8 Conclusion

In this paper, we proposed Transformer-based Implicit Latent GAN (TILGAN), for text generation. It combines a Transformer autoencoder and a GAN through matching the distributions of multi-token sequences in the Transformer's latent space based on KL divergence. To improve the local and global coherence, we introduced a multi-scale discriminator to utilize the semantic information on varying scales. To train the decoder reliably, we enhanced the objective function by another KL term, forcing the decoder to be compatible with the latent-generator. We theoretically connected the proposed formulation with the standard goal of generative modeling. Empirically, TILGAN achieved the state-of-the-art performance on three widely used datasets for unconditional tasks and story completion task, which demonstrated the effectiveness of our method to generate texts of high quality and diversity compared with the existing approaches.

B Proof of Theorem 1

Proof of Theorem 1. In this proof, we let $\boldsymbol{x}$ be the real data, $\boldsymbol{y}$ be the generated data, and $\boldsymbol{z}$ be the latent variable. Let $p_G(\boldsymbol{y},\boldsymbol{z}) = p_\beta(\boldsymbol{z})p_\theta(\boldsymbol{y}|\boldsymbol{z})$ be the joint distribution of $(\boldsymbol{y},\boldsymbol{z})$, where $\boldsymbol{z}$ is sampled from prior $p_\beta(\boldsymbol{z})$ and then $\boldsymbol{y}$ is sampled from the decoder conditional $p_\theta(\boldsymbol{y}|\boldsymbol{z})$. Further let $\mathcal{P}_{\boldsymbol{x},\boldsymbol{y},\boldsymbol{z}}$ denote the set of all joint distributions of $(\boldsymbol{x},\boldsymbol{y},\boldsymbol{z})$ such that $\boldsymbol{x} \sim p_r(\boldsymbol{x})$, $(\boldsymbol{y},\boldsymbol{z}) \sim p_G(\boldsymbol{y},\boldsymbol{z})$, and $\boldsymbol{x} \perp\!\!\!\perp \boldsymbol{y}|\boldsymbol{z}$; let $\mathcal{P}_{\boldsymbol{x},\boldsymbol{z}}$ be the set of marginal distributions of $(\boldsymbol{x},\boldsymbol{z})$ induced by $\mathcal{P}_{\boldsymbol{x},\boldsymbol{y},\boldsymbol{z}}$, that is, the set of distributions with marginals $\boldsymbol{x} \sim p_r(\boldsymbol{x})$ and $\boldsymbol{z} \sim p_\beta(\boldsymbol{z})$.

Recall that n is the sequence length and m is the number of words in the vocabulary. For the i-th word x_i which is an m-dimensional one-hot vector, indicator $\mathbf{1}(x_i = j) = 1$ if the j-th dimension of x_i is equal to 1 and $\mathbf{1}(x_i = j) = 0$ otherwise, for $j = 1, \ldots, m$. Then we have

$$\begin{aligned}
W_1(\mathbb{P}_r,\mathbb{P}_G) \le W_1^\dagger(\mathbb{P}_r,\mathbb{P}_G) &:= \inf_{p\in\mathcal{P}_{\boldsymbol{x},\boldsymbol{y},\boldsymbol{z}}} \mathbb{E}_{\boldsymbol{z}\sim p_\beta(\boldsymbol{z})}\mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x}|\boldsymbol{z})}\mathbb{E}_{\boldsymbol{y}\sim p_\theta(\boldsymbol{y}|\boldsymbol{z})}[c(\boldsymbol{x},\boldsymbol{y})] \\
&= \inf_{p\in\mathcal{P}_{\boldsymbol{x},\boldsymbol{z}}} \mathbb{E}_{\boldsymbol{z}\sim p_\beta(\boldsymbol{z})}\mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x}|\boldsymbol{z})}\left[2\sum_{i=1}^{n}\sum_{j=1}^{m}\mathbf{1}(x_i=j)(1-\bar{G}_{ij}(\boldsymbol{z}))\right] \\
&< \inf_{p\in\mathcal{P}_{\boldsymbol{x},\boldsymbol{z}}} \mathbb{E}_{\boldsymbol{z}\sim p_\beta(\boldsymbol{z})}\mathbb{E}_{\boldsymbol{x}\sim p(\boldsymbol{x}|\boldsymbol{z})}\left[-2\sum_{i=1}^{n}\sum_{j=1}^{m}\mathbf{1}(x_i=j)\ln\bar{G}_{ij}(\boldsymbol{z})\right] \\
&= \inf_{q(\boldsymbol{z}|\boldsymbol{x}):q_z(\boldsymbol{z})=p_\beta(\boldsymbol{z})} \mathbb{E}_{\boldsymbol{x}\sim p_r}\mathbb{E}_{\boldsymbol{z}\sim q(\boldsymbol{z}|\boldsymbol{x})}\left[-2\sum_{i=1}^{n}\sum_{j=1}^{m}\mathbf{1}(x_i=j)\ln\bar{G}_{ij}(\boldsymbol{z})\right] \\
&= \inf_{q(\boldsymbol{z}|\boldsymbol{x}):q_z(\boldsymbol{z})=p_\beta(\boldsymbol{z})} \left\{-2\mathbb{E}_{\boldsymbol{x}\sim p_r}\mathbb{E}_{\boldsymbol{z}\sim q(\boldsymbol{z}|\boldsymbol{x})}[\ln p_\theta(\boldsymbol{x}|\boldsymbol{z})]\right\},
\end{aligned}$$

where the first inequality comes from Tolstikhin et al. (2018, eq. 9), and the second inequality is due to the fact that $1 - l < -\ln l$ for all $l \in (0,1)$, leading to the desired result. $\square$

Implicit Causality Bias and Its Interaction with Explicit Cues in LMs

Abstract

Some interpersonal verbs can implicitly attribute causality to either their subject or their object and are therefore said to carry an implicit causality (IC) bias. Through this bias, causal links can be inferred from a narrative, aiding language comprehension. We investigate whether pre-trained language models (PLMs) encode IC bias and use it at inference time. We find that to be the case, albeit to different degrees, for three distinct PLM architectures. However, causes do not always need to be implicit—when a cause is explicitly stated in a subordinate clause, an incongruent IC bias associated with the verb in the main clause leads to a delay in human processing. We hypothesize that the temporary challenge humans face in integrating the two contradicting signals, one from the lexical semantics of the verb, one from the sentence-level semantics, would be reflected in higher error rates for models on tasks dependent on causal links. The results of our study lend support to this hypothesis, suggesting that PLMs tend to prioritize lexical patterns over higher-order signals.

1 Introduction

Recognising causal links in narrative is an integral component of language comprehension that often relies on implicit cues (Trabasso and Sperry, 1985). Pre-trained language models, which form the basis of many language processing solutions nowadays, should therefore pick up on such cues and integrate them correctly with other signals to enable accurate causal inferences in downstream tasks, including question answering and information extraction.

Psycholinguists have identified one such cue in the implicit causality bias of interpersonal verbs: some interpersonal verbs tend to implicate causality on either their subject or their object (Garvey and Caramazza, 1974). It is this bias that leads to wide agreement among subjects in psycholinguistic studies, that in a sentence like *John appreciates Mary*, the cause for appreciation likely lies with a property or action of Mary's rather than John's. Causality can also be stated explicitly, in the form of a subordinate *because* clause, for instance, and it can optionally contradict the implicit causality of the verb in the main clause. In Figure 1, we show two verbs in the context of explicit statements of causality (EC) that are either congruent or incongruent with their IC bias. Psycholinguistic studies show that congruency affects language comprehension, with human participants taking longer to identify the referent to the pronoun after *because* in incongruent contexts compared to congruent ones (Caramazza et al., 1977). The integration of the two signals costs humans extra effort, but they are eventually able to overcome the false initial expectation based on lexical semantics (i.e. IC) and form a final response that takes into consideration the full sentence-level semantics (i.e. EC). Ettinger (2020) suggests that in the context of such diverging signals, models would likely fail to integrate all signals correctly, producing a response that is consistent with the initial, shallow expectation and therefore incorrect.

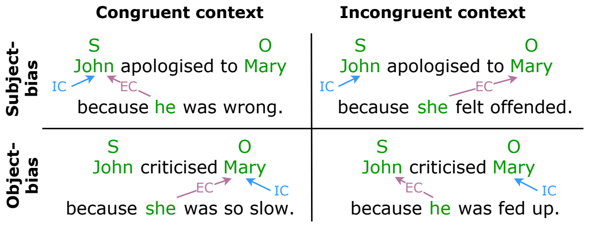

Figure 1: Illustration of implicit causality (IC) and explicit causality (EC) in contexts where the two are congruent, and where they are incongruent.

In this work, we study a range of large transformer-based pre-trained language models (PLMs) with a focus on their awareness of IC bias

and their response to stimuli of the kind shown in Figure 1. Following Ettinger (2020), we hypothesize that a language model aware of IC bias would experience interference from this signal in the context of incongruent EC, resulting in errors of judgement on a co-reference resolution task dependent on causal inference.

In a study of six PLMs from three model families: unidirectional generative, bidirectional generative and bidirectional discriminative, we find that IC bias is reliably encoded by all, but not used to an equal degree when making predictions in a controlled setting designed to test for IC awareness. In line with our hypothesis, we find that models with high IC awareness suffer an interference from IC bias in contexts of incongruent causality. We discuss these findings with reference to model type, size and amount of training data; we also draw general conclusions about the shortcomings of language models, which seem to prioritise a low-level lexical pattern (when they are aware of it in the first place) over a higher-order contextual signal.

2 Related Work

The study of the linguistic capacities of neural language models (LMs) has become especially relevant in current NLP research, where representations from PLMs feed into systems for various complex tasks, typically improving performance. Many of the testing paradigms used in psycholinguistics lend themselves well to LM analysis as they rely on a textual stimulus and a lexical response.

Linzen et al. (2016) were first to borrow from the psycholinguistic testing paradigm, in a study of the capabilities of LSTM-based models to resolve subject-verb number agreement. Goldberg (2019) adopted the psycholinguistic approach in an assessment of BERT (Devlin et al., 2019) on a number of syntactic tasks and found it to perform remarkably well on all. Hawkins et al. (2020) studied the ability of different LMs to capture human preferences as to the argument structure of English verbs.

The analysis of semantic capabilities in LMs includes studies on negative polarity in LSTM LMs (Marvin and Linzen, 2018; Jumelet and Hupkes, 2018), reasoning based on higher-order linguistic skill (Talmor et al., 2019), arithmetic and compositional semantics (Staliūnaitė and Iacobacci, 2020), stereotypic tacit assumptions and lexical priming (Misra et al., 2020; Weir et al., 2020). Many of these studies look at recent PLMs and draw mixed conclusions about the level of semantics encoded by these models. Peters et al. (2018) and Tenney et al. (2019) observed that PLMs do encode some higher-order syntactic abstractions in the higher layers (whereas lower-order syntactic information is encoded in the lower layers). However, in a comparison of contextualized and static word embeddings, Tenney et al. (2019) concluded that PLMs do not generally offer the same improvement with respect to semantics as they do for syntax.

At the crossroad of semantic analysis and psycholinguistic approaches, Ettinger (2020) introduced a suite of six psycholinguistic diagnostics for the analysis of semantic awareness in LMs. The tasks were selected based on a specific pattern observed in the response of human participants in psycholinguistic studies: an initial expectation (marked by an N400 electrophysiological response) that diverges from the final answer in a cloze task that humans offer once they have had time to fully consider the test prompt. Ettinger (2020) suggests that LMs might be “tripped up” in such contexts if they are unable to accurately integrate all the available information—she indeed found that to be the case for role-based event prediction in BERT (Devlin et al., 2019), for example. The phenomenon we study, incongruency in causality signals, has been observed to trigger a similar response in humans (Van Berkum et al., 2007) and can thus be expected to also “trip up” LMs.

Implicit causality bias was previously considered in PLM analysis by two works, both looking at how well unidirectional PLMs capture it. Upadhye et al. (2020) studied IC from the perspective of how different connectives between the main clause and the following clause (*because*, *and as a result*, full stop) affect the strength of the bias. While they did not find strong evidence for a correlation to human-based results in this respect, they did observe that in the context of connective *because* PLMs assigned lower probability to subject-referring pronouns for an object-biasing verb as compared to a subject-biasing verb. Davis and van Schijndel (2020) observed that GPT2-XL (Radford et al., 2019) encodes some level of IC bias in its representations (measured in terms of similarity between the representation of the pronoun and its two potential referents) and its decision on how to resolve a referent at prediction time is weakly influenced by that. They took the analysis one step further and looked at whether GPT2-XL uses IC information to resolve relative clause attachment, which in humans is conditioned by IC bias—no evidence was found to suggest that that was the case. Our study extends previous work on IC bias in several ways: we study both unidirectional and bidirectional models, we measure bias in the same terms as was done in psycholinguistic work and can therefore assess the correlation between the two, and we study the matter from a perspective that has not been considered before, namely the case of incongruent explicit and implicit causality.

3 Materials

Here we describe the two psycholinguistic diagnostics that we draw on: for the study of IC bias in isolation and its integration with EC. We also describe the modifications necessary to make these diagnostics suitable for PLMs.

