g., re-compression artifacts), and the fused features they learned lack correlations across multiple modalities.

To overcome the limitations of existing works, we propose MCAN to learn inter-dependencies among modalities. We extract spatial-domain and frequency-domain features of image, and textual features. Then we fuse them through a deep co-attention model inspired by a realistic scenario.

3 Methodology

3.1 Model Overview

Our model aims to learn multimodal fusion representations by considering dependencies across the modalities. As shown in Figure 2, the proposed model has three major procedures: feature extraction, feature fusion, and fake news detection.

Given news with text and image, we first utilize three different sub-models to extract features from spatial domain, frequency domain, and text. Then the multi-modality features are fused through a deep co-attention model, which consists of multiple co-attention layers. At last, the output of the co-attention model is used for judging the truth of the input news.

3.2 Feature Extraction

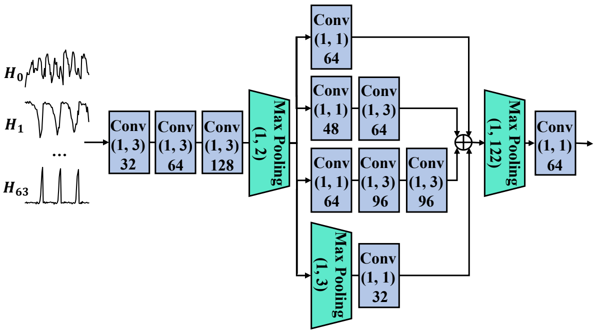

Figure 3: The detailed architecture of feature extraction in frequency domain.

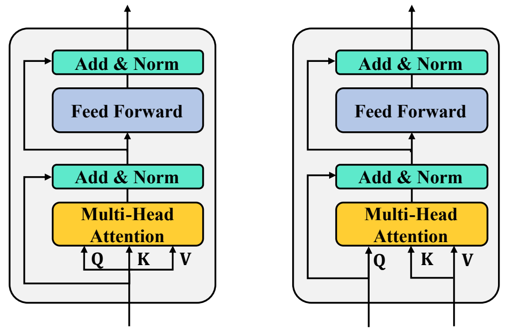
Spatial-Domain Feature. To learn the semantic-level characteristics of the given image, we employ the VGG-19 network (Simonyan and Zisserman, 2014) to extract visual features from spatial domain. After the second of the last layer of VGG-19, we add a fully connected layer (denoted as "s-fc" in Figure 2) with ReLU activation function to generate a $d \times 1$ dimensional feature representation of the input image in spatial domain, which is denoted as $R_S \in \mathbb{R}^{d \times 1}$.

Frequency-Domain Feature. Fake-news images are often re-compressed images or tampered images that show periodicity in frequency domain (Qi et al., 2019), which can be easily captured by CNNs. Thus we design a CNN-based sub-network to extract features from frequency domain, as in Figure 3. The image is transformed from spatial domain to frequency domain through discrete cosine transform (DCT) as in Qi et al. (2019). After that, we obtain 64 vectors $H_0, H_1, \ldots, H_{63}$, which are then sampled to the fixed size 250. For parallel computation, we pick 64 250-dimensional vectors into a matrix $H_F \in \mathbb{R}^{(64\times 250)}$, which is fed to the CNN-based network later. The CNN-based subnetwork consists of a major network along with multi-branch networks. The earlier parts of the major network have three convolutional blocks and a max-pooling layer. The multi-branch networks are the same as architectures in Inception V3 (Szegedy et al., 2016). The last parts of the major network are a max-pooling layer followed by a convolutional block. Each convolutional block is comprised of a two-dimensional convolutional layer with batch normalization and ReLU activation function. After adding a fully connected layer with ReLU activation function (denoted as “f-fc” in Figure 2), we obtain the feature representation of the image in frequency domain $R_F \in \mathbb{R}^{d\times 1}$.

Textual Feature. The text content of the tweet is a sequential list of words denoted as $T = [T_1, T_2, \ldots, T_n]$, where n is the number of words in a tweet, and each word $T_i \in T$ is tokenized by a pre-prepared vocabulary (Devlin et al., 2018). Recently, the BERT model (Devlin et al., 2018) which is pre-trained on a large language corpus, has been proven to perform very well in multiple natural language processing tasks. Thus we utilize BERT to obtain the aggregate sequence representation as textual features we desired. The textual feature is then resized to be a $d \times 1$ dimensional representation (denoted as R_T) by a fully connected layer with ReLU activation function.

3.3 Feature Fusion

Intuitively, people often look at the image first and then read the text when reading the news with image and text. This process may be repeated several times, continuously fusing image and text information. Therefore, we develop a novel fusion approach to simulate this process. Before presenting the fusing process, we first introduce its basic unit, the co-attention (CA) block. We achieve feature fusion by cascaded stacking multiple CA layers, which consists of two parallelly connected CA blocks.



(a) Self-attention block (b) Co-attention block

Figure 4: Illustration of the self-attention block and the co-attention block.

Co-attention block. Co-attention block (Lu et al., 2019) is a variant of the standard multi-head self-attention (MSA) block (Vaswani et al., 2017), which can capture global dependencies of all positions in a sequence and is widely used in NLP and VQA tasks (Nguyen and Okatani, 2018; Gao et al., 2019). The MSA block showed in Figure 4(a) consists of a multi-headed self-attention function and a fully connected feed-forward network, both wrapped a residual connection followed by layer normalization. The input of MSA is first used to compute $(d \times 1)$-dimensional queries, keys, and values packed into matrixes Q, K, V, respectively. The similarity of the dot product between Q and K determines the attention distribution on the V. Multi-head attention function with m heads has m self-attention functions in parallel. For the i-th head, the inputs are transformed from Q, K, and V as follow:

$$Q_i = QW_i^Q,\ K_i = KW_i^K,\ V_i = VW_i^V \tag{1}$$

where $W_i^Q, W_i^K, W_i^V \in \mathbb{R}^{1\times d_h}$ are the projection matrices for the i-th head, $d_h = d/m$ is the dimensionality of the output feature of each head.

The calculation process of multi-head self-attention function can be presented as follows:

$$\begin{aligned} \mathrm{MA}(Q, K, V) &= \mathrm{h}\, W^O \\ \mathrm{h} &= \mathrm{h}_1 \oplus \mathrm{h}_2 \oplus \ldots \oplus \mathrm{h}_\mathrm{m} \\ \mathrm{h}_i = \mathrm{A}(Q_i, K_i, V_i) &= \mathrm{softmax}(\frac{Q_i K_i^T}{\sqrt{d_h}})V_i \end{aligned} \tag{2}$$

where $W^O \in \mathbb{R}^{md_h\times 1}$, $\oplus$ denotes concatenation of vectors.

The fully connected feed-forward network consists of two linear transformations with a ReLU activation function in between,

$$\mathrm{FFN}(x) = \max(0, xW_1)W_2 \tag{3}$$

where the dimensionality of input and output is $d \times 1$, and the inner-layer dimensionality is d_{ff}.

The co-attention block (denoted as ”Co-Attn”) is extended from the MSA block, as shown in Figure 4(b). For a Co-Attn block, the queries are from one modality while keys and values are from another modality. Especially, the query matrice is used as a residual item after the multi-head attention sublayer. The rest architectures are the same as MSA. The Co-Attn block produces an attention-pooled feature for one modality conditioned on another modality. If Q comes from text and k and V come from the attached image, the attention value calculated using Q and K can be used as a measure of the similarity between the text and image, and then weights the image. Just like humans, after reading the text, they will pay more attention to the areas in the image that are similar to the text. We believe that co-attention can simulate this process and learn inter-dependencies between different features.

Co-attention layer. We obtain a CA layer by connecting two Co-Attn blocks in parallel, as shown in Figure 2. Giving two Co-Attn blocks different features, the CA layer computes queries, keys, and values for each Co-Attn block as in a MSA block. Then the keys and values of one Co-Attn block are passed as input to another Co-Attn block. The outputs of two Co-Attn blocks are concatenated together and then fed into a fully connected layer to get the fused representation. The CA layer models dense interactions between input modalities by exchanging their information.

Multiple co-attention stacking. In order to fuse multimodal features deeply, we stack 4 CA layers in depth. The fusion process is progressive, and the output of each CA layer is one of the inputs of the next layer (see Figure 2). We first fuse spatial-domain representation R_S and frequency-domain representation R_F in first CA layer and obtain $R_C^{(1)}$. Then R_F are enhanced to fuse with $R_C^{(1)}$ in the second CA layer which outputs $R_C^{(2)}$. In the third and fourth layers, the inputs are the output of the previous layer and text representation R_T, and outputs are $R_C^{(3)}$ and $R_C^{(4)}$, respectively. The output vector of each CA layer is d-dimensional.The calculation processes are formulated as follows. Due to the page limit, we only show the calculation processes in the first CA layer and skip the repeated calculation details of other layers.

$$R_{C_{S\leftarrow F}} = R_S + \mathrm{MA}(R_S, R_F, R_F) \tag{4}$$

$$R_{C'_{S\leftarrow F}} = R_{C_{S\leftarrow F}} + \mathrm{FFN}(R_{C_{S\leftarrow F}})) \tag{5}$$

$$R_{C_{F\leftarrow S}} = R_F + \mathrm{MA}(R_F, R_S, R_S) \tag{6}$$

$$R_{C'_{F\leftarrow S}} = R_{C_{F\leftarrow S}} + \mathrm{FFN}(R_{C_{F\leftarrow S}}) \tag{7}$$

$$R_C^{(1)} = (R_{C'_{S\leftarrow F}} \oplus R_{C'_{F\leftarrow S}})W_C^{(1)} \tag{8}$$

where $R_{C'_{S\leftarrow F}} \in \mathbb{R}^d$ is the attention-pooled feature for spatial domain conditioned on frequency domain, $R_{C'_{F\leftarrow S}} \in \mathbb{R}^d$ is the attention-pooled feature for frequency domain conditioned on spatial domain, and $W_C^{(1)} \in \mathbb{R}^{2d\times d}$ is the projection matrice of the first CA layer. $R_C^{(1)}$ is transformed to be a $(d \times 1)$-dimensional representation before being input to the next CA layer. Specifically, the first and the third CA layers share parameters, and the second and the fourth CA layers share parameters.

3.4 Model Learning

We have obtained the multimodal feature representation $R_C^{(4)}$ fused features of text, spatial domain, and frequency domain. Let $f = R_C^{(4)}$, which is used to predict. The output of the proposed MCAN is the probability of a tweet being fake:

$$\hat{y} = \mathrm{softmax}\left(\max(0, fW_f)W_s\right) \tag{9}$$

where W_f is parameters of the fully connected layer, and W_s is parameters of the linear layer in the softmax layer. The loss function is devised to minimize the cross-entropy value:

$$L(\Theta) = -y\log(\hat{y}) - (1-y)\log(1-\hat{y}) \tag{10}$$

where y is the ground truth, with 1 representing fake news and 0 representing real news, and Θ denotes all learnable parameters in the proposed model.

4 Experiments

4.1 Datasets

To evaluate the effectiveness of the proposed MCAN, we conduct experiments on two public real-world datasets, which are collected from Twitter and Weibo, respectively. The Twitter dataset was released for Verifying Multimedia Use task at MediaEval (Boididou et al., 2016). The Weibo dataset is collected by Jin et al. (2017). In the

	Twitter	Weibo
# of fake news	8199	4211
# of real news	6681	3639
# of images	512	7850

Table 1: Statistics of two datasets.

Weibo dataset, the real news is verified by an authoritative news agency in China, Xinhua News Agency. The fake news is verified by the official rumor debunking system of Weibo. The tweets in each dataset contain texts, attached images/videos, and social context information. In this work, we focus on text and image information. So we remove the tweets with videos and the tweets without texts or images. In Twitter dataset, 512 images are shared by the remaining data. When preprocessing the Weibo dataset, the steps we used are similar to that in the work (Jin et al., 2017). We keep the same data split scheme as the benchmark on these two datasets. The detailed statistics of the two datasets are listed in Table 1.

4.2 Experimental Settings

The max length of the text is 25 on Twitter and 160 on Weibo. The hidden size of ”s-fc”, ”f-fc” and ”t-fc” are 256. We set d=256, m = 4, and d_{ff} = 512. The hidden size of ”p-fc” is 35. The parameters of VGG-19 and BERT are frozen when training on Twitter dataset due to overfitting, but not on Weibo dataset. The BERT model used on Twitter dataset is multilingual cased BERT-based model and the one used on Weibo dataset is Chinese BERT-based model. Our proposed model is trained for 100 epochs with early stopping. We use Adam (Kingma and Ba, 2014) and AdaBelief (Zhuang et al., 2020) as optimizers on Twitter and Weibo datasets, respectively, to seek the optimal parameters of our model. The optimal hyperparameters of our model are determined by grid searching, and the selection criterion is accuracy. The hyperparameters of baselines are the same as those in respective studies.

4.3 Baselines

To validate the effectiveness of MCAN, we choose two categories of baseline models: unimodal models and multimodal models, which are listed as follows: (1) **Text**: a BERT model coupled with the decision network in MCAN, using textual information. (2) **Spatial**: a model consists of a VGG-19 model and the decision network of MCAN, utilizing image information in spatial domain. (3) **Freq**: proposed MCAN only has the part of dealing with frequency-domain features. (4) **VQA** (Antol et al., 2015): a model aims to answer questions according to the given images. For fair comparisons, we use a one-layer LSTM. (5) **NeuralTalk** (Vinyals et al., 2014): a deep recurrent framework for image caption. The joint representation of image and text is obtained by averaging the output of RNN at each timestep. (6) **att-RNN** (Jin et al., 2017): att-RNN utilizes local attention to fuse textual, visual, and social context features. For a fair comparison, we remove the part dealing with social context information. (7) **EANN** (Wang et al., 2018): A neural network based on the adversarial idea to remove the event-specific features. In EANN, event identification is an auxiliary task, and event labels are not in original datasets. For a fair comparison, we removed the event discriminator. (8) **MVAE** (Khattar et al., 2019): MVAE learns shared representations of text and image using a variational autoencoder coupled with a binary classifier. We use the same model as in the original work (Khattar et al., 2019). (9) **MCAN-A**: MCAN without the part of fusing multimodal features. Spatial-domain features, frequency-domain features, and textual features are simply concatenated for prediction.

4.4 Performance Comparison

Table 2 shows the results of baselines and our proposed model on two datasets. We can observe that the proposed MCAN outperforms all the baselines over all metrics across two datasets.

There are many similar trends on the two datasets. MCAN-A performs better than unimodal models, which indicates that adding features usually improves model performance, but it is not always positively correlated. For example, Text on Weibo dataset is better than MCAN-A. After adding the process of multimodal fusion, our proposed MCAN beats MCAN-A and other multimodal models, which embodies our proposed feature fusion method is indeed better than the simple concatenation method.

There are also some differences on the two datasets. The performance of Text (BERT) and Spatial (VGG-19) on Weibo dataset is much better than that on Twitter dataset. The reason is related to the dataset itself. On Weibo dataset, the average length of a tweet is about 10 times of that of a tweet

Dataset	Method	Accuracy	Fake News			Real News		
			Precision	Recall	F_1	Precision	Recall	F_1
Twitter	Text	0.633	0.656	0.762	0.705	0.587	0.459	0.515
	Spatial	0.671	0.841	0.527	0.648	0.574	0.864	0.69
	Freq	0.665	0.733	0.656	0.692	0.592	0.677	0.631

	MCAN	**0.899**	**0.913**	**0.889**	**0.901**	**0.884**	**0.909**	**0.897**

Table 2: The results of different methods on two datasets

on Twitter dataset, which probably makes BERT perform better on Weibo dataset. Moreover, more than 70% of tweets on Twitter dataset are related to a single event. Thus, the training samples of BERT and VGG-19 are too similar, resulting in poor performance of model generalization. This is the reason why we fine-tuned BERT and VGG-19 on Weibo dataset but not on Twitter dataset. They are easy to overfit on Twitter dataset. But Weibo dataset has no such imbalanced issue.

On Weibo dataset, the accuracy of fine-tuned BERT and VGG-19 all exceed 85%. In this case, our proposed MCAN further improves the accuracy to close to 90% with the help of cascaded way of stacking CA layers. Comparing with the situation on Twitter dataset, we can find that our model performs better in the face of weak unimodal features. In our MCAN model, the representation ability of features can be greatly improved by effectively fusing other features.

4.5 Ablation Analysis

Quantitative Analysis. To evaluate the effectiveness of each component of the proposed MCAN, we remove each one from the entire model for comparison. "ALL" denotes the entire model MCAN with all components, including spatial-domain representation (S), textual representation (T), frequency-domain representation (F), and co-attention layers (A). After removing each one of them, we obtain the sub-models "-S", "-T", "-F" and "-A", respectively. "-F-A" denotes the reduced MCAN without both frequency-domain representation and co-attention layers. The results are exhibited in Figure 5.

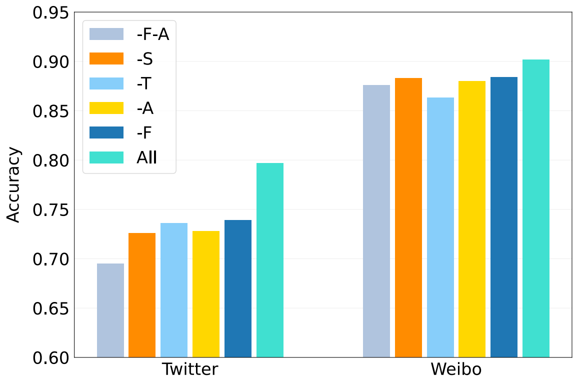

Figure 5: MCAN ablation analysis in Accuracy.

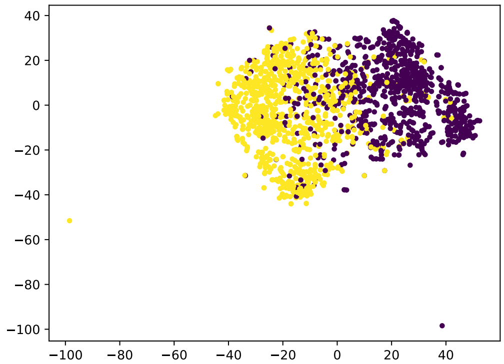
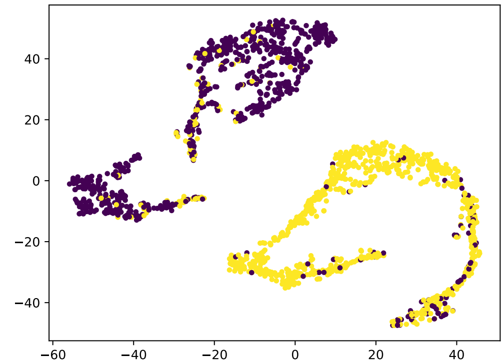
We can see that every component plays a significant role in improving the performance of MCAN. MCAN beats MCAN-F, which reveals that the frequency domain information is indeed helpful to detect fake news. On Twitter dataset, the contribution of textual representations to the entire model is less than that of visual representations, while the situation on Weibo dataset is opposite. This is still due to the imbalanced issue and the less average length of a tweet on Twitter dataset, which decrease the performance of the textual representation. Besides, on Weibo dataset, removing one or two components, the performance of MCAN does not drop significantly as on Twitter dataset. This benefits from balanced data distribution and the stability of fine-tuned BERT and VGG-19, as mentioned in Section 4.4.



(a) MCAN-A



(b) MCAN

Figure 6: Visualizations of learned latent feature representations.

Qualitative Analysis. To illustrate the effectiveness of co-attention layers in MCAN, we qualitatively visualize the joint representation of three modalities learned by MCAN-A and the fused representation $R_C^{(4)}$ learned by MCAN on Weibo testing set with t-SNE (Maaten and Hinton, 2008), as shown in Figure 6. The label of each tweet is real or fake.

From Figure 6, we can observe that the separability of the feature representation learned by MCAN is much better than its reduced model MCAN-A. MCAN-A can learn discriminable features, but many features are still easily misclassified, showing in Figure 6(a). On the contrary, the features learned by MCAN are more discriminable with a more significant segregated area between two types of samples, as exhibited in Figure 6(b). This is attributed to the cascaded way of stacking co-attention layers in MCAN, which fuses the characteristics of multiple modalities deeply and boosts to distinguish fake news and real news.

From the above phenomena, we can conclude that the proposed method MCAN learns better and more distinctive feature representations with the co-attention layers, thus achieving better performance.

4.6 Case Studies

To further illustrate the importance of multimodal features for fake news detection, we compare the results reported by MCAN and unimodal models (Text and Spatial) and exhibit some fake news correctly captured by MCAN but missed by unimodal models.

Before washed away by flood, an Indian man calmly gave the last gesture to a photographer.

A group of dolphins brought a dog that fell into a canal to safe area.

Figure 7: Some fake news detected by MCAN but missed by Text on the Weibo dataset.

Figure 7 shows two top-confident tweets successfully detected by MCAN but missed by text-only MCAN. The textual contents of the two examples can provide little evidence that it is fake news. However, the two attached images seem forged pictures.

The water mantis lives in sewers. Its head has two to three times the poison of pufferfish and has no antidote.

Several urban management officers are frantically plundering street-side property worth more than 100 million yuan.

Figure 8: Some fake news detected by MCAN but missed by Spatial on the Weibo dataset.

In Figure 8, the two examples are detected by MCAN but missed by Spatial. The attached images in two examples look normal. However, the words in the tweet seem exaggerated and unbelievable. It is challenging for spatial-domain-only MCAN to detect, but with multimodal features, our MCAN model identifies them correctly.

These comparative cases prove that when a single-modal model, whether a text-based model or an image-based model, cannot correctly distinguish fake news, the proposed MCAN using multimodal features can give high confidence.

5 Conclusions

In this work, we propose a novel Multimodal Co-Attention Networks (MCAN) to tackle the challenge of fusing multimodal (textual and visual) features for fake news detection. We utilize three different sub-networks to extract features from text, spatial domain, and frequency domain, respectively. Then the three features are deeply fused by stacking co-attention layers, which is inspired by human behavior. When people read news with image, image and text are read once or multiple times, and continuously fused in brain. Experiments on two public benchmark datasets for fake news detection validate the effectiveness of MCAN, and the results show that MCAN outperforms the current state-of-the-art methods. In the future, we plan to extend the co-attention based fusion approach in MCAN to other fake news research, such as fake news diffusion.

Abstract

Current researches on frame semantic parsing include three subtasks, namely frame identification, argument identification and role classification. Most of previous systems process these subtasks independently and ignore their interactions. We introduce a novel architecture based on multi-decoder strategy to handle these subtasks together. The multi-decoder strategy strengthens the interactions. Moreover, we design a hierarchical pointer network for argument identification which reduces the computational complexity. To our best knowledge, it's the first practice to introduce the pointer network into frame semantic parsing. The experiments show improvement over state of the art models on FrameNet dataset.

1 Introduction

Frame semantic parsing is a fundamental study in Natural Language Processing. It aims to parse sentences into frame-style semantic structures defined in FrameNet (Baker et al., 1998).

An example of frame-style semantic structures is shown in Figure 1. The word ***write.v*** is a target that evokes the frame called ***Text_creation***. The phrases underlined with green lines are called arguments. ***Author***, ***Text*** and ***Form*** are roles (also called frame elements) the arguments play in this frame. Hence the frame semantic parsing contains three subtasks, namely frame identification, argument identification and role classification. For a sentence with a given target, the frame identification is to disambiguate the frame for the target based on its contextual information, the argument identification is to identify the boundaries of all the arguments, and the role classification is to assign a semantic role to each argument we have found.

Early work (Hermann et al., 2014; FitzGerald et al., 2015; Hartmann et al., 2017) on frame semantic parsing adopts pipeline strategy. Their models apply independent models to handle different subtasks which ignore the interactions among subtasks. Moreover, the pipeline strategy usually causes error propagation problem. The accuracy of frame identification can become the bottleneck of the overall performance. Later work (Yang and Mitchell, 2017; Peng et al., 2018) processes all the subtasks jointly by optimizing them together during training. Their joint models show improvement over pipeline models, which demonstrates the benefit of joint training strategy. However, their systems don't have specific design to model the interactions among the subtasks.

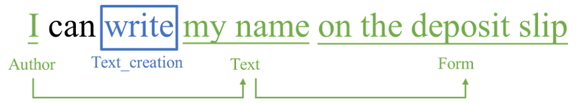

Figure 1: A sentence annotated the arguments and roles of frame ***Text_creation***. The arrow marks indicate the order of arguments identification and roles classification.

To strengthen the interactions of subtasks, we propose a joint framework based on three task-specific decoders. The interactions in our framework are mainly reflected in two aspects. On one hand, the representations of both the target and its frame that derived from frame identification decoder are applied to predict the arguments and roles. On the other hand, the argument identification decoder and the role classification decoder work in an alternate way, and thus they interact with each other during the entire process of decoding.

The interactions bring two benefits. First, the frame information predicted by frame identification decoder makes the predictions of arguments and roles more frame-specific. Second, the alternate decoding strategy makes the current argument's and role's prediction influenced by all previous

SENTENCE	Coming to Goodwill was the first step toward my becoming totally independent.
TARGET	**come.v**(Arriving), **to.prep**(Goal), **first.a**(Ordinal_numbers), **step.n**(Intentionally_act), **become.v**(Becoming), totally.adv(Degree)

Table 1: An example sentence with annotated targets and golden frames from FrameNet dataset. Bold words indicate that the target can evoke multiple frames.

decisions, which captures relations among different arguments and roles. For the sentence shown in Figure 1, the argument ***I*** and its role ***Author*** can contribute to the predictions of the argument ***my name*** and the role ***Text***. Therefore, the argument identification and the role classification can benefit from each other by considering arguments and roles already obtained.

For argument identification, previous models (Yang and Mitchell, 2017; Peng et al., 2018) enumerate all possible spans to identify the arguments, which brings high computational complexity. To reduce the computational complexity, we design a hierarchical pointer network in the argument identification decoder that predicts boundaries of arguments directly.

In addition, we design a target-aware attention mechanism. The target-aware attention mechanism aggregates all targets in the same sentence to model interactions among different targets, since frames evoked by different targets in the same sentence are usually closely related. Such interaction modeling could be helpful in frame identification. For example, the target ***to.prep*** in Table 1 can evoke the frame ***Goal*** or ***Locative_relation***, and other co-occurrence targets (such as ***come.v***) make ***to.prep*** more likely to evoke frame ***Goal*** instead of the other frame.

Overall, our main contributions can be summarized as follows:

- We design a novel multi-decoder framework to jointly process all the subtasks of frame semantic parsing. The multi-decoder strategy strengthens the interactions among frame identification, argument identification and role classification.

- We design a hierarchical pointer network that predicts the boundaries of arguments directly. The hierarchical pointer network predicts arguments within linear computational complexity. To our best knowledge, it's the first practice to introduce the pointer network into frame semantic parsing task.

- We design a target-aware attention mechanism to aggregate the semantic information of other targets in the same sentence.

We evaluate our model on FrameNet dataset, and the experiments show that our model outperforms state of the art models, which demonstrates the effectiveness of our model.

2 Related Work

Frame semantic parsing task is first proposed by Gildea and Jurafsky (2002) and has drawn attention since the SemEval 2007 shared task (Baker et al., 2007) was released. Early researches on frame semantic parsing focus on the feature-engineered methods(Johansson and Nugues, 2007; Das et al., 2010). Most of the early researches regard the frame semantic parsing as a pipeline of classification tasks and employ machine learning algorithms (such as Support Vector Machines etc.).

With the popularity of neural network and representation learning, neural network models are introduced to model frame semantic parsing problem. Hermann et al. (2014) uses distributed representations in frame identification and embedded both frames and the contextual representations of words into a shared low-dimension vector space. FitzGerald et al. (2015) uses a neural network to learn embeddings of both arguments and semantic roles, which adopts fine-grained similarity between roles to overcome the sparsity of some labeled data. Besides, a system based on pre-trained word distributed representations (Hartmann et al., 2017) is developed to improve the domain adaptation of their model. These models still work in pipeline way.

However, pipeline models usually ignore the interactions among subtasks and suffer from the problem of error propagation. Joint models are proposed to solve these problems. Yang and Mitchell (2017) proposes an ensemble strategy that that integrates two different models into an ensemble model. Peng et al. (2018) proposes a multi-task framework which jointly handles two different semantic pars-

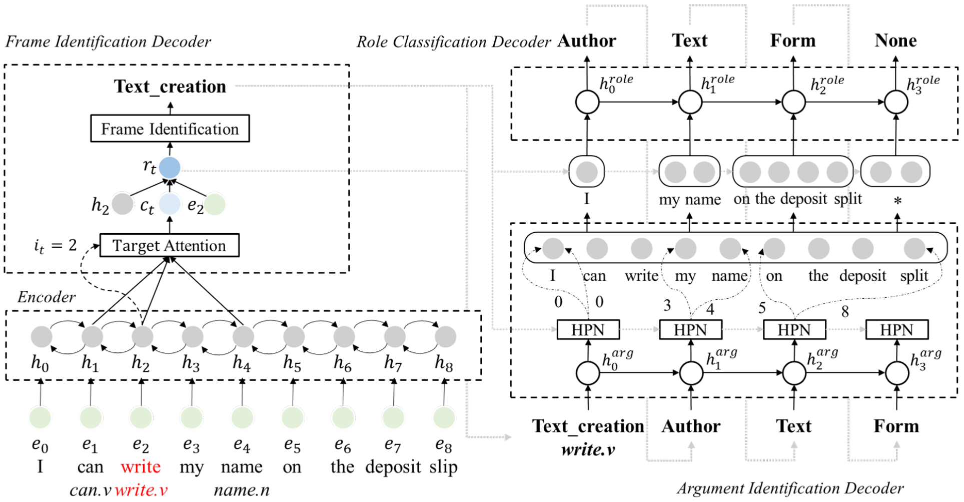

Figure 2: Our framework predicts frames, arguments and roles jointly based on three task-specific decoders. Frame identification module predicts frame ***Text_creation*** evoked by target ***write.v***. Then argument identification module with HPN(Hierarchical Pointer Network) and role classification module predict argument spans ***I***, ***my name*** and ***on the deposit split*** and their roles ***Author***, ***Text*** and ***Form*** alternately. The interactions in our framework are shown as gray dotted lines.

ing tasks from disjoint data. Both of their models process all the subtasks jointly by optimizing them together during training. Their experiments show improvement over previous pipeline models, which proves the benefit of joint training strategy. However their models don't have specific design for the interactions.

The common neural network architectures for frame semantic parsing can be divided into sequence labeling models and relational models. Yang and Mitchell (2017) proposes a sequence labeling model based on BIO tagging scheme. The model contains multiple LSTM layers and a Conditional Random Field (CRF) layer. Swayamdipta et al. (2017) adopts a segmentation RNN and a relational model to capture span-level dependencies between predicate and arguments. The relational model enumerates all possible spans to compute the matching scores. Both of these two type models above require $O(n^2)$ computational complexity. To reduce the high computational complexity, we design a hierarchical pointer network that achieves the identifying arguments within linear computational complexity.

3 Method

As is shown in Figure 2, our framework consists of four modules. (1) the encoder module (2) the frame identification decoder module. (3) the argument identification decoder module. (4) the role classification decoder module.

Specifically, given a target t and a sentence $S = w_0, \dots, w_{n-1}$, the encoder module calculates the contextual representations $h_0, \dots, h_{n-1}$, then all decoder modules handle three subtasks jointly. The frame identification decoder builds a target representation for t and identifies the frame $f \in F$ evoked by t. Suppose that there are k argument spans $a_0, \dots, a_{k-1}$ of f in S. For each argument $a_\tau = w_{i_\tau^s}, \dots, w_{i_\tau^e}$, the argument identification decoder identifies the boundaries i_τ^s and i_τ^e, and the role classification decoder assigns a semantic role $r_\tau \in R_f$ to a_τ. The F and R_f mentioned above are the sets of all frames and all semantic roles of f defined in FrameNet.

Three decoders interact with each other as follows:

- Frame identification decoder builds a target representation for t to identify the frame f. Both the target representation and the embedding of f will be taken as inputs to the other decoders for argument identification and role classification.

- Role classification decoder assigns a role r_τ to current argument span a_τ, and then the embedding of r_τ will be taken as an input to identify the boundary of next argument $a_{\tau+1}$. In other words, these two decoders work in an alternate way, so identifying $a_{\tau+1}$ and $r_{\tau+1}$ will consider all the historical information of $a_0, \dots, a_\tau$ and their roles $r_0, \dots, r_\tau$.

3.1 Encoder Module

Encoder module aims at converting the sentence $S = w_0, \ldots, w_{n-1}$ into a sequence of vectors $h_0, \ldots, h_{n-1}$, where h_i is the contextual representation of word w_i.

For each token, we concatenate its word embedding e_{w_i}, lemma embedding e_{l_i}, POS embedding e_{p_i} and a binary tag embedding e_{b_i}:

$$e_i = [e_{w_i}; e_{l_i}; e_{p_i}; e_{b_i}] \tag{1}$$

The binary tag embedding e_{b_i} is to distinguish t from other words in S. Let i_t be the position index of t in S, then we can calculate e_{b_i}:

$$e_{b_i} = \begin{cases} e_1, & i = i_t \\ e_0, & i \neq i_t \end{cases} \tag{2}$$

At last, e_i is fed to the encoder to get contextual representation h_i:

$$h_i = \text{Encoder}(e_i) \tag{3}$$

The word embedding and lemma embedding are initialized with Glove (Pennington et al., 2014) while POS embedding is randomly initialized. We use Bi-LSTM as the encoder in our experiment, which can be also replaced with any other encoder model such as Bert (Devlin et al., 2018). The dimension of e_i is d_e and the dimension of h_i is d_h.

3.2 Frame identification module

In frame identification module, we build a target representation r_t for t and identify the frame f based on r_t.

As there are likely to be multiple targets $t_0, \ldots, t_{m-1}$ in S evoking multiple frames $f_0, \ldots, f_{m-1}$ and we believe that other targets in S can contribute to identifying current frame f for target t, we design a target aware attention mechanism to aggregate contextual representations of all targets $T_S = \{t_0, \ldots, t_{m-1}\}$ in S (also contains the target t):

$$\alpha_i = \frac{\exp(h_i^\top W_1 h_{i_t})}{\sum_{j \in T_s} \exp(h_j^\top W_1 h_{i_t})} \tag{4}$$

$$c_t = \sum_{i \in T_s} \alpha_i h_i \tag{5}$$

For the target, we concatenate c_t, its contextual representation h_{i_t} and its embedding e_{i_t} to get the target representation r_t:

$$r_t = \text{Relu}(W_2 \cdot [e_{i_t}; h_{i_t}; c_t]) \tag{6}$$

With the target representation, we can generate the probability distribution of frames to identify f by argmax operation:

$$P(f|S,t) = \text{softmax}(W_3 \cdot r_t) \tag{7}$$

W_1, W_2, W_3 are three weight matrixes in $R^{d_h \times d_h}$, $R^{d_h \times (2d_h + d_e)}$ and $R^{|F| \times d_h}$ repectively, where $|F|$ is the size of F.

3.3 Argument Identification Module

Argument identification decoder module identifies the boundaries of argument spans $a_0, \ldots, a_{k-1}$ sequentially. For τ-th argument $a_\tau = w_{i_\tau^s}, \ldots, w_{i_\tau^e}$, the historical information of $a_0, \ldots, a_{\tau-1}$ and their roles $r_0, \ldots, r_{\tau-1}$ is supposed to be utilized. Hence We use LSTM_A to record the historical information, and similarly, another LSTM named LSTM_R is applied in role classification decoder. Argument identification decoder interacts with other decoders by taking their output as input, here is how LSTM_A works at τ-th argument:

$$x_\tau = \begin{cases} [r_t; e_f], & \tau = 0 \\ \left[h_{\tau-1}^{role}; e_{r_{\tau-1}}\right], & \tau > 0 \end{cases} \tag{8}$$

$$h_\tau^{arg} = \text{LSTM}_\text{A}\left(h_{\tau-1}^{arg}, x_\tau\right) \tag{9}$$

h_τ^{arg} and h_τ^{role} are hidden states at timestep τ of LSTM_A and LSTM_R. e_f represents the embedding of f, and $e_{r_{\tau-1}}$ represents the embedding of $r_{\tau-1}$.

As we want to identify the start and end positions of a_τ, namely i_τ^s and i_τ^e, we build two kinds of feature representations to extract boundary feature from h_τ^{arg} and e_f:

$$h_\tau^{STA} = \text{MLP}_\text{s}([h_\tau^{arg}; e_f]) \tag{10}$$

$$h_\tau^{END} = \text{MLP}_\text{e}([h_\tau^{arg}; e_f]) \tag{11}$$

The dimensions of both h_τ^{STA} and h_τ^{END} are the same as contextual representations $h_0, \ldots, h_{\tau-1}$, and the MLP in our experiment consists of two linear layers and a relu activation function in between.

3.3.1 Hierarchical pointer network

With two representations h_τ^{STA} and h_τ^{END}, we apply a hierarchical pointer network to identify i_τ^s and i_τ^e. The hierarchical pointer network contains two pointer networks as is shown in Figure 3. The hierarchical pointer network identifies the i_τ^s firstly and then identify the i_τ^e based on i_τ^s. If we identify them simultaneously, the i_τ^s and i_τ^e may sometimes

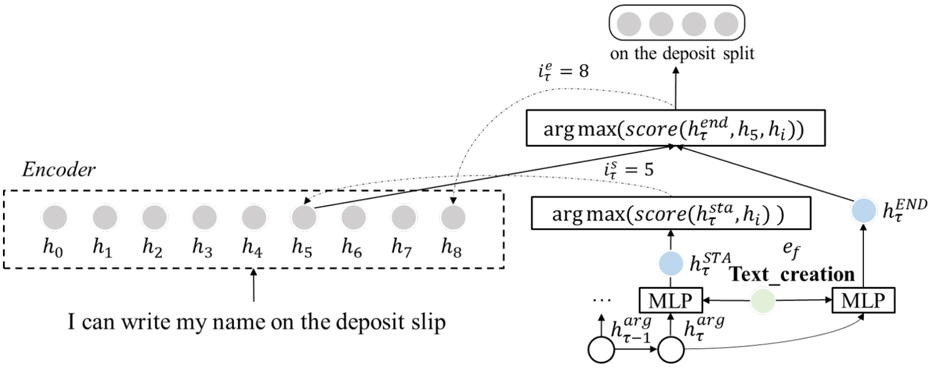

Figure 3: The prediction process of the argument ***on the deposit slip***.

be inconsistent. Besides, to avoid duplicate prediction, all spans in $a_0, \ldots, a_{\tau-1}$ are masked when identifying i^s_τ and i^e_τ. The prediction process is:

$$Score_{STA} = H^\top W_4 h^{STA}_\tau \tag{12}$$

$$P\left(i^s_\tau|S,t,f\right) = \text{softmax}(Score_{STA}) \tag{13}$$

$$i^s_\tau = \text{argmax}(P\left(i^s_\tau|S,t,f\right)) \tag{14}$$

$$Score_{END} = H^\top(W_5 h^{END}_\tau + W_6 h_{i^s_\tau}) \tag{15}$$

$$P\left(i^e_\tau|S,t,f\right) = \text{softmax}(Score_{END}) \tag{16}$$

$$i^e_\tau = \text{argmax}(P\left(i^e_\tau|S,t,f\right)) \tag{17}$$

H is $d_h \times n$ matrix $(h_0, \ldots, h_{n-1})$ that represents the encoder output of sentence S. W_4, W_5 and W_6 are $d_h \times d_h$ weight matrixes.

The hierarchical pointer network achieves arguments identification within linear computational complexity. For an n-tokens and k-arguments sentence, our model can identify the start and end positions of each argument with $O(2n)$ computational complexity, and $O(2n \cdot k)$ for all arguments.

3.4 Role Classification Module

The role classification module assigns semantic roles $r_0, \ldots, r_{k-1}$ to arguments $a_0, \ldots, a_{k-1}$. Assigning r_τ to a_τ also needs to consider the semantic information of $a_0, \ldots, a_{\tau-1}$ and their roles $r_0, \ldots, r_{\tau-1}$. Hence we use the same LSTM architecture named LSTM_R to record them. Both the contextual information of a_τ and the frame embedding e_f are used to predict r_τ:

$$y_\tau = W_7 \cdot [h_{i^e_\tau} + h_{i^s_\tau}; h_{i^e_\tau} - h_{i^s_\tau}; e_f] \tag{18}$$

$$h^{role}_\tau = \text{LSTM}_\text{R}(h^{role}_{\tau-1}, y_\tau) \tag{19}$$

$$P(r_\tau|S,t,f,a_\tau) = \text{MLP}([h^{role}_\tau; y_\tau]) \tag{20}$$

$h_{i_e} + h_{i_s}$ represents the boundary feature of a_τ and $h_{i_e} - h_{i_s}$ represents the inner feature of the span (Wang and Chang, 2016; Cross and Huang, 2016; Ouchi et al., 2018). With the probability distribution $P(r_\tau|S,t,f,a_\tau)$, we can predict the role r_τ.

Moreover, we add a special role ’None’ at the final decoding step and let r_k be ’None’. During the inference stage, the role classification decoder and argument identification decoder will automatically stop when predicting ’None’.

4 Loss Function

We utilize cross-entropy loss to maximize the probability of the oracle frame type, span boundaries (start-end pair) and role types:

$$\mathscr{L}_{frame} = \log(P(\hat{f}|S,t)) \tag{21}$$

$$\begin{aligned}\mathscr{L}_{role} = \sum_{\tau=0}^{k-1} &\log(P(\hat{r}_\tau|S,t,f,a_\tau))+ \\ &\log(P(r_{None}|S,t,f,a_k))\end{aligned} \tag{22}$$

$$\begin{aligned}\mathscr{L}_{span} = &\sum_{\tau=0}^{k-1} \log(P(\hat{i}^s_\tau|S,t,f))+ \\ &\sum_{\tau=0}^{k-1} \log(P(\hat{i}^e_\tau|S,t,f))\end{aligned} \tag{23}$$

We optimize the losses of the three subtasks jointly:

$$\mathscr{L} = \alpha\mathscr{L}_{frame} + \beta\mathscr{L}_{span} + \gamma\mathscr{L}_{role} \tag{24}$$

α, β and γ are hyper-parameters that adjust the direction of training optimization.

5 Experiment

Dataset. We train and evaluate our model on FrameNet 1.5 dataset proposed by (Das and Smith, 2011) following previous work (Yang and Mitchell, 2017; Swayamdipta et al., 2017; Peng et al., 2018).

We also follow the same train/development/test split. Meanwhile, previous work adds the partially-annotated exemplar sentences (each exemplar sentence contains only one target). As is reported in previous work (Das et al., 2014; Yang and Mitchell, 2017; Swayamdipta et al., 2017), the exemplar sentences data can help to improve their models' performance. We add it as pre-train data for our model.

Pre-process. Previous work removes the argument spans longer than 20, which is a constraint that helps to reduce the computational complexity from $O(n^2)$ to $O(n)$. Though our model doesn't need such constraint because of better computational complexity, we hold the same setting as previous work for comparison. We also report the result that training our model without length constraint.

Setup. We train our models by two steps following previous work (Das et al., 2014). At first step, we pre-train our model with partially-annotated exemplar sentences data. Then we train the model on the offcial train set. We evaluate our model on development test and save the best performance model for test.

We use Glove (Pennington et al., 2014) to initialize the word embeddings, and average the existing embeddings for out-of-vocabulary words. We randomly initialize embeddings for part-of-speech tags, and token type tags. All the embeddings are learnable during training.

Other detail hyper-parameters are shown on Table 2.

Model. We compare our model with following previous models:

SEMAFOR: A widely known system(Chen et al., 2010) that uses a variety of syntactic features.

Framat: An open-source semantic role labeling tool proposed by Björkelund et al. (2010).

Framat+context: An extension version of Framat that adds extra context features by Roth and Lapata (2015).

Hermann et al.(2014): A frame identification model uses feature representation based on word embedding and WSABIE algorithm (Weston et al., 2011).

FitzGerald et al.(2015): A pipeline model that improves frame identification performance based on Hermann et al. (2014).

Open-SESAME: A pipeline model that predicts frame by FitzGerald et al. (2015) and designs a softmax-margin segmental RNN to improve argument identification.

5.1 Experiment Metrics And Result

We evaluate our model on the metrics of frame identification accuracy and full structure extraction. Note that previous systems may also report ensemble models based on different ensemble methods to improve models' performance, and the model (Peng et al., 2018) based on multi-task framework brings extra train data. For comparability, we only report the performance of single models that trained on framenet data only. We note that none of above-mentioned previous models are based on Bert which is widely applied in many NLP tasks. To explore the impact of Bert on frame semantic parsing, we implement a Bert-based version of our model and also report results of Bert-based model.

Table 5: Full structure extraction result of our models considering the effect of the interactions among decoders.

Frame Identification. The metrics of frame identification accuracy includes Ambiguous and All as is shown in Table 3. The ambiguous metrics evaluates targets evoking more than one possible frame in FrameNet and All evaluates all the targets. According to Peng et al. (2018), some previous studies' ambiguous lexical unit sets are not the same as the one from the official frame directory, which makes their results uncomparable. Therefore, it's fairer to use ALL to evaluate the performance of frame identification. Our model outperforms all previous models (0.2 point over SOTA). Our Ambiguous set is the same as Peng et al. (2018)'s and our model outperforms theirs by 0.4 point.

Full Semantic Structure Extraction. Full Semantic Structure Extraction is the metrics that measures the overall performance of Frame Semantic parsing. It requires exact match of arguments' boundaries and jointly evaluates the performance of frame identification, argument identification and role classification. (Baker et al., 2007) shows details of the metrics. Table 4 is the result. The first group contains pipeline models and the second group includes joint models. Our model shows improvement over all previous models (0.7 point over SOTA). We notice that our model greatly outperform state of the art models on Recall. We analyze that it's because the decoders of our model fully interact and make the current decision by considering all previous steps' decisions. Such strategy is likely to predict more complete arguments and roles.

Model	**P**	**R**	**F1**

Our Model	75.1	76.9	76.0
wo length constraint	75.1	77.6	76.3

Table 7: Full structure extraction result of our models considering the influence of the length constraint of arguments.

5.2 Ablation study

We train our model in different settings and evaluate them on the metrics of full structure extraction to measure their overall performance. We consider the influences of decoders' interactions, pre-train data (partially-annotated exemplar sentences), targets-aware attention mechanism (TAM) and the length constraint of arguments.

As mentioned before, all the decoders of our model interact with each other and the interactions are reflected in two aspects. To prove the effectiveness of them, we remove the interactive parts of the decoders respectively. Table 5 shows the results of models with following setting:

Without interaction (Arg&Role) means the interaction between argument identification decoder and role classification decoder is deleted.

Without interaction (Frame) means the identified frame information in frame identification decoder is not accessible to the other decoders.

Without interaction (Both) represents that both of the interactions above are removed.

As is shown in Table 5, the performances of the models all drop in varying degrees without any kind of interactive parts. The effect of interaction (Frame) is more pronounced than interaction (Arg&Role) (73.6 to 73.9). The model's performance without both kinds of interactive parts will drop from 76.0 to 75.3. And we noticed that the

Error Type	Description	Proportion(%)	
		Our Model	Peng
Frame error	Frame misprediction	10.5	11.3
Role error	Matching span with incorrect role.	22.0	12.6
Span error	Matching role with incorrect span boundary.	14.1	11.4
Extra predicted arg.	Predicted argument that doesn't overlap any gold argument	20.0	18.6
Missing arg.	Gold argument that doesn't overlap any predicted argument	33.4	43.5

Table 8: Error analysis result on FrameNet development set.

recalling rate of our model is decreasing with the remove of interactions. It verifies the previous analysis that the interactions among decoders make our model predict in a global view and thus our model is likely to predict more complete arguments and roles.

Table 6 shows the performance differences in the influences of pre-train data and targets-aware attention mechanism. The performance of the model without the pre-train step drops by 3.1 points on F1, which demonstrates that adding pre-train data is beneficial to model's performance. The result is consistent with the conclusion of Yang and Mitchell (2017) that models will get a 3-4 points increase on F1 if adding partially-annotated exemplar sentences. Also, we consider the influence of the targets-aware mechanism. The targets-attention mechanism doesn't work at pre-train step because the partially-annotated exemplar sentences only contains one target per sentence. To eliminate the interference of the gap between the train data and the pre-train data, we hold the same setting of skipping the pre-train step. As shown in Table 6, the model without TAM drops from 72.9 to 72.5 on F1. It proves that the targets-aware attention mechanism contributes to overall performance of frame semantic parsing.

As mentioned before, our model has an advantage in terms of computational complexity. We remove the length constraint of spans which is adopted in previous work. Table 7 shows the result. We notice that our model has a slight increase without length constraint of arguments. The result shows that our model get benefit with complete data. Moreover, it proves that the hierarchical pointer network is good at capturing long distance dependency relation. We encourage future work to train and evaluate on complete data if their computational complexity allows.

5.3 Error Analysis

We follow the error analysis method of Peng et al. (2018) and compare our model with theirs. Table 8 shows the proportions of five error types. Though missing arguments is the major error for both of our model and Peng et al. (2018), our model shows a great decrease by 10.1%, which proves that our model prefers to predict more complete arguments and is more likely to overlap gold arguments. However, it correspondingly brings increases on extra predicted arguments, Role error and Span error. We analyze that it's because our model captures the relation between different roles and is able to make current decision by considering all previous steps' action information, it prefers to predict the role which is related to previous predicted roles. Such strategy is more likely to overlap gold arguments. However, it may also predict more arguments and roles than the ground truth.

6 Conclusion

We design a multi-decoder framework to process all the subtasks of frame semantic parsing jointly. The multi-decoder framework strengthens the interactions among these three tasks. Our model works in an alternate way, which predicts the argument and the role by considering all previous decisions. We apply a hierarchical pointer network which achieves the argument identification with linear computational complexity. Experiments show improvement over state of the art models.

Abstract

Although distant supervision automatically generates training data for relation extraction, it also introduces false-positive (FP) and false-negative (FN) training instances to the generated datasets. While both types of errors degrade the final model performance, previous work on distant supervision denoising focuses more on suppressing FP noise and less on resolving the FN problem. We here propose H-FND, a hierarchical false-negative denoising framework for robust distant supervision relation extraction, as an FN denoising solution. H-FND uses a hierarchical policy which first determines whether non-relation (NA) instances should be kept, discarded, or revised during the training process. For those learning instances which are to be revised, the policy further reassigns them appropriate relations, making them better training inputs. Experiments on SemEval-2010 and TACRED were conducted with controlled FN ratios that randomly turn the relations of training and validation instances into negatives to generate FN instances. In this setting, H-FND can revise FN instances correctly and maintains high F1 scores even when 50% of the instances have been turned into negatives. Experiments on NYT10 is further conducted to show that H-FND is applicable in a realistic setting. [1]

1 Introduction

Relation extraction (Zelenko et al., 2003; Mooney and Bunescu, 2006; Zhou et al., 2005) is a core task in information extraction. Its goal is to determine the relation between two entities in a given sentence. For instance, given the sentence "Jobs was born in San Francisco", with head and tail entities "Jobs" and "San Francisco", the relation to be extracted is "Place of Birth". Relation extraction can be applied for many applications, such as question answering and knowledge graph completion. A major difficulty with supervising relation extraction models is the cost of collecting training data, against which distant supervision (DS) (Hoffmann et al., 2011; Surdeanu et al., 2012) is proposed. DS obtains the relational facts from a knowledge base and aligns these facts to all sentences in the corpus to generate learning instances. In specific, if a relation triple $r(h, t)$ exists in a knowledge base, then for a sentence s which mentions both the head entity h and the tail entity t, it is tagged with relation r to form a learning instance (r, h, t, s). Since an effective classifier is expected not only to extract relation triples from a given text but also have to identify those unrelated entity pairs, the negative samples from texts are also needed for the training. In distant supervision, the negative samples are generated by randomly selecting two entities in the given text to form an entity pair that does not appear in any relation triples in the knowledge base.

Knowledge base	Relation	
Steve Jobs, **San Francisco**	PoB	

Corpus	Relation	Type
Jobs was born in **San Francisco**	PoB (✓)	TP
Jobs moved back to **San Francisco**	PoB (✗)	FP
Manuela was born in **New York**	NA (✗)	FN

Table 1: Distant supervision and different types of incorrectly labeled relations. The head and tail entities are shown in boldface, and "PoB" stands for the relation "Place of Birth".

Datasets generated using distant supervision contain considerable noise (Roth et al., 2013). More specifically, the noise generated can be classified into false positives (FP) and false negatives (FN). Table 1 shows an example. The FP "Jobs moved back to San Francisco" should not reflect the relation 'Place of Birth'. Also, an FN: as there is no relation between "Manuela" and "New York" in the knowledge base, "Manuela was born in New

York" is wrongly labeled as a non-relation (NA) under the closed world assumption. Both FP and FN degrade model performance if they are treated as correct labels at training time. FPs harm prediction precision, while excessive FNs lead to low recall rates.

In addition to denoising methods for learning robustly with noisy data (Han et al., 2018; Northcutt et al., 2019), many works focus on alleviating the FP problem in DS datasets, including those on pattern-based extraction (Alfonseca et al., 2012; Jia et al., 2019), multiple-instance learning (Surdeanu et al., 2012; Lin et al., 2016; Zeng et al., 2018), and sentence-level denoising with adversarial training or reinforcement learning (Qin et al., 2018a,b; Feng et al., 2018). However, few investigate the FN problem for distant supervision (Xu et al., 2013; Roller et al., 2015). To the best of our knowledge, there is no previous study on this problem for deep neural networks.

In this paper, we investigate the impact of FNs on neural-based models and propose H-FND, a hierarchical false-negative denoising framework for robust distant supervision. Specifically, this framework integrates a deep reinforcement learning agent which keeps, discards, or revises probable FN instances with a relation classifier to generate revised relations. In addition, to constrain the study to the FN problem and to construct ground-truth relations to further analyze model behavior, we conduct our research on the following two human-annotated datasets: SemEval-2010 (Hendrickx et al., 2010) and TACRED (Zhang et al., 2017), with controlled FN ratios that randomly flip relations of training/validation instances into negatives to generate FN instances. Then, we further conduct our experiment on a distantly supervised dataset NYT10 (Riedel et al., 2010) and fix its positive set, to demonstrate that our framework is applicable for resolving FN problem in a realistic setting. In summary, our contributions are threefold:

- We propose a denoising framework focused on false negatives in relation extraction.

- We present a special transfer learning scheme for pretraining denoising agent as training data is not available for this pretraining task.

- We show that our method revises correctly and maintains high F1 scores even under a high percentage of false negatives, and is applicable in a realistic setting.

2 Related Work

Mintz et al. (2009) propose distant supervision (DS) to automatically generate labeled data for relation classification, a new paradigm that synthesizes positive training data by aligning a knowledge base to an unlabeled corpus, and produces negatives with a closed-world assumption. Although this method requires no human effort for sentence labeling, it introduces FPs and FNs into the generated data and degrades the performance of relation extraction models.

Many previous works have attempted to solve the FP problem. Among these works, denoising methods that utilize reinforcement learning (RL) are the most relevant to ours. Feng et al. (2018) propose a sentence-level denoising mechanism that trains a positive instance selector using RL, and set the RL reward to the prediction probability of the relation classifier. Qin et al. (2018b) also utilizes RL, but in a different way. It learns a denoising agent to redistribute FPs to NA via prediction accuracy of the classifier as the RL reward.

To solve the FN problem, one method is to align the KB to the corpus after performing KB completion using inference (Roller et al., 2015). Although this does reduce the number of FNs in DS datasets, it helps little when the FN relations cannot be inferred from the KB, e.g., the entities mentioned in the FN are not in the KB. IRMIE (Xu et al., 2013), another method, constructs a negative set in a more conservative sense, in which the head or tail entities have already participated in other relation triples in the KB. Other sentences outside the positive and negative sets are left unlabeled (labeled as RAW in original paper) to prevent FNs. After training on the positive and negative sets, positive relation triples are retrieved from the unlabeled set to expand the KB, after which the original DS is performed to improve the quality of relation extraction. The final performance of this method depends heavily on the heuristic for constructing the negative set, which may not be applicable for all possible relation types.

To address the FN problem in DS datasets more generally, we propose a hierarchical denoising method to mitigate the negative effect of FNs, ensuring a more robust relation extraction model when the presence of FN instances is unavoidable.

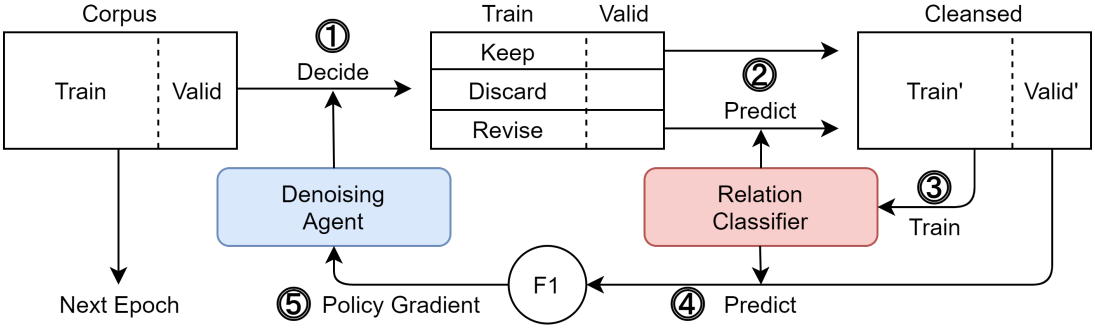

Figure 1: H-FND framework. The process in this diagram is executed per epoch.

3 H-FND Framework

We propose H-FND, a hierarchical false-negative denoising framework that determines whether to keep, discard, or revise negative instances. As illustrated in Fig. 1, H-FND is composed of the denoising agent and relation classifier modules. The denoising agent makes a ternary decision on the action to take on each negative instance, and after discarding, the relation classifier predicts a new relation for each to-be-revised instance to produce a cleaned dataset.

3.1 Convolutional Neural Network

Convolutional neural networks (CNN) are commonly adopted for sentence-level feature extraction (Kim, 2014) in language understanding tasks, such as relation extraction (Zeng et al., 2014; Nguyen and Grishman, 2015). PCNNs (Zeng et al., 2015), a variation of CNN that applies piecewise max pooling, are also widely used for extracting sentence features (Lin et al., 2016; Qin et al., 2018a). We included both as the base model in our experiments to show that our framework is base model agnostic. In our implementation, the extracted features of a learning instance s are fed into a fully connected softmax classifier to compute the final logits:

$$O(r) = \text{softmax}(\text{FC}(\text{CNN}(s))).$$

For detailed mathematical descriptions of CNN and PCNN, please refer to the Appendix.

3.2 Hierarchical Denoising Policy

The proposed hierarchical denoising policy is a framework using policy-based reinforcement learning (RL). Previous work utilizing RL to suppress noise from FPs (Feng et al., 2018; Qin et al., 2018b) can be categorized in two types of strategies: the first decides whether to remove the input instance, and the second decides whether to revise the input instance to be negative. Both policies make a binary decision on each input instance, and successfully reduce FP instances in DS datasets.

While applicable on the FP problem, it is risky to directly apply these strategies on the FN problem. First, discarding a negative instance even when it is most likely positive can result in a loss of useful learning instances. Second, changing a negative instance to positive is not enough for the training process: we must also know which type of positive relation to revise to.

Therefore, we propose a hierarchical denoising policy to perform the FN denoising in two steps. The first step, a soft policy that combines the two above-mentioned denoising methods, is an agent that takes an action from the action set $\{$*Keep, Discard, Revise*$\}$ for a negative instance s:

- *Keep:* maintain s as a negative instance for training/validation;
- *Discard:* remove s to prevent it from misleading the model;
- *Revise:* predict a new relation type for s and treat it as a positive for the following training/validation.

The policy $\pi(a|s)$ of this ternary decision is calculated based on the sentence feature extracted from s with the base model CNN encoder:

$$\pi(a|s) = \text{softmax}(\text{FC}_1(\text{CNN}_1(s)));$$

each action a has the possibility of $\pi(a|s)$ of being taken by the denoising agent.

Then, if the negative instance s is to be revised, the hierarchical policy goes on to the second step and gives the revised relation by selecting the most

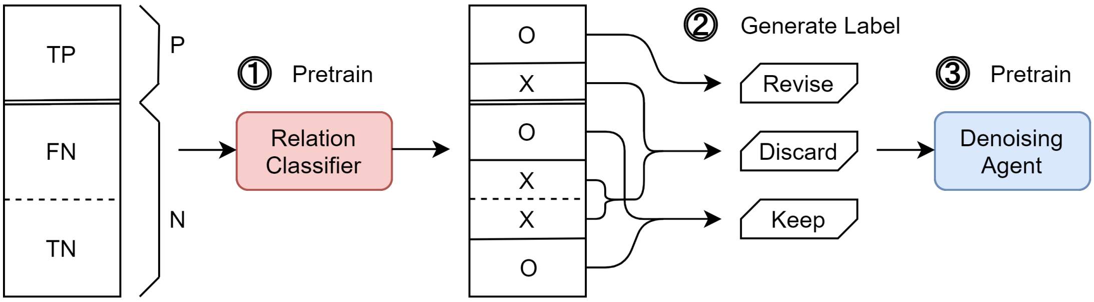

Figure 2: A special transfer learning scheme for H-FND pretraining. Symbols "P" and "N" represent positive and negative instances for relation classifier pretraining. Symbols "O" and "X" indicate two sets of training instances which are correctly predicted and wrongly predicted by pretrained relation classifier correspondingly.

likely relation (excluding NA) predicted by the relation classifier:

$$r' = \arg\max_{r \in R \setminus \{NA\}} \text{FC}_2(\text{CNN}_2(s)).$$

3.3 Pretraining

Supervised pretraining (Qin et al., 2018b), commonly used to accelerate RL agent training, is easily performed for the relation classifier on the original DS dataset (Han et al., 2018). For the denoising agent, however, there is no available training data. Therefore, we propose a special transfer learning scheme that utilizes the learnt knowledge in the relation classifier (source domain) to help generate action labels for pretraining denoising agent (target domain) (See Fig. 2).

First, we select the positives for which the pretrained relation classifier correctly predicts the relation, and tag these with *Revise*. This prepares the denoising agent to identify positive instances in the negative set in future training, and then pass these kinds of instances to the relation classifier to predict the correct positive relations for them. Similarly, we tag with *Keep* those negatives correctly predicted by the relation classifier. Lastly, for instances in which the relation classifier wrongly predicts their relation, we tag them with *Discard*, encouraging the denoising agent to discard such instances to avoid incorrect revisions.

In summary, our pretraining strategy is thus:

1. **Relation classifier pretraining**: pretrain the relation classifier (RC) directly on the original training set with the categorical loss function:

   $$ls_{\text{RC}} = \text{cross-entropy}(O, G),$$

   where G represents the distantly supervised relation in the training set. Then, fix the parameters of the relation classifier for the next step.

2. **Label generation**: generate labels H with the predictions of the relation classifier.

3. **Denoising agent pretraining**: Supervise the denoising agent (DA) with categorical loss:

   $$ls_{\text{DA}} = \text{cross-entropy}(\pi, H).$$

3.4 Co-Training

To combine the training of the relation classifier and the denoising agent, we propose the following co-training framework during each epoch (see Fig. 1):

1. **Denoising agent decision**: At the beginning of each epoch, the denoising agent first executes the denoising policy on the dataset. For both training and validation sets, the policy keeps, discards, or revises NA instances.

2. **Relation classifier revision**: For instances to be revised, the relation classifier generates revision relations for them. Denoising yields the cleaned training and validation sets.

3. **Relation classifier training**: Given the cleaned training set, we train the relation classifier in a supervised fashion based on categorical loss:

   $$ls_{\text{RC}} = \text{cross-entropy}(O, G'),$$

   where G' represents the modified training set, which contains all the positives and the kept or revised negatives. Note that discarded negatives are not included in G'.

4. **Reward determination**: We evaluate the trained relation classifier on the cleaned validation set to obtain the F1 score, which we use as reward R for denoising. As the validation set is cleaned by the denoising policy, R reflects the efficacy of the policy.

Datasets	#training	#validation	#testing
SemEval	6,599	1,154	2,717
TACRED	63,782	20,088	15,509
NYT10	477,454	120,318	194,328

Table 2: Number of instances in each dataset

5. **Denoising policy update**: To maximize the reward R, we adopt policy gradient (Sutton et al., 2000) to optimize the denoising agent by maximizing the objective function $J(\theta)$:

$$J(\theta) \approx \sum \log p(a|\theta)(R - b),$$

where θ is the parameter of the denoising policy, $p(a|\theta)$ represents the softmax probability of the sampled determination or revision step, and b is the baseline which mitigates the high variance of the REINFORCE algorithm (Williams, 1992). We set b to the average reward of the previous five epochs.

For each epoch, we obtain the revised set from the original training/validation set via the denoising policy, and H-FND finds the best denoising policy adaptively between supervised training and reward maximization.

4 Experiment

4.1 Datasets

In order to quantify our model's performance on denoising false negatives, we evaluated the proposed H-FND under two settings, human-annotated datasets with synthetic noise and dataset generated using distant supervision. Table 2 shows the statistics of each dataset used in the experiments.

1. **Human-Annotated Datasets**:

   SemEval-2010[2] contains nine relations with an additional NA as a non-relation, and the number of instances for each relation is roughly equal. TACRED[3] is about 10 times larger than SemEval, and it has 42 relations including NA, and the number of negative instances accounts for 80% of the entire corpus. For SemEval, we used 10% of the training set for validation, and for TACRED we simply used the dev set as the validation set (see Table 2).

   We filtered out the training and validation instances which had relation triples that appeared in the testing set to eliminate any overlap between relation triples in the training, validation, and testing sets, to simulate the held-out evaluation settings in distant supervision (Mintz et al., 2009).

   To simulate FN conditions, we randomly filtered a ratio (10%–50%) of training/validation positives into negatives. Note that the filtering process was only for training/validation: the testing sets were well-labeled under all FN ratios. Also note that the models were not aware in advance which sentences were TN and which were FN.

2. **Distantly Supervised Dataset**: The NYT10 dataset[4] uses Freebase as knowledge base for distant supervision. The relations are extracted from a December 2009 snapshot of Freebase. Four categories of Freebase relations are used: "people", "business", "person", and "location". These types of relations are chosen because they appear frequently in the newswire corpus. All pairs of Freebase entities that are at least once mentioned in the same sentence are chosen as candidate relation instances. For consistency with previous research (Lin et al., 2016; Feng et al., 2018; Qin et al., 2018b), we excluded five relations:
   '/business/company/industry',
   '/business/company_shareholder/major_shareholder_of',
   '/people/ethnicity/includes_groups',
   '/people/ethnicity/people',
   '/sports/sports_team_location/teams'

   This results in a total of 53 relations (including none-relation, 'NA').

   The corpus is chosen from a external source articles published by The New York Times between January 1, 1987 and June 19, 2007. The Freebase relations were divided into two parts, one for training and one for testing. The former is aligned to the years 2005-2006 of the NYT corpus, the latter to the year 2007.

4.2 Baselines and Experiment Settings

A simple H-FND baseline was the original CNN and PCNN relation classifier. To demonstrate the

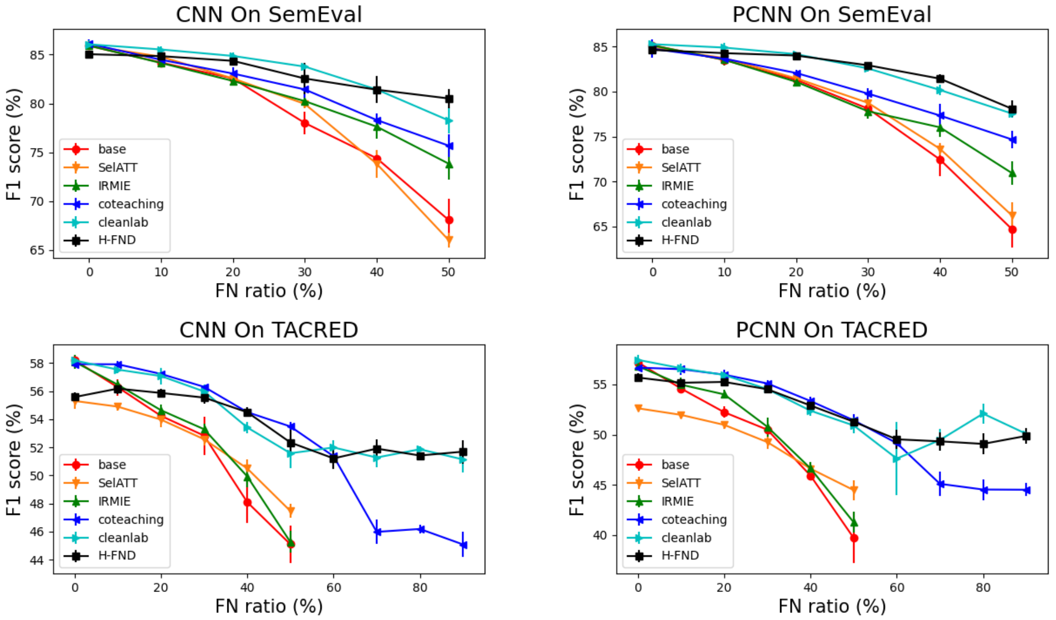

Figure 3: CNN and PCNN results on SemEval and TACRED, where the errorbars represent the standard deviations. The noise rate denotes the percent of positive relation triples flipped to create false negatives. The denoising method cleanlab and our method H-FND perform the best, but cleanlab requires a given noise rate of data, while H-FND does not requires such information.

impact of FNs, we also included SelATT (Lin et al., 2016), an FP noise resistant model.

We further compared our H-FND framework with the following strong baselines: the FN denoising method IRMIE (Xu et al., 2013) and two other general-purpose denoising methods: co-teaching (Han et al., 2018) and cleanlab (Northcutt et al., 2019). Co-teaching is a general training method for deep neural networks to combat extremely noisy labels. It simultaneously maintains two networks (each with the same structure), each of which samples its small-loss instances with a given overall noise rate as clean batches to its peer networks for further training. Cleanlab is a state-of-the-art robust learning method which directly estimates the joint distribution of noisy observed labels and latent uncorrupted labels with a consistent estimator, filters out noisy instances based on this joint distribution, and trains the relation classifier on the cleaned dataset with co-teaching mentioned above. We use these denoising methods to train the base CNN and PCNN models on our simulated FN datasets. [5]

As the focus of this paper is on the FN problem, all the positives of the simulated FN datasets are kept error-free, the H-FND framework assumes that no positives need be changed. Hence, for a fair comparison, we kept the positive sets of the FN datasets unchanged for the two general-purpose denoising methods, preventing them from discarding error-free positives. Also, we fix the positive set of NYT10 to evaluate the applicability of H-FND of resolving FN problem in a realistic setting.

In the experiments on SemEval and Tacred, every data point is the average of five independent runs. In the experiment of NYT10, data points are the average of three best results out of five independent runs for H-FND and all baselines. See Appendix for more detailed information on experiment and model implementation.

4.3 Quantitative Results

The quantitative SemEval results are shown in the upper part of Fig. 3, including both CNN and PCNN. Under the 50% FN ratio, for both the base CNN and PCNN models, with or without SelATT, the F1 scores are heavily influenced by FN sentences: the performance drops by nearly 20%. ERMIE and co-teaching enhance the performance by more than 5% and 8% correspondingly. Except for cleanlab, H-FND denoising remains competitive to the baselines for FN ratios from 10% to 30%, and significantly wins after 30%. Among all

---

[5] The IRMIE KB was reconstructed from the positives of the simulated FN dataset.

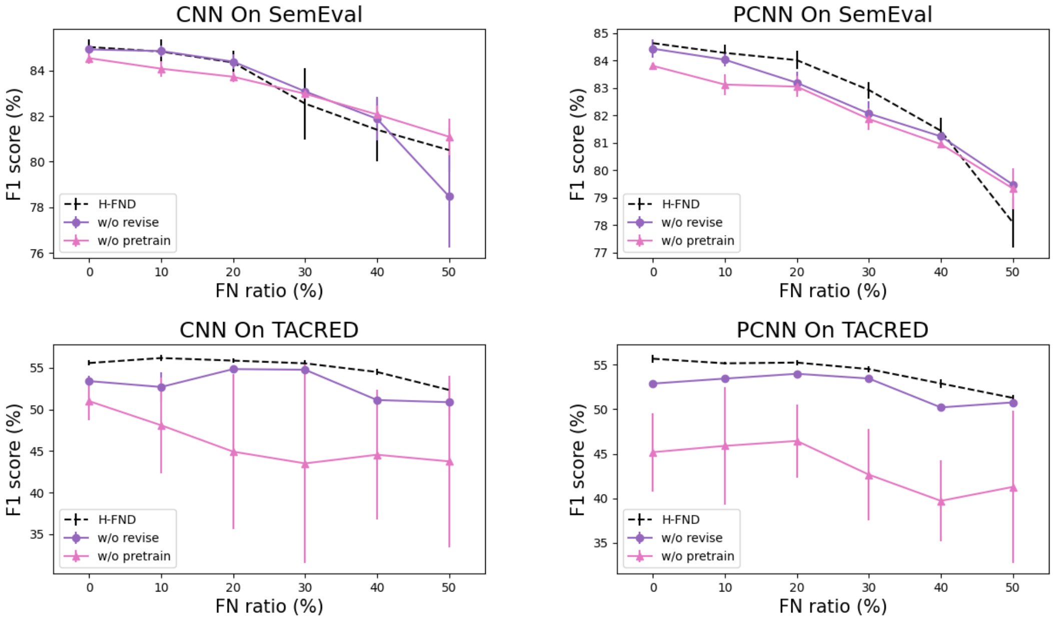

Figure 4: CNN and PCNN ablation analysis on SemEval and TACRED, where the errorbars represent the standard deviations.

baselines, cleanlab's performance is the strongest and is competitive with our approach, but as cleanlab relies on a co-teaching model to train the relation classifier, a given noise rate is required. In our experiments, these are directly provided to the model. However, in practice, the noise rate (the FN ratios in our experiment) is unknown and must be estimated correctly, entailing extra effort. In contrast, H-FND has no such requirement.

The quantitative results on TACRED are shown in the lower part of Fig. 3. CNN, PCNN, and the two models with SelATT are all vulnerable to FN instances. As IRMIE fails to exclude enough FNs from the negative set on TACRED,[6] its performance is also strongly influenced by FN instances. Although the F1 scores of H-FND are 2% behind co-teaching and cleanlab for FN ratios from 0% to 20%, it successfully maintains its performance when the FN ratio exceeds 30% and becomes competitive with these two baselines. This is similar to the experimental results on SemEval for FN ratios less than 30%. Together with the fact that TACRED has many more positives than SemEval, we increased the FN ratio to 90%. The result of this extended experiment shows that when the FN ratio exceeds 60%, the F1 scores for co-teaching drop significantly, whereas H-FND maintains a relatively high F1 score. Here, again, although cleanlab performs similar to ours with the predefined FN ratios,[7] the proposed approach needs no such information, which better fits real-world circumstances of distant-supervised relation classification.

4.4 Ablation Study

Fig. 4 shows the result of the ablation study to justify the effectiveness of the *Revise* action and pretraining strategy. On Semeval, pretraining boosts the F1 score for the PCNN architecture for FN ratios from 10% to 40%, but yields no significant difference for the other ratios. On TACRED, however, the *Revise* action and the pretraining strategy clearly yield improved results. This improvement is substantial in particular for pretraining. As TACRED has more positive relation types and a much larger negative set, the FN denoising problem is more severe than on SemEval; thus the pretraining strategy is crucial to provide a better initial point for the denoising agent and to ensure more stable performance.

4.5 Detailed Analysis

We first analyzed the distribution of the denoising policy for TN and FN instances in the training set. Figure 5 shows the percentage of kept, discarded,

---

[6] The size of the RAW set is less than 10% of the original negative set under all FN ratios.

[7] We have measured the performance of cleanlab when it was provided with a wrong FN ratio - 40% FN ratio. Under the actual FN ratio of 80% , its F1 scores dropped by 0.5% for CNN and 1.8% for PCNN.

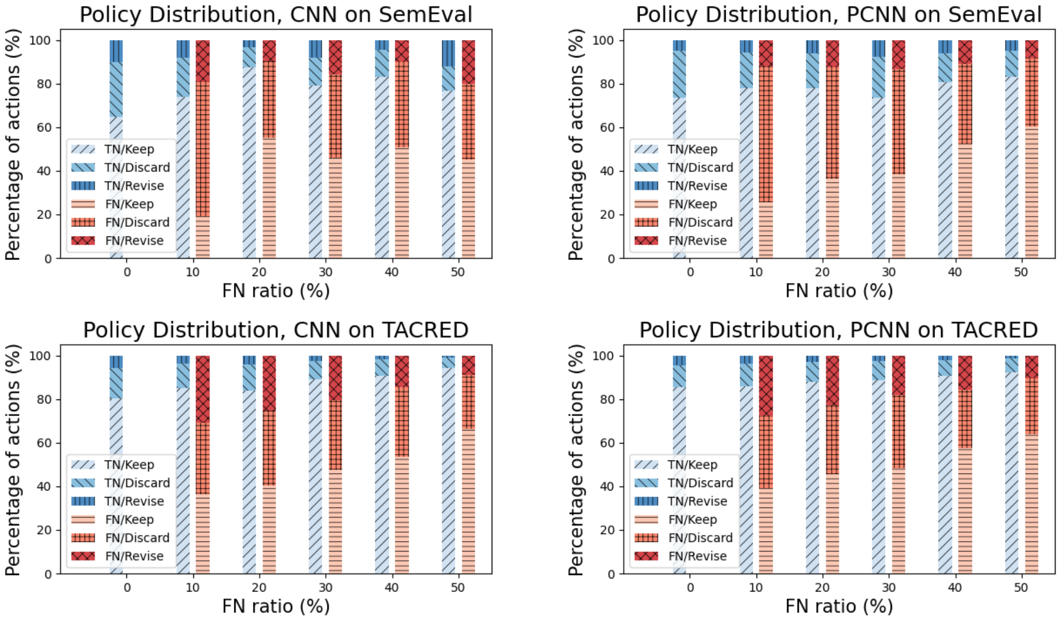

Figure 5: Denoising policy distribution on true negatives and false negatives.

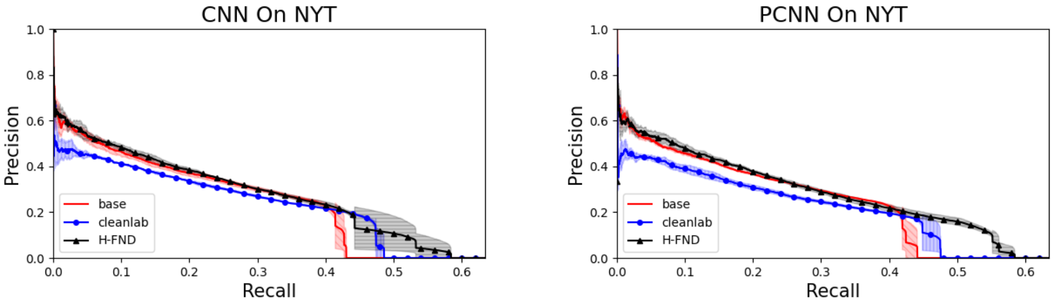

Figure 6: Precision-recall curve on the NYT dataset. The shaded areas indicate one standard deviation. The precision rate of each algorithm run drops to zero at certain recall rate, hence the steep drops in the curves.

or revised training instances. The left histogram under each filter ratio is for TN; the right is for FN.

On SemEval, we observe that for TN instances, H-FND mainly keeps them as NA and revises only a small portion to the wrong relation, even under the 50% filter ratio. For FN instances, H-FND prefers to discard or revise them. This difference shows that H-FND distinguishes FN instances from TN instances, and does not take arbitrary actions on them.

On TACRED, the policy distribution also shares the same tendency, but the portion of kept instances is generally larger. This is due to a higher ratio of negative instances in TACRED. As more negative instances result in more *Keep* labels in the generated pretraining data, after pretraining, the probability of the model taking the *Keep* action is generally higher. It also explains that the portion of kept instances grows when the filter ratio is raised. Note that this prevents H-FND from revising too many instances at the beginning of co-training, making co-training more stable.

Table 3 show the correctness of revisions on FN instances which are determined to be revised. The accuracy is around 90% for both CNN and PCNN architectures and for both SemEval and TACRED. This shows that H-FND accurately corrects FN instances once they are identified and determined to be revised in the first stage.

4.6 Results on Realistic Dataset

Lastly, we evaluated H-FND on real DS dataset NYT10. For baselines, apart from the base model, we included cleanlab, as it is the best performing baseline in the controlled FN experiments. We conducted human evaluation on 200 negative instances randomly sampled from the training set

SemEval	10%	20%	30%	40%	50%
CNN	88.81 ± 3.55	88.07 ± 7.80	88.72 ± 1.04	86.25 ± 1.53	85.94 ± 1.46
PCNN	89.54 ± 1.98	88.04 ± 3.12	86.83 ± 2.11	90.31 ± 0.54	84.17 ± 3.56
TACRED	**10%**	**20%**	**30%**	**40%**	**50%**
CNN	91.43 ± 0.72	90.62 ± 0.99	90.89 ± 0.63	91.65 ± 0.99	93.39 ± 1.79
PCNN	90.99 ± 0.82	89.64 ± 0.39	87.15 ± 0.49	86.75 ± 0.60	86.15 ± 1.16

Table 3: Revision accuracy (%)

and came to an estimate of 14% noise. [8]

We followed Zeng et al. (2015) and plotted the precision-recall curve to demonstrate the result on NYT10 (see Fig. 6). At recall rate lower than 40% cleanlab performs slightly worse than the base model, while H-FND remains competitive in terms of precision. This could be a result of inaccuracies in the estimation of FN rate in the dataset. Since H-FND does not require a given FN rate, it is not encumbered by such estimation error. At higher recall rates ($> 50\%$), H-FND retains significantly higher precision. This result shows that H-FND is applicable for real DS datasets, especially when the recall rate matters.

5 Conclusion and Future Work

In this work, to increase the robustness of DS, we present H-FND, a hierarchical false-negative denoising framework, which keeps, discards, or revises non-relation (NA) inputs during training and validation phases to suppress noise from FN instances. We also present a special transfer learning scheme for pretraining the denoising agent.

To investigate the effects of FN instances addressed by our approach, we generate FN instances from SemEval-2010 and TACRED under controlled ratios. The results show that H-FND revises FN instances and facilitates robust relation extraction. Further experiment on NYT10 demonstrates that our framework is also applicable to realistic DS setting.

In realistic DS setting, both FP and FN instances may emerge simultaneously. Both of which should be addressed. We leave this as future work. Also, we plan to attempt other advanced relation classification approach like R-BERT (Wu and He, 2019) to replace CNN or PCNN in our architecture.

[8] This also demonstrates our synthesized datasets are a good approximation to realistic DS setting: for the NYT10, around 72% of the instances are negatives. This gives us around (0.72 * 0.14) = 10.1% of FN in all triples. For our synthetic dataset, the noise rate is the percent of positive relation triples flipped to create false negatives. Positive triples make up only around 20% of the whole TACRED, and in our experiments, the noise rate indicates that we have flipped 50% of the triples. This gave us a total of around (0.2 * 0.5) = 10% of FN in all triples.

A Appendices

A.1 Convolutional Neural Network

We use a convolutional neural network (CNN) (Nguyen and Grishman, 2015) as our base model for both the denoising agent and the relation classifier. This architecture consists of four main layers (the first three layers compose the CNN encoder):

1. **Embedding**: The embedding layer transforms a word into a vector representation, which is a concatenation of a word embedding V_w and a pair of positional embedding vectors V_{p_1}, V_{p_2} (Lin et al., 2016). Word embedding V_w is a vector that represents the semantics of a word, and positional embedding pair V_{p_1}, V_{p_2} is two vectors representing the relative distance from the current word to two entities in the sentence.

   The final embedding vector V of dimension d_e for each word is the concatenation of V_w, V_{p_1}, and V_{p_2}:

   $$V = [\,V_w|\,V_{p_1}|\,V_{p_2}]\,.$$

2. **Convolution**: The convolutional layer transforms the embedding vectors of words into local features by applying sliding filters over them. Each filter consists of a weight matrix $A_i \in \mathbb{R}^{f\times d_e}$ and a bias term $b_i \in \mathbb{R}$, to extract specific patterns in the embedding vectors. With h filters of length f, the entry in the feature map $C_f \in \mathbb{R}^{h\times(L-f+1)}$ for the i-th filter at position t is

   $$[C_f]_{it} = \sum_{j=1}^{f}\sum_{k=1}^{d_e} A_{ijk}\cdot V_{t+j-1,k} + b_i,$$

   where L is the length of the input sentence. To capture information expressed in phrases of all lengths, we further use n different lengths of filters, and concatenate all C_f under filter size f as the jointed feature map $C \in \mathbb{R}^{nf\times d_e}$:

   $$C = [C_{f_1}|C_{f_2}|\cdots|C_{f_n}].$$

3. **Max pooling**: The max pooling layer captures the most significant feature into the pooling feature P_i by selecting the highest value in the feature map extracted by the i-th filter C_i over all positions:

   $$P_i = \max(C_i).$$

   PCNN (Zeng et al., 2015) involves piecewise max pooling, which better suits the relation extraction task. It divides an input sentence into three segments based on the two selected entities, and then extracts features from all the three segments to capture fine-grained features for relation extraction. For PCNN, the extracted feature map

   $$P_i = [\max(C_{i1})|\max(C_{i2})|\max(C_{i3})],$$

   where C_{i1}, C_{i2}, and C_{i3} are the three feature map segments separated by the two selected entities. We also view P as the sentence feature, as it represents the essential features of the whole sentence.

4. **Fully connected**: The fully connected layer (FC) performs relation classification based on sentence feature P with softmax activation over each relation. The computed logits $O(r)$ is written as

   $$\begin{aligned} O(r) &= \text{softmax}(\text{FC}(P)) \\ &= \text{softmax}(\text{FC}(\text{CNN}(s))). \end{aligned}$$

A.2 Implementation

H-FND was implemented with PyTorch 1.6.0 (Adam et al., 2017) in python 3.6.9. In our implementation, we used pretrained word embeddings provided by SpaCy (Honnibal and Johnson, 2015) as the fixed word embeddings ($d_w = 300$). The positional embedding ($d_p = 50$) was randomly initialized and then trained with the following network; therefore the overall dimension of embedding vector $d_e = d_w + 2d_p = 400$. In the convolutional layer, we applied four different sizes of filters ($f \in$ [2, 3, 4, 5]) and set all of their feature sizes to $h = 230$. Both CNN and PCNN architectures were implemented. The total trainable parameters of each models are listed in table 4. To prevent overfitting, we inserted dropout layers with a dropout rate of 0.5 before the convolutional layer and after the max pooling layer.

We trained H-FND using the Adam optimizer (Kingma and Ba, 2015). In addition, we

#(Params)		SemEval	TACRED	NYT
RC	CNN	1,318,130	1,347,602	1,388,933
	PCNN	1,336,530	1,424,882	1,486,453
RC+SelATT	CNN	1,327,330	1,386,242	–
	PCNN	1,364,130	1,540,802	–
DA	CNN	1,311,683	1,311,683	1,342,883
	PCNN	1,317,203	1,317,203	1,348,403

Table 4: Number of trainable parameters in each model.

used mini-batches (batch size $b = 256$) only when training the relation classifier; the prediction of the relation classifier and both the decision and policy gradient of the denoising agent were executed per epoch. Last, the revised result of H-FND in each epoch was used by the classifier only in the same epoch and did not accumulate over epochs, which means that at the beginning of each epoch, H-FND applied the denoising policy on the original dataset but not on the revised dataset of the last epoch.

We list in Table 5 the learning rates for base CNN and PCNN relation classifiers (RC), for RC with SelATT, and for RC with denoising agent (DA) under pretraining and co-training phrases. The learning rate of RC is selected from {1e-4, 3e-4, 1e-3, 3e-3, 1e-2}, with the F1 score on the noise-free version of SemEval and TACRED as the selection criteria. Except SelATT and DA co-training, the learning rates for the other models are the same to the learning rate of base RC. For SelATT, the learning rate is selected from {1e-6, 3e-6, 1e-5, 3e-5, 1e-4}, also with the F1 score on the noise-free version of the two datasets as the selection criteria. For DA cotraining, the learning rate is selected from {1e-6, 3e-6, 1e-5, 3e-5, 1e-4}, with the F1 score on the SemEval and TACRED under a 50% FN ratio as the selection criteria.

All the RC of each method are trained to converge with validation-based early stopping. In specific, we train all the model for 150 epochs on SemEval and for 200 epochs on TACRED. For NYT, we trained all the models for 30 epochs.

The pretraining of H-FND trains the RC and DA for 5 and 20 epochs respectively. We select these pretraining periods by the criteria that the two models can achieve about 80% performance comparing to the converged ones. By this means, we can prevent H-FND from overfitting the noisy labels (Han et al., 2018) and initialize H-FND with good parameters for co-training.

All the implemented models are trained on NVIDIA GTX 1080 Ti and Intel(R) Xeon(R) Silver 4110 CPU, with 12GN GPU memory, 128GB RAM, clock rate 2.10 GHz, and Linux as the operating system. The expected running time for each model on each dataset is listed in Table 6.

A.3 Performance on Validation Set

The F1 scores of each model running on validation sets of SemEval and TACRED are provided in Figure 7 and 8. Notice that the validation sets are noisy in our experiment, so the performance on validation sets do not fully reflect the robustness of each models. Also, in IRMIE and H-FND, the validation sets are modified, so their validation F1 scores can only be compared with their own across different FN ratios. For more accurate performance measurement, please refer to Figure 3 and 4, whose F1 scores are measured on noise-free testing sets.

Abstract

In this paper, we present **GEM**[1] as a **G**eneral **E**valuation benchmark for **M**ultimodal tasks. Different from existing datasets such as GLUE (Wang et al., 2018), SuperGLUE (Wang et al., 2019), XGLUE (Liang et al., 2020) and XTREME (Hu et al., 2020) that mainly focus on natural language tasks, GEM is a large-scale vision-language benchmark, which consists of **GEM-I** for image-language tasks and **GEM-V** for video-language tasks. Comparing with existing multimodal datasets such as MSCOCO (Chen et al., 2015) and Flicker30K (Vinyals et al., 2015) for image-language tasks, YouCook2 (Zhou et al., 2018) and MSR-VTT (Xu et al., 2016) for video-language tasks, GEM is not only the largest vision-language dataset covering image-language tasks and video-language tasks at the same time, but also labeled in multiple languages. We also provide two baseline models for this benchmark. We will release the dataset, code and baseline models, aiming to advance the development of multilingual multimodal research.

1 Introduction

In recent years, large-scale pre-training has become the new paradigm in the natural language processing (NLP) field. These models have demonstrated surprisingly good generalization abilities and can be applied to different downstream tasks by a simple fine-tuning. Several comprehensive benchmarks are constructed to evaluate such powerful models, including GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019) for evaluating monolingual natural language understanding systems, XGLUE (Liang et al., 2020) and XTREME (Hu et al., 2020) for evaluating multilingual natural language understanding and generation systems. Such pre-trained models have also been extended to vision-language scenarios (Lu et al., 2019; Chen et al., 2019; Li et al., 2020a,b; Ni et al., 2021; Sun et al., 2019b,a; Luo et al., 2020) to handle multimodal tasks such as image(or video)-text retrieval and image (or video) captioning. However, there is still no comprehensive benchmark dataset for evaluating such multimodal pre-trained models. Besides, most existing vision-language datasets are labeled in English only, which cannot be used to evaluate the qualities of such models on other languages.

Motivated by this, we present **GEM**, a **G**eneral **E**valuation benchmark for **M**ultimodal tasks. Comparing with GLUE, SuperGLUE, XGLUE and XTREME, GEM is designed for evaluating the generalization capabilities of vision-language models and consists of two subsets: GEM-I, which evaluates text-to-image retrieval and image captioning capabilities, and GEM-V, which evaluates text-to-video retrieval and video captioning capabilities. Besides, it is also a multilingual dataset, where the natural language contexts are collected from a commercial search engine. We describe two vision-language pre-trained models, M^3P (Ni et al., 2021) and m-UniVL, as the baselines for GEM-I and GEM-V, respectively, where M^3P is an existing multilingual image-language pre-trained model, m-UniVL is a multilingual extension of UniVL (Luo et al., 2020) for multilingual video-language tasks. The evaluation results of these two models on GEM are reported in the experiment part.

The key contribution of this paper is twofold: (1) we build GEM as the first large-scale multilingual multimodal benchmark, which can be used to evaluate the generalization capabilities of vision-language pre-trained models on a set of diversified multimodal tasks. (2) we provide two multilingual multimodal pre-trained models, M^3P and m-UniVL, as the baselines of GEM for image-language and video-language tasks, respectively. We hope GEM can further advance the research in

Table 2: Language distribution and data statistics of GEM-V for multilingual video-language tasks.

the multimodal community, just as its predecessors did in the NLP community.

2 Dataset Construction

To the best of our knowledge, GEM dataset is the first multilingual vision-language dataset constructed for image-language and video-language tasks as the same time. GEM-I contains 1.2 million {*Query, Image, Title*} triplets in 20 different languages for text-to-image retrieval and image captioning tasks. GEM-V contains 99K {*Query, Video, Title*} triplets in 30 languages for text-to-video retrieval and video captioning tasks. In both GEM-I and GEM-V, *Title* denotes the title of the web page where each image (or video) is extracted. This signal can be used as the auxiliary information in all GEM tasks, as it is usually highly relevant to the corresponding image (or video).

Next, we will describe how GEM-I and GEM-V are collected from a commercial search engine.

2.1 GEM-I Construction

First, we collect several billion images with Creative Commons licenses from the Internet, and discard images that contain pornographic or racy content. We also discard images with human faces, to avoid revealing privacy or introducing bias to our data. Besides, we only keep images which are larger than 300×300 pixels to guarantee high image quality. The pornographic classifier, racy classifier, and human face classifier are trained and evaluated on human-labeled data. The (precision, recall) of them are (0.85, 0.92), (0.79, 0.94), and (0.85, 0.92), respectively.

Then, we collect user queries from a commercial search engine for each image based on user historical clicks. We also collect the title of the Web page that contains the image as the additional context, forming {*Query, Image, Title*} triplets. Some text cleanup work is done to only keep high quality queries and contexts, including removing pornographic words and meaningless strings, and discarding very short queries or titles in that they are less likely to depict the image content, etc. We also apply an in-house GBDT model to filter out potentially highly irrelevant {*Query, Image, Title*} triplets, which is trained using a small amount of human-labeled data, to predict the similarity between each {*Query*} and {*Image, Title*} pair.

Finally, we only keep the top 20 languages which have more than 1000 images, and sample 1.2 million {*Query, Image, Title*} triplets in total. The average length of query in GEM-I is 5.5 terms, which is shorter than 10.6 in MSCOCO (Chen et al., 2015) and 12.3 in Flicker30K (Vinyals et al., 2015). Also, the average length of title is 10.1 terms. This makes GEM-I a more practical benchmark, since all data

in GEM-I come from the real world, where the language configuration truly differs from the queries in existing datasets. For example, the queries in GEM were shorter and more concise, without perfect grammar or syntax structure. This makes GEM queries more ”natural”. Therefore, our benchmark can evaluate the models on data closer to real-world scenarios, so that the performance of the models will be more convincing in terms of being used in real-world applications. Based on human assessment on sampled query-image pairs, 83% of the them are well matched pairs in that the query is a plausible caption of its paired image. We randomly split the data into train, dev and test sets within each language. The data statistics and language distribution of GEM-I can be found in Table 1. Figure 1 gives some examples.

2.2 GEM-V Construction

We collect several billion videos from the Internet, and discard videos with pornographic or racy contents. We also discard very long videos to save storage and transfer expenses. For each video, its query and title are collected from a commercial search engine and cleaned-up according to a similar process as we described in GEM-I, where another in-house model is trained to filter out potentially irrelevant $\{Query, Video, Title\}$ triplets.

Finally, we only keep the top 30 languages which have more than 700 videos, and sample 99K $\{Query, Video, Title\}$ triplets in total. The total video length of GEM-V is 2,049 hours, and the average video length is 1.2 minutes. The average length of query in GEM-V is 5.3 terms, and that of title is 8.5 terms. We also conduct human evaluation on some sampled query-video pairs, and find 70% of them are plausible matched pairs. We randomly split the data into train, dev and test sets within each language. The data statistics and language distribution of GEM-V can be found in Table 2. Figure 2 gives some examples.

3 Baseline Models

This section will introduce two baseline models for GEM, including M^{3}P, which is a multilingual multimodal pre-trained model for image-language tasks, and m-UniVL, which is a multilingual extension of UniVL (Luo et al., 2020) for video-language tasks.

3.1 M^{3}P as Baseline of GEM-I

We select M^{3}P (Ni et al., 2021) as the baseline model for tasks in GEM-I, as it is the state-of-the-art multilingual image-language pre-trained model for both image-language understanding and generation tasks.

The M^{3}P model uses the model architecture of BERT for understanding tasks and a BERT-based encoder-decoder architecture for generation tasks.

Figure 2: Examples in GEM-V dataset: Q: Query, T: Title.

For understanding tasks, multilingual masked language modeling, multimodal masked language modeling, masked region modeling and visual-linguistic matching are used as pre-training tasks to train a Transformer-based encoder. For generation tasks, multilingual denoising auto-encoding, image captioning and denoising image captioning are used as pre-training tasks to train a Transformer-based encoder-decoder. By training the encoder and the encoder-decoder with a multitask learning framework, universal representations are learned to map objects occurred in different modalities or expressed in different languages to vectors in a common semantic space.

Fine-tune Tasks Based on the pre-trained M^{3}P model, we further finetune it on our GEM-I data. For the text-image retrieval task, we adopt the BCE loss and NCE loss (Gutmann and Hyvärinen, 2010) (with equal weights) to learn the instance-level alignment between texts and images. The negative samples are generated by randomly forming text-image pairs from different training samples in the same batch. For the image captioning task, we directly learn captioning loss on GEM-I data.

Side-Information Since title is considered as the side-information of the image, we concatenate it together with the image and feed them into the model. During the negative sampling process in the retrieval task, we treat title and image as a whole, i.e., for a certain query, the titles and images from other samples are considered as negatives.

3.2 m-UniVL as Baseline of GEM-V

We adopt the same model structure with the unified video and language pre-trained model UniVL (Luo et al., 2020), which can perform both multi-modal understanding and generation tasks. Specifically, we extend the pre-trained UniVL model from monolingual to multilingual by replacing the BERT-based module with XLM-R (Conneau et al., 2019), and call the new model m-UniVL. m-UniVL adopts an encoder-decoder architecture, including two single-modal encoders to encode the multilingual text and the visual features respectively, and one cross-modal encoder to learn the interactions between the two modalities, and finally an optional decoder for generation tasks. To better leverage the pre-trained models, we initialize each module with different pre-trained weights: for the multilingual text encoder, we directly initialize it with the pre-trained XLM-R[2] (Conneau et al., 2019), and for other modules including the visual encoder, the cross encoder and the decoder, we initialize them with the weights of the pre-trained UniVL[3].

Fine-tune Tasks Based on the pre-trained m-UniVL, we further finetune it using GEM-V data. For the text-video retrieval task, we only employ encoders in m-UniVL in the finetuning stage and use them to predict the matching score between text and video. There are two baseline models for the retrieval task: 1) m-UniVL(loose), the loosely coupled model that only uses the single-modal encoders; 2) m-UniVL(tight), the loosely plus tightly coupled model that includes both the single-modal encoders and the cross-modal encoder. We adopt the NCE loss (Gutmann and Hyvärinen, 2010) to learn to discriminate the positive video-text pairs against negative ones. The negative video-text samples are created by replacing the text or video in a positive sample with randomly-selected text or

---

[2] https://huggingface.co/xlm-roberta-base

[3] https://github.com/microsoft/UniVL

video from other samples. For video captioning task, we employ all modules including all the encoders and decoder to learn the caption generation task.

Side-Information In regard to the titles, we use them as the side-information of the videos for an efficient text-video retrieval. In details, we first map the embedding of the title to the same dimension with the video embedding, and then concatenate them together. Then we encode them using the visual encoder to generate the enhanced video features for further processing.

4 Related Work

4.1 Natural Language Benchmarks

GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019) are two comprehensive datasets that can be used to train and evaluate natural language understanding systems. GLGE (Liu et al., 2020) is another comprehensive dataset for natural language generation evaluation. XGLUE (Liang et al., 2020) and XTREME (Hu et al., 2020) are two recent benchmark efforts that extend the evaluation scenarios from monolingual to multilingual. Recent pre-trained language models benefit a lot from these datasets, by evaluating their effectiveness under a relatively fair environment.

4.2 Vision-Language Benchmarks

A number of vision-language datasets have been widely used in the multimodal research.

MSCOCO (Chen et al., 2015) and Flicker30K (Vinyals et al., 2015) are two datasets for image-text retrieval and image-captioning tasks. These two benchmarks have been extended to multilingual tasks (Elliott et al., 2016, 2017; Miyazaki and Shimizu, 2016; Li et al., 2019) as well. VQA (Antol et al., 2015) and GQA (Hudson and Manning, 2019) are two datasets for visual question answering. VCR (Zellers et al., 2018) is another dataset for visual commonsense reasoning. Comparing with all these existing datasets, GEM-I has unique characteristics. First, it is a large-scale multilingual image-text dataset covering 20 different languages. Second, the query-image pairs in GEM-I come from a commercial search engine. Therefore, it has big practical values. Third, for each query-image pair, the title of the Web page that contains the image is also included as the additional context, which makes GEM-I different from all existing datasets.

HowTo100M (Miech et al., 2019b), YouCook2 (Zhou et al., 2018), and MSR-VTT (Xu et al., 2016) are three typical benchmarks for video-text retrieval and video captioning tasks. TVQA (Lei et al., 2018) and ActivityNet-QA (Yu et al., 2019) are two typical benchmarks for video question answering. Comparing with all these existing datasets, GEM-V is the first video-language benchmark supporting multilingual scenarios. Similar to GEM-I, it also has big practical values, as all data in GEM-V come from a real-world search engine with massive users.

5 Experiments

In this section, we evaluate two baseline pre-trained models (described in Section 3) on GEM. Specifically, M^3P is evaluated on GEM-I for multilingual image-language tasks and m-UniVL is evaluated on GEM-V for multilingual video-language tasks. For both baseline models, we fine-tune them on downstream tasks directly.

5.1 Image-Language Evaluation on GEM-I

5.1.1 Experimental Settings

We select the open-source version[4] of M^3P (Ni et al., 2021) for the image-language evaluation on GEM-I. It uses 101G sentences (in 100 languages) extracted from Wikipedia as the multilingual pre-training corpus, and uses 3.3 million English image-caption pairs in Conceptual Captions (Sharma et al., 2018) as the multimodal pre-training corpus.

For text-to-image retrieval, the hyper-parameters of the encoder are set as follows: 768 hidden units, 12 heads, GELU activation, a dropout rate of 0.1, 128 max input length, 12 layers in encoder. For image captioning, the hyper-parameters of the encoder-decoder are set as follows: 768 hidden units, 8 heads, GELU activation, a dropout rate of 0.1, 128 max input length, 12 layers in both encoder and decoder. The transformer parameters between the encoder and decoder are shared, including embedding modules and self-attention modules.

We fine-tune M^3P on text-to-image retrieval and image captioning tasks. For retrieval, we use Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$, an initial learning rate of 5e-5, a weight decay of 1e-4 and a batch size of 64 to fine-tune M^3P for 30 epochs. For captioning, a learning rate of 1e-4 and a batch size of 16 are used to fine-tune M^3P for 20 epochs. All above calculations are carried on 4 NVIDIA Tesla P100 GPUs.

Table 4: Evaluation results of M^3P on GEM-I test set for image captioning task where ROUGE-L, METEOR and CIDEr are taken as metrics. Only images (without title) are used to test its multilingual multimodal captioning ability. The average score is computed over all 20 languages.

5.1.2 Text-to-Image Retrieval Results

We follow the same evaluation metric, mean-Recall (average score of R@1, R@5, R@10), in M^3P to report its the performance on text-to-image retrieval task on GEM-I dataset.

From the results reported in Table 3, we have several observations:

1) When applying M^3P to GEM-I without fine-tuning (i.e. the zero-shot setting), the general performance is poor. The major reason is that M^3P is pre-trained on a monolingual multimodal corpus and a multilingual monomodal corpus, and both datasets have very different data distributions comparing with GEM-I.

2) By fine-tuning M^3P using all labeled data in different languages (i.e. the fine-tune on all setting), better performance can be obtained. This shows the strong transfer ability of M^3P, when there is a moderate amount of labeled data for fine-tuning.

3) By furthering considering the title signal in this retrieval task, the general performance can be improved significantly. This indicates the strong correlation between the query and the title. Besides, when taking the title signal into the zero-shot setting, we can observe a performance drop. It is due to that M^3P is pretrained with input paradigm Q-I, thus making it not suitable for evaluating Q-I-T paradigm directly.

5.1.3 Image Captioning Results

As in Table 4, we report the performance of image captioning tasks on GEM-I test set with M^3P model where ROUGE-L (Lin and Och, 2004), METEOR (Banerjee and Lavie, 2005) and CIDEr (Vedantam et al., 2015) are taken as the evaluation metrics. To study the image captioning ability of M^3P, we only use images (without title) to generate queries in GEM-I dataset. In general, the M^3P model performs relatively poor on this task, due to that most search queries are short keywords instead of a complete sentence, and they differ from our pre-training data a lot.

From the above results from text-to-image retrieval task and the image captioning task, we can conclude that our proposed GEM-I dataset can demonstrate a model's image understanding and generation ability in 20 different languages.

5.2 Video-Language Evaluation on GEM-V

5.2.1 Experimental Settings

We select the open-source version[5] of UniVL (Luo et al., 2020) and replace the original text encoder with XLM-R (Conneau et al., 2020), to support the multilingual video-language evaluation on GEM-V. The original UniVL is pre-trained on 1.2 million instructional videos with ASR transcripts in HowTo100M (Miech et al., 2019b).

For text-to-video retrieval task, m-UniVL extracts video features using the off-the-shelf pre-trained S3D (Miech et al., 2019a) model. The FPS of the 3D feature extractor is 16 and the dimension is 1,024. The hyper-parameters of the video encoder are set as follows: 768 hidden units, 12 heads, 6 layers of of Transformer blocks to capture the sequential information on the 3D features. The hyper-parameters of the text encoder are identical to the ones in XLM-R: 768 hidden units, 12 heads, 12 layers of Transformer blocks. The cross encoder on the top of the text and video encoders has 2 layers with 768 hidden units and 12 heads. For video captioning, the decoder is with 3 layers, 768 hidden units and 12 heads.

We finetune m-UniVL on text-to-video retrieval and video captioning tasks. For retrieval, a learning rate of 1e-4 and a batch size of 128 are used to fine-tune m-UniVL for 50 epochs. For captioning, a learning rate of 3e-5 and a batch size of 16 are used to fine-tune m-UniVL for 5 epochs. All above calculations are carried on 4 NVIDIA Tesla V100 GPUs.

5.2.2 Text-to-Video Retrieval Results

Following official UniVL on retrieval task, we evaluate the text-to-video retrieval task on our GEM-V using two variants. One is m-UniVL (loose), which encodes the input text query and candidate video clips (and optional title) through the text encoder and video encoder respectively and finally calculates the matching score through dot product. The other is m-UniVL (tight), based on m-UniVL (loose), m-UniVL (tight) further concatenates the encoded features and feeds them to the cross encoder to get unified representation and predict the matching score on the first token '$\langle$s$\rangle$'. The evaluation metric is mean-Recall (arithmetic mean of Recall@K for $K \in \{1, 5, 10\}$).

Tables 5 lists the retrieval results. The results can be divided into two groups. One is from the fine-tuning on all training set across linguistic type (*Fine-tune on ALL*), and the other is from the fine-tuning on individual training set of each language (*Fine-tune on Each*). The target of such a division is to explore whether one language can benefit from other wide languages. Besides, there are 9 languages without training set. We keep such a zero-shot evaluation to explore the transfer ability of the proposed model.

We can get three conclusions from the results:

1) The m-UniVL (tight) outperforms m-UniVL (loose) at the same retrieval settings. It proves that the cross encoder of UniVL enables the multi-modality features to fully interact with each other to capture better alignment.

2) The title of the video introduces a large performance gain and is a good semantic feature of the video. This metadata is especially useful for

Table 6: Evaluation results of m-UniVL on GEM-V for video captioning, where ROUGE-L, METEOR and CIDEr are taken as metrics. **V→Q** and **T→Q** denote the video caption is generated based on video (V) and title (T), respectively. **V+T→Q** denotes the video caption is generated based on both video (V) and title (T). The average score is computed over all 30 languages.

zero shot setting with a significant improvement. They demonstrate that improving the retrieval performance on pure videos without titles is still a challenge. Our proposed GEM develops a chance to push such a multimodal challenge.

3) Fine-tune on all can achieve better results than fine-tune on each. The reason is the former can effectively leverage the data from all languages and benefit the task rather than the latter. Besides, for zero shot languages, fine-tune on all is also very effective. It demonstrates that our proposed GEM can also be used on multilingual research besides multimodal research.

5.2.3 Video Captioning Results

The captioning task aims to generate a caption given a video clip (and optional title) in our setting. Such a generation task is from our practical application. We adopt whole m-UniVL including encoders and decoder to finish the task. The evaluation metric are ROUGE-L (Lin and Och, 2004), METEOR (Banerjee and Lavie, 2005) and CIDEr (Vedantam et al., 2015), whose values are obtained from an open-source tool[6].

Table 6 lists the experimental results. Similar conclusions can be drawn as the retrieval task, and there are two more observations:

1) For captioning task, the performance of the generation on pure videos is low. The reason is that the search queries sometimes are the keywords instead of a whole sentence, thus the task of V→Q is relatively hard.

2) Title is especially important due to the characteristic of this data collection process.

From the above results from the text-to-video retrieval task and the video captioning task, we can conclude that our proposed GEM-V can improve video understanding and generation under the multilingual and multimodal perspective.

6 Conclusion

This paper presents GEM as a benchmark for evaluating the generalization capabilities of vision-language models on image-language and video-language tasks. GEM is also the first large-scale multilingual multimodal dataset, where the natural language contexts are collected from a commercial search engine in 20 and 30 languages for image-related and video-related tasks, respectively. We describe two vision-language pre-trained models for GEM and hope these efforts can advance the development of multilingual multimodal research.

7 Ethical Considerations

We have reviewed our data release process and it has been approved by our institutional review board. Specifically, (a) In GEM-I, all of the images

---

[6] https://github.com/Maluuba/nlg-eval

are with proper Creative Commons Licenses, so that they are safe to be distributed without violating any policies or intellectual rights. Also, we discarded images with human faces to avoid revealing privacy. (b) In GEM-V, all of the videos were originated from Youtube, and we will only provide Youtube URLs to the researchers. We have confirmed with our institutional review board that distributing URLs does not violate any policies or intellectual rights. We didn't do anything specific for human faces in the videos, since we are only distributing video URLs, and modifying the original videos (such as blurring the faces) might violate the copyright of the videos. When releasing GEM to the public, we will indicate the data source, emphasize that the dataset is for research purposes only, and provide an email address for people to contact us to delete any data if any infringement. During data collection, we didn't collect, store, or distribute any private information of the users.

To measure the quality of our dataset, we employed crowd-sourcing judges in the United States and provided labeling guidelines for them. The compensation given to the workers is 15 USD per hour for GEM-I and 25 USD per hour for GEM-V. The level of compensation is determined by: (a) Market price according to similar labeling tasks in the US. (b) The difficulty and labeling speed of this task. This task involves labeling if a query is related to an image or video, so it is considered as a relatively easy task. The labeling speed is about 300 query-image pairs per hour and 180 query-video pairs per hour.

Abstract

Learning low-dimensional representations of networked documents is a crucial task for documents linked in network structures. Relational Topic Models (RTMs) have shown their strengths in modeling both document contents and relations to discover the latent topic semantic representations. However, higher-order correlation structure information among documents is largely ignored in these methods. Therefore, we propose a novel graph relational topic model (GRTM) for document network, to fully explore and mix neighborhood information of documents on each order, based on the Higher-order Graph Attention Network (HGAT) with the log-normal prior in the graph attention. The proposed method can address the aforementioned issue via the information propagation among document-document based on the HGAT probabilistic encoder, to learn efficient networked document representations in the latent topic space, which can fully reflect document contents, along with document connections. Experiments on several real-world document network datasets show that, through fully exploring information in documents and document networks, our model achieves better performance on unsupervised representation learning and outperforms existing competitive methods in various downstream tasks.

1 Introduction

Document networks, such as hyperlink networks of Web pages, citation networks of academic documents, and user profiles in social networks, have long been an intensively studied research subject due to their wide applications. Finding low-dimensional representations of networked documents to preserve document contents and connections among documents simultaneously is a crucial research task. Inspired by the wide application of topic models such as latent Dirichlet allocation (LDA) (Blei et al., 2003) on discovering the latent semantic structure of unconnected documents, a series of Relational Topic Models (RTMs) are proposed to explore the latent topic semantic structure of documents and links among them, based on probabilistic graphical models (Nallapati et al., 2008; Chang and Blei, 2009; Le and Lauw, 2014; Chen et al., 2014; Yang et al., 2016), deep generative models (Acharya et al., 2015; Wang et al., 2017; Bai et al., 2018), auto-encoders (AEs) (Zhang and Lauw, 2020) and graph auto-encoders (GAEs) (Wang et al., 2020a).

However, most RTMs consider only the pairwise correlation or the first-order neighbor correlation (Zhang and Lauw, 2020) among documents. Although the recently proposed deep relational topic model, GPFA (Wang et al., 2020a) based on graph neural networks (GNNs) can consider low-order indirect neighborhood information via stacked graph neural network (GNN) (Kipf and Welling, 2016b) layers, it still suffers from exploiting the deep interactions (higher-order) between indirectly connected documents due to the oversmoothing problem (Li et al., 2018). Such the higher-order correlation structure has been proved to be effective on various tasks (Abu-El-Haija et al., 2019) such as link prediction and recommendation (Zhang and McAuley, 2020).

To address the aforementioned issue, we propose the graph relational topic model (GRTM) for modeling the latent topic structure of document contents and links, based on the higher-order graph attention auto-encoders (HGTAEs), aiming to fully explore and fuse each order proximity (including the low-order and higher-order) of document network. Specifically, we propose to extract the higher-order document proximity network (HDPN) from the adjacent matrix of the document network via the calculation of the shortest path. The higher-order graph attention network (HGAT) is presented

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2604–2613
August 1–6, 2021.

to efficiently model the neighborhood information propagation on HDPN via introducing the log-normal prior into the graph attention. We finally propose our GRTM with the higher-order graph attention auto-encoders (HGTAEs) based on HGAT and HDPN. The main contributions of our paper are as follows:

1. We propose a novel unsupervised deep relational topic model GRTM to fully explore multiple information: the higher-order document relations and latent topic semantic among document contents and networks.

2. We propose a novel graph attention network HGAT to efficiently explore each order correlations among networked documents.

3. Experimental results on document network datasets show that our model outperforms existing competitive methods on unsupervised representation learning, through fully exploring multi-granularity information in document networks.

2 Related Work

In this section, we briefly review existing Relational Topic Models (RTMs), Graph Auto-Encoders (GAEs), and Graph Topic Models.

RTMs generally extended LDA based topic models to further model the links between documents in networks. Chang and Blei (2009) first proposed to introduce additional binary conditional variables in the generation to model the document links. (Chen et al., 2014) (2014) proposed discriminative relational topic models (DRTMs) to learn discriminative latent representations of document networks. Le and Lauw (2014) proposed PLANE which can jointly extract topics and visualization coordinates. To apply the neural network based inference approach to RTMs, Bai et al. (2018) utilized Stacked Variational Auto-Encoder(SVAE) to derive more representative documents in topic distributions. However, these models only consider pair-wise document correlations, fail to model the full structural information (low-order and higher-order) embedded in the document network.