3.1 Context-free IC Bias

Ferstl et al. (2011) studied IC bias in a context free of EC through a sentence completion task where subjects were presented with a stimulus like

(1) John praised Mary because ___

and asked to finish the sentence. Continuations were observed to start with a third person pronoun (*he* or *she*) 94.2% of the time. The researchers counted the ratio of continuations referring back to the subject of the sentence, s_{wins}, and back to the object, o_{wins}, and computed a bias score for each verb as $100 \times (s_{wins} - o_{wins})/(s_{wins} + o_{wins})$. This results in a range of -100 (verbs with extreme Object bias, hereafter O-bias) to 100 (verbs with extreme Subject bias, hereafter S-bias). The study covered 305 interpersonal English verbs with responses from 96 subjects.

In another study of IC bias, Hartshorne and Snedeker (2013) presented subjects with stimuli with a nonce ending, e.g.

(2) John praised Tim because he was a *dax*.

and asked them the question *Who do you think is a dax?* The nonce ending is meant to provide a content-free continuation that does not affect the interpretation of the ambiguous pronoun, neither semantically (as the madeup *dax* carries no meaning), nor syntactically—Hartshorne et al. (2015) conclude that explanations of the form *is a/an X* do not affect people's intuitions about who the explanation referred to.

Our approach is to use the procedure of Ferstl et al. (2011) as is to test unidirectional PLMs, as they are naturally suited to the open-end input format. Since bidirectional PLMs have been trained on complete utterances and may thus act unpredictably in an open-end context,[1] we test such models with a modification of the procedure of Hartshorne and Snedeker (2013):[2] we convert it into a cloze task with a gender mismatch between the participants, such that (3) becomes

(3) John praised Mary because ___ was a *dax*.

We adopt the mismatched-gender setting as it more closely resembles the sentence completion task in Ferstl et al. (2011). In both formats we can now identify the preferred referent by looking at the probability of pronouns *he* and *she* for the empty slot, each one referring unambiguously to only one referent. Inducing a prediction for a pronoun in the empty slot is also a more natural choice of co-reference than repeating one of the names (Holtzman et al., 2019).

In the examples shown throughout the paper, *John* and *Mary* are used as placeholders for the subject and object of the verb of interest. The choice of names to go in these slots can affect model predictions (Abdou et al., 2020), so we generate 200 variants of each stimulus, varying the names and the order between the two genders and we query the PLMs with all of them. The full procedure is described in Appendix B.

We compile a list of 200 nonce words using the 194 nonce words made available by Bangert et al. (2012), five nonce words from Cuskley et al. (2015), manually chosen to resemble English nouns, and *dax*, used in Hartshorne and Snedeker (2013). When presenting a bidirectional PLM with the aforementioned 200 variants of a stimulus, we dynamically draw a nonce word at random from this list without replacement.

The procedure described above is applied to each of the 305 verbs studied in Ferstl et al. (2011).

3.2 IC Bias in the Context of EC

Caramazza et al. (1977) tested the effect of incongruency between IC and EC using pairs of sentences built around the same verb, where one contains an explanation congruent with the verb's bias

---

[1] We find that a common response of generative bidirectional PLMs to stimuli like those in (1) is to predict a full-stop for the empty slot.

[2] See Appendix A.1 for an alternative we considered.

and the other contains an incongruent explanation (refer back to Figure 1 for some examples). Participants were shown one sentence at a time on a screen and asked to say out loud who the referent was to the pronoun after *because*. Caramazza et al. (1977) carried out experiments both with stimuli where the referents are of the opposite gender and where the referents are of the same gender—responses were delayed in the context of incongruent explanations as compared to congruent ones in both settings, the effect being stronger in the mismatched-gender setting.

Our approach is to adopt the mismatched-gender setting and to convert this task into a cloze task as well, an example stimulus being:

(4) John praised Mary because ___ had done well.

The stimuli used by Caramazza et al. (1977) and other related studies like Garnham et al. (1996) use only a handful of verbs (14 and 22, respectively). We therefore found it necessary to develop a more expansive dataset for the purposes of our study. Following the procedure described in Appendix C we constructed pairs of subject-referring explanations and object-referring explanations for 99 verbs, 33 strongly subject-biased verbs (bias$>$ 65), 33 strongly object-biased verbs (bias< -65), and 33 verbs from the middle of the scale, which can be thought of as having no effect on the attribution of implicit cause. Selecting the verbs in this fashion, with large gaps between each group, allows us to see the difference between them most clearly.

Similarly to before, 200 variants of each stimulus are generated, varying the names of the referents and the order between the two genders.

4 Procedure

In this section we describe how we induce responses to the tasks described in §3 for the two experiments in this study: measuring context-free IC bias and IC bias in the context of EC. Six English PLMs are considered in this study, representative of the unidirectional generative, bidirectional generative and bidirectional discriminative paradigms in language modeling. As seen in Table 1, GPT, BERT and ELECTRA are comparable in size and training data. GPT2-M, RoBERTa-L and ELECTRA-L are included as the 'bigger siblings' to the former three models respectively, selected to resemble closely the architecture of their counterparts, while having a larger size and richer training data.[3] Comparisons can therefore be made across the three base models, on one hand, and within each pair of a base model and its larger counterpart, on the other. The three larger models are comparable in size, but not fully comparable in training data, GPT2-M being trained on only a quarter of what the other two models are trained on. In a small multilingual experiment, we also experiment with German BERT, Spanish BERT and mBERT,[4] a multilingual version of BERT.

	Work	Size	Data	Dir	Obj
English					
GPT	Radford et al. (2018)	110	16	Uni	Gen
GPT2-M	Radford et al. (2019)	345	40	Uni	Gen
BERT	Devlin et al. (2019)	110	16	Bi	Gen
RoBERTa-L	Liu et al. (2019)	355	160	Bi	Gen
ELECTRA	Clark et al. (2020)	110	16	Bi	Disc
ELECTRA-L	—"—	335	160	Bi	Disc
German BERT	-	110	12	Bi	Gen
Spanish BERT	Cañete et al. (2020)	110	20	Bi	Gen
mBERT	-	110	194	Bi	Gen

Table 1: Model properties in terms of size (number of parameters in millions), training data (size in GB), directionality (uni- or bi-directional), and token-level training objective (generative or discriminative). German BERT and mBERT are not the product of any published work, but are closely associated with Devlin et al. (2019).

We first describe the procedure for bidirectional generative PLMs which is most straightforward. Both experimental tasks can be formulated as a cloze task (see Examples (3) and (4)). We place a mask tag in the empty slot, pass the input through the model and compute the probability that the models assigns to tokens *he* and *she* for the position of the mask tag.

The procedure is equally trivial when testing unidirectional PLMs for context-free IC bias effects, where the stimuli can naturally take on an open-ended form (see Example (1)). The partial sentence is passed through the model and a probability for the relevant pronouns is computed. Measuring the effect of IC bias in the context of EC, on the other hand, cannot be performed in the next-word prediction paradigm, so for this task we instead use the unidirectional PLMs as language scorers: we

---

[3] For implementational details see Appendix D.

[4] The size of the training data for mBERT is not exactly known—it consists of the 100 biggest Wikipedias. English Wikipedia, as made available on HuggingFace in 2019 is 14 GB in size; with the next 99 Wikipedias being 13% the size of the English Wikipedia on average (based on number of articles), that works out to an estimate of 194GB in total.

Model	Exp	p(he) =
GPT(2)	IC	p(he $\|w_1...w_4$)
	IC+EC	p($w_1...w_4$ he $w_6...w_8$)
(RO)BERT(a)	both	p(MASK==he $\|w_1...w_4$ MASK $w_6...w_8$)
ELECTRA	both	p(class=O $\|w_1...w_4$ he $w_6...w_8$)

Table 2: Probing PLMs for the effect of context-free IC (IC) and IC in the context of EC (IC+EC) experimental paradigm. $w_1...w_4$ = *John praised Mary because*; $w_6...w_8$ = *was a dax / had done well* for IC and IC+EC, resp. The procedure is analogous for *she*.

create two versions of each stimulus, one with pronoun *she*, one with pronoun *he* in the empty slot, and obtain a probability for each as the average over the probabilities of all tokens in the sequence.

The discriminative model ELECTRA is trained to recognize replaced tokens in its input, i.e. for each token it computes a probability over two classes, *replaced* (R) and *original* (O). Based on the reasoning outlined in Appendix E we conclude that the more appropriate way to probe ELECTRA in our experiments is by taking the average over the probability of class O for all tokens in a sequence, instead of looking at the probability of this class for the pronoun of interest alone. In a procedure similar to the one used for GPT2-M when used as a language scorer, we present ELECTRA with two versions of each stimulus , one with *he*, one with *she* in the slot of interest, and we compute the average probability of class O for each. We formalize the handling of all model types in Table 2.

5 Exp. 1: Context-free IC Bias

With this experiment we want to determine whether English PLMs exhibit the same tendencies as humans when it comes to the IC bias of actions/states expressed with interpersonal verbs in a context free of any explicit causes. To this end, we use the materials described in §3.1 and the procedure described in §4. For any given model, the IC bias per verb is measured over the responses of the model to the set of 200 stimuli, each response processed as follows.

5.1 Measuring Bias

For a sentence with a female subject and a male object, the probability of *she* would be denoted as p^s, the probability of *he* as p^o, and $p^s > p^o$ would indicate a preference for the subject for this stimulus. Refer back to Table 2 for a summary of how these probabilities are obtained with each model.

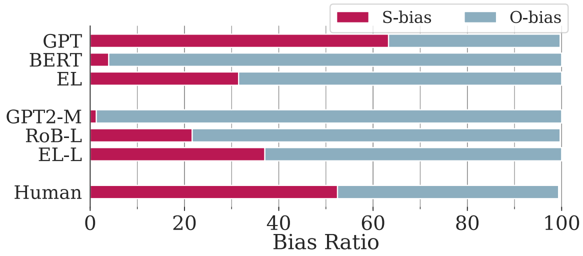

Figure 2: Ratio of S-bias verbs and O-bias verbs.

Having obtained the values p^s and p^o for each of the 200 stimuli per verb, we next calculate the bias of this verb in the following manner:

$$s_{wins} = \sum_{n \in N} (p^s_n - p^o_n) > 0 \tag{1}$$

$$o_{wins} = \sum_{n \in N} (p^s_n - p^o_n) < 0 \tag{2}$$

$$bias = 100 \times \left(\frac{s_{wins} - o_{wins}}{s_{wins} + o_{wins}} \right) \tag{3}$$

where N is the set of 200 stimulus variants per verb. This metric gives us a range from -100 (extreme O-bias) to 100 (extreme S-bias), with 0 indicating an absence of any bias altogether.

5.2 Preliminary analysis

As validation of the experimental procedure, we note that the generative models, BERT, ROBERTa-L, GPT, GPT2-M, ranked one of the two vocabulary items of interest, *he* or *she*, as their top prediction at a rate of 99.0, 99.4, 99.3 and 100.0 percent, respectively. It is reassuring to see that the models behave similarly to humans in this respect, who selected *he* or *she* at a rate of 94.2% as a first token after *because* (Ferstl et al., 2011). That also indicates that the probabilities assigned to the two tokens are meaningful (Holtzman et al., 2019).

Figure 2 shows the ratio of S-bias verbs and O-bias verbs as determined by each of the models and by humans. Compared to human IC bias scores, which give an even distribution of verbs across the S-bias and O-bias classes, we see that most models show an imbalance in this respect–most notably, BERT and GPT2-M show an almost categorical preference for the object of the sentence. These trends could relate to the syntactic role of the participants (subject v. object), to their linear order, or to referent proximity. The first two factors are difficult to decouple in English, a language with a relatively fixed subject-verb-object word order. We discuss the effect of proximity in Appendix A.2.

To gain a clearer understanding of the IC bias awareness of the different models, we analyze the results of this experiment in their raw form and also with discounting for other potential sources of bias. In addition to the object bias discussed above, we include gender and choice of nonce words, which on their own did not appear to have a strong effect, but could combine with each other and with the object bias in unpredictable ways. The discounting for *p(he)*, for example, in the context of stimulus *John apologized to Mary because _ was a dax* is done by subtracting the average probability of pronoun *he* in the context of any stimulus with a male subject and word *dax* in the nonce word slot (152.5 data points on average).

5.3 Results

Table 3 quantifies the correspondence between model IC bias and human IC bias in terms of Spearman's ρ over bias scores and in terms of micro-averaged F1 score over the polarity of the IC bias (subject-bias v. object-bias). For a plot of the exact bias values see Figure 6 in Appendix F. The PLMs most affected by the discounting for other biases are BERT and GPT2-M, which also showed the strongest imbalance as observed in Figure 2. All PLMs show a significant correlation to human IC bias, although this observation has the caveat of a small dataset (only 305 data points).

Within the pairs of related models, we can say that the differences between BERT and RoBERTa-L on the one hand and ELECTRA and ELECTRA-L on the other, are small, which suggests that already with 16GB of training data and 110M parameters, these architectures reach their potential in terms of capturing and using IC bias. For the two unidirectional PLMs, we see that after discounting GPT2-M exhibits a considerably higher correlation to human IC bias scores. This may indicate that the larger size and/or richer training data of GPT2-M have enabled the model to better capture IC bias, although the correlation still remains low in absolute terms.

Comparing unidirectional PLMs to bidirectional ones, we find that the latter obtain a stronger correlation to humans scores. A similar trend holds for the F1 scores, where bidirectional models show a greater awareness of the polarity of the IC bias of verbs (especially after discounting). We refrain from making comparisons across model architectures beyond the uni- v. bidirectional dichotomy, to avoid drawing false conclusions: as we are using different procedures to induce a response from generative and discriminative models, it could be argued that a direct comparison is not methodologically robust. The discriminative models are making a binary decision over two options predefined by us, while the generative models are computing a probability distribution over hundreds of thousands of vocabulary items.

	BERT	RoB-L	GPT	GPT2-M	EL	EL-L
ρ	0.58*	0.67*	0.22*	0.22*	0.72*	0.72*
F1	0.508	0.672	0.607	0.482	0.744	0.754
ρ	0.65*	0.69*	0.23*	0.38*	0.73*	0.71*
F1	0.698	0.734	0.564	0.649	0.774	0.748
LDA	0.67*	0.58*	0.64*	0.46*	0.73*	0.67*
LR	0.71*	0.6*	0.67*	0.49*	0.75*	0.7*

Table 3: Correspondence between human- and model-induced IC bias scores (a) for model predictions, measured in terms of Spearman's ρ correlation over bias scores and F1-score over bias polarity before (rows 1 and 2) and after discounting (rows 3 and 4); and (b) for model representations (rows 5 and 6). * denotes significance at $p < 0.001$.

5.4 Further Analysis

To measure the models' sensitivity to IC bias in a perfectly comparable setting, we carry out an additional comparison on the level of representations, thus abstracting away from the top layers of the models where the differences ensue. We extract 'decontextualized' verb representation from the PLMs following the procedure described in Appendix G. Using those, we carry out two types of probes: an extrinsic one, where we train a linear regression model (LR) to map from a verb's representation to its IC bias; and an intrinsic one, where we use linear discriminant analysis (LDA) to identify the single dimension in the verb representations that is most informative of IC bias.[5] The benefit of the latter approach is that it does not add any newly trained parameters to the computation of the correlation (Torroba Hennigen et al., 2020). In both cases, the result is a vector of scalars (the values predicted by the LR, or the values of the selected dimension)—we measure the correlation between these values and human IC bias to determine how much of the latter can be recovered from the representations.

To reduce overfitting, which is inevitable with

---

[5] As LDA operates over a space of discrete labels, we convert the IC bias scores into 3 classes ($> 0, < 0, = 0$).

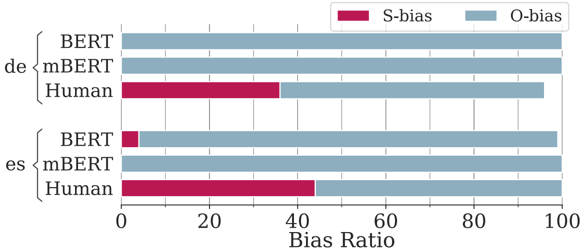

Figure 3: Ratio of S-bias and O-bias verbs in German (top) and Spanish (bottom).

305 datapoints in total and representations of 768 to 1024 dimensions, we apply PCA to the representations prior to fitting the LR and LDA models, reducing the representations to 5% of their original size. Each model (LR and LDA) is fit on a random 50% split of the data and applied on the other 50% to predict (LR) or transform (LDA). This procedure is repeated 100 times for robustness. The mean correlations are reported in the last two rows of Table 3. We see that larger models yield lower correlations than their smaller counterparts, suggesting that the former might encode IC bias in a more distributed manner than the latter.

Comparing models of equal size, we see that a similar pattern holds here as observed over the models' predictions, with the unidirectional models showing a lower correlation than the bidirectional ones, although the gap is substantially smaller in this space. It appears that unidirectional models might encode more IC bias than they exhibit at inference time. ELECTRA shows the highest correlation among the base-size models and ELECTRA-L the highest among the large models–as this comparison abstracts away from the specific objective each models uses (generative v. discriminative), we can conclude that the two ELECTRA models capture IC bias to the greatest extent out of the six PLMs studied here.

5.5 IC Bias in Other Languages

IC bias is not an English-specific phenomenon—Goikoetxea et al. (2008) obtained human judgements for 100 Spanish verbs, and Van den Hoven and Ferstl (2018) did so for 100 German verbs. Here, we probe Spanish (es) BERT, German (de) BERT and mBERT for their IC bias awareness. Details on the choice of proper nouns and nonce words are discussed in Appendix H. As seen in Figure 3 a recency/object bias is observed for the PLMs investigated here as well, so we present the results with and without discounting.

	German		Spanish	
	BERT	mBERT	BERT	mBERT
ρ	0.54*	0.23	0.13	-0.00
F1	0.600	0.600	0.540	0.560
ρ	0.51*	-0.13	0.16	-0.15
F1	0.680	0.380	0.610	0.360
LDA	0.26*	-0.0	0.09	0.08
LR	0.47*	0.02	0.12	0.03

Table 4: Correspondence between human- and model-induced IC bias in German and Spanish. For more details see the caption of Table 3.

Table 4 summarizes the results before (rows 1 and 2) and after discounting (rows 3 and 4). The poor performance of the multilingual mBERT is not surprising—Rönnqvist et al. (2019) found mBERT to be inferior to monolingual models at making a prediction for randomly masked subtokens (specifically looking at German, among other languages); and Vulić et al. (2020) found mBERT and XLM-R to both be inferior to their monolingual counterparts on probing tasks pertaining to lexical semantics.

German BERT shows a medium-strength correlation to human scores, whereas Spanish BERT shows no such correlation at all, both on the level of predictions and model representations. This observation could be attributed to the pro-drop nature of Spanish, wherein pronouns are often dropped when in subject position. This likely makes the learning of IC bias in Spanish harder for a PLM, as less evidence is available in the context to connect the explanation to its referent.

From this section, we conclude that English bidirectional PLMs reliably capture and use IC bias in their predictions. Unidirectional models encode IC bias but do not greatly rely on it at prediction time. Having established that IC bias affects the behavior of at least some PLMs, we now evaluate how these models integrate this implicit signal with more explicit signals from the sentence-level semantics.

6 Exp. 2: IC Bias in the Context of EC

With this experiment, we test the hypothesis that when the IC and EC signals converge in congruent contexts, i.e. they point to the same referent, the models would have more ease predicting the correct referent, whereas when the two signals diverge in incongruent contexts, the models would be more prone to errors. We test this hypothesis using the

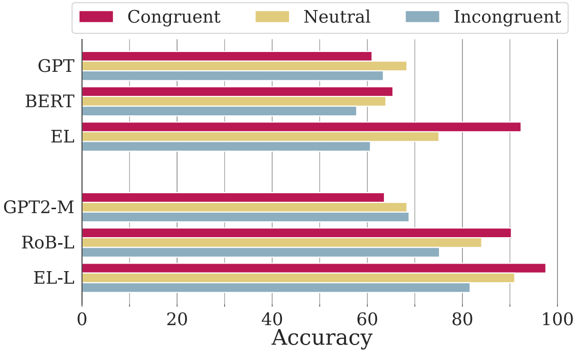

Figure 4: Accuracy on co-reference resolution over stimuli with congruent and incongruent IC and EC.

materials described in §3.2 and the procedure from §4. We present each stimulus to the models in 200 versions varied for subject and object referents. In this experiment, we do not perform discounting: unlike Experiment 1 where we wanted to gain as clear a view as possible of the level of IC bias that models exhibit, isolated from other sources of bias, here we want to see how IC bias interacts with EC, subject to any other potential sources of bias.

6.1 Results

Figure 4 shows the results from this experiment. All models are substantially better at resolving the antecedent correctly on average compared to a random baseline of 50%. Looking at the neutral stimuli as indication for the models' general ability to solve this task, we see that the two largest and most richly trained models, ROBERTa-L and ELECTRA-L, perform best. In line with our expectations, we see that most models score lower on resolving antecedents in incongruent contexts and higher in congruent ones. This is true for the four bidirectional PLMs, which also exhibited higher IC bias in Experiment 1. The gap is largest for ELECTRA and still substantial for ROBERTa-L and ELECTRA-L. The unidirectional models, on the other hand, show a noisier behavior, with a relatively small gap between the three types of stimuli, and an inconsistent ranking between them.

6.2 Discussion

As IC bias contributes to the construction of causal links in narrative and as such aids language comprehension (Trabasso and Sperry, 1985), it is desirable that PLMs capture and use this signal coming from the lexical semantics of interpersonal verbs. In Experiment 1, we found that all PLMs studied show a medium to high correlation with human IC bias scores on the level of representations, with bidirectional ones doing so on the level of predictions, too. While IC bias does contribute to language comprehension, it also has the unfortunate effect of interference in the context of incongruent EC. In this respect, models with higher IC bias awareness, i.e. the bidirectional PLMs in our study, suffer a greater drop in performance. Meanwhile, the unidirectional PLMs studied, which show little awareness of IC bias in a context free of EC, also show no interference from it when resolving referents in the presence of EC. Paradoxically, the superior performance of bidirectional PLMs with respect to IC bias also exposes a limitation of theirs: while these models are advanced enough to use IC bias for their predictions, their interpretation of semantics is still fairly shallow. The lower-order signal coming from lexical semantics is given priority over the higher-order signal coming from the sentence-level semantics. In the experiment presented in this section, this leads to a higher error rate on resolving pronoun antecedents in incongruent contexts, with potential impact on tasks that depend on co-reference resolution, e.g. document summarization (Azzam et al., 1999), question answering (Morton, 1999; Vicedo and Ferrández, 2000), and information extraction (Zelenko et al., 2004).

7 Conclusion

From the comparison of six competitive PLMs, BERT, ROBERTa-L, GPT, GPT2-M, ELECTRA and ELECTRA-L, we conclude that PLMs can exhibit IC bias much like humans do, but that different models do so to a different degree, with bidirectional models showing moderate to strong correlation to human judgements, and unidirectional models showing only a weak correlation. This ability of some PLMs has the unfortunate effect that it makes them prone to higher error rates in contexts of incongruent IC and EC signals, where the PLMs overly rely on IC bias. This finding adds to a growing body of evidence that PLMs prioritize lexical cues over higher-order semantic cues (cf. Tenney et al., 2019). As our hypothesis is inspired by the observation that humans experience a delay in the processing of incongruent contexts (Caramazza et al., 1977), our findings point to the potential of drawing further inspiration from such psycholinguistic phenomena in studying the behaviour of language models (Ettinger, 2020). Seeing that language models show a growing potential as off-the-shelf task solvers

(Radford et al., 2019; Brown et al., 2020), studying their predictions is an important avenue for better understanding their capabilities and limitations.

A Alternative task formulation

A.1 Splitting the clauses

Hartshorne and Snedeker (2013) induce a response by presenting participants with a sentence like

(5) John praised Tim because he was a *dax*.

and asking them the question *Who do you think is a dax?* In the spirit of Radford et al. (2018) and Radford et al. (2019) we considered reformulating this into a task suitable for a language model as:

(6) John praised Tim because he was a *dax*. The one who was a *dax* was ___

This formulation would have allowed us to use unidirectional PLMs in a more natural way, for next-word prediction, since the token of interest now comes at the end of the sequence; and it would have been equally suitable for bidirectional PLMs. We performed experiments with it and found that models largely scored at chance level for the stimuli containing neutral verbs, which renders the results for the congruent and incongruent stimuli invalid. The difficulty PLMs faced in solving this task could stem from the more complex inference required and/or from the border-line unnatural structure of the inputs.

A.2 Swapping the clauses

Seeing that all models show some degree of object bias, we considered an alternative task formulation, where the main clause and the subordinate clause are swapped:

(7) Because ___ was a *dax*, John praised Mary.

In this formulation, the proximity changes for the two referents, such that now the subject is closer to the pronoun of interest. This clause-swapping can only be applied to bidirectional models for the purposes of measuring context-free IC bias as described in Section 3.1. Figure 5 shows the results obtained with this task formulation. Comparing these numbers to the ones presented in Figure 2, we see that all models show a more balanced distribution of verbs across the S-bias and O-bias classes, with the two ELECTRA models closely matching human scores. This suggests that reference proximity is indeed a factor in the choice of the pronoun. Still, we see that RoBERTa-L and especially BERT remain strongly biased towards the object of the sentence, meaning that proximity is not the only factor at play.

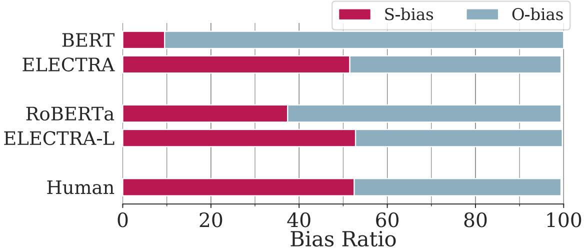

Figure 5: Ratio of S-bias verbs and O-bias verbs with swapped clauses.

Although this task formulation appears to lead to a reduced object bias across the four bidirectional models, we refrain from using it in our main experiments because it is not attested in psycholinguistic studies, i.e. it could have unforeseeable effects on human judgements of IC bias. As our main goal is to analyse the models' behavior *in relation to human behavior*, we follow closely the experimental protocol used in the available psycholinguistic studies on IC bias.