To model the block correlation structure of the document network, Yang et al. (2016) incorporated weighted stochastic block model into relational topic models. Most recently, Zhang and Lauw (2020) proposed AdjEnc to reconstruct both documents and their neighborhoods in the network. However, it can only capture the first-order correlation structure with the adjacent-encoder. Wang et al. (2020a) proposed the deep relational topic model GPFA based GNNs to explore hierarchical relationships of interconnected documents. However, still, it can only capture the low-order hierarchical relationships of interconnected documents due to the well-known smoothing problem of GNNs, while long-range relations among documents are also critical for learning latent representations in document networks. To address this issue, we calculate the higher-order proximity network that allows considering the long-range topological information among documents, rather than merely pairwise or few-order relations.

Recently, GAEs has attracted a lot of attention, which incorporates GNNs into auto-encoder to unsupervised graph embedding learning, motivated by the successful applications of GNNs in modeling graph topological structure. The earliest attempt VGAE (Kipf and Welling, 2016a) extended variational auto-encoder (VAE) onto graph structure data for learning network embedding. Inspired by the advantage of GNNs, some works have explored VGAE for topic modeling, including the deep relational topic model GPFA mentioned before, and GraphBTM (Zhu et al., 2018) which improved the biterm topic model (Yan et al., 2013) with word co-occurrence graph encoded by GCNs. Except studies based on VGAE, there are also works combining topic models with graph neural networks in a different manner, such as the graph attention topic network (GATON) (Yang et al., 2020) proposed for unconnected documents, the dynamic hierarchical topic graph model DHTG (Wang et al., 2020b) used for unconnected document classification, the topic variational graph auto-encoder (TVGAE) (Xie et al., 2021b) for document classification and the graph topic neural network (GTNN) (Xie et al., 2021a) proposed for representation learning of both connected and unconnected documents. Different from them, we target connected documents. Moreover, to fully explore the deep topological structure of document networks, we propose the novel higher-order graph attention network, and then introduce it into the relational topic modelling based on variational graph auto-encoders.

3 Method

In this section, we present our graph relational topic model (GRTM) for the document network. We first introduce the construction of the higher-order proximity networks: HDPN from document adjacency matrices, then we present the novel graph attention network HGAT to fuse the information of HDPN. We end this section by introducing the variational graph auto-encoder structure for building GRTM.

3.1 Higher-order Proximity Network

Formally, we define a given document network as $\mathcal{G} = (D, A, X)$. $D = \{d_1, ..., d_n\}$ is the set of document nodes with n documents and a vocabulary V with m words. Relations between documents are represented as a 0-1 adjacency matrix $A \in \mathbb{R}^{n \times n}$, and $X \in \mathbb{R}^{n \times m}$ is the documen-word index matrix, in which X_{ij} represents the weight (e.g. TF-IDF) of word j in document i. For the given document sets D, Based on the given adjacency matrices A of document network, the key problem is to discover and preserve arbitrary-order neighborhood relations beyond first-order or few-order (including other higher-order). Intuitively, two nodes have a proximity correlation if and only if we can find at least one path between them (Liu et al., 2019). Thus, we can calculate the order of proximity correlation between two nodes according to the length of the shortest path between them based on the adjacency matrix, and directly preserve arbitrary-order information in the same matrix. Denoting the adjacency matrices of HDPN as $\hat{A} \in \mathbb{R}^{n \times n}$, the link of proximity correlation between two documents (d_i, d_j) is defined as:

$$\hat{A}_{i,j} = \begin{cases} k, & \textit{existing a k-length shortest path} \\ 1, & i = j \\ \infty, & \textit{no path} \end{cases} \tag{1}$$

According to the above definition, $\hat{A}$ can be calculated during the data pre-processing step in advance. The length of the shortest path of two nodes is calculated using classical search algorithms such as Dijkstra's algorithm or Bellman-Ford algorithm on the machine learning framework [1]. Compared with existing methods that calculate the higher-order proximity with the power of adjacency matrix or steps in a probabilistic transition process (Abu-El-Haija et al., 2019; Liu et al., 2019), our calculation is more suitable for explicitly calculating the length of the shortest path. Because the k-power of adjacency matrix has proximity information overlap on other power matrices before it, while the calculation of k-walk may lead to nodes return to their neighbors less than k-order rather than reach to their k order neighbor (Zhang and Xu, 2020).

3.2 Higher-order Graph Attention Network

In this section, we focus on how to better fuse information of neighbors at different orders on an HDPN to efficiently learn node representations. Intuitively, for a given node representation, the contributions of its neighbors vary according to their distances. However, directly utilizing GNNs such as graph convolutional networks (GCNs) and graph attention networks (GATs) on the HDPN will treat neighbors of nodes at different orders equally. Therefore, we present the higher-order graph attention network (HGAT) to solve the problem via introducing the log-normal prior into the graph attention.

Instead of utilizing uniform prior in GATs, we exploit the log-normal distribution to model the importance decaying of neighbors of the current node on different orders. For simplicity sake, we use the log-normal distribution with zero-mean value, and calculate the attention coefficient between two nodes i, j:

$$\begin{aligned} \tilde{h_i}^l, \tilde{h_j}^l &= W^l h_i^l + b^l, W^l h_j^l + b^l \\ e_{ij} &= \rho(\lambda \phi(p_{ij})(\tilde{h_i}^l \cdot (\tilde{h_j}^l)^\intercal)) \\ \alpha_{i,j} &= softmax(e_{i,j}) = \frac{\exp(e_{ij})}{\sum_{o \in \mathcal{N}(i)} \exp(e_{io})} \end{aligned} \tag{2}$$

where $\phi(p) = \frac{\exp^{-(\ln p)^2/\sigma^2}}{p\sigma\sqrt{2\pi}}$ is the probability density function of the log-normal distribution, σ is the variance of the log-normal prior, p_{ij} is the length of the shortest path between nodes i, j in a HPN, h_i^l, h_j^l are representations of node i, j in the l-th layer, ρ is the activation function, λ is the parameter to control the influence of the log-normal prior, $\mathcal{N}(i)$ is neighbors of node i in a HPN, W^l, b^l are the weight matrix and bias of the l-th layer. The attention mechanism based on the log-normal prior allow nodes to select their neighbors at arbitrary-order with different importance. Calculated attention coefficients are further exploited to propagate information of neighbors of each node at arbitrary-

---

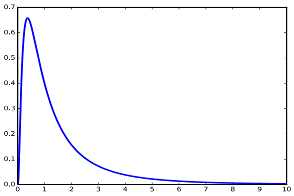

Figure 1: The example of the log-normal distribution with $\mu = 0, \sigma = 1$.

order:

$$h_i^{l+1} = \rho(\sum_{j \in \mathcal{N}(i)} \alpha_{ij} h_j^l) \tag{3}$$

Although there are other distributions, such as the normal distribution used in the Gaussian transformer (Guo et al., 2019), the log-normal is more suitable for model the importance calculation in our case. This is because the density function $\phi(p)$ of the log-normal prior with zero-mean value has always a real value larger than 0 rather than that of the normal distribution with the negative value or Poisson distribution with an integer value. Moreover, $\phi(d)$ always decreases monotonically after $\exp^{-\sigma^2} < 1$, while the path length in our HDPN is always greater or equal to 1. Therefore, the log-normal prior can naturally model the decay of importance weight by increasing the path length between two nodes, as shown in Figure 1. When conducting the HGAT on the vanilla adjacency matrix (only with first-order proximity), the HGAT will be degenerated into the GAT method due to there are only 1 or ∞-length of the shortest path in the vanilla adjacency matrix.

3.3 Graph Relational Topic Modelling

To fully explore the long-range document relations to model the latent topic semantic among document contents and networks, we present the GRTM model with the higher-order graph attention auto-encoders (HGTAEs). Let's assume K is the topic number, θ is the document topic proportion, and β is the topics, namely the topic word proportion.

Firstly, we present the generative process of GRTM as in Algorithm 1. Similar to previous RTMs, we assume the document topic proportion is generated from the Dirichlet prior. However, the Dirichlet prior makes it difficult to make the neural variational inference for GRTM, due to the challenge of reparameterizing the Dirichlet prior. Thus, to simplify the inference process, we approximate the Dirichlet distribution with its Laplace approximation: the logistic normal distribution following many previous works (Srivastava and Sutton, 2017).

Algorithm 1: Generative Process of GRTM

```
for each document $d \in D$ do
    Generate the mean vector:
        $\mu_d^0 \sim \text{HGAT}_\mu(X_d, \hat{A}_d)$.
    Generate the diagonal covariance:
        $\sigma_d^0 \sim diag(\text{HGAT}_\sigma(X_d, \hat{A}_d))$.
    Draw the noise variable $\epsilon_d \sim \mathcal{N}(0, I)$.
    Draw the document topic proportion: $\theta_d \sim$
        $LN(\mu_d^0, \sigma_d^0) = softmax(\mu_d + (\sigma_d^0)^{\frac{1}{2}} \epsilon_d)$.
    for each word $w_{dv} \in V$ do
        Draw the word $w_{dv} | \theta_d, \beta \sim \text{Mult}(\theta_d \beta)$.
for each pair of document $d, d' \in D$ do
    Draw the observed link
        $A_{d,d'} | \theta_d, \theta_{d'} \sim \text{Bernoulli}(f_y(\theta_d, \theta_{d'}))$
```

To incorporate the higher-order relations among documents, we generate the document topic proportion with logistic normal distribution parameterized by HGAT probabilistic encoder. Specifically, for each document d, we draw the mean and covariance of a multinomial distribution variable and then transform it with the softmax function:

$$\begin{aligned}
\mu_d^0 &= \text{HGAT}_\mu(X_d, \hat{A}_d) \\
\sigma_d^0 &= diag(\text{HGAT}_\sigma(X_d, \hat{A}_d)) \\
\theta_d &= softmax(\mu_d^0 + (\sigma_d^0)^{\frac{1}{2}} \epsilon_d)
\end{aligned} \tag{4}$$

where HGAT is the message passing process as in Equation 3, ϵ_d is the noise variable. For HGAT encoders of mean and covariance, the input feature h_d^0 is set to the normalized document-word index feature X_d following previous methods (Kipf and Welling, 2016a). The message passing based on HGAT makes latent topic proportions of each document influenced by its neighbors at different orders with different importance.

In the decoding process, the word is generated from the multinomial distribution based on the topic proportion of the document it belongs to and its topic proportion: $p(w_d | \theta_d, \beta) = \text{Mult}([\theta_d \beta])$. The links between two documents are modeled as Bernoulli binary variables, which are conditionally generated based on the latent topic proportions of these documents: $p(A_{d,d'} | \theta_d, \theta_{d'}) = sigmoid(f_y(\theta_d, \theta_{d'}))$, where f_y is the multi-layer perception.

Following the auto-encoding variational Bayes inference method (Kingma and Welling, 2014), we can yield the evidence lower bound (ELBO) to the marginal log-likelihood according to the above generative process:

$$\begin{aligned}\mathcal{L}(\Theta) = &- D_{KL}[q(\theta|w,\hat{A})||p(\theta|\alpha)] \\ &+ \mathbb{E}_{q(\theta|w,\hat{A})} logp(w|\theta,\beta) \\ &+ \mathbb{E}_{q(\theta|w,\hat{A})} logp(A|\theta)\end{aligned} \tag{5}$$

where Θ is the parameter set of the whole process, $q(\theta|w,\hat{A})$ is the approximate Dirichlet variational posterior as parameterized in Equation 3, $p(\theta|\alpha)$ is assumed the true Dirichlet posterior and α is the prior parameter. We still approximate it with its Laplacian approximation: the softmax variable on the multivariate normal with mean and covariance matrix as follows:

$$\begin{aligned}\mu_d^1 &= log\alpha - \frac{1}{k}\sum_i \alpha_i \\ \sigma_d^1 &= \frac{1}{\alpha}(1-\frac{2}{K}) + \frac{1}{k^2}\sum_i(\frac{1}{\alpha_i})\end{aligned} \tag{6}$$

We seek to minimize the KL divergence between the variational posterior and the true posterior in the first term. The second and third terms aim to reconstruct the document contents and links.

Based on the gradient variational Bayes (SGVB) estimator (Kingma and Welling, 2014), we can further yield the detailed formulation of each term:

$$\begin{aligned}D_{KL} = &\frac{1}{2}\{tr(\sigma^0(\sigma^1)^{-1}) \\ &+ (\mu^1-\mu^0)^T(\sigma^1)^{-1}(\mu^1-\mu^0) \\ &- k + log(\frac{|\sigma^1|}{|\sigma^0|})\}\end{aligned} \tag{7}$$

$$\begin{aligned}logp(w|\theta,\beta) = &\sum_{d=1}^{n} -X_d log(\tilde{X}_d) \\ &- (1-X_d)log(1-\tilde{X}_d) \\ logp(A|\theta) = &\sum_{d=1}^{n} -A_d log(\tilde{A}_d) \\ &- (1-A_d)log(1-\tilde{A}_d)\end{aligned} \tag{8}$$

where $\tilde{X} = (\theta\beta)$ is the reconstructed document contents, $\tilde{A} = sigmoid(f_y(\theta))$ is the reconstructed document links. Based on these, we can optimize the ELBO with stochastic gradient descent to infer the whole model end to end.

Table 1: Statistics of the document network datasets (Zhang and Lauw, 2020)

Datasets	Classes	Documents	Edges	Vocabulary
DS	9	570	1336	3,085
HA	6	223	515	2,073
ML	7	1,980	5,748	4,431
PL	9	1,553	4,851	4,105

4 Experiments

We conduct experiments in several real-world document network datasets. The statistics are reported in Table 1. Four datasets are subsets extracted from Cora: Data Structure (DS), Hardware and Architecture (HA), Machine Learning (ML), and Programming Language (PL) as in (Zhang and Lauw, 2020), in which Cora is the scientific article citation dataset collected from scholar websites. To evaluate the unsupervised representation learning capability of our method, we infer the latent topic portions of documents θ with our model, and then use it for three types of downstream tasks, namely document classification, document clustering, link prediction. We compare our method against baselines from the following three categories:

- **Auto-Encoders**: including variants of auto-encoders such as AE, DAE (Vincent et al., 2010), CAE (Rifai et al., 2011), VAE (Kingma and Welling, 2014), KSAE (Makhzani and Frey, 2014), KATE (Chen and Zaki, 2017) use Auto-Encoder to encode texts;
- **Relational Topic Models**: including generative models based on relational topic model such as RTM (Chang and Blei, 2009), PLANE (Le and Lauw, 2014), NRTM (Bai et al., 2018), ProdLDA (Srivastava and Sutton, 2017), and also a relational topic model based on the auto-encoder method: ADE (Zhang and Lauw, 2020);
- **Graph Embedding**: including graph embedding method based on GCN - VGAE (Kipf and Welling, 2016a).

We follow the settings for all baselines as in (Zhang and Lauw, 2020) and also compare methods in both transductive and inductive learning settings. For inductive learning, we randomly select a subset of 70% documents as the training set, a subset of 10% of documents as the validation set, and use the remaining 20% documents as the testing set. For transductive learning, all documents are involved in the training process. All experimental results are averaged over the results of 10 independent runs. Following (Zhang and Lauw, 2020), we set the topic number K as 64, the layer number L of message passing in HGAT as 1. The hidden size of weight matrices in HGAT is equal to the topic number of 64. For the log-normal prior in HGAT, we set the the parameter $\lambda = \sqrt{\pi}$, the variance $\sigma = \frac{1}{\sqrt{2}}$. We use the tanh activation function in HGAT. We use the Dirichlet distribution with parameter $\alpha = \frac{1}{K}$ for the logistic normal approximation. The learning rate on all datasets is 0.065, the maximum training epochs with Adam is 40000, the early stop epoch is 500. The parameter setting in all baseline models is the same as in (Zhang and Lauw, 2020).

We infer document topic representations with trained GRTM model for both train and test documents, which are then used in three downstream tasks to evaluate the effectiveness: 1) **Document classification**: we adopt K-Nearest Neighbors to predict each document's label based on the Euclidean distance of generated representations. We use the classification accuracy as the metric. 2) **Document clustering**: We also compare our method with baselines in clustering documents via K-means, to investigate whether our method can generate similar representations for documents in the same category. In this case, the ground truth labels are only utilized to calculate normalized mutual information (NMI) in evaluation. 3) **Link Prediction**: The generated representations are used to predict the links between documents in this experiment. We use Mean Average Precision (MAP) as the evaluation metric following the previous method (Zhang and Lauw, 2020). To better understand the semantic information our method captured in generated representations, we also conduct experiments to present a detailed analysis of our generated topics in inductive learning: 1) **Topic Coherence**: As in previous work (Zhang and Lauw, 2020), we adopt PMI - $PMI(w_i, w_j) = log\frac{p(w_i,w_j)}{p(w_i)p(w_j)}$ to evaluate topic coherence. We calculate the average pairwise PMI of the top 10 words in each topic. Better topics should produce higher PMI.

2) **Visualization**: We apply t-SNE to project text representations generated by different models into a 2-dimensional space.

4.1 Overall Results

As shown in Table 2 and 3, our method achieves the best performance in all tasks on the four datasets on both inductive and transductive settings. Compared with auto-encoder based methods (AE, DAE, CAE, VAE, KSAE, and KATE), which only consider document contents without document networks. ADE, relational topic model methods (ProdLDA, RTM, PLANE, NRTM), and our method achieve better performance due to considering the links among documents, which benefits the downstream tasks of document classification/clustering and link prediction. Compared with relational topic model methods (ProdLDA, RTM, PLANE, NRTM), we found that the graph embedding method VGAE and the adjacent auto-encoder method ADE perform better than other baselines, which demonstrates the advantage of using high-order proximity information. But they are still inferior to our proposed GRTM, which proves the benefits of fully exploring information of various orders in document networks. A similar performance among these methods can also be observed in the results of topic coherence in Table 4.

There is no mean standard deviation evaluation by the previous methods (Zhang and Lauw, 2020; Chen and Zaki, 2017), so we only report the results of our method in Table 5 to illustrate the statistical effectiveness of our model. These results are obtained in both transductive and inductive settings through repeating each 10 times.

4.2 Effect of Topic Number

To investigate the sensitivity of our method to topic numbers, we present the classification accuracy of our model on different topic numbers in the inductive setting. As shown in Figure 2, the test accuracy on four datasets generally improves with the increase of the number of topics and reaches the peak when the topic number is around 64. From these curves, we can find that the performance of our model is not too sensitive to the topic number, and also the topic number does not seem to be so related to the ground truth number of classes of datasets. In figure 3, we further show transductive test classification accuracy of different models under different topic numbers. We can see that our model consistently outperforms all baselines under different topic numbers on four datasets.

Table 2: Transductive learning results on document classification, document clustering, and link prediction.

Figure 2: The test classification accuracy of our model vary different topic numbers

4.3 Effect of Log-normal Prior

We vary the variance σ of the log-normal prior to explore the impact of the log-normal prior in HGAT. We present results of our model under the value of $\sigma \in \{\frac{1}{2}, \frac{1}{\sqrt{2}}, 1\}$, and the results are shown in Table 7. The larger value of σ makes the slower decay of the importance on higher-order proximity information otherwise the faster decay. From the table, we can see that our model generally achieves the best performance at $\sigma = \frac{1}{\sqrt{2}}$. We suspect that too much noisy higher-order information is introduced when σ is set too large, while insufficient higher-order information can be used when too small. Hence it yields poor performance in both cases.

4.4 Different layer numbers

Although one layer message passing process of HGAT is able to capture arbitrary-order proximity information among document networks, we can still report the results of our model under the different layers of HGAT in Table 6. We can see that our model with one layer HGAT achieves the best performance under both settings. When the layer number of HGAT is set to 0, the HGAT encoder of our model degenerates to the feed-forward neural network. With two-layer HGAT, document representations may be disturbed by the information of their noisy neighbors.

4.5 Ablation Study

We also perform an ablation study on our method to verify the effectiveness of each module in the inductive setting. We compare our model with its variants by removing one of the components HDPN and HGAT respectively, as shown in Table 8. From which we can see that each component makes a certain contribution to the overall performance. In the case of removing the HDPN (W/HDPN) module, our model directly takes the document adjacency matrix as input, in which it degenerates into the relational topic model based on graph attention auto encoder without considering the higher-order proximity. As in the case of removing the HGAT (W/HGAT), although our model takes the higher-order information into consideration, it doesn't make the important selection for different order correlation information. We can also see that missing the higher-order proximity has a more significant negative influence than missing the HGAT based encoder module, illustrating the relative effectiveness of the higher-order information in improving the discrimination of latent representations.

4.6 Visualization

Finally, to intuitively demonstrate the effectiveness of our model, we visualize the learned representations of the test documents on the ML dataset in Figure 4. It shows that documents are better grouped by our model than ADE (with first-order correlations) and VGAE (with few-order correlations), due to the incorporation of the in-direct correlation information among documents.

5 Conclusion

In this paper, we propose a novel graph relational topic model GTM for document networks to fully explore each order of relations among document networks, which is efficiently fused by a proposed novel graph attention network HGAT equipped with log-normal attention prior. Experimental results show that full consideration of each order proximity information on the document-document graph is beneficial for improving the learned document representations. In future work, we would like to explore the better-suited method and more elegant prior distributions for discovering and fus-

Paths to Relation Extraction through Semantic Structures

Jonathan Yellin **Omri Abend**

Abstract

Syntactic and semantic structure directly reflect relations expressed by the text at hand and are thus very useful for the relation extraction (RE) task. Their symbolic nature allows increased interpretability for end-users and developers, which is particularly appealing in RE. Although they have been somewhat overshadowed recently by the use of end-to-end neural network models and contextualized word embeddings, we show that they may be leveraged as input for neural networks to positive effect. We present two methods for integrating broad-coverage semantic structure (specifically, UCCA) into supervised neural RE models, demonstrating benefits over the use of exclusively syntactic integrations. The first method involves reduction of UCCA into a bilexical structure, while the second leverages a novel technique for encoding semantic DAG structures. Our approach is general and can be used for integrating a wide range of graph-based semantic structures.[1]

1 Introduction

Early work on RE focused on pattern-based rules for capturing the structure of relation-evoking words and phrases. These rules are applied over text to identify entity relations in much the same way a regular expression would be applied to discover matching text. The pattern machinery spans from simple, regular-expression like, surface patterns (Brin, 1999; Agichtein and Gravano, 2000), through systems that integrate both lexical features and syntactic dependencies into the pattern construct (Mintz et al., 2009). The PredPatt and pyBART frameworks (Zhang et al., 2017a; Tiktinsky et al., 2020) are examples of syntactic dependency based systems that leverage a set of rules defined over Universal Dependencies (UD; Nivre et al., 2016) to extract predicate-argument structures.

In supervised RE, a multi-class classifier is trained to determine whether a relation between entities is evoked by a text. With the increased predominance of end-to-end neural network architectures in NLP practice, it is not surprising that recent work on supervised relation extraction has focused on adapting end-to-end neural systems for the task (Peters et al., 2019; Yamada et al., 2020). However, end-to-end neural models pose interpretability and customization challenges (Conneau et al., 2018; Belinkov et al., 2020), motivating the study of hybrid models, in which the neural architecture is fed explicit structure representations. The Contextualized Graph Convolution Network (C-GCN; Zhang et al., 2018) represents a method for exposing structure representation to the machinery of a deep neural network. C-GCN uses a sentence's UD structure as explicit input to the neural network, resulting in a model whose results are both competitive and interpretable.

In this paper we explore whether we can adopt broad coverage semantic structure to the same effect, and whether we are able to observe improved performance in comparison to the baseline model, based on syntactic structure. We focus on the Universal Conceptual Cognitive Annotation (UCCA; Abend and Rappoport, 2013) framework as a test case, but note that our method can be easily extended to other semantic representations. Our results demonstrate that broad coverage semantic structures, including those that, like UCCA, require representation by directed acyclic graphs (DAGs), can be integrated effectively in neural networks for relation extraction.

2 Background

We introduce the representation approaches and datasets we employ in our study.

2.1 Universal Dependencies

Since the late 1990s, various NLP motivated dependency grammar representations have been proposed. Carroll et al. (1999); King et al. (2003); De Marneffe and Manning (2008) are examples of such systems, each one accompanied with corpora of accordingly annotated sentences, used for training supervised models for dependency parsing. The UD (Nivre et al., 2016) project, based on De Marneffe and Manning (2008), is a more recent dependency grammar representation, that emphasizes cross-linguistic consistency and has over 300 contributors producing more than 150 treebanks in 90 languages.[2] UD dependency grammar representations come in three forms: *basic*, *enhanced* and *enhanced++* (Schuster and Manning, 2016); in *basic* the sentence is represented as a tree structure, with every word in the sentence assigned a single head word, while *enhanced* and *enhanced++* are DAG representations, in which a word may have multiple heads, and where otherwise implicit relations between content words are captured explicitly. In this paper, we use UD v1 to maintain consistency with the setup used by Zhang et al. (2018).

2.2 UCCA

The Universal Conceptual Cognitive Annotation framework (UCCA; Abend and Rappoport, 2013) is a multi-layered system for semantic representation that seeks to capture the semantic, rather than syntactic patterns, expressed through linguistic utterances. The UCCA scheme maps sentences to DAGs that embody these semantic structures. In contrast to graphs formed by dependency grammars, whose nodes all represent lexical entities, a UCCA graph contains both nodes that represent word terminals, which are leaves in the DAG, and non-leaf nodes that represent entities according to some semantic consideration. The foundational layer of UCCA covers the semantics of predicate-argument structure evoked by predicates of all grammatical categories (verbal, nominal, adjectival and others). The layer's primary construct is a *Scene*, which captures a temporally persistent state or an evolving event. A Scene contains one or more Participants, and may also contain secondary scenes, known as Adverbials. Scene, Participant and Adverbial manifest as units in the DAG. In appendix A we provide an example to highlight UCCA's semantic dexterity.

TUPA (Transition-based UCCA Parser) is a transition-based parsing model that can be trained to map sentences to their UCCA scene-based foundational layer (Hershcovich et al., 2017). Pre-trained TUPA models are available online;[3] the BERT based pre-trained model is used extensively in this work.

2.3 TACRED

TACRED was designed by Zhang et al. (2017b) to address the dearth of annotated data required for supervised learning for RE. It is based on examples from the corpus used in the yearly TAC Knowledge Base Population (TAC KBP) challenges, conducted from 2009 to 2015 (McNamee and Dang, 2009). In each annual challenge, 100 entities, people, and organizations, were provided to competing systems for them to identify relations between those given entities (referred to as *subjects*), and other *objects* mentioned in the text. The TAC KBP relation extraction task was formulated in terms of slot filling: a person entity is assigned 26 attribute types while an organization is assigned 16 — the challenge posed to competing systems being the extraction of the values of these attributes based on the given corpus (or in other words, the object and relation are given; the challenge is to find the subject). TACRED leverages the results of these challenges to form a set of 106,264 example sentences, each one containing an object and a subject.

Annotation is implemented through crowdsourcing, with each sentence annotation containing the spans of both object and subject, one of the 42 entity relation attributes, or a *no_relation* classification if no relation exists. In addition to the human created annotations for subject and object spans and relation type, the TACRED dataset contains POS tags, named entities and UD parses by the Standford CORENLP parser (Manning et al., 2014). TACRED's dependency representation annotation corresponds to *basic* UD v1.

3 Motivating Experiment: A Rule-based Approach

Syntactic sentence representation is used in both rule-based and supervised methods for relation ex-

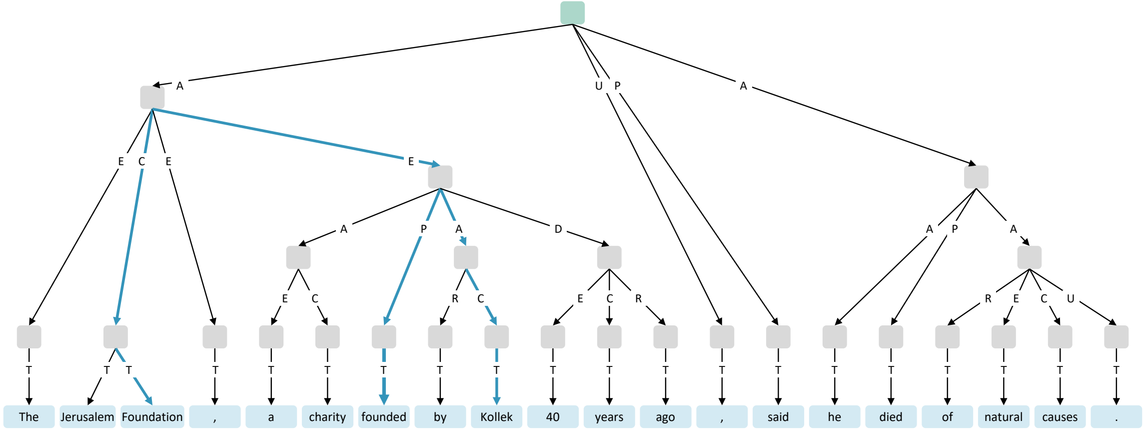
(a) UD Parse Graph



(b) UCCA Parse Graph

Figure 1: UD v1 (basic) and UCCA parse graphs for the sentence 'The Jerusalem Foundation, a charity founded by Kollek 40 years ago, said he died of natural causes.' The diagrams highlight paths from the subject 'Jerusalem Foundation, through the trigger word 'founded' to the object 'Kollek' (sentence 61b3a5c8c9272ce895a6 in the TACRED training dataset). For UD the resulting path pattern is **`<sub>↓appos↓acl<trigger>↓nmod<obj>`**, and for UCCA it is**`<sub>↑C↓E↓P<trigger>↑P↓A↓C<obj>`**.

traction. Our hypothesis is that semantic sentence representation can provide further benefit for this task. We begin the examination of this conjecture by comparing the relation extraction performance of two simple rule-based methods, one using UD and the other using UCCA, both applied to sentences from the TACRED dataset.

Method. Asserting that a relation between two entities is evoked by a text is often contingent on the presence of a "trigger word", or phrase, with semantic application to both entities. We use pattern-based rules that denote a path from the relation subject to the trigger word, and from the trigger word to the relation object. Figure 1 illustrates this by highlighting the path for both UD and UCCA for the sentence "The Jerusalem Foundation, a charity founded by Kollek 40 years ago, said he died of natural causes".

Our procedure comprises three phases: UCCA tagging, pattern extraction for both UD and UCCA, and pattern evaluation.

UCCA Tagging. While the TACRED dataset contains the UD representation for each sentence, it does not contain the corresponding UCCA representation. To begin our experiment, we use TUPA with the BERT based pre-trained model, to create UCCA annotations for all sentences in the training set, producing TACRED sentences that have both UD and UCCA representations. We do the same for the sentences in the test set, which we use for evaluation.

Pattern Extraction. Pattern extraction requires a manual step in which trigger words for the relation in each sentence are identified. With the trigger words identified, automatic pattern construction follows for both UCCA and UD, per relation type. The caption of Figure 1 presents an example. The end result is a list of paths and trigger words for each relation.

We declare a path match to occur when the target sentence contains a subject and object entity pair, any one of the trigger words in our list for the relation, and a path from the subject entity to the trigger word and from it to the object entity, that matches one of our extracted patterns.

Evaluation. We evaluate our system using the *org:founded_by* relation. For precision we count the number of no_relation sentences in the test set incorrectly identified as containing an org:founded_by pair, as a fraction of the total number of no_relation and org:founded_by sentences, to produce a precision value. We ignore sentences containing other relations. For recall, we count the number of correctly identified org:founded_by relations, from the total number in the test set.

Results. For org:founded_by, recall is 0.38 for the UD patterns and 0.2 for UCCA. Interestingly, when applying either UD or UCCA patterns, recall improves to 0.47. The precision result is 0.99 for both UD and UCCA. We note that since the UCCA representation system contains non-terminal nodes, we can expect more variation in a UCCA path than in the terminal-only UD representation-based path, contributing to the inferior recall score of UCCA versus UD.

While our experiment considers entity pairs with an org:founded_by relation or no relation at all, and thus represents a binary classification problem, rather than the multi label classification problem posed by the 41 relations of the TACRED ontology, it nonetheless highlights the potential for leveraging trigger words and sentence graph representations (syntactic as in UD v1 *basic* and semantic as in UCCA) for construction of relation matching systems. Indeed, comprehensive trigger word selection per relation is not scalable if done manually, however we could utilize word embedding techniques, so that trigger word matching could be performed using a vector distance threshold, which would capture similar trigger word terms (Batista et al., 2015).

In the next sections, we describe more sophisticated machinery, which realizes a softer notion of matching between the paths of the training data, and those of the test set.

4 C-GCN for Semantic Representation

We propose a supervised deep-neural-network model that explicitly utilizes sentence graph representations, so that we may compare the utility of UCCA and UD paths (and their combination). The model receives a sentence and two entity spans (subject and object) as input and gives preference to the word representations corresponding to the syntactic or semantic path between subject and object, for processing by the deep neural network. Contextualized Graph Convolution Networks (Zhang et al., 2018) fulfil this requirement, and we select them as the framework for our study.

4.1 The C-GCN Model

At the heart of the graph convolution network method presented by Zhang et al. is the notion that a sentence's bi-lexical dependency structure can be captured as an adjacency matrix and used efficiently to fuse the representation of each token on the path with the representations of its dependency induced neighbors. Zhang et al. experimented with various implementations and hyperparameters; we reference the C-GCN implementation for which their published results are achieved, in which only words on the path or one dependency edge away from the path are considered ("distance-one-pruning"), and which uses two convolution layers.[4]

In the case of UD, where all edges in the dependency graph representation are between terminals, this adjacency matrix stems from the graph representation directly (this is not the case with UCCA that contains non-terminal nodes; see 4.2). The adjacency matrix captures the dependencies between words that are either on the shortest path from subject to object, or are one dependency edge away from a word on the shortest path ("near-path" tokens); all other dependencies are ignored.

C-GCN Architecture. Figure 2 presents the six building blocks of the C-GCN implementation. The nexus of the C-GCN model is in the graph convolution layer (Block 3): it allows the deep neural network apparatus to focus on tokens that are on-path or near-path. Best results are reached by Zhang et al. with two instances of graph convolution, as depicted in the diagram. The first GCN instance receives the $[\texttt{sentence-length} \times 400]$ matrix input from the LSTM and outputs a $[\texttt{sentence-length} \times 200]$ matrix. Subsequent GCN instances all accept as input, and produce as output, $[\texttt{sentence-length} \times 400]$ matrices.

To explain the core GCN mechanism we employ some notation. Let A represent our pruned

---

[4] This is also the model implemented by Zhang et al. and available on GitHub at `https://github.com/qipeng/gcn-over-pruned-trees`.

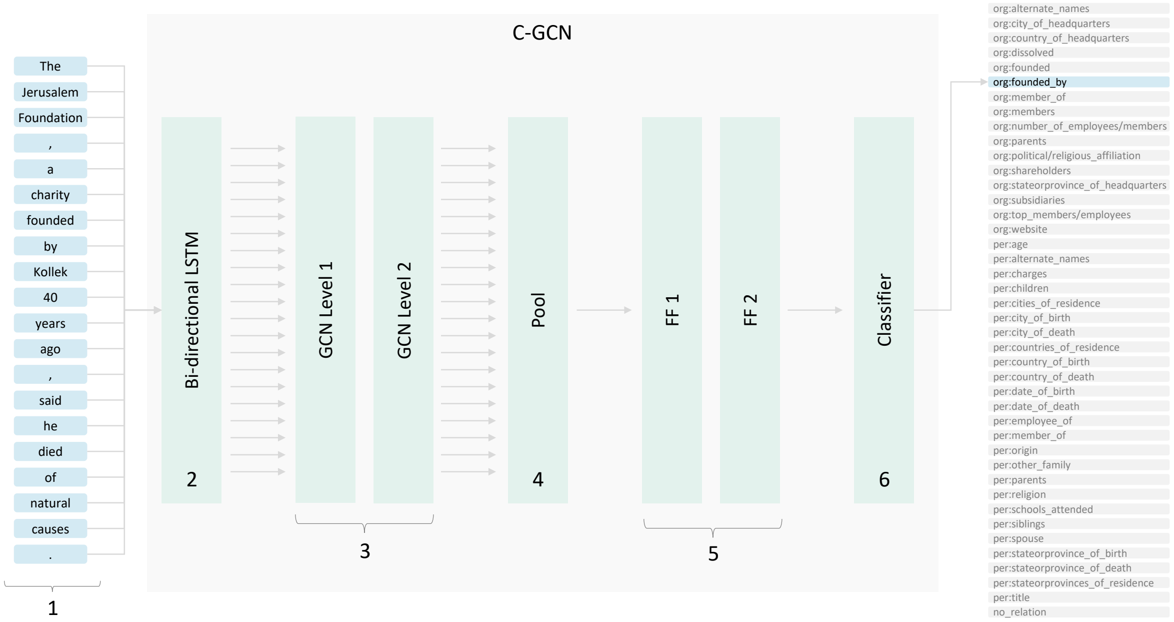


Figure 2: High level overview of the six blocks comprising the contextualized graph neural network, with the sentence from figure 1 as input.

adjacency matrix, where $A_{i,j} = 1$ if both i and j are on the path between subject and object, or one edge away from it, and there exists a dependency between tokens i and j of any kind. The direction of the dependency is ignored by the model, resulting in a symmetric matrix. Each GCN instance is assigned its own weight matrix; the first, of dimensions $[400, 200]$, all others of dimensions $[200, 200]$. Let $\mathrm{W}^{(l)}$ represent the weight matrix corresponding to instance l. Let d_i denote the degree of token i, where a token's degree corresponds to the number of tokens it is connected to directly, according to the dependency graph representation. Finally, let $\mathrm{h}^{(l)}$ and $\mathrm{h}^{(l+1)}$ represent the input to GCN instance l and its output respectively. Then we have:

$$h_i^{(l+1)}{=}\sigma\left(\frac{\sum_{j=1}^{n}(\mathrm{A}{+}\mathrm{I})_{i,j}\mathrm{W}^{(l+1)}h_j^{(l)}}{d_i}{+}b^{(l+1)}\right) \tag{1}$$

In other words, $\mathrm{h}^{(l+1)}$ is computed by applying a non-linearity function to the a linear combination of both its immediate, unpruned, neighbors in the graph, and itself, normalized by the degree of token i. Intuitively, all on, or near-path, tokens are fused with their on or near-path neighbors in the dependency graph, up to a dependency distance that corresponds to the number of GCN instances.

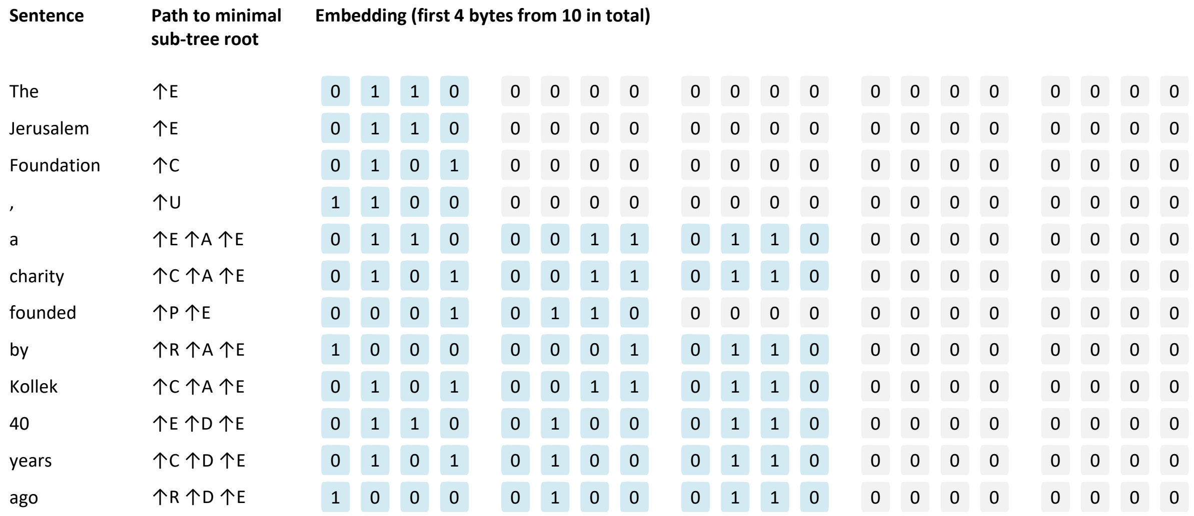
We describe the other network blocks in appendix C.

GCN vs C-GCN In their paper, Zhang et al. analyze two variants of the graph convolution network: C-GCN, and GCN. These models are identical except with regard to an LSTM block, which is only used in C-GCN. The 'C' of C-GCN refers to the contextualization achieved by the LSTM apparatus.

Modification of the C-GCN model to support experimentation with other dependency representations involves multiple stages. In the following sections we review these modifications and the resulting models.

4.2 Converting UCCA Structures to Bi-Lexical Graph

A goal of this study is to apply UCCA's semantic representations to the task of RE, by leveraging UCCA's parse graph in the graph convolutional network machinery of the C-GCN model. As in our motivating experiment (section 3), the preliminary step is to produce UCCA representations for each of TACRED's 106,264 sentences. We again employ TUPA's BERT-based pre-trained model to this end, and generate parse-graph representations for each sentence. We are confronted however with a challenge: C-GCN expects a *tree* structure, where all nodes correspond to tokens in the sentence and have a single parent; UCCA produces a *graph* structure with nodes that correspond to non-terminal units and that have multiple parents.



Sentence	Path to minimal sub-tree root	Embedding (first 4 bytes from 10 in total)																			
The	↑E	0	1	1	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0	0

Figure 3: Representation of the first 4 bytes in the initial UCCA embedding (prior to tuning that occurs during training), for the sentence ”The Jerusalem Foundation, a charity founded by Kollek 40 years ago, said he died of natural causes”. The first 12 terminals in this sentence are contained within the DAG comprised of the lowest common ancestor of both the *subject* (The Jerusalem Foundation) and *object* (Kollek), and the first 20 dimensions of the UCCA embeddings for these are depicted in this illustration. The embedding for all other terminals will be the a $\vec{0}$ vector.

The first step in bridging this gap involves conversion of the UCCA graph into a bilexical structure, where all nodes correspond to a token in the sentence. We employ the method described by Hershcovich et al. (2017), which heuristically selects a head terminal for each non-terminal node and attaches all terminal descendants to the head terminal.[5] Using this conversion procedure, we produce a UCCA-based bi-lexical graph representation for each sentence in the TACRED dataset. Appendix B provides an example of a bi-lexical reduction.

In the bi-lexical representation result, a terminal token may have multiple parents, deeming the structure a non-tree DAG. Indeed, the notion of multiple parents may be viewed as a core feature of semantic representations, reflecting the fact that a word in a sentence or text may have multiple semantic roles (Oepen et al., 2020). We thus modify the C-GCN model implementation, so that it can produce the adjacency matrix using a bi-lexical DAG rather than tree.

4.3 Extending C-GCN for UCCA DAG Representation

Conversion of a UCCA sentence representation into a bi-lexical graph clearly loses extensive semantic information captured in the original structure. We pursue an embedding-based mechanism that will allow us to exploit the full UCCA structure representation in our model.

Our novel approach seeks to utilize a lossless representation of the UCCA DAG structure as training input for an **additional embedding vector**. To this end, we map each token in a sentence to its path to the root of the sentence-representing UCCA DAG. With a set of fourteen different edge labels in UCCA's foundational level, we can encode each label with four 0/1 bits. Given a maximum distance of 18 steps from terminal to root for all sentences in the TACRED dataset, we can encode all paths with up to 72 zero/one bits in total. In a new pre-training step, we collect all distinct paths from terminal to root as derived from TACRED training dataset (for a total of 22,922 distinct paths), assigning each one to an initial 80-dimensional vector, where the value of dimension i corresponds to bit i in the corresponding path (we assign 0 to all beyond-path dimensions).[6] We add a $\vec{0}$ vector for representing out-of-vocabulary paths (necessary for evaluation). Finally, we extend the 360-dimensional representation of each token to 440 dimensions, by concatenating the 80-dimensional representation of the

---

[5] Details of the algorithm in Hershcovich et al. supplementary material `https://www.aclweb.org/anthology/attachments/P17-1104.Notes.pdf`.

[6] This preparatory procedure is somewhat similar to the pre-training step required for word embeddings, in which we collect the set of word embeddings that our training data vocabulary corresponds with for training initialization of word embeddings.

token's path to root. Like word embeddings, the UCCA path-to-root representation embeddings are tuned during training.

While we can assign a UCCA-embedding for each token in the sentence, we would like to focus our network's attention on tokens that relate closely to *subject* and *object*. We achieve this with the help of a ***minimal sub-DAG***, which we define as the DAG comprised of the lowest common ancestor of both *subject* and *object*, and all their descendants. Where there is more than a single lowest common ancestor, we choose the one that induces the smallest number of terminals. All tokens that are outside the *minimal sub-DAG* are assigned the $\vec{0}$ embedding. In figure 3 we provide an example of the embedding vector values before they are fine-tuned during training.

5 Experiments

We perform twenty independent cycles of training-and-test for all our experiments, computing an average of the recall, precision and F$_1$ results across these runs. This technique differs from the common evaluation protocol of selecting the model with the median dev F$_1$ from five independent runs and reporting its F$_1$ result; we frame our approach in terms of statistical significance in Appendix F. We use TACRED's standard train/dev/test splits. Results are reported using the standard F$_1$ score. We use a fork of the source code made available by Zhang et al.[7] In general we maintain the default parameters of Zhang et al., including the default pruning factor of one, by which tokens that are up to one edge away from the path are also considered by the convolution and pruning mechanisms.

As noted, C-GCN is trained on the TACRED dataset.[8] For each of the 106,264 sentences, the dataset contains attributes including the relation type, subject and object span and UD dependency information. The process of model extension begins with the enrichment of the TACRED dataset with representation for additional semantic structures. As additional representation needs to be expressed in terms of the attributes of **tokens** for the enrichment to be valid, alignment on **tokenization** must be reached. In appendix D we describe how this alignment is achieved and reproduce Zhang et al.'s results using our updated tokenization.

System	**Adjacency Combination**			**F$_1$**
	cons	**UD**	**UCCA**	
C-GCN$_{ud}$	✗	✓	✗	66.27
C-GCN$_{ucca}$	✗	✗	✓	66.44
C-GCN$_{ud \cup ucca}$	✗	✓	✓	66.67
C-GCN$_{all}$	✓	✓	✓	66.94

Table 1: Results for different adjacency matrix combinations. C-GCN$_{ud}$ is the baseline model described in Zhang et al. (2018). C-GCN$_{ucca}$ replaces the UD representation with bi-lexical UCCA representation. Best performance is achieved when supplementing the combined UD and UCCA path representations with all tokens between subject and object (C-GCN$_{all}$).

System	**F$_1$**
C-GCN$_{ud+emb}$	66.66
C-GCN$_{ucca+emb}$	66.60
C-GCN$_{all+emb}$	67.32
C-GCN$_{all+emb}$ ensemble	**68.41**

Table 2: The models listed in table 1 are further enriched with UCCA DAG representation, and their resulting scores are listed here. We demonstrate an increase of one F$_1$ point for C-GCN$_{all+emb}$ over baseline model C-GCN$_{ud}$.

The graph-convolution network uses each sentence's UD dependency tree to determine the set of tokens (and their intra-connections) that it should focus on in the convolution and pooling phases of the network operation. As we presented in section 4.1, this is achieved by representing the UD dependency tree as adjacency matrix A_{ud}. The bi-lexical UCCA graph projection we described in section 4.2 is represented by A_{ucca}.

In addition to UD and UCCA structures, we employ a synthetic bi-lexical tree, where, for an n-token sentence, the only dependencies are between *token$_i$* and *token$_{i+1}$* for all $i < n$. This artificial dependency tree will cause the convolution network to focus on all tokens that appear between *subject* and *object* in the surface structure of the sentence (including *subject* and *object* themselves), and, in consideration of path pruning, two additional tokens adjacent to either ends of the span. We denote the adjacency matrix for this artificial structure by A_{cons} ("cons" for consecutive).

We establish a performance baseline by testing different combinations of these adjacency matrices: A_{ud} alone, A_{ucca} alone, $[\mathrm{A}_{ud} \cup \mathrm{A}_{ucca}]$, and finally $[\mathrm{A}_{ud} \cup \mathrm{A}_{ucca} \cup \mathrm{A}_{cons}]$. Our results are presented in table 1.

The UCCA-based adjacency matrix slightly outperforms the UD-based one, providing experiment-based evidence that tokens on the path between *subject* and *object* on the UCCA bi-lexical tree reduction, provide more linguistic cues for the RE task than those on the equivalent UD path. The superiority of the UCCA model is despite some loss of semantic content that occurs when transforming a full UCCA DAG to a bi-lexical one. Interestingly, the addition of A_{cons} further improves the result.

Armed with baseline performance, we employ our novel UCCA terminal-path-to-root embedding method described in section 4.3. We first apply UCCA embeddings to the C-GCN$_{ud}$ model; we observe an F_1 score improvement of close to 0.4 points. We observe a similar improvement when we apply UCCA embeddings to C-GCN$_{all}$: the F_1 score rises from 66.94 to 67.32.

Our headline result is an improvement of 1.05 F_1 points between the C-GCN$_{ud}$ system described by Zhang et al. with a mean score of 66.27, and our C-GCN$_{all+emb}$ system, with a mean score of 67.32. We confirm the statistical significance of these results by conducting Welch's t-tests and Mann-Whitney U-tests. For further discussion, see Appendix F.

We follow the practice of performing ensemble testing (Zhang et al., 2017b; Zhou et al., 2020), by applying a soft-max function on the sum of the classifier's logits from five different C-GCN$_{all+emb}$ models. We repeat the ensemble experiment for all combinations of five models, from the set of C-GCN$_{all+emb}$ models we produced in separate runs of the experiment. We average the F_1 scores for a final score of 68.41. Table 2 summarizes these results.

Finally, we perform a relation-based comparison of C-GCN$_{ucca}$ and C-GCN$_{ud}$, to determine whether the performance improvements are a product of improved results in specific relation categories. Table 3 lists the results for all the relations for which a difference of over 5% was demonstrated. We discuss these results in the next section.

6 Discussion

Our goal is to measure how UCCA performs in comparison with UD based C-GCN model. The results of our baseline experiment provide evidence that the graph convolution network produces a slightly stronger model when the UD sentence representation is substituted for a UCCA bi-lexical representation, and a significantly stronger model when UD and UCCA are used in tandem.

Relation	**Avg. Improvement**
per:country_of_birth	71.7%
per:city_of_birth	29.4%
per:city_of_death	10.5%
per:date_of_death	9.4%
org:country_of_headquarters	8.3%
per:stateorprovinces_of_residence	7.2%
per:stateorprovince_of_death	6.4%
per:schools_attended	-6.2%
org:parents	-8.3%
org:subsidiaries	-8.9%
org:shareholders	-9.4%
per:children	-9.6%
org:political/religious_affiliation	-23.0%
per:other_family	-55.4%

Table 3: Relations with average improvement/decline of above 5% for C-GCN$_{ucca}$ in comparison to C-GCN$_{ud}$.

In our main line of experimentation, we attempted to utilize the entire UCCA representation, rather than its bi-lexical reduction. We tested a system that uses embedding representation of the path of each token, within the minimal sub-DAG that contains both *subject* and *object*, to the root of that sub-DAG. We found that integration of this additional input produces superior results for all the models we tested: C-GCN$_{ud}$, C-GCN$_{ucca}$ and C-GCN$_{all}$; interestingly, the improvement is the smallest for C-GCN$_{ucca}$ itself. We postulate that the results demonstrate the efficacy of this novel approach for embedding semantic representation and believe that further analysis of this method in the context of other systems for semantic representation could be helpful to the NLP community.

As detailed by Zhang et al., the C-GCN pooling mechanism allows for identification of which tokens contribute significantly to the pooling results (block 4 of the network). Thus, it is possible to directly analyze sentences classified correctly by, for example, C-GCN$_{all+emb}$, but incorrectly by C-GCN$_{ud}$, to ascertain which tokens contribute significantly to the pooling stage output in the former but not the latter. We leave this analysis for future work as well.

To complete our study, we compared UCCA and UD performance, relation by relation. All the relations in which UCCA exhibits improved results are location-oriented. Contrarily, UD does considerably better than UCCA for family relations. Why should UCCA do better for location relations at the expense of its performance for family relations? We note that location relations associate a subject, person, or organization, to the object, a location, via an explicit event such as birth, death or residence. This is different from a family relation, for which there is detachment between the event that evoked the relation, and the reality of the relation at the present time. Indeed, for family relations the relation-evoking event may vary considerably for the same relation (consider adoption versus birth). We hypothesize that UCCA, with its improved semantic awareness, is more adept at sensing an event that binds object to subject, as opposed to UD, which performs better for family relations that may emerge more readily from syntax. This finding could lead to improved classification performance by constructing an ensemble of UCCA and UD models, and weighting the softmax function on the sum of the classifiers to favor UCCA results for location relations and UD results for family ones. This experimentation is also left for future work.

7 Conclusion

Much recent work on RE focuses on improving the contextualized representations of words and entities, including by means of injecting knowledge into large pretrained models such as BERT, to be used for a final step of supervised training using comparatively small training datasets like TACRED. This approach is successful in overcoming the dearth of annotated data required for supervised learning for RE and is producing ever-improving bottom-line results. However, it further intensifies the interpretability challenges posed by end to end models and deepens the chasm between the linguistic domain and the practice of NLP.

Our approach also leverages pretrained models that are dependent on extensive prior training data (via the TUPA parser); however, the intention is linguistically explicit: generation of UCCA representations for the sentences in the TACRED dataset. The C-GCN architecture then provides visibility into which words actually contribute to a relation classification, providing a level of transparency devoid in end-to-end models.

Our results indicate that representation of explicit semantic structure is indeed beneficial for the RE task, providing linguistically-explicit means for leveraging prior training to the task of relation extraction.

Because our approach to embedding semantic structure is not specific to UCCA, future work could analyze the effects of integrating other semantic representations, as well as the possibility of embedding semantic structure representation in the latest cutting-edge RE models.

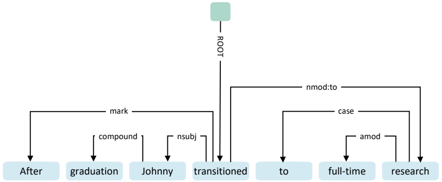
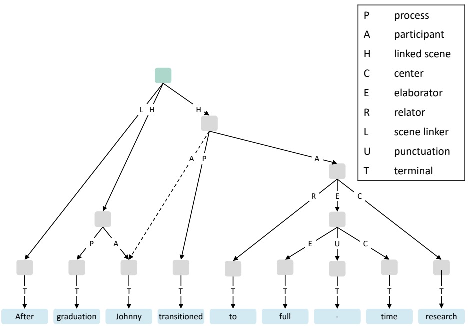
A Example of UCCA Advantage

Figure 4 provides an example of UCCA's advantage over UD in capturing scenes and their participants by representing non-verbal predicates ("graduation") like verbal ones ("transition").



(a) UD Parse Graph



(b) UCCA Parse Graph

Figure 4: UD v1 (enhanced++) and UCCA representation graphs for the sentence 'After graduation Johnny transitioned to full-time research'. The UCCA parse directly captures Johnny's participation in both the occurrences described in the sentence, graduation, and transition. This semantic connection does not arise from the UD representation (not even the enhanced++ flavor).

B Example of Bi-Lexical Reduction for UCCA

Figure 5 provides a graphic illustration for the results of bi-lexical reduction of UCCA representation, for the sentence depicted in figure 4. The product of this bi-lexical reduction is a representation containing terminal nodes only.

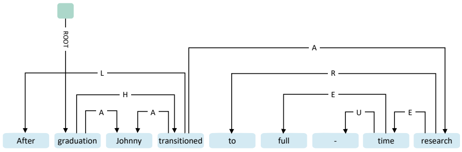


Figure 5: Bilexical UCCA representation of the sentence from 1.

As this example illustrates, the bi-lexical reduction constitutes a DAG; in this example "Johnny" is the child of both the "graduation" and the "transitioned" terminals.

C C-GCN Architecture

We describe the six blocks of the C-GCN model as depicted in figure 2.

Block 1 – Word Embeddings: Zhang et al. use 300-dimensional GloVe vectors to initialize word embeddings corresponding to each token. Each token's initial corresponding GloVe based vectors is further extended with 30-dimensional embedding for the token's part-of-speech, and another 30-dimensional embedding for its entity type. Part-of-speech and entity-type are both provided as input in the TACRED dataset (POS and NER attributes respectively) and are initialized in training with random values for each of the unique classes in the part-of-speech of entity-type sets. All the embeddings undergo fine-tuning during training and are therefore variables of the model.

Block 2 – LSTM: The input vector embeddings do not contain information about word order or contextual cues required for disambiguation. A bi-directional long short-term memory network addresses this, by taking the list of 360-dimensional vectors corresponding to the sentence's tokens and producing a corresponding list of 400-dimensional vectors.

Block 3 – Graph Convolution: We cover the third block in section 4.1

Block 4 – Pool: The fourth block is responsible for converting the two-dimensional sentence representation into a single-dimensional vector. We resort to formalism to describe precisely how this is achieved. Let $\mathcal{H}_p=[h_{p_1},\ldots,h_{p_n}]$ denote the output representations of the final GCN layer for all on-or-near-path tokens, and let $\mathcal{H}_s=[h_{s_1},\ldots,h_{s_n}]$ and $\mathcal{H}_o=[h_{o_1},\ldots,h_{o_n}]$ denote the vector lists corresponding to the *subject* and *object* spans respectably. A simple max pooling function is applied to $\mathcal{H}_p$, $\mathcal{H}_s$ and $\mathcal{H}_o$, resulting in three single vectors, $h_{p_{max}}$, $h_{s_{max}}$ and $h_{o_{max}}$, representing the on-or-near-path tokens, the *subject* and the *object* respectably. The output of block four is a simple concatenation of these vectors resulting in a single 600-dimensional vector.

Block 5 – Feedforward Network Block five is a simple stacked feed-forward network, with each FF layer comprising a single linear transformation followed by a RELU non-linearity. Zhang et al. use two layers as depicted in the diagram. The first layer receives a 600-dimensional vector and produces a 200-dimensional vector as output; all other layers receive and produce 200-dimensional vectors.

Block 6 – Classifier The sixth and final block of the network is a simple feed-forward linearity, which receives the 200-dimensional vector from block five, and outputs a 42-dimensional vector, one dimension per relation category. This final vector is used in both training with a cross-entropy-loss function, and in evaluation, where a soft-max function is applied to produce a probability vector. It is possible to control the recall/precision balance by applying a thresholding mechanism such that a positive classification (i.e. any label other than *no_relation*) must surpass a threshold greater than 0.5, however the model chooses to treat a negative classification symmetrically.

D Token Alignment

TUPA, the UCCA parser we briefly mentioned in the introduction, uses the the SpaCy NLP pipeline for basic NLP tasks including tokenization. SpaCy's default tokenization results vary considerably from TACRED's given tokenization. Indeed, in 30% of train sentences, 28% of dev sentences, and 25% of test sentences tokenization is different. For example, differences arise in the case of intra-word-hyphens[9]. Additionally, the TACRED dataset contains some obvious tokenization errors; for example, there are over 130 entries in which two sentences have been merged into one, by erroneously fusing the last token of the first sentence, it's period punctuation mark, and the first one of the next sentence into a single token.

To address these tokenization concerns, we reparse the entire TACRED dataset with the Standford CORENLP parser, configuring it to adhere to the given tokenization produced by the TUPA parser[10]. This results in a tokenization-aligned standford_pos, stanford_ner, stanford_head and stanford_deprel attribute set (see table 4). For subj_start, subj_end, obj_start and obj_end, which are human annotated properties, we employ a simple algorithm to reassign their index values to correspond to TUPA's tokenization. The end result is a transformed TACRED input dataset where all sentence attributes that require adherence to the sentence's token breakdown conform with TUPA/SpaCy tokenization.

Attribute	**Description**
id	UUID for the sentence
relation	The relation that exists between subject and object (or no_relation) if no relation exists
token	Array of the sentence's tokens, the token at each array position corresponding to the token at the same
subj_start	start zero-based index of the subject token span
subj_end	end zero-based index of the subject token span
obj_start	start zero-based index of the object token span
obj_end	end zero-based index of the object token span
subj_type	Entity type of subject (either organization or person)
obj_type	Entity type of object (not limited to organization and person; 18 different classes of object type, including, for example, location, duration and ideology)
stanford_pos	Array of the sentence tokens' parts-of-speech, the part-of-speech at each array position corresponding to the token at the same
stanford_ner	Array of the sentence tokens' entity types, the entity-type at each array position corresponding to the token at the same (with 'O' used to indicate a non-entity token)
stanford_head	Array of the sentence tokens' head word one-based indices, the index at each array position corresponding to the head of the token at the same
stanford_deprel	Array of the sentence tokens' incoming dependency type, the index at each array position corresponding to the incoming dependency type of the token at the same

Table 4: Main attributes associated with each sentence in the TACRED dataset

As a baseline, we reproduce the experimental setup of Zhang et al. (2018), using the given sentence attributes as they appear in the TACRED dataset. We compare these results with results we attain when using TACRED sentences **re-annotated** by the CORENLP engine, using SpaCy/TUPA sentence tokenization, as described above. Table 5 captures this comparison. We hy-

---

[10] We achieve this by reconstructing a sentence where all TUPA generated tokens are separated by whitespace, and then setting CORE NLP's 'tokenize.whitespace' flag to True

System	Note	F_1
GCN	reported result	64.0
C-GCN	reported result	66.4
C-GCN	our result with given dataset	66.68
C-GCN	our results with TACRED input re-annotated with CORE NLP engine, using SpaCy tokenization	66.27

Table 5: Our results for the unmodified C-GCN model, using given and re-annotated TACRED datasets.

pothesize that the decrease in score when using re-annotated data may stem from errors introduced by our procedure for reassignment of index values for the human annotated subj_start, subj_end, obj_start and obj_end properties.

E Variations of DAG encoding

We test two variations of our UCCA terminal-path-to-root embedding method: the first adds non-zero embedding representations for the token-to-root path of *all* tokens in the sentence; the second uses non-zero embeddings for tokens in the *minimal sub-DAG* only, using zero vector embedding for all other tokens. We also perform an ablation test by using random values for each unique path embedding, rather than values that encode the actual paths.

System	Path Encoding	Min Sub-DAG	F_1
C-GCN$_{ucca}$†	-	-	66.44
C-GCN$_{ucca+emb}$	✗	✓	65.63
C-GCN$_{ucca+emb}$	✓	✗	66.22
C-GCN$_{ucca+emb}$	✓	✓	66.60

Table 6: Measuring impact of UCCA embeddings under different settings. † marks the baseline C-GCN$_{ucca}$ model score as reported in table 1. An ✗ in the **Path Encoding** column indicates the use of random values.

The results in table 6 indicate that using path encodings for tokens in the minimal sub-DAG produce improved results when compared to the plain C-GCN$_{ucca}$ model. While the improvement is marginal – 0.2 F_1 points – we do see a more marked impact, to the negative, when we use random initialization. When we consider all sentence tokens and not just those in the minimal sub-DAG evoked by *subject* and *object* we also see a negative impact, albeit more mild.

F Statistical Significance

We call attention to Reimers and Gurevych (2018), who critique the common evaluation practice of selecting the model with the median dev F_1 from five independent runs and reporting its test F_1 result. As noted, the F_1 scores reported in our experiments are the mean scores on the test set for 20 multiple models, trained according to the parameters of the system at hand (e.g. GCN$_{ud}$, C-GCN$_{ucca}$), using the full TACRED train and dev datasets, and tested with the test dataset.

Our headline result is an improvement of 1.05 F_1 points between the C-GCN$_{ud}$ system described by Zhang et al., with a mean score of 66.27, and our C-GCN$_{all+emb}$ system, with a mean score of 67.32. We conduct two sets of significance tests to validate this result:

Welch's t-test: Welch's t-test assumes that the compared distributions are approximately normally distributed. We apply Welch's t-test to a pair of 20 sample pairs, each pair using the same random seed, with the first set corresponding to C-GCN$_{ud}$, and the second to C-GCN$_{all+emb}$, with a null hypothesis asserting that both systems produce models with similar F_1 scores on the test set. The resulting p-value is 3.015e-09. We subtract 0.75 F_1 from all the samples corresponding to C-GCN$_{all+emb}$ and reapply Welch's t-test. The p-value for this new null hypothesis is 0.019. In other words, we have a statistically significant improvement of 0.75 F_1 points with $p < 0.02$.

Mann-Whitney U-test: We abandon the assumption that our systems produce models with normally distributed F_1 on the test set and apply the Mann-Whitney U test after once again subtracting 0.75 F_1 from the C-GCN$_{all+emb}$ samples. The p-value for this new null hypothesis is 0.027. Restated, we have demonstrated a statistically significant improvement of 0.75 F_1 points with $p < 0.03$.

Dynamic and Multi-Channel Graph Convolutional Network for Aspect-Based Sentiment Analysis

Abstract

Aspect-based sentiment analysis aims to judge the polarity of the given aspect word in reviews. Most recent methods adopt syntax-based Graph Neural Networks to extract the syntactic information from the dependency graph, thinking that would be beneficial for establishing relations between aspect and opinion words. However, these methods may ignore that some sentences have no remarkable syntactic structure, which causes the opposite judgement in sentiment analysis. In this paper, we figure out this problem by means of optimally fusing syntactic information, semantic information and their combinations simultaneously. Firstly, syntactic graphs and semantic graphs are generated by dependency tree and multi-head self-attention respectively. Then we propose a Dynamic and Multi-channel Graph Convolutional Network (DM-GCN) to learn the correlated information from the generated graphs effectively. Our extensive experiments on SemEval 2014 and Twitter datasets confirm that DM-GCN fuses syntactic, semantic and their combinations optimally and outperforms all state-of-the-art alternatives with a large margin.

1 Introduction

Aspect-Based Sentiment Analysis (ABSA) is a fine-grained task of sentiment analysis. Distinguishing from document-based and sentence-based sentiment analysis, aspect-based sentiment analysis aims to determine the sentiment polarities of specific aspect words in given texts. As an example of ABSA, in the sentence *'The food is good but the service is bad'*, the sentiment polarities of given aspect words *food* and *service* are recognized as *Positive* and *Negative*. As such a more detailed analysis of multiple aspect sentiment gives rise to provide targeted insights into reviews.

In general, there are several steps when performing aspect-based sentiment analysis, such as obtain word embeddings, encode the syntactic information and extract semantic information, among which mining the most relevant opinion word plays the pivot role. Benefited from applying attention mechanisms to connect aspect words with their opinion words, a few studies (Wang et al., 2016b; Li et al., 2017; Ma et al., 2017; Fan et al., 2018)have reported attractive results. However, limited by the co-occurrence frequency or long-range word decencies, attention mechanism may assign wrong value for irrelevant words. As an example, *'the stuff should be more friendly'*, due to the high co-occurrence frequency of *'stuff'* and *'friendly'*, attention mechanisms may regard *'friendly'* as the opinion word for *'staff'*, which result in an opposite sentiment judgement completely.

To address those limitations, a slice of studies encode the syntactic structure as crucial information to establish the connections between aspects and their opinion words. A handcrafted syntactic rule (Liu et al., 2013) has been encoded into the model as an early essay.However, it is over-relied upon the quality of the rule. Then dependency trees are regarded as another form of syntactic rule, (Dong et al., 2014; Nguyen and Shirai, 2015; Wang et al., 2016a) have encoded dependency tree by a Recursive Neural Network (RNN). Recently, the rapid development of graph neural networks has attracted a surge of interest, due to the great capacity of learning structure representation, a class of graph neural networks is designed to extract syntactic information from dependency tree (Zhang et al., 2019a; Sun et al., 2019; Huang and Carley, 2019; Wang et al., 2020b; Zheng et al., 2020). Although these approaches make quite a few improvements compared with those attention-based models, the shortcomings should not be ignored. First and foremost, sentences have different sensitivities to syn-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2627–2636
August 1–6, 2021.

tactic information and semantic information. In particular, those sentences that have inconspicuous syntactic structure, are low sensitive to syntactic information, which means that syntactic information may fail to help the model to determine the sentiment polarity of the sentences in some cases. Given as an example, 'Charlie sheen your fucking annoying', a sentence in twitter dataset, prefers to colloquial expression, without explicit syntactic structure, which makes those extracted structure information become noise. Besides, not all the information on the dependency tree is valid for our task, the noise would be encoded by the GNNs-based model, then the secondary noise will be caused if attention mechanism is used on this basis (Zhang et al., 2019a). To make matter worse, GCNs has been proved that fail to optimally integrate node features (semantical information) and topological structures (syntactic structure) in a dependency graph with rich information (Wang et al., 2020b), indicating that GCN may arduous to learn some deep correlation between topological structures (syntactic structures) and node features (semantical information).

In reality, syntax is complementary to semantics. Motivated by this fundamental assumption, our Dynamic and Multi-Channels Graph Convolutional Network (DM-GCN) is designed to get over the weakness mentioned above. Firstly, on purpose to exploit the information in semantic space adequately, the semantic graphs are generated and updated dynamically by a multi-head self-attention mechanism in the graph convolutional network. Secondly, the dependency trees of sentences are transformed into syntactic graphs, which is the same as the model mentioned above (Sun et al., 2019; Zhang et al., 2019a). With the semantic graphs and syntactic graphs, two specific graph convolutional networks are applied to extract two specific information from semantic and syntactic space. Furthermore, considering that the common information of semantic and syntactic space is as significant as the specific information, a parameter sharing graph convolution module is designed to extract the common information. Finally, a trainable parameter matrix is utilized to adaptively learn the importance of different embeddings and fuse them optimally. Extensive experiments are carried out on SemEavl2014 and Twitter datasets, and experimental results demonstrate that DM-GCN achieves predominant performance compared with baseline methods.

The contributions of this paper can be summarized as follows:

- We have come up with a kind of dynamic semantic graph, generated and updated by the multi-head self-attention mechanism, which focuses on extract the most relevant information in the semantic space.
- We propose a novel Dynamic and Multi-channel GCN(DM-GCN) to adaptively learn and fuse according to the characteristics of sentences.
- Extensive results testify the significance of leveraging syntactical, semantical, and their combinational information properly, and demonstrate the availability of our proposed model in extracting and fusing them in sentiment classification.

The rest of the paper is organized as follows. In Section 2 we briefly review the related work of aspect-based sentiment analysis. In Section 3 we develop our proposed model DM-GCN. The evaluation of our model on benchmark datasets and the experimental result analysis are in Section 4.Finally, concluding remarks are presented in Section 5.

2 Related Work

With the appealing development of aspect-based sentiment analysis, numbers of research can be divided into three categories approximately: Attention-based neural models, Syntactic rules neural network, and Syntactic-based graph neural network. Our work is based on a plentiful line of those recent efforts.

Attention-Based Neural Networks: Originated in computer version, attention-based models have led to promising progress in sentiment analysis as well, which are committed to building up connection between aspect word and opinion word precisely. Among them, (Wang et al., 2016b) proposed an attention-based LSTM to obtain significant information for given aspects. (Chen et al., 2017)utilized a multi-layer attention network to address long-distance dependency problem between aspect and opinion words. With transformer being proposed, the pre-trained language model make impressive achievement in NLP including aspect-based sentiment analysis (Xu et al., 2019; Sun et al., 2019; Vaswani et al., 2017).

Syntactic-Based Recurrent Neural Networks: Due to the lack of structural information, attention-based methods may assign the attention weights mistakenly. Some research tries to address this issue by encoding syntactic rules in word representation. (Dong et al., 2014)proposed AdaRNN, which can propagate the sentiment information via syntactic dependency tree. (He et al., 2018a)proposed an attention mechanism that incorporates syntactic information.(Zhang et al., 2019b)tried to utilize the distance between aspect word and context on syntactic dependency tree as auxiliary weight.

Syntactic-Based Graph Neural Networks: More recently, with the rapid development of graph neural networks (Kipf and Welling, 2019; Velickovic et al., 2018), the combination of syntactic dependency tree and graph neural networks have shown gratifying results in ABSA. (Zhang et al., 2019a; Sun et al., 2019) transformed syntactic dependency tree into graph structure and utilized GCN to extract syntactic information. (Tang et al., 2020) proposed Bidirectional-GCN to encode the directional information of syntactic dependency tree. (Wang et al., 2020a) proposed a new GAT model to encode the dependency relations. However, whether the correlated information can be extracted according to the characteristics of the sentence from GNNs adaptively remains indistinct.

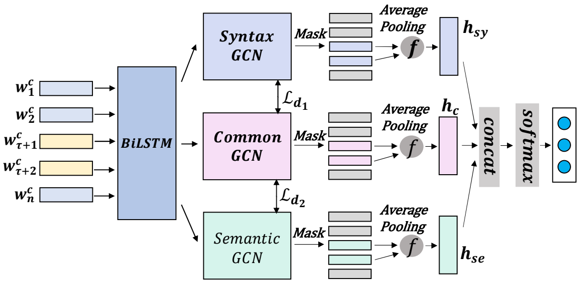

Figure 1: Model Architecture

3 Methodology

In this section, we elaborate on the details of our proposed model. The overall framework of DM-GCN is shown in Figure 1. Inspired by AM-GCN (Wang et al., 2020b), our key idea is that the proposed model should be available to aggregate syntactical features, semantical features and their combination features becomingly to address the issues mentioned before. For this purpose, firstly, semantic graphs are constructed by the multi-head self-attention mechanism. Secondly, syntactic graphs are transformed from the dependency tree of sentences. Then two specific convolution modules and a common convolution module are used to extract corresponding information respectively. Finally, a trainable parameter is used to fuse extracted information more suitably for our task. The components of DM-GCN will be illustrated in the rest of the section.

3.1 Embedding and Bidirectional LSTM

An n-word sentence $x = \{w_1^c, w_2^c, \cdots, w_{\tau+1}^c, \cdots, w_{\tau+m}^c, \cdots, w_n^c\}$ with the aspect $\{w_{\tau+1}^c, \cdots, w_{\tau+m}^c\}$is given, each word in the sentence will be embedded into a low-dimensional vector by looking up in a pre-trained word embedding matrix $E \in R^{|V| \times d_e}$,where $|V|$ is the lexicon size and d_e is the dimension of word embedding (Bengio et al., 2003).With the sentence embeddings, a bidirectional LSTM is constructed to learn the hidden representation of the given sentence x ,which can be conveyed as $\vec{H}^c = \{\vec{h}_1^c, \vec{h}_2^c, \cdots, \vec{h}_{\tau+1}^c, \cdots, \vec{h}_{\tau+m}^c, \vec{h}_{n-1}^c, \vec{h}_n^c\}$ in the forward direction and $\overleftarrow{H}^c = \{\overleftarrow{h}_1^c, \overleftarrow{h}_2^c, \cdots, \overleftarrow{h}_{\tau+1}^c, \cdots, \overleftarrow{h}_{\tau+m}^c, \overleftarrow{h}_{n-1}^c, \overleftarrow{h}_n^c\}$ in the backward direction. Concatenating the forward and backward representation, $H^c = [\vec{H}^c, \overleftarrow{H}^c] \in R^{n \times d_{lstm}}$ is the final representation encoded by Bidirectional LSTM, which contains the contextual information between aspect words and opinion words.

3.2 Syntactic Graph Convolution Module

As previous described (Sun et al., 2019; Zhang et al., 2019a), we transform the dependency tree into the graph structure $G_{sy} = (A_{sy},\ H^c)$, A_{sy} is the adjacency matrix of the graph and H^c is the feature matrix.Then the graph convolutional network is applied to extract the syntactic information, which is formulated as below:

$$GCN(\widetilde{A}, H^{(l)}, W^{(l+1)}) = ReLU(\widetilde{A}H^{(l)}W^{(l+1)}) \quad (1)$$

$$H_{sy}^{(0)} = H^c \quad (2)$$

$$H_{sy,in}^{(l)} = [H_{sy}^{(0)}; \ldots; H_{sy}^{(l)}] \quad (3)$$

$$H_{sy}^{(l+1)} = \mathrm{GCN}(\tilde{A}_{sy}, H_{sy,in}^{(l)}, W_{sy}^{(l+1)}) \quad (4)$$

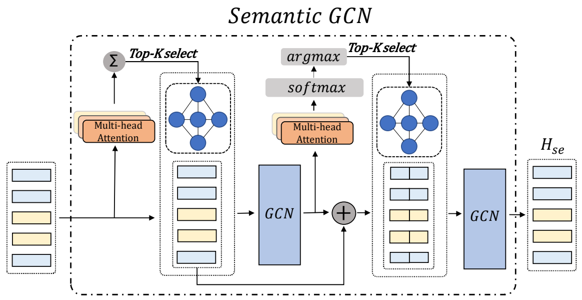

Figure 2: Architecture of Semantic Graph Convolution Module

Where $\widetilde{A}_{sy} = \widetilde{D}^{-\frac{1}{2}}\left(A_{sy}+I_f\right)\widetilde{D}^{-\frac{1}{2}}$ is the adjacency matrix with self-loop (Kipf and Welling, 2019), $H_{sy,in}^{(0)} = H^c \in R^{n \times d_{lstm}}$ is the words representation encoded by Bi-LSTM, we take it as the input of the first GCN layer. When $l \in [1, L-1]$ the input $H_{sy,in}^{(l)}$ is generated by the concatenation of the output produced in layers $0, \cdots, l-1$, $W_{sy}^{(l+1)} \in R^{(d_{lstm}+l*d_{gcn}) \times d_{lstm}}$ is the learnable matrix of the l-th GCN layer, d_{lstm} is the dimension of the hidden representation learned by bidirectional LSTM, d_{gcn} is the dimension of the GCN-layer output and d_{head} is the dimension of each attention head. With l-$step$ convolutional operation, each node can iteratively aggregate the information from its one-hop neighbors and update its representation. Syntactic information is integrated into the final representation $H_{sy}^{(L)}$ successfully by Syntactic Graph Convolutional Module.

3.3 Semantic Graph Convolution Module

As we discuss in Section 1, a few short sentences have vague syntactic structure, if the model extracts the syntactic information stiffly, may trigger the opposite effect. On the other, the original dependency tree can be seen as a form of hard attention mechanism (Xu et al., 2015), which may lead to the information omission when aspects are far away from its opinion words or two words are supposed to be connected but they don't on their dependency tree. Inspired by (Huang and Carley, 2019), we develop Semantic Graph Convolutional Module to distinguish the correlated context words directly.

Specifically, the semantic graph convolution module is divided into initialization and update respectively. we take $H_{se,in}^{(0)}$ as the input of the initialization, the multi-head self-attention will be utilized to construct k attention score matrices based on $H_{se,in}^{(0)}$. On purpose to enhance the robustness of the model, these k matrices will be summed up intuitively. Then a top-k selection is applied on the summed-up matrix, which means that the top-k significant context words are preserved. More specially, the adjacency matrix is supposed to keep symmetry after top-k selection. In this way, we have initialized the adjacency matrix $A_{se}^{(0)}$ and a GCN layer is applied to extract the semantic information preliminarily. The initialization is formulated as:

$$H_{se,in}^{(0)} = H^c \tag{5}$$

$$A_{se,i}^{(0)} = \frac{(H_{se,in}^{(0)} W_{se,k}^{(0)})(H_{se,in}^{(0)} W_{se,q}^{(0)})^T}{\sqrt{d_{head}}} \tag{6}$$

$$d_{head} = \frac{d_{lstm}}{K} \tag{7}$$

Specially, when $l = 0$:

$$A_{se}^{(0)} = top\text{-}k\left(\sum_{i=0}^{K} A_{se,i}^{(0)}\right) \tag{8}$$

$$H_{se}^{(1)} = GCN(\tilde{A}_{se}^{(0)}, H_{se,in}^{(0)}, W_{se}^{(1)}) \tag{9}$$

where $H_{se,in}^{(0)} \in R^{n \times d_{lstm}}$ is the words representation encoded by Bi-LSTM, K is the number of heads, $A_{se,i}^{(0)}$ is the i-th adjacency matrix, $W_{se,k}^{(0)}, W_{se,q}^{(0)} \in R^{d_{lstm} \times d_{head}}$ are trainable weight matrices, $W_{se}^{(1)} \in R^{d_{lstm} \times d_{gcn}}$ is the parameter matrix of the GCN layer.

With the initialized semantic graph $A_{se}^{(0)}$, the process of update is formulated as :

$$H_{\mathrm{se,in}}^{(l)} = [H_{\mathrm{se}}^{(0)}; \ldots; H_{\mathrm{se}}^{(l)}] \tag{10}$$

$$A_{se,i}^{(l)} = \frac{(H_{se,in}^{(l)} W_{se,k}^{(l)})(H_{se,in}^{(l)} W_{se,q}^{(l)})^T}{\sqrt{d_{head}}} \tag{11}$$

$$\mathrm{A}_{se}^{(l)} = argmax[softmax(A_{se,1}^{(l)}, \cdots, A_{se,K}^{(l)})] \tag{12}$$

$$A_{se}^{(l)} = top\text{-}k(A_{se}^{(l)}) \tag{13}$$

$$H_{se}^{(l+1)} = GCN(\tilde{A}_{se}^{(l)}, H_{se,in}^{(l)}, W_{se}^{(l+1)}) \tag{14}$$

Put slightly different, the input $H_{se,in}^{(l)}$ is generated by the concatenation of the output produced

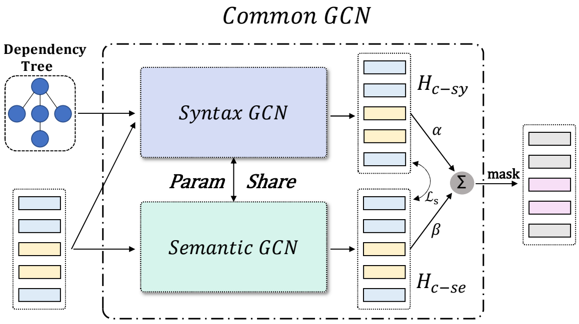

Figure 3: Architecture of Common Graph Convolution Module

in layers $0, \cdots, l-1$, which will be delivered into the multi-head self-attention to generate k attention score matrices just as initialization does. Then we figure out the matrix with maximum probability by $softmax$ function, which can be regarded as the most relevant attention matrix of the semantic graph for the current sentence. After *top-k* selection, a GCN layer is utilized to extract the deep-seated semantic information. We denote the last layer output representation as $H_{se}^{(L)}$, which contains the most relevant semantic information of aspects and its opinion word.

3.4 Common Convolution Module

According to (Liina and Pylkknen, 2019), syntax and semantic space are not totally separating, as the syntactic structure of sentence changes, so does the semantic, which gives reason to believe that extracting the common information shared by syntactic and semantic space is beneficial to comprehend the sentence better. Motivited by (Wang et al., 2020b), a common graph convolutional module (Figure 3) with parameter sharing strategy is applied to obtain the information shared in two spaces.

For simplicity, we represent the Syntactic Graph Convolution Module and the Semantic Graph Convolution Module as:

$$H_{sy}^{(L)} = SYGCN(A_{sy}, H^c, W_{sy}) \tag{15}$$

$$H_{se}^{(L)} = SEGCN(A_{se}, H^c, W_{se}) \tag{16}$$

the common syntactic representation $H_{c\text{-}sy}^{(L)}$ is extracted by common graph convolutional module from syntactic graph $G_{sy} = (A_{sy},\ H^c)$ as follow

$$H_{c\text{-}sy}^{(L)} = SYGCN(A_{sy}, H^c, W_c) \tag{17}$$

Where $W_c = W_c^{(l+1)} \in R^{(d_{lstm}+l*d_{gcn}) \times d_{gcn}}$ is the *l-th* layer learnable weight matrix of Common-GCN, $H_{c\text{-}sy}^{(L)}$ is the final common syntactic representation.

On purpose to extract the shared information, when applying $Common\text{-}GCN$ to learn the node representation from semantic graph $G_{se} = (A_{se},\ H^c)$, we share the same learnable weight matrix $W_c^{(l)}$ for each layer of $Common\text{-}GCN$.

Simply, the calculation is similar to section 3.3:

$$H_{c\text{-}se}^{(L)} = SEGCN(A_{se}, H^c, W_c) \tag{18}$$

Finally, we combine these two representations $H_{c\text{-}sy}^{(L)}$ and $H_{c\text{-}se}^{(L)}$ to obtain the final representation.

$$H_c^{(L)} = \frac{\alpha H_{c\text{-}sy}^{(L)} + \beta H_{c\text{-}se}^{(L)}}{2} \tag{19}$$

Where α and β are trainable parameters, $H_c^{(L)} \in R^{n \times d_{gcn}}$.

3.5 Feature fusion

Before fusing the representation extracted by specific and common convolutional modules, we use the mask mechanism and average pooling to capture the aspect vectors h_{sy}, h_c and h_{se} from $H_{sy}^{(L)}$, $H_{se}^{(L)}$ and $H_c^{(L)}$. Then the final aspect representation is obtained by concatenating h_{sy}, h_c and h_{se}. The formulas are described as:

$$h_{sy} = f(mask(H_{sy}^{(L)})) \tag{20}$$

$$h_c = f(mask(H_c^{(L)})) \tag{21}$$

$$h_{se} = f(mask(H_{se}^{(L)})) \tag{22}$$

$$h_a = [h_{sy}; h_c; h_{se}] \tag{23}$$

where $mask(\cdot)$ represents the masked function, which means that only aspect vectors are activated in $H_{sy}^{(L)}$,$H_{se}^{(L)}$ and $H_c^{(L)}$, the context vectors are discarded. Mask function is formulated as follow:

$$\text{mask} = \begin{cases} 0, & 1 \le t < \tau+1, \tau+m < t < n \\ 1, & \tau+1 \le t \le \tau+m \end{cases} \tag{24}$$

As described in section 3.1: $\tau+1 \le t \le \tau+m$ denotes the aspect words index. $f(\cdot)$ is the average pooling function. The representation h_a is simply concatenated with h_{sy} , h_c and h_{se} , however, it could not distinguish the importance of syntax, semantics and their combination. Considering to reflect the significance of each part, a MLP layer is utilized to learn the adaptive important weights of the representations and fuse them simultaneously. As described in section 3.1: $\tau+1 \leq t \leq \tau+m$ denotes the aspect words index. $f(\cdot)$ is the average pooling function. The representation h_a is concatenated with h_{sy}, h_c and h_{se} , however, it could not distinguish the importance of syntax, semantics and their combination. Considering to reflect the significance of each part, a MLP layer is utilized to learn the adaptive weights of the representations and fuse them simultaneously.

$$\hat{h}_a = ReLU(h_a W_1^T + b_1) \tag{25}$$

By training the learnable weight matrix $W_1^T \in R^{3d_{gcn} \times d_{gcn}}$, our proposed model is able to fuse syntactic, semantic and their combination representations adaptively and derive deeper correlation information for sentiment classification.

Model Training

The final aspect representation $\hat{h}_a$ is sent to a SoftMax layer to calculate the probability distribution of the sentiment polarities as follows:

$$\tilde{y} = softmax((\hat{h}_a)W_2^T + b_2) \tag{26}$$

Considering that the embeddings $H_{sy}^{(L)}$ and $H_{c\text{-}sy}^{(L)}$ are both learned from graph $(A_{sy},\ H^c)$, we hope that different information can be captured by them.Thus, the difference loss between $H_{sy}^{(L)}$ and $H_{c\text{-}sy}^{(L)}$ is defined as $\|H_{sy}^T H_{c\text{-}sy}\|_{l2}^2$.The smaller their inner product is (i.e., orthogonal constraint), the better result is obtained. Similarly, $\|H_{se}^T H_{c\text{-}se}\|_{l2}^2$ is the difference loss between $H_{se}^{(L)}$ and $H_{c\text{-}se}^{(L)}$. We set the difference loss $\mathcal{L}_d$ as:

$$\mathcal{L}_d = \|H_{sy}^T H_{c\text{-}sy}\|_{l2}^2 + \|H_{se}^T H_{c\text{-}se}\|_{l2}^2 \tag{27}$$

In addition, $H_{c\text{-}sy}^{(L)}$ and $H_{c\text{-}se}^{(L)}$ are the outputs of $Common\text{-}GCN$, to confirm that common features are learnt, the smaller the Euclidean distance is, the better representation is obtained. We use $\mathcal{L}_s$ constraint to enhance their similarities:

$$\mathcal{L}_s = \|H_{c\text{-}sy} - H_{c\text{-}se}\|_{l2}^2 \tag{28}$$

Finally, the cross entropy loss with L_2 regularization, as shown in equation(29), all parameters of our proposed model is optimized via backpropagation.

$$\text{L=}-\sum_i \sum_{j=1}^{P} y_i^j \log \hat{y}_i^j + \lambda\|\theta\|^2 + \gamma\mathcal{L}_d + \delta\mathcal{L}_s \tag{29}$$

Table 1: Statistics of datasets

Dataset	Positive		Negative		Neutral	
	Train	Test	Train	Test	Trtain	Test
Rest14	2164	728	807	196	637	196
Lap14	994	341	870	128	464	169
Twitter	1561	173	1560	173	3127	346

where i is the index of i^{th} sample, j is the index of j^{th} sentiment class, P is the number of sentiment classes, y is the real distribution of sentiment and $\hat{y}$ is the predicted one. Besides, λ is the weight of L_2 regularization, θ represents all parameters in the model.γ and δ are hyperparameters of the consistency and disparity constraint terms.

4 Experiment

In this section, we will first introduce the benchmark datasets for evaluation and the baseline models utilized for comparison. Secondly, the experimental implementation and parameter setting will be reported. Then the results of different experiments are analyzed from different perspectives including the comparison with baseline models, ablation study, the effect of hyper-parameters. Finally, some representative cases are discussed.

4.1 Datasets

Our model is evaluated the performance on SemEval 2014(Pontiki et al., 2014) and Twitter dataset provided by (Adaptive recursive neural network for target-dependent twitter sentiment classification), which are authoritative evaluation dataset in ABSA. The statistics of the datasets in Table 1.

4.2 Baseline Methods

We have chosen some mainstream and lasted models in ABSA for comparison, including:

Semantic-based models: ATAE-LSTM)(Wang et al., 2016b), IAN (Ma et al., 2017), RAM (Chen et al., 2017), MGAN (Fan et al., 2018).

Syntax-based models: LSTM+SynATT (He et al., 2018b), AdaRNN (Dong et al., 2014), PhraseRNN (Nguyen and Shirai, 2015), PWCN-Dep (Zhang et al., 2019b), AS-GCN (Zhang et al., 2019a), CDT (Sun et al., 2019), TD-GAT (Huang and Carley, 2019), R-GAT (Wang et al., 2020a), DGEDT (Tang et al., 2020) and Repwalk (Zheng et al., 2020)

Table 2: Sentiment classification results

Category	Method	Twitter		Lap14		Rest14	
		Accuracy	Macro-F1	Accuracy	Macro-F1	Accuracy	Macro-F1

4.3 Implementation and parameter settings

For fairness and validation, the best results of compared models are used in models comparation. The Stanford parser (https://stanfordnlp.github.io/CoreNLP/) is utilized to get syntactic dependency tree in our work. Inspired by CDT (Sun et al., 2019), we exploit 300-dimensional Glove vectors (Pennington et al., 2014)for the word embeddings. Besides, on purpose to enrich the sentence representation, a 30-dimensional part-of-speech (POS) embeddings and 30-dimensional position embeddings are concatenated to word embeddings. The rest of parameter settings is given in the code[1].

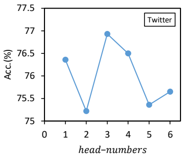

Figure 4(b): Impact of $head-numbers$

4.4 Result and Analysis

4.4.1 Overall Performance Comparison

The results of comparison with all baseline models are shown in Table2. First, compared with the lasted syntactic-based model DGEDT, Repwalk, and R-GAT, DM-GCN significantly improves the accuracy in sentiment classification, which indicates that DM-GCN performs better at encoding the syntactic and semantic information by fusing them adaptively. Second, as the first proposed concept, the common information shared by semantic and syntactic spaces, has been proved its effective in ABSA, which can be judged from the improvement of accuracy on three datasets. The results have proved that only encode semantic or syntactic information is inadequate in aspect-based sentiment classification. On the contrast, fusing the semantic and syntactic information and their combination optimally, just as humanity brain does, is the key to the better performance of our DM-GCN.

4.4.2 Ablation Study

In this section, we further conduct an ablation study to verify the validity of each module in our DM-GCN. The result is in Table 4. The basic DM-GCN is regarded as a baseline model..

First, removal of syntactic information (i.e.DM-GCN w/o H_{sy}) leads to the drop of accuracy drop of 1.42%, 1.11% and 1.65% on Twitter, Lap14 and Rest14 respectively, which demonstrates the significance of syntactic information and verifies syntactic information plays different roles in dif-

---

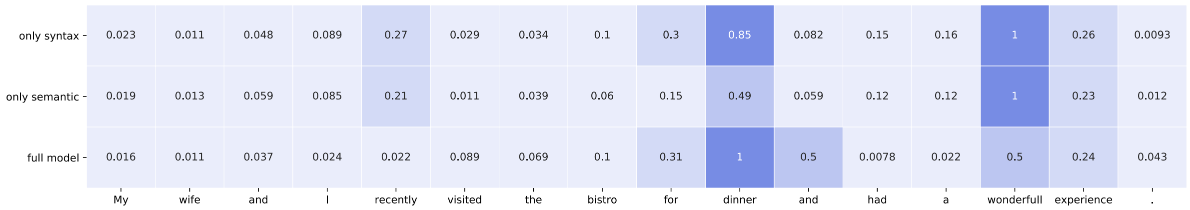

Figure 5: The word relevance scores. The aspect word is ‘dinner’. The ground truth is ‘neutral’ while the prediction of the only syntax, only semantic and full model are ‘positive’, ‘positive’ and ‘neutral’ respectively.

ferent sentence of three datasets. Second, after we get rid of the semantic information (i.e. DM-GCN w/o H_{se}), the model ranges the lowest accuracy on three datasets, which indicates that the dynamic multi-head self-attention mechanism proposed by us is able to capture the most correlated semantic information between aspect and opinion words. As for ‘DM-GCN w/o H_{common}’model, the accuracy decreases 1.3%, 2.54% and 1.63% on Twitter, Lap14 and R Rest14 respectively. Recall the main reason on Lap14, we conclude that the common information mixes up of the characteristics of syntactic and semantic information, which is significant to Lap14 datasets. As a result, the ablation experimental outcomes confirm the contribution of both components.

Table 3: Ablation study results

Model	Twitter Accuracy	Lap14 Accuracy	Rest14 Accuracy
DM-GCN	**76.93**	**78.48**	**83.93**
DM-GCN w/o H_{se}	74.94	75.79	81.92
DM-GCN w/o H_{sy}	75.51	77.37	82.28
DM-GCN w/o H_{common}	75.63	75.94	82.3

* ‘DM-GCN w/o H_{sy}’: removing syntactic convolution module;
‘DM -GCN w/o H_{se}’: removing semantic convolution module;
‘DM -GCN w/o H_{common}’: removing common convolution module.

4.4.3 Hype-parameters Analysis

The results of the research about the hype-parameter k and the head numbers of our proposed semantic convolutional module are in Figure 4.

1. Effect of hype-parameter *k*. From Figure 4a, there are some observation can be noted:1) The best performance appears when k is equals to 3,3 and 4 respectively in Rest14, Lap14 and Twitter datasets. The accuracy decreases on three datasets when k becomes bigger. We conclude that the bigger k we set, the more noise is aggerated from irrelevant words in the sentence, which interferes with our model’s ability to determine the sentiment polarity of sentences.

2. Effect of hype-parameter *head-number*. Take Twitter dataset for example. The result in Figure 4b show the impact of head-numbers in multi-head self-attention mechanism of our models. Intuitively, the best performance appears when head number is equal to 3. Considering the characteristics of multi-head self-attention, we take the attitude that the model becomes haphazard and overfitting when head number decreases and increases respectively.

4.4.4 Case Study and Attention Distribution

In this section, we utilize the method “Mask Experiment” proposed by CDT(Sun et al., 2019)to estimate the sentiment contribution of word w in the sentence a.By leveraging this method,we evaluate the effective of our proposed semantic and syntactic convolution module mathematically. The formula is as follows:

$$\gamma(w,s) = \frac{1}{m}\sum_{i=1}^{d} |\ \hat{h}_a^i - \hat{h}_{(a/w)}^i| \qquad (30)$$

As described in CDT(Sun et al., 2019),where d is the dimension of the final representation $\hat{h}_a$ learned by our model, w is the masked word, which indicates w becomes zero vector,$\hat{h}_{(a/w)}$ is the final representation of sentence a generated by our DM-GCN with the word w masked. If $\hat{h}_a^i = \hat{h}_{(a/w)}^i$, which demonstrates the word w has no sentiment contribution to sentence a.

Figure 5 is the visualization of the attention placed on words, from which can be observed that when syntactic or semantic convolution module (1st or 2nd row) is utilized separately, the model has assigned the highest attention on “wonderful” mistakenly. Regarding “wonderful” as the opinion word of aspect “dinner”, which results in the wrong judgment of the sentence eventually. However, our proposed DM-GCN (3rd row) is able to adaptively reduce the attention on irrelevant word “wonderful” and increase the score on “dinner” adaptively. Implying that our DM-GCN captures the most correlated information from syntactic, semantic and their combination spaces, which verifies the validity of our strategy mentioned before.

5 Conclusion

In this paper, we have proposed a dynamic and multi-channel graph convolution network to encoding the syntactic and semantic information for aspect-based sentiment analysis. Motivated by the human brain's mechanisms of language, we study how to adaptively learned the most correlated information from syntactic, semantic, and their combination spaces and fuse them sufficiently according to the characteristic of sentences. The experimental results on three benchmark datasets showed that we have achieved superior performance over the baseline methods. Besides, the ablation study and case analysis have exploited the influence of hyperparameters and validated the role of each component in our proposed model.

Automatic Text Simplification for Social Good: Progress and Challenges

Sanja Štajner
ReadableAI
Cologne, Germany
`sanja.stajner@readableai.com`

Abstract

Since the late 1990s, automatic text simplification (ATS) was promoted as a natural language processing (NLP) task with great potential to make texts more accessible to people with various reading or cognitive disabilities, and enable their better social inclusion. Large multidisciplinary projects showed promising steps in that direction. Since 2010, the field started attracting more attention but at the cost of major shifts in system architecture, target audience, and evaluation strategies. Somewhere along the way, the focus has shifted from ATS for social good towards building complex end-to-end neural architectures that are not aimed at any particular target population. This study presents the trajectory of ATS for social good, the main issues in current ATS trends, and the ways forward that could bring the field back to its initial goals.

1 Rationale

The right to accessible information is a fundamental right that should be granted to all people (UN, 2020). It is the key factor for personal empowerment and social inclusion. Nevertheless, textual information found on the web, in the news, health leaflets, and other sources is often linguistically too complex for many people and thus impedes their active participation in the society.

1.1 Adult Literacy

In the OECD Adult Literacy Report (OECD, 2013), "literacy is defined as the ability to understand, evaluate, use and engage with written texts to participate in society, to achieve one's goals, and to develop one's knowledge and potential". The literacy scale comprises of six levels:[1]

Below Level 1: Able to read brief texts on familiar topics and to locate a single piece of specific information (the process requires only basic vocabulary knowledge).

Level 1: Able to read very short texts (sometimes non-continuous or mixed) and locate a single piece of information identical or synonymous to the information given in the question/directive (requires only basic vocabulary knowledge). Texts may contain little, if any, competing information.

Level 2: Able to integrate two or more pieces of information, use paraphrasing or low-level inferences, compare and contrast or reason about the information requested.

Level 3: Able to understand dense and lengthy texts, various rhetorical structures, perform various levels of inference, and disregard irrelevant or inappropriate content.

Level 4: Able to integrate, interpret or synthesise information from complex or lengthy texts, perform complex inferences and apply background knowledge, identify and understand one or more non-central idea(s), evaluate subtle evidence-claim or persuasive discourse relationships, discern between the correct and competing information which sometimes appear in almost equal ratio.

Level 5: Able to search for and integrate information across multiple dense texts, synthesise various ideas and points of view, evaluate evidence-based arguments, apply and evaluate logical and conceptual models of ideas, evaluate reliability of the sources, selecting relevant information, notice subtle, rhetorical cues and make high-level inferences or use specialised background knowledge.

The percentage of adults (age 16–65) whose literacy is below Level 2 is 16.7%, on average, across 24 countries taken into account (OECD, 2013).[2] In

---

[1] We shorten the description of the skills at each literacy level and maintain only the information that is most relevant for further discussions. The full description of the literacy levels can be found on the page 64 in (OECD, 2013).

[2] Participating countries: Australia, Austria, Belgium (Flanders), Canada, the Czech Republic, Denmark, Estonia, Finland, France, Germany, Ireland, Italy, Japan, Korea, the

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2637–2652
August 1–6, 2021.

Literacy	US	Spain	Italy	Average (24 countries)	Simplification need
Below Level 2	21.7%	28.3%	28.3%	16.7%	lexical simplification
Below Level 3	≈50%	67.4%	70.3%	50.0%	syntactic simplification
Below Level 4	≈86%	≈95%	≈97%	89.4%	conceptual simplification

Table 1: Percentage of population in need for text simplification (the numbers are inferred from (OECD, 2013)).

Italy, Spain, and United States, this percentage is even higher (Table 1). On average, 0.7% of population has the literacy level 5. According to the definitions of the literacy levels in the OECD report, outlined above, one can conclude that: (1) all people with literacy below Level 4 have difficulties understanding conceptually complex texts; (2) all people with literacy below Level 3 additionally have difficulties understanding syntactically complex texts; and (3) all people with literacy below level 2 have difficulties understanding texts which are linguistically difficult in any sense (lexically, syntactically, or conceptually). This means that, according to the results of the OECD report, approximately 16.7% of population needs lexical simplification of everyday texts, 50% of population needs syntactic simplification, and 89.4% of population needs conceptual simplification (Table 1).

1.2 Manual Text Simplification

Text simplification aims to transform original texts into their simpler variants, which are more understandable to the target reader(s), while preserving the original meaning. Some nuances in meaning would inevitably be lost during that process, but the core information should stay the same.

The first guidelines for how to write more accessible texts for international communication, by using reduced vocabulary and restricted number of grammatical rules, were Basic English (Ogden, 1937) and Plain English initiative (Crystal, 1987). Since the late 1990s, many more initiatives have raised awareness about how to write more accessible texts, e.g. how to write for people with intellectual disabilities (Freyhoff et al., 1998; Mencap, 2002; Karreman et al., 2007), how to make public information more accessible to wider audiences (PlainLanguage, 2011), and how to make web content more accessible (W3C, 2008; Cooper et al., 2010). Specialized websites that offer easy-to-read news are now common in many countries, e.g. Noticias fácil in Spain[3], DR in Denmark[4], News Web Easy in Japan[5].

2 Automatic Text Simplification (ATS)

Manual text simplification, apart from being slow and expensive (requiring trained human editors), cannot keep up-to-date with the new information published online, offer variety of written content, or adaptation at a personal level. That created the need for automatic, or at least semi-automatic (involving a manual post-editing step) TS systems.

The first automatic text simplification (ATS) systems were rule-based, with focus on syntactic simplification in English, and were envisioned mainly as a pre-processing step for various natural language processing (NLP) applications, e.g. parsing, machine translation, summarization, and information retrieval; the clarity of texts for human readers was only one of the possible use cases (Chandrasekar et al., 1996; Chandrasekar and Srinivas, 1997). Subsequent ATS systems were proposed for various languages and were encompassing any number of the following simplification operations: lexical simplification, syntactic simplification, or explanation generation (Shardlow, 2014; Siddharthan, 2014).[6]

2.1 ATS Projects for Social Good

Automatic text simplification gained more interest from research community through several national and international projects that secured public founding for building ATS systems for various vulnerable populations and in various languages (Table 2).

Netherlands, Norway, Poland, the Slovak Republic, Spain, Sweden, the United Kingdom (England and Northern Ireland), the United States, Cyprus, and the Russian Federation.

[6] For a comprehensive overview of ATS, please see the book written by Saggion (2017), and the more recent surveys on ATS, lexical simplification, and sentence simplification (Paetzold and Specia, 2017b; Alva-Manchego et al., 2020b; Al-Thanyyan and Azmi, 2021).

Project	Period	Language	Impairment	Text types
PSET	1996–2000	EN	Aphasia	News
PorSimples	2007–2010	PT (BR)	Low literacy	News and educative articles
Simplext	2010–2013	ES	Down syndrome	News
FIRST	2012–2015	EN, ES, BG	Autism	News, literature, health leaflets
Able To Include	2014–2017	EN, ES, NL	Intellectual	E-mails, short messages

Table 2: Projects proposing automatic text simplification for social good.

All aimed to provide a better social inclusion, thus promoting ATS as an NLP task for social good.

ATS for Readers with Aphasia. PSET (Practical Simplification of English Text) was an UK national project (1996–2000) that aimed to build an ATS system that would make newspaper articles more accessible to people who suffer from aphasia (Carroll et al., 1998). This was the first project that promoted the use of ATS for social good. The solution was envisioned as a modular system consisting of two components: an analyser and a simplifier. The analyser would use lexical tagger, morphological analyser, and parser to recognize potentially difficult words and sentences for aphasic readers. The simplifier would use rule-based syntactic simplification systems to convert passive to active voice, extract embedded clauses, and split conjoined sentences, and a lexical simplification system which would use WordNet (Vossen, 2004) for retrieving substitution candidates and the Oxford Psycholinguistic Database (Quinlan, 1992) to choose the simplest one of them. It was envisioned to evaluate the final system with a group of aphasic readers (Carroll et al., 1998). HAPPI (Helping Aphasic People Process Information) was the continuation of the PSET project, this time with the aim of developing web-based ATS system which would make web content more accessible to aphasic readers by simplifying text vocabulary and syntax (Devlin and Unthank, 2006). To the best of our knowledge, there are no publications about the evaluations of the final systems with the end users.

ATS for Readers with Low Literacy. The PorSimples (Simplification of Portuguese Text for Digital Inclusion and Accessibility) project (Aluísio and Gasperin, 2010) was a Brazilian national project (2007–2010). Its aim was to produce tools and resources for people with low literacy levels (through the assistive technology systems called FACILITA and Educational FACILITA) and authors that want to produce texts for this audience (through an authoring system called SIMPLIFICA). The FACILITA system was envisioned with the focus on summarization and syntactic simplification, i.e. sentence splitting, change of discourse markers, conversion from passive to active voice, inversion of clause order, subject-verb-object order, topicalization and de-topicalization (Watanabe et al., 2009). Educational FACILITA was a web application prototype which offered lexical elaborations and named entity labelling. A pilot study with low-literacy users reported improved text comprehension, though participants reported to be sometimes confused with the offered list of synonyms that had multiple meanings (Watanabe et al., 2010).

ATS for People with Cognitive Disabilities. Simplext (Saggion et al., 2011, 2015) was a Spanish national project (2010-2013) that proposed several modules for automatic simplification of Spanish (news) texts for people with cognitive disabilities (particularly people with Down's syndrome). The modules combined rule-based and corpus-based techniques for reducing syntactic complexity of sentences, deleting unnecessary information, performing numerical simplification, normalizing reporting verbs, and reducing lexical complexity (Saggion et al., 2015). The final ATS system was tested by 44 people with Down's syndrome by measuring reading time and text comprehension. More correct answers were obtained for simplified texts, on average, and participants positively rated the existence of such a tool that is available through different technological channels, e.g. computer, smartphone, tablet (Saggion et al., 2015).

The Able to Include project (2014–2017) was an international project that aimed to improve the quality of life of people with intellectual or developmental disabilities, dementia, or any kind of cognitive impairments.[7] Three applications were built during

---

[7] `http://able-to-include.com`

the project: ABLEsocial (media app), ABLEchat (mobility app), and KOLUMBA (ABLEmail app) by using Simplext (ATS technology), PictoText, and Text2Speech web services.[8] This project did not offer significant advances in core ATS research. Its focus was, instead, on bringing existing ATS solutions to life through freely accessible prototypes.

ATS for Readers with Autism. The FIRST project (2012–2015) was an EC-funded project under the FP7 ICT call concerning smart and personalised inclusion (Orăsan et al., 2018). It provided OpenBook, a software that can automatically identify a range of language phenomena (e.g. complex syntactic structures, complex words and phrases, ambiguous words, and metaphors) that are problematic for people with high-functioning (IQ>70) autism spectrum disorders (ASD), and replace some of them. It also offered adding illustrative pictures and concise document summaries. The tool supported three languages: English, Spanish, and Bulgarian. Acknowledging that ATS was creating a large number of errors for some texts, and that end users have low tolerance for ungrammatical and erroneous text, OpenBook was also offering powerful post-editing options so that carers can post-edit the texts before showing them to the end users (Orăsan et al., 2018). The architecture was highly modular, with separate modules for each transformation, to allow for highest level of personalization possible. The final evaluation with 243 participants with high-functioning autism from UK, Spain, and Bulgaria was performed on texts which were automatically simplified and post-edited (by the clinical teams) using OpenBook. The participants were more successful at answering multiple-choice questions about the simplified than the original texts, and human-aided text conversion time significantly decreased by using OpenBook (Orăsan et al., 2018).

2.2 ATS in Medical Domain

A special type of literacy is health literacy, defined by the European Health Literacy Consortium:

> *"Health literacy is linked to literacy and entails people's knowledge, motivation and competences to access, understand, appraise and apply health information in order to make judgements and take decisions in everyday life concerning health care, disease prevention and health promotion to maintain or improve quality of life during the life course."*

According to the European Health Literacy Survey, nearly half of all adults in the eight European countries covered by the survey were found to have low health literacy skills, which may result in less healthy choices, riskier behaviour, poorer health, less self-management and more hospitalization (WHO, 2013). Due to their potential to improve the health of people with low health literacy skills, attempts at building ATS systems focused on simplifying medical content have recently attracted noticeable attention.

In contrast to the ATS systems mentioned so far, the ATS systems in medical domain are particularly focused on translating highly specialized medical expressions into their layman variants, and thus require domain-specific resources and customized algorithms. Kloehn et al. (2018) proposed an algorithm for automatically generating explanations for difficult (medical) terms in English and Spanish. van den Bercken et al. (2019) explored the possibility of training the earlier proposed general purpose neural text simplification model (Nisioi et al., 2017) on medical parallel corpus. Shardlow and Nawaz (2019) used the general purpose neural text simplification model (Nisioi et al., 2017) augmented with the phrase table of complex-simple medical terminology to automatically simplify clinical letters in English. Cardon and Grabar (2020) used similar approach for biomedical texts in French. Emphasizing the need for high-quality simplification in medical domain, Van et al. (2020) explored the possibility of applying pretrained neural language models to the autocomplete process for sentence-level medical text simplification.

2.3 ATS Research Trends

Research on ATS in English[9] could roughly be divided in three phases: rule-based systems that focus on specific, well-defined transformations (until 2010); data-driven supervised machine learning systems trained on parallel TS data (2010-2014/2016); and neural text simplification systems (from 2015/2017 onward). The neural trends

---

[8] Details about text to pictograph translation and the accessible e-mail client can be found in (Sevens et al., 2017; Saggion et al., 2017).

[9] The vast majority of ATS research was published for English and thus the discussion here is focused on those. Most of the ATS research for other languages uses similar ideas and adapts them to the particular language.

started earlier for purely lexical simplification systems by leveraging word embeddings (Glavaš and Štajner, 2015; Paetzold and Specia, 2016). Sentence simplification systems embraced neural architectures in 2017 by using neural machine translation (Nisioi et al., 2017) and reinforcement learning (Zhang and Lapata, 2017). Those three years (2010, 2015, and 2017) can clearly be observed in Figures 1 and 2, which show the number of scholarly articles that mention the specific TS terms anywhere in the text, and the number of scholarly articles with those TS terms in their title.[10]

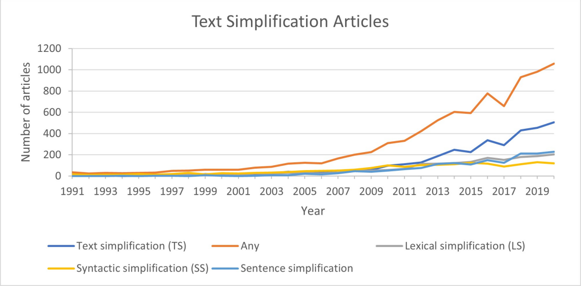

Figure 1: The number of articles in Google Scholar that mention specific text simplification terms.

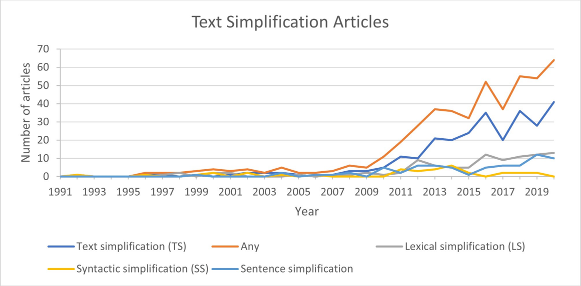

Figure 2: The number of articles in Google Scholar with specific text simplification terms in their title.

Interestingly, the number of articles mentioning syntactic simplification was steadily increasing until 2015, and then again in the period 2017–2019 (Figure 1), while the number of articles with syntactic simplification in their title was increasing until 2014, then noticeably decreased by 2016, to never increase much again (Figure 2). The number of lexical simplification (LS) papers, in turn, has been increasing since 2010, with two peaks, in 2012 and 2016. The peak in 2012 was due to the papers describing systems which participated in the SemEval-2012 English Lexical Simplification task (Specia et al., 2012), and lexical simplification endeavours in the scope of the Simplext project (Bott et al., 2012; Drndarević and Saggion, 2012a,b). Almost all lexical simplification research published in 2016 was focused on LS for non-native speakers.

So far, conceptual simplification has been tackled only through coreference resolution (Orăsan et al., 2018). Although most works mention "text simplification", they actually refer to sentence simplification. The state-of-the-art ATS systems published in top tier NLP/CL/AI conferences, e.g. (Nisioi et al., 2017; Zhang and Lapata, 2017; Surya et al., 2019; Kumar et al., 2020; Mallinson et al., 2020), all describe end-to-end systems for sentence simplification, and are not directed towards any particular simplification transformation or target population.

Very few papers proposed ATS methods that operate beyond sentence level (Glavaš and Štajner, 2013; Narayan and Gardent, 2014; Štajner and Glavaš, 2017). The research interests thus do not seem to follow the reported text simplification needs (see Table 1 in Section 1.1).

3 Challenges in ATS for Social Good

In spite of the evident increased interest for ATS in the last few years, and the obvious benefits it could bring to the society, no commercial systems have been offered so far, proving thus that automatic text simplification is a very challenging task.

The main reason might lie in the multidisciplinary nature of the task, i.e. the need for combining linguistics, psycholinguistics, computer science, and, to be used in real-world applications, advanced software engineering. Only large multidisciplinary teams can ensure solutions that are technically-advanced and, at the same time, truly help the end users. The absence of such multidisciplinary research leads to usage of non-optimal resources and evaluation procedures which do not involve end users, thus steering the field away from any real-world applications.

3.1 Resources

The number of manually simplified texts increases daily due the number of websites that provide easy-to-read materials (Section 1.2). Unfortunately, those materials and their original (non-simplified) versions, are usually not made available for neither research nor commercial purposes. The exceptions are the English and Spanish Newsela corpora,

---

[10] We excluded the patents and citations from this search, and looked for the exact matches of the TS terms. All returned titles were additionally manually checked.

which are available upon request for research purposes (the portion until 2016).[11]

The largest freely available TS corpora up-to-date are those based on matching the original English Wikipedia articles with the articles of the same title in Simple English Wikipedia, the EW-SEW corpora. They are available in several versions, as document-aligned (Kauchak, 2013)[12] and sentence-aligned (Zhu et al., 2010; Coster and Kauchak, 2011b; Kauchak, 2013; Hwang et al., 2015). Apart from not representing a truly parallel corpus but rather just comparable, as the articles in Simple English Wikipedia might have been written completely independently from the articles with the same title in the original English Wikipedia, many objections have been raised regarding the quality of simplifications (Amancio and Specia, 2014; Štajner et al., 2015; Xu et al., 2015; Štajner et al., 2020).