B Proper nouns

In this section we consider a seemingly minor but important consideration. Abdou et al. (2020) showed that model predictions on the Winograd Schema Challenge greatly vary with changes in the gender and identity of proper nouns used in the stimuli. We alleviate this issue by marginalizing over a range of proper nouns. To do so, we create multiple versions of the same stimulus with different proper noun combinations and use the average response of a model over all of the stimuli as an indication of the model's response to an abstract subject and object. We use 10 male names and 10 female names in 200 permutations. To ensure that the names in these lists are perceived as common names for the gender they represent, we used the models themselves to select the names, compiling a list of names unique to each model. We queried each model with the following sequences and took the top 10 names predicted:[6] *She is a woman and her name is* MASK. and *He is a man and his name is* MASK.

C Development of Materials

Neither Caramazza et al. (1977) nor Garnham et al. (1996) provide an explicit description of the procedure used to design their materials, so we extrapolate their methods by observing the materials themselves: the main goal in constructing a stimulus is to ensure that a particular ending is unambiguous (in a standard, most-likely reading) in pointing to exactly one of the two referents. The explanations always start with a verb in the past tense, e.g. *had done well*. And they are simple in the sense that they require little background knowledge. Using these observations as guidelines, we manually constructed pairs of congruent-incongruent contexts for 99 verbs, i.e. 198 stimuli in total. The materials were validated by three native English speakers and one fluent English speaker, who were asked to perform the cloze task on one stimulus from each pair and to mark ambiguous cases as such rather than making a guess at random. Eight contexts were judged as ambiguous and replaced with a better alternative, also validated in turn.

D Model implementations

We use the models as shared in the HuggingFace library (Wolf et al., 2019). In English experiments, we use bert-base-uncased, electra-large/base/small-discriminator, gpt2, and roberta-base. For German we use bert-base-german-cased, german-nlp-group/electra-base-german-uncased, dbmdz/german-gpt2, for Spanish dccuchile/bert-base-spanish-wwm-cased, and for both we use xlm-roberta-base and bert-base-multilingual-cased.

All experiments were run on a MacBook Pro, each taking between 1h (for smaller models) to 4h (for larger models).

E Probing ELECTRA

Consider the example sentence *The cake is very delicious* and a "corrupted" version of it we might present to ELECTRA: *The shoe is very delicious*. The model could give us a label sequence like {OROOO} for the latter, to indicate that shoes do not belong to the world of delicious things. And we could look at the probability distribution for the second token to quantify the strength of ELECTRA's objection to seeing this token in this position. Alternatively, ELECTRA could resolve the conflict with a label sequence like {OOOOR} to indicate that a taste-related adjective is not suitable for describing a shoe. In this case, looking at the probability distribution for the word *shoe* could be rather uninformative. This leads us to conclude that taking the average over the probability of label O for all tokens in a sequence is more informative than looking at the probability of this label for a single token.

F Experiment 1 visualisation

Figure 6 shows the data corresponding to the results described in Section 3.1. We offer this visualisation for the sake of clarity as correlation coefficients can often be misleading without the accompanying data. By and large, the visualisation of the data

---

[6] The mask tag and full-stop were omitted for GPT2-M. As ELECTRA cannot be used in this fashion, we instead used the generative counterpart of the model to obtain the list of names and confirmed that ELECTRA accepts them in their respective contexts (i.e. that it labels them as *original* tokens).

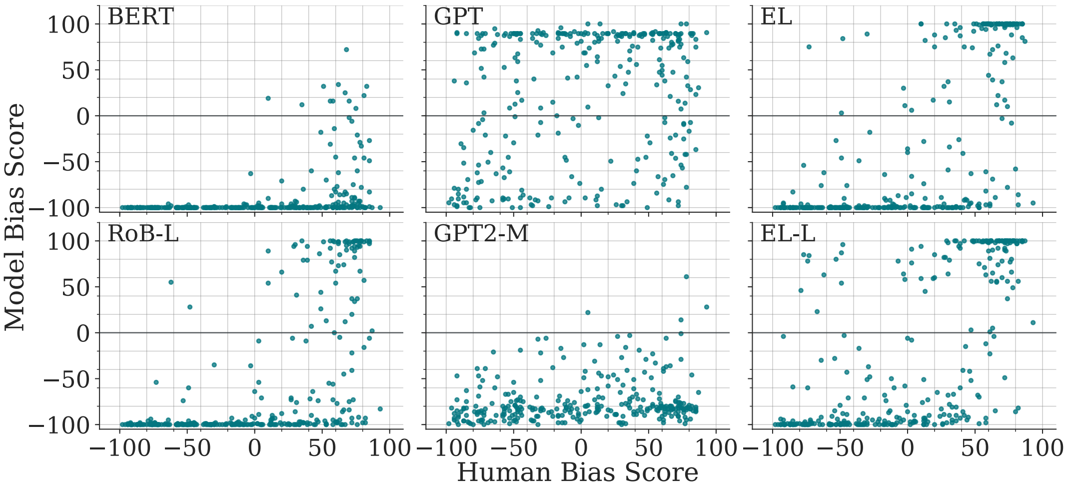

Figure 6: Model bias to human bias agreement.

corroborates the results discussed in the main body of the paper.

One observation here is that human bias scores are uniformly distributed between the two extremes (100 and -100), whereas model bias scores tend to be closer to the two endpoints. The scores obtained in the human-based study represent the responses of 100 people to the same stimulus. Deviation from the extremities here show that people differ in their judgements to some degree. The scores obtained in our study represent the responses of a single model to 200 variants of the same stimulus. In this sense, it is not surprising that the model's scores occupy the two extremities – this shows the models' consistency in judging a given verb to be subject or object biasing.

G Model representations

To obtain a single representation of any given verb from any given model, we encode a sequence like *John praised Mary* and take the representation for the first subtoken of the verb. With BERT's tokenizer, for example, the first subtoken of a verb amounts to the full verb form 57.1% of the time, and to the root of the verb 19.3%; in the remaining 22.6% the unit is 'meaningless.' These numbers vary across models, but in all cases, we are looking at contextualized embeddings, so even 'meaningless' subtokens should be a valid proxy to the verb's representation. To abstract away from the exact choice of proper nouns, we repeat this procedure for the 200 name variants and take the elementwise average over all the representations.

H Spanish and German experiments

The contexts we used for extracting proper nouns from the non-English models were *Er ist ein Mann und heißt* and *Sie ist eine Frau und heißt* for German and *Ella es una mujer y se llama* and *El es un hombre y se llama* for Spanish. For BERT DE we used *Sie heißt* and *Er heißt* instead, as these stimuli more consistently yielded names in the high ranks. Since the generator for ELECTRA DE is not publicly available, we used a different procedure to obtain the lists of personal nouns for this model: we queried WikiData for the top 100 male and female given names for people from Germany and then scored these with ELECTRA in the context shown above. We selected the 10 names for each gender that yielded highest probability of an *O* label.

For the nonce-word slot of the stimuli, we sourced nonce nouns from Dykstra-Pruim (2003) and Zaretsky et al. (2016) (German) and Cantú Sánchez (2011) (Spanish). As these lists contain less than 200 words, here sampling for the nonce-word slot in the 200 variants of a stimulus was done *with* replacement.

Do It Once: An Embarrassingly Simple Joint Matching Approach to Response Selection

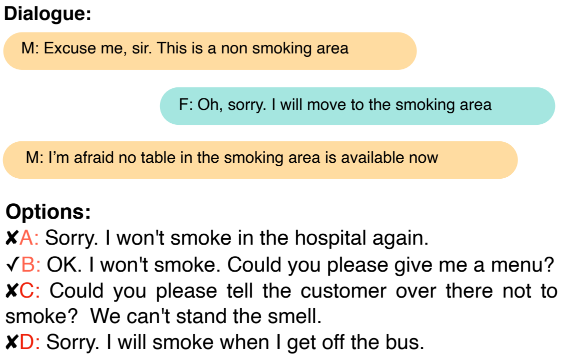
Abstract

Existing matching models for response selection adopt the independent matching (*IM*) approach. To complete a prediction, they have to perform N independent matches, where N is the number of response options. In this paper, we explore a joint matching (*JM*) approach which performs matching only once regardless of the number of options. The *JM* approach does not change the structure of matching component but only modifies its input and output format. It also enables a cheap but effective data augmentation method. Extensive experiments on the MuTual dataset demonstrate that, even with the simplest formulation, JM outperforms *IM* approach by a large margin and reduces training time by over half.

1 Introduction

The availability of large-scale datasets has driven the development of neural dialogue systems. One important task in dialogue systems is response selection, which plays an essential role in retrieval-based chatbots (Ji et al., 2014). It aims to select the best-matched response from a set of response options for a dialogue. As shown in Figure 1, given a dialogue context and four response options, we need to choose the only logically correct one.



Dialogue:

M: Excuse me, sir. This is a non smoking area

F: Oh, sorry. I will move to the smoking area

M: I'm afraid no table in the smoking area is available now

Options:

✘A: Sorry. I won't smoke in the hospital again.
✓B: OK. I won't smoke. Could you please give me a menu?
✘C: Could you please tell the customer over there not to smoke? We can't stand the smell.
✘D: Sorry. I will smoke when I get off the bus.

Figure 1: Example of response selection.

Previous work in response selection follows an *independent matching (IM)* approach and computes a matching score for each of the N response options independently. Various matching models following this approach have been proposed (Zhou et al., 2016; Wu et al., 2017; Zhou et al., 2018; Chaudhuri et al., 2018; Tao et al., 2019; Yuan et al., 2019). Despite its success in pre-BERT era, we argue that the *IM* approach does not make full use of the ability of pretrained encoders (such as BERT and RoBERTa) to encode multiple sentences, hence may hinder both efficiency and effectiveness. Specifically, to complete a prediction, the *IM* approach has to perform N independent matches, which means N gradient computations (where N is the number of response options). Besides, the dialogue context is repeatedly encoded N times, which further contributes to the inefficiency. The other drawback is that options in these models are independent and agnostic of each other. In reality, humans often compare all the options and utilize their correlations to make a comprehensive decision.

In this paper, we describe a *joint matching* (*JM*) approach for this task. For any matching model, we do not change its inner structure but only modify its input and output format. Specifically, we first add a special token at the start of each option, and then concatenate all options into a single sequence. The option sequence is then matched as a whole with the dialogue context. Finally, we extract vectors corresponding with the special token to calculate matching scores. Note that *JM* can complete a prediction with a single match, which means it only requires one gradient computation and context encoding. Besides, thanks to the self-attention mechanism (Vaswani et al., 2017) of BERT-based matching models, options can now directly attend to each other, rather than being agnostic.

Another advantage of *JM* approach is that it nat-

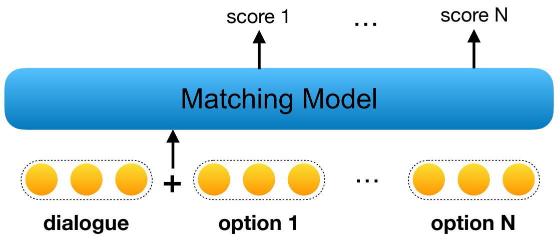
(a) Independent Matching



(b) Joint Matching

Figure 2: Overview of Independent Matching and Joint Matching.

urally enables a simple yet effective data augmentation method. The basic idea is that since options are sequentially concatenated in *JM*, new training instances can be easily created by changing the permutation order of options. Therefore, a dialogue with M response options can create at most $M!$ (factorial M) times as many training instances.

We conduct experiments on the MuTual dataset (Cui et al., 2020), a publicly available English dataset for multi-turn dialogue response selection. Results show that *JM* advances *IM* on three matching models and can significantly reduce training time. Besides, the permutation-based data augmentation method gives further improvement.

2 Model

The overview of IM and JM is shown in Figure 2. We describe the details in the following subsections[1].

2.1 Background

Given a dialogue $\mathcal{D}$ with M utterances $\{U_i\}_{i=1}^{M}$, and a set of N response options $\{O_j\}_{j=1}^{N}$, the goal of response selection is to select the logically correct option $\hat{O}$.

Previous work (Cui et al., 2020) shows that pretrained matching models define the state-of-the-art on this task. Similar to using BERT for sentence-pair classification (Devlin et al., 2019), they first concatenate the context (sentence A) and a candidate response (sentence B) as BERT input (i.e., "[CLS] Excuse me ... [SEP] Sorry ... [SEP]"). On the top of BERT, a fully-connected layer is used for transforming the [CLS] token representation to the matching score. In order to compete a prediction, M independent matchings have to be made, where M is the number of options.

2.2 Joint Matching

Instead of conducting N times of independent matches, we make the first step outside the IM framework and explore a joint matching approach for this task. We first adds a special token [OP]^j at the start of the j^{th} option. It is a token used to aggregate the matching information between the context and the j^{th} option into a single vector. We then concatenate all the options into a single sequence. Formally,

$$S_O = [OP]^1 O_1 [OP]^2 O_2 ... [OP]^N O_N \tag{1}$$

For the dialogue context, we concatenate all the utterances into a single sequence. Formally,

$$S_D = U_1 U_2 ... U_M \tag{2}$$

The two sequences are then separated with a [SEP] token and fed into our pretrained encoder. Formally,

$$X = [CLS] S_D [SEP] S_O [SEP] \tag{3}$$

For any BERT-based matching model, suppose the output embeddings of the model are $H_t \in \mathbb{R}^{|X| \times d}$. To perform scoring, we first extract outputs corresponding to [OP]^j and represent them as $h^{[OP]^j}$. The only new parameters learned are a score vector $W \in \mathbb{R}^d$. The probability of option j being the answer is computed as a dot product between $h^{[OP]^j}$ and W followed by a softmax over all of the options. Formally,

$$P_j = \frac{e^{W \cdot h^{[OP]^j}}}{\sum_i e^{W \cdot h^{[OP]^i}}} \tag{4}$$

The training objective is the log-likelihood of the correct answer[2].