The English and Spanish Newsela corpora (Xu et al., 2015; Štajner et al., 2018), in contrast, provide parallel texts on several complexity levels, manually simplified under strict quality control (Xu et al., 2015).

The other available parallel (document-aligned) TS corpora are significantly smaller and do not provide enough material for training ATS models (Table 3). As their texts were simplified for different target populations, they cannot be combined to make larger training datasets for any specific target population, as it is known that there are no universal native simplified–language speaker (Siddharthan, 2014). Nevertheless, those smaller TS corpora could be used for evaluation of ATS systems aimed at particular target populations.

The sentence-aligned TS corpora, apart from those obtained from Newsela and EW-SEW, are still very scarce and limited in their size (Table 4).

The main problem with most sentence-aligned TS corpora is that they were automatically aligned

---

[11] `https://newsela.com/data/`

[12] `https://cs.pomona.edu/~dkauchak/simplification/`

using various sentence similarity measures with high similarity thresholds. This resulted in high number of pairs of identical, or nearly identical, sentences which, if used for training ATS systems, lead to conservative systems that rarely suggest any changes to the original sentence (Štajner and Saggion, 2015). The newer alignment methods (Hwang et al., 2015; Štajner et al., 2017; Paetzold et al., 2017), offer two types of sentence pairs: full matches and partial matches. In NMT-based TS (Štajner and Nisioi, 2018), the EW-SEW dataset (Hwang et al., 2015) resulted in a model with similarly high percentage of changed sentences as the model trained on Newsela sentence-aligned corpus (Štajner et al., 2017). Those results indicate that the EW-SEW dataset has a potential to be used for training state-of-the-art ATS models, if the sentences are carefully matched and filtered.

For building training datasets for ATS in medical domain, van den Bercken et al. (2019) and Van et al. (2020) used the EW-SEW dataset by retaining only those sentence pairs in which the original sentences contain certain number of medical terms.

One of the biggest challenges in ATS is how to collect a parallel dataset of truly strong paraphrases which are necessary for training ATS systems for people that require higher levels of simplification (e.g. people with cognitive or reading disabilities, and people with low literacy levels).[13] Such sentence pairs are still rarely correctly extracted with automatic alignment methods (Štajner et al., 2018).

The sentence-aligned TS corpora in Brazilian Portuguese, the PorSimples (Specia, 2010) and PorSimplesSent[14] (Leal et al., 2018), compiled under the PorSimples project, are the only ones that did not lose the strong paraphrase pairs due to automatic sentence-alignment, as manual simplifications were performed using a special editing tool which recorded the exact sentence alignments (Caseli et al., 2009). Both datasets are still very small to allow for automatically learning strong paraphrases solely from them. Nevertheless, they demonstrate that by providing editing tools for manual simplification, it is possible to automatically extract strong paraphrases from manually simplified corpora. This approach could thus be used in collaboration with various associations and content editors that perform professional manual simplifications for various target populations, to compile large, high-quality training datasets for building ATS systems aimed for those particular end users.

3.2 Evaluation

Ideally, ATS systems should be evaluated for the output quality, as well as for its usability, i.e. whether or not they make texts easier to read and understand for the particular reader.

3.2.1 Quality

The quality of ATS output should be evaluated for its grammaticality (and naturalness), meaning preservation (ensuring that, albeit some necessary loss of nuances, the core meaning remains unchanged), and preservation of text coherence and cohesion. The last is particularly important for systems that perform syntactic simplifications and sentence splitting which often break the cohesion links and make texts more complex at a discourse level (Siddharthan, 2003, 2006). Meaning preservation is also often compromised, both by syntactic simplification and by lexical simplification. Some unsupervised LS systems (Glavaš and Štajner, 2015; Paetzold and Specia, 2016) particularly suffer from this issue due to the use of word embeddings for synonyms retrieval, which often returns antonyms that appear in similar contexts (Glavaš and Štajner, 2015). Grammatical errors are less common, and can be easily corrected manually in a post-editing step. Manual correction of change in meaning, in turn, can sometimes require more time than simplifying from scratch. Coherence problems in automatically simplified texts are the most expensive, as they might require heavy restructuring of the whole text.

To measure the quality of the automatically simplified texts, Štajner and Glavaš (2017) proposed to measure the post-editing time needed to restore the text's grammaticality, original meaning and coherence. The output quality of the sentence simplification systems is, in contrast, evaluated only for grammaticality and meaning preservation, usually using a five-point Likert scale by native or non-native speakers with high literacy levels.

3.2.2 Usability

Usability of ATS systems should ideally be evaluated by measuring reading time and text com-

---

[13] Strong paraphrases are those paraphrases where vocabulary and sentence structure were changed beyond isolated lexical simplifications, straightforward sentence splitting and passive to active voice conversion. For examples, see Tables 1, 2, and 5 in (Štajner et al., 2018).

[14] `https://github.com/sidleal/porsimplessent`

prehension by end users, usually via eye-tracking methods and comprehension tests. This type of evaluation requires significant time and special training for preparing, collecting and interpreting the data. Preparation of comprehension tests requires experts, and eye-tracking methods require special equipment and trained humans to analyse and interpret the results. The access to vulnerable populations (e.g. people with autism or cognitive disabilities) usually requires special permissions and training. Another obstacle with vulnerable populations is that laboratory conditions and use of comprehension questionnaires provide unnatural reading scenario that sometimes leads to unreliable results (Yaneva et al., 2015, 2016a).

For all those reasons, ATS systems are rarely evaluated for their usability in this way. Notable exceptions are: the eye-tracking analyses of simplification strategies for dyslexic readers (Rello et al., 2013b,c,a), and readers with autism spectrum disorders (Yaneva et al., 2016b), the comprehension-based evaluations of the Simplext system by people with Down's syndrome (Saggion et al., 2015), the OpenBook software by people with ASD (Orăsan et al., 2018), and several ATS systems by non-native low-pay workers (Angrosh et al., 2014).

3.2.3 Simplicity

The usability evaluation with end users requires long time and special expertise. To obtain the results faster, in ATS research papers, it became a common strategy to, instead, evaluate a small portion of automatically simplified sentences for their simplicity using a Likert scale by evaluators who are not the intended end users.

In some studies the evaluators are native speakers, e.g. (Yatskar et al., 2010; Baeza-Yates et al., 2015; Saggion et al., 2015), in some non-native speakers, e.g. (Coster and Kauchak, 2011a; Wubben et al., 2012; Glavaš and Štajner, 2013, 2015; Paetzold and Specia, 2016), in some a mixture of the two (Angrosh et al., 2014; Kumar et al., 2020), and in some not specified, e.g. (Specia, 2010; Xu et al., 2016; Mallinson et al., 2020; Alva-Manchego et al., 2020a). In some of those studies, the evaluators are students, i.e. readers with high literacy levels, and in others, Amazon Mechanical Turk workers whose literacy level is usually unknown. Štajner and Nisioi (2018) found that evaluators with high literacy levels rarely notice any difference in complexity of the original and automatically simplified sentences. Other studies have shown that native and non-native speakers differently perceive sentence complexity (Štajner, 2018) and have different lexical simplification needs (Yimam et al., 2017a,b, 2018). Therefore, a direct comparison of the ATS systems proposed in studies where simplicity was evaluated by different type of evaluators is not possible.

Apart from the type of evaluators, the evaluation procedures used across the ATS community differ also by evaluation type (absolute or relative) and scale (e.g. 0/1, 1–3, 1–5), thus hindering the possibility to directly compare the results reported in different studies (Štajner, 2018). In the absolute evaluation, evaluators are presented with one sentence at the time and asked to rate its simplicity on a certain scale. If provided with different variants of the same sentence one after another, depending on the guidelines, evaluators may sometimes emphasize even the small differences between them by giving them different scores. Similar may happen in relative evaluation of simplicity gain, if evaluators are explicitly asked to count the number of successful lexical and syntactic paraphrases between the two sentences (original and simplified), as in the work of Xu et al. (2016). These approaches are thus helpful if the goal is to spot even the slightest differences between several models. If the goal is, in contrast, to estimate the usability and helpfulness of the systems in a real-world scenario, in a text comprehension task, then the approach in which evaluators are presented with pairs of sentences (original and simplified, without specifying which one is which) and asked whether or not they find one of them easier to understand, proposed by Nisioi et al. (2017), might be better suited.

To enable a direct comparison of results reported in different ATS studies, a standardized evaluation procedure across the field is needed. To establish the right evaluation procedure, it would be necessary to first investigate if some particular group of evaluators can be a good proxy for assessing the complexity of texts/sentences for intended target population. In the case that none of those groups satisfies the condition, the evaluators would have to be provided with detailed evaluation guidelines and trained for spotting potential obstacles for the intended end users. Furthermore, it would be necessary to systematically investigate which evaluation type and scale give the most reliable assessment of potential usability of the ATS systems in a real-world scenario.

3.2.4 Automatic Evaluation

With the goal of offering a more standardized way of measuring ATS systems' performances, several test sets have been compiled for lexical simplification in English (De Belder and Moens, 2012; Specia et al., 2012; Horn et al., 2014; Paetzold and Specia, 2015). De Belder and Moens (2012) propose a test set of 430 sentences, each with one marked word and the list of words that can replace it, ordered by their difficulty. Similarly, Specia et al. (2012) compiled a test set of 1710 sentences, each with one marked word and four substitution candidates ordered by their difficulty. Horn et al. (2014) compiled a set of 500 sentences from English Wikipedia, each with one marked word and 50 substitution candidates collected via crowdsourcing using Amazon Mechanical Turk.

All these datasets rely on suggestions and rankings of either non-native speakers (usually with high education levels), or neurotypical native speakers. Therefore, without systematic investigation of how well they reflect simplification needs of other target populations, it is not clear to which extent, if at all, they could be used to evaluate the performances of ATS systems aimed at them.

For automatic evaluation of sentence splitting modules for English, two datasets are currently available: WebSplit (Narayan et al., 2017) and WikiSplit (Botha et al., 2018). Both datasets were automatically extracted and aligned; the WebSplit from the WebNLG corpus (Gardent et al., 2017), and WikiSplit from Wikipedia edit histories. Recently, a crowdsourced dataset with multiple human simplification suggestions (both syntactic and lexical) for 2,359 original English Wikipedia sentences has been released (Alva-Manchego et al., 2020a). So far, none of them has been tested for how well it could evaluate the usability of real-world ATS systems for any particular target population.

Many ATS systems have been automatically evaluated using the Flesch-Kincaid Grade Level (FKGL) (Kincaid et al., 1975), MT-inspired evaluation metrics, e.g. BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2011), TER (Snover et al., 2009), or more recently proposed TS-specific metrics: SARI (Xu et al., 2016) and SAMSA (Sulem et al., 2018b). None of these metrics, however, can replace the necessary manual evaluation of grammaticality and meaning preservation (at a sentence level), or cohesion and coherence (at a discourse level). Traditional readability metrics such as FKGL were proposed for human-generated texts and are completely oblivious of meaning, i.e. short, meaningless sentences would score very well on those. The use of BLEU for TS evaluation has been reported to have many drawbacks if used for ATS (Štajner et al., 2015; Xu et al., 2016; Sulem et al., 2018a). Some other MT-based evaluation metrics have shown good correlations with human judgements of grammaticality and meaning preservation (Štajner et al., 2014; Popović and Štajner, 2016), but they all favor simplifications that are close to the original sentence (i.e. offer very few changes). SARI, in turn, favors simplifications that are as different from original as possible, thus often rewarding simple sentences which might have significantly altered the meaning.

4 Conclusion and Outlook

In this study, the potential for using ATS for social good and main challenges in the field to achieve that goal were emphasized: the lack of large high-quality TS datasets for training ATS systems for particular target populations, and the lack of standardized evaluation procedures for estimating the usability potential of the proposed ATS systems in real-world scenarios. Due to those, it is not clear if the recently proposed neural ATS systems, published in top tier NLP/CL/AI conferences, e.g. (Nisioi et al., 2017; Zhang and Lapata, 2017; Surya et al., 2019; Kumar et al., 2020; Mallinson et al., 2020), represent a real step forward toward using ATS for social good.

To address the above-mentioned challenges, it seems necessary to: (1) establish multidisciplinary collaborations with associations and content editors which have experience in simplifying texts for specific groups of end users; and (2) prioritize work on highly modular ATS systems, which allow for easy customization of components according to the simplification needs of particular groups of users. Multidisciplinary collaborations would enable compiling of larger high-quality datasets for various target populations, better understanding of which ATS modules require higher prioritization, and the possibility for testing the ATS systems with the real end users.

Acknowledgements

I would like to thank the three anonymous reviewers for their valuable comments and suggestions.

Ethics/Impact Statement

As this is a special theme paper and it does not propose any novel systems, the main focus of this section is the discussion about the general ethical considerations for automatic text simplification and its impact on the society.

Intended Use

Automatic text simplification (ATS) has strong potential to improve social inclusion for many people who are otherwise marginalized in one way or another. While many large-scale projects proved this, the last several years have been dominated by ATS research which does not seem to lead towards practical applications of ATS in the society. The goal of this paper is to raise the awareness among researchers about the original motivations for ATS and its potential for being used for social good, as well as to point out the main challenges in the field, and suggest ways forward.

Failure Modes

As mentioned in Section 3.2, ATS systems often produce ungrammatical sentences, changes to the original meaning, and break the text coherence. For this reason, to avoid potential unintended harm, it is advisable to add post-editing capabilities in ATS systems, as it was done in the OpenBook software (Orăsan et al., 2018). The unintended changes in meaning produced by ATS systems would be especially dangerous in legal and medical domains.

Biases

As all machine learning (ML) systems, ML-based ATS systems can suffer from algorithmic biases. If trained on data that represents manual simplifications performed by trained human editors, the system might inherit the biases and preferences of the editor. If trained on automatically sentence-aligned data, the system might learn transformations which might rather reflect the alignment methods than the actual simplification methods used in the prealigned corpora.

Misuse Potential

As any technological advancement, ATS could also be misused, e.g. by learning to make text more complex with the intention of providing linguistically complex texts to hide non-desirable facts, as it is known that high percentage of people have problems to understand complex texts (Section 1.1), or by unintentionally altering the original meaning thus offering incorrect information.

Potential Harm to Vulnerable Populations

People with low literacy levels, or any kind of reading or cognitive impairments, which cannot understand original texts and thus fully rely on the simplified versions, can potentially be harmed by being provided with incorrect information due to the use of premature ATS systems where the output is not manually checked for meaning preservation. Therefore, it is important that any ATS system intended for those populations offers post-editing capabilities and that its output passes a rigorous manual check for meaning preservation.

Furthermore, if provided by automatically simplified learning material, which was not carefully manually checked for its grammaticality and natural soundness of sentences, children and language learners might learn incorrect word forms or sentences structures.

Computing Time

The latest trends in ATS research steered the systems towards very computationally expensive (and environmentally unfriendly) neural architectures. As the current neural state-of-the-art ATS systems are still far behind the traditional modular rule-based ATS systems (especially for syntactic simplification), many research groups and organizations need numerous attempts with neural architectures even just to be able to publish a paper in a top-tier conference. The current best performing neural lexical simplification systems (Glavaš and Štajner, 2015; Paetzold and Specia, 2016, 2017a; Qiang et al., 2020a,b) perform better than the state-of-the-art non-neural lexical simplification systems (Glavaš and Štajner, 2015; Paetzold and Specia, 2017b; Qiang et al., 2020b). Nevertheless, due to using heavy resources, such as BERT (Devlin et al., 2018) and PPDB (Ganitkevitch et al., 2013), or their multiple operations with word embeddings, they require significant computational power and are too slow to be used in real-world applications.

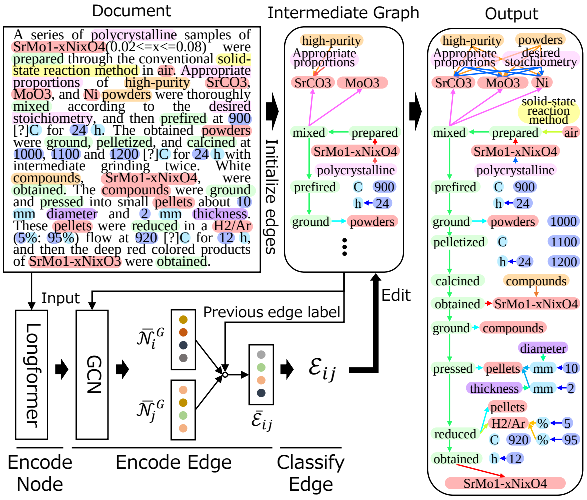
Abstract

In this paper, we propose a novel edge-editing approach to extract relation information from a document. We treat the relations in a document as a relation graph among entities in this approach. The relation graph is iteratively constructed by editing edges of an initial graph, which might be a graph extracted by another system or an empty graph. The way to edit edges is to classify them in a close-first manner using the document and temporally-constructed graph information; each edge is represented with a document context information by a pretrained transformer model and a graph context information by a graph convolutional neural network model. We evaluate our approach on the task to extract material synthesis procedures from materials science texts. The experimental results show the effectiveness of our approach in editing the graphs initialized by our in-house rule-based system and empty graphs.[1]

1 Introduction

Relation extraction (RE), the task to predict relations between pairs of given entities from literature, is an important task in natural language processing. While most existing work focused on sentence-level RE (Zeng et al., 2014), recent studies extended the extraction to the document level since many relations are expressed across sentences (Christopoulou et al., 2019; Nan et al., 2020).

In document-level RE, models need to deal with relations among multiple entities over a document. Several document-level RE methods construct a document-level graph, which is built on nodes of words or other linguistic units, to capture document-level interactions between entities (Christopoulou et al., 2019; Nan et al., 2020). However, such methods do not directly consider interactions among relations in a document, while such relations are often dependent on each other, and other relations can be considered as important contexts for a relation.



A series of polycrystalline samples of SrMo1-xNixO4(0.02<=x<=0.08) were prepared through the conventional solid-state reaction method in air. Appropriate proportions of high-purity SrCO3, MoO3, and Ni powders were thoroughly mixed according to the desired stoichiometry, and then prefired at 900 [?]C for 24 h. The obtained powders were ground, pelletized, and calcined at 1000, 1100 and 1200 [?]C for 24 h with intermediate grinding twice. White compounds, SrMo1-xNixO4, were obtained. The compounds were ground and pressed into small pellets about 10 mm diameter and 2 mm thickness. These pellets were reduced in a H2/Ar (5%: 95%) flow at 920 [?]C for 12 h, and then the deep red colored products of SrMo1-xNixO3 were obtained.

Figure 1: Overview of edge editing approach

We propose a novel, iterative, edge-editing approach to document-level RE. The overview of our approach and an example of the extraction results are illustrated in Figure 1. Our approach treats relations as a relation graph that is composed of entities as nodes and their relations as edges. The relation graph is first initialized using the edges predicted by an existing RE model if provided. Edges are then edited by a neural edge classifier that represents edges using the document information, prebuilt graph information, and the current edge information. The document information is represented with pretrained Longformer models (Beltagy et al., 2020), while the graph information is represented with graph convolutional networks (Kipf and Welling, 2017). Edges are edited iteratively in a close-first manner so that the approach can utilize the information of edges between close entity pairs

in editing edges of distant entity pairs, which are often difficult to predict. We evaluate our approach on the task to extract synthesis procedures from text (Mysore et al., 2019) and show the effectiveness of our approach.

The contribution of this paper is three-fold. First, we propose a novel edge-editing approach for document-level RE that utilizes contexts in both relation graphs and documents. Second, we build a strong rule-based model and show that our approach can effectively utilize and enhance the output of the rule-based model. Third, we build and evaluate a neural model for extracting synthesis procedures from text for the first time.

2 Approach

Our approach extracts a relation graph on given entities from a document. We formulate the extraction task as an edge-editing task, where the approach iteratively edits edges with a neural edge classifier in a close-first manner (Miwa and Sasaki, 2014).

2.1 Iterative Edge Editing

We build a relation graph by editing the edges iteratively using the edge classifier in Section 2.2. The building finishes when all edges are edited. The edges are edited in a close-first manner (Miwa and Sasaki, 2014; Ma et al., 2019) that edits the close edges first and far edges later. The distance between the entity pair is defined based on the appearing order of entities in a document; if two entities in a pair appear m-th and $m + 3$-th, the distance becomes 3. Note that each edge is edited only once throughout the entire editing process.

Algorithm 1 shows the method to build the graph by the iterative edge editing. To reduce the computational cost, the pairs with the same distance are edited simultaneously and the pairs with distances more than or equal to the maximum distance d_{max} are edited simultaneously. This reduces the number of edits from $|\mathcal{N}|^2$ to d_{max}.

2.2 Edge Classifier

An edge classifier predicts the class of the target edge $\hat{\mathcal{E}}_{ij}$ from inputs that are composed of a document information doc, a graph of nodes $\mathcal{N}$ and edges $\mathcal{E}$, and the node pair $(\mathcal{N}_i, \mathcal{N}_j)$ of a target edge. The classifier composed of three modules:

EncodeNode that produces document-based node representations $\bar{\mathcal{N}}$ using the document doc and the entity information of the nodes $\mathcal{N}$.

Algorithm 1: Iterative Edge Editing

```
    Distance($\mathcal{N}, d_1, d_2$) returns pairs that have
    distance $d$ ($d_1 \leq d < d_2$).
  Input: doc: document, $\mathcal{E}$: initial edges
    $d_{max}$: maximum distance
  Output: $\mathcal{E}$: edited edges
    $\bar{\mathcal{N}} \Leftarrow \mathrm{EncodeNode}(\mathrm{doc}, \mathcal{N})$
    while $d$ in $\mathrm{range}(\max(|\mathcal{N}|, d_{max}))$ do
      $\bar{\mathcal{N}}^G \Leftarrow \mathrm{GCN}(\bar{\mathcal{N}}, \mathcal{E})$
      $\bar{\mathcal{E}} \Leftarrow \mathrm{EncodeEdge}(\bar{\mathcal{N}}^G, \mathcal{E})$
      if $d = d_{max}$ then
        $\mathcal{P} \Leftarrow \mathrm{Distance}(\mathcal{N}, d_{max}, \infty)$
      else
        $\mathcal{P} \Leftarrow \mathrm{Distance}(\mathcal{N}, d, d + 1)$
      end if
      while $(i, j)$ in $\mathcal{P}$ do
        $\mathcal{E}_{ij} \Leftarrow \mathrm{ClassifyEdge}(\bar{\mathcal{E}}_{ij})$
      end while
    end while
```

EncodeEdge that obtains the representation of edges $\bar{\mathcal{E}}$ that applies GCN on a prebuilt graph with the node representations $\bar{\mathcal{N}}$ and edges $\mathcal{E}$.

ClassifyEdge that predicts the class of the edge $\hat{\mathcal{E}}_{ij}$ using the edge representation $\bar{\mathcal{E}}_{ij}$ between the node pair $(\mathcal{N}_i, \mathcal{N}_j)$.

We explain the details of these modules in the remaining part of this section.

EncodeNode employs Longformer (Beltagy et al., 2020) to obtain the document-level representation. It aggregates subword representations within each entity by max-pooling Pool and concatenates the aggregated information with the entity's class label representation $\boldsymbol{v}^{lab}$.

$$\begin{aligned} \bar{\mathcal{N}} &= \mathrm{EncodeNode}(\mathrm{doc}, \mathcal{N}) \\ &= [\mathrm{Pool}(\mathrm{Longformer}(\mathrm{doc})); \boldsymbol{v}^{lab}], \end{aligned} \quad (1)$$

where $[\cdot;\cdot]$ denotes concatenation.

To prepare the input to EncodeEdge, the obtained document-based node representation is enriched by GCN to introduce the context of each node in the prebuilt graph: $\bar{\mathcal{N}}^G = \mathrm{GCN}(\bar{\mathcal{N}}, \mathcal{E})$. We add inverse directions to the graph and assign different weights to different classes in graph convolutional network (GCN) following Schlichtkrull et al. (2018). The produced node representation $\bar{\mathcal{N}}^G$ includes both document and prebuilt graph contexts.

EncodeEdge produces the edge representation $\bar{\mathcal{E}}$ from $\bar{\mathcal{N}}^G$. It individually calculates the representation of the edge $\bar{\mathcal{E}}_{ij}$ for each pair of nodes $(\mathcal{N}_i, \mathcal{N}_j)$ by combining the representations of nodes similarly to Zhou et al. (2021) with the embedding of the distance of the entity pair $\boldsymbol{b}_{ij}$ and the edge class $\boldsymbol{e}_{ij}^{old}$ before editing. The distance between the entity pairs is calculated in the same way as in Section 2.1. If the distance exceeds a predefined maximum distance, it will be treated as the maximum distance. We prepare fully connected (FC) layers, FC^H and FC^T, for the start point (head) and end point (tail) nodes and calculate the edge representation as follows:

$$\begin{aligned} \bar{\mathcal{E}}_{ij} &= \mathrm{EncodeEdge}(\bar{\mathcal{N}}^G, \mathcal{E})_{ij} \\ &= [\mathrm{FC}^H(\bar{\mathcal{N}}_i^G)^\top \boldsymbol{W} \mathrm{FC}^T(\bar{\mathcal{N}}_j^G); \boldsymbol{b}_{ij}; \boldsymbol{e}_{ij}^{old}], \end{aligned} \quad (2)$$

where $\boldsymbol{W}$ denotes a trainable weight parameter.

ClassifyEdge classifies the target edge $\mathcal{E}_{ij}$ into a relation class or no relation. It applies a dropout layer (Srivastava et al., 2014), a FC layer for output FC^{out} and softmax to the edge representation $\bar{\mathcal{E}}_{ij}$ to predict the class $\hat{\mathcal{E}}_{ij}$ with the highest probability.

$$\begin{aligned} \hat{\mathcal{E}}_{ij} &= \mathrm{ClassifyEdge}(\bar{\mathcal{E}}_{ij}) = \arg\max \hat{\boldsymbol{p}}_{ij} \\ \hat{\boldsymbol{p}}_{ij} &= \mathrm{Softmax}(\mathrm{FC}^{out}(\mathrm{Dropout}(\bar{\mathcal{E}}_{ij}))) \end{aligned} \quad (3)$$

We maximize the log-likelihood in training the edge classifier.

3 Experiments

3.1 Experimental Settings

We evaluate our approach on the materials science procedural text corpus (Mysore et al., 2019). In the corpus, the synthesis procedures are annotated as a graph in a document, where 19 node types such as materials, operations, and conditions and 15 directed relation types are defined. The corpus consists of 200 documents for training, 15 for development, and 15 for test. The statistics of the corpus are shown in Appendix A. We chose this corpus since this corpus is publicly available, manually annotated, and it deals with a dense document-level relation graph.

We prepared a rule-based model (**RULE**) as a baseline and as an existing model to initialize the edges, which was adapted from the rule-based system in Kuniyoshi et al. (2020). The rules are summarized in Appendix B.

We employ the micro F-score for each relation class as the evaluation metric. We tune the hyper-parameters such as the number and dimensions of layers and dropout rate on the development set using the hyper-parameter optimization framework Optuna (Akiba et al., 2019) and the details are shown in Appendix C. We employ the Adam (Kingma and Ba, 2015) optimizer with the default parameters in PyTorch (Paszke et al., 2019) except for the learning rate. The training was performed without finetuning for the Longformer because the corpus is small to train a large transformer model.

	Dev	Test
EDIT	**0.788**	**0.729**
EDIT-IE	0.732	0.685
EDIT-GCN	0.744	0.703
RANDOM EDIT	0.751	0.690
RANDOM INIT	0.756	0.720

Table 1: Evaluation results in micro F-score without RULE

We compare the following models on graphs initialized by the rule-based model (**with RULE**) and empty graphs (**without RULE**).

EDIT: Proposed model

EDIT-IE: EDIT without iterative edge editing, i.e., $d_{max} = 1$.

EDIT-GCN: EDIT without GCN by replacing $\bar{\mathcal{N}}^G$ with $\bar{\mathcal{N}}$ in Equation (2)

RANDOM EDIT: EDIT with random-order editing

Additionally, we evaluate the following model with randomly initialized graphs.

RANDOM INIT: EDIT with randomly connected edges, the number of which is same as that of the extraction results of RULE, with random classes

Note that although we did not provide the direct comparison with the existing models, our EDIT-GCN without RULE is similar to BRAN (Verga et al., 2018); the only differences are that we use Longformer (Beltagy et al., 2020) instead of transformers, and NER training is not included. Moreover, most of the models for the document-level RE require dataset annotating both entities and their mentions, so the existing models like ATLOP (Zhou et al., 2021) cannot be directly applied to the current task.

3.2 Results without RULE

We show the results with empty initial graphs in Table 1. EDIT shows the highest scores and this indicates the effectiveness of our approach when the initial graphs are empty. When we compare EDIT, EDIT-IE, and RANDOM EDIT, we find that both iterative edge editing and close-first strategy

	Dev	Test
RULE	0.797	0.807
EDIT	**0.878**	0.851
EDIT-IE	0.863	**0.863**
EDIT-GCN	0.857	0.834
RANDOM EDIT	0.791	0.744

Table 2: Evaluation results in micro F-score with RULE

are effective. Since EDIT-GCN extracts from context without graph structure information, the better performance of EDIT over EDIT-GCN shows the effectiveness of the information in the graph structure. The low performance with RANDOM INIT shows that the edge information needs to be reliable.

3.3 Results with RULE

We summarize the results with RULE in Table 2. We show the detailed results for EDIT without RULE, RULE, and EDIT-IE with RULE in Appendix D.

When we compare the results with Table 1, the performance with RULE is better than the counterpart without RULE for all the settings. Furthermore, all the scores in Table 2 are better than those in Table 1, which shows the strength of RULE.

Surprisingly, the results with our approach are better than that of RULE even though RULE is better than our approach without RULE. This indicates our EDIT approach can make the prediction accurate. We can conclude that our EDIT approach can utilize the information from the rule-based model and the initialization of the edges by RULE is useful.

As for the performance of the models, most results are consistent with Table 1 except that EDIT-IE shows the highest score on the test set. This may be partly because the initial graph by RULE is already reliable and editing does not help to improve the context. Results with RANDOM EDIT support this since the performance degradation with RANDOM EDIT is large compared to Table 1 and RANDOM EDIT is harmful in this case. Moreover, the different behaviors on the development and test sets indicate an imbalance in the corpus split.

4 Case Study

We illustrated 6 graphs for an example document (Zhang et al., 2007) in the development data set shown in Figure 2: the result on the right side of Figure 1 shows our best extraction result using EDIT-IE with RULE; Figure 3 shows the correct extraction; Figure 4 shows the extraction result using EDIT without RULE; Figure 5 shows the extraction result using RULE; and Figure 6 shows the extraction result using EDIT with RULE. Figure 3 shows the material synthesis starts from *mixed* with materials *SrCO3*, *MoO3* and *Ni* to *prefired* and so on, and the material *SrMo1-xNixO4* is synthesized. When we compare Figure 6 with Figure 5, the extraction results are similar to RULE. Although the overall performance is low, Figure 4, which does not depend on the rule, extracts relations that are not extracted by the other systems and this shows the models with RULE and without RULE capture different relations.

5 Related Work

RE has been widely studied to identify the relation between two entities in a sentence. In addition to traditional feature/kernel-based methods (Zelenko et al., 2003; Miwa and Sasaki, 2014), many neural RE methods have been proposed based on convolutional neural networks (CNNs) (Zeng et al., 2014), recurrent neural networks (RNNs) (Xu et al., 2015; Miwa and Bansal, 2016), graph convolutional networks (GCNs) (Zhang et al., 2018; Schlichtkrull et al., 2018), and transformers (Wang et al., 2019). However, sentence-level RE is not enough to cover the relations in a document, and document-level RE has increasingly received research attention in recent years.

Major approaches for document-level RE are graph-based methods and transformer-based methods. For graph-based methods, Quirk and Poon (2017) first proposed a document graph for document-level RE. Christopoulou et al. (2019) constructed a graph that included heterogeneous nodes such as entity mentions, entities, and sentences and represented edges between entities from the graph. Nan et al. (2020) proposed the automatic induction of a latent graph for relational reasoning across sentences. The document graphs in these methods are defined on nodes of linguistic units such as words and sentences, which are different from our relation graphs. Unlike our method, these methods do not directly deal with relation graphs among entities.

For transformer-based methods, Verga et al. (2018) introduced a method to encode a document with transformers to obtain entity embedding and

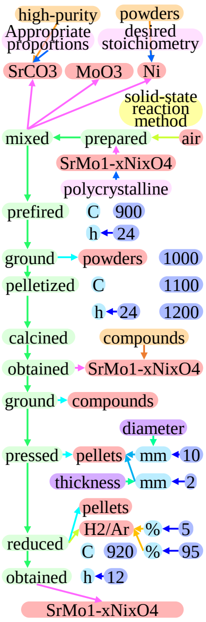

Figure 5: Example extraction results from the document in Figure 2 by RULE

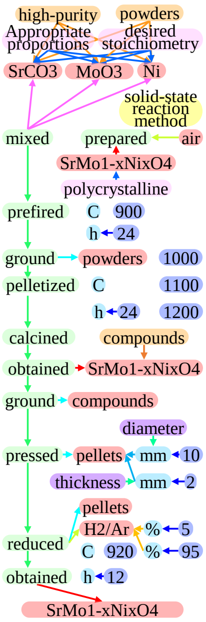

Figure 6: Example extraction results from the document in Figure 2 by our EDIT with RULE

classify the relations between entities using the embedding. Tang et al. (2020) proposed a Hierarchical Inference Network (HIN) for document-level RE, which aggregates information from entity level to document level. Zhou et al. (2021) tackled document-level RE with an Adaptive Thresholding and Localized cOntext Pooling (ATLOP) model that introduces a learnable entity-dependent threshold for classification and aggregated local mention-level contexts that are relevant to both entities.

Several studies focus on procedural texts such as cooking recipes (Bosselut et al., 2018), scientific processes (Dalvi et al., 2018) and open domain procedures (Tandon et al., 2020). They, however, do not directly treat relation graphs. Several efforts have been made to annotate procedural or action graphs in procedural text (Mori et al., 2014; Mysore et al., 2019; Kuniyoshi et al., 2020). Kuniyoshi et al. (2020) and Mehr et al. (2020) individually proposed rule-based systems to extract procedures from a document, but no neural methods have been proposed for the extraction.

6 Conclusions

We proposed a novel edge editing approach for document-level relation extraction. This approach treats the task as the edge editing of relation graphs, given nodes. It edits edges considering contexts in the document and the relation graph. We evaluated the approach on the material synthesis procedure corpus, and the results showed the usefulness of initializing edges by the rule-based model, utilizing prebuilt graph information for editing and editing in a close-first manner. As a result, our model performed an F-score of 86.3% for edge prediction.

In future work, we plan to improve the approach to obtain more consistent and accurate relation graphs. We also would like to apply the approach to other data sets such as cooking recipes (Mori et al., 2014) and temporal graphs (Pustejovsky et al., 2003; Cassidy et al., 2014).

A Statistics of the Materials Science Procedural Text Corpus

We present the statistics of the materials science procedural text corpus[2] proposed by Mysore et al. (2019). Table 3 and Table 4 summarize the numbers of entities and relations, respectively.

---

[2] `https://github.com/olivettigroup/annotated-materials-syntheses`

B Rule-based Relation Extraction Model

We built a rule-based model by defining the rules to extract relations between entity pairs for the materials science procedural text corpus (Mysore et al., 2019). The rules were adapted from the rule-based model in (Kuniyoshi et al., 2020) for the target corpus. The rules depend on labels of the entities of an entity pair, distance, and the order of occurrence of the entities. According to the combination of labels of the entities, our rules are divided into three types: Operation–Operation, Operation–Material and other relations. In the following, the starting point of a relation is called head and the ending point is called tail, and an edge is denoted as Head–Tail.

B.1 Operation–Operation

The relation Operation–Operation takes only a Next_Operation label, which means the progress of operation.

Next_Operation: Close Operation entities are linked with the relation from the beginning to the end in the document order, in which the entities of Operation appear.

B.2 Operation–Material

For the edges of Operation–Material, there are five relation labels: Recipe_Precursor indicates the input of a material; Recipe_Target indicates the generation of a product; Participant_Material indicates the generation of an intermediate product; Solvent_Material indicates the solvent material of an operation; and Atmospheric_Material indicates the atmosphere of an operation.

For Solvent_Material, Atmospheric_Material and Participant_Material labels, a dictionary is prepared manually for each label. The relations are linked from the nearest Operation to a Material in the sentence if the Material match in the dictionary since these relations take specific Material entities. The dictionary is included in the source code.

Recipe_Precursor is linked from all Material that do not match the dictionary of Solvent_Material, Atmospheric_Material, and Participant_Material to the nearest Operation. This rule-based model does not produce the relation Recipe_Target. The reason for these decisions is that it is difficult to classify these relations with simple rules.

Entity class	Train	Dev	Test

Table 4: Relations in the materials science procedural text corpus

B.3 Remaining Relations

The remaining 9 relation labels are defined between the other pairs of entity labels: Property_Of, which indicates a condition of a material; Condition_Of, which indicates a condition of an operation; Number_Of, which indicates the relationship between a number and a unit; Amount_Of, which indicates a condition of a quantity; Type_Of, which indicates a condition of a numerical condition; Brand_Of, which indicates the brand of a material or equipment; Apparatus_Of, which indicates equipment used in an operation; APPARATUS_ATTR_OF, which indicates a numerical condition of on equipment; and DESCRIPTOR_OF, which indicates other conditions. For these labels, the rules are defined based only on the labels of head and tail entities and the distance between them. We explain the detailed rules in the remainder of this section.

PROPERTY_OF: The relation can take PROPERTY-UNIT or PROPERTY-MISC as the head and MATERIAL or NONRECIPE-MATERIAL as the tail. When PROPERTY-UNIT is a head, it is linked with the nearest MATERIAL in the sentence. When PROPERTY-MISC is a head, it is linked to the nearest MATERIAL or NONRECIPE-MATERIAL in the sentence.

CONDITION_OF: CONDITION-UNIT and CONDITION-MISC are linked to the nearest OPERATION with the relation in the sentence.

NUMBER_OF: NUMBER is linked to the nearest PROPERTY-UNIT, CONDITION-UNIT, or APPARATUS-UNIT that appear after the NUMBER in the sentence.

AMOUNT_OF: The relation is linked from AMOUNT-UNIT and AMOUNT-UNIT to the nearest MATERIAL or NONRECIPE-MATERIAL in the sentence.

DESCRIPTOR_OF: When MATERIAL-DESCRIPTOR is a head, it is linked to the nearest MATERIAL or NONRECIPE-MATERIAL in the sentence. When APPARATUS-DESCRIPTOR is a head, it is linked to the nearest SYNTHESIS-APPARATUS in the sentence.

APPARATUS_OF: The relation is linked from SYNTHESIS-APPARATUS and CHARACTERIZATION-APPARATUS to the nearest OPERATION with the priority given to the OPERATION that appear before the APPARATUS in the sentence.

TYPE_OF: PROPERTY-TYPE and APPARATUS-PROPERTY-TYPE are linked to the nearest PROPERTY-UNIT and APPARATUS-UNIT in the sentence with the relation, respectively. When CONDITION-TYPE is a head, it is linked to the nearest CONDITION-UNIT that appears before the CONDITION-TYPE in the sentence.

BRAND_OF: The relation is linked from BRAND to the nearest entities that may have brands (i.e., MATERIAL, NONRECIPE-MATERIAL, SYNTHESIS-APPARATUS, and CHARACTERIZATION-APPARATUS) in the sentence.

Parameter	Range	Value

APPARATUS_ATTR_OF: APPARATUS-UNIT is linked to the nearest SYNTHESIS-APPARATUS or CHARACTERIZATION-APPARATUS.

COREF_OF: The relation is not detected by the rules because it is difficult to describe rules.

C Tuning Details

We tuned our model using a hyper-parameter optimization framework Optuna (Akiba et al., 2019). We searched for the hyper-parameters that maximize micro-F scores within 600 trials on the development set. We employed the tree-structured Parzen estimator algorithm (Bergstra et al., 2011) for the sampler and the successive halving algorithm (Li et al., 2020) for the pruner with default options in Optuna. In each trial of the search, we trained our model for 100 epochs, which was confirmed by preliminary experiments to be sufficient for convergence. We searched hyper-parameters on 20 NVIDIA GPUs, which include Tesla V100, TITAN V, RTX 3090, and GTX TITAN Xp GPUs.

Table 8: Detailed results using EDIT-IE with RULE on the test set

We defined the search space as shown in Table 5; the hyper-parameters for the search are composed of the learning rate for Adam, the number of GCN layers, the maximum edit distance d_{max}, the dimensions of all hidden layers, the number of FC^{out} layers, the number of FC^{h} and FC^{t} layers, the dropout rate, the dimension of $\boldsymbol{e}_{ij}^{old}$, the maximum distance and the dimension for $\boldsymbol{b}_{ij}$ and whether to use bidirectional GCNs or uni-directional GCNs. In the table, the range column shows the range of values to search and the final value column shows the rounded selected values after the optimization.

D Detailed Evaluation Results

Our editing models for evaluation are trained with a TITAN V GPU for EDIT with RULE and a Tesla V100 GPU for the others. The training takes about 6 hours 30 minutes with EDIT-IE using RULE and 21 hours with EDIT not using RULE.

We show the detailed evaluation results with precision (Prec.), recall, and F-score on the test set in Table 6 for EDIT without RULE, Table 7 for RULE, and Table 8 for EDIT-IE without RULE. The results show the relations that are not covered by RULE, i.e., RECIPE_TARGET and COREF_OF, are extracted by our approach, and for these classes, EDIT without RULE show the better performance than the models with RULE. Some relations with high performance by RULE, including NEXT_OPERATION, CONDITION_OF, and DESCRIPTOR_OF, are extracted by EDIT-IE with RULE in high performance. This shows our approach can effectively utilize the outputs of RULE.

Dialogue-oriented Pre-training

Abstract

Pre-trained language models (PrLM) has been shown powerful in enhancing a broad range of downstream tasks including various dialogue related ones. However, PrLMs are usually trained on general plain text with common language model (LM) training objectives, which cannot sufficiently capture dialogue exclusive features due to the limitation of such training setting, so that there is an immediate need to fill the gap between a specific dialogue task and the LM task. As it is unlikely to collect huge dialogue data for dialogue-oriented pre-training, in this paper, we propose three strategies to simulate the conversation features on general plain text. Our proposed method differs from existing post-training methods that it may yield a general-purpose PrLM and does not individualize to any detailed task while keeping the capability of learning dialogue related features including speaker awareness, continuity and consistency. The resulted Dialog-PrLM is fine-tuned on three public multi-turn dialogue datasets and helps achieve significant and consistent improvement over the plain PrLMs.

1 Introduction

Recently, pre-trained language models (PrLMs) have shown impressive improvements for various downstream NLP tasks (Zhou et al., 2020; Ouyang et al., 2021; Zhang and Zhao, 2021; Radford et al., 2018; Yang et al., 2019; Zhang et al., 2020c; Clark et al., 2020; Li et al., 2021), including the response selection task for multi-turn dialogues, which takes a dialogue history as input and aims to select a most suitable response from a collection of answers (Zhou et al., 2016; Wu et al., 2017; Zhou et al., 2018b; Zhu et al., 2018; Zhang et al., 2018; Tao et al., 2019; Gu et al., 2019).

Dialogue History:
A: *Could you please get me a train?*
B: *Sure I can help you find a train.*
B: *where are you coming from?*
B: *What time do you need to leave by?*
A: *I am leaving Leicester and I need to leave by 20:30.*
B: *What is your destination and day of travel?*
A: *Cambridge and on friday.*
A: *Can I just get the travel time for the train? Thanks!*
Response:
B: *The first train leaving after 20:30 is 142 21:09 and the travel time is 105 minutes.*

Table 1: A multi-turn dialogue example with interleaved or continuous utterances between two speakers.

Pre-training tasks of all these PrLMs almost concentrate on two aspects: token prediction and sentence relation prediction. For example, the genetic BERT model (Devlin et al., 2019) uses masked language modeling (MLM) and next sentence prediction (NSP) objectives; ALBERT (Lan et al., 2020) predicts sentence order rather than NSP; ELECTRA (Clark et al., 2020) transfers MLM into a generating and then discriminating process like GAN (Goodfellow et al., 2014). However, these tasks are just devoted to incorporating token-level and sentence-level semantic information into embeddings, and cannot be sufficiently compatible with its dialogue-oriented characteristics.

Table 1 shows a multi-turn dialogue example. Compared with plain text, the utterance turn and speaker role keep shift as a conversation goes on, and the next utterance should keep continuous and consistent with the context. Besides, the two speakers may not follow strict shift rules, and one speaker may continuously shoot multiple utterances. Although some existing works have noticed such

nonlinear nature of multi-turn dialogues, they are limited to conducting post-training or pre-training in a specific domain and do not provide general-purpose dialogue-oriented PrLMs to fundamentally solve this problem (Xu et al., 2021a; Whang et al., 2021; Wolf et al., 2019; Zhang et al., 2020b; Henderson et al., 2020; Bao et al., 2020).

In this work, we make the first attempt to train a general-purpose dialogue-oriented PrLM. However, such a PrLM should be trained on huge dialogue data, which is hard to collect. Thus we propose three novel pre-training strategies (i.e., Insertion, Deletion, Replacement), so that we facilitate plain text originally for common PrLM training to simulate dialogue-like features. The resulted model, we denote as Dialog-PrLM, then is capable of effectively learning speaker awareness, continuity and consistency in a general way. Especially, for the convenient use of the downstream dialogue tasks, we introduce a special token `[SOT]` before each utterance to tell that it is a start of a turn and learn from these three strategies. These targeted pre-training tasks enable `[SOT]` to better represent each context utterance. We mimic dialogue-related features on conventional plain text, which can bring up the possibility that similar techniques could be adopted in other domains not only for dialogues.

Our pre-trained Dialog-PrLM is fine-tuned on three multi-turn dialogue response selection benchmarks, and obtains significant and consistent improvements over the plain PrLMs.

2 Related Work

For multi-turn dialogue response selection task, earlier works conduct single-turn match, which concatenates all the utterances in the history dialogue or just considers the last one to match with the candidate response (Lowe et al., 2015; Kadlec et al., 2015; Yan et al., 2016; Tan et al., 2016; Wan et al., 2016; Wang and Jiang, 2016). Recently, existing works tend to model the interaction between each dialogue utterance and the response, which usually adopt the encoding-matching-aggregation paradigm (Zhou et al., 2016; Wu et al., 2017; Zhang et al., 2018; Zhou et al., 2018a,b; Tao et al., 2019; Yuan et al., 2019). After encoding, distinct matching networks generate features for each utterance which are usually passed to GRU (Cho et al., 2014) for aggregating into a final matching score. Besides, some works adopt topic information (Xing et al., 2017; Wu et al., 2018; Xu et al., 2021b) or conversation disentanglement to select the proper response (Jia et al., 2020; Wang et al., 2020).

There are more and more practice using powerful PrLMs as the model encoder (Zhang et al., 2021, 2020a; Zhu et al., 2020) like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), ALBERT (Lan et al., 2020) and ELECTRA (Clark et al., 2020). Considering task domain difference from the general corpus for PrLM pre-training, recent studies start to conduct post-training on target multi-turn dialogue datasets to incorporate in-domain knowledge (Whang et al., 2020; Lu et al., 2020; Gu et al., 2020; Xu et al., 2021a; Whang et al., 2021). Whang et al. (2020) conduct post-training of MLM and NSP tasks as BERT. Rather than using the same tasks as PrLMs, Xu et al. (2021a) and Whang et al. (2021) both considers auxiliary tasks through post-training to enhance response selection.

Although the PrLMs which are trained on plain text have learned contextual semantic representation from token-level or sentence-level pre-training tasks like MLM, NSP, they all do not consider dialogue related features like speaker role, continuity and consistency. Despite some existing works (Xu et al., 2021a; Whang et al., 2021) considers that when conducting post-training, they are limited to a specific domain. (Wolf et al., 2019; Zhang et al., 2020b; Henderson et al., 2020; Bao et al., 2020) train on open-domain conversational data like Reddit for response selection or generation tasks, but they are limited to original pre-training tasks on plain text and ignore the dialogue related features. Besides, Wu et al. (2020) and Li et al. (2020) conduct task-specific training on collected dialogue corpora, but they also suffer from biased and limited amount of dialogue data.

Different from all the previous studies, we still make an attempt in obtaining a general-purpose PrLM but not aiming at any specific tasks like post-training methods. Meanwhile, our proposed dialogue-oriented pre-training enables the resulted PrLMs to especially capture dialogue related features in a general way.

3 Dialogue-oriented Pre-training

For dialogue-oriented pre-training, we split and sample sentences as ”utterances” from the general Wikipedia corpus to simulate dialogue-like features. We design three dialogue-oriented pre-training strategies (i.e., Insertion, Deletion, Replacement) to jointly learn dialogue related char-

(a) Insertion (b) Deletion (c) Replacement

Figure 1: Three dialogue-oriented pre-training strategies.

acteristics based on the plain PrLMs. A special token `[SOT]` is added before each ”utterance”, which tells that it is a start of a turn and matches the realistic scene of turn shift. The three tasks use the embedding of `[SOT]` to represent each utterance and conduct targeted pre-training, which enables `[SOT]` to learn dialogue related representation about speaker-awareness, continuity and consistency respectively. Figure 1 shows the overview of the three strategies.

Insertion In a real scenario, the speaker role might shift or not for each turn as a conversation goes on. Two speakers may carry out a conversation in turn or one speaker may continuously shoot multiple utterances. Considering a conversation session of four sentences between speaker A and B, we consider three possible cases: AABB, ABAB ABBA. The next time A speaks will happen after 0,1, or 2 turns from the last time. To enable Dialog-PrLM aware of the speaker role information, we should first simulate a two-party conversation on Wikipedia. We sample two continuous sentences $\{u_{A1}, u_{A2}\}$ in one paragraph of an article as the two utterances of A, and sample two continuous ones $\{u_{B1}, u_{B2}\}$ in the following paragraph of the same article as what B says. Sampling from the same article is to ensure they are talking about one topic in general, which is in line with the realistic scenario and increases the difficulty of prediction. The ”continuous” sentences simulate that A continues to express his opinion after being interrupted by B. We insert u_{A2} into $\{u_{B1}, u_{B2}\}$, and add `[SOT]` before each utterance. We will not disrupt the utterance order inside one speaker, and also keep the overall order that A first then B. In this way, we can get three cases mentioned above. One possible input case is listed here:

$$X_{ins} = \texttt{[CLS][SOT]}u_{A1}\texttt{[SOT]}u_{B1}\texttt{[SOT]}u_{A2}\texttt{[SOT]}u_{B2}\texttt{[SEP]}$$

The insertion task is to predict the next utterance of A. The whole sequence is encoded by PrLM, and we calculate the cosine similarity of the `[SOT]` embedding of u_{A1} with the other three utterances as matching scores to predict the u_{A2}. These three scores are passed to a softmax layer and use cross entropy as the insertion loss $\mathcal{L}_{ins}$.

Deletion The plain pre-training tasks like MLM, NSP or SOP of PrLMs just enable the model to learn token-level or sentence-level semantic information, and they fail to catch dialogue related signals like continuity, which also helps to choose the answer that is coherent with context. We sample continuous k sentences $\{u_1, u_2, \cdots, u_k\}$ from one paragraph and randomly delete u_i from the first $k-1$ (We do not choose u_k, as there is no `[SOT]` after u_{k-1}). The input sequence of the PrLM is:

X_{del} = `[CLS]` `[SOT]` $u_1 \cdots$ `[SOT]` u_{i-1} `[SOT]` $u_{i+1} \cdots$ `[SOT]` u_k `[SEP]` `[SOT]` u_i `[SEP]`

We append u_i at end and use `[SEP]` for separation. Similarly, we calculate the cosine similarity of the `[SOT]` embedding of u_i with the other remaining $k-1$ utterances to predict the `[SOT]` of u_{i+1}, where u_i should be inserted back. These $k-1$ scores are passed to a softmax layer and use cross entropy as the deletion loss $\mathcal{L}_{del}$.

Replacement The replacement task is to make Dialog-PrLM recognize the inconsistent utterance within a dialogue session, so that it will select the proper response which is consistent with the context in both style and context. Similar to deletion, we sample continuous k sentences $\{u_1, u_2, \cdots, u_k\}$ from one paragraph, and then we sample one sentence u_r from another article, which is used to replace a randomly chosen u_i in $\{u_1, u_2, \cdots, u_k\}$. The input sequence is:

X_{rep} = `[CLS]` `[SOT]` $u_1 ...$ `[SOT]` u_{i-1} `[SOT]` u_r `[SOT]` $u_{i+1} \cdots$ `[SOT]` u_k `[SEP]`

Each `[SOT]` is gathered after encoding, and passed to a linear layer to get a score:

$$score_{u_j} = W_r E_j + b_r$$

where $j = 1...i-1, r, i+1, ...k$, and W_r, b_r are trainable parameters. E_j is the embedding of the jth `[SOT]`. These k scores are passed to a softmax layer and use cross entropy as the replacement loss $\mathcal{L}_{rep}$.

We adopt multi-task learning and define the final dialogue-oriented pre-training loss $\mathcal{L}_{gen}$ as:

$$\mathcal{L}_{gen} = \mathcal{L}_{ins} + \mathcal{L}_{del} + \mathcal{L}_{rep}$$

4 Use of Dialogue-oriented Pre-training

Our Dialog-PrLM may be used in terms of domain fine-funing or multi-task learning: (1) Domain fine-tuning: Our Dialog-PrLM is fine-tuned on the target response selection task. (2) Specific post-training: Our pre-training strategies are slightly adjusted and applied to specific multi-turn dialogue datasets. (3) Domain multi-task learning: the target response selection task jointly learns with the three auxiliary post-training tasks in (2) on Dialog-PrLM.

4.1 Domain Fine-tuning

After our dialogue-oriented pre-training, the target response selection task can be fine-tuned on our Dialog-PrLM. We denote the dataset as $D = \{(C, R, Y)_k\}_{k=1}^N$, where C is dialogue context, and R is the candidate response, and $Y \in \{0, 1\}$ is the label indicating whether R is a proper response for C. Besides, $C = \{U_1, ..., U_n\}$ and $U_i, 1 \leq i \leq n$ is the i-th utterance in context C. We concatenate all utterances $\{U_i\}_{i=1}^n$ as well as the response R and add `[SOT]` before each to represent the following sequence:

X = `[CLS]` `[SOT]` U_1 `[SOT]` $U_2 ...$ `[SOT]` U_n `[SEP]` `[SOT]` R `[SEP]`

With the pre-training, Dialog-PrLM becomes effectively capable of representing each utterance. Therefore, rather than directly using `[CLS]`, we pass all embeddings E of `[SOT]`s to GRU to model sequential interaction of the context and response, whose final hidden state H is used for generating matching score s for C and R:

$$H = \mathrm{GRU}(E), \\ s = \mathrm{sigmoid}(WH + b)$$

where $E \in \mathbb{R}^{(n+1)\times d}, H \in \mathbb{R}^d$, and $W \in \mathbb{R}^d, b \in \mathbb{R}$ are trainable parameters. The response selection loss $\mathcal{L}_{fine-tune}$ is:

$$p(Y \mid C, R) = sY + (1-s)(1-Y)$$
$$L_{fine-tune} = -\frac{1}{N} \sum_{(C,R,Y)\in D} \log(p(Y \mid C, R))$$

4.2 Specific Post-training

Because the target dataset usually concentrates on a specific domain, existing works tend to introduce self-supervised post-training on the target domain in order to incorporate the in-domain knowledge. Here we can also apply the three strategies to the target multi-turn dialogue dataset as self-supervised auxiliary tasks, which jointly learn with the response selection task in Section 4.1.

To conduct the three auxiliary tasks, we should first sample from multi-turn dialogues to build post-training datasets. For the insertion task, there is a little difference from that in Wikipedia. We randomly choose k continuous utterances $\{u_1, u_2, \cdots, u_k\}$ from a dialogue, and fix u_1 but randomly insert u_2 to any interval among $\{u_3, \cdots, u_k\}$. The input sequence is:

X'_{ins} = `[CLS]` `[SOT]` u_1 `[SOT]` $u_3 \cdots$ `[SOT]` u_i `[SOT]` u_2 `[SOT]` $u_{i+1} \cdots$ `[SOT]` u_k `[SEP]`, We calculate the cosine similarity of the `[SOT]` embedding of u_1 with the other following utterances as matching scores to predict the u_2. The loss is denoted as $\mathcal{L}'_{ins}$. Considering the following turn (u_2) tends to be more related to u_1 compared with the next utterance of u_1's speaker (denoted as u_t), we do not predict u_t as what we do in Wikipredia. But they are both expected to recognize the most related utterance with u_1, which helps select the proper response.

For the deletion and replacement tasks, we sample continuous k utterances from one dialogue, and conduct deletion or replacement in the same way as Wikipedia. The post-training losses for both tasks on the target domain are denoted as $\mathcal{L}'_{del}, \mathcal{L}'_{rep}$ respectively.

4.3 Domain Multi-task Learning

We apply the multi-task learning framework on the target domain on our Dialog-PrLM. Carried with dialogue related features from the general corpus, Dialog-PrLM is expected to learn from the target domain together with the target task. We train the response selection task in the same way as 4.1, and denote the loss as $\mathcal{L}'_{reselect}$. The final loss is to sum up response selection loss and the three auxiliary task losses:

$$\mathcal{L}_{final} = \mathcal{L}'_{ins} + \mathcal{L}'_{del} + \mathcal{L}'_{rep} + \mathcal{L}'_{reselect}$$

5 Implementation of Dialogue-oriented Pre-training

For dialogue-oriented pre-training, we sample train and valid datasets for the insertion, deletion and replacement tasks on both English and Chinese Wikipedia. To prevent information leakage (e.g. the model peeks at the correct utterance order from deletion samples when conducting replacement), we divide all the articles equally into three disjoint equal sets to sample from for the three tasks respectively. Data statistics are in Table 2.

Statistics	English		Chinese	
	Train	Valid	Train	Valid
#articles/task	330k	10k	67k	20k
Insertion	1.5M	47k	638k	189k
Deletion	1M	31k	508k	146k
Replacement	1M	32k	542k	160k

Table 2: Statistics for dialogue-oriented pre-training.

For English Wikipedia (totally 1,060,131 articles), we sample from 330,000/10,000 articles for training/evaluation respectively for each task. To ensure data quality, we omit the ”References” and ”Literature” part. For insertion, we sample twice disjointly from one paragraph which has more than 4 sentences, and then sample twice from the next satisfactory one to construct two training samples, which goes on until the end of an article. For deletion and replacement, we sample k continuous sentences as a training sample from each paragraph with more than k sentences. We limit the maximum words of each sample to 400 to prevent overflows after tokenization.

For Chinese Wikipedia (totally 262,405 articles), we sample from 67,468/20,000 articles for training/evaluation respectively for each task. As Chinese corpus is much smaller than the English one, we sample disjoint k continuous sentences as much as we can from each paragraph with more than k sentences for the deletion and replacement tasks. As to insertion, we conduct sampling the same way as English. The maximum length of each sample is limited to 450.

6 Experiments

6.1 Datasets

For the target response selection selection task, our Dialog-PrLM is fine-tuned on three widely used benchmark datasets: (1) **E-commerce Corpus** (Zhang et al., 2018): includes conversations between customers and shopkeepers from the largest e-commerce platform Taobao in China. (2) **Douban Corpus** (Wu et al., 2017): consists of multi-turn conversations from the Douban group, which is a popular social networking service in China. (3) **Ubuntu Corpus (v1.0)**(Lowe et al., 2015) consists of English multi-turn conversations about technical support collected from chat logs of the Ubuntu forum.

As to the three auxiliary tasks for domain multi-task learning, we conduct sampling from the batch when training the response selection task. Dialogues will be neglected if they are less than 3 utterances. Different from general pre-training, we do not require every dialogue to have at least k sentences for all the three tasks.

For evaluation, we use the same metric $R_n@k$ as previous works, which selects k best matchable candidate responses among n and calculates the recall of the true ones. We also use MAP (Mean Average Precision), MRR (Mean Reciprocal Rank), and Precision-at-one P@1 as previous works.

6.2 Experimental Settings

We work on two different PrLMs: BERT (*bert-base-uncased, bert-base-chinese*) and ELECTRA (*electra-base-discriminator, chinese-electra-180g-base-discriminator*)[1].

For our dialogue-oriented pre-training on Wikipedia, the max input sequence length is set to 512 after WordPiece tokenization. We set the learning rate as 2e-5 with a warmup proportion of 10%. The plain PrLMs are continuously pre-trained with batch size of 8 per task for BERT and 16 per task for ELECTRA. It is trained for 1 epoch and evaluated every 10000 steps. The model with the best average accuracy of the three tasks is saved as Dialog-PrLM. The pre-training experiment needs 4 nVidia RTX 2080 GPUs.

For fine-tuning on our Dialog-PrLMs, the batch size is 32 and the max sequence length is 350. The model is trained for 5 epochs and evaluated after each epoch on the three datasets and both Dialog-PrLMs. Other settings are the same as dialogue-oriented pre-training. For domain multi-task learning on our Dialog-PrLMs, the batch size is 16, and the epoch is 3 for Douban on BERT, 4 for Ubuntu on ELECTRA and 5 for other cases. Other settings are the same as fine-tuning. The k value for both pre-training and domain multi-task learning is 5. The fine-tuning/multi-task learning experiments need 1/2 nVidia RTX 2080 GPUs.

6.3 Results

To verify the effectiveness of our method, we conduct extensive empirical studies on three multi-turn dialogue benchmarks. We are aware that applying complicated matching networks, speaker embeddings (Gu et al., 2020) or other various auxiliary tasks (Whang et al., 2020; Xu et al., 2021a; Whang et al., 2021) would achieve further improvement, but to fairly evaluate the general-purpose pre-training for dialogue tasks, we still follow the standard fine-tuning procedure on Dialog-PrLM by excluding those too advanced auxiliary techniques.

BERT-[CLS]: Each utterance U_i and the candidate response R are concatenated as $[\texttt{CLS}]\, U_1 U_2 ... U_n\, [\texttt{SEP}]\, R\, [\texttt{SEP}]$ and then fed into the pla BERT model. The output embedding of [CLS] is used for classification.

BERT-[SEP]: Rather than just use [CLS], we append [SEP] to each utterance or response to represent the previous sequence: $[\texttt{CLS}]\, U_1\, [\texttt{SEP}]\, U_2 ... [\texttt{SEP}]\, U_n\, [\texttt{SEP}]\, R\, [\texttt{SEP}]$, which is then fed into the original BERT model. The output embeddings of [SEP] are gathered and fed into GRU for a matching vector like Section 4.1.

Dialog-BERT: This model conducts dialogue-oriented pre-training on the original BERT, we fine-tune on our Dialog-BERT through feeding [SOT] embeddings to GRU.

BERT+multi-task: The response selection task is trained with the three auxiliary tasks on target datasets. We also add the special token [SOT], and the only difference from Section 4.3 is that the joint learning is conducted on the original BERT.

Dialog-BERT+multi-task: As described in Section 4.3, we conduct domain multi-task learning on our pre-trained Dialog-BERT.

We also conduct fine-tuning on the English Ubuntu dataset with two dialogue related models: (1) DialoGPT (Zhang et al., 2020b) is an extension of GPT-2 that is pre-trained on Reddit data

---

w/o Insertion	64.9	83.6	97.7	59.0	63.2	45.1	27.8	46.5	83.2	82.1	90.5	97.8
w/o Deletion	64.2	83.7	97.5	59.0	63.1	44.7	27.5	45.9	83.8	82.1	90.6	97.8
w/o Replacement	64.4	84.7	97.6	59.8	63.6	45.4	28.4	46.8	83.6	82.1	90.4	97.8

Table 4: Ablation results for dialogue-oriented pre-training.

from scratch. (2) TOD-BERT (Wu et al., 2020) is trained on a combination of 9 task-oriented dialogue datasets over BERT and incorporates response selection objective. Experiments on ELECTRA are conduct in the same way with BERT. The results are in Table 3. Below PrLM- denotes BERT or ELECTRA.

Compared to the unsatisfactory results from both DialoGPT and TOD-BERT, it demonstrates the powerfulness and universities of our proposed dialogue-oriented pre-training. Compared with PrLM-[CLS], PrLM-[SEP] performs better in general except a little decrease in Ubuntu and Douban on ELECTRA, which shows that modelling the sequential interaction of the dialogue context and response helps improve performance.

After conducting the dialogue-oriented pre-training on Wikipredia, our Dialog-PrLM achieves further improvement on the three datasets and the two PrLMs, which shows that the three targeted training strategies enables the `[SOT]` token in Dialog-PrLM to grasp dialogue related nature (e.g. speaker-awareness, continuity, consistency) at the same time, so that it is more capable of representing an utterance compared with `[SEP]` in the plain PrLM (PrLM-[SEP]).

When we train the response selection task jointly with the three auxiliary tasks on target datasets, the domain multi-task learning on our Dialog-PrLM (Dialog-PrLM+multi-task) is still always performing better than on the plain PrLM (PrLM+multi-task). Having re-learned broader representation on general corpus, domain post-training further incorporates `[SOT]` with dialogue related feature from in-domain multi-dialogues and thus helps choose the correct response.

Compare PrLM-[SEP] with PrLM+multi-task, Dialog-PrLM with Dialog-PrLM+multi-task, domain multi-task learning indeed achieves improvements due to its incorporated in-domain dialogue related knowledge, which verifies the effectiveness of our proposed three strategies when applying to domain multi-turn dialogue datasets.

In conclusion, conducting dialogue related feature pre-training with our proposed three strategies on Wikipredia (Dialog-PrLM) helps achieve improvements when fine-tuning, and it will further improve when applying these strategies to domain multi-turn dialogues (Dialog-PrLM+multi-task).

7 Analysis

7.1 Ablation Study

In order to investigate the performance of each strategy, we conduct ablation experiments for both pre-training and domain multi-task learning. Results are shown in Tables 4 and 5 respectively.

The results in Table 4 indicate that the insertion, deletion and replacement tasks jointly contribute to the final increase. Influence on Ubuntu seems less than that on Douban and E-commerce, as the Ubuntu corpus contains many terminologies that do not usually appear in general corpora (e.g., apt-get, lsmod and grep) (Whang et al., 2020), so according to BERT+multi-task in Table 3, conducting domain post-training is more effective.

We also do ablation study for Douban on Dialog-BERT in Table 5 to explore the performance of three auxiliary tasks when applying to the target multi-turn dialogue datasets. Similarly, removing any part leads to worse performance, showing the necessity of each task.

Model	Douban				
	MAP	MRR	P@1	R_{10}@1	R_{10}@2
Dialog-BERT+multi-task	60.9	64.9	48.0	30.0	47.9
w/o Insertion	58.2	62.5	44.8	27.4	45.0
w/o Deletion	60.6	64.6	47.1	29.1	48.8
w/o Replacement	60.2	64.1	46.3	29.0	48.5

Table 5: Ablation for domain multi-task learning.

7.2 Utterance Representation Test

We have added a special token `[SOT]` before each utterance or response to represent the following sequence. After pre-training on Wikipedia on PrLMs, `[SOT]` of our Dialog-PrLM is expected to obtain the respective utterance representation through the three dialogue-oriented strategies.

Dialogue Context & Response	`[CLS]`	`[SEP]`	`[SOT]`
Douban			
1: *how about going to Xitang during the Spring Festival?*	0.8424	1	-0.4001
2: *I also want to go that time, but it will be more expensive for accommodation than weekend.*	0.9364	1	**0.8666**
3: *have you contacted about where to live?*	0.9694	1	-0.2902
4: *if you haven't booked accommodation, it seems very difficult to book during the Spring Festival.*	0.9495	1	-0.1643
5: *will there be many people, or no shops open during the Spring Festival?*	0.9024	1	-0.5064
6: *it's okay if no stores open. i enjoy quiet and just want somewhere to drink and eat.*	0.9737	1	-0.1644
7: *but traffic is a hassle during the Spring Festival.*	0.9684	1	-0.6139
8: *there are several people in this group xxx who go to Xitang, you can join them to cook together*	0.8865	1	**0.8840**
Response: *is there anyone in Beijing, let's go together sometime.*			
Ubuntu			
1: *hello*	0.9279	0.9956	-0.9791
2: *what is the best server for update ubuntu*	0.8027	0.9957	-0.9653
3: *whichever is closest to you generally they all have the same content*	0.9738	0.9949	-0.8846
4: *have you read the documentation for the script*	0.9643	0.9966	-0.2836
5: *i know thats the error does the script s documentation indicate what modules or packages are quried to run it*	0.8176	0.9964	**0.5233**
6: *u can tell me how to install python modules and i will install the modules in the python script*	0.8940	0.9977	**0.5287**
7: *where did you get this script*	0.9328	0.9980	**0.5105**
Response: *can you be more specific what is this script supposed to do import logging*			
E-commerce			
1: *please help me issue an invoice with the title of xxx.*	0.8864	1	-0.9791
2: *okay.*	0.8726	1	-0.8137
3: *ok, is it difficult to package?*	0.9249	1	-0.6777
4: *not at all.*	0.7843	1	-0.9359
5: *please send me a picture tutorial later, i will do it myself.*	0.8648	1	-0.3668
6: *okay, if you have any question, please feel free to consult us.*	0.9381	1	0.3211
7: *fine, can you deliver it today?*	0.9265	1	**0.9899**
8: *yes, please check the delivery* address.	0.9240	1	**0.7117**
9: *correct.*	0.6862	1	**0.5704**
10: *ok, if pay before 16:00 today, it will be delivered today, otherwise it will be delivered next day.*	0.9550	1	**0.5866**
11: *i've already paid.*	0.8663	1	**0.0622**
Response: *ok, we will deliver the goods as soon as possible today, please wait at patience.*			

Table 6: Examples from test sets of Douban, Ubuntu and E-commerce respectively. Similarity scores $\geq$ 0.5 of our Dialog-BERT(`[SOT]`) are bold, indicating the corresponding utterances are considered relevant to the response.

To explore the semantic information of `[SOT]` of our Dialog-BERT, we calculate the cosine similarity of the correct response to each utterance in the dialogue context (`[SOT]`). Table 6 lists examples from the three target datasets respectively. For comparison, we use BERT to encode each utterance or response and use `[CLS]` for calculation (`[CLS]`). We also concatenate utterances and response with separation of `[SEP]` on BERT and then split to calculate similarity (`[SEP]`).

We observe that for all examples, both BERT(`[CLS]`) and BERT(`[SEP]`) can not discriminate which utterance is related with the correct answer. All the utterances are treated the same way including the irrelevant ones, which leads to much noise for response selection.

After conducting the dialogue-oriented pre-training on Wikipedia, Dialog-BERT learns a stark sense of ”irrelevant” and ”relevant”. It is able to concentrate on the most critical utterances and distinguish from the irrelevant ones by a large margin. For the example of Douban, Dialog-BERT realizes that the second and last utterance are most relevant. The response asks for someone to travel together, and is related to the second utterance which expresses a wish to go and the last one which gives a group to travel together. Dialog-BERT ignores the noise about accommodation and transportation, and is able to select related utterances among noise rather than just use the last one. For Ubuntu, Dialog-BERT concentrates on utterances about script and ignores the previous background information. For E-commerce, it recognizes the related last few utterances about delivery, and ignores the packaging information before. From examples from target datasets, our Dialog-BERT has absorbed related knowledge from our proposed dialog-oriented pre-training. The `[SOT]` could better represent each utterance, which can be utilized in tasks about representation like multi-party dialogue disentanglement.

8 Conclusion

This paper presents a novel general-purpose solution for dialogue tasks with pre-trained language models. To fill the gap between a detailed task and the LM task of PrLM, we propose dialogue-oriented pre-training on large scale of artificially built dialogue data which lets the resulted Dialog-PrLM enjoy both merits of general-purpose and capturing key dialogue related features including speak awareness, continuity and consistence. Our models are evaluated on three benchmark response selection datasets and achieve consistent performance improvement over the plain PrLMs.

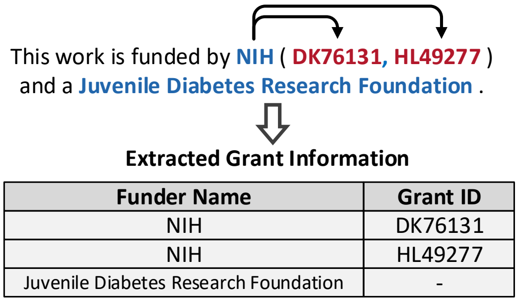
Abstract

As part of scientific articles, grant information refers to funder names and their corresponding grant numbers. Extracting such funding information from articles is of significant importance to both academic and funding bodies. The studies on this topic face two major challenges: 1) no high-quality benchmark datasets; and 2) difficulties in extracting complex relationships between funders and grantIDs. In this paper, we present a novel pipeline framework called GrantRel, which consists of a funding sentence classifier, as well as a joint entity and relation extractor. For this purpose, we manually label two high-quality datasets called Grant-SP and Grant-RE, respectively. In addition, our relation extraction (RE) model uses both position embedding and context embedding in an adaptive-learning way. The experiment results have demonstrated that our model outperforms several state-of-the-art BERT-based RE baselines as higher as 6.5% of F1 scores against the PubMed Central (PMC) test set and 3.5% of that against the arXiv test set.

1 Introduction

As an element of scientific articles, grant information generally includes funder names, grant numbers, and their relations. Specifically, a funder name refers to an agency, organization, or program which provides financial support for the research. A grantID is a numerical string by which to distinguish one grant from another. Such grant source information should be automatically identified. The reasons for this are as follows: (a) The funding bodies need to track their funding statuses; (b) For the academic, the impact of funding agencies in the scientific literature can be measured, and agencies actively supporting specific directions can be identified; and (c) The literature management systems require the funding register information. Therefore, a systematic framework that is capable of automatically extracting grant information from papers is needed.



This work is funded by NIH (DK76131, HL49277) and a Juvenile Diabetes Research Foundation .

Extracted Grant Information

Funder Name	Grant ID
NIH	DK76131
NIH	HL49277
Juvenile Diabetes Research Foundation	-

Figure 1: In this sentence, *DK76131* and *HL49277* are two grant numbers of the agency funder *NIH*. The *Juvenile Diabetes Research Foundation* is another funder.

Generally, authors would express their acknowledgments in the papers if their research receives funding. Based on this fact, an extraction should start with selecting the funding sentences from an acknowledgment. To train such a classifier, we manually build a dataset named Grant-SP with 1402 sentences. After that, a relation extraction (RE) model is applied on funding sentences to identify grant entities and their relations. Specifically, a funder name entity and a grant number entity are viewed as a subject and an object in a relation triplet, respectively. For accurately extracting grant information via RE from scientific articles,

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2674–2685
August 1–6, 2021.

there are, however, two major challenges: 1) no high-quality RE benchmark datasets; and 2) difficulties in extracting complex relationships between funding organizations and grantIDs by using RE models.

The 2017 BioASQ challenge (Nentidis et al., 2017) is about building a system that extracts the funding information from a benchmark dataset on the full text of biomedical papers. From this dataset, only 107 agencies, however, are required to be identified as funder names such as NIH or CIHR. For example, the winning systems on the challenge such as GrantExtractor (Dai et al., 2018) cannot extract the grant funders beyond 107 agencies such as NASA or JSPS. For overcoming this limitation, we propose a manually-crafted dataset Grant-RE which covers nearly 2k different funder names.

There often exist the complex, many-to-many relationships between funder names and grantIDs. This fact makes it difficult to identify such complex relationships by using a RE model. In addition, the Grant-RE dataset has only two types of entities but with a higher frequency in a sentence, compared with common REs. For example, we count the number of entities with the highest number of occurrences in each sentence of CoNLL04 (Roth and Yih, 2004). The average number of such entities is 2.1, while the number is 2.8 in our Grant-RE dataset. This would be challenging to build correct relations between two entities. Further, a grantID or a funder name could even present independently (see Figure 1). To address this challenge, our GrantRel framework includes a novel joint entity and RE model. This model starts with using the powerful encoding layer of BioBERT (Lee et al., 2019), and can jointly extract funders, grantIDs, and their relations by considering grant relation features. It has been demonstrated that our RE model outperforms the state-of-the-art RE baselines in Grant-RE by a large margin.

In summary, this paper has the following contributions: (a) We propose a novel framework called GrantRel that automatically extracts grant information from academic papers. The RE model in GrantRel is designed to accurately extract both grant number, funder name, and their relation by combining the location of grant information in a sentence and its context embedding in an adaptive way. (b) By manually labelling funding sentences, we retrieved the papers from PubMed Central (PMC) and arXiv, and created a classification dataset called Grant-SP with 1402 sentences for training, as well as a grant RE dataset called Grant-RE with 3331 sentences. (c) Extensive experiments have been conducted to test the performance of the whole framework, and to compare RE models with the RE baselines in both biomedical (PMC) and universal (arXiv) domains.

To the best of our knowledge, this is the first work on reporting a benchmark dataset[1] and model for extracting general grant information by the supervised RE.

2 Related work

The prior studies have addressed the problem of grant information extraction with a limited capability by traditional machine learning methods. A naive Bayes method (Kim et al., 2009) was used to locate the grant support (GS) zone from an article text, followed by inferring GS types with a pattern matching method. As such. only fourteen GS types can be identified. Zhang et al. (2009) used a semi-supervised method to detect grant-related zones from online medical articles. Gross et al. (2016) proposed a rule-based model for extracting metadata (grant number and grant sponsor) from articles. All these methods do not establish a specific relationship between a funder and a grant number.

Recently, Dai et al. (2018) built a pipeline system for grant information extraction. They first selected funding sentences by relying on manually designed features, then extracted grantIDs by using the BiLSTM-CRF tagger, finally identified the agencies by applying a multi-class classifier to each grantID with manually designed features. However, this method is still limited, because it cannot recognize new grant agencies other than 107 designated ones. In contrast, GrantRel learns a joint model on the name recognition of funder and grantID, and extraction of their relationship. As such, it can handle new funder names very well.

Traditionally, RE is achieved through a pipeline (Zelenko et al., 2003; Chan and Roth, 2011; Zhou et al., 2005) with two phases: entity recognition and relation classification. Since the two phases may benefit from the use of correlated signals, research for joint entities and relation extraction have attracted more attention. Early work of joint approaches uses feature-based models (Yu and Lam, 2010; Miwa and Sasaki, 2014). Recently, neural network-based models (Zeng et al., 2018; Li et al.,

---

[1] https://github.com/Eulring/GrantRel

2019; Dai et al., 2019; Fu et al., 2019), especially the BERT-based (Devlin et al., 2019) models (Wei et al., 2020; Eberts and Ulges, 2019; Wang et al., 2020) that replace the manually constructed features with learned representation, have achieved the considerable success in completing the RE task. Following this idea, our RE model uses BioBERT (Lee et al., 2019) as an encoding core. Inspired by the CasRel (Wei et al., 2020) further, our RE model establishes a relation as a function that maps funder to grantID. Since an ordinary model cannot accurately distinguish the complex relationship between multiple funders and grantIDs, the features that can describe the interaction between entities become critical. Therefore, we use relative position embedding and localized context embedding (Eberts and Ulges, 2019), which make a significant improvement. In addition, we design a mechanism by adaptively integrating the two embeddings to obtain better performance.

3 Dataset description

Although BioASQ 5c provides a dataset of grant information extraction, it has three serious drawbacks, 1) with only 107 agency names used in the labels, many common funder names are ignored. In fact, there are nearly 57000 different funder names in a funder name database downloaded from crossref [2]; 2) normalized agency names and the corresponding grantIDs are provided without specifying their exact positions in the articles, which is inconvenient for supervised RE training; 3) the quality of annotation is limited (Dai et al., 2018). To address these issues, we therefore manually built two datasets, namely, Grant-RE and Grant-SP, for the two modules in our framework.

3.1 Dataset: Grant-RE

Grant-RE is the dataset for the RE model. We downloaded articles with the original xml format from open access subset of PMC [3]. The raw text from the acknowledgement section of an article was then parsed into readable paragraphs, and the sentences were split by using NLTK[4] tools. We manually selected the funding sentence and labelled grant information. A grant relation is represented as four integers for the intervals of a funder entity and a grantID entity.

As given in Table 1, we present the statistics of the train/dev/test splits for the grant information extraction dataset. There are two versions of test splits. One is from PMC, which is as same as train/dev split, while another from arXiv is used for conducting evaluations of our approaches on the universal domain. To ensure quality, the GrantRE dataset was annotated by 4 well-trained annotators, with each sentence being annotated twice by different annotators. For those sentences having different annotations, we will seek advice to experts to decide their final annotations. Besides, the test data splits were repeatedly checked 3 times.

	train	dev	test	test^{a}
# sentence	2104	477	500	350
# funder entity	4592	1192	1297	706
# grantID entity	4195	1084	1116	646
# grant relation	4107	1097	1179	684

Table 1: Statistics of Grant-RE. Test, train, and dev sets are from PMC. The test^{a} is from arXiv papers.

3.2 Dataset: Grant-SP

Unlike Grant-RE, we sampled sentences from all sections in a paper to annotate a funding sentence classification dataset. Because the numbers of positive and negative sentences were unbalanced, we discarded most of the negative sentences in the train/dev set to accelerate the training.

The test set in Grant-SP is used not only for the classifier evaluation, but also for the whole framework evaluation. For building the test set, we strictly followed our framework pipeline: for each article, we kept all negative sentences, and tagged grant information for positive sentences. Because the classifier has a high recall, when labeling the test split, we borrow the outputs from trained models for the auxiliary reference. For a sentence that the classifier considers to be positive and the RE model can also extract information, we manually relabel it. In Table 2, we report the statistics of train/dev/test splits.

	train	dev	test
# sentence	908	282	16069
# positive	158	51	101
# articles	-	-	50

Table 2: Statistics of Grant-SP

4 Methodology

4.1 Framework

As shown in Figure 2, the left side illustrates the overall workflow of our GrantRel. Given prepossessed sentences from raw articles, the sentence classification module selects the sentences that may contain grant information. Without this step, the framework may suffer from low precision. After this, the RE module will extract grant information.

4.2 Identification of funding sentences

Our models use a pre-trained BioBERT (Lee et al., 2019) to encode context information. Suppose sentence $\mathbf{x}$ is first tokenized into byte-pair encoded (BPE) tokens (Sennrich et al., 2016) $x = \{x_1, x_2, ..., x_l\}$ with length l. BioBERT takes it as an input and outputs a length of $l+2$ embedding sequence $\boldsymbol{e} = \{\boldsymbol{e}_{CLS}, \boldsymbol{e}_0, \boldsymbol{e}_1, ..., \boldsymbol{e}_l, \boldsymbol{e}_{SEP}\}$. The additional embedding $\boldsymbol{e}_{CLS}$ captures the whole sentence context. A Logistic Regression is then used to calculate the probability:

$$p_{sent} = \sigma(W_{sent}\boldsymbol{e}_{CLS} + b_{sent}) \quad (1)$$

Here the $\sigma(\cdot)$ is the sigmoid function, and $\{W_{sent}, b_{sent}\}$ are trainable parameters.

4.3 Joint entity and RE

A grant relation consists of a funder (subject eneity s) and grantID (object entity o). Given input sentence $\mathbf{x}$ and its tokens x, we use T to represent the set of all grant relations of this sentence. The likelihood of all relations $T = \{(s, o)\}$ in this sentence can be written as:

$$\prod_{(s,o)\in T} p(s, o|x) = \prod_{s\in T}\left[p_{fd}(s|x)\prod_{o\in T|s} p_{gr}(o|s, x)\right] \quad (2)$$

In Eq.(2), the role of $p_{fd}(s|x)$ acts as a subject tagger that recognizes funder name entities in the sentence, where $s \in T$ denotes a subject appearing in T. $p_{gr}(o|s, x)$ is to identify the object with only having a relation with the specific s. $o \in T|s$ is the object in T led by subject s. Indeed, this extracting scheme allows us to extract the grantID at once for each funder name. To handle independent grantIDs, we add an additional probability item p_{id} to tag grantID. As such, the overall likelihood of grant information in x is:

$$\prod_{s\in T}\left[p_{fd}(s|x)\prod_{o\in T|s} p_{gr}(o|s, x)\right]\prod_{o\in T} p_{id}(o|x) \quad (3)$$

4.3.1 Funder name detection

The low-level tagging module aims to detect all possible funder entities from x. Similar to sentence classification, BioBERT (Lee et al., 2019) generates the tokens representation $\boldsymbol{e}$. Using the IOB tagging scheme, we predict the IOB tag y for each token. A specific operation on the i^{th} token is as follow.

$$y_i = \text{softmax}(W_{fd}\boldsymbol{e}_i + b_{fd}) \quad (4)$$

4.3.2 Grant relation detection

A funder name is either extracted at the first phase or provided by the dataset during the training. The conditional grant number tagger distinguishes the grantID that only belongs to this particular funder name from other candidates. We first use a fused BERT embedding $\boldsymbol{e}_{fd}$ to represent this funder name:

$$\boldsymbol{e}_{fd} = f_{fd}(\boldsymbol{e}, \boldsymbol{u}_{fd}) \quad (5)$$

where $\boldsymbol{u}_{fd} = [u^{start}_{fd}, u^{end}_{fd}]$ is the position boundary of a funder name entity. Since the length of the funder name can vary, function $f_{fd}(\cdot)$ is used to produce a fixed-size feature for funder names. On choosing $f_{fd}(\cdot)$, we use the average pooling of the entire entity span. For each token, the grant relation module classifies tag $\boldsymbol{z}$ as :

$$z_i = \text{softmax}(W_{gr}[\boldsymbol{e}_{fd}, \boldsymbol{e}_i, \boldsymbol{e}_{gr}] + b_{gr}) \quad (6)$$

where $\boldsymbol{e}_i$ is the encoding of token x_i, and $\boldsymbol{e}_{gr}$ is the grant relation feature explained below (Senction 4.4).

4.3.3 GrantID detection

If a funder name is undetected in the previous step, we will miss the corresponding grant numbers. In addtion, some grant numbers even occur independently for some reasons, such as a sentence segmentation error. For extracting the complete grant information, an auxiliary item $p_{id}(o|x)$ is used to tag all grantIDs . We view the detection of grantIDs as a special case of the grant relation detection by using trainable vector $\hat{\boldsymbol{e}}$ to represent all funder names.

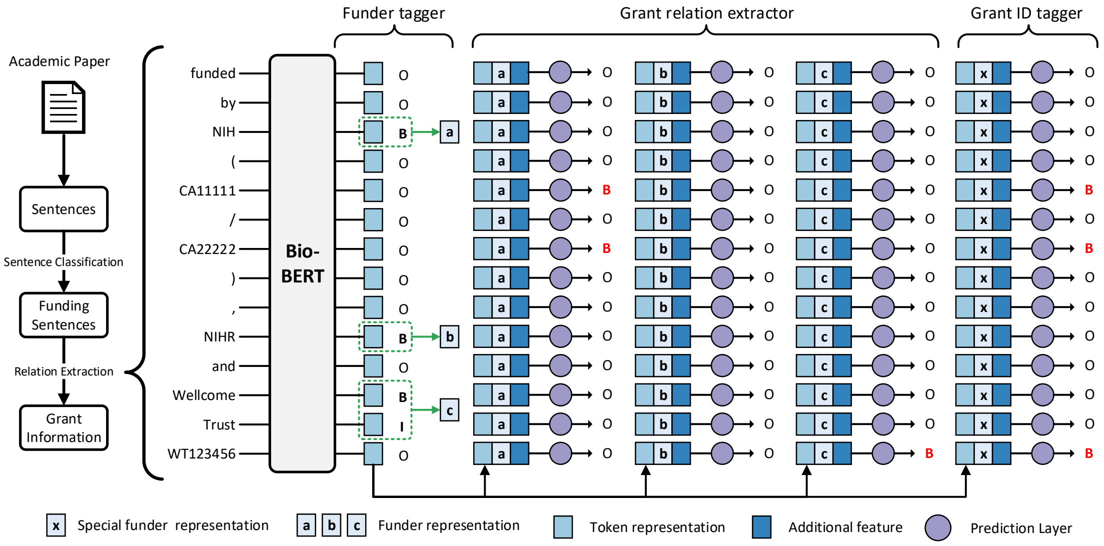

Figure 2: The left side is the grant information extraction pipeline, with the RE model in GrantRel on the right side. For convenience, words are presented without tokenization. The three funders in the sentence are detected by the funder tagger. For each funder name, its corresponding grantID is matched by predicting its label in each position. Note that an ID tagger is able to find all grant numbers at once.

This means that all grantIDs in the sentence should match this special funder name. The operation on the i^{th} token is as follows.

$$o_i = \mathrm{softmax}(W_{gr}[\hat{\boldsymbol{e}}, \boldsymbol{e}_i, \boldsymbol{e}_{gr}] + b_{gr}) \qquad (7)$$

4.4 Grant relation feature

To establish the correct connection between a grantID and a funder name, we use additional features $\boldsymbol{e}_{gr}$ other than entity representation, which characterize the relation between the funder name and the i^{th} token in x in Eq 6. These features can be captured by using information such as the span of funder $\boldsymbol{u}_{fd}$ and input context $\mathbf{x}$.

4.4.1 Position embedding

First, we use the relative distance to measure the two positions:

$$d(i, j) = min(max(-k, (i - j)), k) \qquad (8)$$

where the distance is clipped into a region of $[-k, k]$. The position of an extracted funder entity is an interval $\boldsymbol{u}_{fd}$. Some funder names have relative long spans, so it would be inaccurate to represent all the distances by a single number. We concatenate two relative distance embedding as our final position embedding:

$$\boldsymbol{e}_{pos} = [\mathrm{emb}(d(u_{fd}^{start}, i)), \mathrm{emb}(d(u_{fd}^{end}, i))] \quad (9)$$

where $\mathrm{emb}(\cdot)$ represents a learnable embedding.

4.4.2 Context embedding

We observe that the context for the funder and target token has semantic information that is helpful for establishing relationships. Therefore, we utilize $\boldsymbol{e}$ to represent context embedding $\boldsymbol{e}_{ctx}$. For example, a sentence is: *"funded by NIH (CA123456), and CIHR (R01 12111)"* During the grant relation phase, the subject funder name is *"NIH"*, the target token is *"12111"*, their localized context is the blue part of *"(CA123456), and CIHR (R01"* in the sentence. The max-pooling for encoding $\boldsymbol{e}$ of the localized context is used to generate a fix-size representation $\boldsymbol{e}_{ctx}$.

4.4.3 Adaptive embedding

A combination of two embeddings of position and context can make our model more robust. Furthermore, when the context meaning is abundantly clear, we expect the proposed model can concentrate more on the context information. According to this view, we propose a mechanism that can balance two embeddings to deal with different situations in an adaptive way:

$$\boldsymbol{e}_{gr} = \alpha \cdot \boldsymbol{e}_{pos} + (1 - \alpha) \cdot \boldsymbol{e}_{ctx} \qquad (10)$$

where α is a scalar decided by the context embedding as:

$$\alpha = \sigma(W_{ada}\boldsymbol{e}_{ctx} + b_{ada}) \qquad (11)$$

Table 3: The performance of GrantRel compared with typical RE models on the test sets of PMC and arXiv.

5 Experiments

In this section, we compare the performance of the GrantRel RE model with several RE baselines on the Grant-RE dataset. The varying degree of the improvement of the RE model with different features is also examined. Finally, the overall performance of the proposed GrantRel framework is comprehensively evaluated.

5.1 Experiment settings

In Table 3, we define **GrantRel-base** as the pure RE model without considering additional features. Compared to GrantRel-base, **GrantRel-pos** makes use of the position embedding, while **GrantRel-ctx** uses context embedding. As our ultimate model, GrantRel integrates two embeddings of position and context in an adaptive way. These models both initially encode the input by using the BioBERT pretraining. In particular, **GrantRel**$_{BERT}$ uses the BERT encoding for a fair comparison with other BERT-based baselines: **CasRel** (Wei et al., 2020) the state-of-the-art model of WebNLG (Gardent et al., 2017) and NTY(Riedel et al., 2010) dataset, and **SpERT** (Eberts and Ulges, 2019) the state-of-the-art model of CoNLL2004 (Roth and Yih, 2004) dataset. In order to use the SpERT in Grant-RE, we extend the max span size from the original one of 20 to 25. This increases the training time, but covers the widest span of funders in our dataset. Other baselines settings strictly follow the optimal settings of the original paper.

We used Pytorch to implement the deep learning models. All GrantRel models were trained by using Adam (Kingma and Ba, 2015) optimizer. During the training, the number of epochs was chosen as 30, and the learning rate dropped 20% in every two epochs with an initial learning rate of 5e-5. In addition, the distance threshold k in position embedding was set to 40, together with the batch size of 10, and the dimension of context and position embedding of 768. All of our experiments were conducted on a single GTX 1080Ti GPU.

5.2 Evaluation metrics

In this work, we use f1-score (F1), precision (Prec.), and recall (Rec.) to measure the performance of our models on extracting grant relation, grant number, and funder entities. For all the evaluations, a predicted entity is correct only if both its head and tail are correct.

Grant relation evaluation: For relation evaluation, we tested only the triplets with a complete grantID and funder name in the test dataset by excluding isolated funder names or grantIDs. This also held true for the other RE tasks.

Grant information evaluation: Grant information evaluation aims to test the overall performance for our GrantRel framework. Differing from relation evaluation, the overall evaluations include isolated funder names and grant numbers.

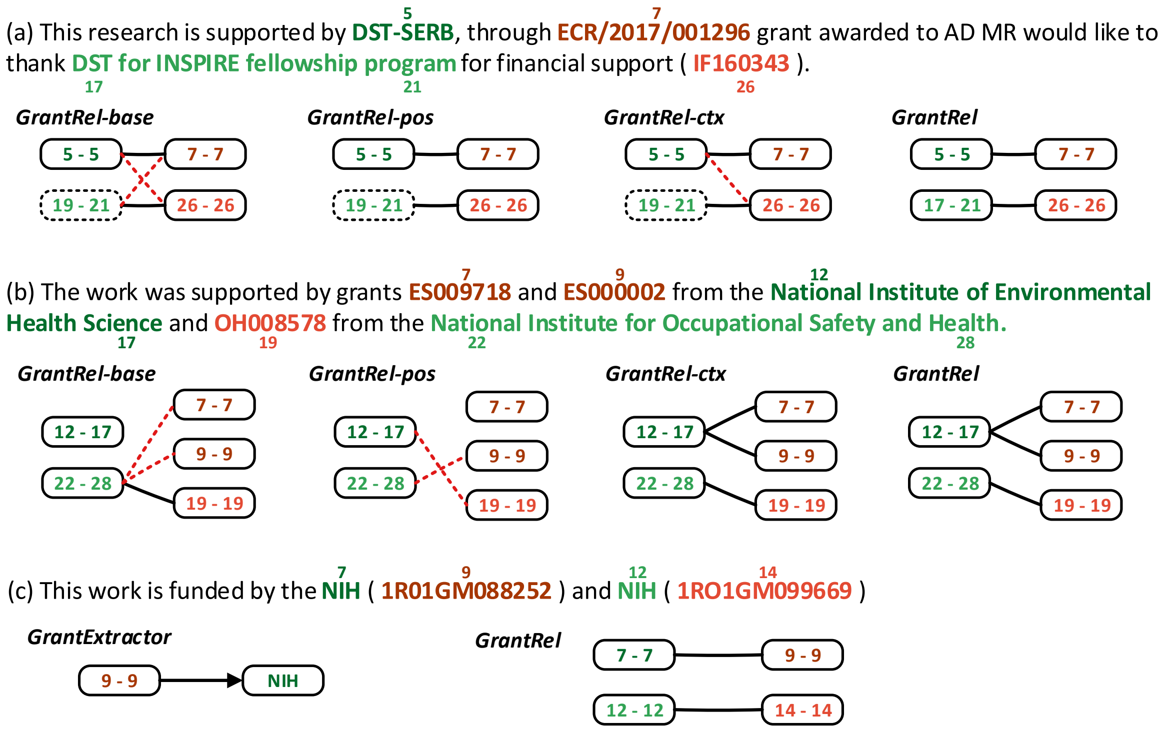

Figure 3: Outputs from different models. Each circle represents an entity, while the number in a circle represents the entity's span positions. A dotted circle indicates an output of a wrong entity span. A red dotted line indicates a wrong relationship. The arrow in case (3) means that the funder was directly inferred from GrantID. In all of these examples, GrantRel outputted correct results.

5.3 Experiment Results: Grant-RE

The experiments here focus only on the RE model, with the funding sentences provided. Main results on the Grant-RE dataset are shown in Table 3. We have four main findings. (1) GrantRel achieves the best performance on both PMC and arXiv test splits, with an increase of 3.9% and 6.5% respectively compared with other baselines. (2) Grant relation features are critically important. Without adding additional features that characterise the relationship between a funder name and a grant number, the GrantRel-base model and CasRel have a bad performance. When the position embedding was integrated (GrantRel-pos), the f1-score, however, increase significantly with 27.5% improvements. Context embedding(GrantRel-ctx) perform better than position embedding by another increase of 1.7%. SpERT using a context embedding also has considerable performance(86.3%). Further, the combination of context embedding and position embedding in GrantRel produce the best f1-score 91.2%. (3) GrantRel$_{BERT}$ perform worse than GrantRel in both test sets. Which means that BioBERT, as an encoding layer, performs better than BERT in terms of grant information extraction. The reason for this is that BERT was trained only from wiki and books, but BioBERT was trained on additional scientific papers. (4) When tested on a new domain (arXiv), the performance of all models dropped slightly. This is because most funder names in the arXiv test set are different from those in PMC.

5.4 Experiment Results: Grant-SP

Before applying relation extraction, we first identify which sentence in a given paper is grant-related by using the sentence classifier. In this experiment, two models are combined into a pipeline. If a sentence is predicted as negative by the classifier, we will exclude it from relation extraction. As we know, the best RE model from Section 5.3 is the downstream module. To verify the effect of the funding sentence classifier, we compared our GrantRel (Clf+RE) with the framework without classifier (RE), framework with key-words sentence matching (Key+RE), and framework with perfect classifier (Gold+RE), respectively. The experiment results are reported in Table 4. Since we discarded most of the negative samples in training, our funding sentence classifier had achieved a

very high recall. Compared with RE and Key+RE models, the framework with the sentence classifier achieved a significantly higher precision. Meanwhile, the sentence classifier could reduce search costs. In our experiments, the RE model could process 25 sentences per second. In contrast, our framework could process 50 sentences per second by filtering out the non-funding sentences.

5.5 Case study

We review the results from different models and select some cases for further analysis in this section.

First, we examine the results from RE models with different features in Figure 3. In case (a), only the GrantRel identified correct funder names and grant relations. The base model GrantRel-base matches each agency to all grant numbers. GrantRel-pos produced the correct relation. However, GrantRel-ctx built the wrong connection between *DST-SERB* and *ID160343*. We speculate that the context information for the entity and the ID may not work. But, the distance between the two entities is too long. As a result, only models that incorporate position information output the correct relation. In case (b), GrantRel-base still had terrible performance. For the sentences with grantIDs that are located at the front of their corresponding funders, GrantRel-pos performed poorly. Nevertheless, this case can be easily handled by considering context information as does in our framework. By analysis, we find that the base model intends to predict whether a funder is associated with numbers first. If it is, the funder will be established the relations with all found grantIDs. If not, the funder will be regarded as isolated. Context embedding can build relations in a complicated semantic situation. Position embedding is particularly helpful when context embedding is inadequate or ambiguous. In case (c), we compare our framework with GrantExtractor (Dai et al., 2018). GrantExtractor can only extract grant number *1R01GM088252* from the sentence and infer the *NIH* by this ID. However, it even misses the number *1RO1GM099669* if the char “0” is wrongly spelled as “O”. It is easy for our model to identify such error-spelled grantIDs.

Second, we carry out the error analysis on wrong cases by GrantRel (see Figure 4). In case (1), grantID *RSG-04-191-01* is related not only to *American Cancer Society*, but also to *Leukemia and Lymphoma Society Scholar Award*. But the RE model treated the following entity as an independent funder. Such an example requires the model to have a deeper understanding of semantic information. Moreover, training data lacks such a kind of samples which make the RE model more difficult to extract. In case (2), GrantRel wrongly recognized the funder name, and this kind of error accounts for the majority. In case (3), GrantRel failed to find the grant number. This can be explained by the fact that the *"ID"* mostly appears independently in training without being tagged as a number entity. Such errors can be corrected by using more fine-grained tokenization.

6 Conclusion

In this paper, we have presented a novel pipeline framework named GrantRel for automatically extracting grant information from academic articles. The framework has two components of the text classification module and the joint RE module. Moreover, we manually labelled two datasets for training and testing modules. Compared to the previous approaches, the proposed framework has achieved significant improvements in extracting any types of funder names mentioned in articles. Overall, the experiments have demonstrated that our RE model outperforms several state-of-the-art baselines of grant extraction.

A Tagging Standard

In the process of dataset construction, it is a challenge to set a standard for annotations, especially for determining funder entities. After reviewing lots of examples, we decided to use the following rules to determine a funder entity in our tagging.

- Apart from agencies, specific programs, awards, foundation, and fellowships are also regarded as funder names.
- If the name of a program, or fellowship, or award, etc., is associated with the corresponding agency, we will treat them as a whole funder name.
- The address or abbreviation associated with a funder name will be included as part of its funder name.
- The sub-division associated with an agency is viewed as part of the funder name.

B Performance Impact of the Funder Representation

In Table 5, we examine the performance under different funder representations e_{fd}. The following RE models all adopted a standard GrandRel structure (Using the adaptive embedding), with differing only in their representation approaches of funder names

	Grant Realtion		
Funder Representation	Prec.	Rec.	F1
Head	91.71	90.00	90.85
Head+Max	91.93	89.83	90.87
Head+Mean	91.89	90.25	91.06
Head+Tail	91.46	88.90	90.16
Max	92.56	89.58	91.04
Mean	92.65	89.75	91.18

Table 5: Results of GrantRel with different funder representations with respect to the PubMed test set.

- **Head**: The funder entity representation uses the first token representation.
- **Head+Max**: The max-pooling of the entity span representation metric concatenates with the first token representation to represent the whole entity.

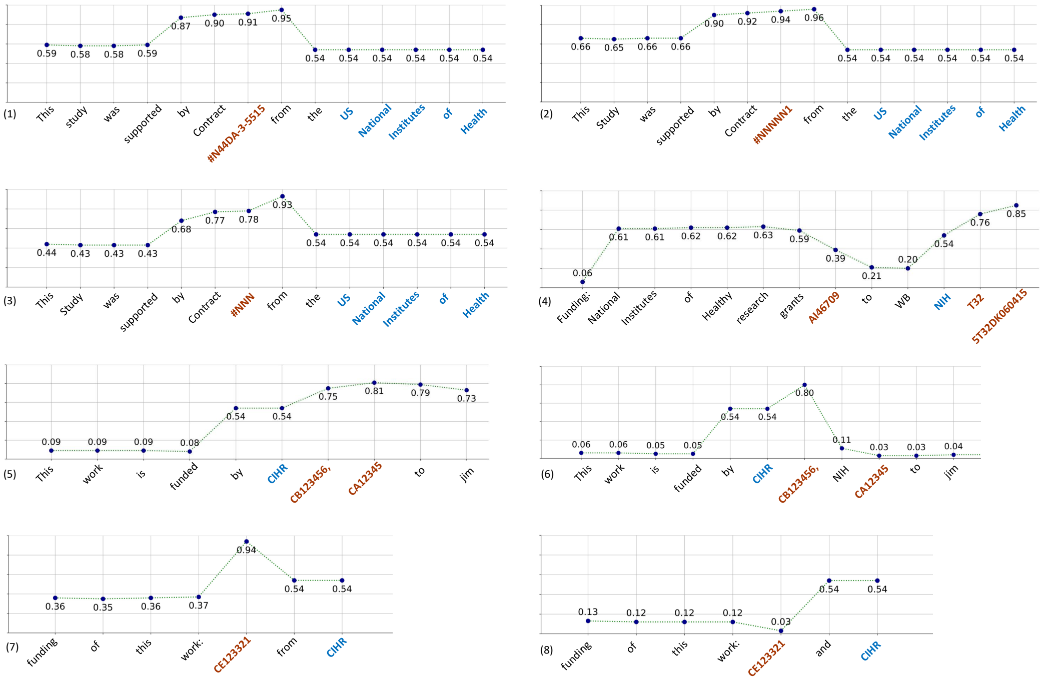

Figure 5: In each sentence, the blue-colored word is the selected funder entity, and the red-colored word is all grant numbers in the sentence. The float number on each word represents its alpha value when calculating the adaptive embedding under the blue-colored funder.

- **Head+Mean**: The average-pooling of the entity span representation metric concatenates with first token representation to represent the whole entity.

- **Head+Tail**: The first token representation concatenates the last token representation.

- **Max**: The max-pooling of the entity span representation metric.

- **Mean**: The average-pooling of the entity span representation metric.

It is observed that the average-pooling of the entity span has the best performance. Hence, we adopted this funder representation method in all our experiments.

C Performance Impact of the Adaptive Mechanism

Our adaptive embedding approach (GrantRel) were compared with the simple fuse approach (GrantRel pos+ctx), which merges both position embedding and context embedding by simply adding them. The results in Table 6 show GrantRel is slightly better.

As shown in Figure 5, we further analyze the impact of α on the embedding by using some chosen samples. For each sentence, given a funder entity being contained in this sentence, GrantRel calculated the value of α among all positions in Eq. (11).

	Grant Realtion		
Model name	Prec.	Rec.	F1
GrantRel pos+ctx	92.63	89.49	91.03
GrantRel	92.65	89.75	91.18

Table 6: Comparisons between GrantRel and GrantRel(pos+ctx) against the test set ofPubMed relation extraction .

For cases (1)-(4), we examine the impact of position embedding. As such, the outputs of GrantRel are compared with those of GrantRel(pos+ctx). In sentence (1), both GrantRel and GrantRel(pos+ctx) could recognize the grant number, but GrantRel(ctx) could not. Besides, we can see that the α value is high for grant number *"#N44DA-3-5515"*. In sentence 2, we manually built a case by replacing the GrantID with a more pseudo one. At a result, GrantRel still identified it as a grant number. But the GrantRel(pos+ctx) whose alpha value is always 0.5 did not recognize. In case (3), without Arabic chars in *"#NNN"*, GrantRel did not identify it as an ID even with a high α

value, either. We can conclude that if a token is close to the funder entity, and the alpha has a high value, the model tends to label an ID-like token into a GrantID. In case (4), GrantRel(pos-ctx) wrongly distributed “AI46706” to “NIH”. In contrast, GrantRel assigned a low α value to “AI46706” according to its context of“to WB” and thus discarded this wrong relation.

In cases (5) to (8), we further explore the impact of different factors, which may influence the α value. For case (5) and case (6), the α values on grantID *“CA12345”* differ largely. But the only difference is that there is an agency of *“NIH”* in (6) between two IDs. We find that α dramatically decreases if the local context has other funder names. In cases (7) and (8), we find that some words can also reduce the α value except for funder names. Thus, the model should automatically pay more attention to context information. For example, the word “and” in (8) means that the previous grant information is parallel to the following grant information. Hence the model did not establish a connection between “CE123321” and “CIHR”.

Enhancing Language Generation with Effective Checkpoints of Pre-trained Language Model

Abstract

This work empirically explores effective exploiting of intermediate output from pre-trained language models (PrLMs) for language generation tasks. For this purpose, we propose an improved method to integrate public checkpoints of PrLMs for the most convenience and perform extensive experiments on 6 different kinds of PrLMs, including BERT, ELECTRA, GPT2, Multi-lingual BERT, and XLM RoBERTa. Evaluation with automatic metrics shows that our approach significantly improves the generation quality on the generation tasks, up to 1.8 BLEU points for neural machine translation (Korean-to-English, Korean-to-Chinese) and 1.8 ROUGE points improvements for text summarization.

1 Introduction

Pre-trained Language Models (PrLMs), such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and ELECTRA (Clark et al., 2020), have thoroughly changed the landscape of state-of-the-art performance on many Natural Language Understanding (NLU) tasks. Also, publicly released checkpoints of the PrLMs allow natural language processing (NLP) researchers to gain SOTA results while saving vast compute and time resources. The widely used method to exploit PrLM is *fine-tuning*. However, for Natural Language Generation (NLG) tasks, such methods do not get as much performance gain as in the NLU task. Several previous studies proposed methods that better use prior knowledge of the PrLM for NLG tasks (Yang et al., 2020; Zhu et al., 2020; Chen et al., 2020). Expending the previous studies, in this paper, we propose an improved method that exploits the checkpoint of the PrLM into the Transformer models (Vaswani et al., 2017).

The existing methods for leveraging PrLM in NLG tasks can be roughly classified into two categories: *Reusing the PrLM as a starting point* and *Integrating the intermediate output of the PrLM*. The former, the widely used in various NLP tasks, denotes to initialize the part of Transformer from the PrLM for generation tasks (Clinchant et al., 2019; Edunov et al., 2019; Rothe et al., 2020) or replace the input embedding with the PrLM. The latter is an approach that first extracts the contextualized representation from a LM for an input sentence and fuses it into a neural model (Yang et al., 2020; Zhu et al., 2020; Chen et al., 2020). As our preliminary experiment shows, we expand this approach and explore in many ways towards better performance. In both of the preceding approaches, whether to freeze or fine-tun the parameter of PrLM is also an important issue. For the former (*Reusing the PrLM*), several works demonstrated that freezing the PrLM at training time led to a significant performance drop. Meanwhile, for the latter approach (*Integrating the PrLM*), prior studies adopted the whole or half-freezing instead of fine-tuning the parameters of the PrLMs. Yang et al. (2020) suggested that the reason why fine-tuning PrLM in neural machine translation (NMT) does not work as well as in other NLP tasks is due to the availability of large training data and the high capacity of baseline NMT models (i.e., Transformer), where excessive fine-tuning leads to the *catastrophic forgetting* phenomenon (Goodfellow et al., 2015). Also, Zhu et al. (2020) shows that freezing the BERT in NMT is better than fine-tuning with a large gap. This is in line with our experimental results. Thus in this empirical study, we freeze the parameters of the PrLMs in our experiments.

This paper focuses on finding an effective

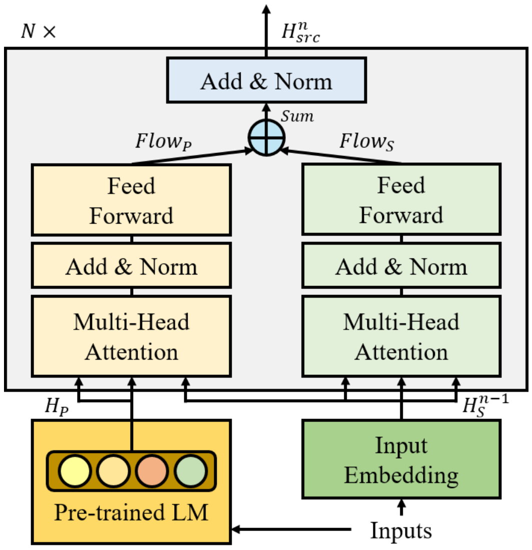

Figure 1: The architecture of our proposed model.

method integrating the intermediate output into the Transformer model to improve the generation quality, unlike the widely used methods such as initializing a part of Transformer and replacing the input embedding with the PrLM. To this end, similar to Zhu et al. (2020), we insert PrLM-dedicated modules that take the intermediate output from the PrLM and make the extra flow for PrLM in Transformer layers. This allows us to integrate PrLM into the Transformer without considering the PrLM's configuration such as modeling, dimension and vocabulary. Based on extensive empirical experiments, we finally adopt an improved method that uses the **Second-to-last (i.g., penultimate) hidden state** of the PrLM as the contextualized representation and proceeds, in only **Source-side (Encoder)**, **Summation** of the source input flow and the PrLM flow generated through the **PrLM-dedicated modules**. In our experiments, we use the publicly released checkpoints of 6 types of PrLMs: BERT, DistilBERT, ELECTRA, GPT2, Multilingual BERT, and XLM-RoBERTa. We release an implementation of our improved method for Korean language generation tasks [1].

2 Model

We propose a modified Transformer-encoder that effectively integrates publicly available checkpoints of PrLMs. Figure 1 shows the architecture of our proposed model. We add an extra flow for PrLM through additional PrLM-dedicated modules including `PrLMAttn`, `Add&Norm`, and `FFN`. Specific mathematical formulations are left at Appendix B. Given an input sequence $x_s = \{x_1, ..., x_N\}$, there is a PrLM-input sequence $x_p = \{x^p_1, ...x^p_M\}$ of length M splited by the PrLM-dedicated tokenizer. The PrLM-input sequence is fed to the PrLM for generating the PrLM representation $H_P = PrLM(x_p)$. Based on preliminary experiment, we adopt the second-to-last hidden state of the PrLM outputs as the contextualized representation. In our proposed encoder, the PrLM representation H_P is merged with the source flow to generate the output H^n_S of n^{th} encoder layer:

$$H^n_S = (Flow_P + Flow_S) + Attn_S, \tag{1}$$

$$Flow_P = \texttt{FNN}(Attn_P + H^{n-1}_S), \tag{2}$$

$$Attn_P = \texttt{PrLMAttn}(H^{n-1}_S, H_P, H_P), \tag{3}$$

$$Flow_S = \texttt{FNN}(Attn_S + H^{n-1}_S), \tag{4}$$

$$Attn_S = \texttt{Attn}(H^{n-1}_S, H^{n-1}_S, H^{n-1}_S), \tag{5}$$

where `PrLMAttn` is the PrLM-dedicated attention module that takes the previous hidden state H^{n-1}_S as a query and the PrLM representation H_P as a key and a value and `Attn` is the original one. We adopt the summation strategy for merging the two different flows, and it gains better results than previous works such as gate network (Yang et al., 2020) and dropnet (Zhu et al., 2020).

3 Experiments

To demonstrate the effectiveness of the proposed method, we perform extensive experiments on two NMT and abstractive text summarization tasks. For translation, we use BLEU (Papineni et al., 2002) for the evaluation of translation quality, and for text summarization, we report unigram and bigram overlap (ROUGE-1 and ROUGE2) to assess informativeness, and the longest common subsequence (ROUGE-L) to assess fluency with ROUGE scores (Lin, 2004). All the model training is on a single NVIDIA Tesla V100 GPU (16130MiB, Google Colab).

3.1 Datasets and Experimental Setting

We evaluate our approach on language generation tasks such as translation and text summarization. For translation tasks, we use two machine translation datasets: AIHub Ko→En [2] (containing 1.6M

training, 3K development and 3K test sentence pairs) and Ko→Ch [3] (317K, 3K, 3K pairs). For text summarization, we use a news document summarization dataset (40K, 1K, 1K pairs) from two institutes [4]. In our experiment, we adopt a `base` Transformer (Vaswani et al., 2017) as the baseline model and use 6 different PrLMs: BERT, DistilBERT, ELECTRA, GPT2, Multi-lingual BERT, and XLM-RoBERTa. More details about the settings are included in Appendix A.

3.2 Experimental Results

Table 1 and 2 report the results of machine translation and abstractive text summarization task, respectively. For the experimental results, we made the following observation: (1) For all the tasks, our proposed methods outperform the strong baseline Transformer w.r.t BLEU (up to 1.8) and ROUGE (up to 1.8). (2) For PrLMs, **ELECTRA base** gains the most significant improvements. Note that **ELECTRA small** is smaller in size than other models, but it shows better performance. This means that factors other than the size of the PrLM have a greater influence on the generation quality. (3) Another observation is that in most cases, using Korean-specific PrLMs leads to better performance than using multi-language PrLMs.

4 Explorations for leveraging PrLM

Our proposed method for leveraging PrLM is to use the **Second-to-last hidden state** of the PrLM as the contextualized representation and proceeds, in only **Source-side (Encoder)**, **Summation** of the source input flow and the PrLM flow after the **FNN**. In this subsection, the setting is the default, and we change only the target part of each experiment. We conducted the following four analyses on the Korean-Chinese and Korean-English datasets.