---

[1] The code is at https://github.com/gitzlh/JM-Matching

[2] For the score layer, an intuitive approach is to use $h^{[CLS]}$ instead of $h^{[OP]}$ and cast the prediction into a M-classes classification. However, we found that this approach leads to poor performance.

In this way, the JM approach only needs to match the context sequence and the option sequence once. Compared with the *IM* approaches, JM is computational efficient in two ways: 1) It encodes the dialogue context only once, instead of *M* times. However, this benefit is partially offset by the fact that the complexity of transformer grow quadratically with the length of input 2) More importantly, IM approaches need to compute gradients *M* times for each training step. Besides, in each self-attention layer of the BERT-based matching model, options can directly attend to and interact with each other. This process mimics how humans solve multi-choice questions, that we often compare all the options before making the decision.

2.3 Permutation-Based Data Augmentation

Another advantage of *JM* is that it naturally enables a permutation-based data augmentation (PBDA) method, which can generate high-quality labeled data to improve response selection.

Specifically, since the input of our model is organized as Equation 3, we can create new training instances by simply changing the concatenation order of the options. For example, from $[OP]^1O_1[OP]^2O_2...[OP]^NO_N$ to $[OP]^2O_2[OP]^1O_1...[OP]^NO_N$, we create a new training example (see Figure 2). Correspondingly, the ground-truth label of the training instance may be changed. In this way, a single dialogue can create at most $M!$ times training instances.

3 Experiments

3.1 Dataset

We evaluate our model on the Mutual dataset (Cui et al., 2020), a human-labeled, open-domain and reasoning-based dataset for multi-turn response selection. Compared with previous datasets (Lowe et al., 2015; Zhang et al., 2018; Welleck et al., 2019), MuTual is more challenging since it requires some reasoning ability. Models that achieve close-to-human performance on previous datasets, still perform far behind human performance on MuTual. The statistics of MuTual are shown in Table 1. Note that since Mutual has 4 options for each dialogue, PBDA can thus creates at most 24 (4!) times as many training instances.

	MuTual
Training set	7088
Validation set	886
Test set	886
# Avg. Turns / Dialogue	4.73
# Avg. Words / Utterance	19.57
# Options	4

Table 1: Statistics of MuTual.

3.2 Settings

We use PyTorch to implement JM on three matching models. We adopt AdamW (Loshchilov and Hutter, 2018) as our optimizer, and the peak learning rate and warmup proportion are set to 1e-5 and 0.06, respectively. We use the largest batch size that fits in the memory of our GPU and use gradient accumulation for an effective batch size of 32. Dropout (Srivastava et al., 2014) is employed before the score layer with a rate of 0.1. We train our model for 15 epochs and choose the model that reports the highest R@1 on the validation set.

Following previous work (Cui et al., 2020), we evaluate our model with recall at position 1 in 4 candidates (R@1), recall at position 2 in 4 candidates (R@2) and Mean Reciprocal Rank (MRR).

4 Results

4.1 Main Performance

Table 2 gives the comparison of IM and JM on three matching models on the MuTual dataset. Note that we only experiment with pretrained matching models given that they have an overwhelming advantage over non-pretrained models. For a fair comparison, we report baseline results both from the official reports of MuTual (Cui et al., 2020) and our own implementation.

Our first observation is that RoBERTa-based models significantly outperform BERT-based models, suggesting that RoBERTa is a more powerful feature extractor. More importantly, we note that our JM approach outperforms IM approach on all three matching models. For example, BERT-JM improves over BERT-IM by 6% (absolute) R@1. We suppose that this is because the JM approach concatenates all the options as the model input, and, thanks to the self-attention mechanism, each option can directly attend to each other. In this way, JM can make a more comprehensive decision and boost the performance especially on challenging datasets like MuTual.

The conclusion holds true for larger pretrained matching models such as RoBERTa-large. As

Methods	R@1	R@2	MRR
Human performance	0.938	0.971	0.964
BERT-IM (Cui et al., 2020)	0.648	0.847	0.795
BERT-IM †	0.641	0.853	0.793
BERT-JM	**0.702**	**0.904**	**0.833**
RoBERTa-IM (Cui et al., 2020)	0.713	0.892	0.836
RoBERTa-IM †	0.770	0.912	0.868
RoBERTa-JM	**0.784**	**0.933**	**0.880**
RoBERTa-large-IM †	0.844	0.958	0.914
RoBERTa-large-JM	**0.870**	**0.973**	**0.930**

Table 2: Main results on MuTual. We can see that *JM* outperforms *IM* approach for every pretrained encoders. † means our own implementation results. Note that the JM results are achieved without data augmentation.

Methods	Forward	Backward	Total
RoBERTa-IM	116	412	528
RoBERTa-JM	**71**	**168**	**239**

Table 3: Average training time (second) per epoch. RoBERTa-IM and RoBERTa-JM both use the largest batch size available on the same GPU.

shown in Table 2, RoBERTa-large-JM brings about 3% (absolute) improvement over RoBERTa-large-IM in terms of R@1 and even surpasses human performance in terms of R@2.

4.2 Training Time

In the task of response selection, the scalability of the model becomes an issue when the number of options increases. In this subsection, We compare JM and IM with respect to training time[3]. As shown in Table 3, RoBERTa-JM reduces the training time by 55% compared with RoBERTa-IM. More detailed analysis shows that the reduction is mostly contributed to the backward propagation process. This is because to complete a prediction, RoBERTa-IM performs M independent matches and thus requires M gradient computations, a costly process. It also needs to encode the dialogue context M times, leading to computational inefficiency especially in multi-turn settings. By contrast, RoBERTa-JM requires only a single match[4].

Methods	R@1	R@2	MRR
RoBERTa-JM	0.784	0.933	0.880
RoBERTa-JM 4x	0.793	**0.947**	0.887
RoBERTa-JM 8x	**0.813**	0.942	**0.896**
RoBERTa-JM 24x	0.807	0.942	0.892

Table 4: PBDA results. 4x, 8x and 24x mean augmenting the data size by 4, 8 and 24 times, respectively.

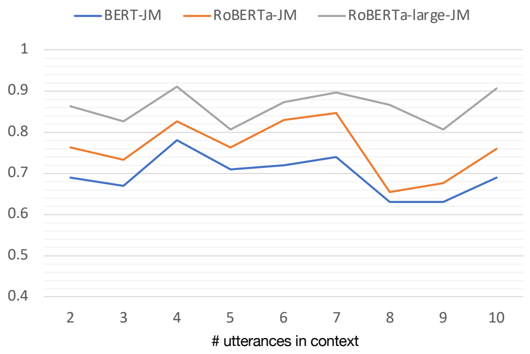


Figure 3: Performance on MuTual dev set across different contexts.

4.3 Data Augmentation

In this subsection, we conduct experiments to verify the effectiveness of PBDA.

As shown in Table 4, PBDA 4x brings a 1% (absolute) improvement in terms of both R@1 and R@2, showing that by simply permuting the options, we can create high-quality training instances. Besides, when increasing the data size by 8 times, we observe another 2% (absolute) improvement in terms of R@1. An interesting observation is that PBDA 24x does not further improve model performance, showing that there is a limit to the improvement brought by data augmentation.

---

[3] Both models are trained on a single NVIDIA TITAN Xp GPU.

[4] We note that this benefit is partially offset by the transformer's quadratic complexity with regard to the length of input. Suppose that the average length of the dialogue utterance and response option is L, then the time complexity of the IM and JM approach is $O((ML+L)^2N)$ and $O((ML+NL)^2)$, respectively

4.4 Context Length

Following previous work (Wu et al., 2017), we further investigate how JM performs cross the length of context. As demonstrated in Figure 3, the performance of BERT-JM and RoBERTa-JM is generally satisfactory, except for the slight deterioration when the context has more than seven utterances. It can also deal with a short context that only has two utterances.

On the other hand, RoBERTa-large-JM consistently performs better than RoBERTa-JM, and when the context becomes longer, the gap becomes larger. It also gives more stable performance across different context lengths, further showing the strong representation ability of RoBERTa-large.

5 Conclusions

In this paper, we make the first step outside the independent matching framework and explore a joint matching approach for response selection. We also present an effective permutation-based data augmentation method. We conduct experiments on the MuTual dataset and demonstrate the effectiveness and efficiency of our approach. Besides, the proposed data augmentation further improves model performance.

Climbing the Tower of Treebanks: Improving Low-Resource Dependency Parsing via Hierarchical Source Selection

Abstract

Recent work on multilingual dependency parsing focused on developing highly multilingual parsers that can be applied to a wide range of low-resource languages. In this work, we substantially outperform such "one model to rule them all" approach with a heuristic selection of languages and treebanks on which to train the parser for a specific target language. Our approach, dubbed TOWER, first hierarchically clusters all Universal Dependencies languages based on their mutual syntactic similarity computed from human-coded URIEL vectors. For each low-resource target language, we then climb this language hierarchy starting from the leaf node of that language and heuristically choose the hierarchy level at which to collect training treebanks. This treebank selection heuristic is based on: (i) the aggregate size of all treebanks subsumed by the hierarchy level and (ii) the similarity of the languages in the training sample with the target language. For languages without development treebanks, we additionally use (ii) for model selection (i.e., early stopping) in order to prevent overfitting to development treebanks of closest languages. Our TOWER approach shows substantial gains for low-resource languages over two state-of-the-art multilingual parsers, with more than 20 LAS point gains for some of those languages. Parsing models and code available at: `https://github.com/codogogo/towerparse`.

1 Introduction

Syntactic parsing – grounded in a wide variety of formalisms (Taylor et al., 2003; De Marneffe et al., 2006; Hockenmaier and Steedman, 2007; Nivre et al., 2016, *inter alia*) – has been the backbone of natural language processing (NLP) for decades, and an indispensable preprocessing step for tackling higher-level language understanding tasks. A recent major paradigm shift in NLP towards large-scale pretrained language models (PLMs) (Devlin et al., 2019; Liu et al., 2019; Brown et al., 2020) and their end-to-end fine-tuning for downstream tasks has reduced the downstream relevance of supervised syntactic parsing. What is more, there is more and more evidence that PLMs implicitly acquire rich syntactic knowledge through large-scale pretraining (Hewitt and Manning, 2019; Chi et al., 2020) and that exposing them to explicit syntax from human-coded treebanks does not offer significant language understanding benefits (Kuncoro et al., 2020; Glavaš and Vulić, 2021). In order to implicitly acquire syntactic competencies, however, PLMs need language-specific corpora at the scale at which it can only be obtained for a tiny portion of world's 7,000+ languages. For the remaining vast majority of languages – with limited-size monolingual corpora – explicit syntax still provides valuable linguistic bias for more sample-efficient learning in downstream NLP tasks.

Reliable syntactic parsing requires annotated treebanks of reasonable size: this prerequisite is, unfortunately, satisfied for even fewer languages. Despite the multi-year, well-coordinated annotation efforts such as the Universal Dependencies (Nivre et al., 2016, 2020) project, language-specific treebanks are unlikely to appear anytime soon for most world languages. This renders the transfer of syntactic knowledge from high-resource languages with annotated treebanks a necessity. A *truly zero-shot* transfer for *low-resource languages* assumes a set of training treebanks from resource-rich source languages and a target language without any syntactic annotations. Effectively, the task is then to identify the subset of source treebanks, the parser trained on which would yield the best parsing performance for the target language. An exhaustive search over all possible subsets of source treebanks is not only computationally intractable[1] but also

---

[1] One can create $2^N - 1$ different training sets from a

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4878–4888
August 1–6, 2021. ©2021 Association for Computational Linguistics

uninformative in true zero-shot scenarios in which there is no development treebank (i.e., any syntactically annotated data) for the target language. Most existing transfer methods therefore either (1) choose one (or a few) best source languages for each target language (Rosa and Zabokrtsky, 2015; Agić, 2017; Lin et al., 2019; Litschko et al., 2020) or (2) train a single multilingual parser on all available treebanks; such parsers, based on pretrained multilingual encoders, currently produce best results in low-resource parsing (Kondratyuk and Straka, 2019; Üstün et al., 2020). Other transfer approaches, e.g., based on data augmentation (Şahin and Steedman, 2018; Vania et al., 2019), violate the zero-shot transfer by assuming a small target-language treebank – a requirement unfulfilled for most world languages.[2]

In this work, we propose a simple and effective heuristic for selecting a good set of source treebanks for any given low-resource target language. In our approach, named TOWER, we first hierarchically cluster all Universal Dependencies (UD) languages. To this end, we compute syntactic similarity of languages by comparing manually coded vectors of their syntactic properties from the URIEL database (Littell et al., 2017). We then iteratively 'climb' that language hierarchy level by level, starting from the leaf node of the target language. We stop 'climbing' (i.e., select the set of source treebanks subsumed by the current hierarchy level), when the relative decrease in linguistic similarity of the training sample w.r.t the target language outweighs the increase in size of the training sample. We additionally exploit the linguistic similarity between the target language and its closest sources with existing development treebanks to inform a model selection (that is, early-stopping) heuristic. TOWER substantially outperforms state-of-the-art multilingual parsers – UDPipe (Straka, 2018), UDify (Kondratyuk and Straka, 2019), and UDapter (Üstün et al., 2020) on low-resource languages, while offering comparable performance for high-resource languages.