4.1 Which hidden state of the PrLM to extract?

We evaluated the impact on how to extract the contextualized representation from the PrLM. As shown in Table 3a, using the second-to-last (i.e., penultimate) hidden state of the PrLM performs the best. It has also been demonstrated in Yang et al. (2020). Moreover, as another attempt, we dynamically extracted the hidden state of each layer based on sentence embedding of n^{th} layer, which can be gained by averaging the PrLM layer (known as PrLM embeddings, Dyn. [Aver] in Table 3a) or using the output of the first token (the [CLS] token, Dyn. [CLS]). However, they did not get a big performance boost.

Target-side	31.29 (+0.9)	41.98 (+0.8)

(d) Adding positions for PrLM.

Table 3: The explorations for leveraging PrLM.

4.2 How to merge the PrLM representation with the source input flow?

We compared the impact of different merging strategies for the contextualized representation of PrLM. There are directly using the PrLM as the input embedding (Direct in Table 3b) and four merging strategies such as Summation, Average, using Gate Network (Yang et al., 2020), and using Dropnet (Zhu et al., 2020) As shown in Table 3b, the summation of the PrLM flow and the source input flow got the better improvement over others, so we adopted the Summation strategy in our experiments.

4.3 Where do the PrLM merge with the source input flow?

In the Table 3c, we analyzed where in the encoder layer of Transformer it would be better to merge the PrLM and source flows. There are four positions in a Transformer-encoder layer: after Attn, after 1^{st} Add&Norm, after FFN, and after 2^{nd} Add&Norm. It is interesting to find that merging after FFN can get the best performance. Another observation is that merging the contextualized representation of the PrLM before the Add&Norm (i.e., after Attn or FFN) works better.

4.4 Where do the PrLM flow add?

We evaluated where to add the PrLM: source-side, target-side, and both sides. As shown in the Table 3d report the results. Among them, adding the PrLM to only source-side (i.e., encoder) gained the best result. Intuitively, since contextual representation from the fixed PrLM contains univeral information, not information for generation tasks, combining it directly with the target context may adversely affect performance improvement.

+(Ko, Han)BERT, ELEC. base	32.19 (+1.8)

Table 4: Leveraging multi-LMs

5 More analyses

5.1 Leveraging Multi-PrLMs

We assumed that because PrLMs were trained with different datasets (size, domain) and diverse configurations, they would contain specific prior knowledge. So, we tried to integrate two or more PrLMs simultaneously (Multi-PrLMs) by adding more extra modules in each encoder layer. Contrary to our expectations, as shown in Table 4, using Multi-PrLMs cannot get a significant performance boost over using single-PrLM.

5.2 Fine-tuning v.s. Freezing

We compared the impact of fine-tuning and freezing the parameters of PrLM when using our method. Table 5 shows the results. We can see that freez-

Systems	Ko→Ch	Ko→En
Transformer	30.35 (-)	41.19 (-)
Freezing PrLM (Ours)

+ELEC. base	139.81 (-17%)	3.92k (-16%)

Table 6: Inference Speed on Ko→En NMT task

ing the parameters of PrLM gains more significant improvement than fine-tuning. Another interesting observation is that using the ELECTRA base (112M parameters) when it is fine-tuning led to a significant performance drop, especially for relatively large corpus (Ko→En, 1.6M). It means that *catastrophic forgetting* issue is more pronounced in a resource-rich scenario and using large PrLM. Additionally, tuning separate learning rates (Yang et al., 2020) for the PrLM and the Transformer model may lead to better performance but we leave this to future work.

5.3 Inference Speed

We experimented with the inference speed of our method. Since our method has to obtain the intermediate output of PrLM for an input sentence, it takes more time in the inference process than the baseline model. The experimental results are shown in Table 6. Integrating PrLM into the Transformer model reduced the inference speed by about 5% (ELECTRA small, 14M parameters) to 17% (ELECTRA base, 112M parameters). However, considering the significant performance improvement and the ease of application to any language, it is acceptable of such extra cost.

6 Related Work

Previous studies relies on the structural compatibility of Transformer and PrLM. For example, Clinchant et al. (2019) presented initializing the encoder of Transformer from BERT (fine-tuned or fixed) and observed that freezing the PrLM causes a considerable performance drop. Conneau and Lample (2019) verified that initialization methods with CLM or MLM trained on multi-lingual corpora and showed such initialization are useful on MT. Rothe et al. (2020) used the publicly available PrLM checkpoints to initialize Transformer. While the initialization method is useful to some extent, there is a prerequisite for matching vocabulary and model size/hyper-parameters to them of PrLM.

Zhu et al. (2020) proposed a new method that extracts the last hidden state of BERT for an input sentence and fuses it into the encoder and decoder of the Transformer through an extra attention module, and evaluated the effectiveness of their method on supervised, semi-supervised and unsupervised NMT. Yang et al. (2020) introduced a concerted training framework with three techniques for fusing PrLM and NMT model. Although they also extract the hidden state of PrLM and integrate it into NMT model, the NMT model must follow the PrLM model's configurations such as word segmentation rule and vocabulary.

Our work is related to both Zhu et al. (2020) and Yang et al. (2020) in the sense that we all aim to extract the intermediate output of the PrLM and integrate it into a neural model for better generation quality. As an extension of Zhu et al. (2020), we propose an upgraded method adopted through extensive empirical experiments. Our work differs from Yang et al. (2020) in that we use the publicly available checkpoints that have various configurations and fix the PrLM at training time.

7 Conclusion

While most of the previous works on PrLM address the integration of PrLMs with *fine-tuning*, we propose an alternative in which a modified Transformer-encoder takes the intermediate output from PrLM to exploit its prior knowledge effectively in a straightforward way. Our method does not have to consider the PrLM's configuration, such as its model size, model dimension, and vocabulary. Correspondingly, our approach and reported empirical settings can be smoothly applied to any languages using any checkpoints of PrLMs.

A Experimental Settings

A.1 Model Setting

In our experiment, we use Transformer (Vaswani et al., 2017) as the baseline model for NMT and abstractive text summarization tasks. Additionally, for NMT tasks, we compare our approach to the following baselines:

- (Zhu et al., 2020): A method that inserts the last-hidden state of fixed PrLM through PrLM-dedicated attention module in Transformer-encoder and decoder.
- (Clinchant et al., 2019) (Direct* in Table 1): A method that replaces the input embedding with the PrLM that is fine-tuned in training time.

They all use ELECTRA base as the PrLM.

For the Transformer model, we use a `base` Transformer configuration (Vaswani et al., 2017) with an embedding size of 512, 6 encoder and decoder layers, 8 attention heads, shared source and target embedding, the standard `relu` activation function, and sinusoidal positional embedding. We train with a batch size of 3500 tokens and optimize the model parameters using Adam optimizer with a learning rate 7e-4 β_1= 0.9 and $\beta_2 = 0.98$, learning rate warm-up over the first 4000 steps. Additionally, we apply label smoothing with a factor of 0.1. We average over the last 5 checkpoints and run inference with a beam size of 5. All models are trained for 50 epochs using the Torch-based toolkit, Fairseq(-py) (Ott et al., 2019). For the text summarization task, we reduce the number of encoder and decoder layers to 4 and use *Trigram Blocking* (Paulus et al., 2018) to reduce redundancy during inference time. Other settings are the same as above.

For all datasets, we first tokenize sentences using language-specific tokenizer such as KoNLPy[5] for Korean, jieba[6] for Chinese, and Moses (Koehn et al., 2007) for English and then apply Byte-Pair Encoding (Sennrich et al., 2016) to the tokenized sentences with 32K merge-operations. Besides, most of PrLMs have a limit for input sequence length (e.g., 512), so we cut out the middle of some long text for text summarization dataset as proposed in Sun et al. (2019).

A.2 Pre-trained Language Model Setting

In our experiments, we use 6 types of different PrLMs including BERT (Devlin et al., 2019), DistilBERT (Sanh et al., 2019), ELECTRA (Clark et al., 2020), GPT2 (Radford et al., 2018), multi-lingual BERT, and XLM-RoBERTa (Conneau and Lample, 2019; Liu et al., 2019). Specifically, we use 10 different pre-trained checkpoints depending on the model size, training data set, and training level:

1. KoBERT: a BERT with 768-hidden, 12-layer, 12-heads, 8002-vocab, Korean dataset (4GB), 92M parameters; `https://github.com/SKTBrain/KoBERT.git`.
2. HanBERT: a BERT with 768-hidden, 12-layer, 12-heads, 54000-vocab, Korean dataset (70GB), 127M parameters; `https://github.com/tbai2019/HanBert-54k-N.git`.
3. DistilKoBERT: a DistilBERT with 768-hidden, 3-layer, 12-heads, 8002-vocab, Korean dataset (10GB), 28M parameters; `https://huggingface.co/monologg/distilkobert`.
4. ELECTRA small: a ELECTRA with 256-hidden, 12-layer, 4-heads, 35000-vocab, Korean dataset (34GB), 14M parameters; `https://huggingface.co/monologg/koelectra-small-v3-discriminator`.
5. ELECTRA base: a ELECTRA with 768-hidden, 12-layer, 12-heads, 35000-vocab, Korean dataset (34GB), 112M parameters; `https://huggingface.co/monologg/koelectra-base-v3-discriminator`.
6. KoGPT2: a GPT2 with 768-hidden, 12-layer, 12-heads, 50000-vocab, Korean dataset (20GB), 125M parameters; `https://github.com/SKT-AI/KoGPT2.git`.
7. Multi-lingual BERT cased: a BERT with 768-hidden, 12-layer, 12-heads, 119547-vocab, 104 languages, 177M parameters; `https://huggingface.co/bert-base-multilingual-cased`.
8. Multi-lingual BERT uncased: a BERT with 768-hidden, 12-layer, 12-heads, 105879-vocab, 102 languages, 167M parameters; `https://huggingface.co/bert-base-multilingual-uncased`.
9. XLM RoBERTa base: a BERT with 768-hidden, 12-layer, 12-heads, 250002-vocab, 100 languages (2.5TB), 277M parameters; `https://huggingface.co/xlm-roberta-base`.

---

[5] https://konlpy.org/en/latest/

[6] https://github.com/fxsjy/jieba

10. XLM RoBERTa large: a BERT with 1024-hidden, 24-layer, 16-heads, 250002-vocab, 100 languages (2.5TB), 561M parameters; https://huggingface.co/xlm-roberta-large.

B Details of the Notations

Let `Attn` denote a multi-head attention module, which takes three matrices containing a query matrix Q, a key matrix K, and a value matrix V and product an output matrix as follows:

$$\texttt{Attn}(Q, K, V) = concat(head_1, ..., head_i)W^o, \tag{6}$$

$$head_i = attn(Q_i, K_i, V_i), \tag{7}$$

$$attn(q, k, v) = softmax(\frac{qW^q kW^k}{\sqrt{d_{model}}})vW^v, \tag{8}$$

where $concat$ denotes a concatenation operation, $softmax$ denotes a softmax function, d_{model} is the dimension of the model, and W^o, W^q, W^k, W^v are parameter matrices. `FFN` consists of two fully-connected layers with a $relu$ activation in between.

$$\texttt{FFN} = max(0, xW^1 + b^1)W^2 + b^2, \tag{9}$$

where $\max(0, x)$ is $relu$ activation function, and W^1, b^1, W^2, b^2 are parameter matrices. Finally, `Attn` and `FFN` are connected with `Add&Norm`, which denotes a combination module containing a residual connection (He et al., 2016) and a layer normalization (Ba et al., 2016).

Abstract

Aspect Term Extraction (ATE), Opinion Term Extraction (OTE) and Aspect Sentiment Classification (ASC) are the essential building blocks of Aspect-based Sentiment Analysis (ABSA). They are typically treated as separate tasks and are individually studied by previous work. Recent studies intend to incorporate multiple sub-tasks into a unified framework, but suffer from the following major disadvantages: (1) ABSA models are extremely fragile when some sub-tasks are absent; (2) the interactive relations among sub-tasks are not adequate. To this end, we propose a multi-task learning approach named MIN (Multiplex Interaction Network) to make flexible use of sub-tasks for a unified ABSA. We divide the sub-tasks of ABSA into extractive sub-tasks and classification sub-tasks, and optimize these sub-tasks in a unified manner with multiplex interaction mechanisms. Specifically, we devise a pairwise attention to exploit bidirectional interactions between any arbitrary pair of extractive sub-tasks and a consistency-weighting to perform unidirectional interaction from an extractive sub-task to a classification sub-task. Since the proposed interaction mechanisms are task-agnostic, our model can also work well when some specific sub-tasks are absent. Extensive experiments on two widely used benchmarks with different numbers of sub-tasks demonstrate the superiority of the proposed model.

1 Introduction

Aspect-based sentiment analysis (ABSA), a fine-grained task of text sentiment analysis (Liu, 2012), aims at summarizing opinions in user comments towards different targets (also known as *aspects*). ABSA generally consists of three specific sub-tasks, namely, aspect term extraction (ATE), opinion term extraction (OTE) and aspect sentiment classification (ASC). For example, consider the sentence "*The price is reasonable although the service is inferior.*", ATE aims to extract a set of aspect terms from the sentence, i.e. {*price, service*}, OTE extracts the opinion words, i.e. {*reasonable, inferior*} , and ASC predicts sentiment polarity for each aspect that is *positive* over the first aspect *price* and *negative* for the second aspect *service*, respectively.

Prevailing solutions of ABSA treated ATE (Liu et al., 2015; Li and Lam, 2017; Angelidis and Lapata, 2018; Liao et al., 2019; Luo et al., 2019b; Ma et al., 2019), OTE (Wang et al., 2017; Wang and Pan, 2019) and ASC (Wang et al., 2016b; Chen et al., 2017; He et al., 2018; Li et al., 2018b; Du et al., 2019; Xu et al., 2021) as separate tasks and were individually studied for decades. These separate tasks need to be integrated into a pipeline for practical use (Hu et al., 2019; Phan and Ogunbona, 2020). The key problem with pipeline approaches is that errors can accumulate and that the pipeline model fails to fully exploit the interactive relations among different sub-tasks (He et al., 2019). Some recent efforts have been proposed to remedy these issues by using joint learning to enhance the interactions among sub-tasks (Wang et al., 2018; Li et al., 2019; He et al., 2019; Luo et al., 2019a; Chen and Qian, 2020; Peng et al., 2020) and achieved better performance than pipeline solutions. To name some, (Li et al., 2019) incorporated ATE and ASC and formulated the problem as a single sequence

labeling task with a collapsed tagging scheme[1]. (Luo et al., 2019a) treated ATE and ASC as two sequence labeling problems to mitigate the confused representation brought by the collapsed tags. More recently, (He et al., 2019; Chen and Qian, 2020; Peng et al., 2020) proposed to utilize OTE as an auxiliary task and further facilitated performance.

Despite their success, existing solutions severely suffer from the following disadvantages: firstly, the approaches fusing ATE and ASC cannot benefit from OTE even though there exists opinion term annotations; secondly, the joint learning model might not work when any of the sub-tasks is absent; thirdly, the interactive relations among sub-tasks are not appropriately explored. For instance, (Luo et al., 2019a; Li et al., 2019) would fail to exploit OTE even if these exists labeled data for training. (Chen and Qian, 2020; Peng et al., 2020) might become fragile when the sub-task of OTE or ATE is absent, due to their special designed complex interactions among the sub-tasks of ATE, OTE and ASC. In a nutshell, the key reason for these disadvantages is that existing studies only consider specific interactive relations among a fixed number of sub-tasks, but are inadequate to use the available sub-tasks flexibly.

In this paper, we propose a simple yet effective neural method named MIN (Multiplex Interaction Network) that can make flexible use of sub-tasks for unified ABSA task. The flexibility comes in two folds: First, the number of sub-tasks is not restricted and any related sub-task can be integrated into the unified framework. Second, the interactive relations among distinct sub-tasks are flexibly modeled in an explicit manner.

To tackle the major challenge of how to manage ABSA with arbitrary number of sub-tasks and allow sub-tasks to share interactive information in a unified learning manner, we divide the sub-tasks of ABSA into two categories, namely extractive sub-tasks (e.g. ATE and OTE) and classification sub-tasks (e.g. ASC), and formulate each sub-task as a sequence labeling problem. MIN is built upon a multi-task learning framework of the shared-private scheme (Collobert and Weston, 2008). Sub-tasks first jointly extract the low-level shared features using multi-layer CNN encoder/pre-trained models. Then the private features of each extractive sub-task are independently learned by a multi-layer CNN network with a pairwise attention mechanism. Such *pair-attention* can capture bidirectional interactions between any two extractive sub-tasks accordingly. Moreover, we devise a *consistency-weighting* mechanism to exploit unidirectional interactions from extractive sub-tasks to classification sub-tasks and assist in private feature extractions in classification sub-tasks. The proposed interaction mechanisms (including pair-attention and consistency-weighting) give the model the flexibility to handle different ABSA situations with different number of sub-tasks of different types. In addition, MIN adopts an information feedback mechanism that first aggregates information from all available tasks and then propagates useful information back to individual tasks, allowing different sub-tasks to positively influence each other. Experiments on two widely used ABSA benchmarks using different numbers of sub-tasks demonstrate the proposed MIN outperforms both pipeline and joint learning SOTA baselines on various settings.

2 Related Work

Separate learning mainly focuses on one of the sub-tasks in ABSA, e.g. aspect term extraction (ATE), opinion term extraction (OTE) or aspect sentiment classification (ASC). For the ATE task, previous methods can be divided into unsupervised and supervised models, respectively. In unsupervised methods, (Liu et al., 2015) utilized rules about grammar dependency relations between opinion words and aspects for aspect terms extraction. (Luo et al., 2019b) presented a neural framework that leverages sememes to enhance lexical semantics for long-tailed aspect extraction. (Liao et al., 2019) utilized the capability of coupling global and local representation to discover aspect terms. For supervised methods (Wang et al., 2016b; Li

---

[1] {B, I, E}-{POS, NEU, NEG} indicates the beginning, inside and end of an aspect-term with positive, neutral or negative sentiment, respectively. O denotes NULL sentiment.

and Lam, 2017; Angelidis and Lapata, 2018; Ma et al., 2019), they were usually formulated as a sequence tagging problem, and various neutral networks with attention mechanisms were proposed to solve the task. For ASC, (Liu and Zhang, 2017; Cheng et al., 2017; He et al., 2018; Tang et al., 2019; Liang et al., 2019; Lei et al., 2019) attempted to exploit contextual and positional proximity of aspect terms for prediction by attentional neural networks. And (Tian et al., 2020) proposed to learn a unified sentiment representation for different sentiment analysis tasks. Recently, capsule network (Du et al., 2019; Chen and Qian, 2019), and graph convolution networks (Zhang et al., 2019) were also utilized in ASC and achieved SOTA performance. These separate learning approaches may have disadvantages in practical applications as they need to be pipelined and the interactions between different sub-tasks are totally neglected.

Joint learning strives to combine sub-tasks of ABSA into a unified learning process. For example, some studies proposed to handle ATE and ASC in a pipeline or an integrated model. The pipeline models (Hu et al., 2019; Phan and Ogunbona, 2020) are extract-then-classify processes and were proposed to solve the two tasks successively. However, they can still derive error accumulations. For integrated models, (Wang et al., 2018; Li et al., 2019) solved ATE and ASC by collapsed tagging that is a unified tagging scheme to link the two tasks. (Luo et al., 2019a) considered the relationship between the two tasks and attempted to investigate useful information from one task to another. Some works (Wang et al., 2017; Dai and Song, 2019; Chen et al., 2020; Zhao et al., 2020) integrated ATE and OTE in the same framework to illustrate these two tasks can benefit from each other. Then emerging methods (He et al., 2019; Chen and Qian, 2020; Peng et al., 2020) proposed to inject OTE as an auxiliary task to further improve the performance of ABSA. However, the number of sub-tasks and interactions among them in existing integrated methods are fixed, which can be restricted when sub-tasks vary in practice.

3 The Multiplex Interaction Network

3.1 Task Definition

All the sub-tasks related to ABSA are categorized into extractive and classification sub-tasks, respectively, in our framework. The extractive sub-tasks extract meaningful subsequences of sentences, such as aspect terms and opinion terms, etc. The classification sub-tasks classify parts of sentences into different classes, e.g. sentiment polarities, genres and etc. We formulate all sub-tasks as sequence labeling problems in our joint learning framework. Given a sequence of tokens $\mathrm{X} = \{x_1, x_2, ..., x_n\}$,

- An extractive sub-task $\mathcal{T}$ is to predict a sequence tag $\mathrm{Y}^{\mathcal{T}} = \{y_1^{\mathcal{T}}, y_2^{\mathcal{T}}, ..., y_n^{\mathcal{T}}\}$ for the sentence $\mathrm{X} = \{x_1, x_2, ..., x_n\}$, where $y_i^{\mathcal{T}} \in \{\mathrm{B, I, O}\}$. Specifically, $\{\mathrm{B, I, O}\}$ denotes beginning of, inside of and out of the extracted targets. For example, the first and the second rows of Table 1 demonstrate the sequence tags of aspect term extraction (ATE) and opinion term extraction (OTE) respectively. In the example, “food” and “orange juice” are annotated as aspect terms, and “good” and “horrific” are labeled as opinion terms.
- A classification sub-task $\mathcal{C}$ is to predict a sequence tag $\mathrm{Y}^{\mathcal{C}} = \{y_1^{\mathcal{C}}, y_2^{\mathcal{C}}, ..., y_n^{\mathcal{C}}\}$ for the sentence $\mathrm{X} = \{x_1, x_2, ..., x_n\}$, where $y_i^{\mathcal{C}}$ is one of the class labels. $y_i^{\mathcal{C}}$ will be marked as “-” if the token x_i does not belong to any category. For example, the last row of Table 1 demonstrates the labels of the aspect sentiment classification (ASC) task for the example sentence. In this example, the “food” is labeled as “POS”, and “orange” as well as “juice” is labeled as “NEG”, according to the ground truth sentiment labels of the two aspect terms. Other tokens are labeled as “-” as they do not have golden labels in this task.

3.2 Model Overview

For the convenience of explanation, we take two extractive sub-tasks, namely ATE and OTE, and a classification sub-task ASC to describe our MIN approach hereafter. The overall architecture of MIN is shown in Figure 1. MIN consists of a shared encode layer, several features extraction modules for different sub-tasks, and an information feedback mechanism.

Private features extraction modules accept the same representation from a shared encode layer then extract their private task-oriented features by specific multi-layer CNN algorithms. In order to enhance flexibility, MIN conducts task interactions for two facets. Firstly, we exploit the bidirectional interaction between two different extractive sub-tasks by a proposed *pair-attention*. Using pair-

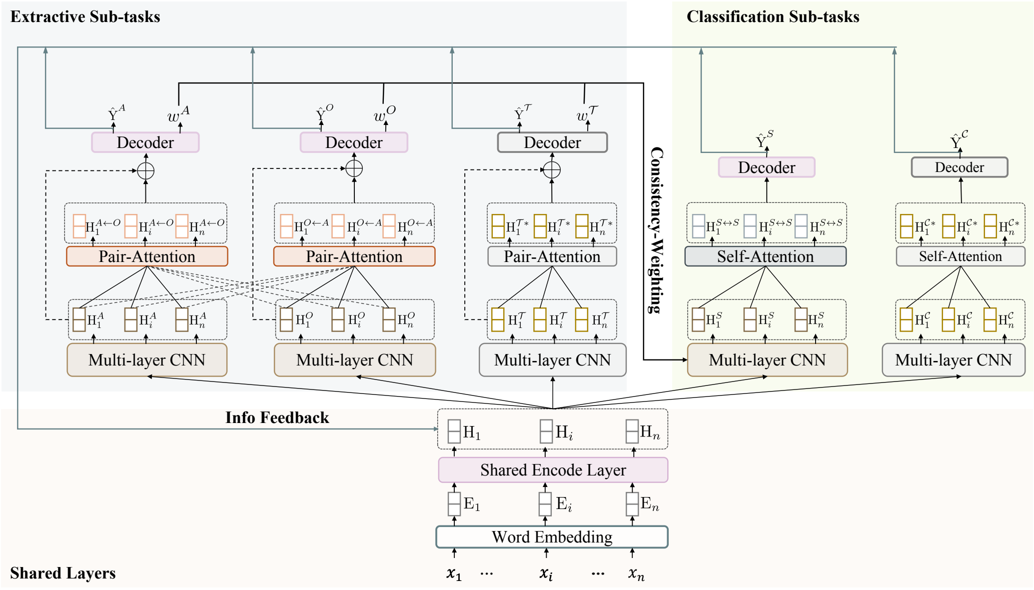

Figure 1: Model Overview of MIN. ATE, OTE and ASC are shown with corresponding interactions. A possible extractive sub-task and a possible classification sub-task are marked in grey colors and some details of them are omitted for easy viewing.

attention, extractive sub-tasks can exchange helpful clues with each other during features extraction. Secondly, we use a *consistency-weighting* mechanism to perform the unidirectional interaction from an extractive sub-task to a classification sub-task. In this way, features with highlight information of extractive sub-tasks will be passed to other classification sub-tasks and assist in their features extractions. Then every sub-task predicts the corresponding sequence labels, i.e., $\hat{\mathrm{Y}}^A$, $\hat{\mathrm{Y}}^O$ and $\hat{\mathrm{Y}}^S$, by its decode layer. The model also adopts an information feedback mechanism that concatenates representations of all sub-tasks to fine-tune the shared representations. In the following, we first describe the MIN model in more detail and then illustrate the learning process.

3.3 Shared Representation Generation

For a sequence of tokens $\{x_1, x_2, ..., x_n\}$, we map the word sequence with either pre-trained double word embeddings (Xu et al., 2018) or pre-trained Bert model to generate a sequence of word vectors $\mathrm{E} = \{\mathrm{E}_1, ..., \mathrm{E}_i, ..., \mathrm{E}_n\} \in \mathbb{R}^{d_e \times n}$, where n denotes the sentence length and d_e denotes the dimension of word vectors. Then we simply feed E into a multi-layer CNN encoder to generate shared features $\mathrm{H} = \{\mathrm{H}_1, ..., \mathrm{H}_i, ..., \mathrm{H}_n\} \in \mathbb{R}^{d_h \times n}$, where d_h denotes the dimension of hidden vectors.

3.4 Features Extraction for Extractive Sub-tasks

3.4.1 Multi-layer CNN

For the extractive sub-tasks, we use a multi-layer CNN structure proposed by (Xu et al., 2018) to learn private features of each task separately. Specifically, there are many 1D-convolution filters in each CNN layer, and each filter has a fixed kernel size of $k = 2c + 1$. As a result, each filter performs convolution operation on a window of k word representations, and compute the representation for the i-th word along with $2c$ nearby words in its context. We can extract private features H^A of ATE and H^O of OTE by the above multi-layer CNN algorithm,

$$\begin{aligned} \mathrm{H}^A &= \mathrm{MC}(\mathrm{H}), \mathrm{H}^A \in \mathbb{R}^{d_p \times n}, \\ \mathrm{H}^O &= \mathrm{MC}(\mathrm{H}), \mathrm{H}^O \in \mathbb{R}^{d_p \times n}, \end{aligned} \tag{1}$$

where MC indicates the multi-layer CNN algorithm, d_p denotes the dimension of the private features for extractive sub-tasks.

3.4.2 Pair-attention

In order to exploit potential interactions, we develop a pair-attention to exchange helpful clues between ATE and OTE based on their semantic correlations. For ATE, the pair-attention matrix

$\mathrm{A}^{A \leftarrow O} \in \mathbb{R}^{n \times n}$ is computed as follows:

$$\begin{aligned} score_{ij}^{(i \neq j)} &= (\mathrm{H}_i^A)^\top \mathrm{H}_j^O, \\ \mathrm{A}_{ij}^{A \leftarrow O} &= \frac{\exp(score_{ij})}{\sum_{k=1}^{n} \exp(score_{ik})}. \end{aligned} \tag{2}$$

By applying a weighted sum operation of pair-attention to the private features H^O of OTE, we get an interactive feature matrix $\mathrm{H}^{A \leftarrow O}$ for ATE:

$$\mathrm{H}_i^{A \leftarrow O} = \sum_{j=1}^{n} (\mathrm{A}_{ij}^{A \leftarrow O} \cdot \mathrm{H}_j^O). \tag{3}$$

Similarly, according to Eq. 2, we exchange H^A and H^O to compute pair-attention matrix $\mathrm{A}^{O \leftarrow A} \in \mathbb{R}^{n \times n}$ then use $\mathrm{A}^{O \leftarrow A}$ and H^A to get interactive feature matrix $\mathrm{H}^{O \leftarrow A}$ for OTE by Eq. 3. In this way, the model exploits bidirectional interactions between the two sub-tasks. After pair-attention, we concatenate the private and the interactive features of the same sub-task, and then feed them to a fully-connected layer to predict the sequence tags as follows:

$$\begin{aligned} \hat{\mathrm{Y}}^A &= \mathrm{softmax}(\mathrm{W}^A(\mathrm{H}^A \oplus \mathrm{H}^{A \leftarrow O})), \\ \hat{\mathrm{Y}}^O &= \mathrm{softmax}(\mathrm{W}^O(\mathrm{H}^O \oplus \mathrm{H}^{O \leftarrow A})). \end{aligned} \tag{4}$$

Note that for other extractive sub-tasks, we can also compute the pair-attention with related extractive sub-tasks in a similar manner.

3.5 Features Extraction for Classification Sub-tasks

Recall that a classification sub-task may benefit from extractive sub-tasks. To name some, knowing the location of aspect terms will enhance the matching degree of aspect terms with corresponding sentiment polarities. For example, the second row and the last row of Table 1 have consistent labels[2] since we expect to perform sentiment prediction for aspect terms than other words. Similarly, the sentiment polarities of aspect terms are mainly influenced by surrounding opinion words. For example, we can find "NEG" labels near to the opinion word "horrific" in the example sentence shown in Table 1.

3.5.1 Consistency-weighting

Inspired by the above observations, we devise a consistency-weighting mechanism to learn private features of ASC task.

First, we compute a set of weights to pass information with salient aspect and opinion terms to ASC. Specifically, the weights of a token i w.r.t. aspect and opinion terms are computed as follows:

$$\begin{aligned} w_i^A &= \sum_{j=1}^{k} (\alpha - \beta \cdot |a_j - i|), \\ w_i^O &= \sum_{j=1}^{k} (\alpha^{'} - \beta^{'} \cdot |o_j - i|) \end{aligned} \tag{5}$$

where k denotes the first k tokens most likely to be aspect or opinion terms, and a_j and o_j are the indexes of j-th aspect and opinion term in the sentence. α, $\alpha^{'}$, β and $\beta^{'}$ are pre-specified constants. We can simply multiply the weights w^A and w^O with interactive features of ATE and OTE to get a distilled representation of every token:

$$\begin{aligned} \mathrm{H}_i^{S \leftarrow A} &= w_i^A \cdot \mathrm{H}_i^A, \mathrm{H}^{S \leftarrow A} \in \mathbb{R}^{d_p \times n}, \\ \mathrm{H}_i^{S \leftarrow O} &= w_i^O \cdot \mathrm{H}_i^O, \mathrm{H}^{S \leftarrow A} \in \mathbb{R}^{d_p \times n}. \end{aligned} \tag{6}$$

Then the shared features are concatenated with such distilled representation, and the private features of ASC are extracted by the same multi-layer CNN algorithm as in the ATE and OTE sub-tasks.

$$\begin{aligned} &\mathrm{H}^S = \mathrm{MC}(\mathrm{H}^{S \leftarrow A} \oplus \mathrm{H}^{S \leftarrow O} \oplus \mathrm{H}), \\ &\mathrm{H}^S \in \mathbb{R}^{d_p \times n}. \end{aligned} \tag{7}$$

By consistency-weighting, the information of aspect and opinion terms are highlighted during the features extraction for the classification sub-task.

3.5.2 Self-Attention

We adopt a self-attention mechanism to learn long-distant dependent information in a sentence for the classification sub-task. Specifically, the self-attention matrix $\mathrm{A}^{S \leftrightarrow S}$ is computed as follows:

$$\begin{aligned} score_{ij}^{(i \neq j)} &= ((\mathrm{H}_i^S)^\top \mathrm{W}^{S \leftrightarrow S} \mathrm{H}_j^S) \cdot \frac{1}{|i - j|}, \\ \mathrm{A}_{ij}^{S \leftrightarrow S} &= \frac{\exp(score_{ij})}{\sum_{k=1}^{n} \exp(score_{ik})}, \mathrm{A}^{S \leftrightarrow S} \in \mathbb{R}^{n \times n}, \end{aligned} \tag{8}$$

where $\mathrm{H}_i^S \mathrm{W}^{S \leftrightarrow S} (\mathrm{H}_j^S)^\mathrm{T}$ and $\frac{1}{|i-j|}$ denote the semantic relevance and distance between H_i and H_j, respectively. After getting the outputs of the self-attention layer, we also exploit a fully-connected layer with softmax activation as a decoder:

$$\begin{aligned} \mathrm{H}_i^{S \leftrightarrow S} &= \sum_{j=1}^{n} (\mathrm{A}_{ij}^{S \leftrightarrow S} \cdot \mathrm{H}_j^S), \\ \hat{\mathrm{Y}}^S &= \mathrm{softmax}(\mathrm{W}^S \mathrm{H}^{S \leftrightarrow S}), \end{aligned} \tag{9}$$

where $\hat{\mathrm{Y}}^S$ is the predicted label sequence for ASC.

---

[2] "Food" is the beginning of an aspect term and it has a positive sentiment; while "pretty" is out of an aspect term and thus has no sentiment in ATE and ASC sub-tasks.

Dataset		Sentence	Opinion	Aspect		
				Pos	Neu	Neg
Res14	Train	3,044	3,484	2,164	807	637
	Test	800	1,008	728	196	196
Lap14	Train	3,048	2,504	994	870	464
	Test	800	674	341	128	169

Table 2: The statistics of datasets.

3.6 Information Feedback Mechanism

MIN exploits an information feedback mechanism to interactively fine-tune the shared feature representations. We denote t as the times of the information feedback. In each round, we utilize the hidden representation before decoder in every sub-task to update the shared features. Specifically, we concatenate the hidden representations with the shared feature matrix, and then use a fully-connected layer with softmax activation to squeeze the vectors to a fixed dimension.

$$\mathrm{H}_t = \mathrm{softmax}(\mathrm{W}(\mathrm{H}_{t-1}^{A \leftarrow O} \oplus \mathrm{H}_{t-1}^{O \leftarrow A} \oplus \mathrm{H}_{t-1}^{S \leftrightarrow S} \oplus \mathrm{H})), \quad (10)$$

where t denotes the t-th feedback update.

3.7 Training Procedure

The overall loss $\mathcal{L}$ consists of cross-entropy losses for all sub-tasks according to final predicted sequence labels.

$$\begin{aligned} \mathcal{L}^A &= -\frac{1}{N}\sum_{i=1}^{N}\frac{1}{n_i}\sum_{j=1}^{n_i}(y_{ij}^A \cdot \log(\hat{y}_{ij}^A)), \\ \mathcal{L}^O &= -\frac{1}{N}\sum_{i=1}^{N}\frac{1}{n_i}\sum_{j=1}^{n_i}(y_{ij}^O \cdot \log(\hat{y}_{ij}^O)), \\ \mathcal{L}^S &= -\frac{1}{N}\sum_{i=1}^{N}\frac{1}{n_i}\sum_{j=1}^{n_i}(y_{ij}^S \cdot \log(\hat{y}_{ij}^S)), \end{aligned} \quad (11)$$

where N denotes the number of training instances, n_i denotes the number of tokens in the i-th instance. The overall loss is the weighted sum of the sub-tasks' losses:

$$\mathcal{L} = a \cdot \mathcal{L}^A + b \cdot \mathcal{L}^O + c \cdot \mathcal{L}^S, \quad (12)$$

where a, b, c are task coefficients, and we set all of them as 1. Following (He et al., 2019), during model training, we only compute ASC loss on tokens which are related to aspect terms, i.e., if a token is not aspect term, we will ignore predicted the sentiment on it. We minimize the $\mathcal{L}$ and determine a suitable t by grid search for information feedback mechanism during the experiment.

4 Experiments

4.1 Datasets

We adopt two widely used datasets from SemEval2014 Task 4 (Pontiki et al., 2014) in our experiment which contain reviews about restaurant and laptop, and the statistics are shown in Table 2. Note that original datasets have ground truth labels for aspect terms and corresponding sentiment polarities, while labels for opinion terms are annotated by (Wang et al., 2016a).

4.2 Compared Methods

We compare our method with recent ABSA methods. To demonstrate the flexibility of our method, we divide the baselines into two categories, namely double-task (ATE and ASC) and triple-task (ATE, OTE and ASC) methods, considering that existing methods are usually designed for fixed sub-tasks.

Double-task methods contain (1) pipeline methods: we take top-performing method **DECNN** (Xu et al., 2018) for ATE, **TNet** (Li et al., 2018a) and **TCaps** (Chen and Qian, 2019) for ASC to construct two pipeline models following (Chen and Qian, 2020). We conduct a pipeline setting of our proposed MIN denoted as **PIPELINE-MIN**, which trains ATE and ASC separately, for fair comparison. (2) unified methods: **MNN** (Wang et al., 2018) and **E2E-ABSA** (Li et al., 2019) jointly solve ATE and ASC by using collapsed tagging schemes, and **DOER** (Luo et al., 2019a) treats these two tasks as two sequence labeling problems and utilized a dual cross-shared RNN.

Triple-task methods aim to solve ATE, OTE and ASC simultaneously, including (1) pipeline methods: following (Chen and Qian, 2020), we combine **CMLA** (Xu et al., 2018) for ATE, **TNet** and **TCaps** for ASC to construct two pipeline baselines.

OTE is integrated into ATE. (2) unified methods: **IMN** (He et al., 2019) is an interactive multi-task model jointly trained on ATE and ASC where OTE is also integrated into ATE. While **RACL** (Chen and Qian, 2020) is trained on ATE, OTE and ASC in parallel that considers four relations among the three sub-tasks.

4.2.1 Settings

Following (He et al., 2019), we adopt double embedding in word embedding layer of **MIN**, where each word embedding is a concatenation of *general embedding* (Pennington et al., 2014) with 300 dimensions and *domain embedding* (Xu et al., 2018) with 100 dimensions. We set the hidden size $d_e = 400$, $d_h = 300$, $d_p = 300$, and the kernel size, number of shared CNN layers to 5 and 2, individually. And the numbers of information feedback in Res14 and Lap14 are set to 2 and 3 respectively. The layers of multi-layer CNN for ATE, OTE and ASC are set to $\{2, 2, 1\}$ and the kernel size is 5 in two dataset. Adam optimizer (Kingma and Ba, 2015) with a learning rate of 1e-4 and a batch size of 8 are utilized for all datasets.

We also combine **MIN** with $\text{BERT}_{\text{Large}}$ to get **MIN-BERT** and $\{d_e, d_h, d_p\}$ is set to $\{1024, 300, 300\}$ with a learning rate of $1e-5$ by grid search. The layers of multi-layer CNN for ATE, OTE, ASC and the number of information feedback are set to $\{1, 1, 1, 2\}$ in the two datasets. The other parameters are the same as the **MIN** model with the double embedding. We meanwhile alternate IMN and RACL with $\text{BERT}_{\text{Large}}$ for further detailed comparison. We use the same metrics as (He et al., 2019), i.e., AE-F1, OE-F1, AS-F1 and O-F1, representing macro F1 scores for ATE, OTE, ASC and overall performance for complete ABSA. We select the model with the best O-F1 on the development set for test.

4.3 Experimental Results

4.3.1 Overall Performance

Table 3 and 4 demonstrate the performance of our method and the compared double-task (i.e., ATE and ASC) and triple-task methods (i.e., ATE, OTE and ASC), respectively. We have several consistent observations from the two tables. Firstly, most unified models perform better than pipeline models, which proves the advantages of exploiting interactions between sub-tasks. Secondly, our MIN can be flexibly applied to either double-task or triple-task scenario and can achieve better performance than all the compared methods on O-F1. We conjecture the possible reason is that the proposed generic interaction mechanism among different sub-task types is independent on any specific sub-task. Thus, our MIN can work well regardless of the number or the type of sub-tasks. Thirdly, we enhance the performance of some compared models with word embeddings provided by $\text{BERT}_{\text{Large}}$ (Devlin et al., 2018) and report the corresponding results in Table 4. We can observe that our MIN-BERT also shows superiority especially on O-F1.

4.3.2 Flexibility

To further investigate the flexibility of MIN, we compare our MIN with variants of strong competitors in triple-task methods by varying the combination of sub-tasks. We remove one of the three sub-tasks and get three different combinations, namely "ATE+OTE", "ATE+ASC" and "OTE+ASC". Note that the double-task methods in table 3 cannot be easily adapted for this comparison due to their special design for specific sub-task combinations.

Table 5 exhibits the corresponding results on two datasets. We can see from the table that MIN

Model	Res14	Lap14
Full Model	70.92	61.35
w/o Pair-attention	69.82	59.37
w/o Consistency-weighting	69.46	60.84
w/o Info Feedback	69.07	59.17
w/o Self-Attention	67.63	57.03

(a) Results on Res14. (b) Results on Lap14.

Figure 2: Effects of parameter t.

outperforms both IMN and RACL on most of the cases, and the two baselines cannot work well when the sub-task combination varies since both of them designed specialized interaction mechanisms for a fixed number of sub-tasks. For example, IMN adopts OTE as an auxiliary task for ATE and thus cannot provide results on "OTE+ASC". RACL, which designs four kinds of collaborative relations among ATE, OTE and ASC, degrades when arbitrary one sub-task is unavailable. However, our MIN separates the sub-tasks by different categories and leverages two category-level interaction mechanisms. It derives a trade-off that the interactions on remaining sub-tasks are still functional although one sub-task is removed. That is where the flexibility of our model comes from.

4.3.3 Ablation Test

In order to verify the effectiveness of different interactive mechanisms in our model, we conduct ablation tests on "ATE+OTE+ASC" unified ABSA. We remove different interaction mechanisms between sub-tasks in turn to observe the effectiveness of them. As the O-F1 results shown in Table 6, all interaction mechanisms are effective in MIN as expected. For example, on Res14, the scores of model without consistency-weighting and the model without self-attention drop largely. It is believed that sentiment polarities are mainly influenced by corresponding aspect and opinion words.

4.3.4 Case Study

Next, we illustrate two cases generated by IMN, RACL and our MIN for further investigation in Table 7. In Case (1), IMN extracts "choice" as an extra aspect without considering the relations between ATE and OTE. In addition, RACL incorrectly identifies "choice" and "craving" as aspect and opinion terms. We conjecture the possible reasons might be the "choice" is paired with "exquisite" as an aspect and the "craving" is recognized as a term expressing opinions by the specifically-designed interaction relations in RACL. However, our proposed pair-attention of MIN is more general, and correctly extracts all the aspect terms and opinion terms. Case (2) explores the effectiveness of our proposed consistency-weighting. Specifically, although IMN extracts the correct opinion word "too sweet", the final sentiment of "mole sauce" is still predicted wrong with a weak help of opinion terms. Meanwhile, although RACL exploits the relation between OTE and ASC, it recognizes the "sweet" incompletely, which might because RACL cannot update representation without the information feedback mechanism. As a result, "sweet" interferes sentiment prediction and leads to a wrong polarity for "mole sauce". In contrast, MIN correctly predicts sentiment polarities by using consistency-weighting based on complete aspect and opinion terms.

4.3.5 Times of Information Feedback

Finally, we investigate the sensitivity of the parameter t in the information feedback mechanism. Figure 2 (a) and (b) show the results of O-F1 on Res14 and Lap14 as t increases. We observe that MIN achieves better performance when $t = 2$ or $t = 3$. And there is no considerable improvement with a further increase of t, because redundant iterations might derive overfitting.

5 Conclusion

In this paper, we propose a novel neural model MIN to make flexible use of sub-tasks for the unified ABSA task. We introduce two sub-task agnostic interaction mechanisms, i.e., pair-attention and consistency-weighting, to exploit interactions among different sub-tasks and an information feedback mechanism to fine-tune the shared feature representation. Experiments with a different number of sub-tasks show the flexibility of MIN. The proposed framework can be potentially applied to similar tasks such as named entity recognition, semantic relation extraction, and etc.

Continual Mixed-Language Pre-Training for Extremely Low-Resource Neural Machine Translation

Zihan Liu, Genta Indra Winata, Pascale Fung

Abstract

The data scarcity in low-resource languages has become a bottleneck to building robust neural machine translation systems. Fine-tuning a multilingual pre-trained model (e.g., mBART (Liu et al., 2020a)) on the translation task is a good approach for low-resource languages; however, its performance will be greatly limited when there are unseen languages in the translation pairs. In this paper, we present a continual pre-training (CPT) framework on mBART to effectively adapt it to unseen languages. We first construct noisy mixed-language text from the monolingual corpus of the target language in the translation pair to cover both the source and target languages, and then, we continue pre-training mBART to reconstruct the original monolingual text. Results show that our method can consistently improve the fine-tuning performance upon the mBART baseline, as well as other strong baselines, across all tested low-resource translation pairs containing unseen languages. Furthermore, our approach also boosts the performance on translation pairs where both languages are seen in the original mBART's pre-training. The code is available at `https://github.com/zliucr/cpt-nmt`.

1 Introduction

Neural machine translation (NMT) (Bahdanau et al., 2015; Luong et al., 2015; Vaswani et al., 2017) has a poor generalization ability to low-resource languages where large monolingual and parallel corpora are not available. Recently, leveraging multilingual pre-trained models (Song et al., 2019; Liu et al., 2020a; Lin et al., 2020) as the starting checkpoints has shown to be effective at building low-resource NMT systems. However, the effectiveness of the pre-training will be vastly limited for low-resource languages that are not in the list of pre-training languages. Given the fact that there are more than 7000 languages around the world (Austin and Sallabank, 2011), it is almost impossible for a multilingual model to include all languages. And it is expensive and time-consuming to pre-train another model from scratch so as to include the languages we need. To address this issue, we propose to leverage the advantages of an off-the-shelf multilingual pre-trained model and focus on better generalizing it to any low-resource language pair. In this paper, we use mBART (Liu et al., 2020a) as the multilingual pre-trained model, given its effectiveness at building low-resource NMT systems.

To simulate the problem, we suppose that we need an NMT system on a low-resource translation pair, and at least one of the languages in the translation pair is an unseen language for the pre-trained model. To adapt mBART into unseen languages in the NMT task, we propose to conduct a continual pre-training (**CPT**) on it with mixed-language training (**MLT**). Concretely, we first follow the noise function used in Liu et al. (2020a) to corrupt the monolingual text of the target language in the translation. Then, we utilize a bilingual dictionary to generate mixed-language sentences and simultaneously delete some tokens based on the corrupted text. After that, we conduct the CPT on mBART to reconstruct the original monolingual text. After the CPT, we follow Liu et al. (2020a) to directly fine-tune mBART on the parallel data of the translation pair. The purpose of producing mixed-language sentences is to make a rough alignment between the languages in the translation pair. Conducting the token deletion is to increase the difficulty of the reconstruction task and the diversity of the noisy mixed-language text, which force the model to quickly learn an unseen language.

We consider an extremely low-resource setting where we have very few parallel data (10k) for

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2706–2718

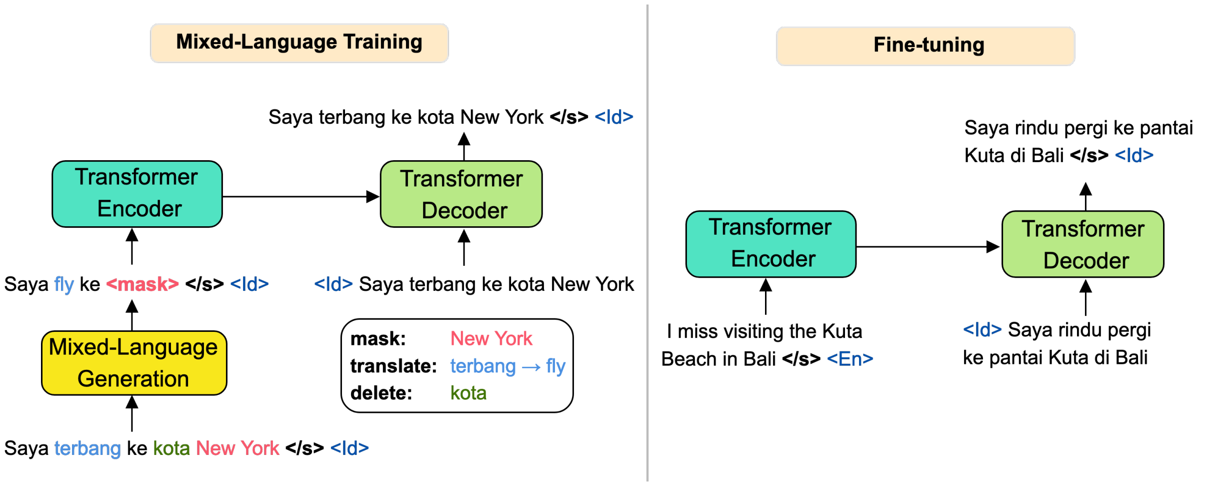

Figure 1: An illustration of adapting mBART to the En-Id translation pair: Continual pre-training with mixed-language training (left) and fine-tuning on the translation task (right).

low-resource translation pairs and very few monolingual data (100k) for each language in the translation. Experimental results show that our proposed pre-training approach is able to consistently outperform the mBART baseline as well as other pre-training baselines across all tested translation pairs that contain unseen languages. Interestingly, we observe that the continual mixed-language pre-training is even beneficial for a translation pair where both languages are in the mBART's pre-training list. Results also show that mBART can achieve better zero-shot performance after applying the CPT with MLT, which illustrates that the mixed-language pre-training is able to make a better alignment. Furthermore, we investigate our method in terms of various low-resource settings where different amounts of parallel and monolingual data are available, and experimental results show that the effectiveness of our approach can be further improved when a larger pre-training corpus is available.

The contributions of this paper are summarized as follows:

- To the best of our knowledge, we are the first to investigate how to effectively adapt a multilingual pre-trained model to unseen languages for the NMT task.
- We show that our proposed method can consistently surpass strong baselines across all the tested translation pairs.
- We conduct in-depth experiments and analyses in terms of different low-resource settings and the effectiveness on the various components of our method.

2 Methodology

In this section, we first give a brief overview of the mBART model (Liu et al., 2020a), and then we introduce our proposed method that aims to adapt mBART to unseen languages in the translation task.

2.1 Model: mBART

The mBART model follows the sequence-to-sequence (Seq2Seq) pre-training scheme of the BART model (Lewis et al., 2020) (i.e., reconstructing the corrupted text) and is pre-trained on large-scale monolingual corpora in 25 languages. Two types of noises are used to produce the corrected text. The first is to remove text spans and replace them with a mask token, and the second is to permute the order of sentences within each instance.

Thanks to the large-scale pre-training on multiple diverse languages, the mBART model has shown its strength at building low-resource NMT systems by being fine-tuned to the target language pair, and it is also shown to possess a powerful generalization ability to languages that do not appear in the pre-training corpora (Liu et al., 2020a).

2.2 Continual Pre-Training

Despite the powerful adaptation ability that mBART possesses, we argue that its performance on unseen languages is still sub-optimal since it has to learn these languages from scratch. Therefore, we propose to conduct the continual pre-training (CPT) on the mBART model to improve its adaptation ability to unseen languages. The process of this additional pre-training task is illustrated in Figure 1, and the details are described as follows.

Pre-Training We denote $\texttt{lang}_1 \rightarrow \texttt{lang}_2$ as the needed translation pair, where $\texttt{lang}_1$ is the source language and $\texttt{lang}_2$ is the target language, and at least one of them is an unseen language for the mBART model. The CPT can be considered as maximizing L_θ:

$$L_\theta = \sum_{X \in D_2} \log P(X | f(X); \theta), \quad (1)$$

where θ is initialized with mBART's parameters, D_2 denotes a collection of monolingual documents in $\texttt{lang}_2$, and f is a function to generate noisy mixed-language text that contains both $\texttt{lang}_1$ and $\texttt{lang}_2$.

Noisy Mixed-Language Function (f) Given a monolingual instance X, we first use the noise function (denoted as g, described in §2.1) used in Liu et al. (2020a) to corrupt the text, and then we use a dictionary of $\texttt{lang}_2$ to $\texttt{lang}_1$ to assist in the function of producing mixed-language sentences (denoted as h). Specifically, after the processing of the noise function g, if the non-masked tokens in $\texttt{lang}_2$ exist in the dictionary, we set a probability to replace it with its translation in $\texttt{lang}_1$. If it is not being replaced, there is a 50% chance that we will directly delete this token, and otherwise, we keep the original token in $\texttt{lang}_2$. More formally, function f (in Eq. (1)) can be considered as the combination of two functions:

$$f(X) = h(g(X)). \quad (2)$$

Notice that $\texttt{lang}_2$ is not always the unseen language (i.e., $\texttt{lang}_1$ could be the only unseen language). Since the inputs are mixed with the tokens in $\texttt{lang}_1$ and $\texttt{lang}_2$, the model can always learn the unseen language.

The reason why we choose to reconstruct $\texttt{lang}_2$ instead of $\texttt{lang}_1$ is because $\texttt{lang}_2$ is the target language that the decoder needs to generate in the translation task, and reconstructing $\texttt{lang}_2$ in the pre-training makes the model easier to adapt to the $\texttt{lang}_1 \rightarrow \texttt{lang}_2$ translation pair. We leverage the noise function g since it has shown its effectiveness at helping pre-trained models to obtain language understanding ability. The intuition of producing mixed-language text for inputs is to roughly align $\texttt{lang}_1$ and $\texttt{lang}_2$, since the model needs to understand the tokens of $\texttt{lang}_1$ so as to reconstruct the translations in $\texttt{lang}_2$. The purpose of not replacing all tokens in the dictionary with their translations is to increase the variety of the mixed-language text, and given that there will be plenty of frequent words (e.g., stopwords), replacing all of them with the corresponding translations could make the sentences unnatural, and the translations of the frequent words in $\texttt{lang}_1$ would likely not match the context in $\texttt{lang}_2$. In addition, adding a probability to delete the original token in function h is to inject extra noise and further increase the diversity of the generated mixed-language text.

3 Experimental Settings

3.1 Datasets

We conduct experiments on 12 low-resource language pairs from OpenSubtitles (Lison and Tiedemann, 2016), resulting in 24 directed translation pairs in total. Each pair has an unseen language for mBART. Concretely, there are 12 translation pairs (out of 24) containing English and another unseen language (Indonesian (Id), Ukrainian (Uk), Bengali (Bn), Afrikaans (Af), Tamil (Ta), Thai (Th) ↔ English (En)), and the rest of the 12 pairs contain two unseen languages (Id ↔ Ta, Bn ↔ Th, Bulgarian (Bg) ↔ Ta, Id ↔ Bn, Macedonian (Mk) ↔ Th, and Slovak (Sk) ↔ Swedish (Sv)). In addition, we evaluate the translation pairs (En ↔ Gujarati (Gu) and En ↔ Kazakh (Kk) (WMT19)), where both languages are in mBART's pre-training list.

To produce noisy mixed-language sentences, we collect monolingual corpora for the target languages from Wikipedia, and we utilize the bilingual dictionaries from MUSE (Lample et al., 2018b)[1] for the En-X and X-En pairs. For a dictionary (denoted as X-Y) that is not available in MUSE (English is not in the pair in this case), we first obtain the token list of language X from the X-En dictionary in MUSE, and then construct the X-Y dictionary utilizing Google Translate[2] to translate the tokens from language X to Y.

3.2 Low-Resource Settings

We focus on an extremely low-resource setting, where we assume that only 10K parallel samples are available. Considering that obtaining a large

---

[1] https://github.com/facebookresearch/MUSE

[2] https://translate.google.com. The constructed dictionaries will be released in `https://github.com/zliucr/cpt-nmt`.

size monolingual corpus could be difficult for some low-resource languages, we constrain the number of monolingual paragraphs to be as few as 100K (the size is $\sim$ 30MB). To do so, we randomly sample 10K parallel examples and 100K monolingual paragraphs from the available corpora. In addition, we also conduct experiments with different numbers of parallel data (from 10K to 100K) and monolingual data (from 100K to 1M) to investigate the effectiveness of the proposed method in different levels of low-resource setting. As for the translation pairs En $\leftrightarrow$ Gu and En $\leftrightarrow$ Kk, we follow the settings in Liu et al. (2020a) and use parallel data with a size of 10K and 91K for the En $\leftrightarrow$ Gu and En $\leftrightarrow$ Kk, respectively.

3.3 Models & Baselines

mBART We directly fine-tune the mBART model on the parallel data of the translation pair. Note that it is already a strong baseline since mBART is shown to possess a good generalization ability to unseen languages (Liu et al., 2020a).

CPT w/ Ori (Src) We follow the **original** objective function of mBART (only using the noise function g in §2.2 to corrupt the text) to continue pre-training it on the **source** language of the translation pair. [3] Then we directly fine-tune it on the translation parallel data.

CPT w/ Ori (Tgt) This baseline is the same as the previous one except that we continue pre-training mBART on the **target** language of the translation pair.

CPT w/ MLT (Src) Different from CPT w/ Ori, we use the noisy mixed-language function (f) to create noisy mixed-language text. However, different from what we propose in Eq. (1), it reverses the pre-training direction (i.e., it corrupts the text in the **source** language instead of the target language).

CPT w/ MLT (Tgt) This is our proposed method described in §2.2. We use Tgt or Src to distinguish the target or source language (in the translation pair), respectively, that mBART needs to reconstruct in the CPT.

mT5 Like mBART, mT5 (Xue et al., 2020) is also a multilingual pre-trained model using a Seq2Seq pre-training. It is pre-trained in 101 languages covering all the languages in our experimental settings. Note that we use the mT5-base (600M parameters) which has a similar size as mBART (610M parameters) to ensure the fair comparison.

3.4 Training Details

Given that the sizes of the pre-training data and the parallel data are relatively small, we freeze the first 8 layers (out of 12) of the encoder and the first 8 layers (out of 12) of the decoder in the CPT, as well as the fine-tuning processes (applied for both mBART and mT5), to avoid the over-fitting issue. Note that we still keep the embeddings layer unfrozen since the model needs to learn the embeddings for unseen languages. For CPT, we control the probability of whether to replace a token with its translation to ensure around 30% of tokens are replaced. In the CPT stage, we train with a dropout rate of 0.1, a batch size of 100, and a learning rate of 3e-5 for 5 epochs. In the fine-tuning stage, we train with a dropout rate of 0.3, a batch size of 32, and 2500 warm-up steps with a maximum learning rate of 5e-5 for all directions. We use the Adam optimizer (Kingma and Ba, 2015) for both the CPT and fine-tuning processes. We set the maximum fine-tuning epochs as 20, and the final model is selected based on the performance on the validation dataset. The final results are reported in the case-sensitive tokenized BLEU (Papineni et al., 2002). We notice that the tokenizer of mBART is the same as that of XLM-R (Conneau et al., 2020) which covers 100 languages. Note that extending the vocabulary may be necessary for new languages that are not included in the original tokenizer, while we do not extend the vocabulary in the experiments since all the languages in the experiments are included in the vocabulary of XLM-R, and we find that the unknown token rates for unseen languages in the experiments are zero. Therefore, for all the models, we directly use mBART's tokenizer on the text for all languages in the experiments to ensure a fair comparison in BLEU, and we use thai-segmenter [4] to pre-tokenize the text in Thai (Th) before using mBART's tokenizer. For inference, we use beam search with a beam size of 5 for all directions.

4 Results & Analysis

4.1 Main Results

The results of our proposed methods and baseline models are illustrated in Table 1, from which we can observe that conducting CPT on mBART is

---

[3] For example, in the Id → Ta translation, the source language is Id and the target language is Ta.

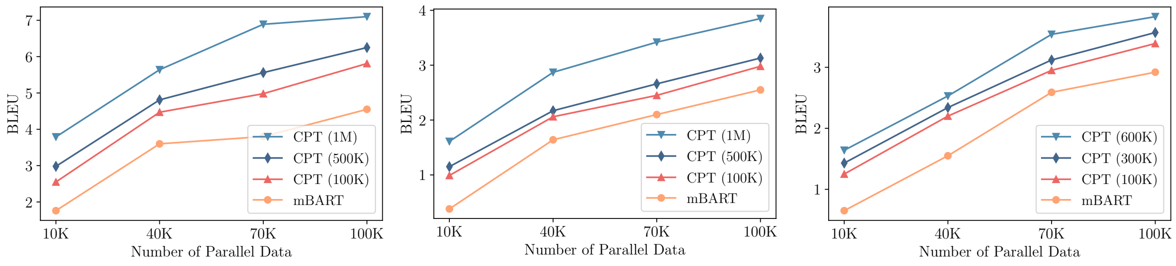
Table 1: Fine-tuning performance on the 10K parallel data for the 24 translation pairs. All CPT methods utilize a corpus with a size of 100K paragraphs. The upper 12 pairs contain one unseen language for mBART (the other seen language is English), and the bottom 12 pairs contain two unseen languages. The CPT using our proposed method consistently outperforms all baseline models.

generally effective in the low-resource scenario of the NMT task, although the size of the pre-training corpus is as few as 100K paragraphs. Also, we can see that the CPT w/ MLT consistently outperforms all baseline models since the additional mixed-language information helps to construct a better alignment between the source and target languages in the translation pair. We observe that the CPT w/ MLT (Tgt) significantly outperforms mBART in multiple translation pairs (e.g., 2.92 BLEU points in En → Id and 2.39 BLEU points in En → Th). We find that, although conducting CPT (w/ Ori or w/ MLT) on the text that contains tokens in the unseen language generally enhance the performance in the translation, the effectiveness of CPT w/ Ori is relatively deficient compared to CPT w/ MLT. We conjecture that the original objective function of mBART loses its advantages when the amount of pre-training monolingual data is small, while MLT is still beneficial thanks to the additional bilingual alignments that it have learned.

Additionally, we find that the direction of the CPT (Src or Tgt) also plays an important role. As we can see from Table 1, conducting CPT by reconstructing the target language in the translation pair generally achieves better performance than reconstructing the source. We conjecture that making the generated language in the CPT stage consistent with that in the fine-tuning stage will increase the benefits from the CPT. This is because, if the generated languages are different in these two stages, the model needs to learn to generate sentences on an entirely different language with only a few data samples in the fine-tuning stage, which could make the fine-tuning task much more challenging. Interestingly, when English (a seen language) is the target language, the CPT w/ Ori (Tgt) becomes less effective, but CPT w/ MLT (Tgt) still works well. The reason is that CPT w/ Ori (Tgt) ignores the unseen language in the continual pre-training stage, while the mixed-language inputs of CPT w/ MLT (Tgt) still contain the tokens in the unseen language, which still enables the model to learn the unseen language. Surprisingly, mT5 performs generally worse than mBART, although it covers all the languages in our experiments. We conjecture that, since the objective function of mT5 is to generate the masked tokens, it makes the averaged length of the generated text relatively shorter than mBART, which might limit its ability to quickly adapt to a generation task in the low-resource scenario.

4.2 Different Low-Resource Settings

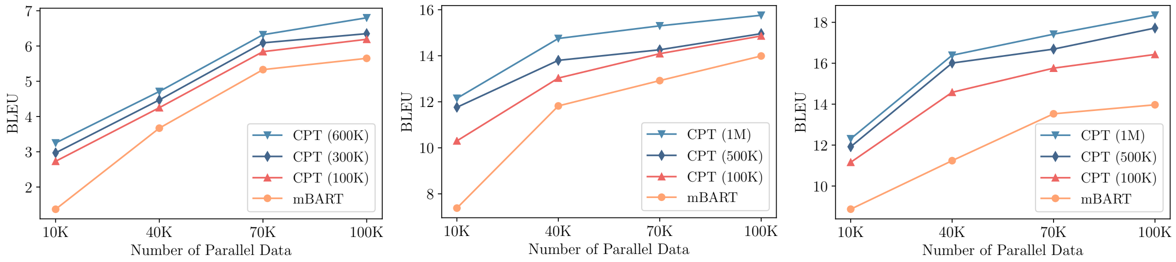
In this section, we investigate whether our method can generalize to other low-resource settings (i.e., different sizes of the parallel data and monolingual



(a) Sk → Sv

(b) Sv → Sk

(c) En → Bn



(d) Bn → En

(e) En → Id

(f) Id → En

Figure 2: The performance over different numbers of parallel data (from 10K to 100K) and pre-training data (from 100K to 1M). CPT denotes our method, CPT w/ MLT (Tgt). Since the maximum number of paragraphs in Wikipedia for Bn is ∼600K, we set the data size in the CPT as 100K, 300K and 600K for En ↔ Bn.

data). We choose three translation pairs (En ↔ Bn, En ↔ Id, and Sk ↔ Sv), which cover two scenarios: 1) only one unseen language in a translation pair; and 2) both languages in a translation pair are unseen. As illustrated in Figure 2, we can observe that our method is able to consistently improve on the mBART baseline in terms of different parallel data sizes, and the improvements can be further boosted when the size of the pre-training data (monolingual data) increases. This is because a larger corpus is able to amplify the benefits of MLT and better align the space between the two languages in the translation. Moreover, we find that our method is especially effective for the Sk ↔ Sv translation pair when the size of the pre-training data reaches 1M. For example, in the Sk → Sv translation, the performance of CPT (1M) with 10K parallel samples (3.79) is on par with mBART with 70K parallel samples (3.80), which might suggest that gathering larger monolingual data (along with a dictionary) can be an alternative to collecting a larger size of parallel data.

4.3 Effectiveness on Seen Languages

As we can see from Table 2, the CPT w/ MLT can also significantly improve the performance on the translation pairs where both languages are in the mBART's pre-training list. The CPT w/ MLT improves by at least 1.2 BLEU points on all translation pairs with only 100K pre-training data. Additionally, the improvement brought by our method can be further boosted when a larger pre-training corpus is available, which accords with the experimental results for the unseen languages.

Language Pairs	**En-Gu**		**En-Kk**	
Direction	←	→	←	→
mBART	3.11	0.10	8.93	2.44
CPT w/ MLT (Tgt, 100K)	4.59	2.01	10.16	4.01
CPT w/ MLT (Tgt, 500K)	5.44	2.91	10.74	4.74
CPT w/ MLT (Tgt, 1M)	**5.97**	**3.89**	**11.45**	**5.29**

Table 2: The effectiveness of our method on seen languages. 100K, 500K and 1M are the corpus sizes for the CPT w/ MLT (Tgt).

Models	**mBART**	**CPT w/ Ori**	**CPT w/ MLT**
Avg	0.00	0.27	**0.53**

Table 3: Averaged performance over the 24 translation pairs in the zero-shot test. Both CPT methods are to reconstruct the target language with 100K samples.

We conjecture two reasons: 1) Continuing pre-training mBART can make the model focus on the languages in the translation pair and increase the model's ability of fast adaptation to the translation task. 2) Continual pre-training with the mixed-language text can further align the two languages in the translation, which gives a better initialization for the low-resource translation task.

Language Pairs	En-Id		En-Af		Id-Ta		Sk-Sv

CPT w/ MLT (Tgt)	**3.85**	3.79	**4.54**	0.70

Table 6: Comparison between conducting and not conducting the pre-tokenization for Thai.

4.4 Zero-shot Performance

To further analyze the alignment quality between the source and target languages in the translation after the CPT, we evaluate the models in the zero-shot scenario, where we directly test the pre-trained models on the test set without any fine-tuning on the parallel data. As illustrated in Table 3, we can see that the zero-shot performance is relatively low since the models are not trained on any parallel or pseudo-parallel data [5], and mBART gets 0 BLEU points due to the unseen languages in the test data.

We find that CPT w/ Ori achieves more than 0 BLEU points, even though it does not utilize any supervision from the bilingual text. We conjecture that this can be attributed to the multilingual ability of mBART. Furthermore, CPT w/ MLT is able to outperform CPT w/ Ori since it learns additional bilingual alignments by reconstructing the target documents from the mixed-language text. In addition, the results are able to further illustrate that our method is able to achieve a better alignment quality than the baseline method.

4.5 Ablation Study

In this section, we first explore how the noise function g and token deletion in function h affect the effectiveness of our method (g and h are described in §2.2). Then, we investigate how the language mixing ratio of the mixed-language text affects our method's performance.

Noise & Deletion As shown in Table 4, we can see that both the noise function and token deletion play an important part in the CPT, and removing both of them further degrades the performance. Given that the number of pre-training documents is as few as 100K, it is relatively difficult for the model to learn a good representation for the unseen language. However, adding the noise function in the CPT forces the model to learn to perform text infilling and sentence reordering, which increases the model's ability to understanding the unseen language. Conducting the token deletion brings two benefits: 1) It increases the variety of the mixed-language text, which makes the model not overfit to a certain mixed-language pattern. 2) It also injects extra noise to the inputs, which further compels mBART to understand the unseen language better. Moreover, incorporating both noise function g and the token deletion further boosts the effectiveness of the pre-training.

---

[5] The results for each translation pair are in Appendix A.

Language Mixing Ratio We control the probability of whether to replace a token with its translation to generate different settings of language mixing ratios and investigate how different ratios affect the effectiveness of the pre-training. As shown in Table 5, using a too high or too low mixing ratio will degrade the advantages of the CPT w/ MLT, [6] and keeping the ratio between 30% and 40% will achieve the best performance. We conjecture that, if the mixing ratio is too low, the dictionary which provides the supervision of bilingual alignment is not well utilized, while if the mixing ratio is too high (e.g., 50%), we replace almost all the tokens existing in the dictionary, which lowers the diversity of the mixed-language text and makes the model more easily overfit to the pre-training data.

4.6 Importance of Pre-Tokenization

Considering that the tokenizer of mBART is created based on the text of the pre-training languages, it might not perform good tokenization for the unseen languages that are diverse from the pre-trained languages. Therefore, it could be a better option to pre-tokenize the text before using mBART's tokenizer. We conduct experiments on the En-Th language pair and compare the performance between performing and not performing the pre-tokenization for Thai. As shown in Table 6, we find that pre-tokenization is able to improve the performance in En → Th significantly, while the improvements are marginal in Th → En. We conjecture that decoding (generating) tokens in the unseen language is much more difficult than encoding those tokens when they are not properly tokenized. This is because the task of the encoder is to understand the meaning of the input text, while the decoder needs to attend to the input text and generate tokens simultaneously, which makes the task of the decoder more difficult than that of the encoder. Therefore, when the unseen language (Thai) becomes the target language in the translation pair, the performance drops remarkably without pre-tokenization.

5 Related Work

5.1 Multilingual Pre-Trained Models

Recently, multilingual pre-trained models based on the masked language modeling (MLM) objective function (Devlin et al., 2019; Conneau and Lample, 2019; Huang et al., 2019; Conneau et al., 2020) have shown their effectiveness at performing cross-lingual classification-based tasks. However, these models are inferior to the generation tasks (Rönnqvist et al., 2019) since they are not pre-trained in a generative way. Multilingual pre-training performed in a Seq2Seq fashion is able to mitigate this issue (Radford et al.; Lewis et al., 2020; Raffel et al., 2019), and has become a strong backbone for building NMT systems, especially in a low-resource scenario (Liu et al., 2020a; Song et al., 2019; Lin et al., 2020; Yang et al., 2020; Xue et al., 2020; Fan et al., 2020; Tang et al., 2020). Liu et al. (2020a) pre-trained a Seq2Seq multilingual model (mBART) by denoising full texts in 25 languages, while Lin et al. (2020) proposed multilingual random aligned substitution to pre-train an NMT model for many languages based on parallel data. Instead of pre-training models from scratch, Wang et al. (2020) proposed to extend multilingual BERT (Devlin et al., 2019) to an unseen language and evaluate it on the named entity recognition task. Although many studies have focused on pre-training multilingual models, few have investigated how to adapt the pre-trained models to new languages effectively. Also, to the best of our knowledge, we are the first to explore how to adapt a multilingual model pre-trained in a Seq2Seq fashion to unseen languages and evaluate the methods on a generative task (the NMT task).

5.2 Low-Resource Machine Translation

Recently, developing algorithms that are able to cope with the scenario where the training data are insufficient have become an interesting and popular research topic across a variety of tasks (Chen et al., 2019a,b, 2020; Brown et al., 2020; Liu et al., 2020c; Lauscher et al., 2020; Winata et al., 2020; Liu et al., 2020b; Peng et al., 2020; Liu et al., 2020d; Yu et al., 2021; Winata et al., 2021). Low-resource machine translation systems (Vandeghinste et al., 2007; Irvine and Callison-Burch, 2013; Zoph et al., 2016; Sennrich et al., 2016; Fadaee et al., 2017; Currey et al., 2017; Imankulova et al., 2017; Gu et al., 2018a; Pourdamghani et al., 2018; Gu et al., 2018b; Lample et al., 2018a,c; Kocmi and Bojar, 2018; Artetxe et al., 2018; Lakew et al., 2018; Imankulova et al., 2019a; Xia et al., 2019; Liu et al., 2019; Guzmán et al., 2019; Imankulova et al., 2019b; Stickland et al., 2020; Siddhant et al., 2020) alleviated the parallel data scarcity issue for low-

---

[6] Note that the maximum mixing ratio will not be larger than 55% since there are substantial infrequent tokens in the target language not existing in the dictionary, which will not be replaced with the source language tokens.

resource languages and improve the models' generalization ability for low-resource language pairs. Pourdamghani et al. (2018) proposed to improve the low-resource NMT performance by boosting the quality of word alignments. Gu et al. (2018b) applied the meta-learning approach into the low-resource NMT task, and Baziotis et al. (2020) incorporated a language model prior to regularize the output distribution of the translation model. Pre-training a multilingual Seq2Seq model (Liu et al., 2020a; Lin et al., 2020) allows it to be directly fine-tuned for supervised machine translation tasks and produces remarkable performance gains in the low-resource scenario over those without pre-training.

6 Conclusion & Future Work

In this paper, we present a continual pre-training framework to improve mBART's generalization ability to extremely low-resource translation pairs that contain unseen languages. We propose to construct noisy mixed-language text from the monolingual corpus to cover both the source and target languages, and then, we continue pre-training mBART to reconstruct the original monolingual text. Results illustrate that our method is able to consistently surpass strong baselines across all tested translation pairs that contain unseen languages, as well as the ones where both languages are seen in the original mBART's pre-training. Moreover, we observe that our method is also beneficial for different low-resource settings, and its performance can be further boosted when a larger pre-training corpus is available. Furthermore, we find that not only mixing the source and target languages, but also increasing the variety of the inputs plays an essential role in the continual mixed-language pre-training. In future work, we will explore more pre-training methods to further boost the performance of pre-trained models on the NMT task. Additionally, we will study more applications of continual mixed-language pre-training, such as applying it to downstream cross-lingual tasks.

A Zero-shot Performance

The zero-shot performance for the 24 translation pairs are shown in Table 7 (in the next page). We find that the CPT w/ MLT generally outperforms the CPT w/ Ori. However, the zero-shot results are relatively low, especially for the translation pairs where both languages are unseen in the original mBART's pre-training, due to the absence of parallel data.

B Data & Code

We will release our split data, dictionaries, as well as the code to ensure the reproducibility of our work.

Transformer-Exclusive Cross-Modal Representation for Vision and Language

Andrew Shin

Abstract

Ever since the advent of deep learning, cross-modal representation learning has been dominated by the approaches involving convolutional neural networks for visual representation and recurrent neural networks for language representation. Transformer architecture, however, has rapidly taken over the recurrent neural networks in natural language processing tasks, and it has also been shown that vision tasks can be handled with transformer architecture, with compatible performance to convolutional neural networks. Such results naturally lead to speculation upon the possibility of tackling cross-modal representation for vision and language exclusively with transformer. This paper examines transformer-exclusive cross-modal representation to explore such possibility, demonstrating its potentials as well as discussing its current limitations and its prospects.

1 Introduction

While early cross-modal models handled visuolinguistic tasks with template-based methods (Barbu et al., 2012; Elliott and Keller, 2013), or as a retrieval model (Farhadi et al., 2010; Ordonez et al., 2011), the advent of deep learning introduced end-to-end learning models for cross-modal tasks, in which convolutional neural networks (CNNs) (Krizhevsky et al., 2012) are employed for vision representation, whereas recurrent neural networks (RNNs), such as LSTM (Hochreiter and Schmidhuber, 1997) or GRU (Cho et al., 2014), are employed for language representation. While a plethora of variations exist, most models proposed in the past few years have invariably relied on the CNN-RNN approach.

Such standardized scheme, however, started to change with the introduction of transformer architecture based on multi-head attention mechanism (Vaswani et al., 2017), which rapidly started to achieve state-of-the-art performance in natural language processing (NLP) (Peters et al., 2018; Dai et al., 2019; Yang et al., 2019) and speech recognition domains (Dong et al., 2018; Wang et al., 2020b), frequently outperforming RNNs. Furthermore, large-scale models based on transformer architecture, such as BERT (Devlin et al., 2019) or GPT-3 (Brown et al., 2020), started to appear, demonstrating that pre-training a sufficiently large model with a very large amount of data results in strong performance with versatility for various downstream tasks.

The success of transformer-based models in NLP and speech recognition naturally led to its adaptation in cross-modal tasks. (Lu et al., 2019) proposed ViLBERT, a pioneering BERT-inspired work that proposed to tokenize the images for compatibility with transformer architecture, and also to extend the pre-training objectives of BERT to reflect the nature of cross-modality. Many other cross-modal models followed, but mostly with similar approaches for image tokenization and pre-training objectives. This line of transformer-based cross-modal works described above, however, still heavily relied on CNN-based models, such as Faster R-CNN (Ren et al., 2015), to extract features from images, and the application of transformer was mostly limited to language representation.

Inspired by the observations made by recent works (Dosovitskiy et al., 2020), which demonstrate that vision tasks can be handled solely by transformer architecture with compatible performances to CNN-based models, this paper examines cross-modal representation for visuolinguistic tasks relying exclusively on transformer architecture, without using CNNs or RNNs. Without any structural modifications or advanced common embedding scheme, and without additional cross-modal pre-training that can be expensive both

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2719–2725
August 1–6, 2021.

computationally and data-wise, our model demonstrates comparable performances to conventional approaches based on CNNs and RNNs in exemplary cross-modal tasks.

2 Related Works

ViLBERT (Lu et al., 2019) was one of the first models to extend transformer architecture to cross-modal visuolinguistic tasks. They propose co-attentional transformer, in which separate transformer modules for each modality run in parallel, with the key and value inputs from one modality entering the transformer block for the other modality, thereby learning cross-modal dependence. In order to tokenize the image, they extract image regions using Faster R-CNN (Ren et al., 2015) along with 5-dimensional location vector. They also extend two unique pre-training objectives of BERT, namely masked language modeling and next-sentence prediction, to cross-modal setting, as masked multi-modal learning and image-sentence alignment classification. In masked multi-modal learning, visual tokens, along with language tokens, are randomly masked, and the model is trained to predict their probability distribution over object classes. In image-sentence alignment classification, a sequence of visual tokens and a sentence are juxtaposed, and the model performs a binary classification task, predicting whether the sentence describes the contents of the image. Many other models, such as VisualBERT (Li et al., 2019), LXMERT (Tan and Bansal, 2019) and Unicoder-VL (Li et al., 2020), also follow nearly identical pre-training objectives as VilBERT. On the other hand, UNITER (Chen et al., 2020) demonstrates improved performance by introducing additional pre-training objective of word region alignment, while MiniVLM (Wang et al., 2020a) achieves comparable performance with up to 70% fewer parameters by utilizing EfficinetNet (Tan and Le, 2019) with their own Compact BERT model.

While all models described above rely on CNN-based models to extract features from images, limiting the scope of applicability of transformer, recent works have demonstrated results that may imply a potential change in such workflow. (Dosovitskiy et al., 2020) proposed Vision Transformer (ViT), which demonstrates that pure transformer architecture without convolution can achieve comparable performance in image classification tasks, while requiring substantially less computational costs. Furthermore, (Touvron et al., 2021) showed via data-efficient image transformers (DeiT) that competitive performance can be achieved with training only on ImageNet (Deng et al., 2009) with no external data.

3 Model

We employ separate transformer models for vision and language, although internal mechanisms are essentially identical. Following (Dosovitskiy et al., 2020), we split an image into N patches x_p of $P \times P$ pixels, each of which is linearly projected into D-dimensional patch embedding, where $P = 16$, and $D = 768$. A learnable embedding x_{class} is prepended to patch embeddings, and positional embeddings are also added. The input sequence z_0 subsequently undergoes alternating layers of layer normalization (Ba et al., 2016) and multi-head self-attention, followed by a 2-layer MLP with GELUs (Hendrycks and Gimpel, 2020) as non-linearity:

$$z_0 = [x_{class}; x_p^1 E; x_p^2 E; ...; x_p^N E] + E_{pos}, \quad (1)$$

$$E \in \mathbb{R}^{(P^2 C)\times D}, E_{pos} \in \mathbb{R}^{(N+1)+D}$$

$$z'_l = \text{MSA}(\text{LN}(z_{l-1})) + z_{l-1}, l = 1...L \quad (2)$$

$$z_l = \text{MLP}(\text{LN}(z'_l)) + z'_l, l = 1...L \quad (3)$$

$$y_{img} = \text{LN}(z_L^0) \quad (4)$$

where

$$\text{MSA}(X) = W_{att}[\text{Att}_1(X), ..., \text{Att}_m(X)]^\top \quad (5)$$

$$\text{Att}_i(X) = \text{softmax}\frac{((W_{Q_i}X)^\top W_{K_i}X)}{\sqrt{D/m}}(W_{V_i}X)^\top \quad (6)$$

for input layer $X \in \mathbb{R}^{D\times N}$, and learnable parameters $W_{Q_i}, W_{K_i}, W_{V_i} \in \mathbb{R}^{\frac{D}{m}\times D}$, $W_{att} \in \mathbb{R}^{D\times D}$ for m attention heads.

For language representation, we employ an off-the-shelf BERT model. An input sequence $s_0 = [w_0, ..., w_S]$ is given with special tokens $[CLS]$ and $[SEP]$ inserted at the beginning and the end of the sequence respectively. In case of two sentences within the input sequences, $[SEP]$ token is also inserted in between the two. Each token is represented as the sum of word embedding, position embedding, and segment embedding, and undergoes bidirectional multi-head self-attention over multiple layers. The representation for the input sequence is obtained as $h_0, ..., h_S$ from the upper-

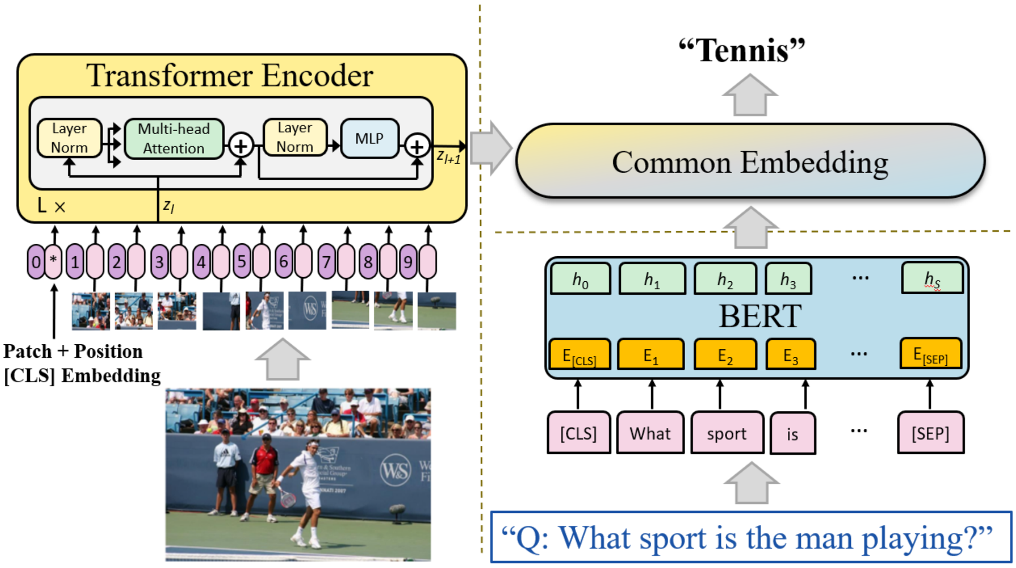

Figure 1: Overview of our model. Images are split into patches, sentences are split into tokens, and both are encoded with transformers, after which they are combined in common embedding space for final classification.

most attention layer:

$$s_0 = [[CLS], w_1, ..., w_{S-1}, [SEP]] \quad (7)$$

$$s'_l = \text{MSA}(\text{LN}(s_{l-1})) + s_{l-1}, l = 1...L \quad (8)$$

$$s_l = \text{MLP}(\text{LN}(s'_l)) + s'_l, l = 1...L \quad (9)$$

$$y_{lang} = \text{LN}(s^0_L) \quad (10)$$

We now project the image and language representations obtained into common embedding space by concatenation:

$$y = \text{Concat}(y_{img}, y_{lang}) \quad (11)$$

Note that we deliberately choose the most elementary common embedding scheme, as our focus is to examine the performance of the features themselves, rather than the embedding scheme. It is thus highly likely that, when coupled with more sophisticated embedding schemes, a significant performance boost will occur. Fig. 1 describes the overall architecture of our approach.

4 Experiments

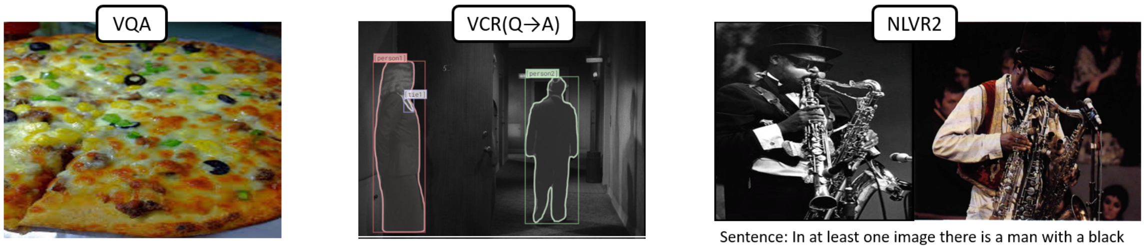
4.1 Setting

For images, we use ViT-B model pre-trained on ImageNet-21k. The model contains 12-layers with 12 attention heads and hidden size of 768, consisting of 86M parameters. For language, we use off-the-shelf BERT$_{\text{BASE}}$ mode, trained with BERT's pre-training objectives of masked language modeling and next sentence prediction on BookCorpus (Zhu et al., 2015) and English Wikipedia. Like ViT-B, the model contains 12-layers with 12 attention heads and hidden size of 768, and consists of 110M parameters. During both training and testing, image and language features are extracted from the uppermost layer of respective model, and we concatenate them to make a 1536-dimensional vector. Concatenated features are trained with cross-entropy loss and Adam (Kingma and Ba, 2014) optimizer.

We evaluate our model on the following commonly tackled cross-modal visuolinguistic tasks; visual question answering (VQA) (Antol et al., 2015; Goyal et al., 2017), visual commonsense reasoning (VCR) (Zellers et al., 2019), and reasoning about natural language grounded in photographs (NLVR2) (Suhr et al., 2019). For VCR, we followed (Lu et al., 2019) by making 4 possible pairs of question and answer. For NLVR2, we follow the *pair* approach of (Chen et al., 2020), by embedding each image and the query, as it is reported to outperform *triplet* approach of embedding two images with the query. We trained with 4 V100 GPUs with batch size 96 for VQA and NLVR2, and 48 for VCR, which were adjusted with respect to the memory constraint of the computational environment. Learning rate was initially set to 1e-4 under linearly decaying schedule with warm up. We trained the model for 25 epochs for each task.

4.2 Results

Table 1 compares our model's performance with other transformer-based cross-modal models. While our model's performance falls below that of state-of-the-art models, it is noteworthy that other models explicitly perform additional cross-modal pre-training on top of already pre-trained vision and



Q: What sort of food is this?
Answer: Pizza

Q: Why is person1 standing behind the open door?
Answer: person1 is trying to hide from person2

Sentence: In at least one image there is a man with a black hat and brown vest playing three saxophones at once.
Answer: True

Figure 2: Qualitative results for each task.

Ours	67.84	68.4	70.2	49.2	65.2

Table 2: Comparison of our model to different combinations. Under the same condition of no explicit cross-modal fine-tuning and the same embedding scheme, our model outperforms other combinations.

language modules. On the other hand, our model simply concatenates two pre-trained models without additional cross-modal pre-training, and is immediately trained with the target task. For example, ViLBERT and DeVLBERT (Zhang et al., 2020) are pre-traiend with Conceptual Captions dataset (Sharma et al., 2018), and our model is at the disadvantage of not having seen 3.3M pairs of image and captions, yet comes fairly close to those pre-trained models. Fig. 2 shows qualitative examples of the model's performance on each task. In addition, while many papers on pre-trained cross-modal representations do not report specific number of parameters, our approximations of other models' sizes based on the implementation details reported in respective papers suggest that our model is reasonably smaller, especially since it completely eliminates the need for external region detector.

4.3 Further Experiments

In order to examine how much each component contributes to performance, we conduct further experiments, replacing each component with conventional modules. We first replace transformer encoder for images with CNN module, specifically with ResNet-50 (He et al., 2016) trained on ImageNet, using global average-pooled features. We also examine replacing BERT module with LSTM (Hochreiter and Schmidhuber, 1997) using early fusion with image features. For fair comparison, we used concatenation as common embedding scheme for all combinations.

Table 2 shows the results. While ResNet/BERT comes fairly close, it falls below our model, and performance drop is clearer with ViT/LSTM, possibly reflecting superior adaptability of BERT compared to LSTM. Our conjecture is that architectural integrity, *i.e.*, using the same architecture for both vision and language, throughout the model, plays an important role in learning cross-modal representations. Note that, however, it would require a more thorough and analytical study to conclusively claim that ViT is superior to ResNet, or that attention is superior to convolution, and our primary purpose in this experiment is simply to demonstrate that transformer-exclusive models can accomplish comparable performance to the models employing CNN. We also examined linearly training a classifier for target task while fixing the extracted features, without fine-tuning. As expected, there is a significant performance drop, reaffirming the premise that the competence of transformer and BERT is attainable via fine-tuning to its downstream tasks.

Note that, although we performed experiments on a small set of cross-modal tasks, given the superior performance of ViT over ResNet on image classification as reported by (Dosovitskiy et al., 2020), and also on other computer vision tasks as reported by models like pyramid vision transformer (Wang et al., 2021), we believe any task that involves vision and language is a potential beneficiary of transformer-exclusive approach, since it enables the architectural integrity for both modalities.

5 Conclusion

This paper proposed to handle cross-modal tasks for vision and language, solely based on transformer architecture, examining it in various cross-modal tasks. Our paper admittedly does not claim state-of-the-art performances, but to the best of our knowledge, our work is one of the first attempts, along with models like ViLT (Kim et al., 2021) and UniT (Hu and Singh, 2021), to examine cross-modal representation for vision and language solely based on transformer architecture, excluding CNNs and RNNs. Without any structural modifications or sophisticated common embedding scheme, and without additional cross-modal pre-training with millions of samples, our model demonstrates comparable performances to state-of-the-art cross-modal models. Since we deliberately chose the smallest baseline models for each component, and a very simple concatenation scheme, we can intuitively expect an enhanced performance by selecting larger pre-trained models at the cost of more parameters, or by selecting more sophisticated common embedding scheme. The same holds true for the amount of pre-training data used, as we can reasonably expect the performance to boost by using the same amount of pre-training data employed by previous models. With transformer's relative computational efficiency as reported by (Dosovitskiy et al., 2020), the architectural integrity proposed in our model is likely to lead to new research direction, and we hope to encourage more advanced models with novel ideas to follow in near future.

Two Parents, One Child:
Dual Transfer for Low-Resource Neural Machine Translation

Meng Zhang, Liangyou Li, Qun Liu
Huawei Noah's Ark Lab
{zhangmeng92, liliangyou, qun.liu}@huawei.com

Abstract

Neural machine translation suffers when parallel data for training is scarce. Previous works have explored transfer learning to assist training in low-resource scenarios. However, they transfer either from high-resource parallel data, or from monolingual data. In this work, we propose a framework to transfer multiple sources of auxiliary data, including both high-resource parallel data and monolingual data of involved languages. Knowledge in those sources is respectively encoded in a high-resource translation model and pretrained language models, and dually transferred to the low-resource translation model by our approach. Extensive experiments show that our approach yields consistent improvements over strong competitors for multiple translation directions. Furthermore, our approach still exhibits benefit on top of back-translation, making it a useful addition to practitioners' toolbox.

1 Introduction

Neural machine translation (NMT) has achieved remarkable success in recent years, but its quality critically hinges on large-scale parallel data. In the low-resource scenarios for most world languages and many domains, its performance usually deteriorates dramatically.

Although parallel data for some translation tasks may be difficult to obtain, monolingual data is usually within reach, and often comes in much larger quantity. Besides, parallel data for several high-resource languages is readily available. These corpora have been used in various methods to help training low-resource NMT. The most relevant method to our work is transfer learning.

Transfer learning starts with training a source task and then initializes the target task with the parameters. Recent advances in pretrained language models (PLM) like BERT (Devlin et al., 2019) can be seen as transfer learning, where language modeling is the source task for downstream target tasks. In low-resource NMT, pretrained language models have also provided noticeable improvements (Clinchant et al., 2019; Imamura and Sumita, 2019). As another source of transfer, high-resource NMT models have also been used for transfer learning low-resource NMT. Zoph et al. (2016) pioneered this direction with NMT based on recurrent neural networks, and coined the high-resource and low-resource models as parent and child models, respectively.

Table 1: An overview of data usage by approaches considered in this work (Section 4.3). H/L: high/low-resource language pair; M: monolingual; P: parallel. BBERT transfer checks all the boxes but uses data in a different way from ours.

However, it is non-trivial to transfer from both PLMs and NMT models. This limitation constrains most existing transfer-learning-based low-resource NMT to a single source of auxiliary data, either monolingual or parallel.

In this paper, we propose a framework for transfer learning low-resource NMT that utilizes both monolingual data and high-resource parallel data (Table 1). Our approach encodes monolingual

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2726–2738
August 1–6, 2021.

knowledge in parent PLMs and translation knowledge in parent NMT models, and transfers both types of models to the child NMT model. Despite its simplicity, our approach shows consistent gains for multiple translation directions. Furthermore, it possesses several desirable features:

- It performs reasonably well even with little or no parallel data in the language pair of interest, alleviating the data issue for low-resource language pairs.
- It is complementary to back-translation, a strong data augmentation approach.
- It is agnostic to network architectures and thus applicable to any translation models.
- It is widely applicable to low-resource languages and can be applied to domain adaptation.
- The same high-resource NMT model can be used to transfer to future low-resource languages, saving computation.

2 Background

2.1 Transfer from Pretrained Language Models

The "pretraining-finetuning" paradigm has been highly successful for various natural language processing tasks. It first pretrains a language model through self-supervised learning, and then finetunes the model along with additional task-specific layers on downstream task data. Here, we exclude pretrained language models trained by sequence-to-sequence learning to simplify discussion[1]. Common pretrained language models include BERT and GPT (Brown et al., 2020).

In NMT with the encoder-decoder architecture (Sutskever et al., 2014; Bahdanau et al., 2015), the direct application of the "pretraining-finetuning" paradigm would be initializing the encoder with PLM and treating the decoder as task-specific layers. However, it is also possible to initialize the compatible modules in the decoder, leaving the cross attention module randomly initialized. Although initializing the decoder does not appear as useful, especially for high-resource language pairs (Rothe et al., 2020), it is not harmful either.

2.2 Transfer from High-Resource Translation Models

Even though the Transformer model (Vaswani et al., 2017) has become more popular than recurrent neural networks for NMT, the transfer procedure proposed by Zoph et al. (2016) still applies as long as the parent model and the child model share the same architecture, which is typically the case. However, one problem still persists. Because the high-resource languages have different vocabularies from the low-resource ones, directly transferring the word embedding layer is not possible.

One way to circumvent this issue is to prepare a joint vocabulary of the involved languages that is shared between the parent and child NMT models (Kocmi and Bojar, 2018). Known as warm-start transfer (Neubig and Hu, 2018), this type of methods need to prepare a new joint vocabulary whenever a new low-resource model is on demand, and retrain both parent and child models. In contrast, cold-start transfer (Kocmi and Bojar, 2020) trains a universal parent NMT model that does not depend on child languages.

Kim et al. (2019) addressed the vocabulary mismatch for cold-start transfer by matching word embeddings across languages. They first learn monolingual word embeddings of the child language with e.g. skip-gram (Mikolov et al., 2013), and then learn a cross-lingual linear mapping to connect child monolingual word embeddings and pretrained parent NMT word embeddings. The child monolingual word embeddings can then be mapped to the parent word embedding space, and be used to initialize the child NMT word embeddings. The cross-lingual linear mapping relies on a bilingual lexicon to learn, which can be induced from parent and child language monolingual data by unsupervised methods like (Lample et al., 2018a).

Our approach also belongs to cold-start transfer in its usage of the parent NMT model. It addresses the vocabulary mismatch by design, without relying on monolingual word embeddings and bilingual lexica.

3 Approach

Our approach is a general framework for transferring from any high-resource language pair to any low-resource language pair, as long as data condition permits. Generally speaking, monolingual data and high-resource parallel data are available in large quantity. We first present the gen-

---

[1] Examples of such models include MASS (Song et al., 2019) and BART (Lewis et al., 2020). If desired, pretrained encoders in these models can be used in our approach.

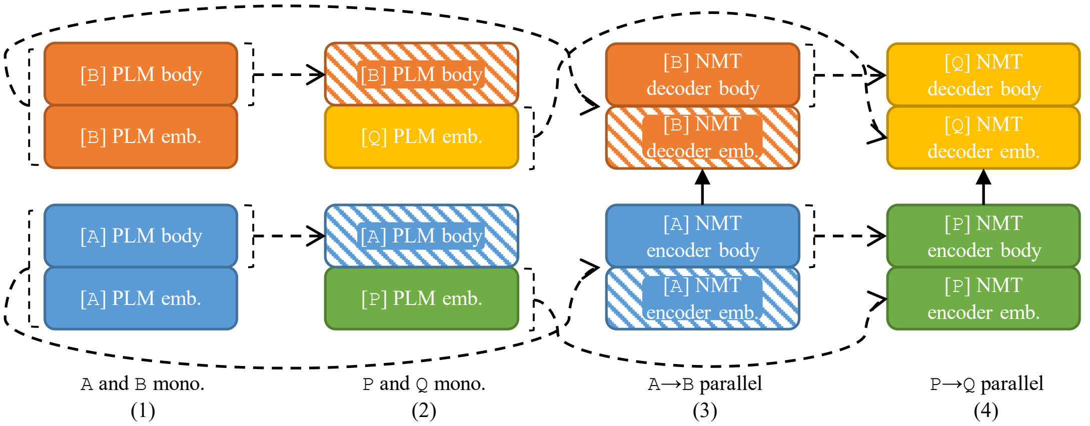

Figure 1: Dual transfer from PLM and high-resource A→B NMT to low-resource P→Q NMT. Dashed lines represent initialization. Parameters in striped blocks are frozen in the corresponding step, while other parameters are trainable. Different colors represent different languages. Data used in each step is also listed.

eral case where we would like to transfer from the high-resource A→B to the low-resource P→Q, where capital letters denote languages. Then we discuss specific cases where some of the involved languages are the same.

3.1 General Transfer

Figure 1 shows the pipeline of our approach, consisting of four major steps, as detailed below.

(1) Train PLM$_{\mathtt{A}}$ and PLM$_{\mathtt{B}}$ on monolingual data of A and B separately.

(2) Train PLM$_{\mathtt{P}}$ and PLM$_{\mathtt{Q}}$ on monolingual data of P and Q as follows.

  - Initialize PLM$_{\mathtt{P}}$ with PLM$_{\mathtt{A}}$ (except word embeddings); freeze parameters other than word embeddings.
  - Initialize PLM$_{\mathtt{Q}}$ with PLM$_{\mathtt{B}}$ (except word embeddings); freeze parameters other than word embeddings.

(3) Train NMT$_{\mathtt{A}\to\mathtt{B}}$ on A→B parallel data as follows: Initialize NMT encoder with PLM$_{\mathtt{A}}$, and decoder with PLM$_{\mathtt{B}}$; freeze word embeddings during training.

(4) Replace word embeddings as follows to initialize NMT$_{\mathtt{P}\to\mathtt{Q}}$, and finetune on P→Q parallel data.

  - Replace NMT$_{\mathtt{A}\to\mathtt{B}}$ encoder word embeddings with those in PLM$_{\mathtt{P}}$.
  - Replace NMT$_{\mathtt{A}\to\mathtt{B}}$ decoder word embeddings with those in PLM$_{\mathtt{Q}}$.

Note that Steps (2) and (3) are independent of each other, and therefore can be done in parallel.

Intuitively, Step (2) learns word embeddings of P and Q that lie in the same semantic space of A and B, respectively. Because only word embeddings are trainable, they are forced to align with pretrained A and B body parameters to do language modeling (e.g. masked language model). In Step (3), NMT$_{\mathtt{A}\to\mathtt{B}}$ needs to learn translation based on the frozen A and B word embeddings space. With P and Q word embeddings swapped in place in Step (4), the body and embedding parameters can cooperate in a close semantic space, allowing finetuning to proceed smoothly.

Like (Kim et al., 2019), our approach solves the vocabulary mismatch issue by manipulation in the embedding space, allowing transfer between arbitrary languages, even with different scripts[2]. Each language now manages its own independent vocabulary. We also tie input and output embeddings of the decoder (Press and Wolf, 2017), so a single decoder embedding block is shown in Figure 1.

We can further generalize our approach by defining *transfer parameters* as those responsible for transforming input into continuous representations shared across languages. In Figure 1, the transfer parameters are simply word embeddings, but we may also use other sets of transfer parameters, e.g. word and position embeddings, or even lower layers of the body. In Step (2), only transfer parameters are trainable, while in Step (3), only non-transfer parameters are trainable, and initialization changes accordingly.

---

[2] We verified the effectiveness of our approach for transferring from `fr→en` to `ru→en` on in-house data.

Our approach defines a framework for transfer learning, which can be applied to various network architectures. For example, if we would like to train a low-resource RNN-based NMT, we can prepare RNN-based PLMs and a high-resource RNN-based NMT. In our experiments, we use Transformer for PLMs and NMT models.

3.2 Shared Target Transfer and Shared Source Transfer

In practice, it is a rare need to train on a low-resource language pair where both languages are low-resource. Typically one of the two languages would be high-resource, e.g. English. In this case, we can choose a high-resource language pair that shares this language on the same side, thereby simplifying our approach.

If the target language (`Q`) of the low-resource language pair (`P`→`Q`) is high-resource, we can choose a high-resource language pair (`A`→`B`) with that language as the target, i.e. `B`=`Q`. In this case, there is no vocabulary mismatch on the target side, so $\text{PLM}_{\texttt{Q}}$ is no longer needed, and decoder word embeddings can be adjusted when training $\text{NMT}_{\texttt{A}\rightarrow\texttt{B}}$ in Step (3). $\text{PLM}_{\texttt{B}}$ also becomes optional, and the randomly initialized decoder of $\text{NMT}_{\texttt{A}\rightarrow\texttt{B}}$ may learn sufficiently from abundant `A`→`B` parallel data.

Likewise, if the source language (`P`) is high-resource, we can let `A`=`P`. Then $\text{PLM}_{\texttt{P}}$ is not needed, and encoder word embeddings are trainable in Step (3). $\text{PLM}_{\texttt{A}}$ may also be dispensed with and the encoder of $\text{NMT}_{\texttt{A}\rightarrow\texttt{B}}$ is randomly initialized.

3.3 Domain Adaptation

By viewing a certain domain as a special language, our approach can also be applied to domain adaptation. In this case, `A`→`B` is a high-resource source domain, and `P`→`Q` is a low-resource target domain. By definition, this setting is general transfer, because neither `B`=`Q` nor `A`=`P` is possible due to domain difference, but typically they will be the same language, respectively.

4 Experimental Setup

We mainly verify our approach in the more realistic shared target and shared source transfer scenarios. We take German-English (`de-en`) as the high-resource language pair, while Estonian-English (`et-en`) and Turkish-English (`tr-en`) are the low-resource language pairs. Previous works mainly consider shared target transfer (Dabre et al., 2020), and we make extensive comparison in the experiment that transfers from `de`→`en` to `et`→`en`. We then verify on other translation directions, including shared source transfer, as well as general transfer, in which we consider an artificial setting of transferring from `de`→`en` to French→Spanish (`fr`→`es`). For domain adaptation we work on `de`→`en`, transferring from news domain to medical domain. We report SacreBLEU[3] (Post, 2018). Further details about data and hyperparameters can be found in Appendices B and C, respectively.

language code	# sentence (pair)
`de-en`	5.9m
`et-en`	1.9m
`tr-en`	207k
`fr-es`	10k
`de-en` medical	347k
`en`	94m
`de`	147m
`et`	139m
`tr`	100m
`fr`	4.1m
`es`	4.2m
`en` medical	4.0m
`de` medical	3.6m

Table 2: Training data statistics.

4.1 Data

We mainly use data from WMT 2018[4]. We use preprocessed parallel data for training NMT models. The provided development data includes multi-parallel data for several languages, which we use for `fr`→`es`. We collect monolingual data for the involved languages and follow the same preprocessing pipeline. Training data statistics is provided in Table 2. Each language is encoded with byte pair encoding (BPE) (Sennrich et al., 2016b). The BPE codes and vocabularies are learned on each language's monolingual data, and then used to segment parallel data. Following (Kim et al., 2019), we use 50k merge operations for English, and 20k for other languages. Sentences with more than 150 subwords are removed from NMT training.

---

[3] SacreBLEU signature: BLEU+case.mixed+numrefs.1+smooth.exp+tok.13a+version.1.4.12.

[4] `http://statmt.org/wmt18/translation-task.html`

4.2 Hyperparameters

We use Transformer base as our NMT model, but with slight modifications that follow the implementation of BERT[5]. The absolute position embeddings are also learned as in BERT. We apply dropout with probability 0.1. Learning rate warms up for 16,000 steps and then follows inverse square root decay. The peak learning rate is 7×10^{-4} for the high-resource `de-en`. For other translation tasks, we grid search over $\{1, 3, 5\} \times 10^{-4}$ for each approach in every experiment, and keep the best model based on development BLEU. We use 8 GPUs for `de-en`, and 1 GPU otherwise. Other hyperparameters follow (Kim et al., 2019).

We train BERT as the PLM in our experiments, with the same number of layers and hidden size as Transformer base. The absolute position embeddings are learned up to 128. We only train with masked language modeling and dispense with next sentence prediction as in (Liu et al., 2019). We train for 480k steps with batch size 180 on 8 GPUs. The peak learning rate is 1.8×10^{-4}, and the number of warmup steps is 18,000.

Rothe et al. (2020) found that for the high-resource `de-en` pair, initializing the decoder with PLM has no advantage over random initialization. Therefore, we only used $\text{PLM}_{\texttt{de}}$ for `de`→`en`, but for `en`→`de`, we used both $\text{PLM}_{\texttt{en}}$ and $\text{PLM}_{\texttt{de}}$ because the vocabulary mismatch is on the target side.

4.3 Baselines

We compare with the following approaches.

No transfer This baseline trains directly on the low-resource parallel data.

(Zoph et al., 2016) This approach transfers from the high-resource language pair. In the original paper, random parent word embeddings are used to initialize child word embeddings. We simply initialize child word embeddings with the truncated normal initializer.

(Kim et al., 2019) This approach transfers from the high-resource language pair and utilizes cross-lingual word embeddings. The authors also proposed other orthogonal data augmentation techniques, but we do not include them in our experiments.

BERT2RND This approach transfers from the source language PLM trained on monolingual data. By comparing with BERT2BERT, we can see if the finding in (Rothe et al., 2020) holds for low-resource language pairs.

BERT2BERT This approach transfers from the source and target language PLMs trained on monolingual data. Note that PLMs for BERT2BERT and BERT2RND are directly trained on monolingual data of `P` and `Q`, different from those obtained by Step (2) of our approach.

As discussed in (Kim et al., 2019), managing independent vocabularies for each language has the advantage of flexibility. However, many approaches rely on shared vocabulary. We nevertheless report their performance for reference.

(Kocmi and Bojar, 2018) This approach uses joint vocabulary of all the involved languages. It first trains the NMT model on the high-resource parallel data, and then finetunes it on the low-resource parallel data. It can be seen as a multilingual NMT in which high-resource performance does not matter. We experiment with transferring from `de`→`en` to `et`→`en`, thus involving three languages. We learn joint BPE with 90k merge operations.

BBERT2BBERT Multilingual PLMs usually rely on shared vocabulary, and bilingual BERT (BBERT) is an example trained on non-parallel data of two languages. We learn joint BPE with 70k merge operations for the source and target languages of the low-resource language pair, and the same vocabulary is used for the source and target sides of NMT. Otherwise this approach is the same as BERT2BERT. This is equivalent to XLM (Conneau and Lample, 2019) used for bilingual PLM and MT.

BBERT transfer Multilingual PLMs are often used for cross-lingual transfer. We apply this approach to NMT, transferring from `de`→`en` to `et`→`en`. First we train a `de-et` BBERT, and use it to initialize the encoder of $\text{NMT}_{\texttt{de}\rightarrow\texttt{en}}$. Then we train on `de`→`en` and finally finetune on `et`→`en`. We learn joint BPE with 40k merge operations for the `de-et` pair. This approach uses exactly the same data as ours because we do not use

---

approach	V	BLEU
no transfer	✓	21.76
(Zoph et al., 2016)	✓	21.07
(Kim et al., 2019)	✓	22.25
BERT2RND	✓	22.89
BERT2BERT	✓	23.44
(Kocmi and Bojar, 2018)	✗	23.58
BBERT2BBERT	✗	23.90
BBERT transfer	✗	24.03
dual transfer (word)	✓	**24.81**
dual transfer (word+position)	✓	24.28

Table 3: BLEU on `et→en`, with the best in bold. "✓" in the "V" column indicates independent vocabulary, while "✗" means the approach relies on shared vocabulary. Our approach (dual transfer) has two variants, with or without position embeddings in the transfer parameters.

PLM$_{\mathrm{en}}$ when transferring from `de→en` to `et→en`.

In their experiments, Zoph et al. (2016) and Kim et al. (2019) only considered shared target transfer, and they found that freezing certain components of the decoder during finetuning can be beneficial. In our `et→en` experiment, we tried freezing the decoder word and position embeddings, and optionally self attention parameters, for their approaches, our approach, and BERT2BERT, but development set results revealed that the only setting which brought improvement was freezing word and position embeddings and self attention parameters for (Kim et al., 2019), possibly due to the relatively large size of `et→en` data. Therefore we only use it for (Kim et al., 2019) in our experiments.

5 Results

In this section, we first report extensive experiments on `et→en` before generalizing to other translation directions. We then present the performance of our approach when used in conjunction with back-translation and self training. Finally we demonstrate that our approach can be used for domain adaptation.

5.1 Results on `et→en`

Table 3 shows the BLEU scores for `et→en`. We report the following findings for this translation direction.

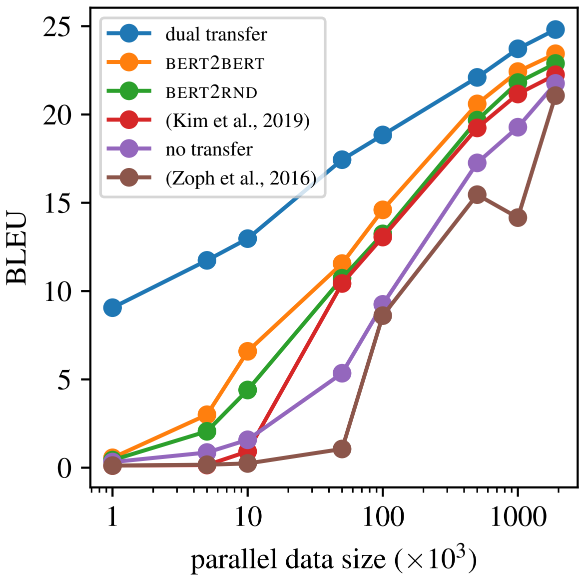

Figure 2: BLEU of different approaches with respect to the number of parallel `et→en` sentence pairs for training. We plot our approach with word embeddings as transfer parameters; additionally transferring position parameters performs similarly.

The approach in (Zoph et al., 2016) only uses high-resource parallel data for transfer, and the approach in (Kim et al., 2019) additionally uses low-resource monolingual data; their BLEU scores are close to the "no transfer" baseline. The approach in (Kocmi and Bojar, 2018) shows positive transfer from high-resource parallel data by forgoing the vocabulary flexibility and relying on joint vocabulary.

Using monolingual data, BERT2RND and BERT2BERT show notable improvement on the "no transfer" baseline. In this relatively low-resource setting, it appears useful to initialize the decoder with BERT, in contrast to `de-en` experiments in (Rothe et al., 2020).

We expected additionally transferring position embeddings to better deal with word order divergence across languages, but after comparing the two variants of our approach, we find no benefit in including position embeddings in the transfer parameters. Our approach with word embeddings as transfer parameters achieves best BLEU, which is a 3.05 improvement over the "no transfer" baseline, and 1.37 over BERT2BERT. Note that we did not use monolingual English data for our approach when the target language is English.

parallel data size ($\times 10^3$)	0	1	5	10	50	100	500	1000
dual transfer (word)	0.43	9.06	11.74	12.97	17.44	18.84	22.10	23.72
+freezing parent NMT encoder	**6.20**	8.82	11.58	12.76	16.62	18.50	21.69	23.59

Table 4: BLEU on `et`→`en`. Freezing the parent NMT encoder helps our approach to perform zero-shot translation.

approach	`tr`→`en`	`en`→`et`	`en`→`tr`	`fr`→`es`
no transfer	15.44	16.29	9.63	10.59
BERT2BERT	19.73	17.36	11.78	18.26
dual transfer (word)	**21.12**	**19.41**	**13.18**	**22.28**
dual transfer (word+position)	20.29	18.79	13.16	-

Table 5: BLEU on translation directions shown in columns, grouped by shared target transfer, shared source transfer, and general transfer. "-" means the experiment was not carried out.

approach	BLEU
no transfer	21.63 (-0.13)
dual transfer (word)	22.53 (-2.28)
dual transfer (word+position)	23.08 (-1.20)

Table 6: BLEU on `et`→`en` augmented with 4m self training data. Numbers in parentheses indicate differences from the corresponding approach trained on authentic parallel data.

5.2 Effect of Low-Resource Parallel Data Size

Arguably, the parallel training data for `et`→`en` is not quite low-resource. But it provides a good test bed for manually adjusting the data size to simulate various degrees of resource scarcity. We sample subsets of $\{1, 5, 10, 50, 100, 500, 1000\} \times 10^3$ parallel sentence pairs, and show BLEU of different approaches in Figure 2. We observe roughly monotonic trend of BLEU with respect to parallel data size, as expected. Our approach performs consistently better than baselines, and the gap is larger with fewer parallel sentence pairs. In the extremely low-resource setting of one thousand pairs, our approach still achieves BLEU close to 10, while all other approaches fail with BLEU close to 0.

5.3 Zero-Shot Translation

Our approach can also be modified slightly to perform zero-shot translation. We conjecture that in Step (3) of our approach, freezing the embeddings alone is insufficient to prevent encoder body parameters from drifting too far away. Therefore we try freezing the entire encoder in Step (3). This technique helps our approach to achieve a zero-shot BLEU score of 6.20, as shown in Table 4. However, it does not have advantage when parallel data is available.