2 Climbing the TOWER of Treebanks

Constructing the TOWER. We start by hierarchically clustering the set of 89 languages from Universal Dependencies [3] based on their syntactic similarity. To this end, we represent each language with its `syntax_knn` vector from the URIEL database (Littell et al., 2017). Features of these 103-dimensional vectors correspond to individual syntactic properties from manually coded linguistic resources such as WALS (Dryer and Haspelmath, 2013) and SSWL (Collins and Kayne, 2009). URIEL's `syntax_knn` strategy replaces feature values missing in those resources with kNN-based predictions (cf. (Littell et al., 2017) for more details). We then carry out hierarchical agglomerative clustering with Ward's linkage (Anderberg, 2014) with Euclidean distances between URIEL vectors guiding the clustering. Figure 1 shows a dendrogram of one part of the resulting hierarchy. We display the complete hierarchy in the Appendix. The syntax-based clustering largely reflects memberships in language (sub)families, with a few notable exceptions: e.g., Tagalog (*tl*), from the Austronesian family appears to be syntactically similar to (and is joined with) Scottish (*gd*), Irish (*ga*), and Welsh (cy) from the Celtic branch of the Indo-European family.

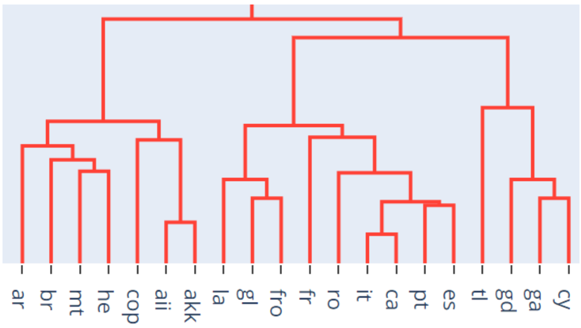

Figure 1: Part of the syntax-based hierarchical clustering of UD languages (ISO 639-1 codes).

Treebank Selection (TBS). For a given test treebank, we start climbing the hierarchy from the leaf node of the treebank's language. Let s_l denote the number of climbing steps we take from the target leaf node l. If the target test treebank also has the corresponding training portion, in-treebank training constitutes the first training configuration (we denote this configuration with $s_l = -1$). For resource-rich languages with several training treebanks, we create the next training sample by concatenating all of those treebanks (we denote this level with $s_l = 0$).[4] For low-resource target lan-

---

collection of N source treebanks.

[2] For the vast majority of world languages there does not exist a single manually annotated syntactic tree.

[3] We worked with the UD version 2.5.

[4] For example, for the Russian test treebank *SynTagRus*, the training set at $s_l = -1$ consists of the train portion of the same *SynTagRus* treebank; at $s_l = 0$, we concatenate

guages without any training treebanks, the first training sample is collected at $s_l = 1$, where the language is joined with other languages. The training set corresponding to a hierarachy level (i.e., each *join* in the tree) concatenates all training treebanks of all languages (i.e., leaf nodes) of the respective hierarchy subtree.[5]

Let $\{S_n\}_{n=0 \text{ (or } -1)}^{N}$ be the set of training configurations collected by climbing the hierarchy starting from the target language l and let $S_n = \cup\{T_k\}_{k=1}^{K}$ be the n-th training set consisting of K training treebanks. As we climb the hierarchy (i.e., as n increases), the training set S_n is bound to grow; at the same time, the sample of training languages becomes increasingly dissimilar w.r.t. the target language l. In other words, as we climb higher up the induced syntactic hierarchy of languages, we train on more data but from a mixture of (syntactically) more distant languages. Let l_k be the language of the training treebank T_k. We then quantify the syntactic similarity $sim(S_n, l)$ between the training set S_n and the target language l as follows:

$$sim(S_n, l) = \frac{1}{|S_n|} \sum_{k=1}^{K} |T_k| \cdot \cos(\mathbf{l}_k, \mathbf{l}) \quad (1)$$

with $\cos(\mathbf{l_k}, \mathbf{l})$ as cosine similarity between URIEL vectors of l_k and l, and relative sizes of individual treebanks $|T_k|/|S_n|$ as weights. We then use the following simple heuristic to select the best training set S_n: we stop climbing when the relative growth of the training set becomes smaller than the relative decrease of the similarity with the target language, i.e., we select the smallest n for which the following condition is satisifed:

$$\frac{|S_{n+1}|}{|S_n|} < \frac{sim(S_n, l)}{sim(S_{n+1}, l)}. \quad (2)$$

Model Selection (MS). Early stopping based on the model performance on a development set (*dev*) is an important mechanism for preventing model overfitting in supervised machine learning. In a truly zero-shot transfer setup, on the one hand, we do not have any development data in the target language. Model selection based on the development set of the source language, on the other hand, overfits the model to the source language, which may hurt effectiveness of the cross-lingual transfer (Keung et al., 2020; Chen and Ritter, 2020). For test treebanks with a respective development portion, TOWER uses that development set for model selection. For low-resource languages l without development treebanks, we compile a *proxy* development set $D_l = \cup\{D_k\}_{k=1}^{K}$ by collecting all development treebanks D_k from the hierarchy level closest to l that encompasses at least one treebank with a development set.[6] Intuitively, the more syntactically similar D_l is to l, the more beneficial the model selection based on D_l will be for performance on l, the optimal model checkpoint w.r.t. l should be closer to the model checkpoint exhibiting best performance on D_l. Accordingly, with M as the model checkpoint with best performance on D_l, we select the model chekpoint $M' = \lfloor sim(D_l, l) \cdot M \rfloor$ (see Eq.(1)) as the "optimal" checkpoint for the target language l.

Shallow Biaffine Parser. TOWER employs the shallow biaffine parser of Glavaš and Vulić (2021), stacked on top of the pretrained XLM-R (Conneau et al., 2020). Compared to the standard biaffine parser (Dozat and Manning, 2017; Kondratyuk and Straka, 2019; Üstün et al., 2020), this shallow variant forwards word-level representations (aggregated from subword output) directly into biaffine products, bypassing deep feed-forward transformations that produce dependent- and head-specific vectors (Dozat and Manning, 2017). The shallow variant is reported to perform comparably (Glavaš and Vulić, 2021), while being faster to train.

3 Evaluation and Discussion

Treebanks and Baselines. We evaluate TOWER on 138 (test) treebanks from Universal Dependencies (Nivre et al., 2020).[7] We compare TOWER against two state-of-the-art multilingual parsers: (1) UDify (Kondratyuk and Straka, 2019) couples the multilingual BERT (mBERT) (Devlin et al.,

---

the training portions of Russian *GSD*, *PUD*, and *SynTagRus* treebanks.

[5] Note that the number of climbs s_l needed to reach some hierarchy level depends on the language l: e.g., the hierarchy level joining Tagalog (*tl*) with Scottish, Irish, and Welsh ($\{gd, ga, cy\}$) is reached in $s_l = 1$ climbs from Tagalog, $s_l = 2$ climbs from Scottish and $s_l = 3$ climbs from Irish and Welsh.

[6] E.g., D_l for l=*tl* consists of develompent portions of *ga* and *gd* treebanks, whereas D_l for l=*cy* consists only of the development set of *ga*.

[7] We work with UD v2.5. Due to mismatches between XLM-R's subword tokenizer and word-level treebank tokens we skip: all Chinese treebanks, Assyrian (AS), Old Russian (RNC and TOROT), Skolt Sami (Giellagas), Japanese (Modern and BCCWJ), A. Greek (Perseus), Gothic (PROIEL), Coptic (Scriptorium), OC Slavonic (PROIEL) and Yoruba (YTB).

Table 1: Parsing performance (UAS, LAS) on different UD treebank subsets for state-of-the-art multilingual parsers UDify and UDapter and variants of our TOWER method. **Bold:** best performance in each column.

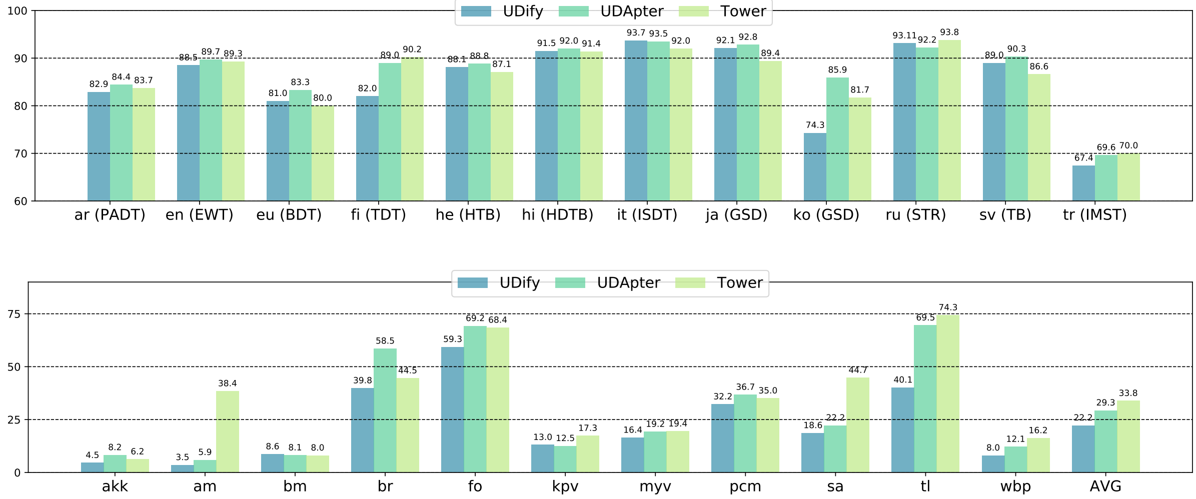

Figure 2: LAS performance of UDify, UDapter and TOWER on 12 high-resource treebanks (top figure), and 11 low-resource languages (bottom figure).

2019) with the deep biaffine parser (Dozat and Manning, 2017) and trains on all UD treebanks; (2) UDapter (Üstün et al., 2020) extends mBERT with adapter parameters (Houlsby et al., 2019; Pfeiffer et al., 2020) that are contextually generated (Platanios et al., 2018) from URIEL vectors – the parameters of the adapter generator are trained on treebanks of 13 diverse resource-rich languages selected by Kulmizev et al. (2019). We additionally quantify the contributions of TOWER's heuristic components (TBS and MS, see §2) by evaluating variants in which we (1) remove TBS and train on the closest language with training data (-TBS), (2) remove MS and just select the model checkpoint that performs best on the proxy dev set D_l (-MS), and (3) remove both TBS and MS (-TBS-MS).

Training and Optimization Details. We limit input sequences to 128 subword tokens. We use XLM-R *Base* with $L = 12$ layers and hidden size $H = 768$ and apply a dropout ($p = 0.1$) on its outputs before forwarding them to the shallow parsing head. We train in batches of 32 sentences and optimize parameters with Adam (Kingma and Ba, 2015) (starting learning rate 10^{-5}). We train for 30 epochs, with early stopping based on dev loss.[8]

Results and Discussion. We show detailed results for all 138 treebanks in the Appendix. In Table 1, we show averages over different treebank subsets: treebanks on which both TOWER and (1) UDify (∩UDify; 111 treebanks) and (2) UDapter (∩UDapt; 39 treebanks) have been evaluated, (3) 12 high-resource languages on which UDapter was trained (HIGH) and (4) 11 low-resource treebanks (LOW) for which all three models have been evaluated. We show LAS scores for languages from

---

[8] For low-resource languages without the dev set, we use the proxy D_l (see 2). We checkpoint the model (i.e., measure the dev loss) 10 times per epoch and stop training when the loss does not decrease over 10 consecutive checkpoints.

HIGH and LOW in Figure 2. Similar trends are observed with UAS scores.

TOWER outperforms UDify and UDapter in all setups except HIGH, with especially pronounced gains for LOW. This renders TOWER particularly successful for the intended use case: low-resource languages without any training data. Admittedly, the fact that TOWER is built on XLM-R, whereas UDify and UDapter use mBERT, impedes the direct "apples-to-apples" comparison. Two sets of results, however, strongly suggest that it is TOWER's heuristics (TBS & MS) that drive its performance rather than the XLM-R (instead of mBERT) encoder. First, UDapter outperforms TOWER on high-resource languages with large training treebanks (i.e., the HIGH setup). For these languages, however, TOWER effectively does not employ its heuristics: (i) TBS selects the large language-specific treebank(s), as adding any other language prohibitively reduces the perfect similarity $sim(S_0, l) = 1$ (see Eq. (1)); (ii) MS is not used because each high-resource treebank has its own dedicated dev set. Secondly, removing TOWER's heuristics (see -TBS-MS in Table 1) brings its performance slightly below that of UDapter, rendering TBS (primarily) and MS (rather than the XLM-R encoder) crucial for TOWER's gains. Comparing -TBS and -MS reveals that, somewhat expectedly, selecting the "optimal" training sample (TBS) contributes to the overall performance more than the heuristic early stopping (MS).