5.4 Other Translation Directions

Table 5 shows the results that include shared target transfer, shared source transfer, and general transfer, comparing our approach with no transfer and BERT2BERT. Our approach consistently outperforms baselines. Previous works (Zoph et al., 2016; Kim et al., 2019) typically conducted experiments on shared target transfer only, and shared source transfer is considered more difficult (Kocmi, 2020), but our approach works well for shared source transfer, as well as general transfer. Also note that, we use the same `de-en` pair for all child languages from diverse language families, which demonstrates the robustness of our approach. It also highlights the advantage of independent vocabularies: We can prepare $\text{NMT}_{\texttt{de}\to\texttt{en}}$ and $\text{NMT}_{\texttt{en}\to\texttt{de}}$ for any future child language, while approaches like (Kocmi and Bojar, 2018) and BBERT transfer have to retrain with the high-resource language every time a new low-resource language is needed.

5.5 Back-Translation and Self Training

Back-translation (BT) (Sennrich et al., 2016a) and self training (ST) (Zhang and Zong, 2016) are data augmentation techniques that generate synthetic parallel data, using target language monolingual data and source language monolingual data respectively. We first experiment with ST for `et`→`en`. We use the "no transfer" $\text{NMT}_{\texttt{et}\to\texttt{en}}$ to translate 4m `et` monolingual data into `en` by greedy decoding, and merge with authentic parallel data. Results in Table 6 show that self training is not helpful for this experiment, and considerably lowers the BLEU of our approach.

approach	BT data size	BLEU
no transfer	4m	19.78 (+3.49)
dual transfer (word)	4m	21.74 (+2.33)
dual transfer (word+position)	4m	**22.34** (+3.55)
no transfer	130m	20.52 (+4.23)
dual transfer (word+position)	130m	22.23 (+3.44)

Table 7: BLEU on `en`→`et` augmented with 4m or 130m back-translation data. Numbers in parentheses indicate differences from the corresponding approach trained on authentic parallel data.

approach	BLEU
no transfer (child)	62.94
BERT2BERT (child)	64.33
finetuning (parent)	64.91
dual transfer (parent)	65.14
dual transfer (child)	**65.40**

Table 8: Domain adaptation results. The transfer parameters are word embeddings for dual transfer. "Parent" indicates using source domain (news) vocabulary, and "child" indicates using target domain (medical) vocabulary.

We then use the same synthetic parallel data for `en`→`et`, turning to the case of BT. The upper rows in Table 7 show that BT is highly beneficial for both the baseline and our approach. Encouraged by this, we further try using all 130m `et` monolingual data with the maximum of 80 tokens and 100 subwords per line. We upsample authentic data to have a 1:4 ratio with synthetic data, following (Caswell et al., 2019). The lower rows in Table 7 show that more BT data can further improve the "no transfer" baseline, though the small improvement appears unattractive considering the cost. As for our approach, going from 4m to 130m yields no gain. Besides, our approach with 4m BT still surpasses no transfer with 130m BT. We conjecture that our approach can work complementarily with a manageable amount of BT data, reducing the need to decode and train on a huge data size.

Finally, note that we use the "no transfer" $\text{NMT}_{\texttt{et}\rightarrow\texttt{en}}$ to generate all synthetic parallel data in our experiments. In practice, the model produced by our approach can be used for decoding, which should result in higher-quality synthetic data. This might also be the reason that ST hurts our approach more than the "no transfer" baseline.

5.6 Domain Adaptation

A simple and effective approach to domain adaptation is finetuning source domain NMT on target domain data (Luong and Manning, 2015; Freitag and Al-Onaizan, 2016). This approach is possible because directly inheriting parent NMT vocabulary is acceptable for domain adaptation. In other words, this is a special case of (Kocmi and Bojar, 2018) where child vocabulary largely overlaps with parent vocabulary. However, our approach allows using a dedicated vocabulary for the target domain. In this case, we learn BPE with the same number of merge operations as the source domain on target domain monolingual data. Table 8 shows that our approach can surpass the baselines, especially with the child (medical domain) vocabulary.

6 Related Work

Low-resource NMT has been researched from many perspectives. Exploiting auxiliary data has been verified to be helpful by various approaches, including data augmentation like back-translation (Sennrich et al., 2016a; Xia et al., 2019), transfer learning as focused in our work, meta-learning (Gu et al., 2018), semi-supervised learning (Cheng et al., 2016), or even unsupervised NMT (Artetxe et al., 2018; Lample et al., 2018b; Chronopoulou et al., 2020).

Transfer learning usually utilizes a single source of knowledge. When multiple sources are available, transfer learning may be applied in a cascaded fashion (Lakew et al., 2018), but catastrophic forgetting may need to be addressed. Maimaiti et al. (2019) proposed multi-round transfer by performing transfer learning for several rounds on multiple high-resource language pairs.

Multilingual NMT (Johnson et al., 2017; Dabre et al., 2019) aims to perform translation for multiple translation pairs in a single model, and positive transfer towards low-resource language pairs typically occurs. In our experiment, we have considered a variant that solely focuses on the low-resource pair (Kocmi and Bojar, 2018; Nguyen and Chiang, 2017).

Outside NMT, Artetxe et al. (2020) proposed a similar partial freezing approach to transferring BERT cross-lingually. As they worked on BERT (Transformer encoder) for natural language understanding tasks, several differences from our work arise. First, we need to consider the initialization of decoder for NMT, and for the shared source case, we need to deal with vocabulary mismatch on the decoder side. Second, we find that additionally transferring position embeddings is not helpful in our experiments. Third, our approach can outperform BBERT transfer, whereas they observe slightly lower performance in their experiments.

7 Conclusion and Future Work

In this work, we propose a framework for transferring from both pretrained language models and neural machine translation models, so that both monolingual data and high-resource parallel data can be used to assist low-resource training. Our approach shows consistent usefulness in a variety of experiments, while also enjoying the flexibility of independent vocabulary.

Recently, a deep encoder and shallow decoder architecture is shown to have comparable translation quality with faster decoding speed (Kasai et al., 2020). While our approach can be applied to such architectures, a shallow decoder means that transferring on the decoder side will be limited by the shallow PLM, which is particularly severe for shared source transfer. In future work we would like to investigate how to work around this issue.

Acknowledgments

We thank Wenyong Huang for his help with the BERT code. We also thank anonymous reviewers for their helpful feedback. We thank MindSpore[6] for the partial support of this work, which is a new deep learning computing framework.

Ethical Considerations

In this paper we have reported experiments with Transformer base, and the computation cost is shown in Table 11 of Appendix A. Scaling up the model may bring further improvement at the cost of computation. However, we have highlighted the benefit of cold-start transfer: Trained high-resource NMT models can be used for future transfer. For example, we can reuse $\text{NMT}_{\texttt{de}\rightarrow\texttt{en}}$ and $\text{NMT}_{\texttt{en}\rightarrow\texttt{de}}$ for a future low-resource language `X` translating to and from English, and $\text{PLM}_{\texttt{X}}$ can be used for both directions if the encoder and the decoder have the same number of layers. We hope such reuse can amortize the cost of preparing parent models. We release the code to facilitate future transfer at `https://github.com/huawei-noah/noah-research/tree/master/noahnmt/dual-transfer`. Besides, our experiment indicates that our approach can reduce the need of back-translation data size, while producing back-translation data and training on augmented data are both costly.

A Runtime

We report the runtime of each step in our dual transfer (word) for NMT$_{\texttt{et}\rightarrow\texttt{en}}$ in Table 11. PLMs for other languages take similar time because we run a fixed number of steps. The runtime of the last finetuning step varies depending on low-resource parallel data size and learning rate. We also report the runtime of the "no transfer" baseline for this language pair as reference.

no transfer	1	20

Table 11: Runtime of each step in dual transfer (word) for $\text{NMT}_{\texttt{et}\rightarrow\texttt{en}}$. The runtime of the "no transfer" baseline for this language pair is also listed.

B Data Source and Preprocessing

We list the data source in Tables 9 and 10. Most of the data is from WMT 2018, unless otherwise noted. Medical data is from WMT 2014 medical translation task[7]. The French and Spanish monolingual data is from WMT 2013 news translation task[8].

All data sets are deduplicated. The Turkish monolingual data is further cleaned by removing lines with more than half non-Turkish characters, and we only use a subset with 100m lines.

C Hyperparameters and Development Performance

As we grid search learning rates in $\{1,3,5\} \times 10^{-4}$, we report the best found learning rate and the corresponding development BLEU in Tables 12, 13, and 14. The development BLEU is calculated by tokenized `multi-bleu.perl`. Due to the large scale of the 130m BT experiment, we directly use the best learning rates for 4m BT, and set other hyperparameters as in high-resource NMT.

Abstract

Multilingual text summarization requires the ability to understand documents in multiple languages and generate summaries in the corresponding language, which poses more challenges on current summarization systems. However, this problem has been rarely studied due to the lack of large-scale supervised summarization data in multiple languages. In this paper, we first provide a large-scale multilingual summarization corpus MLGSum consisting of 1.1 million articles and summaries in 12 different languages. Based on it, we develop a unified summarization model to understand the document and generate summaries in different languages. We use the contrastive learning strategy to train our multilingual summarization system (CALMS), which consists of two training objectives, contrastive sentence ranking (CSR) and sentence aligned substitution (SAS). The two training objectives are designed to share salient information extractive ability and align sentence-level representation across different languages. Experimental results indicate that CALMS achieves significant improvement over monolingual models in all languages. We further transfer CALMS to other languages and find that it will also benefit similar languages. Our code and dataset are available at https://github.com/brxx122/CALMS.

1 Introduction

Automatic text summarization aims at providing a brief summary for a long document. It requires the ability to understand document-level input, catch the main idea of it, and generate a fluent text. Recently, monolingual summarization has witnessed great success with the development of new neural systems (Zhong et al., 2020; Wang et al., 2020) and the availability of monolingual pre-training language models (Kenton and Toutanova, 2019; Liu and Lapata, 2019; Liu et al., 2019; Lewis et al., 2020b). , Inspired by the success of monolingual pre-trained models, researchers further pre-train these models with multiple languages to get the multilingual versions (Huang et al., 2019; Liu et al., 2020; Lewis et al., 2020a), which provide the abilities of understanding and generation in different languages. The multilingual pre-training model can be used as the initialization and finetuned for downstream summarization tasks.

However, the pre-training phase for language models usually focuses on predicting masked tokens or denoising the noisy input, both of which are token-level tasks. It lacks the ability to align sentence-level information among languages and to distinguish which information is the most critical for the document-level input. Most previous multilingual summarization models focus on training one model for different language or partly share encoder/decoder layers (Wang et al., 2018; Lin et al., 2018; Scialom et al., 2020). Cao et al. (2020) and Lewis et al. (2020a) try to train one model for all languages, but they find that although low-resource languages can benefit from the larger training data, the performance of rich-resource languages has been sacrificed. Thus, we want to investigate the following question: *Can we design a unified multilingual summarization model that can benefit both high-resource and low-resource languages?*

In this paper, we design a neural model with the contrastive aligned joint learning strategy for multilingual summarization (CALMS) with two new training objectives: contrastive sentence ranking (CSR) and sentence aligned substitution (SAS). CSR samples sentences from the document and constructs positive and negative pairs based on their saliency. By contrastively learning what is more important, the model is supposed to obtain the ability to distinguish salient information from the document. In order to align sentence-level information among languages, SAS replaces sentences with an-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2739–2750
August 1–6, 2021.

other language and generates the summary based on the noisy input.

We conduct the experiments in five languages: English, Chinese, German, French, and Russian. The experimental results show that CALMS outperforms the monolingual baseline significantly. Further promotion will be gained by finetuning on the specific language. We also transfer our model to 7 languages (Hindi, Spanish, Indonesian, Turkish, Vietnamese, Ukrainian, Portuguese) and achieve great improvements, which indicates our model obtains a better initialization for summarization and can be a better solution for low-resource summarization. We additionally propose a new large-scale multilingual summarization dataset with 12 languages for future multilingual summarization research.

We highlight our contributions as follows:

(1) We design a neural model with the contrastive aligned learning strategy for multilingual summarization (CALMS), which improves summarization performance in both rich-resource and low-resource languages.

(2) We propose two new training strategies to distinguish important information from the document and align sentence-level information across languages.

(3) In order to investigate multilingual summarization, we create a 1.1 million multilingual summarization dataset MLGSum with 12 languages. The experimental results on 5 main languages show that our model significantly outperforms the monolingual summarization model. The extensive experiments on 7 other languages indicate our model can transfer to other similar languages with a good performance.

2 Related Work

Multilingual Summarization Abstractive summarization aims at generating a shorter version of the document while maintaining the most important information. With the large success brought by pre-trained language models in English abstractive summarization (Liu and Lapata, 2019; Lewis et al., 2020b; Zhang et al., 2020), several works focus on summarization in multiple languages. Nguyen and Daumé III (2019) constructs a small cross-lingual dataset with English summaries for non-English articles, and Scialom et al. (2020) proposes MLSUM with 5 languages as the extended version of English summarization dataset CNN/DailyMail (Hermann et al., 2015). Cao et al. (2020) use a Transformer-based model with 6 layers encoder and decoder to combine auto-encoder training, translation and summarization. Different from Cao et al. (2020), we focus on document-level multilingual summarization, which means understanding of long input in different languages is more important for our model. Besides, we propose a large-scale multilingual dataset with 12 languages and each document-summary pair is in the same language.

Contrastive learning in Summarization The goal of contrastive training is to let the model distinguish specific features by constructing positive and negative pairs. For summarization, it is often used to find a better summary. (Shi et al., 2019) randomly replaces a sentence in the ground-truth summary with a random sentence to form the negative sample. Wu et al. (2020) constructs negative samples on different aspects of summary qualities and propose a new summary evaluation method by contrastive learning. Zhong et al. (2020) use a pre-trained extractive model to select several candidates as negative samples and take the ground-truth as the positive. In this work, we dynamically sample several sentences from the document during the training phase and construct the positive and negative pair based on their similarity with the ground-truth summary.

Multilingual Pre-training for Generation Several works try to expand the successful unsupervised pre-training English language model to multiple languages for multilingual understanding and generation (Lample and Conneau, 2019; Huang et al., 2019; Liu et al., 2020; Xue et al., 2020). mBART (Liu et al., 2020) denoises full texts in multiple languages and pre-trains the complete encoder-decoder model, which works well on both sentence-level and document-level machine translation. mT5 (Xue et al., 2020) is the multilingual version of T5 (Kale and Rastogi, 2020) for text-to-text. MARGE (Lewis et al., 2020a) is trained with the multi-lingual multi-document paraphrasing objective, which reconstructs text in one language by retrieving a set of related texts in other languages.

3 Method

Given a document $D = \{x_1, x_2, \cdots, x_M\}$ with M words, the goal of abstractive summarization is to generate a summary with N words $Y = \{y_1, y_2, \cdots, y_N\}$, where $M > N$. For multilin-

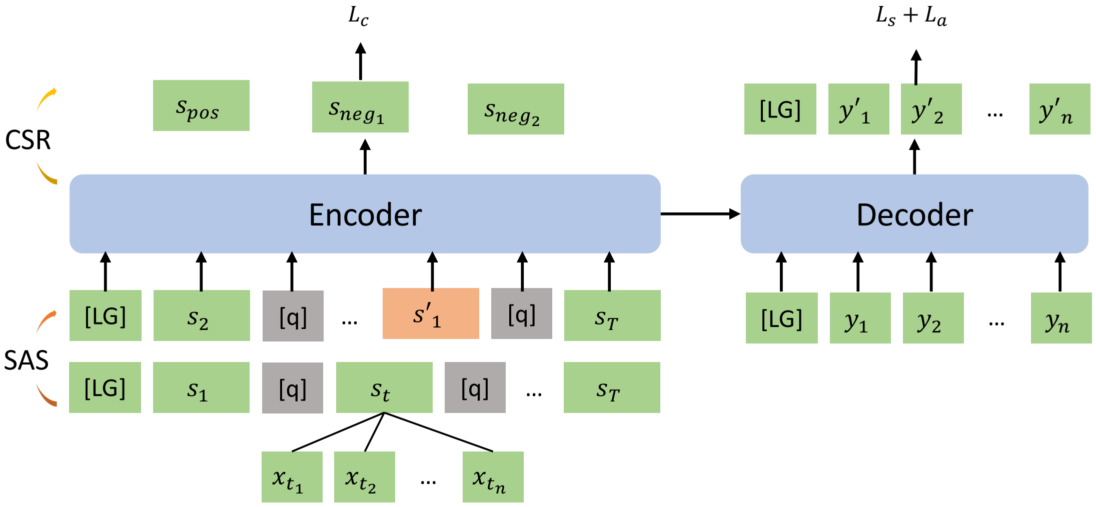

Figure 1: Model Overview. The input and output in green are the same language while the orange is another language. The input document includes T sentences separated by the delimiter '[q]', and each sentence s_t consist of t_n token x. The language indicator '[LG]' is added at the beginning of the encoder and the decoder. CSR selects $q = 3$ sentences from the document and constructs the contrastive pair with one positive and two negative examples. SAS replaces sentence s_1 with the translated s'_1.

gual summarization, the model should be able to deal with inputs in multiple languages and generate the summary in the same language. Formally, for each language l_k in the collection with K languages $L = \{l_1, l_2, \cdots, l_K\}$, the training objective can be defined as

$$\mathcal{L}^{(l_k)} = -\sum_{i=1}^{N_k} logP(Y_i^{(l_k)}|D_i^{(l_k)}), \qquad (1)$$

where $D_i^{(l_k)}$ and $Y_i^{(l_k)}$ are the i-th sample for the language l_k and N_k is the size of examples in l_k.

In this section, we propose a contrastive aligned joint learning strategy for all languages to share the salient information extraction and align sentence-level representations across languages. We propose two extra training objectives for our CALMS and describe them in detail below.

3.1 Multilingual Summarization

To understand and generate text in multiple languages, it is important to have a good multilingual language model. Without loss of generality, we use mBART (Liu et al., 2020) as the model initialization. It is a powerful Transformer-based multilingual pre-trained model trained on monolingual document corpus in 25 languages with denoising training objectives. It provides a shared vocabulary across languages and a good multilingual language model. We fully share model parameters among different languages by jointly training on all summarization data in different languages. A language indicator is used to indicate the language of each example. Thus, the multilingual summarization loss for K languages is written as:

$$\mathcal{L}_s = -\sum_{k=1}^{K}\sum_{i=1}^{N_k} logP(Y_i^{(l_k)}|D_i^{(l_k)}), \qquad (2)$$

3.2 Contrastive Sentence Ranking

Different from pre-trained denoising tasks, the output is much shorter than the input in the summarization task. Therefore, it is important for the summarization model to catch the salient information from the document during the finetuning phrase. We design a contrastive training strategy, contrastive sentence ranking (CSR), to help the model distinguish salient information, which is independent of languages. Inspired by content selection in extractive summarization (Shi et al., 2019; Zhong et al., 2020), we take sentences to construct positive and negative pairs. However, instead of pre-constructing contrastive summaries pairs for the dataset, we dynamically sample sentences from the document during the training phase.

Specifically, for a document D with T sentences $D = \{s_1, s_2, \cdots, s_T\}$, we randomly sample q sentences as candidates and calculate n-gram overlaps between the ground-truth summaries and these candidates. The candidate with the highest overlaps will be viewed as positive and the others are negative. By dynamically sampling, the model is able to explore the whole document. Besides, we can change the negative sample number for each language to alleviate the imbalance between the data. Each time the data loader takes an example from the dataset, it will construct a positive-negative pair and save the corresponding sentence masks. These masks will be used to get sentence representation from the document's hidden state in the last layer of the encoder.

The model is trained with margin-based triplet loss, which is defined as:

$$\mathcal{L}_c = \frac{1}{N}\sum_{k=1}^{K}\sum_{i=1}^{N_k} max\left(0, \sum_{j=1}^{q-1} s_{i,neg_j}^{(l_k)} - s_{i,pos}^{(l_k)} + \epsilon\right), \quad (3)$$

where $s_{i,pos}^{(l_k)}$ is the score of the positive candidate of the i-th example in language l_k, and $s_{i,neg_j}^{(l_k)}$ is the j-th negative candidate for i-th example. We use a linear layer with sigmoid function to get the score from the masked hidden state of the last layer of the encoder. ϵ is a hyper-parameter for the margin distance.

3.3 Sentence Aligned Substitution

Training with multiple languages makes it possible to share the representative space across languages and obtain a universal representation for summarization. Lin et al. (2020) randomly replaces words with a different language during the pre-training phase for machine translation. However, the input for summarization is longer than sentence-level machine translation and the single word replacement shows little influence (Kedzie et al., 2018). Thus, we propose sentence aligned substitution (SAS) for summarization.

We take lead sentences rather than randomly sampling from the document because these sentences are more important in the summarization task. We use an extra translation tool [1] to translate our sentences into another language to get the aligned information. To get rid of the lead bias, we randomly insert the translated sentences back into the original document. The training objective can be defined as:

$$\mathcal{L}_a = -\sum_{k=1}^{K}\sum_{i=1}^{N_k} logP\left(Y_i^{(l_k)}|\mathcal{R}\left(D_i^{(l_k)}\right)\right), \quad (4)$$

where $\mathcal{R}$ is the sentence replacement function. For the document in language l_k, its lead sentences are replaced with the rest languages $l_{k'}$ in ratio r.

Finally, The training objectives of CALMS can be written as:

$$\mathcal{L} = \mathcal{L}_s + \mathcal{L}_c + \mathcal{L}_a. \quad (5)$$

Figure 1 demonstrates the overview of our model. CSR takes the output of the encoder for its margin loss, while SAS replaces sentences before encoding.

4 Experiment

In this section, we describe the multilingual summarization dataset used in our experiment and the experimental settings.

4.1 Dataset

We construct a large-scale summarization dataset MLGSum with 12 languages for the multilingual summarization task. We collect articles from news websites with multiple languages, such as BBC[2] and france24[3], and select faz[4] to extend our dataset with German text. We take the brief introduction written by editors as summaries[5]. We illustrate a short French example in Table 1.

Based on the language size, we divide MLGSum into two parts: the first part includes five high-resource languages: German(De), English(En), Russian(Ru), French(Fr), and Chinese(Zh), which will be used to train our CALMS. The second part has limited training data, which includes Hindi(Hi), Spanish(Es), Indonesian(Id), Turkish(Tr), Vietnamese(Vi), Ukrainian(Uk), and Portuguese(Pt). The data of each language is split into train/dev/test by 95%/5%/5%. Compared with multilingual Gigaword used by Cao et al. (2020), whose average document/summary length is 33.1/8.6, our document and summary are longer. This asks for document-level understanding and generation. The detailed information is listed in Table 2.

4.2 Settings

We use mBART (Liu et al., 2020) as the multilingual initialization. It is the multilingual version of BART-large (Lewis et al., 2020b), which is

---

[5] The summary is tagged with 'story-body__introduction' in BBC, 't-content__chapo' in france24, 'atc-IntroText' in faz. The data is from Jan, 2010 to Sep, 2020. We remove document length smaller than 50 or longer than 5000 and summaries shorter than five words. We provide the url of HTML page for each example.

Article Arsenal, le leader de la Premier League, a été sévèrement corrigé, samedi 14 décembre, par Manchester City (6-3) qui prend la deuxième place du classement à seulement trois points des hommes d'Arsène Wenger. [q] Il s'agit de la huitième victoire de City à domicile où il est invaincu cette saison, et ce contre la meilleure équipe à l'extérieur. [q] Les Londoniens ont commencé à prendre l'eau dès l'entame du match, Sergio Agüero ayant besoin de 14 minutes seulement pour ouvrir la marque et inscrire son 13e but de la saison en championnat.
(*Premier League leaders Arsenal were severely corrected on Saturday 14 December by Manchester City (6-3) who took second place in the standings just three points behind Arsène Wenger's men. [q] It was This is City's eighth home win where they are undefeated this season, against the best away team. [q] Londoners started to get wet from the start of the match, with Sergio Agüero needing just 14 minutes to open the scoring and score his 13th league goal of the season.*)

Summary Irrésistible à domicile depuis le début de la saison, Manchester City a étrillé Arsenal (6-3) lors du match au sommet de la Premier League. [q] Les Mancuniens reviennent à trois points des Gunners en haut du classement.
(*Irresistible at home since the start of the season, Manchester City crushed Arsenal (6-3) in the game at the top of the Premier League. [q] The Mancuniens are three points behind the Gunners at the top of the standings.*)

Table 1: A Fr example of our dataset. The text in brackets is the corresponding English translation. The sentences are separated by '[q]'.

a Transformer-based architecture (Vaswani et al., 2017) with 12 layers of encoder and 12 layers of the decoder. The hidden size is 1024 with 16 attention heads. mBART covers 25 languages and shares the vocabulary with the sentencepiece tokenizer (Kudo and Richardson, 2018), which includes 250,000 subword tokens. We follow the language indicators with mBART, and change its position to the beginning of the source and target sequence. We replace $[q]$ in the dataset with the delimiter $< /s >$ to separate sentences.

We use the first part of our dataset as training languages: De, En, Ru, Fr, Zh. We mix the training examples and do global shuffling to avoid local overfitting on a specific language. For CSR, we random sample $q = 3$ sentences from the document to construct the positive-negative pairs and let the margin $\epsilon = 1.0$. For SAS, we translate sentences to the other four languages with equal probability and substitute sentences with a ratio $r = 0.2$.

We use fairseq[6] (Ott et al., 2019) to implement the architecture. We limit the max tokens to 2048 for each GPU and set the gradient accumulation to 4. The Adam optimizer (Kingma and Ba, 2015) is used with a learning rate of 3e-5 for unified training and 1e-5 for finetuning on the specific language. The other parameters are the same as previous work (Liu et al., 2020). The joint training takes around 7 epochs and each epoch needs 5 hours on two 32G Tesla V100. During inference, we use trigram blocking to avoid repetition.

Language	Size	Doc.	Summ.	Train

Table 2: The dataset statistic. Doc. and Summ. refer to the average length of the document and the summary. Train is the size of the training set.For non-space language like Zh and Ja (with '*'), it is calculated by the character number.

4.3 Models

Here, we describe the models used in our experiments. We first introduce several baseline models and take the strong mBART monolingual model for each language as the main competitor for our unified multilingual summarization model.

Lead2 Lead-K is the common strong baseline for summarization tasks. We select the first two sentences based on the average summary length.

Monolingual Model We train a monolingual model for each language as our baseline. We use a standard Transformer with 12 layers of encoder and decoder with 1024 hidden states and 16 heads and randomly initialize it. The number of parameters is the same as the mBART. We use an independent vocabulary for each language and tokenize them with the sentencepiece model trained on the corresponding language corpus. For the mBART model, we follow the setting of Liu et al. (2020) to finetune it on the monolingual summarization task.

Table 3: The main results. R-1 is the F1 score of ROUGE-1, and Delta is the difference between models and monolingual model initialized with mBART. Avg is the average delta for five languages. The best results are bolded.

Multilingual Model We jointly training summarization in five languages. For Transformer, we use the same shared vocabulary with mBART. We directly finetune mBART on the multilingual summarization task with the language indicator. For CALMS, we add the training objectives CSR and SAS, and the loss is defined as Equal 5. After jointly training, we directly evaluate the unified model on the test set of five languages.

Finetuning We finetune the unified mBART model and CALMS on the specific language for several steps and evaluate it on the test set. The training data for finetuning is the same as the jointly training phrase.

5 Results

We present the main quantitative results and design several qualitative analyses in this section. To better illustrate the improvement, we use the delta between different models and the strong baseline monolingual mBART in five languages for analysis.

For evaluation, we use the automatic summarization metric ROUGE(Lin, 2004)[7]. Since the original ROUGE is only designed for English, we map tokens in other languages to the digit and then calculate ROUGE. For the non-space language such as Chinese, we take each character as a token. We report the F-1 score of ROUGE-1 in the main paper and leave other scores in the appendix.

5.1 Main Results

In Table 3, we show our main results in five languages. We focus on the following questions: 1) Does a unified summarization for all languages perform better than the individual model for each language? 2) Does CALMS perform better on multilingual summarization compared with the unified mBART? 3) Does finetuning on the specific language benefit?

Monolingual v.s Multilingual For Transformer, the joint model performs worse on rich-resource De and En, while it gains improvement on Ru, Fr, and Zh. It indicates that the unified multilingual model without multilingual pre-training sacrifices the rich-resource languages and improve the low-resource languages. However, with the pre-training multilingual language model mBART, the unified model outperforms the monolingual ones on all five languages. This demonstrates that not only low-resource languages can benefit from the larger training data, but also high-resource languages can further be improved by multilingual joint training. Multilingual language models help the model to share the latent space across languages to some extend.

mBART v.s CALMS We directly evaluate the jointly training models on five languages in the test set. Compared with the unified mBART, our CALMS outperforms on all five languages, especially in Fr. For the average delta, CALMS outperforms the monolingual mBART by 0.75 ROUGE-1. The result demonstrates that CALMS is an effective and efficient solution for multilingual summarization. It can handle different languages with one unified model and improve performance on all languages without sacrificing rich-resource languages.

Does Finetuning benefit? Finetuning on CALMS makes the model further move on to the

---

[7] https://github.com/bheinzerling/pyrouge

specific language and get better results, such as En, Ru, and Zh. However, for De and Fr, it is better to directly evaluate the multilingual model, which indicates further finetuning may cause overfitting on several languages. It is similar to unified mBART, where the finetuning fails on De and Fr and benefits on En and Zh.

	De	En	Ru	Fr	Zh
CALMS	26.38	39.83	22.04	37.00	38.83
CALMS w/o CSR	26.24	39.73	22.01	36.95	38.89
CALMS w/o SAS	26.33	39.62	22.12	36.85	38.93
CALMS w/o pre-train	23.83	31.54	15.30	32.30	31.76

Table 4: Ablation study on CALMS on ROUGE-1. CALMS w/o CSR indicates removing CSR loss from CALMS. CALMS w/o mBART indicates randomly initialize the model and train with CSR and SAS.

Ablation Study We conduct the ablation study on each training strategy in Table 4. We jointly train each model and directly evaluate the test set without finetuning.

As it shown, both CSR and SAS contribute to our CALMS. Compared with CALMS w/o CSR and CALMS w/o SAS, we find De, Ru, Zh are more affected by removing CSR, while SAS is more important for En and Fr. When we remove mBART, the performance degrades significantly. This is because the multilingual pre-training language model not only provides a good initialization for multilingual representation but also have a strong generation ability as a language model, which has been proved in monolingual summarization with BART(Lewis et al., 2020b).

CALMS without pre-trained mBART can also be viewed as a jointly training mTransfromer with CSR and SAS. Compared with results in Table 3, we can find that the two training strategies improve performance in Ru, Fr and Zh, but the rich-resource languages De and En have been hurt. It implies that, without multilingual pretrained model, it is difficult for the multilingual model to recover from the denosing task SAS.

Family	Lang	Transformer	mBART	CALMS
Romance	Pt*	15.93	24.82	**25.89**
	Es	21.51	29.37	**29.77**
Slavic	Uk*	11.09	18.62	**19.23**
Turkic	Tr	13.45	**21.97**	21.68
Vietic	Vi	18.82	**30.88**	30.75
Indo-Aryan	Hi	25.53	**33.36**	32.98
Malayo-Polyn	Id*	18.61	27.17	**28.00**
Average	-	17.85	26.60	**26.90**

Table 5: Finetuning on CALMS trained on five languages. The family indicates language family and lang is the abbreviation of language. The Transformer and mBART are monolingual summarization model trained on each language. The languages with '*' are not covered by the pre-training corpus of mBART.

Transfer to other languages Does CALMS really help to learn a unified model for multilingual summarization? In order to answer this question, we further transfer the unified model to other languages. We finetune our CALMS trained on five languages to another 6 languages: Pt, Es, Uk, Tr, Vi, and Hi. Among them, Pt, Uk, and Id are not covered by the pre-training training phrase of mBART. We use '[UNK]' as the language indicator. For comparison, we also take the monolingual summarization model of each language as the baseline, which is similar to monolingual models described in 4.3. The results are listed in Table 5.

As the table shows, CALMS outperforms the monolingual Transformer and mBART in Pt, Es, Uk, and Id. Among these languages, Pt and Es is the same language family as Fr, while Uk and Ru both belong to Slavic. It indicates that our multilingual summarization model CALMS can help similar languages to get a better result against the monolingual model trained on its limited training data. For Id, it is not covered by the pre-training phase and our CALMS also shows better results on it. However, for other languages that far away from the training languages, CALMS has no obvious advantage over the monolingual model.

5.2 Analysis

In this sections, we conduct several in-depth explorations on the two training objectives CSR and SAS.

Negative Sample Number We explore how the candidate number q influences our model. Similar to above, we take the ROUGE-1 improvement against the mBART monolingual model to normalize the improvement. For the document with sentences fewer than q, we repeat the negative examples several times. After training the unified model,

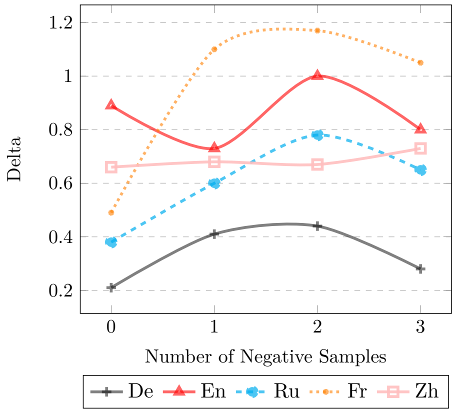

Figure 2: The negative example number of contrastive learning. 0 indicates the mBART unified model. The y-axis is the ROUGE-1 delta between our CALMS and the mBART monolingual model.

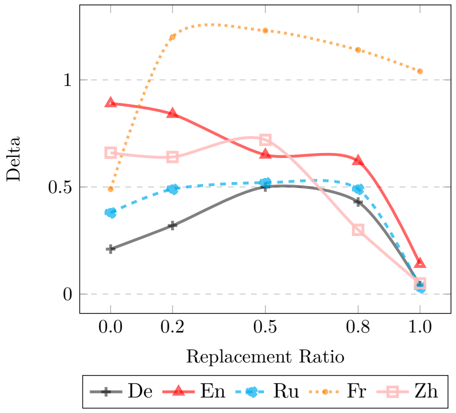

Figure 3: The replacement ratio of SAS. 0 indicates no replacement and 1 indicates each example will be subsituted. The y-axis is the ROUGE-1 delta between our CALMS and the mBART monolingual model.

	De	En	Ru	Fr	Zh
Individual	25.92	38.89	21.52	35.75	38.25
Individual + CSR	26.00	39.25	21.20	36.57	38.63

Table 6: CSA for individual model. The Individual model is trained on mBART for each language.

we directly evaluate them without finetuning.

As Figure 2 shown, The x-axis is the negative sample number, which is $q-1$. When we take two negative examples for contrastive training, most languages get the best results. However, when it comes to three, the performance slips significantly. This is because it is more likely to construct the same contrastive pair during the dynamic sampling due to the limited length of the document. Compared with other languages, the negative sample number has little impact on Zh.

Replacement Ratio We also investigate different replacement ratios r as Figure 3 shown. When $r = 1.0$, it means that we always replace lead sentences with the other language. For $r = 0.0$, we do not replace any sentences, which is the jointly training mBART model. Same as above, we evaluation the unified model directly.

For En, with the ratio increases, the performance degrades, because SAS enforces the model to obtain a more unified representation for all languages by sacrificing the English bias. When the ratio is greater than 0.5, performance begins to degrade in all languages. The Delta is almost 0 when the ratio comes to 1. This indicates that the unified model no longer has the advantage over the individual model. In this case, all the lead sentences will be inserted into the document in different languages. It will mislead the model to ignore the lead bias and the learned language indicator. The ratio between 0.2 and 0.5 is appropriate for all five languages.

CSR for Individual Different from SAS which designed for aligning multiple languages, CSR aims at distinguishing important information. It can also be used on individual models. Thus, we add CSR to the mBART monolingual model for each language and set $q = 3$. The results are listed in Table 6.

We find that De, En, Fr, and Zh all benefit from the original monolingual model, especially Fr. However, the performance degrades for Ru. From Figure 2, we can find that Ru is sensitive to the negative sample number, and Table 2 illustrates Ru have the longest article compared with De, En, and Fr (Zh is calculated by characters). Small q will lead to indistinguishable contrastive pairs during randomly sampling especially for long input, which will cause the performance decline.

6 Conclusion

We propose a contrastive aligned joint learning strategy CALMS. It is an effective and efficient solution for multilingual summarization that can handle different languages with one unified model. The experimental results show that CALMS outperforms the monolingual summarization model in all five training languages, and it can further transfer to similar languages and achieve improvement against monolingual mBART via finetuning. We also provide a multilingual summarization dataset MLGSum with 12 languages for future research.

Acknowledgements

We thank all the anonymous reviewers for their valuable suggestions. We thank the Internet Archive Projects[8] to share the archive's collections for research purposes.

Ethics Consideration

We collect the dataset from three news websites: BBC, france24, and faz. BBC provides news in more than 40 languages and each article is written by native authors. France24 is an international news website with 4 languages and faz is a German website. All of these websites have a highlight written by the editor at the beginning of the news article to summarize the main idea, which can be viewed as the summary. This information can be easily extracted through the HTML tag ('story-body__introduction' in BBC, 't-content__chapo' in france24, 'atc-IntroText' in faz). We collect MLGSum mainly from BBC and use france24 to expand French, English, and Spanish. Faz is used for German.

Similar to XSum (Narayan et al., 2018) and Newsroom (Grusky et al., 2018), we provide the Wayback archived URL of each article and the processing script to release MLGSum. The Wayback Machine[9] is an initiative of the Internet Archive, building a digital library of Internet sites that archive billions of web pages. We search news articles ranging from 2010 to 2020 for the above websites. We emphasize that the intellectual property and privacy rights of the articles belong to the original authors and the corresponding website. We carefully check the terms of use, privacy policy, and copyright policy[10] of the Internet Archive and the dataset construction is consistent with all terms.

We emphasize that we meet the usage requirements: "*Access to the Archive's Collections is provided at no cost to you and is granted for scholarship and research purposes only*" and "*abide by all applicable laws and regulations, including intellectual property laws, in connection with your use of the Archive*". We certify that our use of any part of the Archive's Collections will be limited to non-infringing or fair use under copyright law. If any authors or publishers express a desire for their documents not to be included in MLGSum, we will remove that portion from the dataset.

A Appendices

We present ROUGE-2 and ROUGE-L in Table 7 and Table 8 for models in Table 3.

Different from ROUGE-1, monolingual models show an advantage over multilingual models on ROUGE-2 and ROUGE-L for De, which indicates that the multilingual models have difficulty in catching long patterns of German. However, the situation is the opposite for the French. The other trends are similar with analysis in Section 5.1.

Abstract

As languages evolve historically, making computational approaches sensitive to time can improve performance on specific tasks. In this work, we assess whether applying historical language models and time-aware methods help with determining the correct sense of polysemous words. We outline the task of *time-sensitive Targeted Sense Disambiguation* (TSD), which aims to detect instances of a sense or set of related senses in historical and time-stamped texts, and address two main goals: *1)* we scrutinize the effect of applying historical language models on the performance of several TSD methods and *2)* we assess different disambiguation methods that take into account the year in which a text was produced. We train historical BERT models on a corpus of nineteenth-century English books and draw on the Oxford English Dictionary (and its Historical Thesaurus) to create historically evolving sense representations. Our results show that using historical language models consistently improves performance whereas time-sensitive disambiguation helps especially with older documents.

1 Introduction

As language is in continuous flux, the question arises as to whether (and how) we should adapt Natural Language Processing (NLP) methods to the changing context in which texts are produced.[1] This paper offers a novel contribution by assessing the extent to which making NLP models sensitive to time (or historically-aware) actually improves their performance. We present the task of time-sensitive *Targeted Sense Disambiguation* (TSD), which determines whether or not a token in a given time-stamped text is related to a specific sense of a lemma. TSD is a variation on Word Sense Disambiguation (WSD), but (as we argue) it is of more practical relevance to research in digital history and cultural analysis. For example, if a historian wants to investigate the lemma *machine*[2] in the sense of "anything that transmits force or directs its application", TSD classifies whether the token *machine* (or one of its synonyms, e.g. *machine*) in a given text expresses this sense. This task assists researchers with tracking the evolution of very specific senses across time, instead of just words, as in Michel et al. (2011).

For our experiments, we use the Oxford English Dictionary (OED),[3] which provides a very detailed insight into sense-level change over time, exemplified by time-stamped quotations from a large collection of historical texts. The OED is very fine-grained, with a high number of senses for each entry. The number of historical examples for each sense is limited however, which presents a challenging data sparsity setting,[4] a not uncommon problem in WSD research and also characteristic of Digital Humanities (DH) research, in which often only a small amount of positive examples are available.

Methodologically, our approach to time-sensitive TSD builds upon recent advances in WSD and leverages BERT architectures and contextualized word vectors to address two questions:

RQ1. (time-sensitive embeddings) *Do BERT language models, fine-tuned on specific epochs, yield better representations for historical TSD?* In this scenario, we assess if models trained on data from a certain year range work better on contemporaneous texts compared to standard BERT models.

RQ2. (time-sensitive disambiguation) *When confronted with scarce historical examples, do time-sensitive methods outperform those which ignore the temporal context?* These experiments focus on the impact of time-sensitive strategies.

2 Related work

The main point of reference for Targeted Sense Disambiguation (TSD) is the extensive literature on Word Sense Disambiguation (WSD). WSD tasks can be divided into *lexical sample* and *all words* tasks (Navigli, 2009): in the former approach, models disambiguate a specific (polysemous) word in context, whereas the latter disambiguates all words in a sentence.

WSD research has a long tradition and has achieved good results in synchronic settings (Navigli, 2009; Bhattacharjee et al., 2020). However, time-sensitive WSD has received very little attention, with most literature reviews (e.g. Navigli (2009), Ranjan Pal and Saha (2015), Aliwy and Taher (2019), and Bhattacharjee et al. (2020)) not including it. In spite of the little attention received, time-sensitive WSD has important applications to DH research and the cultural heritage sector. For many applications, it is important to mine historical texts semantically, especially for historical information retrieval, OCR correction and broader research areas such as cultural analytics, as surveyed by (Tahmasebi et al., 2018, 46-47).

As far as we know, Piao et al. (2017) is the only work focusing on a time-sensitive all-words WSD system. The authors present the Historical-Thesaurus-based Semantic Tagger (HTST), a tool to annotate all lexical units of texts with the semantic categories from the Historical Thesaurus of English (Kay et al., 2016). The method by Piao et al. (2017) does not make use of corpus-driven models of word semantics. Over the past few years, a growing body of research has focused on this aspect, and researchers have developed different models for representing words' changing meaning over time. These studies have traditionally employed word embeddings models (Tahmasebi et al., 2018; Kutuzov et al., 2018), which conflate the different senses of words into a single representation. Some work has modelled the diachronic distribution of word senses (Mitra et al., 2014; Tahmasebi and Risse, 2017).

Hu et al. (2019) report on a method for building sense representations using the mapping between example sentences and sense definitions from the synchronic data of the Oxford Dictionary of English.[5] They focus on 4881 target words chosen based on a frequency filter on the COHA corpus. They first feed up to 10 sentences for each sense of every target word to a pre-trained BERT model; they then use the target word's token embeddings from the dictionary's example sentences and average them to obtain 768-dimensional embeddings for its senses. The correct sense is assigned to a token in context by finding the sense whose embedding has the highest cosine similarity score with the token embedding. They also apply their approach to track the development of individual senses of a target word over time via time series decomposition. Their system is able to trace fine-grained lexical semantic shifts as a smooth process, obtaining an improvement over previous models by Frermann and Lapata (2016) and Gulordava and Baroni (2011).

---

[3] www.oed.com.

[4] At the time of writing, the OED contains over 270,000 entries, each of them associated with one or more senses for a total of 800,000 senses (so approximately 3 senses per entry, on average), most of which have one or more quotations associated to them, for a total of over 3 million quotations (so approximately 3.75 quotations per sense, on average). See https://public.oed.com/how-to-use-the-oed/glossary/ for details.

[5] www.lexico.com.

Gonen et al. (2020) propose a new approach to detect usage change of words across corpora that is more stable and interpretable, using the differences in the top nearest neighbors of a word in a vector space as a proxy for usage change of that word. More recently, methods based on token embeddings have shown competitive results (Schlechtweg et al., 2020). Giulianelli et al. (2020) propose the first method for using contextualized (BERT) word embeddings to model sense distributions over time. They build token embeddings and then cluster them into "usage types" (which can be interpreted as senses) using K-means clustering. They then build a probability distribution from the frequencies of these usage types and use it to measure lexical semantic change.

Recent years have seen an increased interest on the application of such methods for modelling semantic change to DH research, primarily using unsupervised methods (McGillivray et al., 2019; Soni et al., 2021). However, in order to be useful, analyses for DH research require a high degree of granularity on highly complex datasets and this has not yet been achieved by state-of-the-art methods. This paper proposes a method which addresses these challenges and is therefore directly relevant and applicable to DH research.

3 Task Definition

We define the task of targeted sense disambiguation as follows: given a target sense σ (realized as a lemma-sense pair), the goal is to determine whether a token τ in a context κ is relevant to the sense σ. For evaluation purposes, we measure relevance by considering only tokens whose sense is identical or synonymous of the target sense. According to this definition, we formulate the task as a *one-vs-all* classification problem, where instances (either definitions or quotations) of the relevant sense (or senses) are considered as examples of the positive class and instances of the remaining senses are regarded as examples of the negative class.

Example. The OED lists twenty-six senses for the lemma *machine*. In this example, we will consider that the relevant sense is the one corresponding to the following definition: "A complex device, consisting of a number of interrelated parts, each having a definite function, together applying, using, or generating mechanical or (later) electrical power to perform a certain kind of work". Example 1 shows a positive (class 1) instance of this sense in a quotation containing *machine*; example 2 is a negative instance of this sense (class 0); example 3 is a quotation that shows a positive instance of a synonymous sense 'plant' (as in mechanical plant, therefore class 1); quotation 4 is a negative example of 'plant' (class 0).

(1) *The calculating **machine** now constructing under the superintendence of the inventor.*

(2) *The Church was excellent as a national refrigerating **machine**.*

(3) *Examples of mobile earthmoving **plant** are bulldozers, graders and scrapers.*

(4) *I could lift the **plant** and be far away before daylight.*

In contrast to the closely-related task of WSD, the objective of TSD is not to provide the most relevant sense for each attestation of a lemma, but to discriminate whether or not a token in a context is related to the pre-selected sense(s). Its aim is to find occurrences of senses related to a selected set of query senses (with the "relation" being an adjustable parameter in the hands of the user, in our case this is synonymy). Importantly, our setup is not static and depends on the user input: we derive an extended group of senses from an initially selected set of relevant sense(s), time period and relation(s). Therefore, depending on these decisions, each of the retrieved senses could either be a positive or a negative example, which makes the task substantively different. Lastly, in our flexible one-vs-all approach, the positive class may be realized by a group of senses (for instance senses that share a common characteristic relevant for the downstream research task) and is suitable to many text mining and information retrieval applications in DH.

4 Data

An important motivation for this work is to provide an efficient framework that leverages semantic information encoded in historical dictionaries and thesauri for research on time-stamped texts.

The Oxford English Dictionary. Considered "the definitive record of the English language" on its webpage,[6] the OED is the result of decades of careful curation by lexicographers. Senses are exemplified by quotations collected over time from

---

[6] https://www.oed.com/

different types of sources, mostly literary works, newspapers, journals, and other periodicals.[7] Each quotation has the form of a time-stamped text snippet containing the headword of the entry, the sense it represents, and is provided with metadata such as the author and title of the source. Each sense is associated with a definition, and is provided with metadata such as the date range of use and the date of its first occurrence. The example below shows a quotation for the noun *machine* with relevant metadata:

Headword: *machine*, n.
Quotation: *Windmills as hitherto made are very costly machines.*
Sense ID: machine_nn01-38475286
Definition: *"A complex device, consisting of a number of interrelated parts, each having a definite function [...]"*
Text daterange: 1659-
Keyword: *machines*
Offset: 43
Year: 1881
Source: *Nature*, by W. Thomson.

Senses are also linked to semantic classes in the Historical Thesaurus of English (HTE), therefore providing access to synonyms and other semantically related senses.

Data preparation. Although our methodology is generally applicable to any word, in our experiments we focused on a set of twelve headwords, selected because these are complex notions, spanning from political terms like *nation* to gendered and emotion words, or ambiguous terms such as *apple*.[8] Each selected headword has multiple senses.

To thoroughly evaluate our approach, we considered as many experimental scenarios as there are senses for a given headword. In each scenario, one of the headword's senses is the targeted sense (also called "seed sense"): its quotations are labeled as positive instances, while the quotations of the remaining senses are labeled as negative instances. In addition, we used the relation between the OED and the HTE to retrieve synonyms for each sense.[9] Henceforth, we will use the terms **seed sense** and **synonym sense** to distinguish between them. We thereupon expanded the set of positive and negative instances as follows:

Positive class. All quotations pertaining to a synonym of the targeted seed sense were labeled with the positive class. This means that we enriched the set of positive examples with quotations that have a different lemma than the original headword (e.g. the mechanical *plant* in the example above).

Negative class. The new lemmas (included through synonymy to expand the set of positive examples) are often ambiguous: they may refer to senses that bear no relation to the seed sense (henceforth **unrelated senses**). Therefore, for each of the new lemmas, we collect the quotations of the unrelated senses as well, and label them with the negative class.

This data expansion step allows us to overcome the problem of data sparsity, since the number of quotations per sense is generally quite low (3.75 on average). In each data set, we removed unambiguous words from the set of expanded lemmas, and held out 25% of the quotations for testing, which is consistently the same for all methods and baselines (whether supervised or unsupervised). For supervised baselines and methods, the remaining 75% is further split into training set (80%) and validation set (20%). Baselines and methods that do not require the distinction between training and validation use both as one. Finally, we consider time to be a determining factor. Therefore, our train, validation and test sets are filtered by time.

Table 1 lists the headwords with the number of seed senses, the averaged number of synonyms and unrelated senses for each seed sense (expanded senses), and the averaged number of the positive and negative quotations per seed sense for the period between 1760 and 1850.[10]

5 Experimental Design

To measure the impact of time, we designed two experiments, each addressing a research question:

---

[7] See https://oed.hertford.ox.ac.uk/ for an in-depth examination and analysis of the contents and sources of the OED.

[8] We focused on the following nouns: *anger*, *apple*, *art*, *democracy*, *happiness*, *labour*, *machine*, *man*, *nation*, *power*, *slave*, and *woman*. We choose to avoid classical semantic change examples, such as *cell*, *gay* or *mouse*, as the semantic evolution of these words is generally well known and not that relevant to current historical or DH research. The number of selected examples was determined by the call limit of the OED API. The OED API is available for researchers upon request. We provide the code to replicate the entire data extraction and processing, as long as the user has OED API credentials.

[9] According to the OED Researcher API documentation, these "may not always be precisely synonymous [...]. Co-occurrence of senses in the same semantic class tends to mean that they are semantically very close, not necessarily synonymous": https://languages.oup.com/research/oed-researcher-api/.

[10] Since there is no space to report the exact numbers for all the experimental configurations, we show the numbers for the experiment that has the strictest filters.

	Seeds	Expanded senses	Quotations
anger	6	17/121	103/564
apple	19	6/61	36/300
art	19	5/47	33/212
democracy	7	6/61	37/301
happiness	5	9/46	57/186
labour	18	4/30	29/148
machine	25	8/83	42/361
man	48	9/78	55/380
nation	15	8/85	53/430
power	39	5/49	34/244
slave	10	20/158	103/670
woman	17	10/81	64/379

Table 1: Headwords used in the experiments, with the number of seed senses, their expanded senses (synonym and unrelated) averaged per sense, and number of quotations (positive and negative examples) averaged per sense.

Experiment 1. To measure **RQ1** (impact of language model fine-tuning), we produced two historical BERT models, trained on different subsections of a 19th century book corpus:[11] one on books predating 1850 (referred to as *BERT_1850*) and one on the whole collection (referred to as *BERT_1900*). To quantify the impact of fine-tuning, we compared the performance of historical models with a standard BERT model (*BERT base uncased*) on different time-stamped subsections of our dictionary data. For each of the three different epochs e (1760-1850, 1760-1920 and 1760-2000) we followed the data preparation procedure as explained in 4 and moreover removed quotations for senses that are not current ("alive") in e.[12] In the test set, we removed all quotations that fall outside the date range defined by e (to establish how well our models work for this specific period based on training data with historically relevant senses). The selected periods align with the different language models we trained on the 19th century corpus, with exception of the last one (1760-2000), which was included to assess if fine-tuning hurts performance when more modern data are included. We hypothesized that the language model closest to the target period will yield the highest scores.

Experiment 2. To answer **RQ2** we followed the same procedure as described above, but focused on evaluating the impact of multiple time-sensitive approaches which take both a token *and* a time stamp as input. As we are primarily interested in understanding how well TSD works as a tool for historical analysis, we only compute scores for the periods 1760-1850 and 1760-1920.

We should stress at this point that the task we pursue is hard, given the complexity of the target concept we attempt to disambiguate (the selected sense and its synonyms) and the minimal number of historical examples at our disposal. At the same time, this makes TSD an excellent task for assessing the gains of historicizing NLP methods. Moreover, we argue that (even taking into account these limitations) TSD is a pragmatic and efficient task to assist with the exploration of historical texts.

6 Embedding Models

In Section 8, two types of language models are used: BERT (contextualized word representations; Devlin et al. 2019) and word2vec (static word representations; Mikolov et al. 2013):[13]

BERT. We used the *BERT base uncased* model and tokenizer as contemporary model,[14] hereinafter referred to as *BERT_base*. To investigate the impact of time on language models, we generated two historical BERT models, *BERT_1850* and *BERT_1900*, by fine-tuning *BERT_base* on a collection of historical books in English digitized by the British Library in partnership with Microsoft (henceforth *MBL*).[15] In *BERT_1850*, the contemporary BERT model was fine-tuned on the historical books published before 1850 (with ≈1.3B words). In *BERT_1900*, all MBL books were used for fine-tuning (≈5.1B words).[16] To fine-tune these models, we firstly preprocessed all books[17] and tokenized them using the original *BERT_base* tokenizer as implemented by HuggingFace[18] (Wolf et al., 2019). The tokenized sentences were then fed into the language model fine-tuning tool in which only the masked language model (MLM) objective was optimized.[19]

---

[11] See Section 6 for more information.

[12] Please note that we retain the senses that *overlap* with e, which entails that some quotations will have dates outside the range of e.

[13] See Hosseini et al. (2021) for a more detailed description of the historical language models.

[14] https://github.com/google-research/bert.

[15] Available via https://doi.org/10.21250/db14 (British Library Labs, 2014).

[16] Note that this dataset includes a few books published after 1900, however, the large majority predates 1900.

[17] We converted the text to ASCII, fixed common punctuation errors, dehyphenated broken tokens, removed most punctuation and separated the remaining punctuation marks from tokens, and finally split token streams into sentences using the *syntok* library: https://pypi.org/project/syntok/.

[18] https://github.com/huggingface/transformers.

[19] The MLM probability was set to 0.15. We used a batch size of 5 per GPU and fine-tuned for 1 epoch over the books.

Word2Vec. We used all the MBL books to train the *w2v* model using skip-gram algorithm as implemented in Gensim (Řehůřek and Sojka, 2010). For training, we chose a context window of five words and embeddings of size 300.

7 Disambiguation Methods

We present here the different approaches tested in our experiments.

7.1 Sense Embeddings from Transformers

Inspired by previous work by Hu et al. (2019) and Kutuzov and Giulianelli (2020), which leveraged contextualized word embeddings built on concrete historical examples, we start by extracting BERT embeddings for each quotation keyword in the training data. The vector we obtain is the concatenation of the last four layers.[20] We then average these keyword vectors by either label or sense: the former method creates a *binary centroid* (one for each class), the latter one for each sense (*sense centroid*). For each quotation in the test set, we produce a vector for the keyword (using the same procedure). In the case of the binary centroid, we assign it to the class of the nearest neighbour; for the sense-level centroid we obtain all sense embeddings that match the lemma of the keyword, and take the class of the nearest sense-centroid, based on cosine similarity.

7.2 Diachronic Sense Embeddings from Transformers

In this scenario, we allow the model to use the timestamp of a quotation to adjust the sense centroid. We compared two broad strategies, namely *filtering* and *weighting*. The filtering approach takes into account those observations in the training data that are temporally close (in absolute distance as $abs(year_{train\_example} - year_{target})$) and ignore the rest. In our experiments, we used the keyword vector of the temporally closest quotation (henceforth *nearest*). The weighting approach (henceforth *weighted*) takes a weighted average over vectors, with the weight determined by the temporal distance to the target quotation. For each example in the training data we *a)* first compute the temporal proximity of the target quotation (from the test set) as $1/(abs(year_{train\_example} - year_{target}) + 1))$ and normalize these scores so they add up to one; and *b)* we multiply the context vector of the keyword by this normalized score. We then simply add these time-weighted keyword vectors into one time-weighted sense centroid, after which we use the same procedure as described in section 7.1.[21]

7.3 Binary Perceptron

Instead of aggregating (collapsing all vectors into binary or sense centroids, in which useful information could get lost), we added one more method that directly uses the keyword vectors extracted from BERT to train a binary classifier. In this case we used a single fully-connected neural network (perceptron) with a RELU activation function (which equates to freezing the BERT model and only fine-tuning one fully-connected layer).

7.4 Baselines

In order to better understand the performance of each method in the different evaluation settings, we compare them to a set of widely established baselines:

Random. First of all, a random baseline, to measure the overall experimental complexity.

Lesk. Then a group of baselines measuring with different strategies the similarity between the positive sense definition and the given textual context. They do so by assessing **token overlap** and **sentence embedding**[22] cosine similarity. Such baselines, in comparison with the next one, show whether it is overall better to rely on the given definitions or on a (small number) of positive examples of quotations.

Supervised classifier. We finally present a Support Vector Machine (SVM) as a supervised binary

---

The choice of batch size was dictated by the available GPU memory (we used 4× NVIDIA Tesla K80 GPUs in parallel). Similar to the original BERT pre-training procedure, we used the Adam optimization method (Kingma and Ba, 2014) with learning rate of 0.0001, $\beta_1 = 0.9$, $\beta_2 = 0.999$ and L_2 weight decay of 0.01. In our fine-tuning routine, we used a linear learning-rate warmup over the first 2,000 steps. A dropout probability of 0.1 was used in all layers.

[20] If a word has multiple subtokens, we averaged their vector representations.

[21] We have experimented with more complex methods, for example using a Gaussian distribution centred on the time of the target quotation to compute weights. As these methods were more complex but hardly showed any improvements, we decided to only report scores for the simpler implementations in the tables below.

[22] We generate sentence embeddings by element-wise average of their word embeddings (here we used the historical Word2Vec model), a common strategy for a well-performing baseline (Shen et al., 2018).

baseline classifier, trained on sentence embedding representations of positive and negative examples of quotations.

8 Evaluation

As mentioned above, in all cases, the experimental setting is very unbalanced, with just a few quotations as positive examples, as opposed to many negative ones. In order to assess the role that *time* plays in these experiments, we report the performance of each method in terms of precision, recall and F1 Score with respect to the *positive class*. Such evaluation highlights which method is most suited to identify occurrences of a pre-determined sense and will also clearly pin-point specific limitations of each approach (for instance methods with high precision, but low recall).

The tables below report performance averaged across all senses and words under study.[23]

Experiment 1. Table 2 shows that BERT approaches outperform the established baselines. Across all models and periods, the *sense centroid* approach returns the highest scores. Moreover, the results confirm our initial intuition that BERT works better when it is fine-tuned on data contemporaneous to the target period. We see for example how the performance of the BERT model trained on the first half of the nineteenth century decreases faster than the other models when more modern data is added, whereas conversely BERT base performs worse (compared to the other models) when older data is added. BERT models that have observed historical data perform better on our examples from the 19th century. Even when more recent data is added, these fine-tuned models work well, although the scores tend to converge. To gauge if historical models perform better, independently of the method used, we computed the gains (or losses) of plugging in different language models directly for all approaches. We observed that while fine-tuning does not always guarantee a jump in performance—e.g., in the binary centroid method the F1-Score declines—the overall improvement is stable for the *BERT_1900* model: given a wide enough range of document, the historical models produce higher scores. The base model fine-tuned on the whole MBL books collection seems to work best for all experiments.

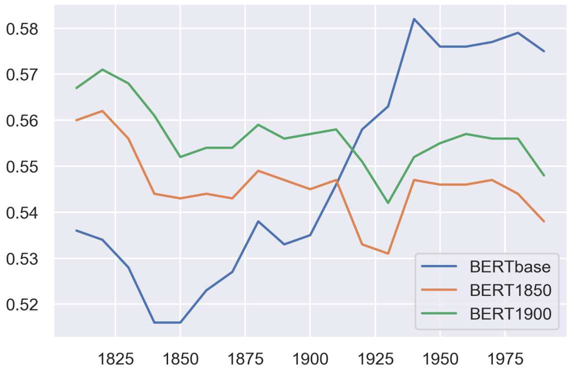

Figure 1: Optimal date range for each language model as measured by the F_1score of the positive class, using the *sense centroid* method: the x-axis represents the average points of rolling 100-year quotation date ranges.

To understand the importance of time, we repeated the experiment above, now using a rolling time-window of 100 years (and step size of 10 years) as our historical periods. Figure 1 presents the performance of our best method in relation to the language model and date range of quotations, for all the headwords. It shows a clear jump in performance for BERT_base towards the later decades of the twentieth century, clearly surpassing the models fine-tuned on nineteenth-century data, which slowly decrease as time advances. A more in-depth analysis of the data indicates that some concepts have a stronger attachment to the period of the data than others. Setting *machine* and *power* apart from the rest of the headwords, for example, indicates that they are responsible for large part of this difference between the language models. In general, *BERT_1850* is the most suitable model for early 19th century sentences, while *BERT_base* clearly outperforms the other models on later data.

If we are to mildly speculate, and attempt to deduce more general lessons from these experiments, then fine-tuning on a historical large corpus could improve results, and is preferable when scrutinizing the semantics of heritage collections. However, success is not guaranteed, as the BERT model trained on books prior to 1850 does not yield the best results when evaluated on quotations from the first half of the century. Higher granularity does not always deliver gains in accuracy, but it does not harm either: note that *BERT_1850* still improves over the base model from which it was originally derived. Also, *BERT_1900* seems to work better

---

[23] All code and models for reproducing these tables are accessible on Github and Zenodo. We should warn that results may slightly differ to those reported below, because the order in which the data are retrieved (using the OED API) and the (number of) quotations themselves might vary. Data used in this paper was downloaded in December 2020.

Table 3: Macro Fscores for time (in)sensitive models sense embeddings.

with a corpus spanning more than two centuries.

Experiment 2. Table 3 inspects the performance of the time-sensitive sense embeddings, applying the filtering and weighting to the *sense centroid* methods as explained in Section 7.2. The *weighted* setting is clearly superior compared to *nearest*, and sometimes outperforms the time insensitive approach. However, interestingly, a closer inspection to the results shows that weighting by time can sometimes hinder rather than help, depending on the scenario. Therefore, whereas it clearly seems to help in our experiments in, for example, headwords that largely correspond to abstract senses (*happiness*, *anger*, *art*, *democracy*, *labour*, and *nation*) and in particular for quotations that are further apart from the language model time range (e.g. *BERT_1900* applied to sentences in the 20th century, or *BERT_base* applied to sentences from the 19th and early 20th century), the *weighted* approach seems to be less helpful (and even harmful) with other headwords that have experimented rougher changes in a smaller period of time, such as words from the technological domain (*machine* and *power*) and especially for those quotations that belonged to the the same period as the the language model training or fine-tuning data.

Case studies. The last set of experiments evaluate the merits of our approach in a more focused research scenario, since—as we argued—the task of targeted sense disambiguation is a pragmatic application of word sense disambiguation tailored to the specific research needs of historians and humanities scholars more generally. We report on a series of case studies that group senses in manually curated and meaningful clusters, to simulate how TSD operates as a tool for historical and cultural analysis, for example detecting metaphorical senses of the word *machine* or scrutinizing *power* in the sense of possessing an ability (in contrast to legal interpretations of the term).[24]

As we group multiple senses, we have more examples for each category, meaning that we can evaluate the methods vertically (↓, limited to senses of *one* lemma, i.e. figurative machines versus all other machine senses) and horizontally (→, including the synonyms of the selected senses, i.e. labour in the sense of physical labour and its synonyms such as *work*). Below we report results in both directions, focusing on disambiguating the selected concepts for the long nineteenth century (1760-1920) and only running the most promising models. Before proceeding we should note that, as opposed to previous experiments, the results below have proven more volatile (i.e. dependent on data used in the

Table 4: Macro Fscores for curated case studies.

train and test split) making reproduction trickier.

Not surprisingly, Table 4 indicates that the vertical comparison generally yields slightly higher scores as it is a more constrained task (stays within one lemma). But even after changing the format of the experiments, the results remain fairly consistent with previous findings, the only exception is the high score for the *BERT_base* perceptron, which suddenly achieved a very high precision in the vertical scenario. Nonetheless, the *BERT_1900* model generally has a slight edge over her BERT peers and the sense embedding methods still outperforms other approaches. An additional promising finding for future research is that time-sensitive models do appear as overall very competitive, even obtaining the highest performance for the horizontal experiments. Because these curated experiments are based on a smaller number of examples, results turned out to vary, but future work will look more closely into these distinctive and realistic historical research settings.

9 Conclusion and future work

As language is historically situated, making computational approaches more sensitive to the past should improve performance on semantic tasks relevant to cultural analysis and history.

While the Oxford English Historical Dictionary is undoubtedly a rich resource, the procedure we propose is not confined to English neither does it necessarily require a vast and fine-grained knowledge base as input. Similar dictionaries exist for other languages.[25] Moreover, the method we propose is not necessarily constrained to dictionary data: a particular strength of our approach is that it can learn from a small number of observations. Even with a few carefully collected historical examples, the procedure we propose can be used for exploring senses in a diachronic setting. The OED provided a convenient substitute for the need for annotated examples.

Focusing on targeted sense disambiguation, we demonstrated in this paper that fine-tuning BERT language models on historical texts yields better results, even when including more modern texts in the analysis. Given the complexity of the task and the minimal amount of data to learn from, this suggests that fine-tuning transformers injects historical knowledge in computational models. Historical language models, in combination with the sense centroid method, proved to be a lightweight but efficient tool for exploring the fine-grained semantics of historical texts, which we plan now to adopt to track semantic change at sense level across multiple nineteenth-century textual collections.

More generally, our paper addressed a profound issue: namely how to adapt NLP methods to time. Developing NLP methods more capable to handle the inherent challenges embedded in diachronic data has applications outside of historical and linguistic research and is relevant to the information retrieval and digital libraries communities as well.

Abstract

Discovering whether words are semantically related and identifying the specific semantic relation that holds between them is of crucial importance for automatic reasoning on text data. For that purpose, different methodologies have been proposed that either (1) tackle feature engineering, (2) fine-tune latent semantic spaces, or (3) take advantage of cognitive links between semantic relations in multitask settings. In this paper, we investigate how feature engineering and multitask architectures can be improved and consequently combined to identify lexico-semantic relations. Evaluation results over a set of gold-standard datasets show that (1) combinations of similar features are beneficial (feature sets), (2) asymmetric distributional features are a strong cue to discriminate asymmetric relations as well as they play an important role in multitask architectures, (3) shared-private models improve over binary and fully-shared classifiers as well as they correctly balance the focus on features between private and shared layers[1].

1 Introduction

The ability to automatically identify lexico-semantic relations is an important issue for Information Retrieval and Natural Language Processing applications such as question answering (Dong et al., 2017), query expansion (Kathuria et al., 2017), or text summarization (Gambhir and Gupta, 2017). Lexico-semantic relations embody symmetric and asymmetric linguistic phenomena such as synonymy (e.g. phone ↔ telephone), co-hyponymy (e.g. phone ↔ monitor), hypernymy (e.g. phone → speakerphone) or meronymy (e.g. phone → mouthpiece), but more can be enumerated (Vylomova et al., 2016).

Most approaches focus on modeling a single semantic relation and consist in deciding whether a given relation r holds between a pair of words (w_1, w_2). The vast majority of efforts (Shwartz et al., 2016; Vulić and Mrkšić, 2018; Wang and He, 2020) concentrate on hypernymy which is the key organization principle of semantic memory, but studies exist on antonymy (Nguyen et al., 2017b; Ali et al., 2019), meronymy (Glavaš and Ponzetto, 2017) and co-hyponymy (Jana et al., 2020). Within this scope, different strategies have been proposed that either define new features (Santus et al., 2017; Vu and Shwartz, 2018) or build specific latent semantic spaces (Nguyen et al., 2017a; Rei et al., 2018; Wang and He, 2020) for the relation at hand.

More recently, multitask strategies have been proposed, which consist in concurrently learning correlated lexico-semantic relations (Attia et al., 2016; Balikas et al., 2019; Bannour et al., 2020), the underlying idea being that if two (or more) tasks are cognitively interlinked, a learning architecture should improve its generalization ability by taking into account the shared information existing between the tasks (Caruana, 1998).

In this paper, we propose to investigate how feature engineering can be coupled to multitask strategies for the identification of lexico-semantic relations. On the one hand, Vu and Shwartz (2018) show that the introduction of the generalized cosine ($Mult$) drastically improves results over the unique concatenation of word embeddings, thus clearly evidencing the limitations of general-purpose latent spaces. However, a complete study of symmetric and asymmetric characteristics, and their combination is still lacking, except (Santus et al., 2017), one of the most complete work in the field.

On the other hand, although existing multitask strategies have been showing promising results,

August 1–6, 2021.

they neither take advantage of specialized features nor they implement state-of-the-art architectures, which have been successful for text classification (Liu et al., 2017). This might be due to the fact that the combination of features within shared-private multitask architectures is not straightforward, and requires specific tuning.

Evaluation results over a set of gold-standard datasets (RUMEN (Balikas et al., 2019), ROOT9 (Santus et al., 2016), WEEDS (Weeds et al., 2004) and BLESS (Baroni and Lenci, 2011)) of an architecture coupling optimized feature sets and shared-private models show that

- The combination of features within a family set improves performance over the use of a unique family member;
- Asymmetric distributional features are a strong cue to discriminate asymmetric lexico-semantic relations;
- Shared-private models improve over binary and fully-shared classifiers (Balikas et al., 2019; Bannour et al., 2020) as well as they correctly balance the focus on features between private and shared layers;
- Asymmetric distributional features play an important role in multitask architectures, being an important source of information for combining both symmetric and asymmetric tasks.

2 Related Work

Three major research directions have been proposed to identify lexico-semantic relations: (1) feature engineering, (2) construction of fine-tuned semantic spaces and (3) multitask architectures.

Within the first topic, (Levy et al., 2015) and (Vylomova et al., 2016) proposed similar evaluations to combine word input vectors ($\overrightarrow{w_1}$, $\overrightarrow{w_2}$), following initial experiments of (Baroni et al., 2012; Roller et al., 2014; Weeds et al., 2014). In particular, word pairs are encoded as the concatenation of the constituent word representations ($\overrightarrow{w_1} \oplus \overrightarrow{w_2}$), their vector difference ($\overrightarrow{w_1} - \overrightarrow{w_2}$) or their sum ($\overrightarrow{w_1} + \overrightarrow{w_2}$). Both studies evidence that the distributional hypothesis is domain-dependent by nature and as such models may not generalize across domains based on these input representations. To overcome such a limitation (Shwartz et al., 2016; Nguyen et al., 2017b) proposed to represent contextual patterns as continuous vectors with successful results, while (Vu and Shwartz, 2018) defined a generalized cosine ($\overrightarrow{w_1} \otimes \overrightarrow{w_2}$) that successfully combines with ($\overrightarrow{w_1} \oplus \overrightarrow{w_2}$).

The second main research direction aims to build fine-tuned neural latent semantic spaces. (Nguyen et al., 2017a) proposed *HyperVec*, where embeddings are learned in a specific order to capture the hypernym–hyponym distributional hierarchy from a background knowledge of hypernym-hyponym pairs. (Vulić and Mrkšić, 2018) rather proposed a post-processing strategy that retrofits the knowledge background into an original latent space. Such methods suffer from limited coverage as they affect only vectors of seen words. To deal with this limitation, (Kamath et al., 2019) presented a post-processing method that specializes vectors of all vocabulary words by learning a global specialization function, and (Wang and He, 2020) followed the same idea but proposed to learn two projection functions. In the same line, (Bouraoui et al., 2020) introduced a framework that fine-tunes BERT (Devlin et al., 2019) to include relational information.

The third approach tackles relation identification from the architecture point of view. Within this context, (Attia et al., 2016) can be viewed as a coarse-grained analysis as they propose a multitask convolutional neural network where one task acts as domain adaptation (relatedness between two words) and the second task is a multiclass classification problem for hypernymy, meronymy, synonymy and antonymy. Instead, (Balikas et al., 2019) proposed a fine-grained approach, that determines whether the learning process of a given semantic relation can be improved by the concurrent learning of another relation, where relations are synonymy, co-hyponymy, hypernymy and meronymy. (Bannour et al., 2020) implemented the same fully-shared model, but introduced the idea of data augmentation via attention models.

Although fine-tuned embeddings have evidenced improved results over generic ones, they are relation- and knowledge-dependent. One exception is proposed by (Meng et al., 2019), which learns text embeddings in a spherical space (aka. JoSE) suitable for relational information. Feature engineering also affords “cheap performance boost” (Vu and Shwartz, 2018) in resource-free environments. But, a complete study of the combination of features is still missing as well as the definition of asymmetric features in the context of continuous spaces, although a great deal of work exists for the discrete case (Kotlerman et al., 2010; Santus et al., 2017). Finally, studies in multitask settings neither take advantage of powerful multitask models such as shared-private architectures (Liu et al., 2017) that allow to combine task-specific and cross-task information, nor benefit from the fruitful combination of distributional and pattern-based features. In this paper, we propose to deal with the aforementioned limitations in a resource-free setup.

3 Feature Engineering

Additionally to word embeddings concatenation, we define three families of features based on the distributional hypothesis (symmetric and asymmetric features) and the paradigmatic approach (pattern-based features) in continuous semantic spaces.

3.1 Distributional Representation

Most studies have been evidencing the superiority of the concatenation of representational word vectors to infer their semantic relationship (Shwartz et al., 2016; Vu and Shwartz, 2018). So, we follow this line of research. Let (w_1, w_2) be a word pair and $\overrightarrow{w_1}$, $\overrightarrow{w_2}$ their respective distributional representations of dimension d. The input distributional feature of the word pair is noted $\overrightarrow{w_1} \oplus \overrightarrow{w_2}$.

3.2 Symmetric Distributional Features

Studies have evidenced the interest of coupling word embeddings with specific features to improve relation identification. In particular, the cosine similarity measure cos has shown promising results (Garten et al., 2015; Barkan, 2017). However, Vu and Shwartz (2018) have demonstrated the effectiveness of integrating the element-wise multiplication of the input vectors, which can be seen as a generalized cosine ($cosG$, aka. $Mult$), which is defined in equation 1.

$$cosG(\overrightarrow{w_1}, \overrightarrow{w_2}) = \bigoplus_{i=1}^{d} w_1^i w_2^i \tag{1}$$

While the cosine only provides a unique value as input, $cosG$ refers to an input of dimension d, thus evidencing a dimensional issue. As a consequence, we propose to transform the $cosG$ into a unique value by using a linear activation layer as in equation 2. The $cosG1D$ can be seen as a control value of $cosG$ taking into account the dimensional bias (from high to low dimension).

$$cosG1D(\overrightarrow{w_1}, \overrightarrow{w_2}) = \sum_{i=1}^{d} \lambda_i w_1^i w_2^i \tag{2}$$

The counterpart of equation 2 is the (d times) duplication of the cosine value. This metric called cosine broadcast ($cosBr$) defined in equation 3 aims to control the dimensional issue from a low to a high dimension.

$$cosBr(\overrightarrow{w_1}, \overrightarrow{w_2}) = \bigoplus_{i=1}^{d} cos(\overrightarrow{w_1}, \overrightarrow{w_2}) \tag{3}$$

As such, in equation 4, we define a family of symmetric distributional features.

$$CosF = (cos, cosG, cosBr, cosG1D) \tag{4}$$

In the next subsection, we detail the design of new asymmetric distributional measures based on the Kullback–Leibler divergence.

3.3 Asymmetric Distributional Features

Asymmetry has shown successful results for the discrete case (Kotlerman et al., 2010; Santus et al., 2017), the underlying idea being that the relation between words may be unbalanced such that one word attracts the other one more than the opposite. Here, we define different asymmetric features in the continuous space based on the Kullback–Leibler divergence (Kullback and Leibler, 1951). To fit to the continuous case, we transform each dimension of a word vector with the sigmoid (σ) function such that all values range between 0 and 1. Thus, each word can be considered as a probability distribution and the asymmetric metric $Kull$ is defined in equations 5.

$$Kull(\overrightarrow{w_1}|\overrightarrow{w_2}) = \sum_{i=1}^{d} log(\frac{\sigma(w_1^i)}{\sigma(w_2^i)})\sigma(w_1^i) \tag{5}$$

To take into account both directions of the asymmetry, we propose to concatenate the $Kull$ values for both directions as defined in equation 6.

$$kull(\overrightarrow{w_1}, \overrightarrow{w_2}) = Kull(\overrightarrow{w_1}|\overrightarrow{w_2}) \oplus Kull(\overrightarrow{w_2}|\overrightarrow{w_1}) \tag{6}$$

Similarly to the $cosG$, we propose to define the multiplicative version of the $kull$, such that $kullG$ integrates the element-wise multiplication of the input vectors as defined in equations 7 (single asymmetry) and 8 (concatenation of both asymmetries).

$$KullG(\overrightarrow{w_1}|\overrightarrow{w_2}) = \bigoplus_{i=1}^{d} log(\frac{\sigma(w_1^i)}{\sigma(w_2^i)})\sigma(w_1^i) \tag{7}$$

$$kullG(\overrightarrow{w_1}, \overrightarrow{w_2}) = KullG(\overrightarrow{w_1}|\overrightarrow{w_2}) \oplus KullG(\overrightarrow{w_2}|\overrightarrow{w_1}) \tag{8}$$

Similarly to $cosG1D$ and to take into account the dimensional issue of the multiplicative version of the Kullback-Leibler, we define $kullG1D$ in equations 9 and 10 .

$$KullG1D(\overrightarrow{w_1}|\overrightarrow{w_2}) = \sum_{i=1}^{d} \lambda_i log(\frac{\sigma(w_1^i)}{\sigma(w_2^i)})\sigma(w_1^i) \quad (9)$$

$$\begin{aligned} kullG1D(\overrightarrow{w_1}, \overrightarrow{w_2}) \quad = \quad & KullG1D(\overrightarrow{w_1}|\overrightarrow{w_2}) \oplus \quad (10) \\ & KullG1D(\overrightarrow{w_2}|\overrightarrow{w_1}) \end{aligned}$$

Similarly to $cosBr$, we propose to define $kullBr$ based on the (d times) duplication of the Kulback-Leibler value for both directions as in equation 11.

$$\begin{aligned} kullBr(\overrightarrow{w_1}, \overrightarrow{w_2}) \quad = \quad & \bigoplus_{i=1}^{d} Kull(\overrightarrow{w_1}|\overrightarrow{w_2}) \quad (11) \\ & \bigoplus_{i=1}^{d} Kull(\overrightarrow{w_2}|\overrightarrow{w_1}) \end{aligned}$$

As such, in equation 12, we define a family of asymmetric distributional features.

$$KullF = (kull, kullG, kullBr, kullG1D) \quad (12)$$

In the next subsection, we present the encoding strategy of patterns embodying the paradigmatic approach.

3.4 Pattern-based Paradigmatic Features

Patterns are part of the paradigmatic approach (Hearst, 1992), which suggests that specific word sequences may exist that link two words in a given relation. Some examples of sequences between word pairs are given in Table 1, which evidence that some of them can be spurious, and do not necessarily include patterns.

Here, we propose to implement the methodology of (Shwartz et al., 2016) to encode patterns into continuous spaces. As such, we transform the k^2 most frequent patterns occurring between w_1 and w_2 using either BiLSTM or the Universal Sentence Encoder (USE) (Cer et al., 2018), and then perform average pooling to get the final input representation. The encoded i-th most frequent pattern is defined in equation 13, where $j \in \{\text{BiLSTM}, \text{USE}\}$, $i \in [1..k]$, and the average representation of the k patterns is noted $\overline{pat}_{*,j}^{w_1,w_2}$.

Relation	Path
Synonymy	**error** or **fault** √ **change** as an **alteration** √ **burning** fuel in the **combustion**
Hypernymy	**aircraft** firing rocket into an enemy **plane** √ **unit** that includes **screen** √ **act** was an unconscious **ritual**

Meronymy	**bowl** from the world of **glass** √ **television** and **video** √ **couch** on **seat** √
Random	**reference** in the book of **mormon** **nothing** to stop the **robber** **driver** was issued traffic **ticket**

Table 1: Examples of patterns for a word pair (in bold).

$$pat_{i,j}^{w_1,w_2} = encoder_j(w_1, path_i, w_2) \quad (13)$$

Similarly to $CosF$ and $KullF$, we define a family of pattern-based features $PatF$ in equation 14.

$$PatF = (\overline{pat}_{*,\text{USE}}, \overline{pat}_{*,\text{BiLSTM}}) \quad (14)$$

In the next section, we present the multitask settings that have been implemented to take into account relations between lexico-semantic relations.

4 Multitask Settings

Multitask architectures have shown to successfully combine closely-related lexico-semantic relations. Within this scope, the fully-shared architecture has systematically been implemented (Attia et al., 2016; Balikas et al., 2019; Bannour et al., 2020), which relies on a unique shared representation capable of solving the different tasks learned concurrently from a given input.

However, the shared-private model has proved to boost results for text classification (Liu et al., 2017). In particular, a shared-private network combines $N + 1$ different representations (one shared and N task-specific). As such, the shared layer should transfer the joint information contained in all tasks, while private layers should focus on the specific information of each task.

Moreover, $N + 1$ different input representations may coexist in the shared-private case, while a unique input representation exists for fully-shared models. Here, we propose to implement both fully-shared and shared-private architectures for different

---

[2] k allows to deal with spurious sequences.

combinations of input representations and features $X = (\overrightarrow{w_1} \oplus \overrightarrow{w_2}, CosF, KullF, PatF)$. In particular, forward selection (Kohavi and Sommerfield, 1995) is used for feature selection, as the search space is huge, 2^{10} possible combinations[3].

4.1 Multitask Architectures

The neural architectures are presented in figure 1 for two tasks. Formally, let X_k be an input vector[4], we compute a shared layer $S(X_k)$ as in equation 15, where W_{S^k} is a weight matrix, b_{S^k} a bias vector, and $k \in [1, K]$ (K the number of shared layers).

$$S(X_k) = \sigma(W_{S^k} X_k + b_{S^k}) = X_{k+1} \qquad (15)$$

A private layer $H^j(Z_q)$, which solves task T_j ($j \in [1, N]$) is defined in equation 16, where $q \in [1, Q]$ (Q is the number of private layers).

$$H^j(Z_q) = \sigma(W^j_{H^q} Z_q + b^j_{H^q}) = Z_{q+1} \qquad (16)$$

For the fully-shared architecture $Z_1 = S(X_K)$ and for the shared-private model $Z_1 = S(X_K) \oplus X^i$, where X^i is the specific input vector for task T_i. Finally, the N decisions are defined in equation 17.

$$O^j = \sigma(W^j_O H^j(Z_Q) + b^j_O) \qquad (17)$$

The parameters are updated by minimising the binary cross-entropy. Hence, the weights of the shared layer are updated by minimising the loss function of each task alternatively, while the private layers are updated for their specific task.

4.2 Forward Selection

In order to optimize the feature combination for all $N + 1$ tasks and thus find the best input vectors for the shared and private layers (i.e. X, X^1 and X^2 in figure 1), we perform forward selection. As such, we first train the given model to find the best combination of features within a given family (i.e. within $CosF$, $KullF$ and $PatF$ individually)[5]. Once the best within-family combination has been defined for all families, we train the model for all combinations of the best within-family combinations of features. Note that for the shared-private architecture, we first train the private models independently to determine X^i ($i \in [1, N]$) and based on these findings, we train the shared-private model to determine X, constrained by the previously learned private models with input X^i.

5 Experimental Setups

5.1 Datasets

There exist a large body of related works for the identification of lexico-semantic relations. The first gold-standard dataset, WEEDS, has been proposed by (Weeds et al., 2004) in the context of studies about measures of lexical similarity. Following the same objective, (Baroni and Lenci, 2011) introduced the well-known BLESS dataset, and (Santus et al., 2016) compiled the ROOT9 dataset[6], which contains word pairs randomly extracted from EVALution (Santus et al., 2015), Lenci/Benotto (Benotto, 2015) and BLESS (Baroni and Lenci, 2011). Within the context of concurrent identification of lexico-semantic relations, (Balikas et al., 2019) recently introduced the RUMEN dataset[7] to include synonymy. As the patterns are not included in the original datasets, we downloaded the English wikipedia dump[8] and extracted all patterns that do not exceed a maximum length of 10 words[9]. All datasets[10] are summarized with their specific characteristics in Table 2.

5.2 Learning Configurations

The output dimension of the Universal Sentence Encoder (USE) equals to 512. The output size of the BiLSTM $\in \{100, 200, 300, 400, 500\}$, the number of patterns ($k \in [1..5]$), the number of hidden layers ($K \in \{1, 2\}$ and $Q \in \{1, 2\}$), the number of neurons $\in \{5, 20, 50, 100, 150, 200, 300\}$ and the number of epochs ([1..100]) are free hyperparameters that are tuned using grid search. The weights are initialised with a uniform distribution scaled as in (Glorot and Bengio, 2010) and updated using Adam (Kingma and Ba, 2014) with a learning rate set to 0.001. The network is trained with batches of 64 examples and the number of iterations is optimized to maximize the F_1 score on the validation set. Word embeddings are initialized with the 300-dimensional representations of GloVe (Pennington

et al., 2014) or JoSE (Meng et al., 2019). All state-of-the-art models presented in section 6 have been implemented to provide average results and perform statistical tests[11].

5.3 Lexical Split

As suggested in (Levy et al., 2015), lexical split is applied to all our experiments so that there is no vocabulary intersection between the test set and the train/validation sets. Note that for learning purposes, each dataset is split into train (50%), validation (20%) and test (30%) sub-datasets.

6 Evaluation

All comparative results against four state-of-the-art models (Shwartz et al., 2016; Vu and Shwartz, 2018; Balikas et al., 2019; Bannour et al., 2020) are presented in Table 3 for an average of 25 runs with evidenced statistical significance over four gold-standard datasets.

6.1 Private Models

We first start by analysing the impact of feature combination on private models, i.e. when a unique lexico-semantic relation is taken into account in the learning process. This stands for the first four rows of Table 3. Unsurprisingly, the introduction of a combination of (eventually new) features (*Best MLP*) outperforms existing models (Shwartz et al., 2016; Vu and Shwartz, 2018) and the multilayer perceptron (MLP) that only includes word embeddings concatenation (i.e. the simplest baseline). Note that the *Best MLP* model includes the architectures of (Shwartz et al., 2016) and (Vu and Shwartz, 2018) as it allows the combination of all family features as input.

To better understand the impact of feature engineering, we illustrate results involving all combinations of within-family features and all combinations of in-between best family features in figure 2 (a). Within the $cosF$ family alone (i.e. only cosine-based metrics are used for the learning process)[12], results clearly evidence the dimensional issue, being cos and $cosG1D$ the one-dimension metrics that evidence worst results individually. The second important finding lies in the fact that metric combination steadily improves over individual metrics. In particular, $(cosG, cosBr, cosG1D)$ gives rise to strongest results in the vast majority of cases, and particularly for hypernymy.

Table 3: Overall results for all architectures with GloVe embeddings. Lexical split is applied. $\star$, † and + denote p-value ≤ 0.05 based on the t-Test assuming unequal sample variances of metric values between respectively (Best MLP) against (Vu and Shwartz, 2018), (Best SP) against (Best MLP), and (Best SP) against (Bannour et al., 2020).

Within the $KullF$ family alone[13], results seem to indicate that $kullBr$ is the less performing (alone and in combination) feature, although regularities are difficult to establish as different results can be observed depending on the dataset. Similarly to the previous observation, the combination of asymmetric features provides improved results for the vast majority of cases, suggesting that individual values encode complementary information.

Within the $PatF$ family[14], the BiLSTM encoding seems to provide superior results to the USE encoding, but more importantly, results clearly show that pattern-based features can be a strong cue for the classification process provided that a large number of patterns can be extracted, as it is shown for ROOT9 (see Table 2 for the number of patterns).

More surprisingly, the $CosF$ features steadily indicate stronger results than the $KullF$ and $PatF$ features for asymmetric relations (hypernymy and meronymy), thus suggesting that symmetry is an important characteristic for all relations.

Finally, results clearly show that the combinations of the best features per family[15] steadily outperform results of individual family features, thus demonstrating their complementarity. In particular, symmetric and asymmetric distributional features successfully combine for asymmetric relations, and the successful combination is with pattern-based and cosine-based features for co-hyponymy. However, only symmetric distributional features allow maximum performance for synonymy, which can easily be understood as this is a symmetric relation. To strengthen our comments, we give the distribution of features for the best configurations in Table 4 (first row) for all datasets and relations.

6.2 Multitask Models

Results of the multitask architectures are presented in rows 5-8 of Table 3. In particular, the *Best Fully-shared* network stands for the model of Balikas et al. (2019) with an optimized set of input features, oppositely to their settings which rely on the unique concatenation of word embeddings. Figures clearly

Table 4: Best combinations of features for all models. 0 and 1 stand for the absence or the presence, respectively, of the given feature within its family, where the order is given by equations 4, 12 and 14.

show the superiority of the shared-private network (*Best SP*) over the fully-shared model (*Best FS*) for most cases, suggesting that the combination of private and shared information is beneficial to the decision process. However, the *Best MLP* is a hard model to beat as the *Best SP* statistically outperforms the former architecture 4 times out of 8, and 2 times out of 8 without statistical significance. But the contrary is only true for ROOT9 (wrt. F_1 score), where *Best MLP* statistically exceeds *Best SP*.

The important issue in shared-private architectures is to understand how well they distribute the feature space between private and shared layers. For that purpose, we analyse figure 2 (b), which shows feature combinations for the shared layer, i.e. when two tasks are learned concurrently. Note that in this case, best combinations from the private models (learned separately) restrict the learning process. The first main conclusion is that asymmetric distributional features ($KullF$) steadily compete with cosine-based features ($CosF$), even clearly outperforming the latter for BLESS, which is definitely not the case within private models. The same conclusion can be drawn

for pattern-based features $PatF$, which impact is much more important in the shared layers than it is the case in the private models when compared to $CosF$. This suggests that when private models focus more on symmetric features, shared-private models take advantage of asymmetric features to capture task dissimilarity (indeed in the concurrent tasks there is always at least one asymmetric task).

Another interesting observation is that best models are usually not a combination of different family features. Only 2 cases out of 8 show improved results with feature combination. In fact, such results suggest that private and shared layers distinctively balance the family feature space. We clearly see this situation in Table 4 by looking at the complementarity of the input feature vectors of private (row 1) and shared-private models (row 3). For instance, when maximizing the hypernymy task within the shared-private model over RUMEN, the private input vectors are $(cosG, cosBr, cosG1D, kull, \overline{pat}_{*,\text{BiLSTM}})$ for hypernymy and $(cosG, cosBr)$ for synonymy, while the shared input vector is $(kullG, kullBr, kullG1D)$. It is worth noticing that this situation does not hold for the fully-shared models as they are clearly biased towards cosine-based metrics and rarely include asymmetric distributional and pattern-based features.

6.3 Spherical text embeddings

We propose to compare our feature-based architectures with relational embeddings, namely JoSE (Meng et al., 2019), the underlying idea being to understand how feature-based strategies can compare and eventually add-on to fine-tuned neural semantic spaces. Results are illustrated in Table 5.

Results of the baseline *MLP* model do not evidence a clear advantage of relational embeddings compared to general-purpose ones like GloVe, BLESS being the only exception. However, it is interesting to notice that the proportion of improvement is much more important for JoSE embeddings when introducing combinations of features. Indeed, while the *MLP* model with GloVe overtakes the JoSE version 5 times out of 8, the *Best MLP* model with JoSE overtakes the GloVe version 5 times out of 8, thus suggesting that spherical embeddings are sensitive to feature engineering.

Finally, while shared-private architectures provide overall best results, a clear distinction between both embeddings is difficult to establish, although a small tendency towards JoSE embeddings seems to emerge. Indeed, while the hypernymy relation is better tackled by relational embeddings (3 out of 4 configurations), meronymy is better handled by GloVe although being an asymmetric relation. With respect to symmetric relations (synonymy and co-hyponymy), the situation slightly converges towards relational embeddings with better results in 2 out of 3 experiments.

7 Conclusions

In this paper, we proposed the definition of asymmetric distributional features in continuous spaces based on the Kullback-Leibler divergence, and suggested to combine them with families of symmetric distributional and pattern-based characteristics using a feature selection process. We proposed to analyse the impact of feature combination in multi-task settings, which combine private and shared layers. Results evidenced the benefits of feature combination in the private models, and they highlighted the importance of asymmetric (distributional and paradigmatic) features in the shared layers. Moreover, share-private architectures showed the capacity of balancing feature families between private and shared layers thus taking full advantage of most features in the decision process.

Abstract

Increasing studies leverage pre-trained language models and meta-learning frameworks to solve few-shot text classification problems. Most of the current studies focus on building a meta-learner from the information of input texts but ignore abundant semantic information beneath class labels. In this work, we show that class-label information can be utilized for extracting more discriminative feature representation of the input text from a pre-trained language model like BERT, and can achieve a performance boost when the samples are scarce. Building on top of this discovery, we propose a framework called Label-semantic augmented meta-learner (LaSAML) to make full use of label semantics. We systematically investigate various factors in this framework and show that it can be plugged into the existing few-shot text classification system. Through extensive experiments, we demonstrate that the few-shot text classification system upgraded by LaSAML can lead to significant performance improvement over its original counterparts.

Banking
Class 1: *can you give me a hand paying my water bill*

1 Introduction

The remarkable capability of quickly learning new concepts from a few training samples is one of the advantages of the human learning system over the current machine learning system. Motivated by this gap, research in few-shot learning has received increasing attention in the past decade. Meta-learning (Vinyals et al., 2016; Snell et al., 2017; Finn et al., 2017), as the dominant methodology in few-shot learning, tackles the problem by learning a mapping function from a few support samples to a classifier through a meta-training dataset. Most existing meta-learning systems (Snell et al., 2017; Sung et al., 2018) were developed or at least evaluated in the field of computer vision. More recently, few-shot learning has been introduced to the NLP field and in particular, text classification (Yu et al., 2018; Geng et al., 2019), as it is the fundamental task in natural language understanding. In parallel to few-shot learning, pre-trained language models (PLMs) (Devlin et al., 2019; Radford et al., 2019) have revolutionized the NLP fields and show strong evidence of being able to perform well in low data regime when transferred to downstream tasks.

Despite the impressive progress of meta-learning and PLMs, however, most existing few-shot classification systems (Geng et al., 2019; Bao et al., 2020) ignore an important information source — semantic of class labels. When the number of training samples is limited, merely using the input texts per class can lead to ambiguity in interpreting the definition of class. Considering the two groups of examples in Figure 1 which shows four samples belonging to different intent classes, even humans cannot fully understand the semantic meaning of those samples if the definition of labels are not given. For example, it is hard to tell if class 1 and class 2 are about the type of bill — water or gas, or class 3 and class 4 are about the destination of the travel — USA or Germany. However, this ambiguity can be easily resolved if the class definition or simply the class name is provided.

Just as understanding class names can help humans to interpret sentences of a given class, we made an interesting observation that the BERT will extract more discriminative features if we append the class name to the input sentence, and it can boost the classification performance in low-shot scenarios. Motivated by the above observations, this work explores how to better leverage the semantic information beneath class names for few-shot learning. Our key idea is to use meta-learning to further strengthen the guidance of class-label semantics for few-shot classification. Specifically, we use meta-learning to encourage the features extracted from class-name-appended samples to be more class-relevant and compatible to the query features. Moreover, we systematically study the issue of how to extract the label-semantic guided feature representation from the support samples and how to make the query sample features compatible with the meta-learner generated from the support set. Our research leads to a framework that can be plugged into the existing few-shot meta-learner and we call our method Label-semantic Augmented Meta-Learner (LaSAML). To demonstrate the power of LaSAML, we use LaSAML to upgrade the Prototypical Network and creates a new method called LaSAML-PN. By conducting the extensive experimental studies, we show that LaSAML-PN achieves excellent few-shot learning performance and LaSAML upgraded meta-learning obtains superior performance over its original counterpart. Our code has been released at: `https://github.com/luoqiaoyang/ACL2021-LaSAML`.

2 Related work

This section discusses the related work from three aspects: few-shot learning, few-shot text classification, and low-shot learning with label information.

Few-Shot learning Meta-learning approaches have made substantial progress with few-shot learning (FSL) tasks. The focus of the current meta-learning framework is how to construct the meta-learner. For examples, a meta-learner could be constructed by learning a metric between samples and classes(Koch et al., 2015; Vinyals et al., 2016; Snell et al., 2017; Sung et al., 2018), based on a differentiable learning process (Bao et al., 2020), or based on a few-shot gradient update (Mishra et al., 2018; Finn et al., 2017). A complete review of meta-learning is beyond the scope of this paper, and we refer readers to the recent survey (Hospedales et al., 2020).

Few-shot text classification Few-shot text classification (FSTC) has also gained increasing attention in recent years. ROBUSTTC-FSL (Yu et al., 2018) uses an adaptive metric learning approach to adaptively select an optimal distance metric for different tasks. Induction Network (Geng et al., 2019) utilizes the dynamic routing algorithm (Sabour et al., 2017) to learn a generalized class-wise representation. Pre-trained language models have also been applied to few-shot text classification. LEOPARD (Bansal et al., 2020) uses BERT (Devlin et al., 2019) with optimization-based meta-learning framework to achieve good performance on diverse NLP classification tasks. More recently, GPT-3 (Brown et al., 2020) shows that the language model itself can be used to perform few-shot text classification without using meta-learning. Meanwhile, another recent work (Bao et al., 2020) points out meta-learning for text classification may have different characteristics to the cases in computer vision. They propose to use distributional signatures to enhance the generalization capability of meta-learner. Our method is still a meta-learning-based few-shot text classification method. The key contribution of our work is the discovery that using label information together with BERT can lead to significantly better generalization performance.

Using label information for text classification An increasing number of recent works have realized the value of label semantics. The matching between label information and text can naturally lead to zero-shot learning. For example, CDSSM (Chen et al., 2016) explores zero-shot intent classifications based on class names. Prompt-based strategies (Puri and Catanzaro, 2019; Schick and Schütze, 2020) have been developed to implicitly match text against class names. In the context of few-shot learning, (Hou et al., 2020) incorporate label semantics into the TapNet (Yoon et al., 2019) for few-shot slot tagging tasks. Different from the above works, this paper explores both pre-trained language models and label semantics for few-shot learning. We only require the name of classes rather than manually constructed prompts or templates to convey label semantics. TARS (Halder et al., 2020) also leverages pre-trained language models and label semantics based on binary text classification. However, our method further strengthens generalization ability via meta-learning framework especially in cross-domain and fine-grained cases.

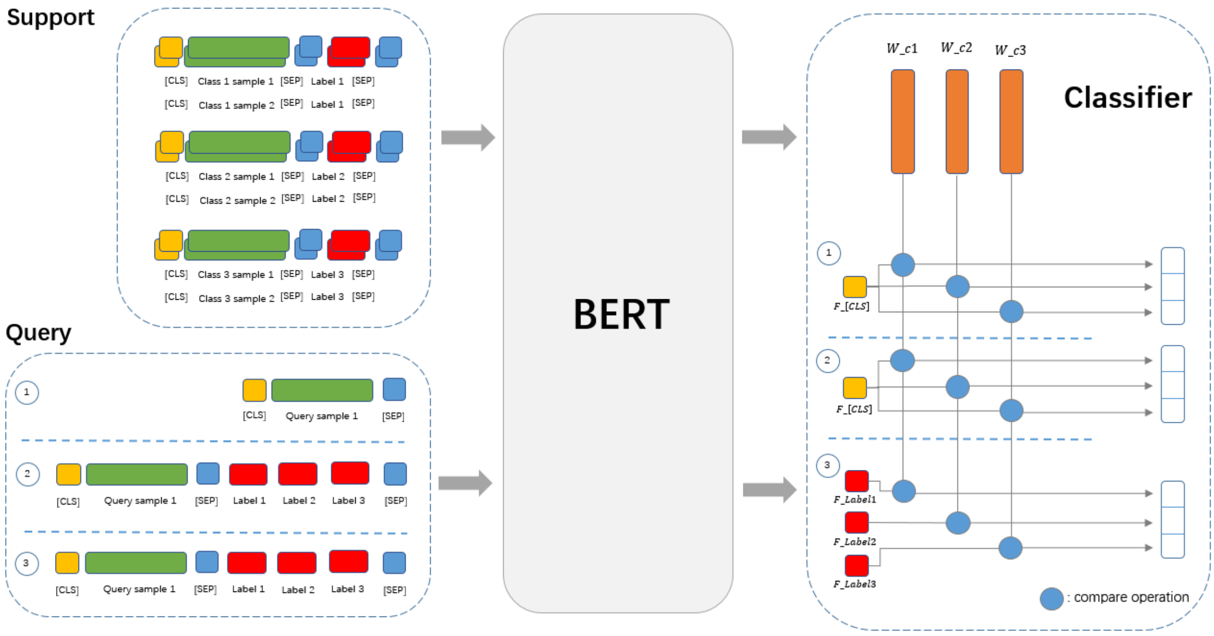

Figure 2: The main framework of LaSAML.This graph gives an example on how LaSAML process a 3-way 2-shot few-shot task. All support samples append with the corresponding class name to format as "[CLS] + Sentence + [SEP] + Label + [SEP]". The query data can be one of three forms: ① remains original form while ② and ③ append all three class names. ① and ② use BERT emebeddings from [CLS] token, ③ uses all label embeddings.

Appending Word	Number of training samples per class	
	5	10
None	0.6425	0.7324
class name	0.7437	0.7925

Table 1: Results of fine-tuning BERT with only 5 or 10 labeled data per class on the AGNews dataset. None: the standard input format for the BERT classifier, class name: appending the respective class names for each training sample.

3 Our method

3.1 The value of label information in the low data regime

As described in the introduction, label information is essential for human to accurately interpret the meaning conveyed in the limited number of training samples. In this section, we demonstrate that label information is also useful for extracting discriminative features from a pre-trained language model [1]. More specifically, we consider the following modification to input of BERT for text classification: we append the corresponding class name after each training sentence (for which we know the ground-truth classes) and a [SEP] token. In other words, we use the following input format "[CLS] sentence [SEP] class name [SEP]" rather than "[CLS] sentence [SEP]" as the common practice of using BERT for text classification. Then we extract embeddings from the [CLS] token to train a linear classifier. The reason of appending "class name [SEP]" is to mimic the scenario of the next sentence prediction (NSP) task for training BERT. To perform well in the NSP task, BERT needs to extract information that are most predictive for the next sentence from the first sentence. In our case, we replace the next sentence with the class name and consequently, we expect that BERT can extract information that is relevant to the class name from the input sentence. We call this method label-semantic augmented feature extraction hereafter.

From the experimental results are shown in Table 1, we can clearly see that the classifier trained from label-semantic augmented feature extraction achieves better performance than the baseline approach. When only five samples are used per class, the improvement can be as significant as 10%.

From this motivating experiment, we clearly see the potential of incorporating class-label information. To further strengthen BERT's capability of leveraging class-label semantic information, we incorporate the above idea into the meta-learning framework, lending itself to a new meta-learning framework termed label-semantic augmented meta-

---

[1] Throughout our experiments, we use BERT (Devlin et al., 2019) as the PLM unless specified otherwise.

learner (LaSAML). We expect that through fine-tuning a PLM by the meta-learning process, the network can find an optimal way of building meta-classifiers with the guidance of class-labels.

3.2 The general framework of the label-semantic augmented meta-leaner

We first present the proposed LaSAML in its general form and then dive into more details of this framework. Formally, we consider the following problem setting. Our aim is to build a meta-learner which can convert a set of support samples, denoted as $\mathcal{X}_s = \{x_s, y_s, t_s\}$, into a classifier $\phi(\cdot; \mathcal{X}_s)$, where x_s, y_s and t_s denote the input text, class label, and the lexical definition of the class, i.e., the class name, respectively [2] Applying $\phi(\cdot; \mathcal{X}_s)$ to test data, i.e., query data x_q, we could obtain the predicted class $\hat{y}_q$ through $\phi(x_q; \mathcal{X}_s)$. The meta-learner is trained from the meta-training set, from which one can randomly construct a support set $\mathcal{X}_s^C = \{x_s^c, y_s^c, t_s^c\}$ and a query set with ground-truth class name, $\mathcal{X}_q^C = \{x_q^c, y_q^c\}$ for C-Way K-shot settings, where $c \in C$. Therefore, the performance of $\phi(\cdot; \mathcal{X}_s^C)$, classifier generated from the meta-learner, can be evaluated by comparing the predicted class against the ground-truth query label $\{y_q^c\}$. The key difference of traditional meta-learner and the proposed LaSAML is that the lexical definition of class name $\{t_s^c\}$ will be used for building the meta-learner.

In particular, we consider the meta-learner that can be written in the following form:

$$\{\mathbf{w}_c\} = \psi(f(\{x_s^c\}), \{y_s^c\}) \quad c = 1, \cdots, C$$
$$q_c = m(g(x_q); \mathbf{w}_c), \quad \hat{y} = \underset{c}{argmax}\, q_c, \qquad (1)$$

where f and g denotes the feature extractors which convert the input text to a feature vector. For many meta-learning approaches, $f = g$. ψ is a mapping function to map the support set data to a set of class vectors, one for each class. Then the classifier is defined by a function $m(\cdot, \cdot)$ that measures the compatibility, q_c, between a query sample x_q and the class vector $\mathbf{w}_c$. The class with highest q_c is the predicted class.

The above formulation encompasses a wide range of meta-learning approaches. For example, for Prototypical network (Snell et al., 2017), $\mathbf{w}_c$ is the c-th class mean vector calculated from the feature extractor and $m(\cdot, \cdot)$ is simply a negative Euclidean distance between $g(x_q)$ and $\mathbf{w}_c$.

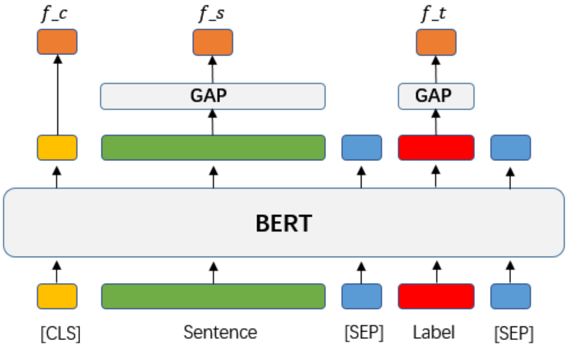

Figure 3: This graph shows how we extract support sample features from various positions. GAP refers to the global average pooling operation.

The proposed LaSAML introduces label-semantic guidance to $f(\cdot)$ and $g(\cdot)$. In other words, the feature extractors f and g may take the class name as an additional input. Due to that the availability of class name information will be different for support set samples and query set samples, i.e., we know the ground-truth class name for support set samples but not for query samples, we may choose different ways of incorporating label information into the feature extractor, resulting in different implementation of f and g.

3.3 Incorporating label information into feature extractors

This subsection discusses various options of incorporating label information into f and g. We show the possible configurations in Figure 3. For the feature extractor of the support set, f, we append the corresponding ground-truth class name to each sentence. Then we have different options of extracting sentence feature representations. In our study, we consider extracting sentence features from [CLS] token, the global average pooling (GAP) of embeddings of sentence tokens, GAP of embeddings of the class name (since a class name may contain multiple tokens), and the average of them.

For the feature extractor of the query set, g. We consider three cases. First, the most straightforward way is not appending anything since we do not know the ground-truth class name for query samples. Second, we can append all class names, as shown in Figure 2. Finally, we can append all class names but extract C features from the corresponding class name, one for each class. Then the c-th feature will be compared against the c-th

---

[2] In our following discussion, we slightly relax the distinction between "class label", "class name" and "class tag" and use them exchangeably when no confusion is caused.

class vector and calculate the matching score with m. The class corresponding to the highest matching score will be the prediction. This scheme is visualized in Figure 2 option 3 for query. Formally, this process can be written as:

$$\hat{y}_q = \underset{c}{argmax}\, m(g(x_q, t_c), w_c), \tag{2}$$

where $g(x_q, t_c)$ denote the feature extracted from class name token t_c.

We will leave the detailed comparison results and discussion of those schemes to Section 4.2 and Section 4.3. Here, we report our major discovery. (1) For supporting set samples, extracting sentence features from different positions leads to similar performance. Extracting features from "[CLS]" and "[CLS]+Tag" in general is slightly better than other options. (2) For query samples, without appending all class-label names leads to the overall best performance for our best performed method. In the following, we by default consider the setting of extracting features from "[CLS]" and not appending class names to a query sample unless otherwise specified.

3.4 Upgrade existing meta-learner with LaSAML

The proposed LaSAML can be incorporated into a variety of existing meta-learning frameworks. In our study, we mainly consider Prototypical Network (Snell et al., 2017) as the meta-learning framework and upgrade it with LaSAML.

The Prototypical Network (Snell et al., 2017) is a metric-based meta-learning framework, which calculates the class vector by averaging the same-class features extracted from the support set. In its LaSAML-upgraded version (denoted as LaSAML-PN), we calculate the class vector $\mathbf{w}_c$ by

$$\mathbf{w}_c = \frac{1}{|\mathcal{X}_s^c|} \sum_{(x_s^c, t_s^c) \in \mathcal{X}_s^c} f(x_s^c, t_s^c), \tag{3}$$

where $f(x_s^c, t_s^c)$ indicates the feature extracted by incorporating class name information.

Then, we make the decision by comparing the feature extracted from a query sample against $\{\mathbf{w}_c\}$:

$$P(c|x_q) = \frac{\exp(-d(g(x_q^c), \mathbf{w}_c))}{\sum_{c' \in C} \exp(-d(g(x_q^c), \mathbf{w}_{c'}))} \tag{4}$$

where $d(\cdot, \cdot)$ is the squared Euclidean distance.

4 Experimental results

In this section, we conduct experiments to evaluate the performance of LaSAML. We first introduce our experimental setting. Then, we present the main results by comparing LaSAML against various existing few-shot text classification approaches. Finally, we provide ablation studies to investigate multiple factors in the proposed method.

4.1 Experimental Setting

4.1.1 Datasets

Three text classification datasets are used in our experiment.

HuffPost is a dataset including a wide range of news topics. The dataset consists of 36900 news headline samples and 900 samples for each class. Following the settings from (Bao et al., 2020), we use the same 20/5/16 classes for training, validation, and testing, respectively, for a fair comparison. Due to the limited number of classes, we only consider the 5-way 1-shot and 5-way 5-shot text classification tasks in this dataset.

Banking77 published by (Casanueva et al., 2020) is a dataset for intent classification tasks. The dataset covers 13,083 fine-grained intents from 77 classes in the banking domain. We construct the few-shot tasks in 10-way 1-shot, 10-way 5-shot, 15-way 1-shot, and 15-way 5-short. The dataset is partitioned into a training, a validation, and a testing dataset. 30, 15, and 32 classes are sampled for each partition[3].

Clinc150 is a cross-domain intent classification dataset which was originally proposed in (Larson et al., 2019). It provides 22,500 in-scope queries and 150 intent classes from 10 domains. Each domain contains 15 intent classes, and there is no overlap between those classes. We use this dataset to evaluate the performance of meta-learner under domain shift. We split the datasets into 4/1/5 domains for training, validation, and testing.

4.1.2 Comparing methods

We compare the proposed method against several commonly used few-shot learning approaches, which have shown promising results in both computer vision and natural language processing fields. For all the compared methods expect distributional signature (Bao et al., 2020) which shows better performance without BERT, we re-implement them

Table 3: Ablation study results of extracting support data features from varies positions and its combinations on HuffPost and Clinc150 (cross domain). According to the results on another ablation study in Table 5, we pick up different query settings ① and ② in Figure 2 for LaSAML-PN and LaSAML-RRML individually.

with the BERT encoder as the feature extractor. Note that this might lead to different (in most cases higher) performance than the one originally reported.

Prototypical Network (Snell et al., 2017) is a metric-based few-shot learning method. Our LaSAML-PN is an upgraded version of it. We use two implementations of PN. One extracts features from the [CLS] token, and another applies a multi-layer-perceptron (MLP) for the embedding of [CLS] token. The latter was used in a recent study (Bao et al., 2020). We denote the original implementation of Prototypical Network as PN and the implementation with an MLP as PN*.

Relation Network (Sung et al., 2018) (RN) does not directly compare class vector against the query feature but compare through a relation module learned during meta-training.

Induction Network (Geng et al., 2019) (IN) integrates the dynamic routing algorithm into the relation network to learn the class vectors during the meta-learning process. The original induction network uses LSTMs as the encoder. To make a fair comparison, we replace the encoder with the BERT encoder in our experiment.

Ridge Regression Meta-Learner (Bertinetto et al., 2019) (RRML) calculates the class vector by solving a Ridge regression problem on the support set. The solution has a closed-form, and thus it is possible to directly back-propagate training error to the feature extractor used in the optimization problem.

Distributional Signature (Bao et al., 2020) (DS) learns how to use the statistic pattern of tokens to selectively attend key information of the input text and build a meta-learner with better generalization performance. The method in (Bao et al., 2020) can be applied to a wide variety of meta-learning methods. In (Bao et al., 2020), the combination with RRML shows the best performance (DS+RRML).

4.1.3 Implementation Details

In our methods, $\text{BERT}_{\text{BASE}}$ is employed as the feature encoder and meta-learner. We construct 100, 100, and 1000 random sampled tasks for each training, validation, and testing epoch individually.

Moreover, we use the Adam algorithm (Kingma and Ba, 2015) as the optimizer. For better training performance, we set different learning rates for the BERT encoder and the other modules, that is, $2e{-5}$ for the BERT encoder and $1e{-3}$ for other modules. Both Relation Network and Induction Network consist of a relation module, and we set the dense hidden layer dimension to 50 for the relation module. We follow other settings of Induction Network in the original paper (Geng et al., 2019).

4.2 Main results of LaSAML

The main experiment results are displayed in Table 1. From the result, we make the following observations: (1) The proposed LaSAML-PN achieves significant performance improvement over the original PN, especially on the one-shot classification setting: on average, the improvement is around 6% to 16%. With more training data, the gap between LaSAML-PN and PN becomes smaller: on Banking77, LaSAML-PN and PN become comparable; but we can still see 3-5% improvement on Clinc150 and HuffPost. This is understandable because, with more samples, the class-related text patterns become more pronounced. However, this might be data-dependent. In general, if the difference between classes is more subtle, i.e., fine-grained classes, more samples might be needed and consequently, the guidance from class name/definition will be more beneficial. (2) We find that the original implementation of the Prototypical network performs much better than the one used in (Bao et al., 2020) which employs an additional MLP. The former achieves even higher performance than the method proposed in (Bao et al., 2020) (which is DS+R2D2. Our re-implementation achieves almost the same performance in (Bao et al., 2020)). (3) Another surprising finding is that the Relation Network and Induction network do not perform better than the traditional Prototypical network. From the above observations, we may conclude that using modules without prior information of a language model, e.g., the MLP whose parameters are randomly initialized rather than pre-trained as in the PLM, leads to poor generalization performance. In contrast, methods directly fine-tuning parameters inside a PLM, e.g., PN, RRML, and our methods, tend to perform better. This observation can somehow be supported by the argument in (Bao et al., 2020). In (Bao et al., 2020), it points out that in NLP, “the lexical features highly informative for one task may be insignificant for another. ” Thus, the weight learned from those randomly initialized modules may overfit the meta-training set and cannot generalize well to the target task. In (Bao et al., 2020), the authors suggest a solution by building a meta-learner with the generalizable statistics of words. In our study, we find that this solution might not be stable in all cases. For example, DS+RRML does not perform well in Banking77 and Clinc150. Instead, our results suggest an alternative solution: building the meta-learner by not introducing additional parameters to BERT parameters, since the latter is pre-trained from a large corpus and tends to generalize better across tasks.