Looking at individual low-resource languages (Fig. 2), we observe largest gains for Amharic (*am*) and Sanskrit (*sa*). While Sanskrit benefits from TOWER selecting training languages from the same family (Marathi, Urdu, and Hindi), Amharic (Afro-Asiatic family), interestingly, benefits from treebanks of syntactically similar languages from another family (cf. the full TOWER hierarchy in the Appendix) – Tamil and Telugu (Dravidian family). Similarly, Tagalog (Austronesian language) parsing massively benefits from training on Scottish and Irish treebanks (Indo-European, Celtic).

4 Conclusion

We proposed TOWER, a simple yet effective approach to the crucial problem of source language selection for multilingual and cross-lingual dependency parsing. It leverages the language hierarchy, induced from syntax-based manually coded URIEL language vectors, and simple treebank selection heuristics to inform the source selection. A wide-scale UD evaluation and comparisons to current state-of-the-art multilingual dependency parsers validated the effectiveness of TOWER, especially in low-resource languages. Moreover, while the main experiments in this work were based on one particular state-of-the-art parsing architecture, TOWER is fully independent of the chosen underlying parsing model, and thus widely applicable.

Abstract

The notorious one-to-many nature of open-domain dialogues poses huge challenges for automatic evaluation methods. Recent studies attempt to mitigate this issue by considering the similarity of the generated response with the conversational context and design discriminative models to learn from multiple positive responses. Despite the promising results, they can not be applied to general scenarios where training data with multiple responses is unavailable. To this end, in this paper, we propose a self-supervised setting to obtain a smooth latent space that can both capture discourse-level context information and implicitly model more references in latent space. Specifically, we present EMS, an **E**nhanced dialogue evaluation **M**etric in latent **S**pace. Experimental results on two real-world dialogue datasets confirm the superiority of our method for open-domain dialogue evaluation, where both Pearson and Spearman correlations with human judgments outperform all baselines.

1 Introduction

With the surge of deep learning techniques, generation-based open-domain dialogue systems have witnessed significant improvement in recent years. Plenty of novel and effective models (Sutskever et al., 2014; Serban et al., 2016; Li et al., 2015; Serban et al., 2016; Zhao et al., 2017; Gu et al., 2018; Qiu et al., 2019; Chan et al., 2019b; Serban et al., 2017; Wolf et al., 2019; Hu et al., 2019; Chen et al., 2020) are proposed and have greatly promoted the development of the open-domain dialogue generation. Unlike the endless emergence of novel methods, however, there is still no meaningful and widely accepted automatic evaluation metric for dialogue generation yet. As we know, automatic evaluation allows quick and effective comparison between different systems and is crucial for the development of natural language generation (NLG) tasks (Dathathri et al., 2019; Gu et al., 2019; Gao et al., 2019; Chan et al., 2019a, 2020). The lack of meaningful automatic evaluation metrics has become a significant impediment for open-domain dialog generation research.

Over the past decade, many automatic evaluation metrics are proposed to evaluate the open-domain dialogue systems. Among them, the word overlap-based automatic evaluation metrics from NLG tasks, such as BLEU (Papineni et al., 2002) in machine translation and ROUGE (Lin, 2004) in text summarization, are popular. In addition, Embedding Metrics (Mitchell and Lapata, 2008; Forgues et al., 2014; Rus and Lintean, 2012) have been utilized to evaluate the open-domain dialogue systems (Gu et al., 2018; Chan et al., 2019b; Shen et al., 2018). Recently, with the fantastic development of the large-scale pre-training model (Devlin et al., 2018; Liu et al., 2019; Radford et al., 2019), researchers proposed to enhance the embedding metrics by converting the dialogue sentences to hidden space via pre-training model (Zhang et al., 2019; Sellam et al., 2020; Zhao et al., 2019; Xiang et al., 2021). The common idea behind these metrics is that they measure the semantic similarity between a reference response and a generated response, independent on the conversational context. However, due to the notorious one-to-many nature (Li et al., 2015; Zhao et al., 2017; Qiu et al., 2019; Gu et al., 2018) of open-domain dialogue, a good response should be related well to its context yet may be largely different from a reference response in semantics.

Some other works (Tao et al., 2018; Ghazarian et al., 2019; Sinha et al., 2020) thereby proposed to build automatic dialogue evaluation metrics by considering the similarity of the generated

responses with the conversational context. Specifically, these works design discriminative models which can judge whether the generated responses match the conversational context well, which learn from $\{$*conversational context*, *response reference*, *negative sample*$\}$ pairs in unsupervised learning manner. Zhao et al. (2020) further proposed to enhance such discriminative evaluation metrics by finetuning on a few human-annotated data to improve the robustness. These discriminative metrics trained using a single relevant response and multiple negative samples. However, Sai et al. (2020) argued that such discriminative metrics should be trained on multiple relevant responses (i.e., positive samples) and multiple negative samples, to favor the one-to-many nature in open-domain dialogues. Therefore, they collected a new dataset which contains multiple relevant and irrelevant responses for any given conversational context to train their discriminative evaluation model and the model trained by multiple relevant responses shows impressive performance. However, there are no organized relevant multiple responses in most existing datasets. Collecting a new dataset is expensive and time-consuming. Thus, we aim to learn multiple reference information with limited data.

Inspired by the impressive effectiveness of the Variational Auto-encoder (VAEs) and Conditional Variational Auto-encoder (CVAEs) on the representation learning and dialogue modeling, we propose to learn the dialogue representations via VAEs/CVAEs for better evaluation. Equip with such dialogue representations, we obtain an **E**nhanced dialogue evaluation **M**etric in latent **S**pace (EMS). EMS is a self-supervised evaluation metric with a two-stage training procedure. It represents dialogue sentences in a smooth latent space to both capture discourse-level context information and model more feasible latent references. Specifically, in the first stage, we build a VAE based model to map the dialogue sentences into a latent (or semantic) space. Li et al. (2019) showed that VAEs can be viewed as a regularized version of the auto-encoder and learn a smooth latent space through the regularization from the Gaussian prior. Then, we train our model by optimizing CVAEs' objective which forces the prior distribution to capture the feasible latent references information (details in Section 3.3). In the second stage, we combine the dialogue representations and the captured feasible latent reference information to train a discriminative model. Meanwhile, we give a potential explanation of our motivation about why using feasible latent reference information can lead to a better evaluation (details in Section 3.1). Experimental results on two real-world dialogue datasets confirm the superiority of our method for open-domain dialogue evaluation, where both Pearson and Spearman correlations with human judgments outperform all baseline methods.

In a nutshell, our contributions can be summarized as follows:

- We proposed a novel automatic evaluation metric, i.e., EMS, for open-domain dialogue systems;
- We proposed a pre-training variational model to capture the feasible latent references;
- Experiments performed on two large datasets demonstrate the effectiveness of our proposed model and outperform all baseline methods.

2 Related Work

Word overlap-based Metrics. Several word overlap-based automatic evaluation metrics, such as BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and ROUGE (Lin, 2004), have been widely used to evaluate the quality of generated responses. These word overlap-based metrics measure how many words overlap in a given generated response when compared to a reference response. Liu et al. (2016); Lowe et al. (2017); Tao et al. (2018) argued that these word overlap-based metric scores are weakly correlated to human judgment due to ignoring the notorious one-to-many nature of the open-domain dialogues. Therefore, Yuma et al. (2020) proposed the improved BLEU, which compares the generated response with multiply diverse references.

Embedding-based Metrics. Unlike word overlap-based metrics comparing two raw sentences, Embedding Metrics (Mitchell and Lapata, 2008; Forgues et al., 2014; Rus and Lintean, 2012) map sentences to a high dimensional space, and calculate similarity based on the high-dimensional representations. Embedding Metrics are recently popular for evaluating the generation tasks, such as text summarization (Gao et al., 2020; Chen et al., 2021), question answer (Gao et al., 2019) and text generation (Hashimoto et al., 2019; Chan et al., 2020). Meanwhile, several works (Qiu et al., 2019; Chen et al., 2020; Gao et al., 2021) have shown their effectiveness in the open-domain dialogue systems. With the development of the large-scale pre-training model (Devlin et al., 2018; Liu et al., 2019; Radford et al., 2019), some studies, e.g., BERTScore (Zhang et al., 2019) and MoverScore (Zhao et al., 2019), further enhance the quality of representations via a large-scale pre-training model. However, these embedding-based metrics perform a better comparison compared to word overlap-based metrics but still ignore the one-to-many nature of open-domain dialogues.

Learning-based Metrics. Recent studies (Tao et al., 2018; Sinha et al., 2020) attempt to mitigate the one-to-many issue by considering the similarity of the generated response with the conversational contexts. The similarity is calculated by a designed discriminative model which learns to evaluate whether a response matches the conversational context well. The discriminative model is learned from tuples of data, {*conversational context*, *response reference*, *negative sample*}, in an unsupervised learning manner. However, these learning-based metrics rely on a sophisticated sampling technique. Lan et al. (2020) proposed a sampling strategy to collect the valuable negative samples for the discriminative training. Bak and Oh (2020) conduct speaker sensitive response evaluation by conducting negative sampling from several levels. To further improve the robustness, Zhao et al. (2020) proposed to enhance the discriminative model by finetuning on a few human-annotated data. Sai et al. (2020) argued that these discriminative metrics should be trained on multiple relevant responses and multiple irrelevant samples for any given context. Therefore, they collected such a dataset and improved the evaluation performance greatly. However, collecting a new dataset is expensive and time-consuming. In this work, we propose a method to improve the effectiveness of the discriminative metrics based on the VAEs/CVAEs.

3 Methodology

In this paper, we propose an Enhanced dialogue evaluation Metric in latent Space (EMS), which contains two training stages (illustrated in Fig. 2). In this section, we first conduct some discussions about our motivations in Section 3.1. Then, we introduce the overall architecture in Section 3.2. The two training stages are described in Section 3.3 and Section 3.4, respectively. Finally, we describe the inference process in Section 3.5.

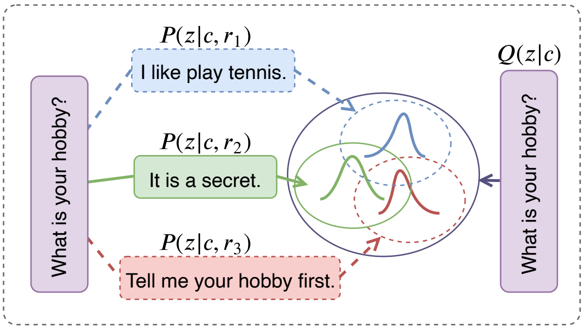

Figure 1: Distributions in latent space. Each circle represents a Gaussian distribution while three small circles refer to a special Gaussian distribution for each corresponding response. Naturally, the biggest circle indicates the prior Gaussian distribution. We use the prior distribution to approximate all the response conditional distribution. Dotted lines indicate the latent response.

3.1 Discussion about Motivation

We conduct a discussion about our motivation from information theory. Let r_i denotes a feasible response coming from $\{r_k\}_{k=1}^N$ which represents N feasible latent references. Assume a binary label $l \in \{0, 1\}$ indicates whether a response matches its context well. Existing works (Tao et al., 2018; Ghazarian et al., 2019; Sinha et al., 2020; Zhao et al., 2020) training with single relevant response are actually maximizing $I(l; c, r_i)$. Recently, Sai et al. (2020) proposed to training with multiple relevant responses, which actually maximizes $I(l; c, \{r_k\}_{k=1}^N)$. An intuitive explanation for the surprising improvement in Sai et al. (2020) is that $I(l; c, \{r_k\}_{k=1}^N) \geq I(l; c\ , r_i)$[1].

However, there are no organized relevant multiple responses in existing datasets and collecting a new dataset is expensive and time-consuming. Therefore, we aim to capture the feasible latent reference information with limited data. Inspired by previous works which model multiple responses for dialogue (Zhao et al., 2017; Qiu et al., 2019; Chan et al., 2019b), we utilize CVAEs (details in Section 3.2) which build a prior distribution $P(z|c)$ to capture the feasible latent reference information in the latent space. Specifically, when training CVAEs, $P(z|c)$ is forced to be close to the posterior distribution $Q(z|c, r_i)$ for any reference response r_i as illustrated in Fig. 1. In this sense, if z is sampled from $P(z|c)$, z may contain some information of any r_i in some extent, and z can be used as a surrogate of $\{r_k\}_{k=1}^K$. Therefore, we can expect

---

[1] There is a brief proof in Apendix A.

$I(l; c, \{r_k\}_{k=1}^{N}) \geq I(l; c, r_i, z) \geq I(l; c, r_i)$.

3.2 Overall Architecture

Previous works (Li et al., 2019; Gururangan et al., 2019; Li et al., 2020) concluded that VAEs can learn a smooth latent space through the regularization from the gaussian prior. Inspired by Li et al. (2020), we propose a novel architecture which can be regarded as a large-scale pretrained language model (PLM) based on VAEs/CVAEs.

Encoder. Li et al. (2019) argue that the VAEs might benefit from initialization with a non-collapsed encoder, because the encoder provides useful information from the beginning of training. We use the Masked PLMs (Devlin et al., 2018; Liu et al., 2019) as the text encoder because of their impressive effectiveness in natural language understanding tasks. We describe the encoding process as following,

$$\begin{aligned} h_q &= \text{PLM}([c; r]), \\ h_p &= \text{PLM}(c) \end{aligned} \tag{1}$$

where c, r indicate conversational context and response reference, respectively.