Model	HuffPost		Clinc150	
	5-way		15-way	
	1-shot	5-shot	1-shot	5-shot
BERT+PN	0.4611	0.6556	0.6303	0.8163
LaSAML-PN	**0.6216**	**0.7011**	**0.7248**	**0.8489**
BERT+RRML	0.4078	0.6198	0.5761	**0.8076**
LaSAML-RRML	**0.6260**	**0.6808**	**0.6201**	0.8051

Table 4: Ablation study results for integrating LaSAML with RRML and testing performance on HuffPost and Clinc150 (cross domain).

4.3 Ablation Study

In this section, We investigate LaSAML in depth by answering three questions. First, whether LaSAML is applicable to other meta-learning frameworks. Second, what is the impact of different ways of extracting features from BERT for support set samples? Third, how to leverage class name information for query samples? We conduct a serial of experiments on HuffPost and Clinc150 datasets to answer those questions.

LaSAML with other meta-learning framework To further explore the potential of LaSAML, we incorporate it into the Ridge Regression Meta-learner (RRML) (Bertinetto et al., 2019), which is achieved by simply replacing the feature extractor f and g with the feature extractors used in LaSAML-PN. The results are shown in Table4. As seen, using LaSAML leads to significant improvement in one-shot cases for the RRML. For five-shot cases, the improvement gain becomes smaller for Clinic-150 but still significant in HuffPost. This experiment result suggests that the proposed LaSAML has a great potential to upgrade a wide variety of meta-learning approaches.

Comparing support set feature extraction strategies In LaSAML, the input format of a sup-

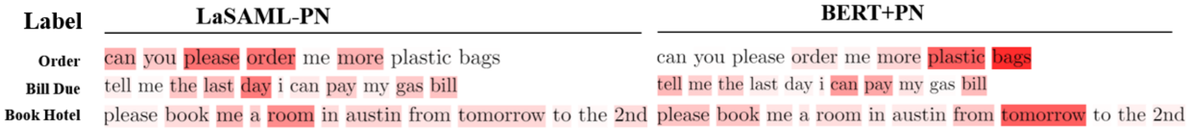

Figure 4: Visualization of BERT attention maps for LaSAML-PN and PN. The darker red color refers to higher attention weight.

port set sample is "[CLS] sentence [SEP] class name [SEP]". As mentioned in Section 3.3, we may extract sentence features from the last layer embedding of the [CLS] token, the average embedding of sentence tokens, the embedding (average embedding) of the class name, and various combination of them. Table 3 provides the comparison of the results. From the results, we can see that no single strategy achieves consistently better performance than the others. Their performance, in most cases, is also similar. Therefore, we extract the sentence feature from the last layer embedding of the [CLS] token for simplicity.

Comparing query feature extraction strategies In this section, we further investigate the impact of the input format for query samples. Three configurations, not appending class names and extracting features from [CLS] (L: None F: CLS), appending all class names but extracting features from [CLS] (L: All F: CLS), appending all class names but extracting features from the respective class (L: All F: Tag), and make a prediction by using Eq. 2. We also make our comparison with the LaSAML upgraded PN, or LaSAML-RRML. The experiment results are shown in Table 5. From the results, we can see that the best strategy seems to be method dependent. Appending all class names leads to better performance for LaSAML-RRML, but for LaSAML-PN, the best strategy is not appending any class names. Another observation is that extracting features from the respective class tag and comparing them against the respective class vector may lead to worse performance. However, extracting features from the respective class tag is capable of achieving better performance (or comparable performance on 5-shot classification in Clinc150 dataset) than previous state-of-the-art methods.

			HuffPost		**Clinc150**	
			5-way 1-shot	5-way 5-shot	15-way 1-shot	15-way 5-shot
M	**L**	**F**				
LaSAML-PN	None	CLS	0.6216	**0.7011**	**0.7248**	**0.8489**
LaSAML-PN	All	CLS	0.6291	0.6726	0.6962	0.8423
LaSAML-PN	All	Tag	**0.6365**	0.6560	0.6680	0.7877
LaSAML-RRML	None	CLS	**0.6284**	0.6631	0.5751	0.7834
LaSAML-RRML	All	CLS	0.6260	**0.6808**	**0.6201**	**0.8051**
LaSAML-RRML	All	Tag	0.5814	0.6782	0.5599	0.7897

Table 5: Ablation study results for process query data in three different ways. M refers to the models including: prototypical network, relation network and ridge regression classifier. L refers to whether query samples append all class names or none. F refers to the features used. Here, support data append related class name and use [CLS] token features.

5 What has been learned in LaSAML

In this section, we demonstrate what has been learned by LaSAML-PN. We use an example in Figure 4 to highlight the difference between LaSAML-PN and the standard prototypical network. By investigating the attention weight with respect to the [CLS] token (we average the attention value across all heads in the last layer of BERT), we can see that the prototypical network fails to attend the words relevant to the class. In contrast, LaSAML-PN successfully attends the relevant keywords.

6 Conclusion

In this paper, we systematically study the potential of using class name information for few-shot text classification tasks. We identify that appending the class name to the sentence as the input to a BERT encoder can lead to more discriminative sentence features. By adopting this scheme to meta-training, we propose a new meta-learning framework called LaSAML. Implementing this framework with the Prototypical network (Snell et al., 2017), we achieve significant improvement over the existing few-shot text classification methods.

Abstract

Among the various modes of communication in social media, the use of Internet memes has emerged as a powerful means to convey political, psychological, and socio-cultural opinions. Although memes are typically humorous in nature, recent days have witnessed a proliferation of *harmful memes* targeted to abuse various social entities. As most harmful memes are highly satirical and abstruse without appropriate contexts, off-the-shelf multimodal models may not be adequate to understand their underlying semantics. In this work, we propose two novel problem formulations: *detecting harmful memes* and *the social entities that these harmful memes target*. To this end, we present HarMeme, the first benchmark dataset, containing $3,544$ memes related to COVID-19. Each meme went through a rigorous two-stage annotation process. In the first stage, we labeled a meme as *very harmful*, *partially harmful*, or *harmless*; in the second stage, we further annotated the type of target(s) that each harmful meme points to: *individual*, *organization*, *community*, or *society/general public/other*. The evaluation results using ten unimodal and multimodal models highlight the importance of using multimodal signals for both tasks. We further discuss the limitations of these models and we argue that more research is needed to address these problems.

1 Introduction

The growing popularity of social media has led to the rise of multimodal content as a way to express ideas and emotions. As a result, a brand new type of message was born: *meme*. A meme is typically formed by an image and a short piece of text on top of it, embedded as part of the image. Memes are typically innocent and designed to look funny.

Over time, memes started being used for harmful purposes in the context of contemporary political and socio-cultural events, targeting individuals, groups, businesses, and society as a whole. At the same time, their multimodal nature and often camouflaged semantics make their analysis highly challenging (Sabat et al., 2019).

Meme analysis. The proliferation of memes online and their increasing importance have led to a growing body of research on meme analysis (Sharma et al., 2020a; Reis et al., 2020; Pramanick et al., 2021). It has also been shown that off-the-shelf multimodal tools may be inadequate to unfold the underlying semantics of a meme as (*i*) memes are often context-dependent, (*ii*) the visual and the textual content are often uncorrelated, and (*iii*) meme images are mostly morphed, and the embedded text is sometimes hard to extract using standard OCR tools (Bonheme and Grzes, 2020).

The dark side of memes. Recently, there has been a lot of effort to explore the dark side of memes, e.g., focusing on hate (Kiela et al., 2020) and offensive (Suryawanshi et al., 2020) memes. However, the harm a meme can cause can be much broader. For instance, the meme[1] in Figure 1c is neither hateful nor offensive, but it is harmful to the media shown on the top left (ABC, CNN, etc.), as it compares them to China, suggesting that they adopt strong censorship policies. In short, the scope of harmful meme detection is *much broader*, and it may encompass other aspects such as cyberbullying, fake news, etc. Moreover, harmful memes have a target (e.g., news organization such as ABC and CNN in our previous example), which requires separate analysis not only to decipher their underlying semantics, but also to help with the explainability of the detection models.

WARNING: This paper contains meme examples and words that are offensive in nature.

[1] In order to avoid potential copyright issues, all memes we show in this paper are our own recreation of existing memes, using images with clear licenses.

Figure 1: Examples from our HarMeme dataset. The labels are in the format `[Intensity, Target]`. For `Intensity`, {0, 1, 2} correspond to *harmless*, *partially harmful*, and *very harmful*, respectively. For `Target`, {0, 1, 2, 3} correspond to *individual*, *organization*, *community*, and *society*, respectively. Examples 1b and 1c are harmful, but neither hateful, nor offensive. Example 1d is both harmful and offensive. Source (a); Source (b); Source (c) 1, Source (c) 2, Source (c) 3; Source (d); Source (e) 1, Source (e) 2, Source (e) 3; License 1 License 2.

Our contributions. In this paper, we study harmful memes, and we formulate two problems. **Problem 1 (Harmful meme detection)**: Given a meme, detect whether it is *very harmful*, *partially harmful*, or *harmless*. **Problem 2 (Target identification of harmful memes)**: Given a harmful meme, identify whether it targets an *individual*, an *organization*, a *community/country*, or the *society/general public/others*. To this end, we develop a novel dataset, HarMeme, containing $3,544$ real memes related to COVID-19, which we collected from the web and carefully annotated. Figure 1 shows several examples of memes from our collection, whether they are harmful, as well as the types of their targets. We prepare detailed annotation guidelines for both tasks. We further experiment with ten state-of-the-art unimodal and multimodal models for benchmarking the two problems. Our experiments demonstrate that a systematic combination of multimodal signals is needed to tackle these problems. Interpreting the models further reveals some of the biases that the best multimodal model exhibits, leading to the drop in performance. Finally, we argue that off-the-shelf models are inadequate in this context and that there is a need for specialized models

Our contributions can be summarized as follows:

- We study two new problems: (*i*) detecting harmful memes and (*ii*) detecting their targets.
- We release a new benchmark dataset, HarMeme, developed based on comprehensive annotation guidelines.
- We perform initial experiments with state-of-the-art textual, visual, and multimodal models to establish the baselines. We further discuss the limitations of these models.

Reproducibility. The full dataset and the source code of the baseline models are available at

`http://github.com/di-dimitrov/harmeme`

The appendix contains the values of the hyperparameters and the detailed annotation guidelines.

2 Related Work

Below, we present an overview of the datasets and the methods used for multimodal meme analysis.

Hate speech detection in memes. Sabat et al. (2019) developed a collection of $5,020$ memes for hate speech detection. Similarly, the Hateful Memes Challenge by Facebook introduced a dataset consisting of $10k+$ memes, annotated as hateful or non-hateful (Kiela et al., 2020). The memes were generated *artificially*, so that they resemble real ones shared on social media, along with "benign confounders." As part of this challenge, an array of approaches with different architectures and features have been tried, including Visual BERT, ViLBERT, VLP, UNITER, LXMERT, VILLA, ERNIE-Vil, Oscar and other Transformers (Li et al., 2019; Su et al., 2020; Zhou et al., 2020; Tan and Bansal, 2019; Gan et al., 2020; Yu et al., 2021; Li et al., 2020; Vaswani et al., 2017; Lippe et al., 2020; Zhu, 2020; Muennighoff, 2020). Other approaches include multimodal feature augmentation and cross-modal attention mechanism using inferred image descriptions (Das et al., 2020; Sandulescu, 2020; Zhou and Chen, 2020), as well as up-sampling confounders and loss re-weighting to complement multimodality (Lippe et al., 2020), web entity detection along with fair face classification (Karkkainen and Joo, 2021) from memes (Zhu, 2020), cross-validation ensemble learning and semi-supervised learning (Zhong, 2020) to improve robustness.

Meme sentiment/emotion analysis. Hu and Flaxman (2018) developed the TUMBLR dataset for emotion analysis, consisting of image–text pairs along with associated tags, by collecting posts from the TUMBLR platform. Thang Duong et al. (2017) prepared a multimodal dataset containing images, titles, upvotes, downvotes, #comments, etc., all collected from Reddit. Recently, SemEval-2020 Task 9 on Memotion Analysis (Sharma et al., 2020a) introduced a dataset of $10k$ memes, annotated with sentiment, emotions, and emotion intensity. Most participating systems in this challenge used fusion of visual and textual features computed using models such as Inception, ResNet, CNN, VGG-16 and DenseNet for image representation (Morishita et al., 2020; Sharma et al., 2020b; Yuan et al., 2020), and BERT, XLNet, LSTM, GRU and DistilBERT for text representation (Liu et al., 2020; Gundapu and Mamidi, 2020). Due to class imbalance in the dataset, approaches such as GMM and Training Signal Annealing (TSA) were also found useful. Morishita et al. (2020); Bonheme and Grzes (2020); Guo et al. (2020); Sharma et al. (2020b) proposed ensemble learning, whereas Gundapu and Mamidi (2020); De la Peña Sarracén et al. (2020) and several others used multimodal approaches. A few others leveraged transfer-learning using pre-trained models such as BERT (Devlin et al., 2019), VGG-16 (Simonyan and Zisserman, 2015), and ResNet (He et al., 2016). Finally, state-of-the-art results for all three tasks —sentiment classification, emotion classification and emotion quantification on this dataset,— were reported by Pramanick et al. (2021), who proposed a deep neural model that combines sentence demarcation and multi-hop attention. They also studied the interpretability of the model using the LIME framework (Ribeiro et al., 2016).

Meme propagation. Dupuis and Williams (2019) surveyed personality traits of social media users who are more active in spreading misinformation in the form of memes. Crovitz and Moran (2020) studied the characteristics of memes as a vehicle for spreading potential misinformation and disinformation. Zannettou et al. (2020a) discussed the quantitative aspects of large-scale dissemination of racist and hateful memes among polarized communities on platforms such as 4chan's /pol/. Ling et al. (2021) examined the artistic composition and the aesthetics of memes, the subjects they communicate, and the potential for virality. Based on this analysis, they manually annotated 50 memes as viral vs. non-viral. Zannettou et al. (2020b) analyzed the “Happy merchant” memes and showed how online fringe communities influence their spread to mainstream social networking platforms. They reported reasonable agreement for most manually annotated labels, and established a characterization for meme virality.

Other studies on memes. Reis et al. (2020) built a dataset of memes related to the 2018 and the 2019 election in Brazil ($34k$ images, $17k$ users) and India ($810k$ images, $63k$ users) with focus on misinformation. Another dataset of 950 memes targeted the propaganda techniques used in memes (Dimitrov et al., 2021a), which was also featured as a shared that at SemEval-2021 (Dimitrov et al., 2021b). Leskovec et al. (2009) introduced a dataset of 96 million memes collected from various links and blog posts between August 2008 and April 2009 for tracking the most frequently appearing stories, phrases, and information. Topic modeling of textual and visual cues of hate and racially abusive multi-modal content over sites such as 4chan was studied for scenarios that leverage genetic testing to claim superiority over minorities (Mittos et al., 2020). Zannettou et al. (2020a) examined the content of meme images and online posting activities to identify the probability of occurrence of one event in a specific background process, affecting the occurrence of other events in the rest of the processes, also known as Hawkes process (Hawkes, 1971), within the context of online posting of trolls. Wang et al. (2020) observed that fauxtographic content tends to attract more attention, and established how such content becomes a meme in social media. Finally, there is a recent survey on multi-modal disinformation detection (Alam et al., 2021).

Differences with existing studies. Hate speech detection in multimodal memes (Kiela et al., 2020) is the closest work to ours. However, we are substantially different from it and from other related studies as (*i*) we deal with *harmful* meme detection, which is a more *general* problem than *hateful* meme detection; (*ii*) along with harmful meme detection, we also identify the *entities that the harmful meme targets*; (*iii*) our HarMeme comprises *real-world memes* posted on the web as opposed to using synthetic memes as in (Kiela et al., 2020); and (*iv*) we present a unique dataset and benchmark results for harmful meme detection and for identifying the target of harmful memes.

3 *Harmful* Meme: Definition

Here, we define *harmful memes* as follows: *multimodal units consisting of an image and a piece of text embedded that has the potential to cause harm to an individual, an organization, a community, or the society more generally*. Here, *harm* includes mental abuse, defamation, psycho-physiological injury, proprietary damage, emotional disturbance, and compensated public image.

Harmful vs. hateful/offensive. *Harmful* is a more general term than *offensive* and *hateful*: *offensive* and *hateful* memes are *harmful*, but not all *harmful* memes are *offensive* or *hateful*. For instance, the memes in Figures 1b and 1c are neither offensive nor hateful, but harmful to *Donald Trump* and to *news media* such as CNN, respectively. Offensive memes typically aim to mock or to bully a social entity. A hateful meme contains offensive content that targets an entity (e.g., an individual, a community, or an organization) based on its personal/sensitive attributes such as gender, ethnicity, religion, nationality, sexual orientation, color, race, country of origin, and/or immigration status. The *harmful* content in a harmful meme is often camouflaged and might require critical judgment to establish its potencial to do hard. Moreover, the social entities attacked or targeted by harmful memes can be any individual, organization, or community, as opposed to *hateful* memes, where entities are attacked based on personal attributes.

4 Dataset

Below, we describe the data collection, the annotation process and the guidelines, and we give detailed statistics about the HarMeme dataset.

4.1 Data Collection and Deduplication

To collect potentially harmful memes in the context of COVID-19, we searched using different services, mainly *Google Image Search*. We used keywords such as *Wuhan Virus Memes*, *US Election and COVID Memes*, *COVID Vaccine Memes*, *Work From Home Memes*, *Trump Not Wearing Mask Memes*. We then used an extension[2] of Google Chrome to download the memes. We further scraped various publicly available groups on *Instagram* for meme collection. Note that, adhering to the terms of social media, we did not use content from any private/restricted pages.

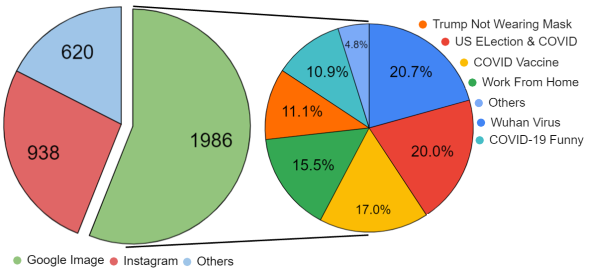

Figure 2: Statistics about the HarMeme dataset. On the left, we show the distribution by source, while on the right, we show the percentage of memes collected by corresponding keywords in Google Image Search.

Unlike the Hateful Memes Challenge (Kiela et al., 2020), which used synthetically generated memes, our HarMeme dataset contains *original memes* that were actually shared in social media. As all memes were gathered from real sources, we maintained strict filtering criteria[3] on the resolution of meme images and on the readability of the meme text during the collection process. We ended up collecting $5,027$ memes. However, as we collected memes from independent sources, we had some duplicates. We thus used two efficient de-duplication repositories[4] [5] sequentially, and we preserved the memes with the highest resolution from each group of duplicates. We removed $1,483$ duplicate memes, thus ending up with a dataset of $3,544$. Although we tried to collect only harmful memes, the dataset contained memes with various levels of harmfulness, which we manually labeled during the annotation process, as discussed in Section 4.3. We further used Google's OCR Vision API[6] to extract the textual content of each meme.

4.2 Annotation Guidelines

As discussed in Section 3, we consider a meme as harmful only if it is implicitly or explicitly intended to cause *harm* to an entity, depending on the personal, political, social, educational or industrial background of that entity. The intended *harm* can be expressed in an obvious manner such as by abusing, offending, disrespecting, insulting, demeaning, or disregarding the entity or any sociocultural or political ideology, belief, principle, or doctrine associated with that entity. Likewise, the *harm* can also be in the form of a more subtle attack such as mocking or ridiculing a person or an idea.

[5] http://github.com/arsenetar/dupeguru

[6] http://cloud.google.com/vision

We asked the annotators to label the intensity of the harm as *harmful* or *partially harmful*, depending upon the context and the ingrained explication of the meme. Moreover, we formally defined four different classes of targets and compiled well-defined guidelines[7] that the annotators adhered to while manually annotating the memes. The four target entities are as follows (c.f. Figure 1):

1. **Individual:** A person, usually a celebrity (e.g., a well-known politician, an actor, an artist, a scientist, an environmentalist, etc. such as *Donald Trump, Joe Biden, Vladimir Putin, Hillary Clinton, Barack Obama, Chuck Norris, Greta Thunberg, Michelle Obama*).

2. **Organization:** An organization is a group of people with a particular purpose, such as a business, a governmental department, a company, an institution or an association, comprising more than one person, and having a particular purpose, such as research organizations (e.g., *WTO, Google*) and political organizations (e.g., *the Democratic Party*).

3. **Community:** A community is a social unit with commonalities based on personal, professional, social, cultural, or political attributes such as religious views, country of origin, gender identity, etc. Communities may share a sense of place situated in a given geographical area (e.g., a country, a village, a town, or a neighborhood) or in virtual space through communication platforms (e.g., online forums based on religion, country of origin, gender).

4. **Society:** When a meme promotes conspiracies or hate crimes, it becomes harmful to the general public, i.e., to the entire society.

During the process of collection and annotation, we rejected memes based on the following four criteria: (*i*) the meme text is in code-mixed or non-English language; (*ii*) the meme text is not readable (e.g., blurry text, incomplete text, etc.); (*iii*) the meme is unimodal, containing only textual or visual content; (*iv*) the meme contains cartoons (we added this last criterion as cartoons can be hard to analyze by AI systems).

4.3 Annotation Process

For the annotation process, we had 15 annotators, including professional linguists and researchers in Natural Language Processing (NLP): 10 of them were male and the other 5 were female, and their age ranged between 24–45 years. We used the PyBossa[8] crowdsourcing framework for our annotations (c.f. Figure 3). We split the annotators into five groups of three people, and each group annotated a different subset of the data. Each annotator spent about 8.5 minutes on average to annotate one meme. At first, we trained our annotators with the definition of harmful memes and their targets, along with the annotation guidelines. To achieve quality annotation, our main focus was to make sure that the annotators were able to understand well what harmful content is and how to differentiate it from humorous, satirical, hateful, and non-harmful content.

---

[7] More details of the annotation guidelines are presented in Appendix B.

[8] `http://pybossa.com/`

	Phase	Annotators		κ
Harmful meme detection	Trial Annotation	α_1	α_2	0.29
		α_1	α_3	0.34
		α_2	α_3	0.26
	Final Annotation	α_1	α_2	0.67
		α_1	α_3	0.75
		α_2	α_3	0.72
Target identification	Trial Annotation	α_1	α_2	0.35
		α_1	α_3	0.38
		α_2	α_3	0.39
	Final Annotation	α_1	α_2	0.77
		α_1	α_3	0.83
		α_2	α_3	0.79

Table 1: Cohen's κ agreement during different phases of annotation for each task: harmful meme detection (3-class classification) and target identification (4-class classification) of harmful memes.

Dry run. We conducted a dry run on a subset of 200 memes, which helped the annotators understand well the definitions of harmful memes and targets, as well as to eliminate the uncertainties about the annotation guidelines. Let α_i be a single annotator. For the preliminary data, we computed the inter-annotator agreement in terms of Cohen's κ (Bobicev and Sokolova, 2017) for three randomly chosen annotators $\alpha_{[1,2,3]}$ for each meme for both tasks. The results are shown in Table 1. We can see that the score is low for both tasks (0.295 and 0.373), which is expected for the initial dry run. With the progression of the annotation phases, we observed much higher agreement, thus confirming that the dry run helped to train the annotators.

Final annotation. After the dry run, we started the final annotation process. Figure 3a shows an example annotation of the PyBossa annotation platform. We asked the annotators to check whether a given meme falls under the four rejection criteria as given in the annotation guidelines. After confirming the validity of the meme, it was rated by three annotators for both tasks.

Consolidation. In the consolidation phase, for high agreements, we used majority voting to decide the final label, and we added a fourth annotator otherwise. Table 2 shows statistics about the labels and the data splits. After the final annotation, Cohen's κ increased to 0.695 and 0.797 for the two tasks, which is moderate and high agreement, respectively. These scores show the difficulty and the variability in gauging the *harmfulness* by human experts. For example, we found memes where two annotators independently chose *partially harmful*, but the third annotator annotated it as *very harmful*.

4.4 Lexical Analysis of HarMeme

Figure 4 shows the length distribution of the meme text for both tasks, and Table 3 shows the top-5 most frequent words in the union of the validation and the test sets. We can see that names of politicians and words related to COVID-19 are frequent in *very harmful* and *partially harmful* memes. For the target of the harmful memes, we notice the presence of various class-specific words such as *president, trump, obama, china*. These words often incorporate bias in the machine learning models, which makes the dataset more challenging and difficult to learn from (see Section 6.4 for more detail).

5 Benchmarking HarMeme dataset

We provide benchmark evaluations on HarMeme with a variety of state-of-the-art unimodal textual models, unimodal visual models, and models using both modalities. Except for unimodal visual models, we use MMF (Multimodal Framework)[9] to conduct the necessary experiments.

5.1 Unimodal Models

▷ **Text BERT:** We use textual BERT (Devlin et al., 2019) as the unimodal text-only model.
▷ **VGG19, DenseNet, ResNet, ResNeXt:** For the unimodal visual-only models, we used four different well-known models – VGG19 (Simonyan and Zisserman, 2015), DenseNet-161 (Huang et al., 2017), ResNet-152 (He et al., 2016), and ResNeXt-101 (Xie et al., 2017) pre-trained on the ImageNet (Deng et al., 2009) dataset. We extracted the feature maps from the last pooling layer of each architecture and fed them to a fully connected layer.

5.2 Multimodal Models

▷ **Late Fusion:** This model uses the mean score of pre-trained unimodal ResNet-152 and BERT.
▷ **Concat BERT:** It concatenates the features extracted by pre-trained unimodal ResNet-152 and text BERT, and uses a simple MLP as the classifier.
▷ **MMBT:** Supervised Multimodal Bitransformers (Kiela et al., 2019) is a multimodal architecture that inherently captures the intra-modal and the inter-modal dynamics within various input modalities.
▷ **ViLBERT CC:** Vision and Language BERT (ViLBERT) (Lu et al., 2019), trained on an intermediate multimodal objective (Conceptual Captions) (Sharma et al., 2018), is a strong model with task-agnostic joint representation of image + text.

thinks (0.0308	donald (0.0241)	work (0.0222)	obama (0.0217)	ensure (0.0645)	wuhan (0.0359)	temperatures (0.0309)
killed (0.0269)	virus (0.0213)	day (0.0188)	covid (0.0203)	qanon (0.0600)	cases (0.0319)	killed (0.0271)

Table 3: Top-5 most frequent words per class. The tf-idf score per word is given within parenthesis.

▷ **Visual BERT COCO:** Visual BERT (V-BERT) (Li et al., 2019) pre-trained on the multimodal COCO dataset (Lin et al., 2014) is another strong multimodal model used for a broad range of vision and language tasks.

6 Experimental Results

Below, we report the performance of the models described in the previous section for each of the two tasks. We further discuss some biases that negatively impact performance. Appendix A gives additional details about training and the values of the hyper-parameters we used in our experiments.

Evaluation measures We used six evaluation measures: Accuracy, Precision, Recall, Macro-averaged F1, Mean Absolute Error (MAE), and Macro-Averaged Mean Absolute Error (MMAE) (Baccianella et al., 2009). For the first four measures, higher values are better, while for the last two, lower values are better. Since the test set is imbalanced, measures like macro F1 and MMAE are more relevant.

6.1 Harmful Meme Detection

Table 4 shows the results for the harmful meme detection task. We start our experiments by merging the *very hateful* and the *partially hateful* classes, thus turning the problem into an easier *binary classification*. Afterwards, we perform the 3-class classification task. Since the test set is imbalanced, the majority class baseline achieves 64.76% accuracy. We observe that the unimodal visual models perform only marginally better than the majority class baseline, which indicates that they are insufficient to learn the underlying semantics of the memes.

Moving down the table, we see that the unimodal text model is marginally better than the visual models. Then, for multimodal models, the performance improves noticeably, and more sophisticated fusion techniques yield better results. We also notice the effectiveness of multimodal pre-training over unimodal pre-training, which supports the recent findings by Singh et al. (2020). While both ViLBERT CC and V-BERT COCO perform similarly, the latter achieves better Macro F1 and MMAE, which are the most relevant measures.

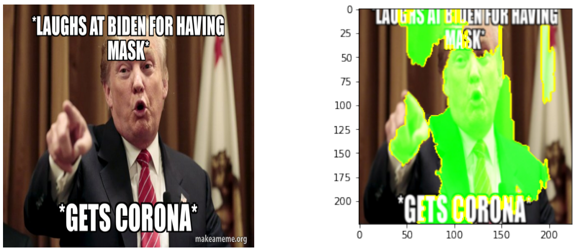
Table 5: Performance for target identification of harmful memes (†human accuracy on the test set).

6.2 Target Identification for Harmful Memes

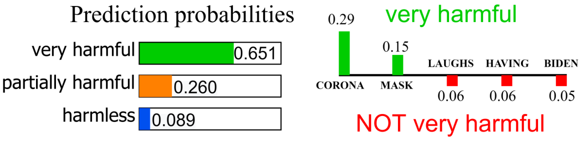
Table 5 shows the results for the target identification task. This is an imbalanced 4-class classification problem, and the majority class baseline yields 46.60% accuracy. The unimodal models perform relatively better here, achieving 63% – 70% accuracy; their F1 Macro and MMAE scores are also above the majority class. However, the overall performance of the unimodal models is poor. Incorporating multimodal signals with fine-grained fusion improves the results substantially, and advanced multimodal fusion techniques with multimodal pre-training perform much better than simple late fusion with unimodal pre-training. Moreover, V-BERT COCO outperforms ViLBERT CC by 8% of F1 score and by nearly 0.3 of MMAE.

6.3 Human Evaluation

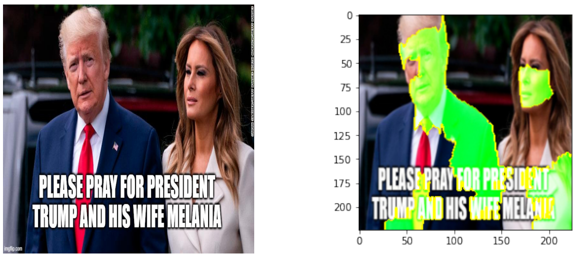
To understand how human subjects perceive these tasks, we further hired a different set of experts (not the annotators) to label the test set. We observed 86% – 91% accuracy on average for both tasks, which is much higher than V-BERT, the best-performing model. This shows that their is a potential for enriched multimodal models that better understand the ingrained semantics of the memes.



(a) Very harmful meme (b) LIME output - image



(c) LIME output - text



(d) Harmless meme (e) LIME output - image

Figure 5: Example of explanation by LIME on both visual and textual modalities and visualization of bias in V-BERT for both tasks.

6.4 Side-by-side Diagnostics and Anecdotes

Since the HarMeme dataset was compiled of memes related to COVID-19, we expected that models with enriched contextual knowledge and sophisticated technique would have superior performance. Thus, to comprehend the interpretability of V-BERT (the best model), we used LIME (Locally Interpretable Model-Agnostic Explanations) (Ribeiro et al., 2016), a consistent model-agnostic explainer to interpret the predictions.

We chose two memes from the test set to analyze the potential explanability of V-BERT. The first meme, which is shown in Figure 5a, was manually labeled as *very harmful*, and V-BERT successfully classified it, with prediction probabilities of 0.651, 0.260, and 0.089 corresponding to the *very harmful*, the *partially harmful*, and the *harmless* classes respectively. Figure 5b highlights the most contributing super-pixels to the *very harmful* (green) class. As expected, the face of Donald Trump, as highlighted by the green pixels, prominently contributed to the prediction. Figure 5c demonstrates the contribution of different meme words to the model prediction. We can see that words like *CORONA* and *MASK* have significant contributions to the *very harmful* class, thus supporting the lexical analysis of HarMeme as shown in Table 3.

The second meme, which is shown in Figure 5d, was manually labeled as *harmless*, but V-BERT incorrectly predicted it to be *very harmful*. Figure 5e shows that, similarly to the previous example, the face of Donald Trump contributed to the prediction of the model. We looked closer into our dataset, and we found that it contained many memes with the image of Donald Trump, and that the majority of these memes fall under the *very harmful* category and targeted and individual. Therefore, instead of leaning the underlying semantics of one particular meme, the model easily got biased by the presence of Donald Trump's image and blindly classified the meme as *very harmful*.

7 Conclusion and Future Work

We presented HarMeme, the first large-scale benchmark dataset, containing 3,544 memes, related to COVID-19, with annotations for degree of harmfulness (*very harmful*, *partially harmful*, or *harmless*), as well as for the target of the harm (an *individual*, an *organization*, a *community*, or *society*). The evaluation results using several unimodal and multimodal models highlighted the importance of modeling the multimodal signal (for both tasks) —(*i*) detecting harmful memes and (*ii*) detecting their targets—, and indicated the need for more sophisticated methods. We also analyzed the best model and identified its limitations.

In future work, we plan to design new multimodal models and to extend HarMeme with examples from other topics, as well as to other languages. Alleviating the biases in the dataset and in the models are other important research directions.

Ethics and Broader Impact

User Privacy. Our dataset only includes memes and it does not contain any user information.

Biases. Any biases found in the dataset are unintentional, and we do not intend to do harm to any group or individual. We note that determining whether a meme is harmful can be subjective, and thus it is inevitable that there would be biases in our gold-labeled data or in the label distribution. We address these concerns by collecting examples using general keywords about COVID-19, and also by following a well-defined schema, which sets explicit definitions during annotation. Our high inter-annotator agreement makes us confident that the assignment of the schema to the data is correct most of the time.

Misuse Potential. We ask researchers to be aware that our dataset can be maliciously used to unfairly moderate memes based on biases that may or may not be related to demographics and other information within the text. Intervention with human moderation would be required in order to ensure that this does not occur.

Intended Use. We present our dataset to encourage research in studying harmful memes on the web. We distribute the dataset for research purposes only, without a license for commercial use. We believe that it represents a useful resource when used in the appropriate manner.

Environmental Impact. Finally, we would also like to warn that the use of large-scale Transformers requires a lot of computations and the use of GPUs/TPUs for training, which contributes to global warming (Strubell et al., 2019). This is a bit less of an issue in our case, as we do not train such models from scratch; rather, we fine-tune them on relatively small datasets. Moreover, running on a CPU for inference, once the model has been fine-tuned, is perfectly feasible, and CPUs contribute much less to global warming.

Acknowledgments

The work was partially supported by the Wipro research grant and the Infosys Centre for AI, IIIT Delhi, India. It is also part of the Tanbih mega-project, developed at the Qatar Computing Research Institute, HBKU, which aims to limit the impact of "fake news," propaganda, and media bias by making users aware of what they are reading.

A Implementation Details and Hyper-Parameter Values

We trained all the models using the Pytorch framework on an NVIDIA Tesla T4 GPU with 16 GB of dedicated memory and with CUDA-10 and cuDNN-11 installed. For the unimodal models, we imported all the pre-trained weights from the TORCHVISION.MODELS[10] subpackage of PyTorch. We initialized the non pre-trained weights randomly with a zero-mean Gaussian distribution with a standard deviation of 0.02. To minimize the impact of the label imbalance in the loss calculation, we assigned larger weights to the minority class. We trained our models using the Adam optimizer (Kingma and Ba, 2014) and the negative log-likelihood loss as the objective function. Table A.1 gives the values of all hyper-parameters we used for training.

We trained the models end-to-end for the two classification tasks, i.e., the memes that were classified as *Very Harmful* or *Partially Harmful* in the first classification stage were sent to the second stage for target identification.

B Annotation Guidelines

B.1 What do we mean by *harmful* memes?

The entrenched meaning of harmful memes is targeted towards a social entity (e.g., an individual, an organization, a community, etc.), likely to cause calumny/vilification/defamation depending on their background (bias, social background, educational background, etc.). The *harm* caused by a meme can be in the form of mental abuse, psycho-physiological injury, proprietary damage, emotional disturbance, compensated public image. A harmful meme typically attacks celebrities or well-known organizations, with the intent to expose their professional demeanor.

Characteristics of *harmful* memes:

- Harmful memes may or may not be offensive, hateful, or biased in nature.
- Harmful memes expose vices, allegations, and other negative aspects of an entity based on verified or unfounded claims or mocks.
- Harmful memes leave an open-ended connotation to the word *community*, including *antisocial* communities such as terrorist groups.
- The harmful content in harmful memes is often implicit and might require critical judgment to establish its potential to do harm.
- Harmful memes can be classified at multiple levels, based on the intensity of the harm they could cause, e.g., *very harmful* or *partially harmful*.
- One harmful meme can target multiple individuals, organizations, and/or communities at the same time. In that case, we asked the annotators to go with the best personal judgment.
- Harm can be expressed in the form of sarcasm and/or political satire. Sarcasm is praise that is actually an insult; sarcasm generally involves malice, the desire to put someone down. On the other hand, satire is the ironical exposure of the vices or the follies of an individual, a group, an institution, an idea, the society, etc., usually with the aim to correcting it.

B.2 What is the difference between *organization* and *community*?

An organization is a group of people with a particular purpose, such as a business or a government department. Examples include a company, an institution, or an association comprising one or more people with a particular purpose, e.g., a research organization, a political organization, etc.

On the other hand, a community is a social unit (a group of living things) with a commonality such as norms, religion, values, ideology customs, or identity. Communities may share a sense of place situated in a given geographical area (e.g., a country, a village, a town, or a neighborhood) or in the virtual space through communication platforms.

B.3 When do we *reject* a meme?

We apply the following rejection criteria during the process of data collection and annotation:

1. The meme's text is code-mixed or not in English.
2. The meme's text is not readable. (e.g., blurry text, incomplete text, etc.)
3. The meme is unimodal in nature, containing only textual or only visual content.
4. The meme contains a cartoon.

Figure B.1 shows some rejected memes.

Abstract

Non-autoregressive translation (NAT) significantly accelerates the inference process via predicting the entire target sequence. However, recent studies show that NAT is weak at learning high-mode of knowledge such as one-to-many translations. We argue that modes can be divided into various granularities which can be learned from easy to hard. In this study, we empirically show that NAT models are prone to learn fine-grained lower-mode knowledge, such as words and phrases, compared with sentences. Based on this observation, we propose progressive multi-granularity training for NAT. More specifically, to make the most of the training data, we break down the sentence-level examples into three types, i.e. words, phrases, sentences, and with the training goes, we progressively increase the granularities. Experiments on Romanian-English, English-German, Chinese-English and Japanese-English demonstrate that our approach improves the phrase translation accuracy and model reordering ability, therefore resulting in better translation quality against strong NAT baselines. Also, we show that more deterministic fine-grained knowledge can further enhance performance.

1 Introduction

Non-autoregressive translation (NAT, Gu et al., 2018) has been proposed to improve the decoding efficiency by predicting all tokens independently and simultaneously. Different from autoregressive translation (AT, Vaswani et al., 2017) models that generate each target word conditioned on previously generated ones, NAT models suffer from the multimodality problem (i.e. multiple translations for a single input), in which the conditional independence assumption prevents a model from properly capturing the highly multimodal distribution of target translations. To reduce the modes of training data, sequence-level knowledge distillation (KD) (Kim and Rush, 2016) is widely employed via replacing their original target samples with sentences generated from an AT teacher (Gu et al., 2018; Zhou et al., 2020; Ren et al., 2020).

Granular.	**AT**	**NAT**			
		Raw	△	KD	△
WORD	59.8	57.1	-2.7	59.0	-0.8
PHRASE	36.0	31.7	-4.3	34.2	-1.8
SENTENCE	29.2	24.5	-4.7	27.0	-2.2

Table 1: Translation performance at different granularity on the WMT14 English⇒German dataset. "△" indicates the performance gap between the NAT and AT.

Although KD reduces the learning difficulty for NAT, there are still complicated word orders and structures (Gell-Mann and Ruhlen, 2011) in the synthetic sentences, making the NAT performance sub-optimal. To answer this challenge, Saharia et al. (2020); Ran et al. (2021) propose to lowers the bilingual modeling difficulties under the *monotonicity assumption*, where bilingual sentences are in the same word order. However, they make extensive modifications to model structures or objectives, limiting the applicability of their methods to a boarder range of tasks and languages.

Accordingly, we turn to break down the sentence-level high modes into finer granularities, i.e. bilingual words and phrases, where we assume that finer granularities are easy to be learned by NAT. As shown in Table 1, we analyzed the translation accuracy at three linguistic levels (i.e. word, phrase and sentence) and found that although KD brings promising improvements at three granular-

	Source	**Targets**
Word	bank	银行 岸 储库
Phrase	hollow structural	中空 结构 空心 的 结构 镂空 结构
Sentence	He is very good at English.	他 英文 很 好。 他 非常 擅长 英语 。 他的 英语 水平 很 高 。

Table 2: Examples of different translation granularities.

ities, there are still some gaps with AT teacher. Also, we showed that finer granularities are easier to be learned, that is, accuracy gap "Δ" of WORD is small than that of PHRASE, and SENTENCE ($0.8<1.8<2.2$). Thus, we propose a simple and effective training strategy to enhance the ability to handle the sentence-level high modes. More specifically, we generate bilingual lexicons from parallel data by leveraging word alignment and phrase extraction in statistical machine translation (SMT, Zens et al., 2002). Then we guide the NAT model to progressively learn the bilingual knowledge from low to high granularity. Experimental results on four commonly-cited translation benchmarks show that our proposed PROGRESSIVE MULTI-GRANULARITY (PMG) training strategy consistently improves the translation performance. The main contributions are:

- Our study reveals that NAT is better at learning fine-grained knowledge. Training with sentences merely may be sub-optimal.
- We propose PMG training to encourage NAT models to learn from easy to hard. The fine-grained knowledge distilled by SMT will be dynamically transferred during training.
- Experiments across language pairs and model structures show the effectiveness and universality of PMG training.

2 Methodology

2.1 Motivation

We investigated theories in second-language acquisition: one usually learns a foreign language from word-to-word translation to sentence-to-sentence translation, namely from local to global (Onnis et al., 2008). Bilingual knowledge is at the core of adequacy modeling (Tu et al., 2016), which is a major weakness of the NAT models due to the lacks of autoregressive factorization. Table 2 demonstrates the English⇒Chinese multimodality at different granularities (i.e. word, phrase, sentence levels). As seen, the sentence-level consists of various kinds of modes, including word alignment ("English" vs. "英语"/"英文"), phrase translation ("be good at" vs. "...非常 擅长..."/"...水平 很 高"), and even reordering ("英语" can be subject or object). However, phrase-level modes are less complex with similar structure and word-level modes are simple with token-to-token mapping. Generally, the lower level of bilingual knowledge, the easier for NAT to learn. This example explains why the sentence level performance gaps between NAT and AT are significant than that of word and phrase in Table 1. Based on the above evidence, it is natural to suspect that the existing sentence-level NAT training is sub-optimal.

2.2 Fine-grained Bilingual Knowledge

Phrase table is an essential component of SMT systems, which records the correspondence between bilingual lexicons (Koehn and Callison-Burch, 2009). For each training example in the original training set, we sample its all possible inter-sentence bi-lingual phrases from the phrase table that obtained with phrase-based statistical machine translation (PBSMT) model (Koehn et al., 2003). The GIZA++ (Och and Ney, 2003) was employed to build word alignments for the training datasets. We leave the exploitation of more advanced forms bilingual knowledge such as syntax rules (Liu et al., 2006) and discontinuous phrases (Galley and Manning, 2010) for future work. Take the sentence pair in Table 2 for example, we can obtain the bilingual En-Zh phrase pairs "*very good* ||| 很好", "*good at English* ||| 擅长英语" from original sentence pair, informing the NAT model the explicit phrase boundaries.

2.3 Progressive Multi-Granularity Training

We present an extremely simple progressive multi-granularity (PMG) training fashion. Concretely, we progressively schedule the PMG: learn from "low" to "high" granularity, i.e. word→phrase→sentence. And we empirically set the training steps for each training stage. Our work can be seen as a typical determinism-based curriculum learning (CL) (Bengio et al., 2009) method, where the finer granular-

ities are more deterministic than sentences. Thus we compare with typical CL works (Zhang et al., 2019; Platanios et al., 2019) in Section 3.2.

3 Experiment

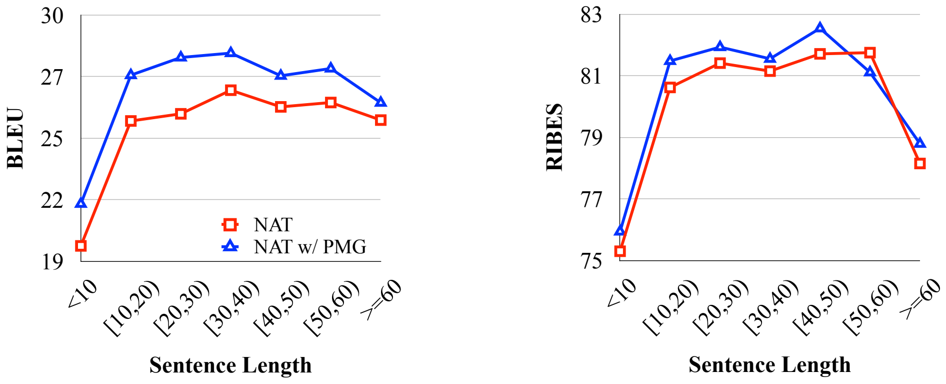
3.1 Setup

Data Experiments were conducted on four widely-used translation datasets: WMT14 English-German (En-De), WMT16 Romanian-English (Ro-En), WMT17 Chinese-English (Zh-En) and WAT17 Japanese-English (Ja-En), which consist of 4.5M, 0.6M, 20M and 2M sentence pairs, respectively. It is worthy noting that Ro-En, En-De and Zh-En are low-, medium- and high- resource language pairs, and Ja-En is word order divergent language direction. We use the same validation and test datasets with previous works for fair comparison. To avoid unknown works, we preprocessed data via byte-pair encoding (BPE) (Sennrich et al., 2016) with 32K merge operations. We evaluated the translation quality with BLEU (Papineni et al., 2002) with statistical significance test (Collins et al., 2005). For fine-grained bilingual knowledge, e.g. word alignment and phrase table, to ensure the source to target mapping more deterministic, we set 0.05 as the probability threshold. Taking WMT14 En-De for example, there are 3M words and 156M phrases in the original phrase table extracted by SMT methodology. We then filter the items whose translation probability is lower than 0.05 and obtain 0.3M words and 56.5M phrases as the final data.

Non-Autoregressive Models We validated our progressive multi-granularity training strategy on two state-of-the-art NAT model structures:

- *Mask-Predict* (MaskT, Ghazvininejad et al. 2019) that uses the conditional mask LM (Devlin et al., 2019) to iteratively generate the target sequence from the masked input;
- *Levenshtein Transformer* (LevT, Gu et al. 2019) that introduces three steps: deletion, placeholder prediction and token prediction.

For regularization, we empirically set the dropout rate as 0.2, and apply weight decay with 0.01 and label smoothing with $\epsilon = 0.1$. We train batches of approximately 128K tokens using Adam (Kingma and Ba, 2015). The learning rate warms up to 5×10^{-4} in the first 10K steps, and then decays with the inverse square-root schedule. We train 50k steps on word-level data and 50k steps on phrase-level data, respectively. And then update the remaining 200K steps for sentence-level training. Following the common practices (Ghazvininejad et al., 2019; Kasai et al., 2020), we evaluate the performance on an ensemble of 5 best checkpoints (ranked by validation BLEU) to avoid stochasticity.



(a) Translation Quality (b) Reordering Difference

Figure 1: Performances of our proposed approach on different length bins against the vanilla NAT model.

Autoregressive Teachers We closely followed previous works to apply sequence-level KD. More precisely, we trained two kinds of Transformer (Vaswani et al., 2017) models, including Transformer-BASE and Transformer-BIG. The main results employ BIG for all directions except Ro-En, which is distilled by BASE. The architectures of Transformer-BIG utilizes a large batch (458K tokens) training strategy.

3.2 Experimental Results

Main Results Table 3 lists the results of previous competitive NAT models (Gu et al., 2018; Kasai et al., 2020; Gu et al., 2019; Ghazvininejad et al., 2019). Clearly, our approach "+PMG Training" consistently improves translation performance (BLEU↑) over four language pairs. Specifically, our PMG training strategy achieves on average +0.53 BLEU scores improvements on four language pairs upon two NAT model structures. Note that our approaches introduce no extra parameters, thus does not increase any latency ("Speed").

Comparison to Curriculum Learning The existing CL methods can be divided into two categories, "Discretized CL (DCL)" (Zhang et al., 2019) and "Continuous CL (CCL)" (Platanios et al., 2019). Sentence length is the most significant variable in our multi-granularity data, therefore we implemented discretized and continuous CL with the sentence length (source side) criteria.

Our DCL setting explicitly predefined the number of data bins, while CCL method continuously samples the shorter examples with the training progresses. For DCL, we split the training samples into a predefined number of bins (5, in our case). As for CCL, we employ their length curriculum and square root competence function. We find that on WMT14 En-De dataset with MaskT model, DCL performs worse than KD baseline (-0.6 BLEU) while CCL outperforms KD baseline by +0.3 BLEU points. Our approach (+0.6 BLEU) is the most effective one.

3.3 Analysis

In this section, we conducted analytical experiments to better understand what contributes to translation performance gains. Specifically, we investigate whether the PMG 1) enhance the phrasal pattern modeling ability? 2) improve the reordering? and 3) gain better performance with higher quality fine-grained knowledge?

Better Phrasal Pattern Modelling Our method is expected to pay more attention on the bi-lingual phrases, leading to better phrase translation accuracy. To evaluate the accuracy of phrase translations, we calculate the improvement over multiple granularities of n-grams in Table 4, our PMG training "NAT w/ PMG" consistently outperforms the baseline, indicating that our proposed multi-granularity training indeed raise the ability of NAT model on capturing the phrasal patterns.

Better Reordering Ability The SMT-distilled bilingual phrasal information could intuitively inform the NAT model the bi-lingual phrasal boundaries, leading to better reordering ability. We compare the reordering ability of NAT model w/ & w/o PMG training with RIBES[1] (Isozaki et al., 2010), which is designed for measuring the reordering performance for distant language pairs. We cate-

N-gram	2	3	4	5	6
Δ BLEU	0.5	0.3	0.3	0.2	0.2

Table 4: Improvements of our proposed PMG training strategy on different N-grams against vanilla NAT.

Ratio	10%	35%	50%	100%
Δ BLEU	+0.3	+0.6	+0.7	+0.6

Table 5: Improvement of PMG training strategy on different fine-grained data scales against vanilla NAT.

gorize the test set into several bins according the sentence length and report the BLEU and RIBES scores, simultaneously in Figure 1. As seen, the proposed PMG training strategy could improve the translation (BLEU↑) and reordering performance (RIBES↑), confirming our claim. Our finding is consistent with Ding et al. (2020a), where they explicitly injected the SMT-guided alignment information into the MT models, achieving better performance.

Effect of Fine-Grained Text Quality The acquired fine-grained bilingual knowledge, i.e. word alignments and phrase tables, still have extremely large volumes after filtering. Taking WMT14 En-De for example, there are over 56M phrase pairs after filtering with translation probability threshold 0.05. To make the knowledge being more deterministic, we control the quality of fine-grained text with the third party scorer – BERTScore (Zhang et al., 2020). As illustrated in Table 5, keeping the high quality bilingual knowledge (e.g. 50%) can achieve further improvements, showing the great potential of our approach. We will leave the exploration of high-quality bilingual knowledge for NAT as a future work.

4 Related Works

Non-Autoregressive Translation There still exists a performance gap between AT teacher and its NAT student. To bridge this gap, many studies have been proposed. Ghazvininejad et al. (2019); Gu et al. (2019); Kasai et al. (2020) designed novel model structures to considerably improve the NAT model capacity. Wang et al. (2019); Ran et al. (2021); Ding et al. (2021b); Du et al. (2021) explored to improve the model performance with additional training signals or objectives. Guo et al. (2020b); Su et al. (2021) delivered the knowledge from pretrained language models to the NAT models. Above works improve the NAT at the model level, while we improve NAT at the data level.

Most related to our work, Ding et al. (2021a) proposed data-level strategies, including reverse distillation and bidirectional distillation, to make the most of the parallel data. Differently, we break the sentences into fine-grained granularities to fully exploit the parallel data. Note that our model-agnostic method can be applied to any NAT structures.

Curriculum Learning Our proposed training strategy is a novel technique for NAT by exploiting curriculum learning (CL). Recent works have shown that CL can help the autoregressive translation (AT) models achieve fast convergence and better results (Platanios et al., 2019; Liu et al., 2020b; Zhan et al., 2021; Zhou et al., 2021). However, CL for non-autoregressive translation (NAT) models has not been well studied. Among the few attempts, Guo et al. (2020a); Liu et al. (2020a) respectively investigated "parameter- and task-level" curriculum learning approaches, while we proposed progressive multi-granularity training for NAT at "data-level". To the best of our knowledge, this is the first work to investigate the effects of different granularities of data on NAT models.

5 Conclusion

In this paper, we investigated the translation accuracy of different granularities in NAT, and found that the NAT models are better at dealing with fine-grained bilingual knowledge (e.g. words and phrases). Based on this finding, we proposed a simple progressive multi-granularity training strategy. Experiments show that our approach consistently and significantly improves translation performance across language pairs and model architectures. In-depth analyses indicate that our approach generates better word order and phrase patterns, outperforming typical curriculum learning methods.

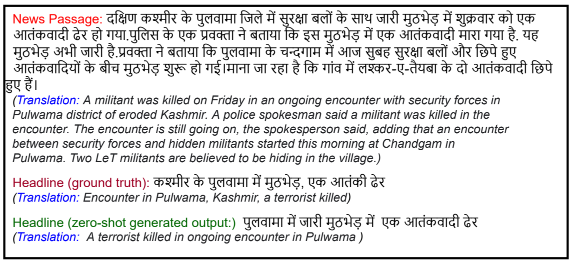
Abstract

Despite the recent advancement in NLP research, cross-lingual transfer for natural language generation is relatively understudied. In this work, we transfer supervision from high resource language (HRL) to multiple low-resource languages (LRLs) for natural language generation (NLG). We consider four NLG tasks (text summarization, question generation, news headline generation, and distractor generation) and three syntactically diverse languages, i.e., English, Hindi, and Japanese. We propose an unsupervised cross-lingual language generation framework (called ZmBART) that does not use any parallel or pseudo-parallel/back-translated data. In this framework, we *further* pre-train mBART sequence-to-sequence denoising auto-encoder model with an auxiliary task using monolingual data of three languages. The objective function of the auxiliary task is close to the target tasks which enriches the multi-lingual latent representation of mBART and provides good initialization for target tasks. Then, this model is fine-tuned with task-specific supervised English data and directly evaluated with low-resource languages in the Zero-shot setting. To overcome catastrophic forgetting and spurious correlation issues, we applied freezing model component and data argumentation approaches respectively. This simple modeling approach gave us promising results. We experimented with few-shot training (with 1000 supervised data-points) which boosted the model performance further. We performed several ablations and cross-lingual transferability analysis to demonstrate the robustness of ZmBART.



News Passage: दक्षिण कश्मीर के पुलवामा जिले में सुरक्षा बलों के साथ जारी मुठभेड़ में शुक्रवार को एक आतंकवादी ढेर हो गया.पुलिस के एक प्रवक्ता ने बताया कि इस मुठभेड़ में एक आतंकवादी मारा गया है. यह मुठभेड़ अभी जारी है.प्रवक्ता ने बताया कि पुलवामा के चन्दगाम में आज सुबह सुरक्षा बलों और छिपे हुए आतंकवादियों के बीच मुठभेड़ शुरू हो गई।माना जा रहा है कि गांव में लश्कर-ए-तैयबा के दो आतंकवादी छिपे हुए हैं।

(Translation: A militant was killed on Friday in an ongoing encounter with security forces in Pulwama district of eroded Kashmir. A police spokesman said a militant was killed in the encounter. The encounter is still going on, the spokesperson said, adding that an encounter between security forces and hidden militants started this morning at Chandgam in Pulwama. Two LeT militants are believed to be hiding in the village.)

Headline (ground truth): कश्मीर के पुलवामा में मुठभेड़, एक आतंकी ढेर
(Translation: Encounter in Pulwama, Kashmir, a terrorist killed)

Headline (zero-shot generated output:) पुलवामा में जारी मुठभेड़ में एक आतंकवादी ढेर
(Translation: A terrorist killed in ongoing encounter in Pulwama)

Figure 1: Zero-shot news headline generation from ZmBART in Hindi language

1 Introduction

Recent advancement in natural language generation (NLG) is heavily oriented towards large annotated training data. Such large task-specific annotated data is available for high resource language (HRL) like English. The tasks become challenging when limited training data is available. This is often observed for low-resource languages (LRLs) like Hindi, Japanese, etc. Manually annotating large data is time-consuming, expensive and uninteresting. This limits the model development and product deployment for LRLs. Moreover, despite large active research in cross-lingual representation learning (Hu et al., 2020; Conneau et al., 2020; Lewis et al., 2020b), the area of cross-lingual transfer and generation is relatively under-explored. Motivated by these factors, we propose a novel framework to transfer supervision from HRL to LRLs where model is trained on one language and directly evaluated for unseen languages. This enables cross-lingual transfer and generation for low resource languages in zero and few-shot settings for different tasks. The framework can be easily extended to other tasks and languages.

We carefully selected four challenging NLG tasks i.e., news headline-generation (NHG), question generation (QG), abstractive text summarization (ATS) and distractor generation (DG) to validate the framework's performance. NHG and ATS require understanding of input passage to generate meaningful headline and summary respectively. QG task should accumulate information from a passage and answer to generate high-quality questions.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2804–2818
August 1–6, 2021.

Distractor generation is the task of generating incorrect options from reading comprehension MCQ. It is challenging because generated distractors should be in the context with question but should not be semantically equivalent to the answer. We consider two LRLs i.e., Hindi and Japanese from two different language families. English is selected as the HRL from which the learning would be transferred to the LRLs. All three selected languages are different in their syntactic structures and typologically diverse. As there is no established publicly available dataset for DG in Hindi, we also create a new DG dataset for Hindi called as **HiDG**[1].

Our proposed framework to achieve this transfer of supervision from HRL to LRL under multiple languages and multiple tasks is named as ZmBART. ZmBART is based on mBART (Liu et al., 2020), a pre-trained model for cross-lingual natural language generation (NLG). We *further* pretrain mBART with a novel auxiliary task. Then the trained model is fine-tuned on large task-specific supervised data in English and evaluated directly on Hindi and Japanese languages in zero/few-shot setting for the tasks under consideration. We observe that the auxiliary task plays a critical role on the model's performance and needs to be carefully designed. This framework can be directly applied to multiple cross-lingual generation tasks without even the need to modify model hyper-parameters. Figure-1 shows a zero-shot NHG sample output generated by the ZmBART model. Our main contributions in this work can be summarized as:

1. We propose a novel zero-shot cross-lingual generation framework called ZmBART without parallel data and without back-translation. The framework can be directly applied across multiple tasks without even modifications in hyper-parameter values.
2. We demonstrate the effectiveness of ZmBART on four cross-lingual generation tasks across three typologically diverse languages.
3. We have created *HiDG*, a high-quality distractor generation dataset for the Hindi language.

2 Related Work

Early works on cross-lingual generation rely on machine translation (MT). In the very first work, Wan et al. (2010) leveraged the MT pipeline for cross-language document summarization. They first translate the non-English test instances to English. This translated text is fed through the supervised model (trained with document summarization data in English) to generate English summaries. Finally, these summaries are translated back to the target language. Shen et al. (2018) and Duan et al. (2019) used MT systems to generate pseudo training data for cross-lingual summarization and news headline generation respectively. However these MT based models are not suitable for low resource languages as they do not share parameters across-languages and generated translations are error-prone.

Recently there are a few works in the direction of supervision transfer from HRL(s) to LRL(s) for language generation. Kumar et al. (2019) used back-translation (needs MT system) and annotated supervised data for cross-lingual question generation. Chi et al. (2020) used parallel data to train a sequence-to-sequence model for zero-shot cross-lingual abstractive text summarization and question generation. Lewis et al. (2020a) proposed a pre-training based on mono-lingual paragraphs. Then this pre-trained model is used for zero-shot abstractive text summarization (ATS) in multiple languages. They trained a model on the ATS dataset on all the languages except the test language. This approach needs annotated data in multiple languages. Existing supervision transfer methods require parallel data for the cross-lingual tasks. Either they use available parallel corpora directly, or they translate/ back-translate data to generate pseudo-parallel corpora. Both these approaches pose significant challenges, as task-specific parallel data for multiple languages is difficult to obtain, and MT are far from perfect, especially for low resource languages.

Unlike the previous approaches, we did not use any parallel data or back-translation in our proposed framework. We did not pre-train any model from scratch. Instead, we leveraged the existing pre-trained model mBART. We included four challenging generation tasks across three syntactically diverse languages. Even we did not modify any hyper-parameters across the tasks and languages. All these considerations make the framework simple and easy to use. Further, it enables the addition of different other languages and NLG tasks in the proposed framework a simple extension exercise.

---

3 Methodology

Figure 2 shows an outline of our proposed ZmBART framework. ZmBART is based on pre-trained mBART (Liu et al., 2020) model. In our framework, we take the mBART model and *further pre-train* it on an auxiliary task. The auxiliary task is designed in such a way that the objective function of auxiliary task is close to fine-tuning tasks and only utilizes the mono-lingual data from the selected languages. Similar to mBART model we use language identifier tag with slight modification. We concatenate $< fxx >< 2xx >$ tags in input data instance where xx indicates the language tag. Given an input sentence and the language tag the model encodes the sentence in multi-lingual space. By conditioning on the encoded representation and language tag the decoder generates output text in target language.

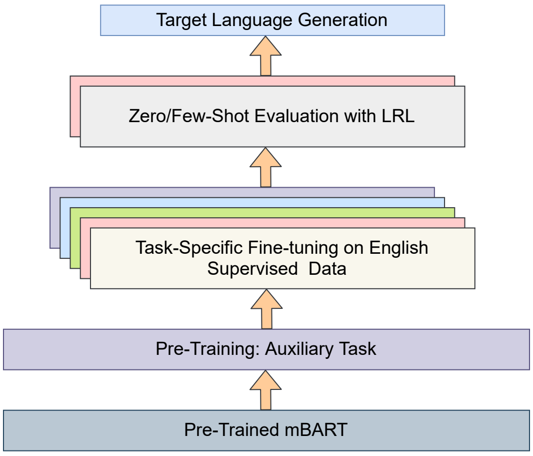

Figure 2: Architecture diagram of ZmBART

3.1 Multilingual BART (mBART)

Multilingual BART (Liu et al., 2020) is an extension of BART model (Lewis et al., 2020c) to multiple languages. It is a transformer-based sequence-to-sequence pre-trained model. The model is trained on monolingual data in many languages from Wikipedia Common Crawl corpus with BART language model objective. Particularly, The training data is concatenation of data from K languages i.e., $\mathcal{D} = \{\mathcal{D}_1, \mathcal{D}_2 \dots \mathcal{D}_K\}$ where $\mathcal{D}_i$ is a collection of monolingual documents in language i. They introduced two types of noises to corrupt the text: (1) random token span masking and (2) sentence order permutation. mBART is trained as denoising autoencoder. During training, the model has to predict text X from it's corrupted version $g(X)$, where g is noise function. The aim is to maximize the following objective function

$$\mathcal{L}_\theta = \sum_{\mathcal{D}_i \in \mathcal{D}} \sum_{x \in \mathcal{D}_i} logP(x|g(x); \theta), \qquad (1)$$

where x is a data instance of language i. Probability distribution P is defined by the sequence-to-sequence model. mBART gave state-of-the-art results in sentence and document level machine translations tasks. Details about mBART model can be found in Liu et al. (2020).

3.2 Unsupervised Auxiliary Task

Although the mBART pre-trained model encodes a multi-lingual latent space, it can not be used directly for cross-lingual generation. This is because the model is jointly trained on denoising objectives which do not directly follow auto-regressive decoding, thereby causing mismatch between pre-training and fine-tuning objectives. To overcome this problem, an unsupervised auxiliary task is introduced. We design the auxiliary task with the following desiderata in mind. It (1) should only utilize mono-lingual data from selected languages, (2) should enrich the mBART latent representations for selected languages and (3) train the decoder in pure auto-regressive manner with a training objective which is close to multiple fine-tuning tasks.

The auxiliary task in ZmBART is an additional pre-training step for *better warm-start* to downstream auto-regressive NLG tasks - although the final task (Distractor/Question/Summary generation) can be different from the auxiliary task. Additionally, this step allows the model to have a closer look at the languages under consideration and enrich/adjust the representations and parameters accordingly.

Outputs of the NLG tasks considered in this work are expected to contain words from different parts of the input. Generation of the output tokens are handled by the framework using an encoder-decoder setup. Hence we decide to have an auxiliary task that also encodes the input, and attends to this encoded representation to generate the output words in auto-regressive manner. This way, a single auxiliary task can help to enrich the token representations, warm up the encoder-decoder weights for fine tuning, and also caters to the multiple final output tasks. We define the auxiliary task as: *Given an input passage, generate few random sentences (called rand-summary) from the passage*. After experimentation we found that randomly generating 20% sentences from passage works the best.

Particularly, the input passage has length between 5-25 sentences and output is 1-5 random sentences from the passage. We do not assume any relations among sentences of the passage. We sample equal proportion of monolingual data from three languages. Data preparation steps for the auxiliary task are given below:

1. Generate a random number $k \in \{5. \cdots, 25\}$. k denotes the size of input passage
2. PASSAGE: Append k continuous sentences, starting from a random index of monolingual corpus D_i of the i^{th} language
3. RAND-SUMMARY: Randomly select 20% sentences from the passage
4. Repeat steps 1 to 3 for p languages
5. Repeat steps 1 to 4 for N times, to collect Np <PASSAGE, RAND-SUMMARY> pairs

3.3 Fine-Tuning on Downstream NLG Tasks

The proposed pre-trained model is directly fine-tuned on four downstream tasks: Question Generation (QG), News Headline Generation (NHG), Abstractive Text Summarization (ATS) and Distractor Generation (DG). First, the model is fine-tuned on large task-specific English supervised data and then this trained model is directly evaluated on Hindi and Japanese evaluation datasets in zero-shot setting. To validate the hypothesis that the ZmBART framework is robust across multiple tasks and languages, we did not modify any hyper-parameters during fine-tuning. It is often observed that including a few instances from LRL to supervised data boosts the model performance. To validate this point we further fine-tuned ZmBART with 1000 task-specific supervised data-points in Hindi and Japanese languages in few-shot setting which boosts the model performance.

3.4 Dealing with Catastrophic Forgetting and Spurious Correlation

During experimentation with the zero shot setup, it is observed that the model always generates the output text in English irrespective of input and language tag. We suspect this to be due to catastrophic forgetting problem (Van de Ven and Tolias, 2019). The supervised training completely overrides/erases the pre-trained learning. The generator (decoder) becomes biased towards English due to the explicit supervision learned from large task-specific English data. To overcome this problem, we freeze all word embeddings and all the parameters of decoder layers during fine-tuning with English data. Although this resolves the problem for NHG, QG and DG, the problem did not get completely resolved for the ATS task. We noticed that the zero-shot ATS output now is not completely in English, but it became of code-mix nature. In other words, the number of English words in the output reduced, but still lot many English words remained. The code-mixed outputs were logical and meaningful. We assume this to be due to spurious correlation issue, also reported in (Gu et al., 2019). To resolve this issue, we added a few examples (25 in number) of the auxiliary-task data during the fine-tuning step. This augmentation was helpful to address the spurious correlation issue for ATS. It is to be noted that the non-English data used for this augmentation is still of unsupervised and monolingual nature.

4 Experimental Setup and Results

We conduct experiments over four NLG tasks in three languages. We compare the performance of ZmBART with strong and MT pipeline based baseline models. We use both automated and manual evaluation metrics to evaluate model performances.

4.1 Baselines

Prior results are not available in literature for selected languages and datasets. Hence, for performance comparison, we developed several strong baselines based on recent models and architectures. Details of these baselines are mentioned below:

- **MT Pipeline (mBART):** Here, we fine-tune mBART on task-specific English data. Non-English test data instances are first translated into English and passed to the fine-tuned model. The output is translated back to the input language. Google Translator is used for translations.
- **mBART+MADMo:** This is an **mBART** based baseline where the auxiliary task has **M**asking **A**nd **D**enoising objective with **Mo**no-lingual data in three languages. The aim is to enrich the cross-lingual latent representation space of mBART for English, Hindi and Japanese.
- **mBART+MADPd:** Inspired from (Chi et al., 2020), we took **P**arallel **D**ata (English-Hindi and English-Japanese) and concatenate each parallel instances of two languages. Then we used this data with **M**asking **A**nd **D**oising objective to further train mBART. Including parallel data provides explicit supervision while generating Hindi and Japanese text.

4.2 Evaluation

We use both automated and manual evaluation metrics for performance comparison. Multiple metrics are used in literature for NLG tasks. Since we are considering multiple tasks, for brevity, against each task we only report values of the metrics commonly used by the community for that particular task. For automatic evaluation we used both lexical match (**BLEU** (Papineni et al., 2002) and **ROUGE** (Lin, 2004)) as well as embedding based evaluation metrics (**BERTScore** (Zhang et al., 2020)). To evaluate question generation and distractor generation tasks we use case-mix BLEU-4 (BL) score from sacreBLEU implementation, ROUGE-L (R-L) and BERTScore (BS). For ATS and NHG tasks ROUGE-1, ROUGE-2 and ROUGE-L are used.

We follow a similar approach for manual evaluation as Chi et al. (2020). We sampled 50 generated data points each for QG, ATS and NHG tasks in both Hindi and Japanese languages. We use three metrics: *Fluency* (Flu), *Relatedness* (Rel) and *Correctness* (Corr). **Fluency** measures *how fluent the generated text is*. **Relatedness** indicates *how much the generated outputs are in the context with input(s)*, **Correctness** measures *semantics and meaningfulness*. For DG, we use an additional metric called **Distractibility** that measures *the degree of confusion for generated incorrect options*. For DG task, there can be large number of good distractors for given input, in such situation the manual evaluation is more reliable. We sample 100 generated outputs for DG task. We employed large pool of evaluators from native Hindi and Japanese speakers to evaluate Hindi and Japanese output texts respectively. We asked each annotator to rate the generated texts on a scale of 1-5 (1 is very bad and 5 is very good) for all the metrics. We intentionally selected outputs of ZmBART and two best baselines to reduce the evaluators workload.

4.3 News Headline Generation (NHG)

In this task, *given a news article, we generate grammatically coherent, semantically correct and abstractive headline*. We use 500k/30k/30k (train/validation/test) English NHG data splits from *Gigaword* headline generation corpus[2]. For Hindi and Japanese we use 1k/1k/5k spilt from Kaggle[3] (we manually filtered high-quality news and headlines) and (Iwama and Kano, 2019) respectively.

In a zero-shot setting we fine-tune ZmBART model on supervised data and directly evaluate results on Hindi and Japanese test datasets. Automated evaluation results are included in Tables 1 and 2. We observe that, quality of generated headlines in Hindi is better compared to Japanese. The possible reasoning can be the input size. ZmBART outperforms the baseline with an absolute difference of 5.22 ROUGE-L score. mBART+MADMO is best among others which shows that masking and denoising with monolingual data indeed enrich the multi-lingual latent space for selected three languages. mBART+MADMO generates code mixed (Hindi-English or Hindi-Japanese) output which degrades the model performance. Few-shot training fills the mistakes of zero-shot models and generates better quality output. Manual evaluation scores (Tables 3 and 4) and automated scores correlate well validating ZmBART's performance on NHG task.

4.4 Question Generation (QG)

In the Question Generation (QG) task, *given an input passage and an answer, the aim is to generate semantically and syntactically correct questions that can produce the answer.* We use SQuAD 1.1 (Rajpurkar et al., 2016) English data for supervised training. SQuAD is popular question answering dataset consisting of 100k+ <passage, question, answer> tuples. Following (Zhao et al., 2018), we combine the train and validation sets of SQuAD and then spilt it as 80k/8k/10k training/validation/test tuples. For Hindi we use 1k/5.5k (train/test) from MLQA (Lewis et al., 2020d) and TyDiQA-GoldP (Clark et al., 2020) datasets. We use 1k/1k/5k for Japanese data from (Takahashi et al., 2019). Hindi and Japanese data are available in SQuAD data format which maintains consistency in terms of passage size, question and number of answers. For given passage and question we randomly selected one answer to form the dataset. We combine answer and passage as single input sequence separated by special token <s>.

Even without any parallel data, ZmBART outperformed all the baselines consistently across all automated evaluation metrics for zero-shot setting. Regarding manual evaluations, we see that Hindi questions received good score from the annotators, whereas the questions generated for the Japanese language inputs were considered as poor. Upon closer inspection of the generated text we find that several generated questions start with English wh-

Table 4: Manual evaluation results of Zero-shot generated outputs for Japanese language

words. This mixing of English 'code' in the output happened somewhat seamlessly for the Hindi data as tokens in both languages are written in left-to-right manner. Moreover, Hindi-English code-mixed data is now getting very common and the annotators mostly accepted the mixing of the wh-words with the Hindi texts. Such mixing is not very common with Japanese text. As a result, the annotators assigned lower scores to such texts.

We then tried to understand the reason for getting the wh-words at the beginning of the output. English interrogative sentences often introduce wh-words at the beginning even though they are not present in the original data. The model gets exposed to such special characteristics of the English interrogative sentences during the fine tuning. The output from other languages get impacted due to this in zero-shot settings. However, the semantics of the text is captured well for the model as demonstrated by the high BERTScore, indicating good cross-lingual transfer of semantic knowledge.

4.5 Abstractive Text Summarization (ATS)

In Abstractive Text Summarization (ATS), we aim to *generate grammatically coherent, semantically correct and abstractive summary given an input document*. We use recently released WikiLingua (Ladhak et al., 2020) cross-lingual abstractive summarization dataset containing data in 18 languages. Prior splits are not available for this dataset. We use 131k/5k/5k (train/validation/test) splits for English, and 1k/1k/5k splits for Hindi and Japanese.

By skimming through data in Hindi we observe that many input documents consist of technical instructions on usage of softwares/tools. Summarizing these instructions are challenging. Zero-shot ZmBART performed better as compared to baselines as shown in human evaluation (Tables 3 and 4 for Hindi and Japanese respectively). The human evaluation results correlate with automated evaluation as shown in Tables 1 and 2. Ladhak et al. (2020) reported cross-lingual ATS score with same data for four different languages. The R-L score for four languages are 34.06, 37.09, 31.67 and 32.33. We obtain R-L scores of 27.22 and 33.49 for Hindi and Japanese respectively, which shows that the few-shot performance of ZmBART is acceptable.

4.6 Distractor Generation (DG)

The final task to judge ZmBART's performance is Distractor Generation (DG). It is the task of generating incorrect options (also known as distractors) from reading comprehension MCQ. The generated distractors should be in the context with the question but shouldn't be semantically equivalent to the answer. Formally, *for given passage, question and answer triplet, generate a long, coherent, and grammatically correct wrong option*. Considering the fact that for a given triplet there can be many incorrect options that are completely different from each other, the problem is even more challenging. We use English DG dataset from (Maurya and Desarkar, 2020) which consists of approx 135k/17k/17k (train/validation/test) split. We were unable to find a suitable dataset in Japanese language. For Hindi language we created a dataset called ***HiDG***[4] of 1k/1k/5k split. Similar to QG, to create input for ZmBART we concatenate the answer, question and passage in the same order and separate them with special token <s>.

To generate HiDG, we first extracted <passage, question, answer> triplets from English SQuAD 1.1 with atleast 150 tokens in the triplet. We generate distractors for these examples using model proposed by Maurya and Desarkar (2020). The distractors were translated to Hindi using Google Translator service. The translated distractors were manually verified or corrected (if necessary) by human annotators.

The evaluation of the task is challenging because: 1) there can be more then one correct distractors. Automated evaluation metrics may not able to capture this aspect as only one ground truth distractor is available and 2) it may possible that the generated distractor is semantically similar to answer with high lexical overlap with reference distractor in those situation lexical match based metrics are not suitable. To evaluate the DG task we mainly rely on BERTScore and manual evaluation. Towards this effort we consider higher number of DG samples for manual evaluation. Results from Tables 1 and 3 indicate the superiority of ZmBART over the baseline models for this task.

To summarize, we have performed experiments for 14 different task-setup combinations involving low resource languages. With four tasks in Hindi and three tasks in Japanese, and each task in zero shot and few shot setup, we provide detailed comparative evaluation for the tasks. The tasks are of different natures, and each task offers its own unique challenge. We critically analyze the performances to show the robustness and the range

---

[4] Implementation, dataset, pre-trained checkpoints and ZmBART generated text are available at `https://github.com/kaushal0494/ZmBART`

of applicability for the proposed ZmBART framework. We use fairseq library (Ott et al., 2019) for all the implementation and experiments. The implementation details are included in supplementary.

5 Results Analysis and Ablation Study

In this section, we provide further analysis of the experimental results. We also perform ablation studies to understand the impacts of the different modeling decisions made in designing the framework.

•**Supervised Training Results:** Table 5 shows the comparative results of fine-tuned mBART with and without auxiliary task on task-specific supervised English data. We observe that there is no significant performance degradation of ZmBART over original mBART model with pure supervised training. Even, the auxiliary task helps in achieving slight improvement over the original mBART performance in most setups. This concludes that ZmBART can be adopted as replacement of original mBART model with additional functionalities.

Task	Setting	BL	R-1	R-2	R-L	BS
NHG	W/ Aux-Task	15.9	43.22	21.33	40.88	90.13
	W/O Aux-Task	15.9	43.15	21.25	40.77	90.13
QG	W/ Aux-Task	20.6	53.20	26.53	51.37	92.18
	W/O Aux-Task	21.4	52.66	26.63	51.25	92.41
ATS	W/ Aux-Task	16.0	40.01	18.11	38.29	90.20
	W/O Aux-Task	15.8	39.52	18.00	37.91	90.10
DG	W/ Aux-Task	10.3	31.76	14.89	31.18	89.33
	W/O Aux-Task	10.0	31.87	14.59	31.30	89.42

Table 5: Automated evaluation results of mBART on task-specific supervised English dataset (with and without Auxiliary Task)

•**Effect of Auxiliary Task:** Table 6 includes the results with and without auxiliary task of ZmBART for ATS and QG tasks in zero-shot setting. It can be inferred that without the auxiliary task, lexical match based scores are poor because the decoder generates code-mixed outputs. We see that the BERTScore is still reasonable without auxiliary task owing to the multilingual mBART embedding. However, generation of the data in appropriate language is enabled only after inclusion of the auxiliary task. The auxiliary task contributes in two ways: it enables zero-shot generation and improves the mBART multilingual latent space even more as indicated by the improved BERTScore.

With these results we now want to understand *whether the auxiliary task is able to generalize across multiple tasks, or favors specific tasks.* Among the tasks considered in this work, we see that generation of meaningful summaries/headlines require understanding/abstracting of input text which is unlikely to be obtained by repeating sentences from input passages, as done in the auxiliary task. ZmBART achieves good zero-shot/few-shot/supervised results (Tables 1-5) on ATS and NHG over strong baselines. The generated headlines and summaries were found to be mostly abstractive, they don't contain large continuous sequences from input text. As described in Sections 4.4 and 4.6, Question Generation and Distractor Generation are more challenging tasks and have objectives vastly different from the auxiliary task's objective. Even for these tasks, decent evaluation scores (Tables 1-5) and improvements over the baselines across the languages considered indicate that the solutions are not spurious. Incorporation of auxiliary task improves the performance of diverse downstream tasks on real benchmark datasets, and does not favor any specific task or dataset.

Model	Abstractive TS			Question Generation		
Metrics	R-1	R-2	R-3	BL	R-L	BS

Table 6: Zero-shot results of ZmBART with and without auxiliary task for Hindi and Japanese

- **Approaches to avoid Catastrophic Forgetting:** We use two approaches to address the catastrophic forgetting problem, (a) Freezing model components and (b) optimized regularization (Van de Ven and Tolias, 2019). Tables 7 and 8 show the automated evaluation results with different approaches used to deal with the catastrophic forgetting problem. It can be noted that the proposed modelling setup (i.e., ZmBART) gives best results.

- **Effect of Architecture on Few-shot Training:** In this set-up we experiment with few-shot training with mBART (directly fine-tuned on task-specific supervised English data) and ZmBART (trained with auxiliary task and fine-tuned with English data). The results are presented in Table 9. We find that ZmBART does better than mBART in corresponding setups. Moreover, although freezing the decoder layer and word embeddings helps in zero-shot setting, it is natural and useful to unfreeze them during few shot training.

- **Few-shot performance with Supervised data:** Figures 3 and 4 show the trends of few-shot training of ZmBART with respect to supervised Hindi and Japanese training data for ATS

Table 9: Hindi language few-shot results for different architectural setups. *WE* indicates that word embeddings and decoder layer parameters are frozen

and QG tasks respectively. We observe that with a small number of supervised examples (e.g. 100) the model achieves decent few-shot performance. We found the trends for different tasks to be similar. The improvement in model performance tends to be minimal after 1000 examples.

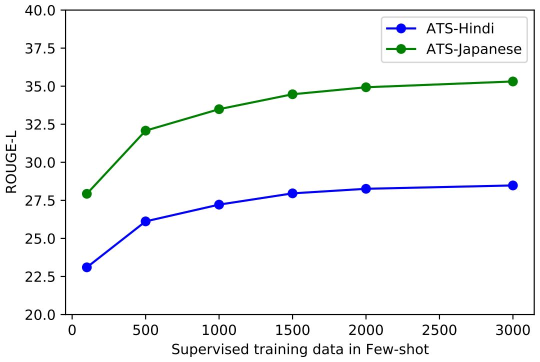

Figure 3: ZmBART model few-shot performance with supervised Hindi/Japanese data for ATS task

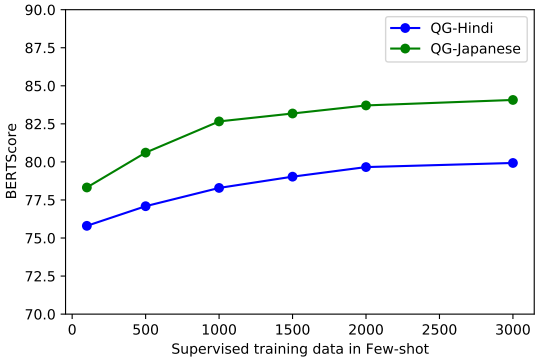

Figure 4: ZmBART model few-shot performance with supervised Hindi/Japanese data for QG task

6 Conclusion

In this paper, we propose a novel unsupervised framework (ZmBART) for cross-lingual transfer and generation. The framework transfers supervision from HRL to LRLs which enables zero-shot language generation. The framework does not use any direct or pseudo-parallel data. ZmBART is directly applied to multiple generation tasks and languages. The model includes a carefully designed auxiliary task that further improved the multilingual embedding space, and helped to initialize encoder-decoder weights to enable zero shot language generation. We performed experiments in three languages and 18 task-setup combinations: four supervised tasks in English, four tasks in Hindi (each with zero-shot and few-shot), and three tasks in Japanese (each with zero-shot and few-shot). Except zero-shot question generation tasks, for all other tasks involving LRLs, the proposed model generated good quality results as validated by automated and manual evaluation measures. In future we want to extend this work by adding multiple other languages and tasks, and also explore other choices of auxiliary tasks for better model transfer.

Acknowledgments

We thank the support from Nvidia AI Technology Center (NVAITC) towards the requirements of computing power and compute infrastructure. We thank the human annotators for human evaluation and the anonymous reviewers for their constructive feedback.

7 Supplementary Materials

7.1 Implementation Details:

We use a standard sequence-to-sequence Transformer architecture with 12 layers (each 16 heads) for encoder and decoder. The model has a dimension of 1024 (approx 680M parameters). Additional layer-normalization was used with both the encoder and decoder. We found FP16 precision stabilized the training. We trained all the models on 4 Nvidia V100 GPUs (32GB). Similar to mBART we use the Adam optimizer ($\epsilon = 1e$-6, $\beta_2 = 0.98$) and linear learning rate decay scheduling. The training started with a dropout value 0.3 and was later reduced to 0.2 after 20k steps and 0 after 40k steps. The loss function was cross-entropy label smoothing loss. 2500 warm-up steps and $3e$-5 learning rate were used. The model selection was done based on validation data likelihood. We use beam-search with beam size 5 in the decoding for all the tasks. We loaded mBARTCC25 pre-trained checkpoint weights and further pre-train/fine-tune model on task-specific data with teacher forcing method.

The above set of parameters are used for all the target tasks as well as the auxiliary task. We process different batch sizes of input for different tasks. We use 2048, 3000, 4096, 2048, and 5000 tokens per GPU for ATS, DG, QG, auxiliary, and NHG tasks, respectively. We use shared Byte Pair Encoding (BPE) vocabulary from sentencepiece tokenizer of size 250k. We use 34k/1k/1k (train/validation/test) data-points for auxiliary language (approx 11333 from each languages). We train the mBART model with the auxiliary task around 10k steps. Training time for the auxiliary task is around 2-3 hours. The fine-tuning times for TS, QG, NHG, and DG were around 4-5, 1-2, 1-2, and 2-3 hours. We observe a longer fine-tuning time for ATS because of long passages. We selected the best model based on loss and perplexity on the validation datasets. We checked with early-stopping and other checkpoints, which resulted in poor performance.

7.2 Evaluation Metric and Tokenizer Details:

For Automated evaluation, we use sacreBLEU implementation, ROUGE-L, and BERTScore. For ATS and NHG tasks, ROUGE-1, ROUGE-2, and ROUGE-L are used. We explicitly use community-adopted language specific-tokenizers. Links for language-specific tokenizers are given below:

- **English:** Default sacreBLEU tokenizer i.e, `https://github.com/mjpost/sacrebleu`
- **Hindi:** `https://anoopkunchukuttan.github.io/indic_nlp_library/`
- **Japanese:** `http://www.phontron.com/kytea/`

Links of publicly available implementations of automated evaluation metrics which we use directly in this work:

- **BLEU:** `https://github.com/mjpost/sacrebleu`
- **ROUGE:** `https://github.com/pltrdy/files2rouge`
- **BERTScore:** `https://github.com/Tiiiger/bert_score`

7.3 Few Zero-shot Generated outputs from ZmBART:

In the next few figures, we present sample outputs generated by the model in zero-shot setups, for Hindi and Japanese languages.

Abstract

Relation extraction (RE) is an essential topic in natural language processing and has attracted extensive attention. Current RE approaches achieve fantastic results on common datasets, while they still struggle on practical applications. In this paper, we analyze the above performance gap, the underlying reason of which is that practical applications intrinsically have more hard cases. To make RE models more robust on such practical hard cases, we propose a case-oriented construction framework to build a **H**ard **C**ase **R**elation **E**xtraction **D**ataset (**HacRED**). The proposed HacRED consists of 65,225 relational facts annotated from 9,231 documents with sufficient and diverse hard cases. Notably, HacRED is one of the largest Chinese document-level RE datasets and achieves a high 96% F1 score on data quality. Furthermore, we apply the state-of-the-art RE models on this dataset and conduct a thorough evaluation. The results show that the performance of these models is far lower than humans, and RE applying on practical hard cases still requires further efforts. HacRED is publicly available at `https://github.com/qiaojiim/HacRED`.

Figure 1: Cases and corresponding triples in WebNLG and practical applications.

1 Introduction

Relation extraction (RE) is one of the core NLP tasks and plays an increasingly important role in knowledge graph completion (Bordes et al., 2013) and question answering (Dong et al., 2015). RE aims to extract structured relational facts, i.e., triples such as (*Bill Gates*, `founder_of`, *Microsoft*) from plain texts. Recently, various models (Zeng et al., 2018; Takanobu et al., 2019; Fu et al., 2019; Wei et al., 2020) have been proposed to identify the relational facts and achieved state-of-the-art (SOTA) performance, among which the latest method CasRel achieves notable 91.8% F1 score on WebNLG (Gardent et al., 2017) and 89.6% on NYT (Riedel et al., 2010).

However, can these seemingly fantastic results prove that the current RE models are powerful enough to perform well in practical applications. To answer the question, we employ CasRel on 300 randomly selected samples of WebNLG and the same number of data from practical DuIE[1]. The F1 scores under these scenarios drop significantly from 89.3% to 62.8%. As illustrated in Figure 1, CasRel extracts correct triples (*Elliot See*, `place_of_birth`, *Dallas*) and (*Elliot See*, `place_of_death`, *St. Louis*) in WebNLG where keywords such as *born* and *died* explicitly express the relation information. In contrast, CasRel fails to extract triples such as (*Yang Jima*, `graduate_from`, *Communication University of China*) where no keywords like *graduate* are mentioned. The most significant reason why CasRel performs well on WebNLG but struggles on practical data is that more challenging instances which

August 1–6, 2021.

we refer to as hard cases exist in the practical applications. Moreover, according to the statistics of entity description documents in CN-DBpedia (Xu et al., 2017), at least 40.1% relational facts can only be extracted from hard cases. Therefore, relation extraction from hard cases can not be neglected and demands more attention.

Although many datasets (Li et al., 2016; Yao et al., 2019) have been proposed for RE, they rarely analyze the performance gap and focus on the hard cases. In order to make models robust on hard cases and more fit practical scenarios, in this paper, we aim to build a RE dataset with sufficient hard cases. To this end, we propose a case-oriented construction framework based on the challenging instances and build a **Ha**rd **C**ase **R**elation **E**xtraction **D**ataset (**HacRED**). Specifically, we first obtain general, massive, and various contexts as well as relational facts from CN-DBpedia to construct a distantly supervised dataset. The crucial part is to distinguish hard cases from abundant data. Therefore, we formulate nine indicators through systematic analysis of hard cases to quantify them. Then, we conduct feature engineering based on the valid indicators. Afterwards, a classifier is trained for distinguishing the desired hard cases. Finally, we develop a crowdsourcing platform with a novel three-stage annotation strategy and effective aggregation method CrowdTruth2.0 (Dumitrache et al., 2018) to guarantee the data size and quality.

In total, HacRED consists of 9,231 instances with 26 predefined relations and 9 types of entities. To the best of our knowledge, it is one of the largest document-level RE benchmark. Moreover, HacRED contains sufficient and diverse hard cases in line with practice. We conduct extensive experiments and systematic error analysis of SOTA models on HacRED. A sharp performance drop on HacRED compared to the existing benchmarks proves that RE in practical applications remains an open problem and still requires further research.

To recap, our main contributions are three-fold:

- We first analyze the performance gap between popular datasets and practical applications, and therefore construct one of the largest Chinese document-level RE dataset which contains sufficient and diverse hard cases to improve the evaluation for complex RE tasks.

- We propose a case-oriented construction framework to build RE dataset toward special cases. Meanwhile, we design a novel three-stage annotation method applicable for crowdsourcing of complex RE.

- We systematically evaluate the current mainstream RE models on HacRED and justify its effectiveness in depth.

2 Related Work

2.1 Datasets for Relation Extraction

A series of datasets have been built for RE as of late, which have extraordinarily advanced the improvement of RE systems. RE datasets such as SemEval-2010 Task 8 (Hendrickx et al., 2009) and ACE05 are constructed through human annotation with relatively limited relation types and size. A large-scale dataset TACRED (Zhang et al., 2017) is obtained via crowdsourcing to satisfy the training of data-hungry models.

As RE applications differ much in various scenarios, constructing datasets aimed at specific targets is a popular trend in RE. DocRED (Yao et al., 2019) is constructed to accelerate the research on document-level RE. To meet the challenges of few-shot RE, FewRel (Han et al., 2018) as well as FewRel 2.0 (Gao et al., 2019) have been presented. RELX (Koksal and Ozgur, 2020) is a benchmark for cross-lingual RE. Jia et al. (2020) propose the task of interpersonal RE in dyadic dialogues and further construct a corresponding dataset called DDRel.

Compared with previous RE datasets, HacRED is derived from the analysis of the performance gap between popular datasets and practical applications. It targets towards promoting the RE models to extract information from the complex contexts.

2.2 Models for Relation Extraction

Recently, many exciting works have been proposed to solve the RE tasks. **(1)Joint Model:** NovelTagging (Zheng et al., 2017) first formulates the task as a sequence labeling problem and presents a novel tagging schema to jointly extract entities and relations. CopyRE (Zeng et al., 2018) extracts triples based on a sequence-to-sequence structure and integrates the copy mechanism for entity generation. GraphRel (Fu et al., 2019) uses graph convolutional network (GCN) to capture features of words and text. CasRel (Wei et al., 2020) is different from the past and is able to extract more triples by learning relation-specific entity taggers. **(2)Pipeline Model:** PURE

(Zhong and Chen, 2020) is a simple pipelined approach which learns an entity model and a relation model independently. DGCNN-BERT is a powerful pipeline method that first identifies multiple relations and then labels the head and tail entities given a relation. It achieves 89.3 F1 scores and has won the champion in the Competition of DuIE held by Baidu Inc. **(3)Document-level Relation Classification Models:** LSR (Nan et al., 2020) is a model that empowers the relational reasoning across sentences by automatically inducing the latent document-level graph. GAIN (Zeng et al., 2020) introduces a path reasoning mechanism based on a heterogeneous mention-level graph and an entity-level graph. ATLOP (Zhou et al., 2020) proposes two techniques, adaptive thresholding and localized context pooling. SSAN (Xu et al., 2021) designs several transformations to incorporate mention structural dependencies for document-level relation classification (DocRC).

Text 1: "..." said *Joseph Bastianich*, who owns Del Posto with his mother, *Lidia Bastianich*, and the chef, *Mario Batali*. **Annotation**: `NA` **Prediction**: `children_of` **Indicators**: Distractor, Homogeneous Entities **Interpretation**: Three entity mentions with the same type of `PERSON` are mentioned in the text and the word *mother* may lead to wrong prediction `children`.
Text 2: ... Lieberman, who was defeated by the political upstart Ned *Lamont* in *Connecticut*'s Democratic primary earlier this month. **Annotation**: `place_lived` **Prediction**: `place_of_birth` **Indicators**: Similar Relations **Interpretation**: The relation `place_lived` and `place_of_birth` are similar in semantics.
Text 3: One of the most brutal tyrants of recent history, Saddam *Hussein* unleashed devastating regional wars and reduced oil-rich *Iraq* to a claustrophobic police state. **Annotation**: `nationality` **Prediction**: `place_of_death` **Indicators**: Reasoning **Interpretation**: Reasoning is required to get the relation `nationality` based on the context that *Hussein* is the *tyrants* of *Iraq*.

Table 1: Examples of hard cases in NYT. The *head* and *tail* mentions are colored accordingly.

3 Easy Cases vs. Hard Cases

To analyze where models struggle in practical instances and distinguish the hard cases, we conduct a manual exploratory analysis on the error-prone instances of SOTA models (CGCN, CasRel, DGCNN-BERT) on NYT, DuIE and industry data. Then we formulate the potential causes of the errors with nine indicators illustrated as follows:

Text Length. We notice that models tend to fail on instances with longer text. The experiments of Alt et al. (2020) also reflect that RE models get a relatively higher error rate with the length of sentence greater than 30 in TACRED.

Argument Distance. We observe that the performance of the models declines when the arguments (i.e., head and tail entity mentions) are far away, especially in inter-sentence RE.

Distractors. Extracting triples in contexts with linguistic distractors is tough for current models. For example, *drop out* will contribute to wrong relation `graduate_from` between entity mentions with `PERSON` and `SCHOOL` type.

Reasoning. Reasoning is needed to extract the relation mentioned implicitly in the text. Recent work suggests that future researchers consider incorporating common sense knowledge or improved causal modules in RE tasks (Han et al., 2018).

Homogeneous Entities. The context contains multiple homogeneous entity mentions with identical types. We observe the high error rate in relations like `children` and `parents` when the text mentions different entities with type `PERSON`.

Similar Relations. Models struggle to identify the correct relation among those semantically similar ones concurrently mentioned in context. A sharp decrease is also found in few-shot RE when selecting N similar relations on N-way K-shot settings (Han et al., 2020).

Long-tail Relations. Only a handful instances are available for long-tail relations in common datasets. Current data-hungry models struggle to learn the semantic patterns on these relations.

Multiple Triples. Models always get a poor performance on the instances with numerous triples.

Overlapping Triples. Different triples involve the identical entity mentions. Many existing models can not well handle the *EntityPairOverlap* and *SingleEntityOverlap* (Zeng et al., 2018) instances.

Table 1 provides various examples from NYT and corresponding hard case indicators. In Table 2, the proportion growing on the error instances reflects the gap between existing datasets and practical data, which also proves the effectiveness of these indicators.

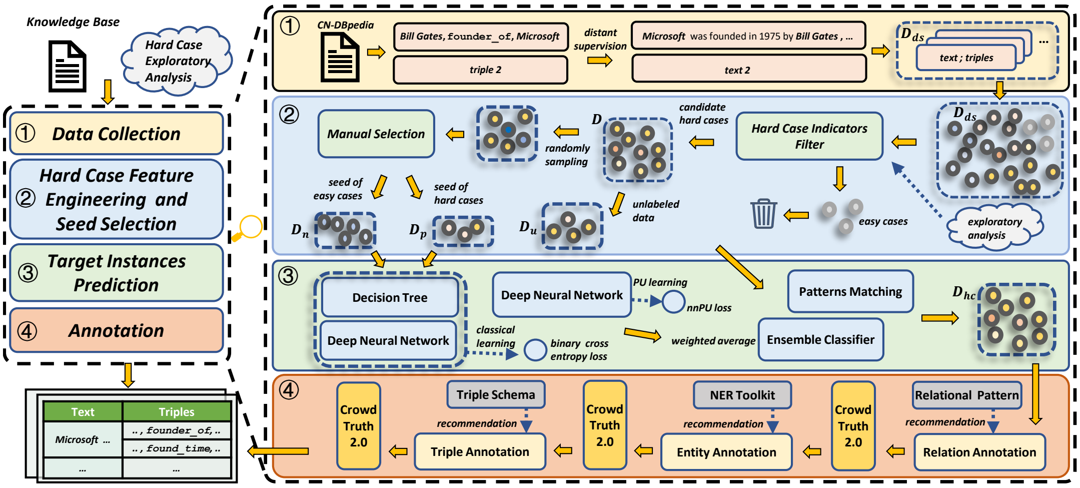

Figure 2: The case-oriented construction framework of building HacRED which consists of four stages. The right part correspondingly describes each stage. Through the construction, the texts and triples are established.

Indicator	WebNLG		DuIE	
	original	error	original	error
Text Length	18	39	3	32
Argument Distance	12	30	5	17
Distractors	1	5	4	13
Reasoning	-	3	1	9
Homogeneous Ent.	2	34	19	21
Similar Rel.	9	54	27	17
Long-tail Rel.	1	5	-	2
Multiple Triples	17	59	8	93
Overlapping Triples	25	64	16	33

Table 2: The proportion of indicators in randomly selected samples of original test set and error-prone instances. Note that one case may fit multiple indicators.

4 HacRED Dataset Construction

The overall architecture of the proposed case-oriented construction framework is illustrated in Figure 2. Different from previous works (Zhang et al., 2017, Zaporojets et al., 2020) which start crowdsourcing annotation straight after the data collection stage, we introduce additional stages of hard case feature engineering and target instance prediction. Moreover, we design a novel three-stage annotation method and employ CrowdTruth2.0.

4.1 Data Collection

To avoid data bias to high-frequency entities and relations, we first obtain about 5 million plain texts and 800 thousand triples from CN-DBpedia. The abundant texts and triples contribute to a more reasonable distribution. We use fine-grained named entity recognition (NER) toolkit TexSmart (Zhang et al., 2020) and entity linking (Chen et al., 2018) to align mentioned entities in texts to those in triples. Finally, we construct a distantly supervised dataset D_{ds} with 1.6 million instances, where we select challenging instances in the following steps.

4.2 Hard Case Feature Engineering and Seed Selection

To build a dataset toward practical hard cases, we systematically formulate the nine indicators of hard cases (refer to Section 3) and introduce measurements to quantify them. For example, we calculate the *Argument Distance* as the number of tokens between the head and tail entity mentions in the text. More details of feature engineering are described in Appendix A. After hard case oriented feature engineering, we discard the instances in D_{ds} without any indicator of hard cases. The remaining part forms a hard case candidate dataset D with about 108 thousand instances.

We randomly sample 3,500 instances from D and ask experts to select the hard cases given the context and features. Specifically, if an instance with multiple hard case indicators or with only one indicator but selected by all three experts based on their expertise, it is regarded as a hard case. To further evaluate the quality of selected hard cases, we utilize DGCNN-BERT to test the selected and unselected data. If the F1 score drops δ=10% on the hard cases, we reserve the data to constitute the high quality seeds of hard case D_p. The remaining data is easy case D_n. In total, we obtain 1,431 seeds of hard cases.

4.3 Classifier Training and Hard Case Prediction

It is impossible to manually select all instances to construct a large-scale dataset. So we utilize a classifier to recall more hard cases similar to the seed samples selected by experts. The classifiers consist of three categories: (1) Decision tree (Quinlan, 1986); (2) Deep classifiers by positive negative (PN) learning (Rakhlin, 2016); (3) Deep classifiers by positive unlabeled (PU) learning (Kiryo et al., 2017; du Plessis et al., 2015). First of all, we adopt the decision tree to make the classifier aware of the indicators explicitly. Then, we form the representation vector as recommended in Baldini Soares et al. (2019) and utilize classical PN learning on D_p and D_n to train the basic classifiers. Since the easy cases are extremely diverse and D_n can not represent the entire distribution of easy cases, we leverage the massive unlabeled data in D_{ds} by introducing PU learning to improve the generalization of hard cases classification. Besides, we train deep models based on different neural network structures, including CNN (LeCun et al., 1998) and BiLSTM (Hochreiter and Schmidhuber, 1997), to capture the context information. More training details can be found in Appendix B.

We ensemble multiple classifiers by weighted average and distinguish hard cases with high confidence in the original massive unlabeled dataset. Besides, we directly select instances by implicit semantic patterns to explore more hard cases fitting the indicator of *Reasoning* which is not well quantified by the auxiliary features. Finally, we obtain the dataset D_{hc} ready for annotation.

4.4 Crowdsourcing

To make instances in D_{hc} fully and accurately labeled, we develop a novel three-stage RE annotation platform taking the following two aspects into consideration: (1) Heavy workload of annotating all information at once results in growing negative feedback as the task goes on; (2) Aggregated method, such as majority vote (Dumitrache et al., 2018), is insufficient for complicated and open-ended tasks. To relieve the pressure of workers, we divide the whole task into three partitions consisting of *Relation Annotation*, *Entity Annotation*, and *Triple Annotation*. Moreover, we utilize patterns and toolkits to provide high-quality recommendations in each stage for higher recall. To capture the label disagreement more thoroughly among workers, we employ CrowdTruth2.0 (Dumitrache et al., 2018), which models the quality of workers, documents, and annotations.

In short, in the *Relation Annotation*, workers select the missed relations or delete wrong recommended ones. When all relations are annotated, NER toolkit recommends multiple entity mentions with the corresponding type based on schema information. Workers also need to append new entity mentions or delete incorrect ones in the *Entity Annotation*. As for *Triple Annotation*, workers verify the correctness of a candidate triples automatically generated by permutation of entity arguments and relations based on schema. Note that every input data in the three stage is assigned to three different annotators and aggregated by CrowdTruth2.0. Detailed annotation process is in Appendix D.

5 Experiments

In this section, we first compare our HacRED with existing datasets. Then we re-evaluate the SOTA RE models on HacRED and systematically analyze their abilities on different experiment settings. At last, we demonstrate the effectiveness of HacRED via a case study.

5.1 Data Analysis

In this section, we analyze various aspects of common RE datasets and HacRED.

Data Size. As shown in Table 3, HacRED has a greater average number of words, entities, and triples in each text than all of the sentence-level datasets. Thus we regard HacRED as a document-level RE dataset. Compared with the document-level datasets, DocRED aims at common document-level RE but not consider performance gaps and various hard cases in practical scenarios. BC5CDR is specially designed for biomedical domain. By contrast, we are the first to analyze the performance gap between popular datasets and practical applications, and propose HacRED which focuses on different kinds of hard cases in general domain. Besides, HacRED is larger in scale and contains much more various relational facts than BC5CDR and DocRED but with lower duplicated triples ratio.

Data Distribution. We calculate three global statistic metrics about data distribution of common datasets and HacRED. Table 4 show the results. Specifically, 84.29% of the triples in NYT and 91.20% in WebNLG are duplicate, which results in a bias to high-frequency triples of same entity pairs (known as *semantic bias* for models). For example, (*Beijing*, `capital_of`, *China*) occurs frequently in corpus and models still extract this triple from *Beijing is a historic city in China*. Mean-

Dataset	# Text	# Relation	# Triple	# Fact	Avg. Sent.	Avg. Word‡	Avg. Ent.	Avg. Triple
sentence-level dataset								
SemEval10	13,434	10	13,434	10,251	1.0	17.4	2.0	1.0
NYT	66,194	24	104,339	16,387	2.1	37.8	2.2	1.6
WebNLG	6,222	171	14,485	1,275	2.5	24.0	3.15	2.3

HacRED	**9,231**	26	**67,047**	**65,225**	5.0	126.6	10.8	7.4

Table 3: Statistics of common RE datasets and HacRED. Note that the *Avg.Word* is computed at word-level vocabulary, which means “中国” (China), two characters in Chinese, is regarded as one word. The average length of documents at character-level is 204.2 in HacRED.

Dataset	Duplicated Triples	Biased Relations	Top 20% Relation Triples
sentence-level dataset			
SemEval10	23.69%	0.00%	44.92%
NYT	84.29%	58.33%	98.93%
WebNLG	91.20%	94.74%	77.57%
TACRED	72.55%	9.52%	91.33%
document-level dataset			
BC5CDR	21.89%	-	-
DocRED	11.15%	12.50%	71.46%
HacRED	**2.72%**	**0.00%**	49.96%

Table 4: Data distributions of common RE datasets and HacRED. The ratio of duplicate triples, biased relations, and top 20% relation triples is calculated as $1-\frac{\#Facts}{\#Triples}$, $\frac{\#Biased\ Rel}{\#Rel}$, $\frac{\#Triples\ of\ top20\%\ Rel}{\#Triples}$, respectively. If the highest-frequency mention is involved in more than 10% triples of the given relation, we regard it as a biased relation.

Indicators		Ratio
Text Length & Argument Distance		25.40%
Distractors & Reasoning		21.20%
Homo. Entities & Similar Relations		9.67%
Long-tail Relations		13.66%
Multiple Triples	1-3	38.87%
	4-9	36.67%
	10-15	14.27%
	16+	10.20%
Overlapping Triples		13.20%

Table 6: Statistics about the proportion of instances fitting different hard case indicators on HacRED.

CrowdTruth 2.0		Human (%)	
Avg. UQS ↑	0.9373	Precision	97.29
Avg. AQS ↑	0.9446	Recall	94.64
Avg. WQS ↑	0.9557	F1	95.94

Table 7: Results of different quality metrics on HacRED.

Dataset	Relation Example	Highest-frequency Mention (Ratio)
WebNLG	`county_seat`	*Texas* (72.73%)
NYT	`person_profession`	*Bavetta* (50.00%)
DocRED	`sister_city`	*Chipilo* (35.29%)
HacRED	`dynasty`	*Tang* (4.20%)

Table 5: Example of relations which could lead to *selection bias* in WebNLG, NYT, and DocRED. In HacRED, the ratio of the highest-frequency mention in all relations is only 4.20%.

while, the top 20% relations in NYT nearly cover the entire relation triples. The numbers of top and last 20% relation triples in WebNLG, TACRED and DocRED also vary greatly. As a result, models perform well on popular relations but fail on long-tail ones. The experiments in the Section 5.4 prove this and we regard it as *relation bias*. In addition, 94.74% relations in WebNLG, 58.33% in NYT and 12.5% in DocRED contribute to the *selection bias*. In WebNLG, 72.73% triples with relation `county_seat` involve the mention *Texas*, as illustrated in Table 5. Models could memorize the cooccurrence between high-frequency mentions and the relation while low-frequency mentions are neglected. All these three aspects reveal the unreasonable data distribution of common datasets.

In comparison, we observe a more reasonable data distribution in HacRED from Table 4 and Table 5. HacRED has a low ratio of duplicate triples and contains various relational facts, which addresses *semantic bias*. No biased relation existing in HacRED reduces the risk of *selection bias*. The proportion of top 20% relations promotes the alleviation of *relation bias* on HacRED. The more comparison of overall data distribution can be found in Appendix E.

Data Quality. We evaluate the quality of HacRED through both automatic metrics and human evaluation. Specifically, we first compute the average *unit quality score* (UQS), *annotation quality score* (AQS), and *worker quality score* (WQS) of the whole 9,231 instances. *UQS*, *AQS* and *WQS* are proposed by CrowdTruth2.0 (Appendix F provides more calculation details). The closer these

Model	Precision	Recall	F1

Table 8: Model performance on HacRED test set(%). NER results are computed based on the entities involved in the gold triples of each instance.

scores are to 1, the higher quality of the crowdsourcing is. Meanwhile, we randomly sample 400 instances from HacRED and compute the precision, recall, and F1 score with annotations based on the revision of humans. The evaluation scores are reported in Table 7. From this table, our HacRED achieves a considerable annotation quality. As a comparison, NYT contains about 31% noise instances (Riedel et al., 2010) and TACRED has poor annotation quality (Alt et al., 2020).

Hard Case Types. We group the randomly sampled 400 instances into nine categories as shown in Table 6. The proportions of different kinds of instances reflect that HacRED contains a various range of hard cases, which evaluates models comprehensively for practical applications.

5.2 Model Evaluation

As DGCNN-BERT has been used in the main process of construction, we evaluate other strong RE models including joint RE models, pipeline RE models, and DocRC models on HacRED. First, we limit the relation set within 20 types both in HacRED and DuIE, and then separate a part of instances in DuIE to form the contrastive easy case dataset D_{ec}. We carry out the equivalent substitution of hard cases in HacRED for easy ones in D_{ec} in different proportions. Figure 3 shows the F1 curve of the performances w.r.t. the proportion of substitution. As the ratio of replacement increases, models generally have a growing trend in performance. The SOTA model CasRel still outperforms other joint models and achieves great F1 on 100% D_{ec}. However, the performance drops on data with more complex instances. We notice that F1 value of easy cases is generally greater than that of hard cases in different substitution ratio settings, which illustrates that RE models indeed struggle when tackling hard cases. Note that by combining HacRED with easy cases in existing datasets, it is easy to simulate diverse practical scenarios.

Model	Precision	Recall	F1
		End-to-end	
CasRel	58.76	45.43	51.24
PURE	56.52	65.15	60.53
Human	**90.21**	**84.59**	**87.31**
		Relation Classification	
ATLOP	78.33	76.70	77.51
Human	**96.21**	**93.03**	**94.59**

Table 9: Human performance (%).

In addition, we split HacRED into train, dev, and test sets with 6231, 1500, 1500 instances respectively. The precision, recall, and F1 score of the three major categories of models are shown in Table 8. The joint and pipeline learning strategies do not contribute to a great F1 on triple extraction. For the NER task, PURE has a separate entity model but results in a 30.61% F1 when all entities in a document are considered, including entities with no positive relation labels. This also reflects the challenge to obtain complete entity information in practical scenarios. On the other hand, the relation classification performances of DocRC models are far from satisfactory. The results suggest that existing models have remarkably poor performance on HacRED compared with humans (Table 9), which indicates that RE applicable for practical hard cases still requires further research.

5.3 Human Performance

We randomly select 200 contexts from test set and ask three volunteers to extract relational facts in an end-to-end manner. Schema information like entity type set as well as relation set is provided but no entity mentions. As for relation classification task, three volunteers select the relation, including NA regarded as negative, of the given entity pair. As demonstrated in Table 9, humans fulfill excellent results which indicate the possible ceiling performance on HacRED.

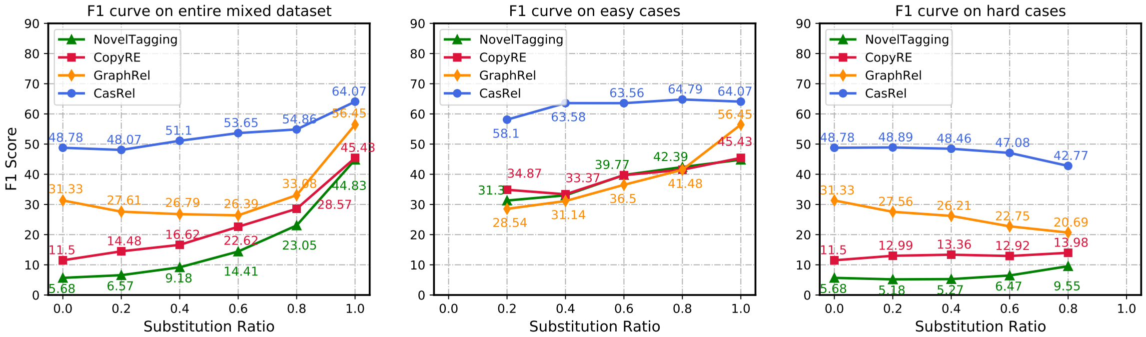

Figure 3: The F1 curve of the model performance on different mix ratios of hard and easy cases.

Model	Text Length Argument Distance	Homo. Ent. Similar Rel.	Long-tail Rel.	Overlapping Triples	Distractor Reasoning	Overall
NovelTagging	4.99	4.33	1.72	3.99	9.23	5.31
CopyRE	5.47	3.90	1.28	6.59	7.30	11.12
GraphRel	30.15	27.82	0.08	34.67	29.81	32.65
CasRel	45.34	45.60	13.54	53.34	44.00	48.85

Table 10: F1 score on HacRED instances with different indicators of hard cases (%).

5.4 Detailed Analysis

In this section, we give insight into the abilities of current mainstream joint models when tackling different kinds of hard cases and propose some research indications as well. As it is hard to obtain complete entity information in practical scenarios, we do not consider DocRC models in this section that entity information is provided as input.

Multiple Triples. Table 11 shows the F1 score of existing models when extracting from texts with different number of triples. The performance of NovelTagging and CopyRE decreases as the number of triples increases, which indicates that the novel tagging schema and multiple decoder mechanism are not able to address the challenge of *Multiple Triples*. Since GraphRel predicts relations for all word pairs and CasRel learns separate entity tagger for different relations, these two models alleviate this problem. An interesting point is that the performance of GraphRel and CasRel rises as the number of triples increases when the triples number is less than 16, indicating that these two models work well in texts with number of triples nearing the average. However, all models get F1 score below average when text mentions have more than 16 triples.

Text Length and Argument Distance. To assess the abilities of models in capturing the long-distance context, we provide the evaluation on instances with indicators of *Text Length* and *Argument Distance* in Table 10. The GCN-based models (i.e., GraphRel) outperforms the BiLSTM-based neural models like NovelTagging and CopyRE. The performance improvement on CasRel suggests the powerfulness of BERT encoder in the long-distance context.

Model	Number of triples			
	1-3	4-9	10-15	16+
NovelTagging	17.92	12.18	8.60	3.29
CopyRE	12.69	10.58	8.82	3.38
GraphRel	29.49	35.23	37.04	29.24
CasRel	43.42	51.05	54.90	43.18

Table 11: F1 score on HacRED test set with different number of triples (%).

Homogeneous Entities and Similar Relations. Since the text mentions multiple homogeneous entities and semantically similar relations, models are required to distinguish the fine-grained difference of the context to extract the correct triples. The first two columns in Table 10 have similar results, which indicates that the contexts with homogeneous entities and similar relations are as challenging as the long-distance contexts.

Long-tail Relations. We observe a dramatic decrease on the instances with long-tail relational triples. As long-tail relations are common in real-world scenarios, a more efficient learning method is required to make RE models applicable for practical applications.

Overlapping Triples. CasRel achieves a better performance on extracting overlapping triples. This proves the effectiveness of cascade binary tagging strategy by first identifying the head mention and then extract the corresponding tail mention given a relation. Specifically, the F1 scores of

Case in HacRED

Hard Case Indicators

Homogeneous Entities, Similar Relations, Distractor, Reasoning

Figure 4: An example of hard cases in HacRED with multiple indicators.

overlapping head and tail mentions are 66.38% and 47.44% respectively. Similarly, results of the two above metrics in CopyRE are 13.31% and 3.57%. The relative higher performance on overlapping head mentions than tail mentions also suggests that the order of extracting arguments could have effect on the results.

Distractor and Reasoning. We manually select instances with *Distractor* and *Reasoning* indicators in HacRED because they cooccur frequently in corpus. As illustrated in Table 10, we observe a drop of the F1. This suggests that models are vulnerable to this kind of instances. However, there are lots of texts with distractions or implicit expression, which needs reasoning, and even common sense. The model design should take the reasoning mechanism into consideration in the future work.

5.5 Case Study

As shown in Figure 4, the text mentions multiple organization entities and similar relations including `graduate_from` and `affiliation_of`. The incorrect triple (*Lu*, `graduate_from`, *Yanjing University*) extracted by CasRel represents that models struggle to capture fine-grained semantic information. The distractive phrases *study for a doctorate* could result in the incorrect extraction (*Wu*, `graduate_from`, *University of Chicago*), which can be rectified by comprehending the context of *before finishing his doctoral dissertation*. Reasoning is needed to extract the triple (*Wu*, `affiliation_of`, *Yanjing University*) since he worked as a professor in the organization.

6 Conclusion

In order to effectively evaluate the RE models and accelerate the research of practical RE, we first analyze the performance gap between popular datasets and practical applications. Therefore, we construct a large-scale and high-quality HacRED with reasonable data distribution and sufficient hard cases. To focus on the practical challenging cases, we propose a case-oriented construction framework. We also design a novel annotation method to guarantee the quality of HacRED. Finally, we conduct extensive experiments and analyze the abilities of SOTA models from various aspects, which provides a deeper understanding of RE models and inspiration for further improvement.

A More Examples of Hard Cases in NYT

In Table 12, we provide additional error-prone examples in NYT that fit other indicators of practical hard cases including *Text Length*, *Argument Distance*, *Multiple Triples*, and *Overlapping Triples*. We have illustrated the instances with other indicators in Section 3.

Text 1: *Sixten Ehrling*, ..., and directed the conducting programs at the *Juilliard School* and ...
Annotation: `affiliation of`
Prediction: `major shareholder of`
Indicators: Text Length, Argument Distance
Interpretation: The text contains many words and the distance between head and tail mention is much far. There is no indicating phrases such as *work in* directly revealing the relation `affiliation of`.

Text 2: Though officials in Addis *Ababa* , *Ethiopia*'s capital , ...
Annotation: `administrative divisions, contains, capital`
Prediction: `capital of`
Indicators: Multiple Triples, Overlapping Triples
Interpretation: The text mentions multiple triples and entities such as *Ethiopia* are involved in different triples.

Table 12: Examples of hard cases in NYT. The *head* and *tail* mentions are colored accordingly.

B Details of Feature Engineering

We calculate the *Text Length* and *Argument Distance* as the number of tokens in the text and between the head and tail entity mentions. *Homogeneous Entities* are measured by the NER results of TexSmart and equal to number of entities with same NER tag. The measurements of *Distractors*, *Similar Relations* are based on pre-defined schemas and auxiliary information, part of which is shown in Table 13. *Multiple Triples* and *Overlapping Triples* are computed by the triples from DS. As reasoning can not be implicitly quantified, we suppose the deep neural models to capture the features of context.

C Details of Classifier Training

A decision tree is learned by the auxilliary features calculated in stage 2. For deep models, we concatenate multiple embeddings and auxilliary features to make up the input. We add special tokens to mark the border of each entity and generate the representation vector as recommended in Baldini Soares et al. (2019). We assign a label 1 to

Relation	Type of Arguments	Similar Relations	Explicit Phrase	Distractors
`graduate_from`	PERSON, ORG	`affiliation _of`, `founder_of`	graduate, receive a degree	drop out college, visit
`spouse`	PERSON, PERSON	`parent`, `children`	marry, wife, tie the knot with	ex-wife
`director`	PERSON, FILM / TV SERIES	`cast_member`, `scriptwriter_of`	directed	watch
`anchorperson_of`	PERSON, VARIETY SHOW	`invited_guest_of`	emcee, host	
...	...	...	...	...

Table 13: Examples of pre-defined schemas and simple auxiliary informations to measured the *indicator_distractor* and *similar_rels*. Experts define some implicit expressions such as *receive a degree* reveals the relation *graduated_from* and distractive phrases like *ex-wife* for *spouse*.

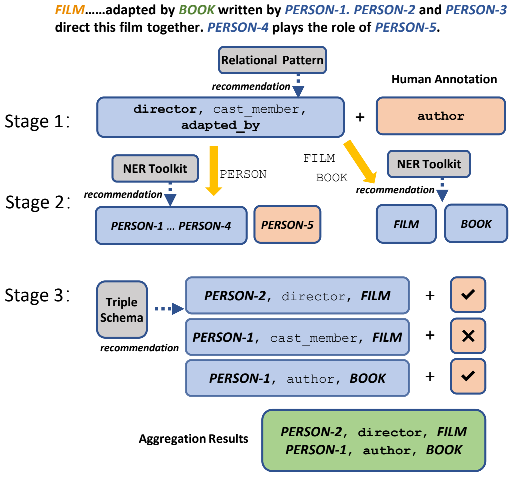

Figure 5: The illustration of three-stage annotation method.

each instance in D_p and -1 in D_n. The deep models output the probability of the instance belonging to hard cases and are optimized with the binary cross entropy loss objective. To start PU learning, we sample from D to form a unlabeled dataset D_u and set the hyperparameter $\pi_p = 0.41$ estimated by the proportion of hard cases selected by experts. We implement nnPU (Kiryo et al., 2017) which is efficient for massive data and deep learning and use J_{nnpu} as the optimized objective,

$$\begin{aligned} J_{nnpu} = \pi_p \cdot & E_{p(x|y=1)}[l(g(x))] + \\ & max\{0, E_{p(x)}[l(-g(x))] - \\ & \quad \pi_p \cdot E_{p(x|y=1)}[l(-g(x))]\} \quad (1) \end{aligned}$$

where $\pi_p = p(y = 1)$, g is decision function, l is surrogate loss function. We choose the double hinge loss $l = max(-z, max(0, \frac{1}{2} - \frac{1}{2}z))$ proposed by (du Plessis et al., 2015).

D Three-stage Annotation Method

We illustrate the three-stage annotation method. Given the context in Figure 5, `director`, `cast_member`, and `adapted_by` is appended to the annotation of Stage 1 by relational pattern. Crowdsourcing workers select the missing relation such as `author`. When all relation mentions are annotated, NER toolkit recommend multiple entity mentions with the corresponding type. Workers need to select the highlighted words that are not covered by entity recommendation in the Stage 2. After stage 2, all mentions in context with specific type are obtained. As the example shown in Figure 5, given the target entity type of `PERSON`, platform recommends the candidates including *PERSON-1* to *PERSON-4*. Workers select highlighted words *PERSON-5* which is missed. In the final stage, we generate the candidate triples automatically by permutation of arguments and relations based on triple schema. Due to the relation `director` connects arguments with entity type `PERSON` and `FILM`, we generate the triple (*PERSON-2*, `director`, *FILM*) and ask annotator to verify the correctness. Note that we employ the powerful quality control method crowdtruth2.0 in every stages to prevent error propagation. As a result, all triples marked as valid are saved.

E Calculation of the UQS, AQS, and WQS Metrics in CrowdTruth2.0

We give the details of the calculation in data quality evaluation. We calculate the three metric unit quality score (UQS), annotation quality score (AQS), and worker quality score (WQS) by CrowdTruth2.0 (Dumitrache et al., 2018) on the whole 9,231 instances in HacRED proposed as follows, where W_1, W_2 is the weight of the iteration method and is initialized as one, u is the unit for annotation,a is one annotation given a unit, i, j denotes the different workers. We straightforward report the average of these metrics in Section 5.1.

$$UQS(u) = \frac{\sum_{i,j} W_1(i,j,u)WQS(i)WQS(j)}{\sum_{i,j} WQS(i)WQS(j)} \tag{2}$$

$$AQS(a) = \frac{\sum_{i,j} WQS(i)WQS(j)P_a(i|j)}{\sum_{i,j} WQS(i)WQS(j)} \tag{3}$$

$$\begin{aligned} WQS(i) &= WUA(i)WWA(i) \\ WUA(i) &= \frac{\sum_u W_2(u,i)UQS(u)}{\sum_u UQS(u)} \\ WWA(i) &= \frac{\sum_{j,u} W_1(i,j,u)WQS(j)UQS(u)}{\sum_{j,u} WQS(j)UQS(u)} \end{aligned} \tag{4}$$

Do Multilingual Neural Machine Translation Models Contain Language Pair Specific Attention Heads?

Abstract

Recent studies on the analysis of the multilingual representations focus on identifying whether there is an emergence of language-independent representations, or whether a multilingual model partitions its weights among different languages. While most of such work has been conducted in a "black-box" manner, this paper aims to analyze individual components of a multilingual neural translation (NMT) model. In particular, we look at the encoder self-attention and encoder-decoder attention heads (in a many-to-one NMT model) that are more specific to the translation of a certain language pair than others by (1) employing metrics that quantify some aspects of the attention weights such as "variance" or "confidence", and (2) systematically ranking the importance of attention heads with respect to translation quality. Experimental results show that surprisingly, the set of most important attention heads are very similar across the language pairs and that it is possible to remove nearly one-third of the less important heads without hurting the translation quality greatly.

1 Introduction

Recent work on analyzing the internals of Transformer-based models (Vaswani et al., 2017) sheds some light on how different components within the models affect the final performance (Bogoychev, 2020; Behnke and Heafield, 2020), and are closely related to playing linguistically interpretable roles (Voita et al., 2019; Jo and Myaeng, 2020). Moreover, studies on the analysis of multilingual representations (Conneau et al., 2020b; Dufter and Schütze, 2020; Wang et al., 2020b) focus on identifying whether there is an emergence of language-independent representations in multilingual models, or whether multilingual models partition their weights among different languages.

In this paper, we investigate if similar analysis can be made for pretrained multilingual neural machine translation (NMT) models regarding language pair specificity. More precisely, we analyze multi-head attention in a many-to-one (Transformer-based) NMT model and try to find, through an extensive ablation method on selection of the attention heads, whether some heads are more specific to the translation of a certain language pair than others.

Our contributions are the following: (1) we examine the effectiveness of different attention-based metrics on pruning encoder self-attention and cross attention heads; (2) we find that while it is possible to discover rare heads that are specific to a language pair by using a proposed head selection method, most important heads are language-independent; (3) we also show that around 30% of heads can be removed with very little loss of performance.

2 Related Work

Recent studies analyzed the roles of attention heads in the Transformer models either in language modeling (LM) (Michel et al., 2019; Clark et al., 2019; Jo and Myaeng, 2020) or NMT (Voita et al., 2019; Behnke and Heafield, 2020; Michel et al., 2019). It has been shown that a set of attention heads might be redundant at inference and can be pruned with almost no loss in performance. In addition, some studies (Voita et al., 2019; Clark et al., 2019) suggested a linguistic interpretation of self-attention heads. However, most of these analyses were carried out for a single language (in case of LM) or a single language pair (in case of NMT).

In the meantime, efficiency in the cross-lingual transfer of recently released pretrained multilingual language models (Devlin et al., 2019; Conneau et al., 2020a) has boosted an active line of research trying to analyze their representations to

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2832–2841
August 1–6, 2021.

understand what favors the emergence of an *interlingua*. For instance, Pires et al. (2019); Dufter and Schütze (2020); Karthikeyan et al. (2020) tried to decouple the effect of shared "anchors"[1] from the rest of the model. Very recently, Muller et al. (2021) performed a more fine-grained analysis, examining representations at each layer of the model.

Despite the success of massively multilingual NMT models (Johnson et al., 2017; Bapna and Firat, 2019; Aharoni et al., 2019; Zhang et al., 2020), less effort has been made in analyzing multilingual NMT representations. Kudugunta et al. (2019) clustered the representations of different languages learned by multilingual NMT models showing that common representations emerge in the encoder. Mareček et al. (2020) found that while RNN models (Attention Bridge architecture) (Cífka and Bojar, 2018; Lu et al., 2018) learn to capture certain linguistic properties with an increasing number of target languages, Transformer models are largely unaffected. Recent work of Zhang et al. (2021) introduced a conditional routing layer in a form of gate selection between language-specific and language-independent projection, providing some insights on which components allow for the emergence of *interlingua*.

Our work builds on the findings from the attention heads analyses (Voita et al., 2019; Michel et al., 2019) but attempts to extend them to multilingual NMT, investigating whether it is possible to discover attention heads that are language pair specific. Also, we experimented with a set of attention-based metrics and analyzed how effective they are in pruning under different language pairs and types of attention.

3 Methodology

As our goal was to identify "important" attention heads for different language pairs, we first needed to define a metric or a procedure that can capture the notion of "importance" of an attention head, and selected heads based on this importance.

In Section 3.1, we present a set of metrics that quantify certain aspects of attention weights, which to some extent, can be considered as the importance. Section 3.2 illustrates a more direct approach where the importance of a head is defined as the extent of decrease in BLEU scores (Papineni et al., 2002) resulted in pruning the head.

3.1 Metrics Based on Attention Weights

We experimented with three types of metrics that are defined for each attention head, $\texttt{head}_{l\in L,h\in H}$, where l and h are the indices of layer and multi-head, respectively. In what follows we define how the metrics were computed for one sentence. Each metric was computed and averaged over a set of development sentences, then normalized to zero mean and unit standard deviation for ease of comparison. We note that $|I|$ and $|J|$ were the number of source tokens and/or target tokens, depending on whether we looked at the self-attention of encoder or the encoder-decoder cross attentions.

Confidence Voita et al. (2019) defined the notion of confidence of a head to be the mean of its maximum attention weights, and showed that only a small set of heads are confident and responsible for most of the model's performance.

$$\mathrm{conf}(\mathrm{head}) := \frac{1}{|I|}\sum_{i\in I}\max_{j\in J}\alpha_{i,j}$$

Variance Inspired by Vig and Belinkov (2019), we computed the expected position of attention for token i as $\mu_i := \mathbb{E}[j|i] = \sum_{j\in J} j\cdot\alpha_{i,j}$, and measured how much each individual position was away from it:[2]

$$\mathrm{var}(\mathrm{head}) := -\sum_{i\in I}\sum_{j\in J}\alpha_{i,j}\,(\mu_i - j)^2$$

Coverage Tu et al. (2016) defined the notion of coverage for encoder-decoder attentions which computes the amount of attention a source token has received. We extended the idea to the self-attentions in encoder as well.

$$\mathrm{cov}(\mathrm{head}) := \sum_{j\in J}\left(\sum_{i\in I}\alpha_{i,j}\right)^2$$

More details on the metrics are provided in Appendix C.

3.2 Sequential Backward Selection of Heads

Intuitively, a head can be considered as important if its removal results in a drastic decrease in the BLEU scores. As different combinations of heads can affect the performance differently, we followed the sequential backward selection (SBS) algorithm (Aha and Bankert, 1996), which is a top-down algorithm starting from a feature set of all features (in

---

[1] either shared vocabulary or shared special tokens such as ⟨SEP⟩, ⟨EOS⟩, etc.

[2] As we wanted the important heads to have lower variance, we multiplied the score with -1.

Algorithm 1: SBS for Head Selection

```
selections ← $\emptyset$;
while $|\text{selections}| < |L| \cdot |H|$ do
    bleuMin ← $\infty$;
    headMin ← $\emptyset$;
    for $\forall\ \text{head}_{l \in L, h \in H} \notin$ selections do
        masks ← selections $\cup$ $\text{head}_{l,h}$;
        trans ← Translate(masks);
        bleuDrop ← Evaluate(trans);
        if bleuDrop < bleuMin then
            bleuMin ← bleuDrop;
            headMin ← $\text{head}_{l,h}$;
        end if
    end for
    selections ← selections $\cup$ headMin;
end while
return selections;
```

our case, a set of all heads) and sequentially removing the most irrelevant features that maximize the evaluation metric (in our case, the BLEU score).

The pseudo-code for the head selection procedure is illustrated in Algorithm 1. The algorithm first selects a head that, when masked, results in the smallest decrease in the BLEU score; and adds it to selections. For subsequent iterations, it proceeds similarly, but the masks now include the heads in selections as well as the candidate head. The procedure terminates when all heads are selected. Note that the time complexity of the algorithm is $\mathcal{O}(|L|^2|H|^2)$, where L and H denote the set of layers and attention heads, respectively. It is a computationally intensive procedure as for each iteration, a test set is translated and evaluated.

4 Experiments and Results

4.1 Preliminary Experiment

We conducted a preliminary experiment using a many-to-one multilingual model trained on a TED talk dataset (Qi et al., 2018), covering top-20 source languages with the most data. We observed that patterns of attention heads (measured with the "confidence" metric) for both encoder self-attention and encoder-decoder attention were very similar among the language pairs.

For the main experiment, we decided to use a larger and stronger multilingual model for the following reasons: (1) the TED dataset is quite small and the model trained on it achieves lower BLEU scores and may not be regularised very well; (2) the network capacity of the TED model could be too limited for the language-pair-specific patterns to emerge (if any). According to a study on BERT's multilinguality (Dufter and Schütze, 2020), the increased network capacity (i.e., overparameterization) is shown to lead to more decoupled representations between languages.

As the multilingual model described in Section 4.2 is trained on much larger datasets, and has a network capacity larger than the initial TED model while covering fewer language pairs, we expect that the language-pair specificity (if any) is more likely to emerge.

4.2 Experimental Settings

For the sake of reproducibility, all experiments were conducted using a strong publicly available many-to-one multilingual NMT model released by Bérard et al. (2020). The model can translate French, German, Italian, Spanish, and Korean sentences into English. It is trained with standard open-accessible datasets, including biomedical corpora where available. The model uses a variant of the Transformer-Big architecture (Vaswani et al., 2017) with a shallower decoder: 16 attention heads, 6 encoder layers, and 3 decoder layers. The model produces SOTA- or near-SOTA-level results for news, IWSLT, and biomedical translation tasks.

As the model is many-to-one, we could set up a controlled experiment where the BLEU scores were directly compared among the language pairs. We employed the development and test sets from the TED talk dataset, and utilized only the multilingual sentence pairs where both source and reference sentences were present for all five language pairs.[3] After the filtering, the development and test sets contained 1771 and 2137 pairs, respectively.

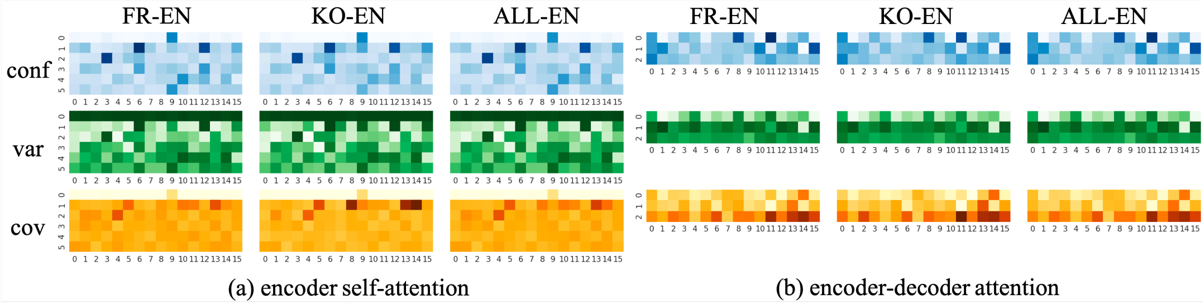
As we were using a many-to-one model, we conducted experiments on both encoder self-attentions and encoder-decoder attentions. In our experiments, we did not re-train or fine-tune the model when masking each head, making procedure lighter than other approaches involving the re-training.

4.3 Results

Heads importance across languages Figure 1 shows the heatmaps for each importance metric (Sect. 3.1) for the self-attention and cross-attention

---

[3] Note that the English reference sentences were the same across the language pairs.



(a) encoder self-attention

(b) encoder-decoder attention

Figure 1: Each heatmap of a language pair shows the corresponding normalized metric scores for every **(a) encoder self-attention** and **(b) encoder-decoder attention** head, broken out by layer (vertical axis) and head (horizontal axis). For each metric, the color scales are identical across language pairs.

heads, respectively. The heatmaps were computed for each language pair separately (FR-EN, KO-EN, etc.) or jointly for all pairs (ALL-EN).[4] The main finding is that even if each metric displayed a different heatmap, the important heads were the same for all language pairs according to these metrics. In other words, the metrics did not highlight the emergence of language pair specific (encoder or cross) attention heads. Comparing among the metrics, *variance* and *confidence* tended to emphasize the same heads (with the exception of the first self-attention heads of each layer which were systematically rated as important by the *variance* metric). On the other hand, *coverage* highlighted different heads compared to the other two metrics.

Impact of head selection on NMT performance In the previous paragraph, we explored several metrics that could help capturing the importance of an attention head. We now analyze if these metrics could be used to prune heads and the corresponding impact on MT performance. We also investigate a more direct (but more costly) approach to measure how heads contribute to MT performance.

Figure 2 shows the evolution of BLEU curves as more and more heads were pruned. Head pruning was based on the importance metrics (removing least important heads first according to the metrics presented in Sect. 3.1) or on the SBS algorithm (Sect. 3.2). Head selection was conducted separately for each language pair,[5] and the curves were drawn from fitting polynomial regressions. First, we observed that, for both encoder self-attentions and cross attentions, it was possible to remove around 30% of the less important heads without much decrease of BLEU. Next, we noted that for cross attention head pruning, *coverage* seemed to be a better alternative than *confidence* and *variance*, while for encoder self-attention pruning *confidence* remained the most efficient. Intuitively, *coverage* metric is complementary to *confidence* in case of cross attention as it measures whether the whole input has been attended to. On the other hand, self-attention heads seemed devoted to specific phenomena (Voita et al., 2019; Clark et al., 2019) and there was no need to attend to the whole sentence for this matter. Finally, we also display the BLEU curves for randomly ranking (`rand-ranking`) the attention heads, confirming that the metrics proposed can be used as a proxy to measure the importance of heads and prune the least important ones. However, the exhaustive (but costly) SBS algorithm logically led to the best results.

Is there really no emergence of language-specific heads? We verified how statistically significant the BLEU differences were between *language-specific* and *language-independent* heads selection processes according to various metrics with Mann–Whitney U tests (Mann and Whitney, 1947).[6] We found no significant difference between language-specific and language-independent head rankings, even if some differences emerged for results obtained by SBS ranking.

Finally, we looked at how the individual head rankings were varied according to the SBS algorithm. Figure 3 illustrates the standard deviation of each head position among the rankings of the five different language pairs. We observed that there were a few heads whose relative importance varied greatly among the language pairs. For example,

---

[4] We only display FR-EN and KO-EN, reader should refer to Appendix B for all language pairs.

[5] The language-independent selection of heads led to a very similar plot as Fig. 2 and is provided in Appendix E

[6] We report p-values for Mann–Whitney U tests in the Appendix D.

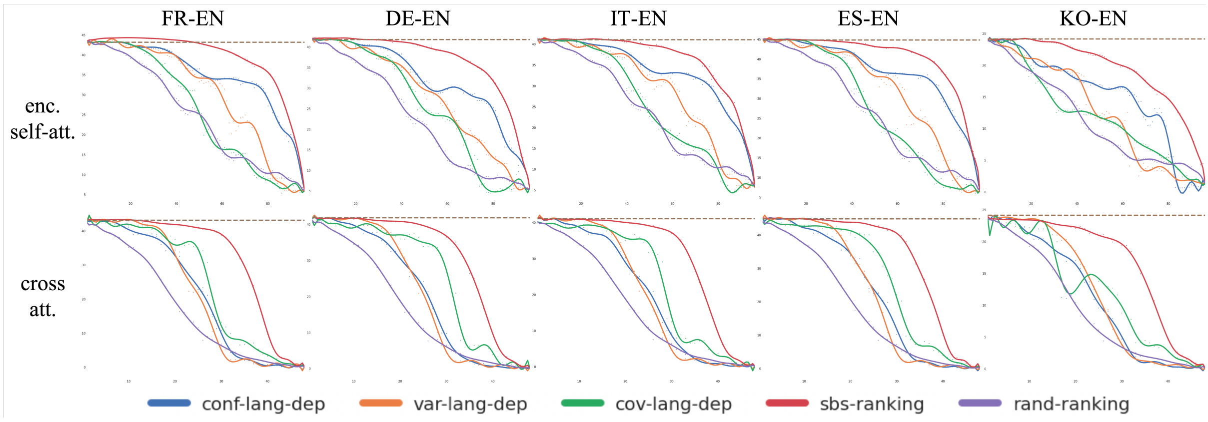


Figure 2: BLEU curves on test set when pruning subsequent **self-attention** and **cross attention** heads based on different importance metrics (or SBS) computed from dev set (language pair dependently). To be seen in color.

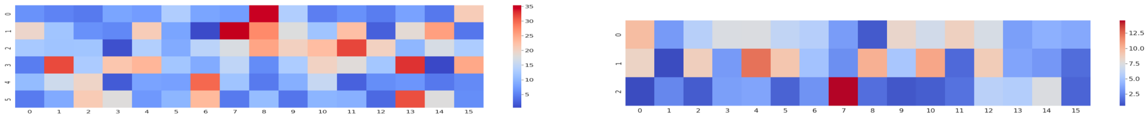

(a) encoder self-attention

(b) encoder-decoder attention

Figure 3: Standard deviation of each **(a) encoder self-attention** and **(b) encoder-decoder attention** head ranking with SBS algorithm. SBS rankings range from 1 to 96 for self attention and from 1 to 48 for cross attention and standard deviation is calculated for each head, using these scores, among the five language pairs.

the $\texttt{head}_{2,7}$ of the encoder-decoder attention was ranked as least important for KO-EN but quite important for the other four language pairs.[7] Similarly, $\texttt{head}_{1,7}$ for encoder self-attention was ranked as not important for ES-EN while very important for KO-EN. This analysis showed that, even though the majority of important heads seemed to be language-independent, certain heads may capture different linguistic phenomena.

5 Conclusion and Future Work

We investigated if there are attention heads that are language pair specific within a many-to-one multilingual NMT model. We examined different metrics for heads selection process and found that *confidence* is a good proxy for self-attention heads "prunability", and *coverage* is a better indicator for cross attention heads "prunability".

We showed that, although it is possible to find the rare heads specific to a language pair via the extensive SBS procedure, the most important heads are language-independent; and it is possible to prune around 30% of the heads with no retraining and almost no loss in BLEU.[8]

As the findings from the SBS procedure indicated that some language pair specific heads do exist, a promising future direction is to perform pruning at different level of granularity (Frankle and Carbin, 2019; Zhao et al., 2020) (as opposed to single scalar values computed by the metrics) in order to identify which part of the model is more language-specific. Such analysis could help us to deploy multilingual models with better efficiency / performance trade-offs.

Acknowledgments

This work was done as part of the Multidisciplinary Institute in Artificial Intelligence MIAI@Grenoble-Alpes (ANR-19-P3IA-0003). Authors would like to thank Jaesong Lee and Hyun Chang Cho from NAVER Corp., Kwang Hee Lee from KAIST for insightful comments on the experiments. We would also like to extend our gratitude to the anonymous reviewers for their valuable feedback.

---

[7] Masking this single head alone, resulted in an increase in BLEU for KO-EN by 0.03, while for others, a decrease in BLEU up to 0.5.

[8] It is possible that fine-tuning the model after pruning the heads may lead to better BLEU scores, and therefore more aggressive pruning (Behnke and Heafield, 2020; Wang et al., 2020a).

A Experimental Details

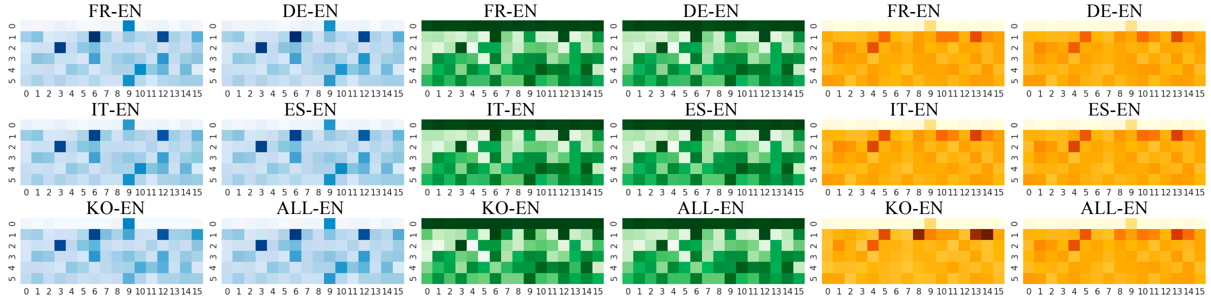
All the experiments were conducted using PyTorch (Paszke et al., 2019) and Fairseq (Ott et al., 2019) toolkit. The multilingual NMT model used in the experiments can be downloaded online.[9] Please refer to Bérard et al. (2020) for more details on the model.

When running an experiment for each language pair, a single V100 GPU was used. We note that computing the SBS rankings for encoder self-attention was the most computationally intensive part, where almost 96^2 translations of the development set were conducted.

When computing the BLEU curves for the `rand-ranking`, we ran the procedure with a randomly created ranking five times, and averaged the resulting BLEU scores.

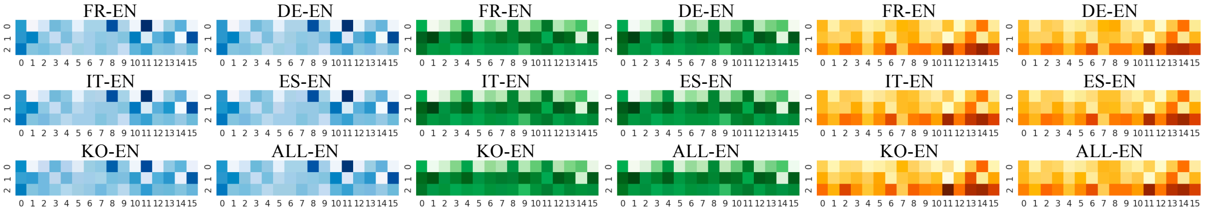
B Heatmaps of Metric Scores for All Language Pairs

Figure B illustrates the normalized metrics scores for every attention head. We observed that for each metric, the patterns are consistent across all language pairs.



(1) confidence (2) variance (3) coverage

(a) encoder self-attention



(1) confidence (2) variance (3) coverage

(b) encoder-decoder attention

Figure B: Each heatmap of a language pair shows the corresponding normalized metric scores for every **(a) encoder self-attention head** and **(b) encoder-decoder attention head**, broken out by layer (vertical axis) and head (horizontal axis). For each metric, the color scales are identical across language pairs.

C Remarks on the Importance Metrics

We denote $|L|$ and $|H|$ to be the number of layers and heads, respectively, while $|S|$ and $|T|$ represent the number of source and target tokens. When calculating each metric, we began with the tensor shape, $(|L|, |H|, |S|, |S|)$ or $(|L|, |H|, |T|, |S|)$, depending on whether we were computing for the encoder self-attention or the cross attention. After the computation, the shape of the outcome tensor was: $(|L|, |H|)$.

C.1 Confidence

We noted that the patterns of the confidence scores for each head tended to vary depending on the length of sentences we used to compute the scores. This was due to the fact that the metric was calculated by averaging over the maximum attention, which was inversely proportional to the length of sentences.

---

[9] `https://github.com/naver/covid19-nmt`

C.2 Variance

The variance metric was defined so that heads with a small variance were considered to be important. A small variance was achieved when most of the attention weights were focused on one or a few positions. While this intuition came initially from encoder-decoder attention (interpreting attention as a source-target alignment), it is less clear if it holds for encoder self-attention as well (our results seemed to suggest that it is not the case).

C.3 Coverage

While the notion of coverage was initially proposed for encoder-decoder attention, we extended it to the encoder self-attention. We may consider it as how much a source token has been attended from its neighbouring source tokens. Similar to the variance metric, for the encoder self-attention, the importance of high coverage is less clear where a head may play a specific role as discussed in Voita et al. (2019); Clark et al. (2019). This probably accounts for the reason that the head pruning of the encoder self-attention was not as effective as that of the cross attention.

D P-Values for Mann–Whitney U tests

As the BLEU curves obtained from language-specific pruning and language-independent pruning were very similar, we performed a non-parametric statistical test, namely, Mann-Whitney U test, to compare the outcomes. The test checks whether two samples are likely to derive from the same population (i.e. that the two populations have the same shape).

Table D shows the p-values for the two-sided tests between BLEU curves computed using language-specific and language-independent metrics for encoder self-attention and cross attention.

The high p-values (> 0.05) across all language pairs suggest that the differences in the BLEU scores computed from the two scenarios were statistically insignificant.

Abstract

We propose a model that learns both the sequential and the structural features of code for source code summarization. We adopt the abstract syntax tree (AST) and graph convolution to model the structural information and the Transformer to model the sequential information. We convert code snippets into ASTs and apply graph convolution to obtain structurally-encoded node representations. Then, the sequences of the graph-convolutioned AST nodes are processed by the Transformer layers. Since structurally-neighboring nodes will have similar representations in graph-convolutioned trees, the Transformer layers can effectively capture not only the sequential information but also the structural information such as sentences or blocks of source code. We show that our model outperforms the state-of-the-art for source code summarization by experiments and human evaluations.

1 Introduction

Descriptions of source code are very important documents for programmers. Good descriptions help programmers understand the meaning of code quickly and easily.

Source code has sequential information (code tokens) and structural information (dependency and structure). To understand the content of the code and generate a good summary, both pieces of information are essential to understand the summary. However, most previous works used only one kind of information. Iyer et al. (2016); Liang and Zhu (2018); Hu et al. (2018b); Allamanis et al. (2016) simply converted the source code into sequences of tokens and tried to extract the features of the source code from the sequential information of the source code. They rarely considered the structure information about the relationship between tokens. On the other hand, Shido et al. (2019); Harer et al. (2019); LeClair et al. (2020); Scarselli et al. (2008) proposed tree-based models to capture the features of the source code. They used the structural information from parse trees but hardly considered the sequence information of code tokens.

In order to accurately understand and represent the source code, it is necessary to encode the structural information as well as the sequential information. Recently, Ahmad et al. (2020) tried to represent both the sequential and the structural information using the Transformer model with relative encoding. Since relative encoding clipped the maximum distance for attention without considering the parse tree, it is limited to represent the structure of the code.

In this work, we propose a model that learns both the structural and sequential information of source code. We represent code snippets as abstract syntax trees (ASTs), and apply graph convolution (Kipf and Welling, 2017) to the ASTs to obtain the node representation reflecting the tree structure such as parents, children, and siblings. Nodes that are close to each other in a tree, such as parent and child nodes and sibling nodes, will have similar representations. Next, we convert the graph-convolutioned ASTs into sequences by the pre-order traversal and process them with Transformer layers (Vaswani et al., 2017). Since structurally-neighboring nodes have similar representations, such nodes will pay more attention to one another in the Transformer layers. Thus, the Transformer layers can easily capture not only the sequential information but also the structural information such as sentences or blocks of source code.

We also modify ASTs to better represent the structural information of the source code. We add sibling edges to represent neighboring blocks in source code and add a node representing the name of the function for Python. With the modification,

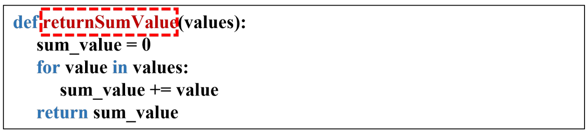
our model can better catch the blocks in the source code.

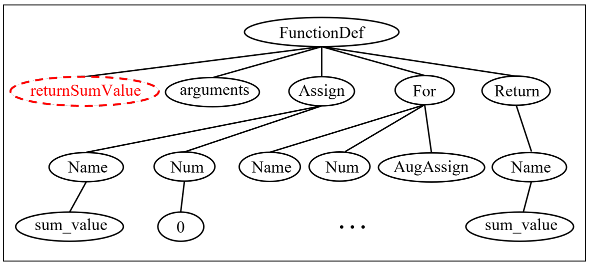
In the experiment, we show that our model outperforms the state-of-the-art for source code summarization. We use two well-known Java (Hu et al., 2018b) and Python (Wan et al., 2018) datasets collected from Github. We additionally perform human evaluations and analyze the attention maps between code tokens to see how well the model has captured the structural information of code. The result proves that it is very effective to model both structural and sequential information for source code summarization.

We describe the modified AST (mAST) in Section 2 and present the proposed approach in Section 3. In Section 4, we show the superiority of our approach with experimental results and human evaluations. We describe the related work in source code summarization and compare their approaches with our proposed approach in Section 5. Finally, we conclude the paper in Section 6.



```
def returnSumValue(values):
    sum_value = 0
    for value in values:
        sum_value += value
    return sum_value
```

(a) Source Code



(b) AST

Figure 2: An example of Python code and Abstract Syntax Tree. The Python AST parser we used does not create a node for the function name unlike the Java AST parser. Since the function name is a very important keyword in generating summaries, we add the function name in the red box (a) to *FunctionDef* node in the Python AST.

2 Representing Code as mAST

Figure 1 shows a code snippet and its AST in Java. The abstract syntax tree (AST) is a structure to represent the abstract syntactic structure of code in a programming language. Source code is separated into blocks and can be transformed into a tree structure. The leaf nodes of an AST represent code identifiers and names. The non-leaf nodes represent the grammar or the structure of the language. All non-leaf nodes in an AST have the structural information about which blocks they belong to (parent node) and which block they have (child nodes). So, we can easily catch the structure information of code from ASTs.

In order to more effectively represent structural information, we modify ASTs by adding edges between siblings. Statements or blocks at the same level in a code snippet are represented as sibling nodes. For example, *Expression* node (line 2 in the code), *Foreach* node (line 3) and *Return* node (line 7) are the statements or blocks at the same level, and they are represented as siblings in the AST. However, in ASTs, blocks at the same level (sibling nodes) are not directly connected as shown in Figure 1b. We can indirectly catch such information via parent nodes.

Neighboring blocks are very important for the sequential and structural understanding of source code. To directly represent neighboring blocks, we

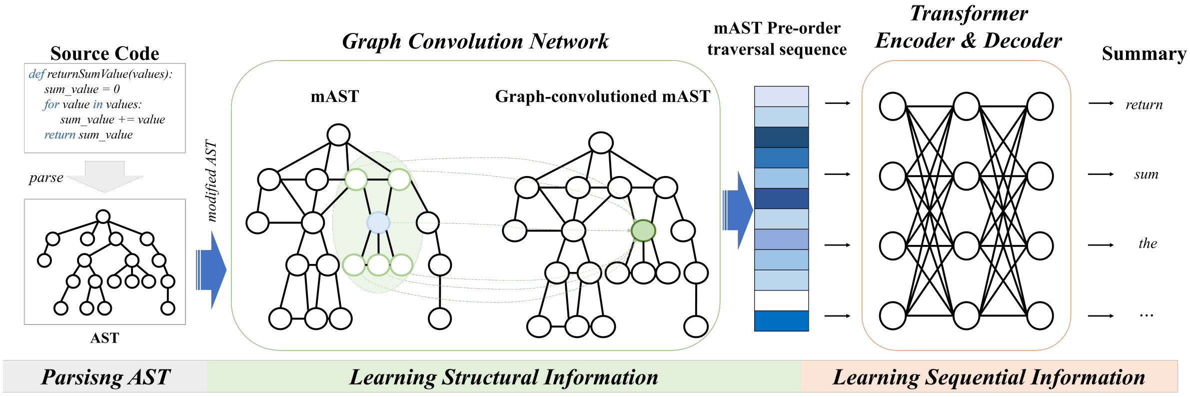


Figure 3: Overview of our proposed model.

add sibling edges to ASTs as shown in Figure 1c (red dotted lines).

In the case of Python, the Python AST parser we used does not create a node for the function name, unlike the Java AST parser. As the function name is a very important keyword in generating summaries, we add the function name to *FunctionDef* node as a child in the Python AST as shown in Figure 2. Then, we modify Python ASTs by adding sibling edges.

3 Proposed Model

We propose a model using graph convolution layers and transformer layers to summarize the source code. To encode both the structural and the sequential information of code, we combine both of the above layers.

Figure 3 shows the overview of our model. A given snippet is represented as a modified AST (mAST). The initial representation of nodes in the mAST is generated by the embedding layer. Since the embedding layer generates the representation considering only nodes themselves, we use graph convolution to capture the structural information. We apply graph convolution to each node in mAST. Then, we can have node representations considering the structural features as well as the node features.

The graph-convolutioned mASTs are converted into sequences by pre-order traversal, and the sequences are given to the Transformer encoder. Since structurally-neighboring nodes have similar representations, the Transformer encoder can effectively capture not only the sequential features but also the structural features such as sentences or blocks of source code. After the Transformer encoder generates the representations by reflecting the sequential and structural information, the Transformer decoder generates summaries.

3.1 Graph Convolution Network

Graph convolutional network (Kipf and Welling, 2017) is one of graph neural networks for representing nodes based on neighborhood features of each node in graph data. In this paper, graph convolution layers are used to capture the structure information of mASTs. Since the mAST extracted from a given code C is a graph, we denote an AST as $G(C) = \{V, E\}$, where V is a set of nodes and E is a set of edges. Initially, nodes in V are one-hot encoded tokens and then mapped into representation vectors, X, by the embedding layer.

Given representation X of nodes and E of edges, new representations of nodes are calculated by graph convolution layers as follows.

$$H^0 = X, X \in \mathbb{R}^{n \times d}$$

$$H^{(l+1)} = \sigma(AH^{(l)}W^{(l)}), W^l \in \mathbb{R}^{d \times d}$$

where A is the adjacency matrix, W^l is the graph convolution weight matrix in the l-th layer, σ is the activation function, n is the total number of nodes in an mAST, and d is the embedding dimension. The feature of each node represented by the graph convolution layer is denoted as H. In the experiment, the dimension of the weight matrix in a graph convolution is d=512.

3.2 Transformer Encoder-Decoder

After graph convolution layers, the mAST is converted into a sequence by pre-order traversal. The pre-order traversal is applied to the original AST, not the mAST, because mASTs are transformed

Dataset	**Java**	**Python**

Unique tokens in summaries	46,895	56,189
Avg. nodes in AST	131.72	104.11
Avg. tokens in summary	17.73	9.48

Table 1: Statistics of Java and Python dataset

into graphs by adding sibling edges. The mAST is used to obtain the structural representation of nodes by considering nodes and their neighbors. Since the original AST contains the original structure of the source code, we use it to obtain a sequence.

The Transformer encoder and decoder follow the graph convolution layers. The sequence of the mAST nodes is processed into the Transformer encoder. The Transformer architecture is good at capturing long-term dependencies in a sequence. Since we used graph convolutions, which generate similar representations for structurally-neighboring nodes, the Transformer encoder can easily capture dependencies between nodes in the same code block, between similar code blocks, and between code blocks at the same level. As a result, the Transformer encoder can generate new representation vectors which well reflect sequential and the structural information.

Next, the Transformer decoder generates the token of summary from the vectors generated by the Transformer encoder. In the experiment, the dimension of nodes and summary tokens is d_{model}=512. The Transformer encoder and decoder are respectively composed of a stack of N = 6 layers.

4 Experiment

We perform various experiments to show the superiority of our model for source code summarization.

4.1 Setup

Datasets We evaluate our model using Java dataset (Hu et al., 2018b) and Python dataset (Wan et al., 2018). The statistics of the experiment datasets are shown in Table 1. We used the Java parser used by Alon et al. (2019) and the Python parser used by Wan et al. (2018) for extracting the abstract syntax tree of the code.

Metrics We adopt 3 performance metrics: BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and ROUGE-L (Lin, 2004).

Baselines We compare our model with baseline models based on sequential information by Iyer et al. (2016); Hu et al. (2018a,b); Wei et al. (2019); Ahmad et al. (2020) and based on structural information by Eriguchi et al. (2016); Wan et al. (2018). We refer to the baseline results reported by Ahmad et al. (2020).

Hyper-parameters We set the maximum length to 200, and the vocabulary sizes for code and summary to 50,000 and 30,000, respectively. We train our proposed model using Adam optimizer (Kingma and Ba, 2015). The mini-batch size and dropout rate are 32 and 0.2. We set the maximum training epoch to 200, and use early stopping. We adopt beam search during inference time and set the beam size to 4.

4.2 Quantitative Result

Overall Result Table 2 shows the overall performance of the models. We present three proposed models: *AST-Only*, *AST+GCN* and *mAST+GCN*.

AST-Only is the proposed model without graph convolution layers. The model converts code snippets into ASTs and does not include graph convolutions. The sequenced AST nodes are given to the Transformer encoder and decoder. We present this model to verify how much ASTs are effective for source code summarization. It performs better than the baselines except for TransRel model proposed by Ahmad et al. (2020). This result shows that AST, which has more structural information on source code, is better than simple code for source code summarization.

AST+GCN is the proposed model with graph convolution layers but without AST modification (adding sibling edges). Code snippets are converted into ASTs and node representations are generated by graph convolutions. The sequenced graph-convolutioned AST nodes are input to the Transformer encoder and decoders. This model can verify how much the graph convolutions are useful. It shows better performance than the baselines.

mAST+GCN is the proposed model with modified ASTs by adding sibling edges and with graph convolution layers. It outperforms all baseline models. The performance improves by 0.91 and 0.3 BLEU, 0.74 and 0.35 METEOR, and 0.06 and 0.08

Table 2: Comparison of our proposed model with the baseline models.

ROUGE-L points in comparison to TranRel for Java and Python datasets, respectively. The proposed model with the AST modification has better performances on BLEU, METEOR, and ROUGE-L (excepts for METEOR in Java) than without the modification. This proves that modified ASTs help models learn more structural information of code than general ASTs.

Position of graph convolution layers We perform additional experiments with different positions of graph convolution layers. The positions are the front of the Transformer encoder, the back of the Transformer encoder, and both the front and back of the Transformer encoder.

Table 3 shows the performance scores according to the position of the graph convolution layers. The *front* model is the same as *mAST+GCN* which has one graph convolution layer in front of the encoder.

The *back* model does not have graph convolution layers in front of the Transformer encoder but has one next to the encoder. Nodes in an mAST are input to the encoder without graph convolutions, but graph convolutions are applied to the output of the encoder. Since the Transformer encoder can catch structural patterns in simple sequences, the graph convolution in the back of the encoder may work better than the one in front because it can feed more sharp structural information to the decoder.

The *front+back* model has two graph convolution layers: one in front and the other in the back of the Transformer encoder. It may catch much stronger structural patterns. The structurally encoded representations by a graph convolution layer are fed to the encoder and the output of the encoder is structurally enhanced once more by a graph convolution layer.

Table 3 shows the best result when located in front of the Transformer encoder. The *front+back* model is next to the *front*, and the *back* is the worst, which means that the graph convolution before the encoder is effective.

Since the Transformer has the ability to extract comprehensive features considering not only sequential but also structural information in sequences, the convolution layer in the back of the encoder may destruct such features and degrade the performance. However, the graph convolution layer in front of the encoder can help the encoder analyze structural patterns and to extract better features because it enhances structural information.

Position	BLEU	METOR	ROUGE-L

Figure 4: Attention maps of mAST+GCN, AST+GCN, and the baseline models for a code in Figure 5. (a), (b) and (c) are the attention maps of the first Transformer encoder layer and (d), (e), and (f) are the attention maps of the last Transformer encoder layer. A red box in (a) represents blocks in the snippets. We can see that the structural features are clearly captured in the red box. Our model effectively captures large and hierarchical structural features.

```
private int currentDepth(){
  try {
    Integer oneBased=((Integer)DEPTH_FIELD.get(this));
    return oneBased - 1;
  }
  catch ( IllegalAccessException e) {
    throw new AssertionError(e);
  }
}
```

Figure 5: An example of Java code. We draw attention maps for this in Figure 4.

Number of graph convolution layers We analyze the performance according to the number of graph convolution layers. Graph convolutions are effective at capturing structural features, so more layers can help improve the performance. We tried one to three layers in front of the encoder.

Table 4 is the result of each model with 1, 2 and 3 layers. The results show that our proposed model with one graph convolution layer in front of the Transformer encoder has better performance than others. We think that this is because the graph structure of AST is not as complex as the general graph structure. So, the node representation has the over-smoothing problem when the graph convolution layer is stacked deep.

4.3 Qualitative Result

We present the qualitative analysis of our model. The attention map of an example code is compared to show how much our model catches the structural information. In order to further validate the performance metrics of our model, we perform a human evaluation on randomly sampled code snippets.

Attention Map Comparison We analyze attention maps of *mAST+GCN*, *AST+GCN* and the baseline by Ahmad et al. (2020) to verify how our model generates node representations compared to the others. Since we try to emphasize the structural information, we need to verify how much our model reflects the structural information to generate representations.

We observe the attention maps for the sample code in Figure 5. We draw an attention map by evaluating the pairwise dot product of the output of a Transformer layer in the encoder. For *mAST+GCN* and *AST+GCN*, the output of a layer is the sequence of the mAST nodes, and for the baseline, it is the sequence of the program tokens.

We compare the attention maps of the first and the last Transformer layer in the encoder of each model. Figure 4a, 4b and 4c are the attention maps of the first layer of *mAST+GCN*, *AST+GCN* and the baseline. Figure 4d, 4e and 4f are the attention maps of the last layer of *mAST+GCN*, *AST+GCN* and the baseline.

Rectangles on the diagonal as shown in a red box in Figure 4a represent blocks in the snippets. Since nodes or tokens in a block may have high similarities, we can see rectangles along with the diagonal. In the attention maps of the first layers, the rectangles are faint because the structural information has not been processed much yet, but we can see many distinct rectangles which means that the structural features are clearly captured.

If we compare the attention maps by our models and the baseline, there are many small rectangles in the baseline. On the contrary, in our models, we can see a few large rectangles in which there are small rectangles. We see a hierarchical structure in the attention maps of our model.

The fact that the baseline produces many small rectangles implies that the baseline can capture only small structural features. We can also note that these small structural features are smaller than statements, considering that the example snippets have only 4 lines. The baseline hardly captures large structural features.

On the other hand, our model effectively captures large and hierarchical structural features. We can easily identify rectangles that match with statements or blocks in the attention maps by our proposed models.

The attention maps from *mAST+GCN* and *AST+GCN* are very similar. However, we can see differences in each attention map of the first and the last layer. If we compare the first layer attention maps, the blocks of *mAST+GCN* are more distinct, which implies that the modification of ASTs by adding sibling edges is helpful to model structural information. If we compare the last layer attention maps, we can see that hierarchical structures of rectangles are clear in the map by *mAST+GCN*, which also says that the modification is effective to capture structural features.

Human Evaluation We performed human evaluation (Kryscinski et al., 2019) on the Java dataset to prove the effectiveness of how good summaries our model generates. We randomly choose 100 snippets and ask 4 people with knowledge of the Java language to evaluate the summaries. They are CS graduate students and have many years of experience in Java languages. We ask them to evaluate the 3 following aspects:

- Fluency (quality of the summary)
- Relevance (selection of the important content from source code)
- Coverage (selection of the whole content of source code)

	Fluency	**Relevance**	**Coverage**
Wins	**146**	**145**	**144**
Losses	130	135	140
Ties	124	120	116

Table 5: Human evaluation of the appropriateness of the generated summaries on the Java dataset. We ask annotators to select a more appropriate summary from two candidates generated by different models. Our proposed model outperforms the baseline.

We show pairs of summaries from our model and the baseline (Ahmad et al., 2020) to the annotators, and ask them to select one of win, tie, and loss in the three aspects, respectively. Our model shows superiority in all aspects as shown in Table 5. The scores of fluency and relevance are higher than the baseline, which means that our model generates more appropriate summaries using more natural expressions.

Figure 6 shows some examples of summaries for the qualitative comparison. We choose 6 Java snippet examples. We choose them from the snippets on which all the annotators make the same decision in each aspect. The three snippets on the left are the ones that the annotators choose win (our model is better) and the right ones for loss.

5 Related Work

As techniques and methods of deep learning have developed, researches for source code summarization have been studied based on sequence-to-sequence models. Iyer et al. (2016) proposed a model that performed source code summarization task for the first time. Allamanis et al. (2016) summarized the source code using a convolutional attention network model. Hu et al. (2018a) proposed an RNN-based sequence-to-sequence model using the pre-order traversal sequence of the abstract syntax tree. Also, Hu et al. (2018b) summarized source code with the knowledge on imported APIs using two encoders (source code encoder and API encoder). Ahmad et al. (2020) proposed a Transformer model with a relative position for summarizing source code. Wei et al. (2019) proposed a dual model that learned the code and summary sequence simultaneously. Wan et al. (2018) adopted

```

Figure 6: Examples for the qualitative comparison. The left examples are chosen from the ones that have 4 wins (all the annotators agree that our model is better), and the right examples are chosen from the opposite cases.

reinforcement learning to summarize source code. These approaches mainly focused on the sequential and context information of code, but little considered the structural information about the relationship between code tokens.

There are also studies that convert source code to AST to represent the structure of source code. Liang and Zhu (2018) proposed a tree-based recursive neural network to represent the syntax tree of code. Shido et al. (2019) represented source code using the tree structure encoder of tree-LSTM. Harer et al. (2019) adopted tree-transformer to encode the structure of ASTs. Fernandes et al. (2019) proposed the structured neural model for source code summarization. Alon et al. (2019) represented source code based on AST paths between pairs of tokens. LeClair et al. (2020) proposed a model that encoded the AST of source code using graph neural networks. These approaches utilized ASTs to capture structural features, but less considered the sequence characteristics of code in a program language.

6 Conclusion

We proposed a model that learned both the sequential and the structural features of code for source code summarization. We adopted the abstract syntax tree (AST) and graph convolution to model the structural information and the Transformer to model the sequential information. We also modified the AST to deliver more structural information.

We verified that modified ASTs and graph convolutions were very effective to capture the structural features of code through quantitative and qualitative analysis. We also showed the superiority of our model over the state-of-the-art for source code summarization by experiments and human evaluations.

Abstract

Unknown intent detection aims to identify the out-of-distribution (OOD) utterance whose intent has never appeared in the training set. In this paper, we propose using energy scores for this task as the energy score is theoretically aligned with the density of the input and can be derived from any classifier. However, high-quality OOD utterances are required during the training stage in order to shape the energy gap between OOD and in-distribution (IND), and these utterances are difficult to collect in practice. To tackle this problem, we propose a data manipulation framework to **G**enerate high-quality **O**OD utterances with importance weigh**T**s (**GOT**). Experimental results show that the energy-based detector fine-tuned by GOT can achieve state-of-the-art results on two benchmark datasets.

1 Introduction

Unknown intent detection is a realistic and challenging task for dialogue systems. Detecting out-of-distribution (OOD) utterances is critical when employing dialogue systems in an open environment. It can help dialogue systems gain a better understanding of what they do not know, which prevents them from yielding unrelated responses and improves user experience.

A simple approach for this task relies on the softmax confidence score and achieves promising results (Hendrycks and Gimpel, 2017). The softmax-based detector will classify the input as OOD if its softmax confidence score is smaller than the threshold. Nevertheless, further works demonstrate that using the softmax confidence score might be problematic as the score for OOD inputs can be arbitrarily high (Louizos and Welling, 2017; Lee et al., 2018).

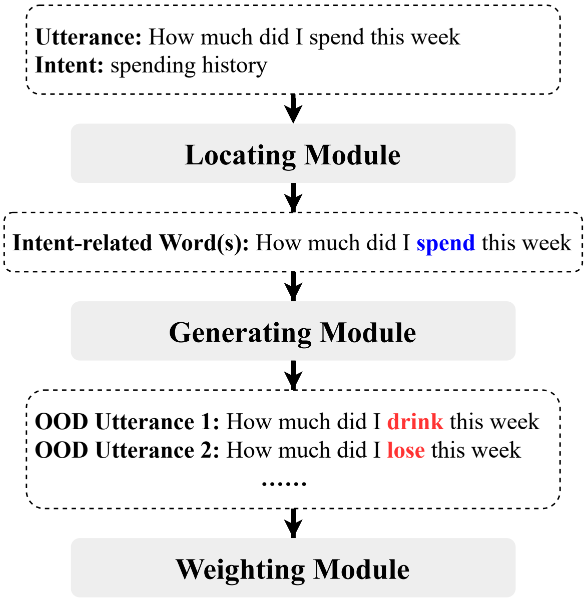

Figure 1: An overview of our framework GOT. For the utterance "How much did I spend this week" from CLINC150 dataset (Larson et al., 2019). Our locating module locates the intent-related word "spend". And then our generating module generates words "drink", "lose" to replace it and obtains OOD utterances. Finally, our weighting module assigns a weight for each of OOD utterances.

Another appealing approach is to use generative models to approximate the distribution of in-distribution (IND) training data and use the likelihood score to detect OOD inputs. However, Ren et al. (2019) and Gangal et al. (2019) find that likelihood scores derived from such models are problematic for this task as they can be confounded by background components in the inputs.

In this paper, we propose using *energy scores* (Liu et al., 2020) for unknown intent detection. The benefit is that energy scores are theoretically well aligned with the density of the inputs, hence more suitable for OOD detection. Inputs with higher energy scores mean lower densities, which can be

classified as OOD by the energy-based detector. Moreover, energy scores can be derived from any pre-trained classifier without re-training. Nevertheless, the energy gap between IND and OOD utterances might not always be optimal for differentiation. Thus we need auxiliary OOD utterances to explicitly shape the energy gap between IND and OOD utterances during the training stage (Liu et al., 2020). This poses a new challenge in that the variety of possible OOD utterances is almost infinite. It is impossible to sample all of them to create the gap. Zheng et al. (2019) demonstrate that OOD utterances akin to IND utterances, such as sharing the same phrases or patterns, are more effective, whereas these high-quality OOD utterances are difficult and expensive to collect in practice.

To tackle this problem, we propose a data manipulation framework **GOT** to generate high-quality OOD utterances as well as importance weights. GOT generates OOD utterances by perturbing IND utterances locally, which allows the generated utterances to be closer to IND. Specifically, GOT contains three modules: (1) a locating module to locate intent-related words in IND utterances; (2) a generating module to generate OOD utterances by replacing intent-related words with desirable candidate words, evaluated in two aspects: whether the candidate word is suitable given the context, and whether the candidate word is irrelevant to IND; (3) a weighting module to reduce the weights of potential harmful generated utterances. Figure 1 illustrates the overall process of GOT. Experiments show that the generated weighted OOD utterances can further improve the performance of the energy-based detector in unknown intent detection. Our code and data will be available at: `https://github.com/yawenouyang/GOT`.

To summarize, the key contributions of the paper are as follows:

- We propose using energy scores for unknown intent detection. We conduct experiments on real-world datasets including CLINC150 and SNIPS to show that the energy score can achieve comparable performance as strong baselines.
- We put forward a new framework GOT to generate high-quality OOD utterances and reweight them. We demonstrate that GOT can further improve the performance of the energy score by explicitly shaping the energy gap and achieves state-of-the-art results.
- We show the generality of GOT by applying generated weighted OOD utterances to fine-tune the softmax-based detector, and the fine-tuned softmax-based detector can also yield significant improvements.

2 Related Work

Lane et al., 2006, Manevitz and Yousef, 2007 and Dai et al., 2007 address OOD detection for the text-mining task. Recently, this problem has attracted growing attention from researchers (Tur et al., 2014; Fei and Liu, 2016; Fei et al., 2016; Ryu et al., 2017; Shu et al., 2017). Hendrycks and Gimpel (2017) present a simple baseline that utilizes the softmax confidence score to detect OOD inputs. Shu et al. (2017) create a binary classifier and calculate the confidence threshold for each class. Some distance-based methods (Oh et al., 2018; Lin and Xu, 2019; Yan et al., 2020) are also used to detect unknown intents as OOD utterances highly deviate from IND utterances in their local neighborhood. Simultaneously, with the advancement of deep generative models, learning such a model to approximate the distribution of training data is possible. However, Ren et al. (2019) find that likelihood scores derived from these models can be confounded by background components, and propose a likelihood ratio method to alleviate this issue. Gangal et al. (2019) reformulate and apply this method to unknown intent detection.

Different from these methods, we introduce the energy score for this task. Liu et al. (2020) prove that the energy score is theoretically aligned with the density of the input, and can be derived from any classifier without re-training, hence desirable for our task. We further propose a data manipulation framework to generate high-quality OOD utterances to shape the energy gap between IND and OOD utterances.

Note that there are some related works that also generate OOD samples to improve OOD detection performance. Lee et al. (2017) generate OOD samples with Generative Adversarial Network (GAN) (Goodfellow et al., 2014), and Zheng et al. (2019) explore this method for unknown intent detection. However, there are two major distinctions between our study and these works. First, they generate OOD utterances according to continuous latent variables, which cannot be easily interpreted. In contrast, our framework generates utterances by performing local replacements to IND utterances, which is more interpretable to human. Second, our framework additionally contains a weighting module to reform the generated utterances. Our work is also inspired by Cai et al. (2020), which proposes a framework to augment the IND data, while our framework aims to generate OOD data.

3 Preliminary

In this section, we formalize unknown intent detection task. Then we introduce the energy score, and its superiority and limitations for this task.

3.1 Problem Formulation

Given a training dataset $\mathcal{D}_{\text{in}}^{\text{train}} = \{(\mathbf{u}^{(i)}, y^{(i)})\}_{i=1}^{N}$ where $\mathbf{u}^{(i)}$ is an utterance and $y^{(i)} \in Y_{\text{in}} = \{y_1, y_2, ..., y_K\}$ is its intent label. In testing, given an utterance, unknown intent detection aims to detect whether its intent belongs to existing intents Y_{in}. In general, unknown intent detection is an OOD detection task. The essence of all methods is to learn a score function that maps each utterance $\mathbf{u}$ to a single scalar that is distinguishable between IND and OOD utterances.

3.2 Energy-based OOD Detection

An energy-based model (LeCun et al., 2006) builds an energy function $E(\mathbf{u})$ that maps an input $\mathbf{u}$ to a scalar called energy score (i.e., $E : \mathbb{R}^D \to \mathbb{R}$). Using the energy function, probability density $p(\mathbf{u})$ can be expressed as:

$$p(\mathbf{u}) = \frac{\exp(-E(\mathbf{u})/T)}{Z}, \qquad (1)$$

where $Z = \int_{\mathbf{u}} \exp(-E(\mathbf{u})/T)$ is the normalizing constant also known as the partition function and T is the temperature parameter. Take the logarithm of both side of (1), we can get the equation:

$$\log p(\mathbf{u}) = -E(\mathbf{u})/T - \log Z. \qquad (2)$$

Since Z is constant for all input $\mathbf{u}$, we can ignore the last term $\log Z$ and find that the energy function $-E(\mathbf{u})$ is in fact linearly aligned with the log likelihood function, which is desirable for OOD detection (Liu et al., 2020).

The energy-based model has a connection with a softmax-based classifier. For a classification problem with K classes, a parametric function f maps each input $\mathbf{u}$ to K real-valued numbers (i.e., $f : \mathbb{R}^D \to \mathbb{R}^K$), known as logits. Logits are used to parameterize a categorical distribution using a softmax function:

$$p(y|\mathbf{u}) = \frac{\exp[f_y(\mathbf{u})/T]}{\sum_{y'} \exp[f_{y'}(\mathbf{u})/T]}, \qquad (3)$$

where $f_y(\mathbf{u})$ indicates the y^{th} index of $f(\mathbf{u})$, i.e., the logit corresponding the y^{th} class label. And these logits can be reused to define an energy function without changing function f (Liu et al., 2020; Grathwohl et al., 2020):

$$E(\mathbf{u}) = -T \cdot \log \sum_{y'} \exp\left[f_{y'}(\mathbf{u})/T\right]. \qquad (4)$$

According to the above, a classifier can be reinterpreted as an energy-based model. It also means the energy score can be derived from any classifier.

Due to its consistency with density and accessibility, we introduce the energy score for unknown intent detection, and utterances with higher energy scores can be viewed as OOD. Mathematically, the energy-based detector G can be described as:

$$G(\mathbf{u}; \delta, E) = \begin{cases} \text{IND} & E(\mathbf{u}) \leq \delta, \\ \text{OOD} & E(\mathbf{u}) > \delta, \end{cases} \qquad (5)$$

where δ is the threshold.

Although the energy score can be easily computed from the classifier, the energy gap between IND and OOD samples might not always be optimal for differentiation. To solve this problem, Liu et al. (2020) propose an energy-bounded learning objective to further widen the energy gap. Specifically, the training objective of the classifier combines the standard cross-entropy loss with a regularization loss:

$$\mathcal{L} = \mathbb{E}_{(\mathbf{u},y)\sim\mathcal{D}_{\text{in}}^{\text{train}}}[-\log F_y(\mathbf{u})] + \lambda \cdot \mathcal{L}_{\text{energy}}, \qquad (6)$$

where $F(\mathbf{u})$ is the softmax output, λ is the auxiliary loss weight. The regularization loss is defined in terms of energy:

$$\begin{aligned}\mathcal{L}_{\text{energy}} &= \mathbb{E}_{(\mathbf{u},y)\sim\mathcal{D}_{\text{in}}^{\text{train}}}(\max(0, E(\mathbf{u}) - m_{\text{in}}))^2 \\ &+ \mathbb{E}_{\hat{\mathbf{u}}\sim\mathcal{D}_{\text{out}}^{\text{train}}}(\max(0, m_{\text{out}} - E(\hat{\mathbf{u}})))^2, \qquad (7)\end{aligned}$$

which utilizes both labeled IND data $\mathcal{D}_{\text{in}}^{\text{train}}$ and auxiliary unlabeled OOD data $\mathcal{D}_{\text{out}}^{\text{train}}$. This term differentiates the energy scores between IND and OOD samples by using two squared hinge loss with the margin hyper-parameters m_{in} and m_{out}.

Ideally, one has to sample all types of OOD utterances to create the gap, which is impossible in practice. Zheng et al. (2019) demonstrate that OOD utterances akin to IND utterances could be more effective, but more difficult to collect. To address this problem, we propose a data manipulation framework, which can generate these high-quality OOD utterances and assign each generated utterance an importance weight to reduce the impact of potential bad generation.

4 Approach

In this section, we will introduce our data manipulation framework GOT in detail. GOT aims to generate high-quality OOD utterances by replacing intent-related words in IND utterances, and then assign a weight to each generated OOD utterance. Eventually, the weighted OOD utterances can be used to shape the energy gap.

4.1 Locating Module

Since not all words in utterances are meaningful, such as stop words, when generating OOD utterances, replacing these words may not change the intent. It is more efficient and effective to replace those intent-related words. Hence, we design an intent-related score function S to measure how a word w related to an intent y:

$$S(w,y) = \sum_{\mathbf{u}\in\mathcal{D}_y^{\text{train}}} \sum_{w_j\in\mathbf{u}} \mathbb{I}(w_j = w)[\log p(w_j|\boldsymbol{w}_{<j}, y) - \log p(w_j|\boldsymbol{w}_{<j})], \quad (8)$$

where $\mathcal{D}_y^{\text{train}}$ is the subset of $\mathcal{D}_{\text{in}}^{\text{train}}$, which contains utterances with intent y, $\mathbb{I}$ is the indicator function, w_j is the j^{th} word in $\mathbf{u}$, and $\boldsymbol{w}_{<j} = w_1, ..., w_{j-1}$.

Given w and y, the intent-related score function is the sum of the log-likelihood ratios for all w in $\mathcal{D}_y^{\text{train}}$. If w is related to y, w tends to occur more frequently in $\mathcal{D}_y^{\text{train}}$ than other words. For each occurrence of w, i.e., w_j equals w, $p(w|\boldsymbol{w}_{<j}, y)$ should be higher than $p(w|\boldsymbol{w}_{<j})$ as the former is additionally conditioned on the related y, while the latter is not, hence resulting in a higher $S(w,y)$. In contrast, if w is not related to y, $p(w|\boldsymbol{w}_{<j}, y)$ is much less likely to be higher than $p(w|\boldsymbol{w}_{<j})$, or w tends to have a lower frequency in $\mathcal{D}_y^{\text{train}}$, hence $S(w,y)$ is likely to be small. Therefore, $S(w,y)$ can serve as a valid score function to measure how a word w is related to an intent y.

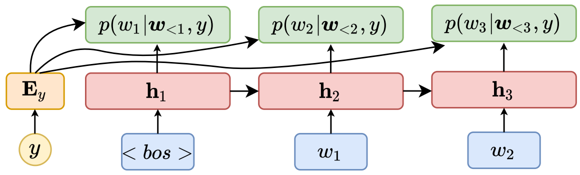

Figure 2: A class-conditional language model to estimate $p(w_j|\boldsymbol{w}_{<j}, y)$.

With the help of S, given an utterance to be replaced and its intent label, the locating module calculates the intent-related score for each word in this utterance, and a word with a higher score (i.e., larger than a given threshold) can be viewed as an intent-related word.

Implementation: We use two generative models to estimate $p(w_j|\boldsymbol{w}_{<j}, y)$ and $p(w_j|\boldsymbol{w}_{<j})$ separately. Specifically, we train a class-conditional language model (Yogatama et al., 2017) with $\mathcal{D}_{\text{in}}^{\text{train}}$ to estimate $p(w_j|\boldsymbol{w}_{<j}, y)$, shown in Figure 2. To predict the word w_j, we can combine the hidden state h_j with the intent embedding from a learnable label embedding matrix E_y, then pass it through a fully connected (FC) layer and a softmax layer to estimate the word distribution. In the training process, the input is the utterance with its intent from $\mathcal{D}_{\text{in}}^{\text{train}}$, and the training objective is to maximize the conditional likelihood of utterances. To estimate $p(w_j|\boldsymbol{w}_{<j})$, we directly use pre-trained GPT-2 (Radford et al., 2019) without tuning. Note that the whole training process only needs $\mathcal{D}_{\text{in}}^{\text{train}}$, and does not need auxiliary supervised data.

4.2 Generating Module

After detecting intent-related words in the utterance $\mathbf{u}$, for each of the intent-related words w_t, the generating module aims to generate the replacement words from the vocabulary set to replace w_t and obtain OOD utterances. We design a candidate score function Q to measure the desirability of the candidate word c:

$$Q(c; \mathbf{u}, w_t) = \log p(c|\boldsymbol{w}_{<t}, \boldsymbol{w}_{>t}) - \log \sum_{y\in Y_{\text{in}}} p(c|\boldsymbol{w}_{<t}, y)p(y). \quad (9)$$

The first term of the right hand side is the log-likelihood of c conditioned on the context of w_t; the higher it is, the more suitable c is given the context. The second term of the right hand side is the negative log of the average likelihoods of c conditioned on the IND label and previous context;

the higher it is, the less relevant c is to IND utterances. Therefore, if c has a higher candidate score, that means it fits the context well and has a low density under the IND utterance distribution, thus can be selected as the replacement word to replace w_t. The resulting generated OOD utterance is:

$$\hat{\mathbf{u}} = \{\boldsymbol{w}_{<t}, c, \boldsymbol{w}_{>t}\}. \tag{10}$$

Implementation: Similar with the locating module, we also do not need auxiliary supervised data to train the generating module. We use the same class-conditional language model mentioned in Section 4.1 to estimate $p(c|\boldsymbol{w}_{<t}, y)$. $p(y)$ is the training set label ratios. To estimate $p(c|\boldsymbol{w}_{<t}, \boldsymbol{w}_{>t})$, we use pre-trained BERT (Devlin et al., 2018) without tuning.

4.3 Weighting Module

Since we cannot ensure the generation process is perfect, given a generated OOD utterance set $\mathcal{D}_{\text{out}}^{\text{gen}} = \{\hat{\mathbf{u}}^{(i)}\}_{i=1}^{M}$, there might be some unfavorable utterances that are useless or even harmful for tuning the classifier. To fit these utterances, the generalization ability of the classifier will decrease. The weighting module aims to assign these utterances small weights.

We first use Equation 6 as the loss function to train a classifier by taking $\mathcal{D}_{\text{out}}^{\text{gen}}$ as $\mathcal{D}_{\text{out}}^{\text{train}}$. Then we calculate the influence value $\phi \in \mathbb{R}$ (Wang et al., 2020) for each generated utterance $\hat{\mathbf{u}}$. The influence value approximates the influence of removing this utterance on the loss at validation samples. An utterance with positive ϕ implies that its removal will reduce the validation loss and strengthen the classifier's generalization ability, thus we should assign it a small weight.[*] In particular, given ϕ, we calculate weight α as follows:

$$\alpha = \frac{1}{1 + e^{\frac{\gamma\phi}{\max_\phi - \min_\phi}}}, \tag{11}$$

where $\gamma \in \mathbb{R}^{+}$ is used to make the weight distribution flat or steep, $\max_\phi$ and $\min_\phi$ are the maximum and minimum influence value of utterances in $\mathcal{D}_{\text{out}}^{\text{gen}}$.

Implementation: We still do not need auxiliary supervised data for this module. The validation loss is the cross-entropy loss on the validation set.

Algorithm 1 Data Manipulation Process

```
Input: Training set $\mathcal{D}_{\text{in}}^{\text{train}}$, intent-related score function $S$,
    candidate score function $Q$, intent-related word threshold
    $\epsilon$, candidate number K, weight term $\gamma$
Output: Generated weighted OOD utterances set $\mathcal{D}_{\text{out}}^{\text{gw}}$
 1: $\mathcal{D}_{\text{out}}^{\text{gen}} = \{\}$ # generated OOD utterances without weights
 2: for $(\mathbf{u}, y) \in \mathcal{D}_{\text{in}}^{\text{train}}$ do
 3:     for $w_j \in \mathbf{u}$ do
 4:         if $S(w_j, y) > \epsilon$ then
 5:             $\mathcal{C} = \mathrm{top{-}K_c\, Q(c; \mathbf{u}, w_j)}$
 6:             for $c \in \mathcal{C}$ do
 7:                 $\hat{\mathbf{u}} = \{\boldsymbol{w}_{<j}, c, \boldsymbol{w}_{>j}\}$
 8:                 Add $\hat{\mathbf{u}}$ into $\mathcal{D}_{\text{out}}^{\text{gen}}$
 9:             end for
10:         end if
11:     end for
12: end for
13: $\mathcal{D}_{\text{out}}^{\text{gw}} = \{\}$        # generated weighted OOD utterances
14: for $\hat{\mathbf{u}} \in \mathcal{D}_{\text{out}}^{\text{gen}}$ do
15:     Calculate the weight $\alpha$ by Equation 11
16:     Add $(\hat{\mathbf{u}}, \alpha)$ into $\mathcal{D}_{\text{out}}^{\text{gw}}$
17: end for
18: return $\mathcal{D}_{\text{out}}^{\text{gw}}$
```

4.4 Overall Data Manipulation Process

We summarize the process of GOT in Algorithm 1. Line 4 shows that w_j can be viewed as an intent-related word for y if $S(w_j, y)$ is greater than the intent-related word threshold ϵ. Line 5 shows that we generate K replacement words with the top-K $Q(c; \mathbf{u}, w_t)$.

4.5 Shape the energy gap with GOT

After obtaining weighted OOD utterances set $\mathcal{D}_{\text{out}}^{\text{gw}}$, we can explicitly shape the energy gap with them, resulting in IND utterances with smaller energy scores and OOD utterances with higher energy scores. Specifically, we redefine the regularization loss in Equation 6 as follows and use it to re-train the classifier:

$$\begin{aligned}\mathcal{L}_{\text{energy}} &= \mathbb{E}_{(\mathbf{u},y)\sim\mathcal{D}_{\text{in}}^{\text{train}}}(\max(0, E(\mathbf{u}) - m_{\text{in}}))^2 \\ &+ \mathbb{E}_{(\hat{\mathbf{u}},\alpha)\sim\mathcal{D}_{\text{out}}^{\text{gw}}}\alpha(\max(0, m_{\text{out}} - E(\hat{\mathbf{u}})))^2. \end{aligned} \tag{12}$$

In the testing process, we can calculate the energy score for the utterance by Equation 4, and identify whether it is OOD by Equation 5.

5 Experimental Setup

5.1 Datasets

To evaluate the effectiveness of the energy score and our proposed framework, we conducted experiments on two public datasets:

- CLINC150[†] (Larson et al., 2019): this dataset

---

[*] Details about how to calculate the influence can be found in (Koh and Liang, 2017; Wang et al., 2020).

[†] https://github.com/clinc/oos-eval

Statistic	CLINC150	SNIPS
Train	15000	9385
validation	3000	500
Test-IND	4500	486
Test-OOD	1000	214
Test-IND: Test-OOD	4.5: 1	2.3: 1
Number of IND classes	150	5

Table 1: Statistics of CLINC150 and SNIPS datasets.

covers 150 intent classes over ten domains. It supports some OOD utterances that do not fall into any of the system's supported intents to avoid splitting unknown intents manually.

- SNIPS[‡] (Coucke et al., 2018): this dataset is a personal voice assistant dataset that contains seven intent classes. SNIPS does not explicitly include OOD utterances. We kept two classes *SearchCreativeWork* and *SearchScreeningEvent* as unknown intents.

Table 1 provides summary statistics about these two datasets. Note that the training set and validation set do not include OOD utterances.

5.2 Metrics

We used four common metrics for OOD detection to measure the performance. AUROC (Davis and Goadrich, 2006), AUPR In and AUPR Out (Manning et al., 1999) are threshold-independent performance evaluations and higher values are better. FPR95 is the false positive rate (FPR) when the true positive rate (TPR) is 95%, and lower values are better.

Considering the smaller proportion of OOD utterances in the test set on two datasets, AUPR Out is more informative here.

5.3 Baselines

We introduce the following classifier-based methods as baselines:

- MSP (Hendrycks and Gimpel, 2017) trains a classifier with IND utterances and uses the softmax confidence score to detect OOD utterances.

- DOC (Shu et al., 2017) trains a binary classifier for each IND intent and uses maximum binary classifier output to detect OOD utterances.

- Mahalanobis (Lee et al., 2018) trains a classifier with softmax loss and uses Mahalanobis distance of the input to the nearest class-conditional Gaussian distribution to detect OOD utterances.

- LMCL (Lin and Xu, 2019) uses LOF (Breunig et al., 2000) in the utterance representation learned by a classifier. In training, they replace the softmax loss with LMCL (Wang et al., 2018).

- SEG (Yan et al., 2020) also uses LOF in the utterance representation. In training, they use semantic-enhanced large margin Gaussian mixture loss.

5.4 Implementation Details

For a fair comparison, all classifiers used in the above methods and ours are pre-trained BERT (Devlin et al., 2018) with a multi-layer perceptron (MLP). We select parameter values based on validation accuracy. For energy score, we follow Liu et al. (2020) to set T as 1, λ as 0.1, m_{in} as -8 and m_{out} as -5. For influence value, we focus on changes on MLP parameters and use stochastic estimation (Koh and Liang, 2017) with the scaling term 1000 and the damping term 0.003. For LMCL implementation, we set nearest neighbor number as 20, scaling factor s as 30 and cosine margin m as 0.35, which is recommended by Lin and Xu (2019). For SEG, we follow Yan et al. (2020) to set margin as 1 and trade-off parameter as 0.5.

For our framework, we set candidate number K as 2, weight term γ as 20. In particular, for CLINC150, we set threshold ϵ as 150 and generate 100 weighted utterances for each intent. For SNIPS, we set threshold ϵ as 1500 and generate 1800 weighted utterances for each intent. The difference in settings between two datasets is due to the different sizes of per intent in the training set.

6 Results and Analysis

In this part, we will show the results of different methods on two datasets and offer some further analysis.

6.1 Overall Results

As shown in Table 2, we can observe that:

- The energy score can achieve comparable results on two datasets. Note that on SNIPS dataset, the advantages of the energy score are not as obvious. The reason is that SNIPS dataset is not as challenging as CLINC150 dataset, most methods can achieve good results, such as AUPR out is greater than 0.9.

[‡] https://github.com/snipsco/nlu-benchmark

Method	CLINC150				SNIPS			
	AUROC ↑	**FPR95↓**	**AUPR In↑**	**AUPR Out↑**	**AUROC ↑**	**FPR95↓**	**AUPR In↑**	**AUPR Out↑**
MSP	0.955	0.164	0.990	0.814	0.951	0.370	0.970	0.922
DOC	0.943	0.221	0.985	0.790	0.938	0.493	0.956	0.910
Mahalanobis	0.969	0.118	0.993	0.871	0.979	0.088	0.989	0.964
LMCL	0.962	0.124	0.992	0.810	0.976	0.087	0.987	0.960
SEG	0.959	0.152	0.991	0.823	0.974	0.074	0.986	0.948

Table 2: AUROC, FPR95, AUPR In, AUPR Out on CLINC150, SNIPS datasets. Best results are in bold. All results are averaged across five seeds.

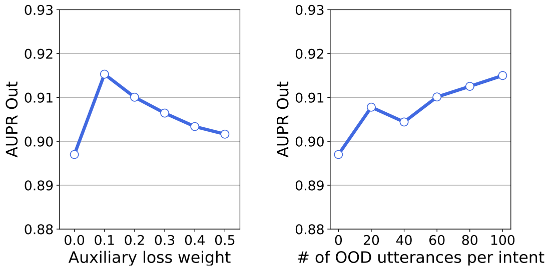

Figure 3: Effect of the auxiliary loss weight (left) and the number of generated weighted OOD utterances per intent (right).

- Energy + GOT achieves better results on two datasets as compared to the raw energy score. It indicates that our generated weighted OOD utterances can effectively shape the energy gap, resulting in more distinguishable between IND and OOD utterances.

- We also report ablation study results. “w/o weighting” is the energy score tuned by OOD utterances without reweighting. We can see that there is a decrease in performance on both datasets, which shows the advantage of the weighting module (p-value < 0.005).

6.2 Effect of Hyper-parameters

During the training process, we find that the method performance is sensitive to two hyper-parameters: auxiliary loss weight λ and the number of generated weighted OOD utterances per intent. We conduct two experiments to demonstrate their effects separately. We choose CLINC150 dataset as it is more challenging as mentioned before.

Auxiliary Loss Weight: We set the auxiliary loss weight λ from 0 to 0.5 with an interval of 0.1 to observe its impact.

Results are shown in Figure 3 (left). With the increase of auxiliary loss weight, the performance increases first and then decreases. $\lambda = 0.1$ achieves the highest AUPR Out 0.914 and outperforms $\lambda = 0$ with an improvement of 1.7% (AUPR Out). The results suggest that although shaping the energy gap can improve the performance, there exists a trade-off between optimizing the regularization loss and optimizing cross-entropy loss.

Method	AUROC ↑	FPR95↓	AUPR In↑	AUPR Out↑
Energy	0.967	0.143	0.991	0.897
Energy + Wiki	0.961	0.170	0.988	0.889

Table 3: Effect of using Wikipedia sentences to shape the energy gap.

Method	AUROC ↑	FPR95↓	AUPR In↑	AUPR Out↑
MSP	0.955	0.164	0.990	0.814
MSP + GOT	0.972	0.118	0.993	0.903

Table 4: Effect of using GOT to fine-tune the softmax-based detector.

Number of OOD Utterances: we compare the performance of generated weighted utterance numbers for each intent by adjusting the number from 0 to 100 with an interval of 20.

Results are shown in Figure 3 (right). As a whole, AUPR Out increases as more OOD utterances are incorporated into training. We can see that the performance is also improved even with a small generated number, which indicates the necessity of explicitly shaping the energy gap.

6.3 Compare with Wikipedia Sentences

An easy way to obtain OOD utterances is from the Wikipedia corpus. We investigate the effect of regarding Wikipedia sentences as OOD utterances to shape the energy gap on CLINC150 dataset. The Wikipedia sentences are from Larson et al. (2019) and the number is 14750.

As shown in Table 3, we can observe that these sentences cannot improve the performance and even have a negative effect (We experimented with several hyper-parameters, this is the best result we could get). After observing these Wikipedia sentences, we find that they have little relevance to

Intent	IND utterance and intent-related word [w]	Replacement word	Weight
Insurance	i need to know more about my health [**plan**]	problems	0.50
	what [**benefits**] are provided by my insurance	services	0.19
Credit Limit Change	can i get a higher limit on my american express [**card**]	ticket	0.46
	can you [**increase**] how much i can spend on my visa	guess	0.54
Reminder	can you list each item on my [**reminder**] list	contacts	0.50
	what's on the [**reminder**] list	agenda	0.78
Redeem Rewards	walk me through the process of cashing in on [**credit**] card points	those	0.22
	i have credit card [**points**] but don't know how to use them	privileges	0.50

Table 5: Weighted OOD utterances generated by GOT on CLINC150 dataset.

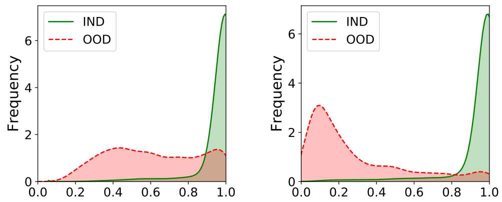

Figure 4: Histogram of the softmax confidence score from MSP (left) and MSP + GOT (right).

IND utterances. Therefore, simply using Wikipedia sentences is unrepresentative and ineffective for shaping the energy gap.

6.4 GOT for Softmax-based Detector

As mentioned in Section 1, when using the softmax-based detector, OOD inputs may also receive a high softmax confidence score. To tackle this problem, Lee et al. (2017) replace the cross entropy loss with the confidence loss. The confidence loss adds the Kullback-Leibler loss (KL loss) on the original cross entropy loss, which forces OOD inputs less confident by making their predictive distribution to be closer to uniform.

To verify the generality of GOT, we directly use the generated weighted OOD utterances to fine-tune the softmax-based detector with the confidence loss. The results are shown in Table 4. Our MSP + GOT has a significant improvement and outperforms MSP by 8.9% (AUPR Out). Figure 4 provides an intuitive presentation. The softmax confidence scores of OOD from MSP form smooth distributions (see Figure 4 (left)). In contrast, the softmax confidence scores of OOD from MSP + GOT concentrate on small values (see Figure 4 (right)). Overall the softmax confidence score is more distinguishable between IND and OOD after tuning by GOT.

6.5 Case Study for GOT

We sample some intents and showcase generated weighted OOD utterances in Table 5. We can observe that intent-related words that located by our locating module are diverse, containing not only words appeared in the intent label. The replacement word fits the context well, and the intent of the generated utterance is exactly changed in most conditions. Admittedly, GOT may have a bad generation, like replace "benefits" with "services" in the second utterance, which leads the generated utterance is still in-domain. Fortunately, the weighting module assigns these utterances a lower weight to reduce their potential harm.

7 Conclusion and Future Work

In this paper, we propose using energy scores for unknown intent detection and provide empirical evidence that the energy-based detector is comparable to strong baselines. To shape the energy gap, we propose a data manipulation framework GOT to generate high-quality OOD utterances and assign their importance weights. We show that the energy-based detector tuned by GOT can achieve state-of-the-art results. We further employ generated weighted utterances to fine-tune the softmax-based detector and also achieve improvements.

In the future, we will explore more operations, such as insertion, drop, etc., to enhance the diversity of generated utterances.

Abstract

The automated *transcription* of *spoken language*, and meetings, in particular, is becoming more widespread as *automatic speech recognition* systems are becoming more accurate. This trend has significantly accelerated since the outbreak of the COVID-19 pandemic, which led to a major increase in the number of online meetings. However, the transcription of spoken language has not received much attention from the NLP community compared to documents and other forms of *written language*. In this paper, we study a variation of the summarization problem over the transcription of spoken language: given a transcribed meeting, and an *action item* (i.e., a commitment or request to perform a task), our goal is to generate a coherent and self-contained *rephrasing* of the action item. To this end, we compiled a novel dataset of annotated meeting transcripts, including human rephrasing of action items. We use state-of-the-art supervised text generation techniques and establish a strong baseline based on BART and UniLM (two pretrained transformer models). Due to the nature of natural speech, language is often broken and incomplete and the task is shown to be harder than an analogous task over email data. Particularly, we show that the baseline models can be greatly improved once models are provided with additional information. We compare two approaches: one incorporating features extracted by coreference-resolution. Additional annotations are used to train an auxiliary model to detect the relevant context in the text. Based on the systematic human evaluation, our best models exhibit near-human-level rephrasing capability on a constrained subset of the problem.

1 Introduction

Most of *natural language processing (NLP)* research focuses on written language, such as emails or Web pages, and less on an increasingly large body of spoken language converted to text via *automatic speech recognition (ASR)*. Particularly, today, more and more meetings are conducted online, especially since the COVID-19 social distancing constraints. Online meetings may be transcribed upon request, generating a huge amount of spoken language text.[1]

Spoken language has different characteristics from written language, and, from our experience, it is typically vaguer and harder to understand: sentences tend to be broken, less orderly, incomplete (relying on subtext), and prone to speech-to-text transformation errors (see Section 5).

Action items (AIs) are a common and particularly important part of workplace meetings. An AI is a commitment or a request to perform a certain task by any of the parties involved. For example,

> *"I will send you the file later today."*

AIs occur naturally during conversations, but are not always clear without relevant *context*. For example, the AI *"I will do it"* contains a commitment to act, but the nature of this action is unclear. Nevertheless, the context of the AI might make it clearer; e.g., if the AI is preceded by a sentence such as *"Can you prepare a presentation for Thursday?"*. In the context of written communication, action items have been researched in a variety of ways, such as AI detection (Bennett and Carbonell, 2007, 2005), summarization and rephrasing of AIs in emails (Mukherjee et al., 2020; Rambow et al., 2004), and more. Verbal communication, in contrast, has not received much attention.

In this paper, we focus on the task of *rephrasing* an action item from a transcribed meeting into a coherent and self-contained utterance. Such an utterance may be also referred to as a paraphrase,

---

[1] For example, Microsoft Teams, a popular online communication platforms, has reached 115 Million daily users on October 2020.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2862–2873
August 1–6, 2021.

or a summary. Conceptually, the rephrasing task may be split into two sub-tasks: one is *locating* those parts in the context that are relevant to the AI; the other is *forming* a coherent and self-contained AI sentence from the original AI and the relevant context. While even "off the shelf" summarization models (e.g., HIBERT (Zhang et al., 2020)) may do well in forming an action item sentence, manual observation of the data showed that such models often fail to locate relevant context in the transcript. As we show in Section 6, the same applies to models trained specifically for the rephrasing task too. To overcome this, we introduce *"hints"* – additional annotations that are added to the rephrasing models' input to help the model better locate relevant spans of text (see Figure 1). We use two kinds of hints: *coreference hints*, which are obtained from a pre-trained model for the coreference resolution task, and *context hints* that are generated by a model trained specifically for the task based on our train data.

Our contribution may be summarized as follows:

1. We created a new dataset (coined *AIR*) including AIs extracted from transcribed meetings, with human annotations of context and AI rephrasing.

2. We show that models intended for AI rephrasing in email perform considerably worse on transcript data. Accordingly, we train transformer-based models for AI rephrasing – both on email data, reporting new state-of-the-art performance, as well as on transcript data – so as to form a baseline for the task.

3. We show that the baseline can be greatly improved by adding "hints" to the model's input. This results in near-human-level performance on a constrained subset of the problem. We believe that this approach may apply to various other problems.

We support our claims by extensive experimentation and evaluation, including independent human evaluation.

2 Related work

While AI extraction and summarization of emails have been researched extensively (Lin et al., 2018; Mukherjee et al., 2020; Rambow et al., 2004; Scerri et al., 2010), meeting transcripts have not received as much attention from the community. Closest to our work is the work of Mukherjee et al (Mukherjee et al., 2020), which focuses on the extraction and rephrasing of AIs over emails. While their goal is very similar to ours, rephrasing transcripts is very different from rephrasing emails, as we show in Section 5.

A: At the b- furthermore , I told Jerry that I was gonna finish it before he got back. So.
C: That's approaching. He's coming back when ? next -
A: I think - we think we'll see him definitely on Tuesday for the next - Or, no, wait. The meetings are on Thursday .
A: Well, we'll see him next week .
A: I was thinking about that. I think I will try to work on the SmartKom stuff and I'll if I can finish it today , ▲ I'll help ▼ you with that tomorrow.
A: if you work on it?
A: I don't have a problem with us working on it though? So.

Einolghozati et al. (2020) applied a pre-trained BART with a copy mechanism for the task of rephrasing virtual assistance messages. However, they are focused on style adaptation and personal pronouns modification while we focus on context-based enrichment.

Meeting summarization has been explored in the past (Oya et al., 2014; Garg et al., 2009). However, these works focus on full meeting transcript summarization, where we focus on extracting and rephrasing information specific to a given AI. In this perspective, our work can be viewed as a variation of the known *query based summarization* problem (Rahman and Borah, 2016), where given a document and a query, the algorithm goal is to extract information regarding the query from the document. While this topic has been studied in the past (Saggion et al., 2003; Bosma, 2003; Nema et al., 2017), to the best of our knowledge, there has been no work that relates to meeting transcripts, especially in the context of AIs.

3 The AIR Dataset

We create AIR **A**ction **I**tem **R**ephrasing, a new dataset focused on professional meetings AI rephrasing. The dataset is composed of instances, where each instance contains ten utterances, where the 8th utterance includes an AI. The labels are a human-produced rephrasing of the AI. The annotation process was split into three parts; acquiring raw data from multiple sources, AI extraction, and AI rephrasing. We now describe each of these steps.

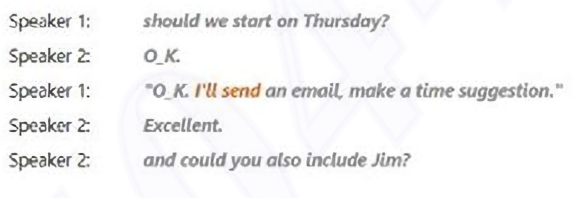
3.1 Dataset Construction

Several datasets of manually transcribed records of meetings were used to accumulate action items and generate rephrasing. The result is a diverse dataset, containing a collection of different meeting types, such as software development, product design, financial, and board meetings[2].

ICSI meeting corpus (Janin et al., 2003) contains 75 meetings recorded in a conference room at the International Computer Science Institute in Berkeley.

Augmented Multi-party Interaction (AMI) meeting corpus (Carletta et al., 2006) is a multimodal dataset consisting of 100 recording hours of 154 meetings, and their manually annotated transcripts. Some of the meetings are naturally occurring, and some are elicited, particularly using a scenario in which the participants play different roles in a design team, taking a design project from kick-off to completion over the course of a day.

Board Meetings (LSC) is an open to public board meetings transcripts of the legal services corporation (LSC) and other transcribed board meetings that were extracted from available public resources.



Speaker 1:	*should we start on Thursday?*
Speaker 2:	*O_K.*
Speaker 1:	*"O_K. I'll send an email, make a time suggestion."*
Speaker 2:	*Excellent.*
Speaker 2:	*and could you also include Jim?*

Figure 2: The UI used by the human annotators for AI detection.

Internal Dataset (ID) that contains internal ***[3] manually transcribed meetings which mostly revolve around software development topics.

Parts of these datasets contain sensitive information, so while datasets will be made publicly available in the future, some parts of the data cannot be shared.

Table 1 describes relevant AIR statistics. Note that to better compare the two AIR versions, the dev and test set are identical between the public and restricted versions. Both development and test sets were composed of ISCI dataset. we used ICSI for the test and development set because ISCI samples contained the highest intra-judgment score as discussed in Appendix A.

3.2 Action Items Detection

Action Items are rare in conversations and are found in roughly 1% of sentences. To reduce annotation costs, we wish to increase the percentage of AIs in the data. To this goal, the transcripts are filtered by a pre-classifier – a list of regular expressions. The pre-classifier filters out 93% of the sentences, with a precision of 17% and recall of 90% over Action Items.

AI candidates that passed the pre-classifier were labeled using human annotators. The action item annotation task was composed of five sequential utterances. The sentence that includes the AI candidate was the third sentence and two previous and following utterances were shown as context, as seen in Figure 2. Each annotator was asked if the third utterance contains an AI or not.

As preparation for the annotation task, each judge reviewed the annotation guideline and was required to successfully pass a test of ten samples before granted access to the data. The candidate sentences were tagged by five annotators. If the agreement between judges was lower than 80%, four more annotators were added. Each AI candidate was labeled as Action Item or not, according

---

[2] Each of the datasets was adjusted slightly to make relatively uniform samples. e.g. all speakers roles were converted to the form ”speaker_X, where X is a running number

[3] Organization name is omitted to preserve anonymity

Name	# of meetings	Average # of utterances	# of AIs	# of rephrasing
ID	594	374	5356	14820
ICSI	75	1428	722	2487
AMI	145	820	461	1445
Board Meetings	206	787	1283	3286
Overall	1020	598	7957	22038
Overall public	426	911	2519	7218

Table 1: AIR Source datasets statistics including the number of meetings, number of utterances per meeting, number of AIs extracted from the full dataset, and the number of rephrasing.

to a majority vote of the annotators.

3.3 Action Items Rephrasing

Action Items were rephrased by human annotators. Similar to the AI detection stage, the datasets were divided into samples that contain ten utterances, seven utterances before the AI, and two utterances after. Preliminary analysis showed an accelerated decline in context relevance when moving away from the action item, with less than 1% contribution to the seventh sentence before the AI. This justified the decision to present no more than seven pre-AI sentences. The distribution of context over the seven pre-AI and two post-AI utterances is shown in Figure 3

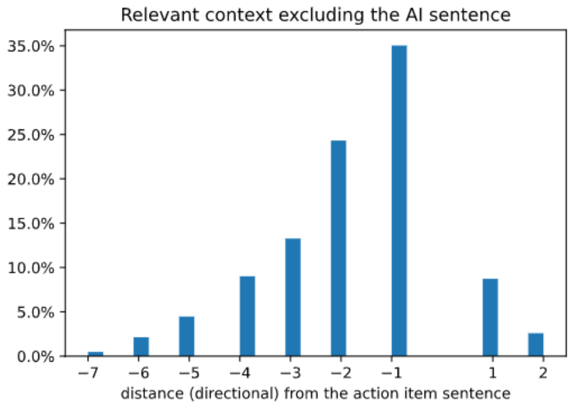


Figure 3: Percentage of the instances containing relevant context relative to the AI sentence.

Set	# of AIs	# of rephrasing
Train	2219	6318
Validation	150	450
Test	150	450

Table 2: Number of AIs and Rephrasings in train and test sets for the public dataset.

While this truncation might make some AIs unclear due to lack of relevant content, this is a good trade-off between loss of information and annotation efficiency and accuracy. Human annotators were asked to write a self-explanatory sentence in their own words, based on the Action Items and their surrounding context. In text rephrasing, like other text generation tasks, there is not a single correct answer. Therefore, each sample was rephrased up to six times[4]. Multiple rephrasing per Action Item also helped us to assess the quality of the rephrasing. The overall number of AIs and Rephrasing ,train and test sets for the public dataset are described in table 2[5]. All samples in the test and validation sets were chosen from the ISCI dataset for uniformity (in both public and private variations).

4 Model and Hints

In this section we show how to fine-tune a pre-trained model using the AIR data set. Additionally, we show how to add hints – extra annotations that improve the model ability to find relevant context, and generate more accurate and self-contained rephrasing. Hints and several versions of model rephrasing on the test set appear in Figure 1.

Base model The base model is based on BART (Lewis et al., 2020), a transformer based model (Vaswani et al., 2017), that was pre-trained by noising the input text and guiding the model to output, a de-noised version of the input. The BART model seems suitable for the rephrasing task. In this task, similar to the BERT pre-training task, the output

---

[4] Initially each sample was rephrased multiple times to check similarity of rephrasing and agreement. Later rehearsing was tagged between one to three times.

[5] Test and validation set were contracted as described in Appendix A

is a better version of the input; the ambiguity is cleaned from the AI and the output is a comprehensible and full version of the input. The de-noising ability of BART can also assist in overcoming noise of ASR systems or the speaker's partial and incoherent sentences. Our experiments in Section 6.2.2 further support this claim.

The model input is inspired by (Mukherjee et al., 2020). The input includes the sentence with AI, the previous seven sentences and the following two sentences. For each utterance in the input, we add the speaker name, and OOV markers to indicate the speaker's name and the AI, For example:

> <speaker>John</speaker><AI>I will send </AI>the presentation tomorrow.

The model is trained using teacher forcing and cross entropy loss over the predicted token.

4.1 Hints

One of the shortcomings of the base model is its limited ability to correctly identify relevant context with regard to the AI. Therefore, the rephrased AIs are often inaccurate and include irrelevant information from unrelated parts of the input text. To mitigate this, we propose two improvements to the base model.

Coreference model Given an input text, the task of *coreference resolution (CR)* aims to cluster entities that appear in different parts of the input text but refer to the same entity. This task has been thoroughly researched (Sukthanker et al., 2020; Soon et al., 2001), and in recent years gained a boost in performance, thanks to neural architectures (Xu and Choi, 2020; Joshi et al., 2020; Meged et al., 2020; Caciularu et al., 2021; Cattan et al., 2020). We hypothesize that CR models can capture semantic relations that the base model will miss because they are trained specifically for this task using vast amounts of data.

We use the CR model from Allennlp (Gardner et al., 2019), which uses SpanBERT for contextualized embedding (Joshi et al., 2020) and (Lee et al., 2017) method for CR. This model was trained on the OntoNotes dataset (Hovy et al., 2006).

Using the coreference model, we add hints to the text (see Figure 1b), identifying coreference clusters within the text. Text embedding includes cluster-marks appearing in square brackets around each of the cluster spans. For example:

> *"[c:0 Jon] works at the [c:1 cinema] , [c:0 he] loves working [c:1 there] ."*

We only mark clusters that have at least one instance in the AI utterance. This annotated text is input to the rephrasing model (both at the training phase and inference phrase). Note that training is applied only to the rephrasing model, whereas the CR model's weights are held constant.

Context detection model Another approach to improve the rephrasing model's ability to detect relevant spans is to directly train a model to detect them. To achieve this, we ask annotators to mark spans of text that are relevant to the AI. This data is used to train a *context detection model.* Spans of relevant text are transformed into binary token labels ('relevant' or 'irrelevant'). Accordingly, we train a token-classification model, based on the RoBERTa (Liu et al., 2019) pretrained transformer encoder, which is added to a fully-connected layer to perform per-token classification, given RoBERTa's output representation of each token. The model is fine-tuned end-to-end over the collected token annotations.

We found that the collected context information suffers from a low agreement between the judges. We use Kripendorff's alpha (Hayes and Krippendorff, 2007; Artstein and Poesio, 2008) coefficient to measure the judges (dis)agreement.We measure both an alpha score for the entire annotation task, as well as the pairwise agreement between the judges – both exhibiting values on the order of 0.4, which is considerably low. One reason for a low agreement may be an incomplete or incorrect understanding of the text: annotators are detached from the larger context of the meeting and from the subject matter; oral communication tends to be implicit and relies on pre-understanding; spoken sentences tend to be broken and less organized. Another reason might be the task itself, whose definition inevitably bears some level of ambiguity and arbitrariness.

Low agreement between annotators does necessarily undermine machine learning in its attempt to generalize from the train set (see Sect. 4.1.4 in (Artstein and Poesio, 2008), (Reidsma and Carletta, 2008)). It is important, however, to account for it when *measuring* classification performance on the test set. Each test instance for the context detection model consists of a transcript snippet containing a set of tokens for binary classification, and a human annotation of the tokens as relevant or irrelevant. Per test instance, we measure: (a) token

Model	Rouge-1	Rouge-2
SmartToDo (BiLSTM)	0.6	0.41
Human annotator	0.6	0.37
BART	0.63	0.43
BART (only subject & AI)	0.628	0.43
BART (No subject)	0.58	0.39
BART (AI only)	0.56	0.33

Table 3: Different variations of the email AI dataset.

ranking by the model (in accordance to the model's output scores) is evaluated by *average precision (AP)*; (b) F1-score of model's predictions. To aggregate on the test set, we have taken the mean of each value, resulting in *mean average precision (MAP)* and *mean F1-score (MF1)*.[6]

In order to assess the judges' disagreement on the test set, for each of the test instances, we collected 3 to 6 annotations. Per test instance, the optimal AP is obtained when ordering the token according to their "soft" label – mean of judges' scores (0 or 1).[7] We denote by oMAP the mean of optimal AP over all test instances. Similarly, oMF1 is defined as the mean of instances' F1-scores for judges' majority prediction per token.

The context model's *normalized MAP* score (namely, $\frac{\text{MAP}}{\text{oMAP}}$) and *normalized MF1* score (namely, $\frac{\text{MF1}}{\text{oMF1}}$) are both 0.82. Similarly to the CR model, the context detection is used to add hints to the rephrasing models' input (see Figure 1a). Training the rephrasing model designates a second usage of the corpus, now with human rephrasing annotations.[8] Despite a relatively low agreement between the judges, context annotations significantly improve the rephrasing model's performance.

5 Comparison of Emails and Transcripts

AI rephrasing was applied over emails in (Mukherjee et al., 2020). We evaluate this model over meeting transcripts and show that despite its success over emails, it is less suitable for transcripts. At a first glance, email and meeting transcript AI rephrasing might seem similar. In this section, we challenge this assumption by highlighting three key differences.

Email subject We use the dataset from (Mukherjee et al., 2020) to evaluate performance over emails compared to transcript data. Their data is based on the Avocado dataset (Douglas Oard, William Webber, David A. Kirsch, 2015), where each instance contains a pair of emails (an email with an AI and the previous email in the correspondence), and a rephrasing of the AI. To build a rephrasing model, the authors used the following approach: 1. Chose relevant sentences from each email by similarity to the AI sentence. 2. Create an input that contains the chosen sentences, the mails authors, and the mails subjects, tagging each part of the data with dedicated markers. 3. Learn a model using a BiLSTM with copy mechanism (Zeng et al., 2016).

We test a number of variations based on this approach. 1. We replace the BiLSTM with BART (BART); 2. Similar to (1), but we omit the email's subject from the input (No subject); 3. Similar to (1), but remove all the email's body text besides the AI sentence (only subject & AI); 4. Leaving only the AI sentence (AI only). The results are presented in Table 3. The BART base model unsurprisingly outperforms the BiLSTM model. But surprisingly, a model that is exposed to the Subject alone performs almost as well as the full model. Additionally, most of the improvement compared to the base (AI only) model comes from adding the email's subject. This means that the body of the emails play a minimal role in the email's rephrasing. Unfortunately, meeting transcripts do not have an equivalent to a subject, which forces the model to rely solely on the transcript text.

Number of utterances While two emails often supply enough context for rephrasing, transcript samples contains ten utterances, which require the model to "find" the right spans from a relatively large pool of text.

Malformed language In contrast to written text, spoken language is less formal. This results in people making grammatical mistakes like stopping at the middle of a sentence ("I will take the... yes, that's right" or repeating words ("I... ah... I... think that it's OK"). This new grammar is very different from the pretrained text most pretrained models were trained on.

---

[6] Due to the nature of the problem, there are considerably more negatives than positives, and thus we choose two metrics that embody the precision/recall tradeoff, which is indifferent to true negative predictions, rather than the true-positive/true-negative tradeoff.

[7] AP calculation takes token-level steps, updating precision and recall according to *all* judges' annotations at once.

[8] In the training phase, as in the inference phase, the context model's predictions are used, rather than the judges' annotations.

Model	ROUGE-1	ROUGE-2	BLEU
Human	0.519	0.305	0.737
Base model	**0.645**	**0.459**	**0.763**

Table 4: ROUGE and BLEU score of the base model and human rephrasing.

6 Experiments

We evaluate our various models compared to a human annotator, and between themselves, in two ways. The first is automatic n-gram based metrics and the second is direct human evaluation. All models were trained using the Huggingface framework(Wolf et al., 2019) with the following configuration: **batch size:** 8, **lr:** $3 \cdot 10^{-5}$, **epocs:** 5 (20 with public dataset).

6.1 N-gram Based Metrics

There are a variety of n-gram based methods that evaluate the quality of text generation tasks (Lin, 2004; Banerjee and Lavie, 2005; Papineni et al., 2001). In this work, we use the ROUGE-1 and ROUGE-2 (Lin, 2004) as it is a widely used measure for summarization evaluation.

We evaluate the base model vs. a gold rephrasing produced by a human annotator. We also include another human rephrasing that represents human evaluation level. The results are shown in Table 4. Even the base model suppresses the human-produced rephrasing and achieves a higher ROUGE score. While this result looks impressive, we claim it simply highlights the limitation of ROUGE, and other n-gram based metrics to evaluate the rephrasing quality (see (Mathur et al., 2020)). We provide the following rational:

Frequent words Not all words have the same value when evaluating the quality of a sentence. For example, entity mentions and verbs are more relevant to the sentence meaning than stop words, but n-grams models give each word an equal weight for the overall score. While human annotators are good at finding rare words that convey meaning, automatic models are good at using very frequent words. Using these words increase the model's score, while not contributing to the quality of the rephrasing.

Lacking of "true" gold samples Typically, machine-learning algorithms are evaluated based on a gold standard that is generated by humans. It is also typical for ground truth to have some error rate, and there are techniques to reduce the probability of error, e.g., taking a majority vote. In contrast, in the case of text generation, there are usually many results (sentences) that can be considered 'good', having very different wording. BLEU (Papineni et al., 2001) addresses this difficulty by comparing the generated text to a number of different human-generated labels. While this somewhat reduces the chance that a good text generation will get a low score, it does not eliminate it.

Models might outperform humans as we show in Section 6.2.1, our models might achieve higher quality than the human-produced rephrasing. N-gram based models treat each deviation from the human model as an error, although it might achieve a better paraphrasing[9].

For these reasons, we turn to human evaluation as the main models' evaluation method.

6.2 Human Evaluation

We evaluate our models by using the following procedure - Each instance contains the model input (transcript + speakers + AI) and three[10] different rephrasings. The judges were instructed to assign each rephrasing a score from the set {1,2,3}, while considering these questions (arranged by importance):

1. Does the action described in the rephrasing accurately describe the action in the context + AI?
2. Does the rephrasing contain all the details that are described in the context + AI?
3. Is the rephrasing grammatically correct?
4. How easy was it to understand the rephrasing?

The judges UI is shown in Figure 5 on Appendix B.

6.2.1 Main Results

Using the AIR-internal dataset, we compare the three models with each other and with a human-produced rephrasing. We applied two evaluations. First, we compare the human-produced rephrasing, the base model, and the coreference model. The

---

[9] This indicates that the automatic metrics might underestimate automatic models.

[10] We use three models per instance (instead of four) to reduce the load from the judges.

Models	Result
Human/Coref	**56.0% / 44.0%**
Human/Base	**68.2% / 31.8%**
Base/Coref	**39.4% / 60.6%**
Context/Coref	**59.1% / 40.9%**
Human/Context	50.9% / 49.1%

Table 5: Comparison of the base, coreference, and context models. Bold results are significant.

Models	Result
Base/Coref	**43.4% / 56.6%**
Context/Coref	50.5% / 49.5%
Context/Base	**58.4% / 41.6%**

Table 6: Unilm comparison.

Models	Result
human/BART	50.8% / 49.2%
human/Unilm	53.1% / 46.9%
BART/Unilm	53.0% / 47.0%

Table 7: Cross LM comparison. Both models used the context annotations.

Models	Result
Human/Coref	56.1% / 43.9%
Human/Base	**68.2% / 31.8%**
Base/Coref	**40.1% / 59.9%**
Context/Coref	46.1% / 53.9%
Human/Context	54.3% / 45.6%

Table 8: Result on the public dataset. Using the base, coreference, and context models. Bold results are significant.

second comparison compares the human rephrasing, coreference-based, and context-based rephrasing. The results are presented in Table 5. The Human rephrasing outperforms all models, while the context achieves the closest performance, followed by the coreference and the base models. All results are statistically significant, except the context and human comparison. We used double evaluation of the human and coreference model rephrasing to calculate the judge's agreement, which resulted in a Kappa value of 0.604. Both the coreference and context model achieve close to human performance when the context-based model is almost equal to the human rephrasing.

6.2.2 Language Model Comperison

We choose BART as the base language model (LM) for our work because its denoising pre-train objective function seems suitable to deal with the noisy transcripts data. To evaluate this, we compare our results to another model - unilm (Bao et al., 2020). This model was trained as both masked LM and autoregressive LM and showed improvement on a variety of downstream tasks. To compare BART and unilm, we first compare our three candidate models using each of the LM, and then compare the best models with each LM. The results of the unilm variations are presented in Table 6. The hierarchy between the model variations remains, while the differences between models are smaller and become statistically insignificant. Nevertheless, we chose the context model as the best model for the cross LM comparison. The results are presented in Table 7. BART outperforms Unilm both on direct comparison and in its performance vs. the human rephrasing.

6.2.3 Public Dataset Results

The ID dataset contains sensitive and personal data and cannot be released to the public. In this subsection, we ran the same comparison of base/coreference/context and human annotators using the AIR-public dataset. These results can also highlight the dependency of the algorithm performance on the dataset size. The results are presented in Table 8. The human rephrasing is still the best model compared to all the others, but surprisingly it does not have a bigger gap in performance compared to the full dataset. We explain this by the mix of the different datasets. Each of the datasets contains a different distribution of AIs. Removing the ID dataset allows the model to overfit to the remaining existing datasets. The context model suffered the most from the reduced size of the dataset and is outperformed by the coreference model. We attribute this to the fact that the model trains twice on the data set (first for context detection, then for rephrasing). This shows that the coreference hints are best utilized when the dataset size is small.

7 Conclusion

In this work, we present the problem of action items rephrasing in meeting transcripts. We introduce a new dataset for the task and establish a baseline attributed to the BART transformer model. We then present two novel ways to considerably improve the baseline. Particularly, by collecting context annotations, and despite a relatively low agreement between the annotators, we are able to considerably improve the rephrasing model's performance. We evaluate our work by automated metrics, as well as independent human evaluators.

A Test and Validation Sets Construction

Before evaluating the full test set, we ran a small subset of tests (60 instances overall) of the test set to get initial results. We compared the human rephrasing to the base model.The results are surprising, where most base models scored higher than the human rephrasing. While these results are attractive, manual examination showed that the base model often made mistakes that a human annotator could handle easily. Additionally, we checked the agreement between the judges on the same instances using Cohen's kappa (Cohen, 1960). The agreement was unexpectedly low 0.39. We explain these two phenomena by offering the hypothesis - some samples are very hard / impossible to rephrase properly. We suggest three reasons:

Context not in the sample In these samples the required context is not found in the part of the transcript that is included in the sample (each sample includes seven sentences before the AI, and three after).

Context requires real-world knowledge In some samples, some real-world knowledge is required to understand the AI. For example, our internal dataset is composed of technical team meetings that require prior knowledge in programming, software engineering, and NLP. Our annotators occasionally lack the technical knowledge required to understand the full AI meaning.

Rephrasing is hard Some samples were very hard to rephrase, even for humans, and often require a number of passes over the text to rephrase properly. Even though all of our annotators are proficient in English, they still had a very hard time rephrasing part of the questions. This results in bad rephrasing.

Surprisingly, when both the model and human fail, the human judge tends to prefer the model output. We attribute this to the fact that the model output was always grammatically and semantically correct, while the human had a tendency to write malformed sentences when the rephrasing was unclear.

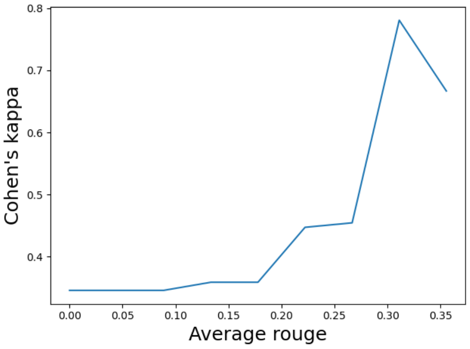

Figure 4: Cohen's Kappa as a function of a threshold serving as lower bound on the samples' average rouge.

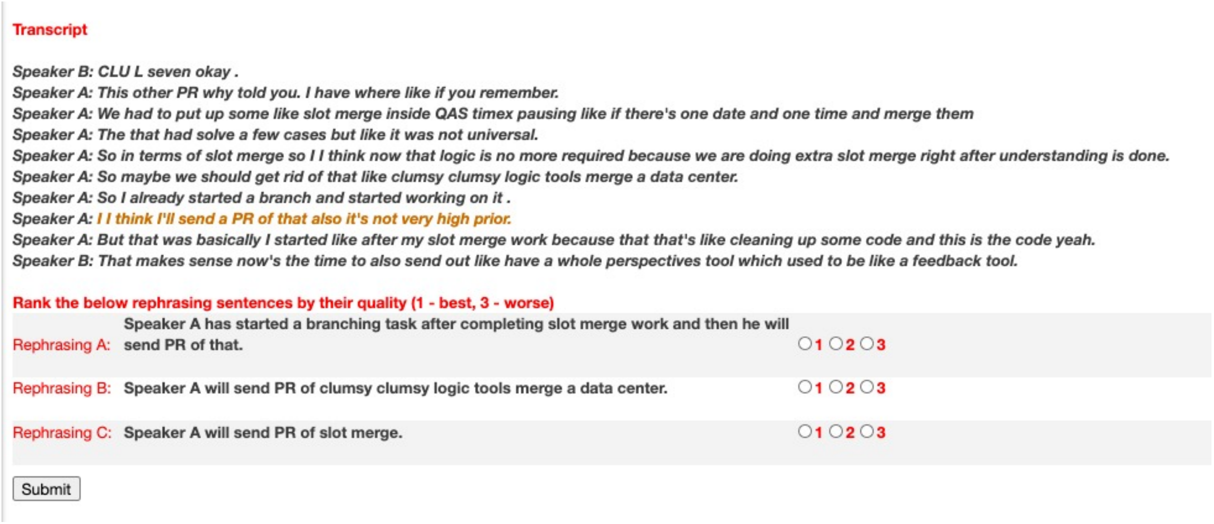
Rephraseable instances In cases where human annotators produce relatively similar rephrasing, we can presume the model will do the same, and thus we can think of those samples as 'easy to rephrase', or *rephraseable*. In order to find these, we take the *average rouge score* between all pairs of human rephrasing, as follows:

$$score(s) = \frac{1}{|R_s|^2} \sum_{\langle r,r' \rangle \in R_s} rouge_2(r, r')\,, \qquad (1)$$

where s is a input sample, R_s is the set of all human rephrases of s, and $rouge_2(\cdot,\cdot)$ is the Rouge-2 measure. As *rephraseables*, we consider half of the samples – those with higher average rouge per (1). Figure 4 shows that, as one may expect, by considering the more rephraseable samples (i.e., putting a lower bound on the samples' average rouge score), the agreement between the judges on the related task of marking relevant context increases.

We use these insights to construct the test set and validation set by randomly sampling instances with an average rouge score ≥ 0.3. In Section 6, we show that using this test set, the judges' agreement is significantly higher (0.61) on Cohen's Kappa.

B Rephrasing Evaluation UI



Transcript

Speaker B: CLU L seven okay .
Speaker A: This other PR why told you. I have where like if you remember.
Speaker A: We had to put up some like slot merge inside QAS timex pausing like if there's one date and one time and merge them
Speaker A: The that had solve a few cases but like it was not universal.
Speaker A: So in terms of slot merge so I I think now that logic is no more required because we are doing extra slot merge right after understanding is done.
Speaker A: So maybe we should get rid of that like clumsy clumsy logic tools merge a data center.
Speaker A: So I already started a branch and started working on it .
Speaker A: I I think I'll send a PR of that also it's not very high prior.
Speaker A: But that was basically I started like after my slot merge work because that that's like cleaning up some code and this is the code yeah.
Speaker B: That makes sense now's the time to also send out like have a whole perspectives tool which used to be like a feedback tool.

Rank the below rephrasing sentences by their quality (1 - best, 3 - worse)

Rephrasing A:	Speaker A has started a branching task after completing slot merge work and then he will send PR of that.	○1 ○2 ○3
Rephrasing B:	Speaker A will send PR of clumsy clumsy logic tools merge a data center.	○1 ○2 ○3
Rephrasing C:	Speaker A will send PR of slot merge.	○1 ○2 ○3

Abstract

Pre-trained multilingual language models (LMs) have achieved state-of-the-art results in cross-lingual transfer, but they often lead to an inequitable representation of languages due to limited capacity, skewed pre-training data, and sub-optimal vocabularies. This has prompted the creation of an ever-growing pre-trained model universe, where each model is trained on large amounts of language or domain specific data with a carefully curated, linguistically informed vocabulary. However, doing so brings us back full circle and prevents one from leveraging the benefits of multilinguality. To address the gaps at both ends of the spectrum, we propose MERGEDISTILL, a framework to merge pre-trained LMs in a way that can best leverage their assets with minimal dependencies, using *task-agnostic* knowledge distillation. We demonstrate the applicability of our framework in a practical setting by leveraging pre-existing teacher LMs and training student LMs that perform competitively with or even outperform teacher LMs trained on several orders of magnitude more data and with a fixed model capacity. We also highlight the importance of teacher selection and its impact on student model performance.

1 Introduction

While current state-of-the-art multilingual language models (LMs) (Devlin et al., 2019; Conneau et al., 2020) aim to represent 100+ languages in a single model, efforts towards building monolingual (Martin et al., 2019; Kuratov and Arkhipov, 2019) or language-family based (Khanuja et al., 2021) models are only increasing with time (Rust et al., 2020). A single model is often incapable of effectively representing a diverse set of languages, evidence of which has been provided by works highlighting the importance of vocabulary curation and size (Chung et al., 2020; Artetxe et al., 2020), pre-training data volume (Liu et al., 2019a; Conneau et al., 2020), and the curse of multilinguality (Conneau et al., 2020). Language specific models alleviate these issues with a custom vocabulary which captures language subtleties[1] and large magnitudes of pre-training data scraped from several domains (Virtanen et al., 2019; Antoun et al., 2020). However, building language specific LMs brings us back to where we started, preventing us from leveraging the benefits of multilinguality like zero-shot task transfer (Hu et al., 2020), positive transfer between related languages (Pires et al., 2019; Lauscher et al., 2020) and an ability to handle code-mixed text (Pires et al., 2019; Tsai et al., 2019). We need an approach that encompasses the best of both worlds, i.e., leverage the capabilities of the powerful language-specific LMs while still being multilingual and enabling positive language trans-

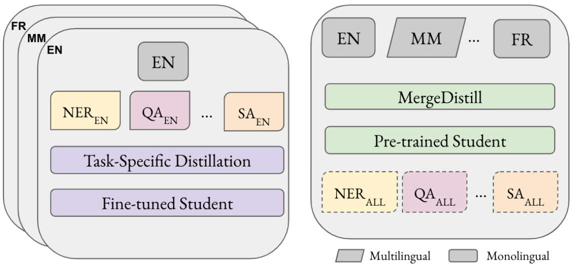

Figure 1: Previous works (left) typically focus on combining *fine-tuned* models derived from a single pre-trained model using distillation. We propose MERGEDISTILL to combine *pre-trained* teacher LMs from multiple monolingual/multilingual LMs into a single *multilingual task-agnostic* student LM.

---

[1] For example, in Arabic, (Antoun et al., 2020) argue that while the definite article "Al", which is equivalent to "the" in English, is always prefixed to other words, it is not an intrinsic part of that word. While with a BERT-compatible tokenization tokens will appear twice, once with "Al-" and once without it, AraBERT first segments the words using Farasa (Abdelali et al., 2016) and then learns the vocabulary, thereby alleviating the problem.

Figure 2: *Overview of* MERGEDISTILL: The input to MERGEDISTILL is a set of pre-trained teacher LMs and pre-training transfer corpora for all the languages we wish to train our student LM on. Here, we combine four teacher LMs comprising of three monolingual (trained on English, Spanish and Korean respectively) and one multilingual LM (trained on English and Hindi). The student LM is trained on English, Spanish, Hindi and Korean. Pre-training transfer corpora for each language is tokenized and masked using their respective teacher LMs vocabulary. We then obtain predictions for each masked word in each language, by evaluating *all* of their respective teacher LMs. For example, we evaluate English masked examples on both the monolingual and multilingual LM as shown. The student's vocabulary is a union of *all* teacher vocabularies. Hence, the *input, prediction and label indices* obtained from teacher evaluation are now mapped to the student vocabulary, and input to the student LM for training. Please refer to Section 3.1 for details.

fer.

In this paper, we use knowledge distillation (KD) (Hinton et al., 2015) to achieve this. In the context of language modeling, KD methods can be broadly classified into two categories: task-specific and task-agnostic. In task-specific distillation, the teacher LM is first fine-tuned for a specific task and is then distilled into a student model which can solve that task. Task-agnostic methods perform distillation on the pre-training objective like masked language modeling (MLM) in order to obtain a task-agnostic student model. Prior work has either used task-agnostic distillation to compress *single*-language teachers (Sanh et al., 2019; Sun et al., 2020) or used *task-specific* distillation to combine multiple fine-tuned teachers into a multi-task student (Liu et al., 2019b; Clark et al., 2019). The former prevents positive language transfer while the latter restricts the student's capabilities to the tasks and languages in the fine-tuned teacher LMs (as shown in Figure 1).

We focus on the problem of merging *multiple* pre-trained LMs into a single multilingual student LM in the *task-agnostic* setting. To the best of our knowledge, this is the first effort of its kind, and makes the following contributions:

- We propose MERGEDISTILL, a task-agnostic distillation approach to merge *multiple* teacher LMs at the *pre-training* stage, to train a strong multilingual student LM that can then be fine-tuned for *any* task on all languages in the student LM. Our approach is more maintainable (fewer models), compute efficient and teacher-architecture agnostic (since we obtain offline predictions).

- We use MERGEDISTILL to **i)** combine *monolingual* teacher LMs into a single *multilingual* student LM that is competitive with or outperforms individual teachers, **ii)** combine *multilingual* teacher LMs, such that the overlapping languages can learn from *multiple* teachers.

- Through extensive experiments and analysis, we study the importance of typological similarity in building multilingual models, and the impact of strong teacher LM vocabularies and predictions in our framework.

2 Related Work

Language Model pre-training has evolved from learning pre-trained word embeddings (Mikolov et al., 2013) to contextualized word representations (McCann et al., 2017; Peters et al., 2018; Eriguchi et al., 2018) and to the most recent Transformer-based (Vaswani et al., 2017) LMs (Devlin et al., 2019; Liu et al., 2019a) with state-of-the-art results on various downstream NLP tasks. Most commonly, these LMs are pre-trained with the MLM objective (Taylor, 1953) on large unsupervised corpora and then fine-tuned on labeled data for the task at hand. Concurrently, multilingual LMs (Lample and Conneau, 2019; Siddhant et al., 2020; Conneau et al., 2020; Chung et al., 2021), trained on massive amounts of multilingual data, have surpassed cross-lingual word embedding spaces (Glavaš et al., 2019; Ruder et al., 2019) to achieve state-of-the-art in cross-lingual transfer. While Pires et al. (2019); Wu and Dredze (2019) highlight their cross-lingual ability, several limitations have been studied. Conneau et al. (2020) highlight the curse of multilinguality. Hu et al. (2020) highlight that even the best multilingual models do not yield satisfactory transfer performance on the XTREME bechmark covering 9 tasks and 40 languages. Importantly, Wu and Dredze (2020) and Lauscher et al. (2020) observe that these models significantly under-perform for low-resource languages as representation of these languages in the vocabulary and pre-training corpora are severely limited.

Language-specific LMs are becoming increasingly popular as issues with multilingual language models persist. As language identification systems are extended to 1000+ languages (Caswell et al., 2020), increasing capacity for a single model to uniformly represent all languages is prohibitive. Often, practitioners prefer to have a model performing well on a subset of languages that their application calls for. To address this, the community continues its efforts in building strong multi-domain language models using linguistic expertise. A few examples of these are AraBERT (Antoun et al., 2020), CamemBERT (Martin et al., 2020), and FinBERT (Virtanen et al., 2019).[2]

Knowledge Distillation in pre-trained LMs has most commonly been used for task-specific model compression of a teacher into a single-task student (Tang et al., 2019; Kaliamoorthi et al., 2021). This has been extended to perform task-specific distillation of multiple single-task teachers into one multi-task student (Clark et al., 2019; Liu et al., 2020; Turc et al., 2019). In the task-agnostic scenario, prior work has focused on distilling a single large teacher model into a student model leveraging teacher predictions (Sanh et al., 2019) or internal teacher representations (Sun et al., 2020, 2019; Wang et al., 2020) with the goal of model compression. To the best of our knowledge, this is the first attempt to perform task-agnostic distillation from *multiple teachers* into a *single task-agnostic student*. In the context of neural machine translation, Tan et al. (2019) come close to our work where they attempt to combine multiple single language-pair teacher models to train a multilingual student. However, our work differs from theirs in three key aspects: 1) our students are task-agnostic while theirs are task-specific, 2) we can leverage pre-existing teachers while they cannot, and 3) we support teachers with overlapping sets of languages while they only consider single language-pairs teachers.

3 MERGEDISTILL

Notations: Let K denote the set of languages we train our student LM on and T denote the set of teacher LMs input to MERGEDISTILL[3]. Consequently, $\mathrm{T_k}$ denotes the set of teacher LMs trained on language k, where $|\mathrm{T_k}| \geq 1 \; \forall \; \mathrm{k} \in \mathrm{K}$.

3.1 Workflow

An overview of MERGEDISTILL is presented in Figure 2. Here we detail each step involved in training the student LM from multiple teacher LMs.

Step 1: Input

The input to MERGEDISTILL is a set of pre-trained teacher LMs and pre-training transfer corpora for all the languages we wish to train our student LM on. With reference to Figure 2, the student LM is trained on $\mathrm{K} = \{$English (en), Spanish (es), Hindi (hi), Korean (ko)$\}$. We combine four teacher LMs comprising of three monolingual and one multilingual LM. The monolingual LMs are trained on English ($\mathrm{M_{en}}$), Spanish ($\mathrm{M_{es}}$), and Korean ($\mathrm{M_{ko}}$) while the multilingual LM is trained on English

---

[2] (Nozza et al., 2020) maintain an ever-growing list of BERT models here

[3] Note that T can comprise of monolingual or multilingual models

and Hindi ($\mathrm{M_{en,hi}}$). Therefore, for each language, the corresponding set of teacher LMs ($\mathrm{T_k}$) can be defined as: [$\mathrm{T_{en}} = \{\mathrm{M_{en}}, \mathrm{M_{en,hi}}\}, \mathrm{T_{es}} = \{\mathrm{M_{es}}\}$, $\mathrm{T_{hi}} = \{\mathrm{M_{en,hi}}\}, \mathrm{T_{ko}} = \{\mathrm{M_{ko}}\}$]. First, the pretraining transfer corpora is tokenized and masked for each language using their respective teacher LM's tokenizer. For the language with two teachers, English, we tokenize each example using both the teacher LMs.

Step 2: Offline Teacher LM Evaluation

We now obtain predictions and logits for each masked, tokenized example in each language, by evaluating their respective teacher LMs. For English, we obtain predictions from both $\mathrm{M_{en}}$ and $\mathrm{M_{en,hi}}$ on their respective copies of each training example. In an ideal situation, we believe that multiple strong teachers can present a multi-view generalisation to the student as each teacher learns different features in training. Let x denote a sequence of tokens where $\mathrm{x_m} = \{\mathrm{x_1, x_2, x_3 ... x_n}\}$ denote the masked tokens, and $\mathrm{x_{-m}}$ denote the non-masked tokens. Let v be the vocabulary of student LM θ_s. In the conventional case of learning from gold labels, we minimize the cross-entropy of student logit distribution for a masked word $\mathrm{x_{m_i}}$, with the *one-hot label* $\mathrm{v_j}$, given by:

$$\mathrm{P(x_{m_i}, v_j)} = \mathbf{1}(\mathrm{x_{m_i} = v_j}) \times \log \mathrm{p(x_{m_i} = v_j | x_{-m}; \theta_s)} \tag{1}$$

With the teacher evaluations, we obtain predictions (and corresponding logits) of the teacher for the masked tokens. Let us denote the teacher output probability distribution (softmax over logits) for token $\mathrm{x_{m_i}}$ by $\mathrm{Q(x_{m_i} | x_{-m}; \theta_t)}$. Therefore, in addition to the loss from gold labels, we minimize the entropy between the student logits and the *teacher distribution*, given by :

$$\begin{aligned}\hat{\mathrm{P}}(\mathrm{x_{m_i}, v_j}) = \mathrm{Q(x_{m_i} = v_j | x_{-m}; \theta_t)} \times \\ \log \mathrm{p(x_{m_i} = v_j | x_{-m}; \theta_s)}\end{aligned} \tag{2}$$

It is extremely burdensome (both memory and time) to load multiple teacher LMs and obtain predictions during training. Hence, we first store the *top-k* logits for each masked word offline, loading and normalizing them during student LM training, similar to (Tan et al., 2019). Additionally, obtaining offline predictions gives one the freedom to use expensive teacher LMs without increasing the student model training costs and makes our framework teacher-architecture agnostic.

Step 3: Vocab Mapping

A deterrent in attempting to distill from multiple pre-trained teacher LMs is that each LM has its own vocabulary. This makes it non-trivial to uniformly process an input example for consumption by both the teacher and student LMs. Our student model's vocabulary is the union of *all* teacher LM vocabularies. In the vocab mapping step, the *input indices*, *prediction indices*, and the *gold label indices*, obtained after evaluation from each teacher LM are processed using a teacher→student vocab map. This converts each teacher token index to its corresponding student token index, ready for consumption by the student model. For simplicity, each teacher and student LM uses WordPiece tokenization (Schuster and Nakajima, 2012; Wu et al., 2016) in all our experiments.

Step 4: Student LM Training

The processed *input indices*, *prediction indices*, and *gold label indices* can now be used to train the multilingual student LM. In training, examples from different languages are shuffled together, even within a batch. We train the student LM with the MLM objective. Let $\mathrm{L_{MLM}}$ denote the MLM loss from gold labels. Therefore, with reference to Equation 1 :

$$\mathrm{L_{MLM}(x_m | x_{-m})} = -\frac{1}{\mathrm{n}} \sum_{\mathrm{i=1}}^{\mathrm{n}} \sum_{\mathrm{j=1}}^{|\mathrm{v}|} \mathrm{P(x_{m_i}, v_j)}$$

In addition to learning from gold labels, we use teacher predictions as soft labels and minimize the cross entropy between student and teacher distributions. Let $\mathrm{L_{KD}}$ denote the KD loss from a single teacher LM. With reference to Equation 2:

$$\mathrm{L_{KD}(x_m | x_{-m})} = -\frac{1}{\mathrm{n}} \sum_{\mathrm{i=1}}^{\mathrm{n}} \sum_{\mathrm{j=1}}^{|\mathrm{v}|} \hat{\mathrm{P}}(\mathrm{x_{m_i}, v_j});$$

The total loss across all languages is minimized, as shown below:

$$\mathrm{L_{ALL}} = \sum_{\mathrm{k=1}}^{\mathrm{K}} \lambda(\mathrm{L_{KD}^{T_k}}) + (1 - \lambda)\mathrm{L_{MLM}^{k}}$$

In the case of multiple teacher LMs, we have n tokenized instances for a given example (where n denotes the number of teachers for a particular language). In this case, each example in English has two copies – one tokenized using $\mathrm{M_{en}}$ and another using $\mathrm{M_{en,hi}}$. Thus, we explore two possibilities of training in this multi-teacher scenario :

- Include all the copies in training. Here the model is exposed to n different teacher LM predictions, each presenting a multi-view generalisation to the student LM.
- Include the best copy in training. The best copy is the one having minimum teacher LM loss for a given example. Here the model is only exposed to the best teacher LM predictions for each example.

4 Experiments

In this section, we aim to answer the following questions :

1) How effective is MergeDistill in combining *monolingual* teacher LMs, to train a *multilingual* student LM that leverages the benefits of multilinguality while performing competitively with individual teacher LMs? (Section 4.2)

2) How effective is MergeDistill in combining *multilingual* teacher LMs, trained on an overlapping set of languages, such that each language can benefit from *multiple* teachers? (Section 4.3)

3) How important are the teacher LM vocabulary and predictions in MergeDistill? Further, can MergeDistill enable pre-trained zero-shot transfer? (Section 4.4)

4.1 Setup

Data: For all our experiments, we use Wikipedia data as pre-training transfer corpora to train the student model, irrespective of the data used in training individual teacher LMs. We use $\alpha = 0.7$ for exponential smoothing of data across languages, similar to mBERT (Devlin et al., 2019).

Model Size: Since transformer-based models perform better as capacity increases (Conneau et al., 2020; Arivazhagan et al., 2019), we keep the number of parameters close to mBERT ($\sim$178M) by appropriately modifying the vocabulary embedding size (like Lan et al. (2019)) to isolate the positive effects of learning from teacher LMs.

Student	Language	Language Family	Model
$\mathrm{Student_{similar}}$	English	Indo-European	BERT(Devlin et al., 2019)
	German	Indo-European	DeepSet(Chan et al., 2020)
	Italian	Indo-European	ItalianBERT(Schweter, 2020b)
	Spanish	Indo-European	BETO(Cañete et al., 2020)
$\mathrm{Student_{dissimilar}}$	Arabic	Afroasiatic	AraBERT(Antoun et al., 2020)
	English	Indo-European	BERT(Devlin et al., 2019)
	Finnish	Uralic	FinBERT(Virtanen et al., 2019)
	Turkish	Turkic	BERTurk(Schweter, 2020a)
	Chinese	Sino-Tibetan	ChineseBERT(Devlin et al., 2019)

Table 1: *Monolingual BERT Models* used as teacher LMs. Please refer to Section 4.2 for details.

Distillation Parameters: We have two hyperparameter choices here: 1) k in top-k logits - as it increases, we observe that while performances remain similar, storing k>8 number of predictions for each masked word offline significantly increases resource requirements[4]. Hence, we set k=8 in all our experiments. 2) the value of λ in the loss function, which decides the proportion of teacher loss, is annealed through training similar to Clark et al. (2019).

Evaluation Metrics: We report F1 scores for structured prediction tasks (NER, POS), accuracy (Acc.) scores for sentence classification tasks (XNLI, PAWS-X), and F1/Exact Match (F1/EM) scores for question answering tasks (XQuAD, MLQA, TyDiQA). We also report a task-specific *relative deviation from teachers* (**RDT**) (in %) averaged across all languages (n). For each task, **RDT** is calculated as:

$$\mathrm{RDT}(\mathrm{S}, \{\mathrm{T}_1, ..., \mathrm{T}_\mathrm{n}\}) = \frac{100}{\mathrm{n}} \sum_{\mathrm{i}=1}^{\mathrm{n}} \frac{(\mathrm{P}_{\mathrm{T}_\mathrm{i}} - \mathrm{P}_\mathrm{S})}{\mathrm{P}_{\mathrm{T}_\mathrm{i}}} \tag{3}$$

where $\mathrm{P}_{\mathrm{T}_\mathrm{i}}$ and P_S are performances of the i^{th} teacher and student LMs, respectively.

4.2 Monolingual Teacher LMs

Pre-training: In this experiment, we use pre-existing monolingual teacher LMs, as shown in Table 1, to train a multilingual student LM on the union of all teacher languages. In this setup, $|\mathrm{T}_\mathrm{k}| = 1 \ \forall \ \mathrm{k} \in \mathrm{K}$, i.e., each language can learn from its respective monolingual teacher LM only.

Our teacher selection and setup follows a two-step process. First, we aim to select languages having pre-trained monolingual LMs available, and evaluation sets across a number of downstream tasks. This makes us choose teacher LMs for : Arabic (*ar*), Chinese (*zh*), English (*en*), Finnish (*fi*),

---

Table 2: Results for *monolingual teacher LMs and multilingual students* on downstream tasks as described in Section 4.2. Relative deviations of 5% or less from teacher (i.e., $\text{RDT} \geq -5\%$) are marked in bold. We find that Student$_{\text{similar}}$ outperforms individual teacher LMs, with a maximum gain of upto +2.8/+3.7% for QA, while Student$_{\text{dissimilar}}$ is competitive with teacher LMs, with a maximum drop of -1.3/-1.4% for QA. Please refer to Section 4.2 for details.

Student	Language	Teacher LM Tokens	Student LM Tokens	% of Data
Student$_{\text{similar}}$	English	3300M	2285M	69.25%
	German	23723M	847M	3.57%
	Italian	13139M	506M	3.85%
	Spanish	3000M	639M	21.31%
	Total	**43162M**	**4277M**	**9.9%**
Student$_{\text{dissimilar}}$	Arabic	8600M	135M	1.58%
	English	3300M	2285M	69.25%
	Finnish	3000M	83M	2.77%
	Turkish	4405M	60M	1.36%
	Chinese	71M	71M	100.00%
	Total	**19376M**	**2634M**	**13.6%**

Table 3: *Number of Tokens (in Millions)* in the teacher (Table 1) and student LMs as described in Section 4.2

German (*de*), Italian (*it*), Spanish (*es*), and Turkish (*tr*). Second, as previous work has evidenced positive transfer between related languages in a multilingual setup (Pires et al., 2019; Wu and Dredze, 2020), we further group the chosen teacher LMs based on language families as shown in Table 1, where:

i) Student$_{\text{similar}}$ is trained on four closely related languages from the Indo-European family – *de*, *en*, *es* and *it*.

ii) Student$_{\text{dissimilar}}$ is trained on languages from different language families – *ar*, *en*, *fi*, *tr* and *zh*.

Both student LMs have a BERT-base architecture. Student$_{\text{similar}}$ has a vocabulary size of 99,112 with a total of 162M parameters, while Student$_{\text{dissimilar}}$ has a vocabulary size of 180,996 with a total of 225M parameters. We keep a batch size of 4096 and train for 250,000 steps with a maximum sequence length of 512.

Fine-tuning: We evaluate both the teacher and student LMs on three downstream tasks with in-language fine-tuning for each task[5] :

i) Named Entity Recognition *(NER)*: We use the WikiAnn (Pan et al., 2017; Rahimi et al., 2019) dataset for all languages.

ii) Part-of-Speech Tagging *(UDPOS)*: We use the Universal Dependencies v2.6 (Zeman et al., 2020) dataset for all languages.

iii) Question Answering *(QA)*: We use DRCD for *zh* (Shao et al., 2018), TQuAD[6] for *tr*, SQuADv1.1 (Rajpurkar et al., 2016) for *en*, SQuADv1.1-translated for *it* (Croce et al., 2018) and *es* (Carrino et al., 2020) and the TyDiQA-GoldP dataset (Clark et al., 2020) for *ar* and *fi*.

Results: We report results of our teacher and student LMs in Table 2. Overall, we find that Student$_{\text{similar}}$ outperforms individual teacher models on NER (+0.6%) and QA (+2.8/3.7%) while performing competitively on UDPOS (-0.1%). Student$_{\text{dissimilar}}$ is competitive with the teacher LMs with only small differences of up to 1.3/1.4% (QA), as shown in Table 2. For each language, we find Student$_{\text{similar}}$ is either competitive or outperforms its respective teacher LM. Our results provide evidence for positive transfer across languages in two ways. First, we observe that Student$_{\text{similar}}$ outperforms Student$_{\text{dissimilar}}$ for the common language - English. Given that the English teacher (BERT) and the pre-training transfer corpora[7] is common for both student LMs,

---

[5] More details in Appendix A.3

[6] https://tquad.github.io/turkish-nlp-qa-dataset

[7] In fact, we can hypothesize that Student$_{\text{dissimilar}}$ sees more English tokens as compared to Student$_{\text{similar}}$ because the Non-English languages in Student$_{\text{dissimilar}}$ are relatively low resourced (a sum total of 349M unique tokens) in comparison to Student$_{\text{similar}}$ (a sum total of 1992M unique tokens)

Table 4: *Results for multilingual teacher and student LMs* on the XTREME benchmark. We compare performances of three student LM variants as described in Section 4.3 to the two teachers mBERT and MuRIL. Relative deviations of 5% or less from teacher (i.e., $\mathrm{RDT} \geq -5\%$) are marked in bold. Overall, we find that $\mathrm{Student}_{\mathrm{MuRIL}}$ performs the best among all student variants and report its RDT (in %) (Equation 3) from the two teachers. Please refer to Section 4.3 for a detailed analysis.

we can attribute this gain to the fact that English is trained with linguistically and typologically similar languages in $\mathrm{Student}_{\mathrm{similar}}$. Second, $\mathrm{Student}_{\mathrm{similar}}$ outperforms its teacher LMs while $\mathrm{Student}_{\mathrm{dissimilar}}$ is competitive for *all* languages. These two results across *all* languages point towards $\mathrm{Student}_{\mathrm{similar}}$ benefiting from a positive transfer across similar languages. In Table 3, we observe that $\mathrm{Student}_{\mathrm{similar}}$ is trained on 9.9% of the total unique tokens seen by its respective teacher LMs and $\mathrm{Student}_{\mathrm{dissimilar}}$ lies close with 13.6%. Despite this huge disparity in pre-training corpora, student LMs are competitive with their teachers. This encouraging result proves that even with very limited data, MERGEDISTILL enables one to combine strong monolingual teacher LMs to train competitive student LMs that can leverage the benefits of multilinguality.

4.3 Multilingual Teacher LMs

Pre-training: In this experiment, we make use of pre-existing multilingual models: mBERT and MuRIL. mBERT is trained on 104 languages and MuRIL covers 12 of these (11 Indian languages + English): Bengali (*bn*), English (*en*), Gujarati (*gu*), Hindi (*hi*), Kannada (*kn*), Malayalam (*ml*), Marathi (*mr*), Nepali (*ne*), Punjabi (*pa*), Tamil (*ta*), Telugu (*te*), and Urdu (*ur*), with higher performance for these languages on the XTREME benchmark. We train the student model on all 104 languages. In this case, the *MuRIL Languages* (MuL) have two teachers (mBERT and MuRIL) and the *Non-MuRIL Languages* (Non-MuL) can learn from mBERT only. Therefore, while we only use mBERT as the teacher LM for Non-MuL across all experiments, we consider three possibilities for MuL :

i) $\mathbf{Student}_{\mathbf{MuRIL}}$: We only use MuRIL as the teacher LM and each input training example is tokenized using MuRIL.
ii) $\mathbf{Student}_{\mathbf{mBERT}}$: We only use mBERT as the teacher LM and each input training example is tokenized using mBERT.
iii) $\mathbf{Student}_{\mathbf{Both}}$: As highlighted in Section 3, we consider two possibilities to incorporate both teacher LM predictions in training:

- **$\mathbf{Student}_{\mathbf{Both\_all}}$**: Tokenize each input example using mBERT and MuRIL separately and include both copies in training.
- **$\mathbf{Student}_{\mathbf{Both\_best}}$**: Tokenize each input example using mBERT and MuRIL separately and include only the best copy in training. The best copy is the one having minimum teacher LM loss for the example.

Note, it is non-trivial to tokenize each example in a way that is compatible with all teacher LMs. One must resort to tokenization using an intersection of vocabularies which is sub-optimal.

All the student LMs use a BERT-base architecture and have a vocabulary size of 288,973. We reduce our embedding dimension to 256 as opposed to

---

as shown in Table 3

Model	Vocabulary	Labels	PANX	UDPOS	PAWSX	XNLI	XQUAD	MLQA	TyDiQA	Avg.
SM1	mBERT	Gold	63.2	73.0	94.8	71.2	70.2/57.9	65.1/51.3	60.8/48.7	71.2
SM2	mBERT∪MuRIL	Gold	**69.3**	**73.9**	95.3	71.2	**76.2/63.1**	71.1/56.0	70.9/56.0	**75.4**
SM3	mBERT∪MuRIL	Gold+Teacher	**69.3**	72.3	**95.4**	**71.9**	75.7/62.1	**72.0/56.3**	**70.7/59.2**	75.3
SM2_100k	mBERT∪MuRIL	Gold	65.5	72.3	94.3	67.5	72.3/58.2	66.9/51.5	62.5/51.9	71.6
SM3_100k	mBERT∪MuRIL	Gold+Teacher	71.2	73.5	93.1	69.6	76.4/62.9	69.1/53.9	68.6/54.9	74.5

Table 5: *Importance of teacher vocabulary and predictions in* MERGEDISTILL. We observe maximum performance gains, by changing the vocabulary from mBERT in SM1 to (mBERT∪MuRIL) vocabulary in SM2. Here, SM3 is the standard $\mathrm{Student}_{\mathrm{MuRIL}}$. We also observe that SM3_100k, trained for 20% of the total training steps, is competitive to SM3 and significantly outperforms SM2_100k, highlighting the importance of teacher LM predictions in a limited data scenario. Please see Section 4.4 for details.

768 to bring down the model size to be around 160M, comparable to mBERT (178M). We keep a batch size of 4096 and train for 500,000 steps with a maximum sequence length of 512.

Finetuning: We report zero-shot performance for all languages in the XTREME (Hu et al., 2020) benchmark[8].

Results: We report results of our teacher and student LMs in Table 4. Overall, we find that $\mathrm{Student}_{\mathrm{MuRIL}}$ performs the best among all student variants. For Non-MuL, $\mathrm{Student}_{\mathrm{MuRIL}}$ beats the teacher (mBERT) by an average relative score of 3.8%. For MuL, $\mathrm{Student}_{\mathrm{MuRIL}}$ beats one teacher (mBERT) by 8.8%, but underperforms the other teacher (MuRIL) by 3.8%. There can be two factors at play here. MuRIL is trained on monolingual and parallel data [9] while the student LMs only see $\sim$22% of unique tokens in comparison. MuRIL also has different language sampling strategies ($\alpha = 0.3$ as opposed to 0.7 in our setting, where a lower α value upsamples more rigorously from the tail languages), which have a significant role to play in multilingual model performances (Conneau et al., 2020). We also observe a significant drop in $\mathrm{Student}_{\mathrm{mBERT}}$'s performance for MuL when compared to the other student LM variants. This might be because the input is tokenized using the mBERT tokenizer which prevents learning from MuRIL tokens in the student vocabulary. For $\mathrm{Student}_{\mathrm{Both}}$, we do not observe much of a difference between $\mathrm{Student}_{\mathrm{Both\_all}}$ and $\mathrm{Student}_{\mathrm{Both\_best}}$. This observation may differ with one's choice of teacher LMs depending on how well it performs for a particular language. In our case, we don't observe much of a difference in incorporating mBERT predictions for MuL.

4.4 Further Analysis

The importance of vocabulary and teacher LM preditions: In Table 4, we see that $\mathrm{Student}_{\mathrm{MuRIL}}$ significantly outperforms mBERT for MuL, despite both being trained on Wikipedia corpora, and having comparable model sizes. With regard to MuL, $\mathrm{Student}_{\mathrm{MuRIL}}$ differs from mBERT in two main aspects – **i)** $\mathrm{Student}_{\mathrm{MuRIL}}$'s vocabulary is a union of mBERT and MuRIL vocabularies. **ii)** $\mathrm{Student}_{\mathrm{MuRIL}}$ is trained with additional MuRIL predictions as soft labels. To disentangle the role both these factors play in $\mathrm{Student}_{\mathrm{MuRIL}}$'s improved performance, we train two models :
i) SM1 is trained exactly like $\mathrm{Student}_{\mathrm{MuRIL}}$, but with mBERT vocabulary and on gold labels.
ii) SM2 is trained using $\mathrm{Student}_{\mathrm{MuRIL}}$'s vocabulary (mBERT ∪ MuRIL) but on gold labels only, without teacher predictions.

The results are summarized in Table 5. Note, we refer to $\mathrm{Student}_{\mathrm{MuRIL}}$ as SM3. Overall, we observe a $\sim$**4.2%** gain in average performance for SM2 over SM1. This clearly highlights that given fixed data and model capacity, LM training significantly benefits by incorporating a strong teacher's vocabulary.

Furthermore, we also observe that SM2 and SM3 achieve competitive performances despite SM3 being additionally trained on teacher LM labels. To motivate the need for teacher predictions, Hinton et al. (2015) argue that when soft targets have high entropy, they provide much more information per training case than hard targets and can be trained on *much less data* than the original cumbersome model. In our case, we hypothesize that training on 500,000 steps exposes the model to sufficient data for it to generalize well enough and mask the benefits of teacher LM predictions. To validate this, we evaluate the performances of SM2 and SM3,

---

[8] More details in Appendix A.3

[9] More details in Appendix A.2

20% into training (i.e. 100,000 steps / 500,000 total steps) as shown in Table 5. We observe a ∼**2.9%** gain in average performance for SM3 over SM2, clearly highlighting the importance of teacher LM predictions in a limited data scenario. This is especially important when one has access to very limited monolingual data and a strong teacher LM for a particular language.

Pre-trained zero-shot transfer: Interestingly, $\text{Student}_{\text{MuRIL}}$ performs the best on almost all tasks for *Non-MuL*. This hints at positive transfer from strong teachers to languages that the teacher does not cover at all, due to the shared multilingual representations.[10] This would mean that learning from strong teachers can improve the student model's performance in a zero-shot manner on related languages not covered by the teacher. This would make MERGEDISTILL highly beneficial for low-resource languages that do not have a strong teacher or limited gold data. We leave this exploration to future work.

5 Conclusion

In this paper we address the problem of merging multiple pre-trained teacher LMs into a single multilingual student LM by proposing MERGEDISTILL, a task-agnostic distillation method. To the best of our knowledge, this is the first attempt of its kind. The student LM learned by MERGEDISTILL may be further fine-tuned for any task across all of the languages covered by the teacher LMs. Our approach results in better maintainability (fewer models) and is compute efficient (due to offline predictions). We use MERGEDISTILL to **i)** combine *monolingual* teacher LMs into one student multilingual LM which is competitive with the teachers, thereby demonstrating positive cross-lingual transfer, and **ii)** combine multilingual LMs to train student LMs that learn from *multiple* teachers. Through experiments on multiple benchmark datasets, we show that student LMs learned by MERGEDISTILL perform competitively or even outperform teacher LMs trained on orders of magnitude more data. We disentangle the positive impact of incorporating strong teacher LM vocabularies and learning from teacher LM predictions, highlighting the importance of the latter in a limited data scenario. We also find that MERGEDISTILL enables positive transfer from strong teachers to languages not covered by them (i.e. zero-shot transfer). Our work bridges the gap between the universe of language-specific models and massively multilingual LMs, incorporating benefits of both into one framework.

6 Acknowledgements

We would like to thank the anonymous reviewers for their insightful and constructive feedback. We thank Iulia Turc, Ming-Wei Chang, and Slav Petrov for valuable comments on an earlier version of this paper.

A Appendix

A.1 Knowledge Distillation

We train our LMs with the MLM objective. Let x denote a sequence of tokens where $\mathrm{x_m} = \{\mathrm{x_1, x_2, x_3 ... x_n}\}$ denote the masked tokens, and $\mathrm{x_{-m}}$ denote the non-masked tokens. Let v be the vocabulary of LM θ. The log-likelihood loss (cross-entropy with one-hot label) can be formulated as follows:

$$\mathrm{L_{MLM}(x_m|x_{-m})} = -\frac{1}{\mathrm{n}}\sum_{\mathrm{i=1}}^{\mathrm{n}}\sum_{\mathrm{k=1}}^{|\mathrm{v}|}\mathrm{P(x_{m_i}, k)};$$

$$\mathrm{P(x_{m_i}, k)} = \mathbf{1}(\mathrm{x_{m_i} = k})\mathrm{log p(x_{m_i} = k|x_{-m}; \theta)}$$

In a distillation setup, the student is trained to not only match the one-hot labels for masked words, but also the probability output distribution of the teacher t. Let us denote the teacher output probability distribution for token $\mathrm{x_{m_i}}$ by $\mathrm{Q(x_{m_i}|x_{-m}; \theta_t)}$. The cross entropy between the teacher and student distributions then serves as the distillation loss :

$$\mathrm{L_{KD}(x_m|x_{-m})} = -\frac{1}{\mathrm{n}}\sum_{\mathrm{i=1}}^{\mathrm{n}}\sum_{\mathrm{k=1}}^{|\mathrm{v}|}\hat{\mathrm{P}}\mathrm{(x_{m_i}, k)};$$

$$\begin{aligned}\hat{\mathrm{P}}\mathrm{(x_{m_i}, k)} = \mathrm{Q(x_{m_i}} &= \mathrm{k|x_{-m}; \theta_t)} \\ \mathrm{log p(x_{m_i}} &= \mathrm{k|x_{-m}; \theta)}\end{aligned}$$

The total loss is then defined as :

$$\mathrm{L_{ALL}} = \lambda \mathrm{L_{KD}} + (1-\lambda)\mathrm{L_{MLM}}$$

With the addition of the teacher, the target distribution is no longer a single one-hot label, but a smoother distribution with multiple words having non-zero probabilities which yields in a smaller variance in gradients (Hinton et al., 2015). Intuitively, a single masked word can have several valid predictions, which appropriately fit the context.

Teacher	Language	Teacher LM Tokens	Student LM Tokens	% of Data
MuRIL	Bengali	1181M	27M	2.30%
	English	6986M	2816M	40.30%
	Gujarati	173M	7M	3.90%

	Urdu	722M	23M	3.21%
	Total	**13709M**	**3018M**	**22%**

Table 6: *Number of Tokens (in Millions)* in the teacher (MuRIL) and student LMs as described in Section 4.3. Note, we only show the *MuRIL Languages* here because for *Non-MuRIL Languages*, the teacher (mBERT) and student variants are trained on the same data.

A.2 Pre-training Details

A.2.1 Monolingual Teacher LMs

We pre-train our student models using the BERT base architecture. $\text{Student}_{\text{similar}}$ has a vocabulary size of 99112 and a model size of 162M parameters. $\text{Student}_{\text{different}}$ has a vocabulary size of 180996 and a model size of 225M parameters. We keep a batch size of 4096 and train for 250k steps with a maximum sequence length of 512. We use TPUs, and it takes around 1.5 days to pre-train each student LM.

A.2.2 Multilingual Teacher LMs

We pre-train our student models using the BERT base architecture. All student LMs have a vocabulary size of 288973. Hence, we reduce our embedding dimension to 256 as opposed to 768 to bring down the model size to be around 160M, comparable to mBERT (178M). We keep a batch size of 4096 and train for 500k steps with a maximum sequence length of 512. We use TPUs, and it takes around 3 days to pre-train each student LM.

We present pre-training data statistics for MuRIL and the student LMs in Table 6. Here we only include the monolingual data statistics, but MuRIL is additionally trained on parallel translated and transliterated data.

Task	Batch	Learning Rate	No. of Epochs	Warmup Ratio	Max. seq. Length
NER	32	3e-5	10	0.1	256
POS	32	3e-5	10	0.1	256
QA	32	3e-5	10	0.1	384

Table 7: Hyperparameter Details for each fine-tuning task in Section 4.2

A.3 Fine-tuning Details

A.3.1 Monolingual Teacher LMs

Data Statistics We evaluate our monolingual teacher LMs and multilingual student LMs, as described in Section 4.2, on three tasks as follows:

i) Named Entity Recognition (NER): We use the WikiAnn (Pan et al., 2017; Rahimi et al., 2019) dataset for all languages. Each language comprises of a train/dev/test split of 20000/10000/10000 tokens. Specifically, we use the huggingface re-packaged implementation of the dataset[11].

ii) Part-of-Speech tagging (POS): We use the Universal Dependencies v2.6 (Zeman et al., 2020) dataset for all languages. Detailed statistics for each language can be found in Table 9. Specifically, we use the huggingface re-packaged implementation of the dataset[12].

iii) Question Answering (QA): We use the TyDiQA dataset (Clark et al., 2020) for *ar* and *fi*, SQuADv1.1 (Rajpurkar et al., 2016) for *en*, SQuAD-translated for *it* (Croce et al., 2018) and *es* (Carrino et al., 2020), DRCD for *zh* (Shao et al., 2018) and TQuAD[13] for *tr*. Detailed statistics for each language can be found in Table 10. Note, we use the dev set as our test sets, since most datasets only have a train/dev split. We use 10% of randomly shuffled training examples as our dev sets.

Hyperparameter Details: We use the same hyperparameters for fine-tuning all teacher and student LMs, as shown in Table 7. We report results on the best-performing checkpoint for the validation set. The performance of the best checkpoint on validation sets are shown in Table **??**

A.3.2 Multilingual Teacher LMs

Data Statistics We evaluate all the teacher (mBERT and MuRIL) and student ($\mathrm{Student}_{\mathrm{MuRIL}}$, $\mathrm{Student}_{\mathrm{mBERT}}$ and $\mathrm{Student}_{\mathrm{Both}}$) LMs on the XTREME (Hu et al., 2020) benchmark. We fine-tune the pre-trained models on English training data for the particular task, except TyDiQA, where we use additional SQuAD v1.1 English training data, similar to (Fang et al., 2020). All results are computed in a zero-shot setting.

Hyperparameter Details We use the same hyperparameters for fine-tuning all teacher and student LMs, as shown in Table 11. We report results on the best-performing checkpoint for the eval set.

Task	Batch	Learning Rate	No. of Epochs	Warmup Ratio	Max. seq. Length
PANX	32	2e-5	10	0.1	128
UDPOS	64	5e-6	10	0.1	128
PAWSX	32	2e-5	5	0.1	128
XNLI	32	2e-5	3	0.1	128
XQuAD	32	3e-5	2	0.1	384
MLQA	32	3e-5	2	0.1	384
TyDiQA	32	3e-5	2	0.1	384

Table 11: Hyperparameter Details for each task in XTREME

A.4 Different top-k values

We present results for $\mathrm{Student}_{\mathrm{MuRIL}}$ trained with different top-k values from teacher predictions in Table 8. We observe that while performances remain similar for higher values of k, storage becomes increasingly expensive. Hence, we stick to a value of k=8 in all our experiments.

On Sparsifying Encoder Outputs in Sequence-to-Sequence Models

Abstract

Sequence-to-sequence models usually transfer *all* encoder outputs to the decoder for generation. In this work, by contrast, we hypothesize that these encoder outputs can be compressed to shorten the sequence delivered for decoding. We take Transformer as the testbed and introduce a layer of stochastic gates in-between the encoder and the decoder. The gates are regularized using the expected value of the sparsity-inducing L_0 penalty, resulting in completely masking-out a subset of encoder outputs. In other words, via joint training, the $\mathcal{L}_0$Drop layer forces Transformer to route information through a subset of its encoder states. We investigate the effects of this sparsification on two machine translation and two summarization tasks. Experiments show that, depending on the task, around 40–70% of source encodings can be pruned without significantly compromising quality. The decrease of the output length endows $\mathcal{L}_0$Drop with the potential of improving decoding efficiency, where it yields a speedup of up to 1.65× on document summarization and 1.20× on character-based machine translation against the standard Transformer. We analyze the $\mathcal{L}_0$Drop behaviour and observe that it exhibits systematic preferences for pruning certain word types, e.g., function words and punctuation get pruned most. Inspired by these observations, we explore the feasibility of specifying rule-based patterns that mask out encoder outputs based on information such as part-of-speech tags, word frequency and word position. [1]

1 Introduction

Neural sequence-to-sequence (Seq2Seq) models have dominated various text generation tasks, including machine translation (Vaswani et al., 2017) and abstractive document summarization (Gehrmann et al., 2018; Liu and Lapata, 2019). These models generally follow the encoder-decoder paradigm, where the encoder interprets source context and converts source words into vector representations such that the decoder has sufficient information to predict the target sequence. Early Seq2Seq models (Sutskever et al., 2014; Cho et al., 2014) provided only the last and/or first encoder states to the decoder. In contrast, modern approaches rely on the attention mechanism (Bahdanau et al., 2015) and implicitly make an assumption that information from *all* encoder outputs should flow to the decoder.[2] However, this assumption neglects the fact that a large portion of source words in machine translation receives just minor attention as shown in Figure 1, let alone in summarization where the input contains redundant expressions and large parts of text are not relevant to any plausible summary. Moreover, information content varies

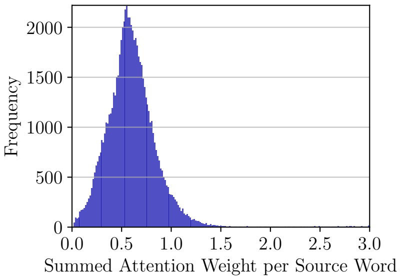

Figure 1: Distribution of the summed attention weight per source word estimated on the English-German WMT14 test set. For each (source sentence, translation) pair, we extract the attention matrices from all encoder-decoder attention sublayers in Transformer and average them over different (8) heads and (6) layers. The attention value for each source word is summed over all target words in the translation. Higher attention weights suggest larger impacts on translation. Around 49.7% source words get attention weights of less than 0.6, compared to the mean value of 1.03.

Vanilla Attention

Sparse Attention

L_0Drop(Ours)

Figure 2: Encoder-decoder attention distribution of target words (y-axis) over source words (x-axis) for the vanilla attention (Vaswani et al., 2017), the sparse attention (Correia et al., 2019) and our model. Darker color indicates larger attention weight, and the white blocks denote an attention weight of 0. The source words whose encoding is pruned by $\mathcal{L}_0$Drop (receiving zero weight) are highlighted in red.

across words, for example, it is negatively correlated with event frequency (Shannon, 1948; Zipf, 1949). When moving from word-level to character-level processing, the notion of encoding information and computing attention on the level of characters also seems excessive. Previous work has proposed hierarchical architectures where character-level encodings are compressed into word-level or span-level states (Ling et al., 2015; Lee et al., 2017).

In this work, we hypothesize that encoder outputs are compressible and we can force Seq2Seq model to route information through their subset. Figure 2 illustrates our intuition as well as the difference with existing work (Vaswani et al., 2017; Correia et al., 2019). Instead of dynamically sparsifying attention weights for individual decoder steps (Correia et al., 2019), we aim at detecting uninformative source encodings and dropping them to shorten the encoding sequence before generation. To this end, we build on recent work on sparsifying weights (Louizos et al., 2018) and activations (Bastings et al., 2019) of neural networks. Specifically, we insert a differentiable neural sparsity layer ($\mathcal{L}_0$Drop) in-between the encoder and the decoder. The layer can be regarded as providing a multiplicative scalar gate for every encoder output. The gate is a random variable and, unlike standard attention, can be exactly zero, effectively masking out the corresponding source encodings. The sparsity is promoted by introducing an extra term to the learning objective, i.e. an expected value of the sparsity-inducing L_0 penalty. By varying the coefficient for the regularizer, we can obtain different levels of sparsity. Importantly, the objective remains fully end-to-end differentiable.

Given an encoding sequence of length N, the vanilla attention model attends to it recurrently for M steps at the decoding phase, leading to a computational complexity of $\mathcal{O}(NM)$ ($N = 6$, $M = 6$ in Figure 2). This could be costly if N or M is very large. With the induced sparse structure by $\mathcal{L}_0$Drop, we introduce a specialized decoding algorithm which lowers this complexity to $\mathcal{O}(N'M)$ ($N' \leq N$, and $N' = 3$ in Figure 2). As a result, $\mathcal{L}_0$Drop can improve decoding efficiency by reducing the encodings' length, especially for long inputs.

We apply $\mathcal{L}_0$Drop to Transformer (Vaswani et al., 2017), the state-of-the-art Seq2Seq model. We conduct extensive experiments on WMT translation tasks with two language pairs and document summarization tasks covering single document and multiple documents settings. We also explore character-based machine translation where the lengthy character sequence often leads to slow inference. We analyze how pruning source encodings impacts the generation quality and which word types get pruned. Inspired by the analysis of $\mathcal{L}_0$Drop, we further study rule-based sparsity patterns , such as deterministically filtering out the encodings of words with specific POS tags, high-frequency words or simply attending to every other word in the sequence.

Our main findings are summarized as follows:

- We confirm that the encoder outputs can be compressed, around 40–70% of them can be dropped without large effects on the generation quality.
- The resulting sparsity level differs across word types, the encodings corresponding to function words (such as determiners, prepositions) are more frequently pruned than those of content words (e.g., verbs and nouns).
- $\mathcal{L}_0$Drop can improve decoding efficiency particularly for lengthy source inputs. We achieve a decoding speedup of up to 1.65× on document summarization tasks and 1.20× on character-based machine translation task.
- Filtering out source encodings with rule-based sparse patterns is feasible, and confirms information-theoretic expectations, although rule-based patterns do not generalize well across tasks.

2 Related Work

Approaches to compression in Seq2Seq models fall into the category of model parameter compression (See et al., 2016), sequential knowledge distillation (Kim and Rush, 2016) or sparse attention induction that ranges from modeling hard attention (Wu et al., 2018) to developing differentiable sparse softmax functions or regularizing attention weights for sparsity (Niculae and Blondel, 2017; Correia et al., 2019; Cui et al., 2019; Zhang et al., 2019). Unfortunately, the success of all these studies builds upon the access to all source encodings in training and decoding. Learning which encoder outputs to prune in Seq2Seq models, to the best of our knowledge, has never been investigated before. Sukhbaatar et al. (2019) learn attention spans in self-attention and discard information from states outside of the span; this method is not directly applicable to encoder-decoder attention.

We use the differentiable L_0-relaxation which was first introduced by Louizos et al. (2018) in the context of pruning individual neural network parameters. It was previously used to prune heads in multi-head attention (Voita et al., 2019). Our work is more similar in spirit to Bastings et al. (2019) where they used the L_0 relaxations to construct interpretable classifiers, i.e. models that can reveal which words they rely on when predicting a class. In their approach, the information from dropped words is lost rather than rerouted into the states of retained words, as desirable for interpretability but problematic in the text generation set-up.

The number of the source encodings selected by $\mathcal{L}_0$Drop is sentence-dependent, which differs from the linear-time model of Wang et al. (2019), although both can accelerate decoding. Our study of rule-based sparsity patterns is in line with the sparse Transformer (Child et al., 2019) though we also explore the use of external linguistic information (POS tag) in our sparsification rules, and focus on encoder outputs instead of self-attention.

Character-based translation gained increasing popularity due to its capability of handling out-of-vocabulary issues while avoiding tokenization and subword segmentation (Ling et al., 2015; Costa-jussà and Fonollosa, 2016; Sennrich, 2017; Cherry et al., 2018). Recent efforts often focus on closing the performance gap against its subword-level counterpart (Libovický and Fraser, 2020; Gao et al., 2020), but little study explores solutions to improve its inefficient inference resulted from the long character sequences. In this respect, Cherry et al. (2018) proposed to use conditional computation to dynamically compress encoder states. Similar to our results, they also observed a trade-off between the translation quality and the degree of compression.

3 Background: Transformer

We take Transformer (Vaswani et al., 2017) as our testbed. Transformer uses the dot-product attention network as its backbone to handle intra- and inter-sequence dependencies:

$$\textsc{Att}(\mathbf{H}, \mathbf{M}) = \mathbf{AV} = \textsc{Sm}\left(\frac{\mathbf{QK}^T}{\sqrt{d}}\right)\mathbf{V}, \qquad (1)$$

where $\mathbf{Q}, \mathbf{K}, \mathbf{V} = \mathbf{HW}_q, \mathbf{MW}_k, \mathbf{MW}_v$. The input $\mathbf{H} \in \mathbb{R}^{J \times d}$ of length J queries and summarizes task-relevant clues from the memory $\mathbf{M} \in \mathbb{R}^{I \times d}$ of length I based on their dot-product semantic matching $\mathbf{A} \in \mathbb{R}^{J \times I}$. $\textsc{Sm}$ denotes the softmax function, d is the model dimension, and $\mathbf{W}_q$, $\mathbf{W}_k, \mathbf{W}_v \in \mathbb{R}^{d \times d}$ are trainable model parameters. Vaswani et al. (2017) also extend this mechanism to multi-head attention.

Given a source sequence $X = (x_1, x_2, \ldots, x_N)$, Transformer maps it to the target sequence $Y = (y_1, y_2, \ldots, y_M)$ following the encoder-decoder paradigm (Bahdanau et al., 2015):[3]

$$\begin{aligned} \mathbf{X}^L &= \text{Encoder}\left(\mathbf{X}^0\right) && (2) \\ &\overset{L}{\underset{l=1}{:=}} \textsc{Ffn}\left(\textsc{Att}(\mathbf{X}^{l-1}, \mathbf{X}^{l-1})\right), \\ \mathbf{Y}^L &= \text{Decoder}\left(\mathbf{Y}^0, \mathbf{X}^L\right) && (3) \\ &\overset{L}{\underset{l=1}{:=}} \textsc{Ffn}\left(\textsc{Att}\left(\overline{\textsc{Att}}(\mathbf{Y}^{l-1}, \mathbf{Y}^{l-1}), \mathbf{X}^L\right)\right), \end{aligned}$$

where $\mathbf{X}^0 \in \mathbb{R}^{N \times d}$ and $\mathbf{Y}^0 \in \mathbb{R}^{M \times d}$ stand for the source and the shifted target sequence embedding, respectively, enriched with positional encoding (Vaswani et al., 2017). $\textsc{Ffn}(\cdot)$ is a point-wise feed-forward network. $\overline{\textsc{Att}}(\cdot, \cdot)$ in the decoder denotes masked $\textsc{Att}(\cdot, \cdot)$ which prevents access to future target words. Both the encoder and the decoder involve a stack of L identical layers, with the encoder output $\mathbf{X}^L$ fed to the decoder via an encoder-decoder attention sublayer, i.e. the $\textsc{Att}(\cdot, \cdot)$ in Eq. (3). Based on the decoder output $\mathbf{Y}^L$, Transformer performs the next-word prediction and adopts the maximum likelihood loss for training.

4 Neural Sparsity Layer: $\mathcal{L}_0$Drop

In this section, we introduce a neural sparsity layer ($\mathcal{L}_0$Drop), which we use to prune encoder outputs.

---

[3] Each sublayer ($\textsc{Att}$/$\overline{\textsc{Att}}$/$\textsc{Ffn}$) in the encoder and decoder is wrapped with residual connection (He et al., 2015) followed by layer normalization (Ba et al., 2016), which are dropped in Eq. (2) and (3) for clarity.

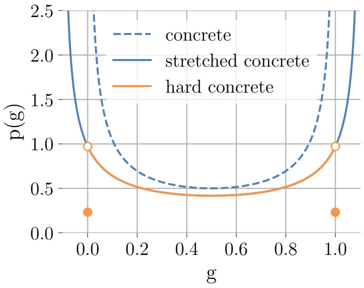

Figure 3: Hard concrete distribution (orange curve): samples are first stretched from the binary concrete distribution (dashed blue curve) to a stretched distribution (solid blue curve), and then rectified to collapse the probability mass of the shadow areas into $\{0\}$ and $\{1\}$ (solid orange points).

At inference time, only retained encoder outputs will be used as input to the decoder.

4.1 Training with $\mathcal{L}_0$Drop

Intuitively, $\mathcal{L}_0$Drop assigns each encoder output $\mathbf{x}_i^L$ a gate $g_i \in [0, 1]$ ($i \in \{1, \ldots, N\}$)

$$\mathcal{L}_0\text{Drop}(\mathbf{x}_i^L) = g_i \mathbf{x}_i^L, \tag{4}$$

and prunes encodings by closing their gates, i.e. $g_i = 0$, relying on adding a differentiable sparsity-inducing penalty to the objective.

More formally, to achieve sparsity, each gate is assumed to be a random variable and its value is drawn from the HardConcrete distribution:

$$g_i \sim \text{HardConcrete}(\alpha_i, \beta, \epsilon), \tag{5}$$

where α_i, β and ϵ are shape parameters of the distribution. HardConcrete (Louizos et al., 2018) is a parameterized family of mixed discrete-continuous distributions over the closed interval $[0, 1]$. These distributions have point mass at 0 and 1 and continuous density in-between, i.e. in $(0, 1)$, as shown in Figure 3. Thus, the gates will have a non-zero probability of being exactly 0, corresponding to masking out the input completely.

Specifically, the sample from HardConcrete distribution is obtained by stretching and rectifying samples from BinaryConcrete distributions (Maddison et al., 2017; Jang et al., 2017):

$$s_i \sim \text{BinaryConcrete}(\alpha_i, \beta) \tag{6}$$
$$\bar{s}_i = s_i (1 + 2\epsilon) - \epsilon, \tag{7}$$
$$g_i = \min(1, \max(0, \bar{s}_i)). \tag{8}$$

In the above expression, we first obtain a sample from the BinaryConcrete distribution (Eq. (6)), then stretch it from $(0, 1)$ to $(-\epsilon, 1 + \epsilon)$ (Eq. (7), $\epsilon > 0$), and finally rectify with a hard sigmoid to the closed interval $[0, 1]$ (Eq. (8)).

The probability of g_i being exactly 0 ($p(g_i = 0|\alpha_i, \beta, \epsilon)$) equals the probability of $\bar{s}_i$ hitting $(-\epsilon, 0)$ and is available in a closed form (Louizos et al., 2018):

$$p(g_i = 0|\alpha_i, \beta, \epsilon) = \sigma(\beta \log \frac{\epsilon}{1 + \epsilon} - \log \alpha_i),$$

where $\sigma(\cdot)$ denotes the sigmoid function. The parameter α_i (i.e. the location parameter of BinaryConcrete) is predicted relying on the encoder output $\mathbf{x}_i$:

$$\log \alpha_i = \mathbf{x}_i^L \mathbf{w}^T, \tag{9}$$

where $\mathbf{w} \in \mathbb{R}^d$ is a learned parameter vector; the temperature β and the stretch degree ϵ are treated as hyperparameters. By adjusting α_i the model can change the shape of the HardConcrete distribution, and dynamically decide which outputs to pass to the decoder and which to prune.

Note that the sum

$$\mathcal{L}_0(X) = \sum_{i=1}^{N} 1 - p(g_i = 0|\alpha_i, \beta, \epsilon), \tag{10}$$

yields the expected number of open gates, or, equivalently, the expected L_0 loss on gate vector $(g_1, \ldots, g_N)$. Minimizing the loss encourages the model to prune encoder outputs.

Once $\mathcal{L}_0$Drop is integrated as a new layer into Transformer, the decoder, previously defined in Eq. (3), becomes:

$$\mathbf{Y}^L = \text{Decoder}(\mathbf{Y}^0, \mathcal{L}_0\text{Drop}(\mathbf{X}^L)). \tag{11}$$

Other components in Transformer are kept intact, except for using a modified objective $\mathcal{L}(X, Y)$:

$$\begin{aligned} &\mathcal{L}_{\text{MLE}}(X, Y) + \lambda \mathcal{L}_0(X) \\ &= -\log \mathbb{E}_{\mathbf{g} \sim p(\mathbf{g}|\phi)} [p(Y, \mathbf{g}|X)] + \lambda \mathcal{L}_0(X) \\ &\leq \mathbb{E}_{\mathbf{g} \sim p(\mathbf{g}|\phi)} [-\log p(Y, \mathbf{g}|X)] + \lambda \mathcal{L}_0(X) \\ &= \mathcal{L}(X, Y) \end{aligned} \tag{12}$$

where ϕ is short for $(\alpha, \beta, \epsilon)$, $\lambda \in \mathbb{R}^+$ is a hyperparameter defining the level of sparsity. The bound is derived by applying Jensen's inequality.

Importantly, the objective remains fully differentiable as we can rely on the reparameterization technique (Kingma and Welling, 2013) to sample $\tilde{\mathbf{g}}$ for computing unbiased estimates of the gradients. Adding $\mathcal{L}_0$Drop and the regularizer introduces only a negligible computational overhead to training compared to the original Transformer.

Algorithm 1 Decoding algorithm for $\mathcal{L}_0$Drop

```
Input: Source encodings, $\mathbf{X}^L \in \mathbb{R}^{N \times d}$;
       Gates, $\hat{\mathbf{g}} \in \mathbb{R}^N$;
       Query state, $\mathbf{y}_j^l \in \mathbb{R}^d$;
Output: Attention vector for the query
    ▷ step 1: reorganize source-side inputs
    ▷ note this step can be done before the decoder
1:  $I \leftarrow \{i|\hat{g}_i \neq 0\}$    ▷ $N' \leftarrow |I|$
2:  $\hat{\mathbf{g}}' \in \mathbb{R}^{N'}, \mathbf{X'}^L \in \mathbb{R}^{N' \times d} \leftarrow \hat{\mathbf{g}}[I], \mathbf{X}^L[I]$
3:  $c \leftarrow N - N'$
4:  $\bar{\mathbf{X}}^L \leftarrow [\mathbf{0} \in \mathbb{R}^d, \mathbf{X'}^L \odot \hat{\mathbf{g}}'], \mathbf{c} \leftarrow [c, \mathbf{1} \in \mathbb{R}^{N'}]$
    ▷ step 2: attention with counts
5:  $\mathbf{q}, \mathbf{K}, \mathbf{V} \leftarrow \mathbf{y}_j^l \mathbf{W}_q, \bar{\mathbf{X}}^L \mathbf{W}_k, \bar{\mathbf{X}}^L \mathbf{W}_v$
6:  $\mathbf{e} \in \mathbb{R}^{N'+1} \leftarrow \mathbf{q}\mathbf{K}^T / \sqrt{d}$
    ▷ perform softmax with counts
7:  $\mathbf{a} \leftarrow \mathbf{c} \odot \exp(\mathbf{e}) / \sum_i (c_i \exp(e_i))$
8:  $\mathbf{v} \in \mathbb{R}^d \leftarrow \mathbf{a}\mathbf{V}$
9:  return $\mathbf{v}$
```

4.2 Decoding with $\mathcal{L}_0$Drop

At test time we do not sample gate values but estimate their expected value g_i, following Louizos et al. (2018):

$$\hat{g}_i = \min(1, \max(0, \sigma(\log \alpha_i)(1+2\epsilon) - \epsilon)), \quad (13)$$

which often turns out to be exactly either 0 or 1, albeit being in-between in some cases. Encodings corresponding to non-zero $\hat{g}_i$ are preserved and simply weighted by the expectation $\hat{g}_i$.

To leverage the induced sparse structure, we revise the decoding procedure as in Algorithm 1. The notation $[\cdot, \cdot]$ refers to row-wise concatenation, $[I]$ stands for extracting elements with the indices I, $\odot$ is element-wise multiplication, and $\mathbf{1} \in \mathbb{R}^{N'}$ indicates a vector of ones of length N'. We first reorganize the gates $\hat{\mathbf{g}} \in \mathbb{R}^N$ and the source encodings $\mathbf{X}^L \in \mathbb{R}^{N \times d}$ by eschewing the entries corresponding to closed gates ($\hat{g}_i = 0$, line 1-2). We augment the compressed sequence $\mathbf{X'}^L \in \mathbb{R}^{N' \times d}$ with a dummy zero encoding vector $\mathbf{0} \in \mathbb{R}^d$ to represent all pruned encodings, and record their count into a counting vector $\mathbf{c} \in \mathbb{R}^{N'+1}$ (line 4).[4] Notice that this step is decoder-agnostic, which only relies on the source encodings and $\mathcal{L}_0$Drop gates. We then modify the attention process to enable the inclusion of this counting information (line 5-8) for correctly estimating the attention weights. Note that the shortened source sequence $\bar{\mathbf{X}}^L$ is reused across decoder layers and steps. $\mathcal{L}_0$Drop changes the dependency of the encoder-decoder attention on source sequence from $\mathcal{O}(NM)$ to $\mathcal{O}(N'M)$, and allows for efficiency gains even with moderate sparsity, especially for large L, N and M.

5 Experimental Setup

We study $\mathcal{L}_0$Drop on machine translation tasks (WMT14 English-German (En-De) (Bojar et al., 2014) and WMT18 Chinese-English (Zh-En) (Bojar et al., 2018)[5]) and document summarization tasks (CNN/Daily Mail (Hermann et al., 2015)[6] and WikiSum (Liu et al., 2018)[7]). We adopt BLEU (Papineni et al., 2002) and ROUGE-L (Lin, 2004) to evaluate the translation and summarization quality, respectively. Other details, including model settings, are given in the Appendix A. For character-based translation, we employ the same model architecture and hyperparameters for training and decoding as specified in Appendix A, except that we adopt larger-batch training (∼85K characters) and encourage longer sequence decoding (length penalty of 1.0).

6 Results and Analysis

How much can encoder outputs be sparsified? We answer this question by analyzing the impact of pruning source encodings on the generation quality. We first train a baseline Transformer model, and then finetune this model using $\mathcal{L}_0$Drop (Eq. (12)) with varied λ to explore different levels of sparsity. We sample λ with a range of $(0, 1.5]$ and a step size of 0.1, and finetune WMT14 En-De and WMT18 Zh-En models for extra 50K steps, and CNN/Daily Mail for extra 20K steps. We use the *sparsity rate* to measure the sparsity; we define it as the ratio of the pruned source encoding number $\#(\hat{g}_i = 0)$ to the total number of source words.

Figure 4 shows the results. The generation quality exhibits a negative correlation with the sparsity rate across different tasks, reflecting the usefulness of encoder outputs for generation. However, the fact that we can remove about 40% source encodings without largely degrading the generation performance (-0.5 BLEU and -0.1 ROUGE-L) supports our hypothesis that we can force Seq2Seq

---

[4] Note that $N' \leq N$. $\mathcal{L}_0$Drop could increase the sequence length if no source encoding is pruned, which is not observed in our experiments.

Table 1: Decoding results for different tasks when finetuning with $\lambda = 0.3$. "Time": the decoding time (in seconds) of the whole test set. "Sparsity": the sparsity rate, 0.00% indicates the Transformer baseline. "Speedup": the decoding acceleration over the baseline. "Quality": BLEU for WMT tasks and ROUGE-L for summarization tasks. "Char": the character-level models, where we set $\lambda = 0.02$. We evaluate the decoding time on GeForce GTX 1080 Ti, with a batch size of 32 for WMT tasks and 10 for summarization tasks.

model to route information through a subset of its source encodings. We also observe that the compressibility seems relatively language independent (the curves of WMT14 En-De 4(a) and WMT18 Zh-En 4(b) are similar) but clearly task dependent. Compared to translation tasks, the summarization task seems less sensitive to the pruning of source encodings. We ascribe this to the property of summarization where the summary only reflects a part of the input document, rather than the entire document.

Does $\mathcal{L}_0$Drop improve the decoding speed? With appropriate finetuning, $\mathcal{L}_0$Drop can shorten the encoding sequence fed to the decoder, reducing the calculation amount of the encoder-decoder attention. However, the encoder-decoder attention corresponds to about 1/3 of the decoder calculations,[8] and Algorithm 1 also brings in extra overhead, such as gathering and indexing operations. Thus, a speed-up is not guaranteed, and we report empirical decoding time across different tasks.

Results in Table 1 show that $\mathcal{L}_0$Drop only marginally improves the decoding speed for subword-based machine translation, despite a high sparsity rate of 46.7% (WMT14 En-De) and 39.1% (WMT18 Zh-En). By contrast, $\mathcal{L}_0$Drop yields a speedup of 1.21× and 1.65× on CNN/Daily Mail and WikiSum, respectively. One explanation lies at the significant difference in target sequence length, where the average length per summary is >60, compared to ∼25 in machine translation. Note that $\mathcal{L}_0$Drop achieves a substantially higher sparsity rate of 71.5% on WikiSum with the same $\lambda = 0.3$. This is because the input paragraphs overlap in content; the information about redundant words does not need to be routed into other encoder states, making it easier to prune them.

When it comes to character-based translation, we observe that $\mathcal{L}_0$Drop performs comparably to the baseline (-0.05 BLEU) with a high sparsity rate of 46.1%. This echoes with our findings on subword-based translation, except that $\mathcal{L}_0$Drop also improves inference efficiency here due to the higher sequence length with a decoding speedup of 1.20×. In comparison to adaptive compression (Cherry et al., 2018), $\mathcal{L}_0$Drop delivers higher compression ratio with almost no quality loss. This further demonstrates the effectiveness of $\mathcal{L}_0$Drop in handling lengthy inputs. We notice that character-level models still underperform their subword-level counterparts with the standard Transformer, but

---

[8] At decoding, the encoder-decoder attention accounts for about 34.4% decoder time according to profiling on our implementation.

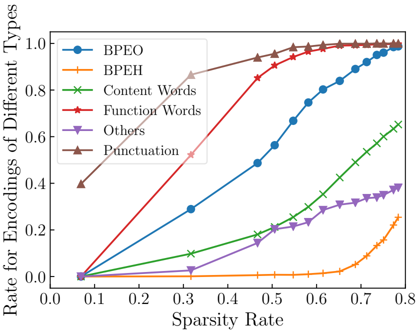

Figure 5: Curves for sparsity rate of different types of encoding on the WMT14 En-De test set. x-axis denotes the overall sparsity rate. The encoding of content words and BPEH is more valuable for generation, compared to that of function words and punctuation.

closing this performance gap is beyond the scope of this study.

Note that the pretraining-then-finetuning schema is mainly used for saving training efforts. By scheduling λ linearly with training steps, we can train models with $\mathcal{L}_0$DROP (Eq. (12)) from scratch, and obtain a BLEU score of 27.03 ($\lambda = 0.2$, warmup step of 200K) on WMT14 En-De (using subwords), comparable to using finetuning (27.04).

What types of source encoding are required for generation? Our goal here it to understand encodings of which types of tokens are retained. For each source encoding, we regard the POS of its corresponding word as its type. We take WMT14 En-De as our benchmark, where we annotate POS for source sentences in the test set using the Stanford POS tagger (Toutanova et al., 2003). We handle subwords separately by labeling its first piece as *BPEH* while the others as *BPEO*, regardless of the POS of its unsegmented form. We group different POS tags into 6 categories for the sake of analysis: BPEH, BPEO, function words, content words, punctuation and the rest.[9]

Figure 5 shows how the sparsity rate of each encoding type changes as a function of the overall sparsity rate. We find that $\mathcal{L}_0$DROP first choose to eliminate the encoding of punctuation, followed by that of function words. These words often signal structural and grammatical relationships that, while important to build up a representation of the sentence, can be easily compressed. In contrast, pruning content words, which express richer lexical meaning, is more difficult. The sharp increase of content word sparsity after the overall sparsity rate of 0.5 in Figure 5 correlates with a sharp drop in translation quality (see Figure 4(a)). We also observe that there is a large difference between BPEO and BPEH, albeit both from the same word. $\mathcal{L}_0$DROP favours to prune the encoding of BPEO, indicating that the model learns to use word-initial representations (BPEH) to represent whole words.

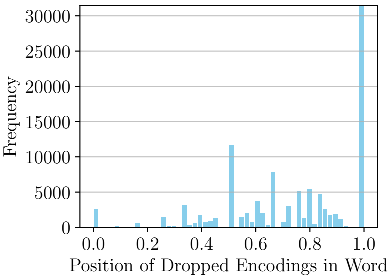

Figure 6: Distribution of the position of pruned source characters within a word on the WMT14 En-De test set. x-axis: 0.0 and 1.0 corresponds to the beginning and ending of one word, respectively.

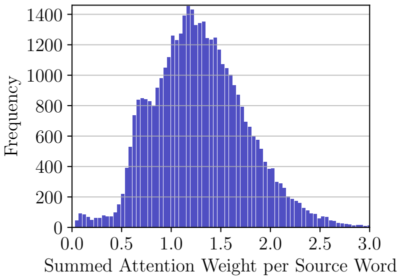

Figure 7: Distribution of the summed attention weight per source word on the WMT14 En-De test set for Transformer with $\mathcal{L}_0$DROP (sparsity rate 47%, BLEU 27.06). Only 4.5% source words get attention weights of less than 0.6.

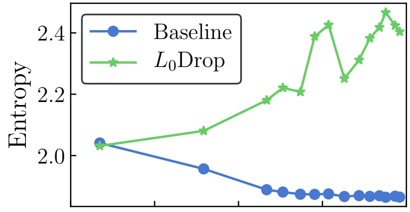
For character-level models, we observe that $\mathcal{L}_0$DROP identifies the inter-word structure in character sequences, and removes 89.2% encodings of the space symbol. We didn't find any other character-specific pruning patterns, but Figure 6 reveals that the encodings of characters near the ending of a word are more likely to be pruned compared to those at the beginning positions. This result resonates with our above observation on subword pruning, where $\mathcal{L}_0$DROP prefers to drop the encoding of BPEO rather than BPEH.

What's the effect of $\mathcal{L}_0$DROP on Transformer? Transformer can lose the access to around 40% source encodings while largely retaining the same performance. We try to figure out what has changed inside Transformer in order to support $\mathcal{L}_0$DROP,

---

[9] Function words include *CC, IN, RP, TO, UH, DT* and *WP*. Content words include *MD, JJ, NN, RB* and *VB*. Others include other POS tags except for punctuation and BPEO/BPEH, such as *CD, EX, FW* and *SYM*.

(a) Retained Encodings



(b) Pruned Encodings

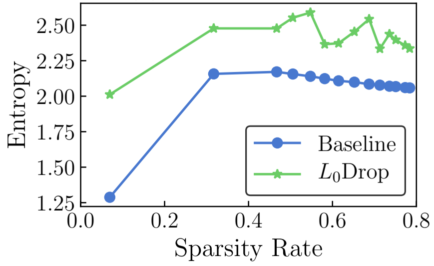


Figure 8: Entropy of the retained source encodings (top) and the pruned ones (bottom) versus the sparsity rate on the WMT14 En-De test set. We use the sparsity variable $\hat{\mathbf{g}}$ learned by $\mathcal{L}_0$DROP to classify the encodings of our baseline Transformer. Higher entropy indicates that the distribution tends to be uniform. With fewer retained encodings, Transformer tends to spread its attention weights to include more source-side information.

and analyze the attention weights (i.e. $\mathbf{A}$ in Eq. (1)) of all encoder-decoder attention sublayers and the last encoder self-attention sublayer; these sublayers are directly connected with $\mathcal{L}_0$DROP in the computation graph. We test on WMT14 En-De.

We visualize the distribution of the encoder-decoder attention weight per source word for Transformer with a sparsity rate of 47% (BLEU 27.06). Compared to the vanilla Transformer (Figure 1), distributions in Figure 7 show that the average attention weight obtained by each source word has increased (+0.77, 1.03→1.80), and the proportion of source words receiving attention weights of less than 0.6 is substantially reduced, by a factor of 10 (49.7%→4.5%). This indicates that $\mathcal{L}_0$DROP forces Transformer to distribute its attention more evenly among retained source encodings.

Apart from the encoder-decoder attention, we also inspect the self-attention in the last encoder layer. We average the self-attention weights over 8 different heads, and compare the attention entropy of the retained source encodings ($\hat{g}_i \neq 0$) and the pruned ones ($\hat{g}_i = 0$). We report average entropy values over the whole test set. Figure 8 shows how increasing sparsity affects the entropy. Although $\mathcal{L}_0$DROP selects to drop uninformative encodings, the increase in the entropy of the retained encodings (Figure 8 (a)), when compared to the baseline, suggests that the encoder actually encodes more context information into these representations, confirming that the model learns to compress context information when sparsity is enforced. Another observation is that the entropy curve of $\mathcal{L}_0$DROP for the pruned encodings is in line with that of the baseline, albeit on a larger scale (Figure 8 (b)). This signifies that $\mathcal{L}_0$DROP enforces Transformer to adapt its attentions to better coordinate with source context representations, which ensures its effectiveness on generation.

Can we prune encodings earlier in the encoder? Rather than stacking $\mathcal{L}_0$DROP on top of the encoder outputs, we insert $\mathcal{L}_0$DROP in-between every adjacent pair of encoder layers. We work on WMT14 En-De and finetune with $\lambda = 0.2$. We get a sparsity rate of 0.0%, 0.0%, 8.6%, 8.6%, 8.7% and 34.0% for the first to the last $\mathcal{L}_0$DROP layer, respectively, with a BLEU score of 26.74. This result suggests that Transformer does not gain much benefit from pruning encodings earlier. The model tends to retain encodings at shallow levels (0.0%/8.6% $<$ 34.0%), and loses 0.3 BLEU compared to its $\mathcal{L}_0$DROP baseline ($\lambda = 0.2$, sparsity rate 31.7%, BLEU 27.04). We believe that the encoder relies on low-level information (including the words) to fully 'understand' the sentence, though part of the final encodings is discardable.

7 Exploring Rule-based Sparse Patterns

Our analysis shows that the sparsity induced by $\mathcal{L}_0$DROP follows certain patterns, with the encodings of 'less content-bearing' words pruned first. This suggests that we may be able to define heuristic patterns manually. In this section, we explore the following three rule-based patterns according to our study on WMT14 En-De:

POS Pattern This pattern discards the source encodings of those easy-to-prune types, including function words, punctuation, BPEO and *MD, EX*, which account for 46.4% of the source-side WMT14 En-De training data.

Freq Pattern Inspired by the fact that punctuation and function words are high frequency words, we propose to filter out the source encodings corresponding to top-frequent words with a threshold of 46.3% (top 100 words). We also include an inverse version, *Inv Freq Pattern*, for comparison, which drops the encodings of most rare words; source words whose fre-

Pattern	WMT14 En-De		CNN/Daily Mail	
	Sparsity	BLEU	Sparsity	RL
Baseline	0.00%	27.59	0.00%	36.88
$\mathcal{L}_0$DROP	46.7%	27.06	47.6%	36.51
POS Pattern	46.7%	27.11	39.6%	35.57
Freq Pattern	42.1%	26.98	47.8%	35.67
Group Pattern	50.0%	26.82	50.0%	30.69
Inv Freq Pattern	44.7%	26.42	39.0%	27.89

Table 2: Sparsity and generation quality for different models on the WMT14 En-De (measured by tokenized case-sensitive BLEU) and the CNN/Daily Mail (measured by ROUGE-L or RL) test set. The sparsity rate is evaluated on test set.

quency ranks lower than 452 are removed, covering ∼40.0% of the source training data.

Group Pattern We explore a position-based pattern that only feeds the encodings at odd positions to the decoder, indicating a sparsity rate of ∼50%. This pattern is partially motivated by Child et al. (2019).

The design of these patterns follows our analysis on $\mathcal{L}_0$DROP, where we match the sparsity rate in each pattern to the optimal rate of $\mathcal{L}_0$DROP on WMT14 En-De. We examine the feasibility of these patterns on WMT14 En-De and CNN/Daily Mail.

Table 2 shows the results. On WMT14 En-De, Transformer using these rule-based patterns achieves comparable translation quality to $\mathcal{L}_0$DROP (-0.24 to +0.05 BLEU) with similar sparsity rate. One interesting observation is that Transformer also works with language- and context-agnostic sparsity patterns (Freq Pattern). The performance drop by Inv Freq Pattern (-0.64 BLEU) is in line with the information-theoretic expectation that information from frequent words is easier to compress than that of rare words.

However, note that we developed our heuristics to mimic the behaviour of $\mathcal{L}_0$DROP for WMT14 En-De task. $\mathcal{L}_0$DROP has the advantage that it is data-driven and task-agnostic so that we can easily apply $\mathcal{L}_0$DROP to summarization. By contrast, these rule-based patterns discovered on translation tasks are not optimal for other tasks, which results in deteriorated performance on CNN/Daily Mail (-5.82 to -0.84 RL). In particular, Transformer suffers from a large performance drop with the Group pattern (-5.82 RL). These results suggest that using rule-based sparse patterns to manually define the sparsity of encoder outputs is possible though the patterns lack generalization ability to different tasks.

8 Conclusion and Future Work

By introducing a L_0-regularized neural sparsity layer ($\mathcal{L}_0$DROP) in Transformer, we confirm that the encoder outputs are compressible to varying degrees. Pruning encoder outputs often results in a drop in performance, but we can get comparable results with 40–70% source encodings dropped. One benefit of pruning source encodings is to shorten encoding sequences for the decoder, which is especially beneficial for efficiency on long sequences, and accelerates the decoding speed by up to 1.65× on document summarization tasks and 1.20× on character-based machine translation. Our analysis on WMT14 En-De shows that $\mathcal{L}_0$DROP learns to drop the encodings of (relatively frequent) function words and retain encodings of (relatively rare) content words, but relies on self-attention to reroute information from these to-be-pruned positions. Based on our analysis, we define rule-based sparsity patterns, which also allow for compression without degrading translation quality much, and show that frequent tokens are more amenable to sparsification than rare tokens. However, we find that our rule-based patterns do not generalize across tasks, while $\mathcal{L}_0$DROP is data-driven and applicable across tasks. We hope that, besides practical implication, our work contributes to better understanding encoder-decoder models.

For future work, we find that the sparsity induced by $\mathcal{L}_0$DROP is highly task-dependent and hardly manipulated. We will develop novel algorithms to make the sparsity induction more controllable.

Acknowledgments

We thank the reviewers for their insightful comments. A Experimental Settings

Machine Translation We train translation models on the WMT14 English-German translation task (En-De) (Bojar et al., 2014) and the WMT18 Chinese-English translation task (Zh-En) (Bojar et al., 2018). WMT14 En-De and WMT18 Zh-En contain around 4.5M and 25M training sentence pairs, respectively. We use newstest2013 as the validation set for WMT14 En-De and newstest2017 for WMT18 Zh-En. We evaluate the translation quality with BLEU metric (Papineni et al., 2002), and report tokenized BLEU on newstest2014 for WMT14 En-De and detokenized BLEU on newstest2018 for WMT18 Zh-En using *sacreBLEU* (Post, 2018). We apply the byte pair encoding (BPE) algorithm (Sennrich et al., 2016) with 32K merging operations to handle rare words for both translation tasks.

Document Summarization We train abstractive summarization models on the CNN/Daily Mail dataset (Hermann et al., 2015) and the WikiSum dataset (Liu et al., 2018) for single- and multi-document summarization task, respectively. We use the non-anonymized version of CNN/Daily Mail (Gehrmann et al., 2018). We pre-process this dataset with a BPE vocabulary of 32K and truncate each article to 400 subwords (Gehrmann et al., 2018). We use the ranked version of WikiSum (Liu and Lapata, 2019), where top-40 paragraphs are extracted for each instance paired with a summary of 121 words on average. We concatenate all these paragraphs into one source sequence following the given ranking order. CNN/Daily Mail pairs news articles (791 words on average) with multi-sentence summaries (63 words on average), and involves 287,227 training pairs, 13,368 validation pairs and 11,490 test pairs. WikiSum contains 1.58M training pairs, 38,144 validation pairs and 39,357 test pairs. We employ BPE preprocessing following Liu and Lapata (2019) and truncate each source sequence to 2048 subwords. We evaluate the summarization quality using the F_1 score of ROUGE-L (Lin, 2004). The used parameters for ROUGE-1.5.5.pl are *-m -a -n 2*.

Model Settings We formulate all the tasks as sequence-to-sequence tasks, and experiment with the base setting of Transformer (Vaswani et al., 2017): $d = 512$, the middle layer size of $\textsc{Ffn}(\cdot)$ is 2048, and the number of attention head is 8. Following Louizos et al. (2018), we set $\epsilon = -0.1$, and $\beta = {}^2/_3$ for $\mathcal{L}_0\textsc{Drop}$. We tune the hyperparameter λ for different tasks. We augment the MLE loss with label smoothing of 0.1. We use Adam optimizer ($\beta_1 = 0.9, \beta_2 = 0.98$) (Kingma and Ba, 2015) for parameter tuning, and schedule the learning rate based on the inverse square root of running steps with a warm-up step of 4K. We apply dropout to attention weights and residual layers to avoid overfitting, with a rate of 0.1/0.1 except for CNN/Daily Mail where 0.3/0.5 is used. We train different models with varied training steps: 300K for WMT14 En-De, 500K for WMT18 Zh-En, 100K for WikiSum and 80K for CNN/Daily Mail, where sequence pairs of roughly 25K target subwords are organized into one minibatch. We average the last 5 checkpoints for evaluation where beam search is adopted for decoding with beam size of 4 and length penalty of 0.6.

FrameNet-assisted Noun Compound Interpretation

Abstract

Given a noun compound (NC), we address the problem of predicting the appropriate semantic label linking the constituents of the NC. This problem is called *Noun Compound Interpretation (NCI)*. We use FrameNet as a semantic label repository. For example, given the noun compound (*board approval*), we predict the frame (DENY_OR_GRANT_PERMISSION, as per FrameNet) as appropriate and the semantic role of the modifier word (AUTHORITY) as the semantic label linking *board* and *approval*; the resulting label is DENY_OR_GRANT_PERMISSION:AUTHORITY.

Our semantic label repository is very large ($\approx$ 11k labels) compared to the NC data available for training (approx 1900). Thus, learning in this case, especially for unseen semantic labels, is hard. We propose to solve this problem by predicting semantic labels in a *continuous label embedding space*, which is novel. This embedding space is created by learning label embeddings using the FrameNet data. The embeddings are then used to train two separate models – one for predicting Frames and the other for FEs. As the label embedding space captures the semantics of the labels, using these embeddings enables generalizing well on unseen labels, thus achieving zero-shot learning. Our preliminary investigations show that the proposed approach performs well for unseen labels, achieving 5% and 2% points improvements over baselines for the frame and FE prediction, respectively. The study shows the promise of the use of continuous space embeddings for noun compound interpretation and points to the need for further investigation.

1 Introduction

A noun compound is a sequence of two or more nouns that act as a single entity with well-defined meaning (*e.g.*, *paper submission*, *colon cancer*, *etc.*). Semantic relations between the component nouns are implicit. For instance, the information that 'it is a *juice* made from *orange*' is hidden in *orange juice*. Uncovering this semantic relation is called the problem of *Noun Compound Interpretation (NCI)*. NCI needs ML, as the task faces the challenge of ambiguity, and disambiguation by rules is well nigh impossible because of multifarious complex underlying language phenomena. The proposition of storing NCs and doing table lookup for interpretation is also impractical due to a large number of NCs and the challenge of high productivity (new nouns and NCs get created frequently, *e.g.*, *corona vaccine* is a relatively new NC).

Often, the exact relation, sentiment, *etc.* are also governed by contextual pragmatics. For instance, the sentiment towards *tax money* depends on who the beneficiary is, which again depends on the predicate. The predicate *give* could indicate negative sentiment (for the tax-payer), whereas the predicate *receive* would indicate positive sentiment (for the government). Due to such instances, NLP tasks such as machine translation (Baldwin and Tanaka, 2004; Balyan and Chatterjee, 2015), textual entailment (Nakov, 2013), question answering (Ahn et al., 2005), *etc.* suffer when they encounter noun compounds. For example, from the below text-question pairs, a system would need to interpret the underlying semantics within the compound, to answer the question correctly.

(a) *"student protest"*: *"who is protesting?"*,

(b) *"fee-hike protest"*: *"why protest?"*, and

(c) *"university protest"*: *"where is the protest?"*

In this work, we interpret only *compositional* noun-noun compounds. A noun-noun compound is categorised as compositional, if the meaning of the compound can be composed from the semantics of the individual noun units present.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 2901–2911
August 1–6, 2021. ©2021 Association for Computational Linguistics

From a relation representation perspective, noun compounds are interpreted in two ways: via *labelling* and *paraphrasing*. Labelling involves assigning an abstract semantic relation from a predefined set, for example, *orange juice*: MADEOF, *hillside home*: LOCATION, *etc.* There are many inventories of predefined semantic relations.

We use the FrametNet based labels proposed by Ponkiya et al. (2018a). As per their convention, the head noun of a compound invokes the frame, and the modifier noun fits in one of the frame elements of the invoked frame, *vide 'board approval'* in the abstract.

There are more than 11,000 FEs in FrameNet, and we have about 1900 training examples. Thus, the average number of examples for each label is quite small, and many labels do not have a training example. In summary, the contributions of this paper are three-fold:

1. We embed FrameNet entities in a continuous space, perform prediction in the continuous space to generalize over unseen labels, and show performance improvement on the unseen labels.
2. We create a noun-compound annotation tool that assists annotators in providing manual labels, and we release it publicly.
3. Using the above tool, we extend the dataset released by Ponkiya et al. (2018a) with 326 more manually-annotated gold samples, and release it for further research.

The rest of the paper is organized as follow: Section 2 discuss related work, Section 3 gives an overview of foundations for the work. Section 4 details our approach. Section 5 provides experimental details: the dataset used and training/testing setup. Section 6 discusses the results and analysis, followed by a conclusion and future work. The code, dataset and the tool can be downloaded from `http://www.cfilt.iitb.ac.in/nc-dataset`.

2 Related Work

A relation between the components of a noun compound (say, *chocolate cake*) can be represented in one of the following two ways: (1) assigning a relation from a predefined set of semantic relations (MADEOF), or (2) using a paraphrase to convey the underlying semantic relation (*"cake made using chocolates"* or *"cake with chocolate flavor"*).

Noun-compound (NC) interpretation via **labelling** is the most commonly used methodology for NC interpretation. Scholars have proposed many inventories of semantic relations (Levi, 1978; Warren, 1978; Vanderwende, 1994; Lauer, 1995; Barker and Szpakowicz, 1998; Ó Séaghdha, 2007; Rosario et al., 2001; Tratz and Hovy, 2010; Fares, 2016; Ponkiya et al., 2018a). A recent FrameNet-based inventory by Ponkiya et al. (2018a) proposed FEs (Frame Elements) from FrameNet as labels (or, semantic relations). They released a dataset by annotating each noun compound with a frame and a frame element; and proposed this annotation for predicate 'nominalization'. However, it also works for most of the cases of 'predicate deletion'.

For automatic labelling, Dima and Hinrichs (2015) and Fares et al. (2018)'s architecture is similar to ours. Dima and Hinrichs (2015) proposed a feed-forward neural network-based approach. This network takes concatenated embeddings of component nouns as an input and predicts one of the labels from the Tratz and Hovy (2010)'s label set. Fares et al. (2018) used a similar feed-forward network to predict two types of relations. This network, however, shares initial layers and separates output layers for each label type.

NC interpretation via **paraphrasing** is another methodology that contains approaches such as prepositional and free paraphrasing. Prepositional paraphrasing, *i.e.*, paraphrasing using a preposition, for example, *student protest*: "*protest by student(s)*", is a relatively well-attended problem (Lauer, 1995; Lapata and Keller, 2004; Ponkiya et al., 2018b). All the above approaches proposed for prepositional paraphrasing use the fixed-set of eight prepositions proposed by Lauer (1995). The other set of approaches, *i.e.*, free paraphrasing, however, has not received much attention. Apart from two SemEval tasks (Butnariu et al., 2009; Hendrickx et al., 2013), it does not have much literature available. A recent study (Ponkiya et al., 2020) expresses paraphrasing as a "fill-in-the-blank" problem, and utilizes pre-trained language models, for the task of noun-compound interpretation.

3 Foundations

Levi (1978) performed a linguistic study to understand how noun compounds are generated. They call such compounds *nominal compounds*. This theory puts nominal compounds into two categories, based on the compounding process, as

1. **Predicate Deletion:** Here, a predicate between the components is dropped to create a compound.

   For example, *apple pie* is a "pie made from apple." The predicate made from is dropped in this case. Similarly, for *elbow injury*, *gas pipeline*, *etc*.

2. **Predicate Nominalization:** Here, the head noun is a nominalized form of a verb, and the modifier is an argument of the verb.

   For example, "The union demonstrated against the price hike..." becomes "The union demonstration against the price hike..."

   Verbal noun as head: *student demonstration*, *government approval*, *opposition objection*, *etc*.

   Verb form as head: *student protest*, *government support*, *competition schedule*, *etc*.

Levi (1978) also proposed a set of abstract predicates[1] for the former category, but no relation for the latter category. Later, Ó Séaghdha (2007) revised this inventory and proposed a two-level hierarchy of semantic relations.

Ponkiya et al. (2018a) proposed a method to use FrameNet based labels for noun compounds. Here, the head noun invokes a frame, and the modifier noun fits in one of the slots of the frame. They also prepared a dataset by annotating each noun compound with a frame and a frame element. Ponkiya et al. (2018a) proposed this annotation for predicate nominalization, which also works for most cases of predicate deletion.

3.1 FrameNet

FrameNet[2] (Baker et al., 1998) is a taxonomy based on Fillmore's theory of Frame Semantics. This theory claims that most words' meanings can be inferred based on a semantic frame: a conceptual structure that denotes an abstract event, relation, or entity and the involved participants. For example, the concept of questioning involves a person asking a question (Speaker), person/people begin questioned Addressee, the content of the question Message, and so on. In FrameNet, such a concept is represented by Questioning frame. The participating entities, such as Speaker, Addressee, Message, *etc*., are called *frame elements* (FEs). Such frames are invoked in running text via words known as *lexical units*. Some of the lexical units for the Questioning frame are *ask, grill, inquire, inquiry, interrogate, query*, *etc*. FrameNet data provides two types of linkages between entities:

(a) relations: linking among frames or among FEs, and

(b) mappings: linking from words to frames and from frames to FEs.

3.1.1 Relations

FrameNet includes a graph of relations between frames along with relations among frames. Some of the important frame relations are:

- **Inheritance:** close to a typical Is-A relation, *e.g.*, Protest $\xrightarrow{\text{Is-A}}$ Intentionally_act
- **Using:** the child frame presupposes the parent frame, *e.g.*, Protest $\xrightarrow{\text{Uses}}$ Taking_sides
- **Subframe:** the child frame is a subevent of a complex parent event, *e.g.*, Trial $\xrightarrow{\text{Subframe}}$ Verdict

Along with each frame relation, FrameNet also consists of relations between FEs of parent-child frames. Following are illustrative examples for FE relations for the above frame relations:

- Protest:Protester $\xrightarrow{\text{Is-A}}$ Intentionally_act:Agent.
- Protest:Protester $\xrightarrow{\text{Uses}}$ Taking_sides:Cognizer
- Trial:Judge $\xrightarrow{\text{Subframe}}$ Verdict:Judge

3.1.2 Mappings

FrameNet data provides two types of mappings: (a) words to frames (via lexical units), and (b) frames to FEs. For instance, *protest* word can invoke three frames: Protest, Political_actions, and Judgment_communication. Similarly, using the frame to FEs mapping, we can list all FEs of the Protest frame, which are Action, Issue, Protester, Side, Degree, Descriptor, Duration, Explanation, Frequency, Manner, Means, Place, Purpose, Time, *etc*.

---

[1] RDP (Recoverable Deleted Predicates)

[2] `https://framenet.icsi.berkeley.edu`

In our work, we utilize *Relations* for the generation of frame and frame element embeddings (§3.2). We, further, utilize the *Mappings* to prune the search space (§4.1).

3.2 Knowledge Graph Embeddings

A Knowledge Graph $\mathcal{G}$ is a set of relations $\mathcal{R}$ defined over a set of entities $\mathcal{E}$. Formally, it is comprised of a set of N triples (h, r, t), where h and t are called *head* and *tail* entities, and r denotes a relation among them.

$$\mathcal{G} = \{(h, r, t) : h, t \in \mathcal{E}; r \in \mathcal{R}\}$$

Knowledge Graphs are widely used to store knowledge in a structured format, and they play an important role in representation learning. Methods for learning representations for both entities $\mathcal{E}$ and relations $\mathcal{R}$ have been explored (Wang et al., 2017) with an aim to represent graphical knowledge.

Various algorithms for representation learning have been proposed, which help tasks such as link prediction *etc*. TransE (Bordes et al., 2013) is a method that models relationships by interpreting them as translations operating on the low-dimensional embeddings of the entities. We use the ConvE (Dettmers et al., 2018) algorithm to get embeddings of frames and frame elements. For the training of ConvE, we treat all relations from FrameNet as triples of a knowledge graph.

3.2.1 ConvE

Convolution-based **E**mbeddings is a multi-layer 2D-convolution network model proposed by Dettmers et al. (2018). It usages fewer parameters, yet efficient compared to similar models. It defines the scoring function (for each relation r) as follows:

$$\psi_r(e_h, e_t) = f(vec(f([\overline{e}_h; \overline{e}_r]w))W)e_t \qquad (1)$$

where, e_h, e_r and e_t are embeddings of head h, relation r and tail t, respectively, $\overline{x}$ denotes reshaping of vector x to a matrix, f is a rectified linear unit (relu) function, vec converts a matrix into a flat vector, w is convolution kernel, and W is the parameter of a fully connected layer.

For training, it applies logistic sigmoid function $\sigma(\cdot)$ to the scores, and minimize the binary cross-entropy computed using the following formula:

$$L_{CE} = -\frac{1}{N}\sum_i (t_i \cdot \log(p_i) + (1 - t_i) \cdot \log(1 - p_i)) \qquad (2)$$

where, $p = \sigma(\psi_r(e_h, e_t))$ and t is 1 when $(h, r, t) \in \mathcal{G}$, 0 otherwise.

ConvE uses two embedding layers: one for entities and the other for relations, which initializes the embeddings layers randomly. The embeddings layers get updated during the training. At the end of the training, the embedding layers contain the embeddings for entities and relations.

4 Our Approach

FrameNet has 1223 frames and 11,473 frame elements. However, the existing dataset for FrameNet-based noun compound interpretation does not have examples for many frames and frame elements. However, unlike other relation inventories, we have FrameNet taxonomy, which can help in building a better model. We first explain our frame prediction approach and then extend the same for FE prediction.

4.1 System Architecture

We encode a given noun compound $nc = w_1\ w_2$ (say, *divorce rate*) using a feed-forward network to get vector v_{nc}. Using FrameNet API, we create a set of candidate frames that can be invoked by w_2 (*rate* → {Assessing, Proportion, Speed_description, etc.}). For each candidate frame f_i, we take its frame embedding e_{f_i} from the frame embedding layer. We take the dot product of v_{nc} with embedding e_{f_i} of each frame f_i to compute the score for the frame. For testing, we use the following formula to predict a frame:

$$f^* = \text{argmax}_i\ v_{nc} \cdot e_{f_i} \qquad (3)$$

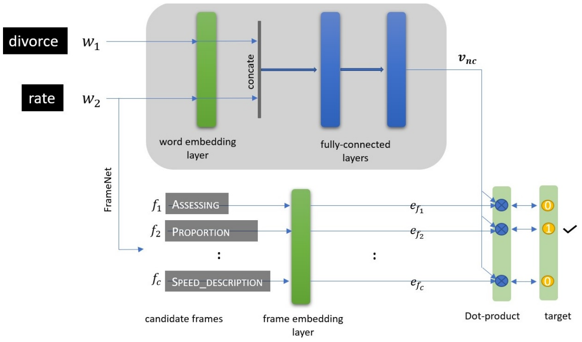

Figure 1: Basic system architecture illustrating frame prediction for *divorce rate*.

Dima and Hinrichs (2015) and Fares et al. (2018) use a simple feed-forward network. In our model, if we remove the frame/FE embedding matrix and use them as weights of one more dense layer (after the "fully-connected layers"), *our model becomes identical to theirs*. In doing so, **(a)** our model will NOT need any extra computation to compute the score of labels that are NOT part of the candidate set, and **(b)** the back-prorogation does not have to pass through an additional layer which might not be effective.

We implement these models in PyTorch (Paszke et al., 2017). We initialize the word embedding layer with Google's pre-trained embeddings[3] and initialize the frame embedding layer with random values, in one case, for baseline, and pre-trained frame embedding, in another case.

We use the same architecture to train another model for FE prediction, replace the frame embedding layer with an FE embedding layer, and candidates FEs are the FEs from all candidate frames. We take all FEs as a candidate set if no such mapping is found.

4.2 Frame and Frame Element Embeddings

Inspired by Kumar et al. (2019)'s approach for the task of Word Sense Disambiguation (WSD), we propose a similar approach to perform NC interpretation. Our approach uses the definition of entities (along with the relations) to learn entity embeddings and relation embeddings. It uses an encoder (Bi-LSTM) to encode the definition of an entity and uses encoded representation as an embedding of the entity for ConvE. During the training, it also optimizes both: the encoder and ConvE. After the training, the encoding of definitions is taken as entity embeddings.

We train ConvE twice to get frame and frame element embeddings separately. ConvE training is independent of the main training.

5 Experimental Setup

In this section, we explain our dataset, baseline, training, and evaluation metrics.

5.1 Dataset Creation and Analysis

We use the dataset released by Ponkiya et al. (2018a) as D1. The dataset contains 1546 noun-noun compounds with two labels: frame and FE. The dataset was created by extracting noun compound along with labels from the FrameNet data. As the extraction is automatic and the manual step only confirms the correctness of the labelling, the labels are not exhaustive. For instance, a noun compound *student demonstration* has been annotated with PROTEST:PROTESTER. However, the following labels are also applicable: REASONING:ARGUER and CAUSE_TO_PERCEIVE:ACTOR. So, we annotate more examples with all possible labels.

Manual Annotation

We manually annotate 326 noun compounds, and call it D2. We extend D1 by merging these examples from D2 to perform our experiments. The annotation is performed by one of the authors and hence does not warrant discussion on the inter-annotator agreement. However, please allow us to point out that our annotations are still manually performed by a human, which begets the consideration of these annotations to be gold-standard. The author chose the examples from Tratz and Hovy (2010)'s dataset randomly. During the annotation process, we found some difficulties because of the coverage issue of the FrameNet. The word-to-frame mapping in FrameNet has a coverage issue, and it has been widely reported in the literature (Pavlick et al., 2015; Botschen et al., 2017).

We categorize the coverage issues into the following:

No Candidate Frames: The word-to-frame mapping returned no candidate frame. In some cases, we could find a frame with manual effort (ref. Table 1). However, despite manual efforts, some cases, we could not find an appropriate frame all the time (*e.g.*, *star autograph*, *employee misconduct*, *etc.*).

No Suitable Frame in the Candidate Set: In this set, word-to-frame mapping retrieved candidate frames, but none of the candidates was found to be appropriate. For example, candidate frames for *heat* returned by the mapping are: CAUSE_TEMPERATURE_CHANGE

Word	Manually extracted frames
funding	FUNDING
authorities	LEADERSHIP, AUTHORITY
eradication	REMOVING
harvesting	FOOD_GATHERING
analyst	PEOPLE_BY_VOCATION

Table 1: Examples where FrameNet data does not contain an appropriate mapping but we manually find suitable frames.

and Change_of_temperature. However, none of the two frames is appropriate for *body heat*.

In some cases, we could find an appropriate frame that was not a part of the candidate set. For example, for noun compound *ulcer drug*, candidate frames are Intoxicants and Cause_harm, but the appropriate frame is Cure.

No Suitable Frame Element in the Frame: We could find an appropriate frame, but no frame element from the frame is appropriate. For instance, the Business frame is suitable for *retail operation*, but no frame element from the frame is suitable for the modifier noun *retail*.

NC Annotation Tool

To handle the first two cases (finding of a frame), we use synonyms from WordNet (Miller, 1994) and FrameNet+ data (Pavlick et al., 2015). To simplify the annotation process, we develop a tool (Figure 2) that makes the annotation process easier.

We split each dataset – D1 and D1+D2 – randomly for 5-fold validation. Each fold contains three disjoint sets: training set (60% compounds), validation set (20% compounds), and test set (20% compounds). We use the same folds across all experiments, so results across different models are comparable.

5.2 Frame and Frame Element Embeddings

To get frame embeddings, we consider frames as entities and frame relations from FrameNet as relations between the entities. Then we train ConvE (§4.2) to learn frame embeddings. We use these entity embeddings to initialize the frame embedding layer. Table 2 shows the ten most similar frames for Friendly_or_hostile frame based on cosine similarity between frame embeddings. Similarly, we get embeddings of frame elements using frame elements and their relations in FrameNet.

5.3 Baseline

The first baseline is a **random prediction**: the probability of predicting a label from a candidate set is uniform. We take expected counts to compute metrics. For instance, we compute random accuracy using the following formula:

$$\text{Acc}_{\text{random}} = \frac{1}{N} \sum_{nc_i \in \text{Test-set}} \frac{1}{|\text{candidates}(nc_i)|} \quad (4)$$

We also use **Support Vector Machines** (SVM) (Cortes and Vapnik, 1995) as a baseline approach for this task. We use the *sklearn* library (Pedregosa et al., 2011) with default parameters for

this approach. The input for the SVM-based approach is the concatenated vector of individual lexical units.

We provide results for **another baseline** approach where we use the same architecture (§4.1) with random initialization for frame/FE embeddings.

5.4 Training

Given a noun compound, we get candidate labels using FrameNet mapping. We compute scores for candidate labels and compare them with the target to compute loss value. We minimize categorical cross-entropy with stochastic gradient descent (with momentum). Frame/FE embedding layer remains fixed (non-trainable) for the initial few epochs. For stopping criteria, we monitor performance on the validation set.

5.5 Evaluation

We report weighted **P**recision, **R**ecall, and **F1**-score for our experiments. The weight values for each label is in proportion to the number of test examples for the label. Following is a formula for computing (weighted) precision:

$$\text{Precision} = \sum_{l} P_l * \frac{N_l}{N} \tag{5}$$

$$P_l = \frac{\text{TP}_l}{\text{TP}_l + \text{FP}_l} \tag{6}$$

where, P_l is the precision score, TP_l is the number of true-positives and FP_l is the number of false-positives for a label l. N_l is the number of instances with label l in the test set, and N is the total number of instances in a test set.

The above metrics are based on the top prediction. We also report accuracy at k, which treats a prediction as a true prediction if the correct label is in top k predicted labels. We report (micro-averaged) accuracy, computed using the following formula:

$$\text{Acc} = \frac{\text{No. of correctly classified instances}}{\text{Total instances in test-test}} \tag{7}$$

We compute all of these metrics for frame and frame element independently. We use the Scikit-learn library (Pedregosa et al., 2011) to compute all of these metrics.

6 Results and Analysis

The reported results are averaged across 5-fold cross-validation. We define a subset of all test samples, whose output label does not have any samples in the training set, as *unseen*-set. In a fold (of D1) with 310 test samples, the following are the statistics about the "unseen set": (1) 30 unique frames, covering 32 test samples, (2) 75 unique FEs, covering 82 test samples. *These cases are challenging to handle.* Our prediction in continuous space helps in such cases, as the target space embeds the labels.

Table 3 reports the performance of the baselines compared to our system for frame prediction on the entire test-set. Our system beats the random baseline and SVM model across all metrics by a significant margin. Similarly, as observed from Table 4, it can be seen that frame prediction on the "unseen" set improvises over the random baseline in both the cases, *viz.,* WITH and WITHOUT frame embeddings. The performance improvement is quite significant over both the datasets (D1 and

	D1			D1+D2

WITHOUT frame embedding	40.38	38.42	39.07	41.29	42.42	40.82
WITH frame embeddings	46.83	43.75	**44.63**	48.25	44.98	**45.78**

Table 4: Comparison of our approach for *frame prediction* with random prediction baseline on examples with **unseen-set**, achieving zero-shot learning **for frame prediction**. (**P**: Precision@1; **R**: Recall@1; **F**: F1-score@1)

D1+D2). We attribute the performance improvement in both cases to the fact that our model captures frame semantics for a frame in a continuous space, better than the baseline metrics. However, as seen in Table 3, the model which tries to predict WITHOUT frame embeddings shows comparable results with the model which predicts WITH frame embeddings. This marginal improvement does not seem to be significant, and the results for both these cases are almost similar. Eventually, with the improvement in dataset size, we expect the system with frame embeddings to perform better than the system without frame embeddings.

We discuss the task of frame prediction above and present our results for frame element prediction here. As it can be observed from Table 5, random baseline and SVM based models are outperformed for the task of frame element prediction as well, when compared with the results of our methodology. The improvements over both datasets (D1 and D1+D2) are at least 5% (D1+D2/SVM). With the extended dataset (D1 + D2), the performance of our approach shows an improvement across all three (precision, recall and f-score) measures. In Table 3, for frame prediction, we observe an increase in the stronger baseline score (SVM) when the extended dataset is used. However, we observe that our results for frame element prediction show that the model which uses frame embeddings is significantly outperformed by the model which does not use frame embeddings. Upon manual analysis of our train set, we find that our datasets have multiple cases where the number of examples per frame element is very few (sometimes even 1, as discussed below). This results in a data skew where the sample would either be used for training or testing, thus rendering the model either untrained for that test case, or no testing of the model trained for that single frame element. In Table 6, we see that the random baseline outperforms our method because of the data skew discussed here. There are multiple frame elements that are present in the unseen test data for which the model has not been trained at all. We do not report SVM performance in Table 6 and Table 4, since the precision, recall, and f-score for SVM were all 0. This performance can be attributed to the fact that SVM does not perform well with unseen examples, and in this case, does not perform at all.

For frame element prediction, in Table 5, we observe that the extended dataset helps improve the over quality of predictions with an improved score for each approach, including the baseline. These results signify that the dataset extension does indeed help the task of NC interpretation.

In Figure 3, we see that the average number of candidate FEs for a test sample is only 26. Without even a single training example, our system is able to correctly predict 51.22% (more than half) of unseen samples among the top-7 predictions, which is higher than the top-1 accuracy of any baseline approach on the complete test-set. With an increase

	D1			D1+D2		
	P	R	F	P	R	F
Random baseline	13.75	9.68	11.36	14.48	10.20	11.97
SVM	43.99	49.13	43.73	46.55	50.85	45.14
WITHOUT frame element embedding	49.42	52.14	**49.28**	51.13	54.08	**50.29**
WITH frame element embeddings	48.18	48.50	46.61	50.47	50.23	49.73

Table 5: Performance of our approach for *frame element prediction* compared to the baseline approach on **test set** from D1 and D1+D2 datasets. (**P**: Precision@1; **R**: Recall@1; **F**: F1-score@1)

	D1			D1+D2		
	P	R	F	P	R	F
Random baseline	13.28	10.35	**11.64**	15.36	9.26	**11.56**
WITHOUT frame element embedding	2.43	2.33	2.36	3.45	2.53	2.67
WITH frame element embeddings	5.05	4.96	4.70	5.23	5.23	5.28

Table 6: Comparison of our approach for *frame element prediction* with random prediction baseline on examples with **unseen-set**. (**P**: Precision@1; **R**: Recall@1; **F**: F1-score@1)

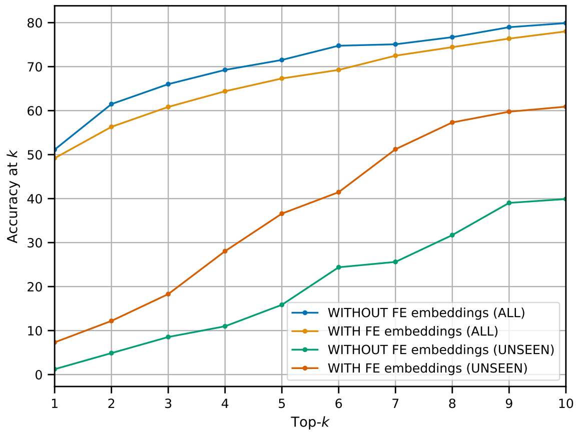

Figure 3: Accuracy@k for frame element prediction (WITH and WITHOUT frame element embeddings; on full test set and *unseen*-set)

in k, the margin between the performance of our system and baseline remains nearly the same on the whole test set. However, on unseen labels, the system with FE embeddings significantly outperforms the baseline, with an increase in k.

Overall, we observe a significant improvement in results with the help of our method. We also show that our extended dataset does help improve the performance of models in both cases.

7 Conclusion and Future Work

In this paper, we proposed a novel method for using FrameNet for NC interpretation in a continuous space. We use FrameNet mappings (word to frame and frame to frame element) to prune our search space. Our approach – prediction in continuous space – outperforms the random baseline and a stronger baseline approach. We show that the label embeddings generated using our approach help in the generalisation over unseen labels.

We annotated more noun compounds and analysed the issue in finding frame and frame elements. We create and release a tool that assists annotators in frame identification, for further research. We also show that extending the dataset created with our tool improves the system performance. Our experiments evaluate our proposed method on a small annotated dataset compared to the overall number of labels. We extend this existing dataset by annotating more NCs for various labels. Our study on the coverage issue for the annotation process helps develop a tool that assists the annotators in finding an appropriate frame. We provide promising results for the task of frame prediction. We analyse our results and discuss them in detail with respect to both frame and frame element prediction tasks.

In the future, we aim to find other ways of using FrameNet data for this task. We would also like to investigate why our approach provides promising results for the task of frame prediction but not for frame element prediction. We would like to explore more approaches to predict the frame elements effectively. We believe that using FrameNet embeddings can prove to be helpful for other tasks.