Latent Variable Modeling. For modeling the latent variable, we hypothesize that the approximated variational prior and posterior follows an isotropic multivariate Gaussian distribution $\mathcal{N}(\mu, \sigma^2 I)$, where I represents the diagonal covariance. We use a recognition network $q_\phi(z|h_q)$ and a prior network $p_\theta(z|h_p)$ to approximate the posterior $Q(z|c, r)$ and the prior $P(z|c)$, respectively.

Decoder. The reconstruction process[2] forces the latent variable to contain the useful posterior information, which is a crucial step in the variational training. We use another PLM as the decoder to reconstruct the original input texts. For transporting the latent variable to the PLM decoder, we use the memory mechanism mentioned in Li et al. (2020) where the latent variable plays the role of an additional memory vector for the PLM decoder to attend. Specifically, the latent variable z is converted through a Multilayer Perceptron (MLP) and separated into several vectors, each of which is transported to the PLM decoder via attention mechanism.

3.3 Stage 1: Representation in Latent Space

Our first stage is to learn the latent representation of the dialogues and capturing the feasible latent reference information. Specifically, we first optimize our model via VAEs' objective to model a smooth latent space. Then, we train our model by CVAEs' objective to capture the feasible latent reference information. We describe the details as following.

A smooth latent space. Following Li et al. (2020), we first train the posterior module by optimizing the VAEs' objective. Li et al. (2019) showed that VAEs can be viewed as a regularized version of the autoencoder and can learn a smooth latent space. Based on this, we convert sentences in a universal smooth latent space. In a smooth latent space, latent representation of similar sentences should be close to each other and vice versa (Li et al., 2019). Therefore, it is a great outset for our model. To train this model, the log-likelihood objective is maximized through pushing up its variational lower bound:

$$\begin{aligned} &- \mathbf{KL}(p_\theta(z|h_q)||q(z)) \\ &+ \mathbf{E}_{p_\theta(z|h_q)}[\log p_\theta([c; r]|z, h_q)], \end{aligned} \tag{2}$$

where $\mathbf{KL}(\cdot)$ represents the KL-divergence term, which serves as the regularization that encourages $p_\theta(z|h_q)$ to approach to $q(z)$, i.e., a standard Gaussian distribution; $\mathbf{E}[\cdot]$ is the term of reconstruction loss, reflecting how well the decoder performs.

Feasible latent reference information. The one-to-many nature of the open-domain dialogues poses that there can be a lot of reasonable responses for the same conversational context. Therefore, we handle this one-to-many nature by CVAE as previous works (Zhao et al., 2017; Gu et al., 2018; Chan et al., 2019b) to capture the feasible latent reference information. As shown in Fig. 1, CVAE builds Gaussian posterior distributions for each feasible reference and forces the prior distribution to approach the posterior distributions. Ideally, a well-learned prior distribution will cover all the feasible latent reference information. We train our model by optimizing the following variational lower bound:

$$\begin{aligned} &- \mathbf{KL}(q_\phi(z|h_q)||p_\theta(z|h_p)) \\ &+ \mathbf{E}_{q_\phi(z|h_q)}[\log p_\theta([c; r]|z, h_q)] \end{aligned} \tag{3}$$

where $\mathbf{KL}(\cdot)$ represents the KL-divergence term, which serves as the regularization that encourages the prior $p_\phi(z|h_p)$ to approach the approximated

---

[2] Note that the reconstruction process doesn't only indicate the autoregressive generation but also the masked causal generation.

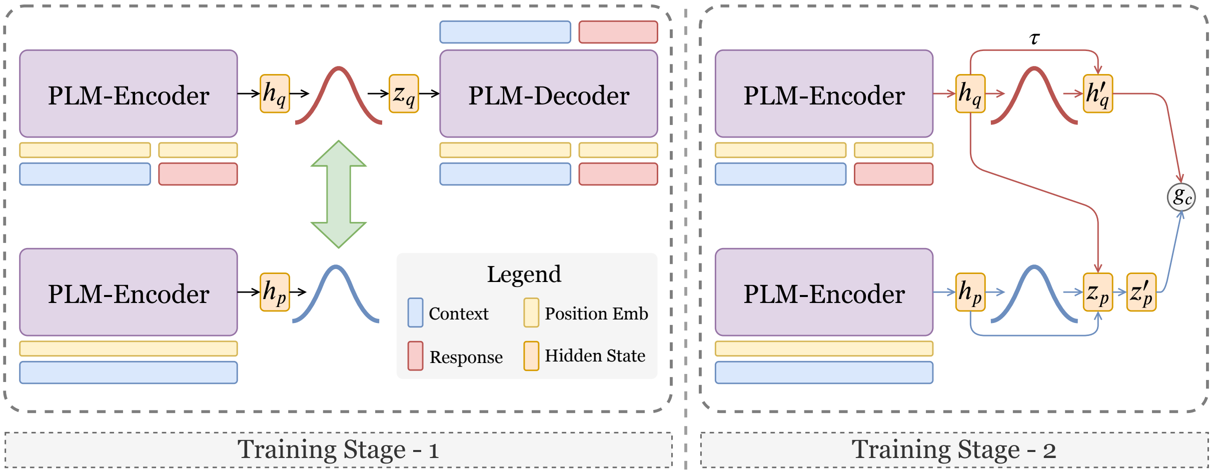

Figure 2: The detailed architecture of our proposed EMS and there are two stages in the training process. The first and second training stage is described in Section 3.3 and Section 3.4, respectively. In the second training stage, the response input is replaced by the generated responses which need be evaluated. The *Position Emb* indicates the Position Embedding.

posterior $q_\theta(z|h_q)$, i.e. a conditional Gaussian distribution.

Training procedures. Previous works (Bowman et al., 2015; Zhao et al., 2017) mentioned that VAE and CVAE training is challenging due to the KL vanishing issue, where the decoder ignores the conditional information and all the resulting posteriors almost collapse to a same Gaussian prior. To mitigate this issue, first, we initialize our model with Optimus (Li et al., 2020), a large-scale VAE-based PLM model, while optimizing Eq. 2.

To mitigate the same issue while optimizing Eq. 3, we use the cyclical KL annealing schedule (Fu et al., 2019). Specifically, we add a hyperparameter α to control the weight of the KL-divergence in Eq. 3. We set α close to zero in the first half of cyclic schedule, linearly anneal α to 1 in the next one-fourth of cyclic schedule and kept α = 1 in the remaining cyclic schedule.

Moreover, the Free Bits (Bowman et al., 2015) is also crucial for the training. It replaces the KL-divergence in Eq. 3 by a hinge loss

$$\max(\gamma, \mathbf{KL}(q_\phi(z|h_q)||p_\theta(z|h_p))) \tag{4}$$

where γ is a hyperparameter which controls the information space for the each dimension of the latent variable. Finally, an extra bag-of-word loss (Zhao et al., 2017) is also used during the training.

3.4 Stage 2: Matching Training

In the second stage, we learn to judge the similarity between the conversational context and the response using the learned representations. Li et al. (2020) argue that the KL regularization applied on z has a large impact on the preceding layer feature, thus, the preceding layer feature also contains the information of z. Therefore, we consider combining h_q and z into the final representation,

$$h'_q = (1-\tau)\cdot h_q + \tau \cdot z_q, \tag{5}$$

where τ is a hyperparameter and z_q indicates the latent representation from the posterior network. Meanwhile, we use the feasible latent reference information, captured by our prior network, to enhance the matching. We combine these two representations as following,

$$\begin{aligned} e &= \sigma(\mathrm{W}_g \cdot [h_p; h_q; z_p] + \mathrm{b}_g) \\ z'_p &= e \cdot z_p + (1-e)\cdot h_p \end{aligned} \tag{6}$$

where W_g and b_g are trainable parameters, and e is learned by the gate mechanism that controls the fusion of z_p and h_p. Note that z_p indicates the latent representation from the prior network. The activation function σ is sigmoid. Finally, we infer matching score between the conversational context and generated reference as follows,

$$g_c = \sigma(\mathrm{W}_s \cdot ([h'_q; z'_p]) + \mathrm{b}_s) \tag{7}$$

where W_s and b_s are trainable parameters and the activation function σ is sigmoid. Finally, we optimize our model with positive sampling and negative sampling (Lan et al., 2020) based on the discriminative training scheme.

3.5 Inference

In the inference process, we input the conversational context and response candidate as the c and r in Eq. 1, and conduct the operation as Eq. 5, Eq. 6 and Eq. 7 to obtain the score g_c. We use the g_c as matching degree of the response candidate.

4 Experiments

4.1 Dataset

To evaluate the effectiveness of our proposed automatic evaluation metric EMS, we conduct experiments on the following two open-access datasets.

Persona-Chat Dataset. The persona-chat dataset (Zhang et al., 2018) is a large persona-conditioned chit-chat style dialogue dataset which consists of 10,907 multi-turn dialogue sessions[3].

DailyDialog Dataset. The dailydialog dataset (Li et al., 2017) is an another widely-used large collection of human-human dialogues which consists of 13,118 multi-turn dialogue sessions[4].

Human-annotated Dataset. We collect the human-annotated datasets from Amazon Mechanical Turk and obtain two human-annotated datasets which consist of 750 context-response pairs in the persona-chat dataset and 800 ones in the dailydialog dataset, respectively. Following Zhao et al. (2020), the generated references come from several classical dialogue models, i,e., Seq2Seq (Sutskever et al., 2014), Seq2Seq with Attention (Serban et al., 2016), HRED (Serban et al., 2017), VHRED (Serban et al., 2016), GPT-2 (Wolf et al., 2019).

4.2 Baselines

We compare our proposed method with the following highly related and strong baselines.

BLEU. We utilize BLEU score (Papineni et al., 2002) to measure n-grams overlaps between response reference and generated response. Specifically, we follow the conventional setting in Sinha et al. (2020) and use the multi-bleu[5].

ROUGE. ROUGE (Lin, 2004) is the most popular metric in the text summarization task. There, we report the f1 score of Rouge-$\{$1,2,3,L$\}$ and Rouge-L identifies the longest common subsequence between the generated and reference to better account for sentence-level structure when computing word overlap.

METEOR. The METEOR (Banerjee and Lavie, 2005) is designed as an improvement on BLEU using a harmonic mean of precision and recall, as well as stemming and synonyms.

Embedding Metrics. Embedding Metrics compute the similarity between the embeddings representations of generated results and reference. The used embeddings come from glove[6]. In particular, we calculate three metrics: 1) *Average*, cosine similarity between the averaged word embeddings in the two sentences (Mitchell and Lapata, 2008); 2) *Extrema*, cosine similarity between the largest extreme values among the word embeddings in the two sentences (Forgues et al., 2014); 3) *Greedy*, i.e., greedily matching words in two sentences based on the cosine similarities, and the total scores are then averaged across all words (Rus and Lintean, 2012).

BERTScore. BERTScore (Zhang et al., 2019) uses a strong PLM model to greedily match each word in a reference response with one word in the generated response. By doing so, it computes the recall of the generated sequence. BERTScore was shown to have strong system-level and segment-level correlation with human judgment on several machine translation tasks.

BLEURT. BLEURT (Sellam et al., 2020) is based on the BERTScore and finetuned on human judgments after pretraining on large-scale synthetic data with multiple automatic metrics as supervision signals. BLEURT has shown its strong correlation with human judgment on machine translation tasks.

RUBER. RUBER (Tao et al., 2018) is an unsupervised automatic evaluation metric that considering the similarity of the generated response with conversational context and response reference.

MAUDE. MAUDE (Sinha et al., 2020) proposed an unreferenced automated evaluation metric that uses large-scale PLMs to extract hidden representations of dialogue sentences, and leverages the temporal transitions that exist between them.

4.3 Settings

The dimension of latent variable z is set to 768 to improve the information bottleneck. As we mentioned before, the encoder and the decoder in our model are BERT (Devlin et al., 2018) and GPT-2 (Radford et al., 2019), respectively. We use the

---

[5] `https://github.com/OpenNMT/OpenNMT-py/blob/master/tools/multi-bleu.perl`

[6] `http://nlp.stanford.edu/data/glove.840B.300d.zip`

Tokenizer of BERT to conduct the texts for BERT and tokenizer of GPT-2 for GPT-2 in all experiments. We use the Optimus (Li et al., 2020) to save the time consumption of the VAE training. The recognition network and prior network are consist of 3 layers MLP with Dropout layer and GELU function. When training, we set the mini-batch size to 16. The AdamW optimizer is used to train the VAEs module with the initial learning rate 5e-5, and the learning rate warmup and decay strategy is employed. The value of τ in Eq. 5 is set to 0.01. When we conduct the matching training, we change the initial learning rate to 3e-6, and the learning rate warmup and decay strategy is also employed.

5 Results and Analysis

5.1 Overall Performance

We examine the performance of our model compared with baselines on two open-access datasets and the results.

The word-overlap metrics based on n-gram perform worst. As shown in Table 1 and Table 2, the word-overlap evaluation metrics, i.e., BLEU, ROUGE, and METEOR, obtain the worst performance in the dialogue evaluation on both two datasets. Among them, BLEU (hybrid) scores on two datasets are both less than 0.1, though it is the most widely used metric in machine translation. Intuitively, the information from n-gram is more accurate with a larger n (the most accurate information comes from the whole sentence). However, as the results shown in the Table 1 and Table 2, the correlation score decays when n increases. The same phenomenon is observed when using ROUGE. It seems using n-grams as the representation of the dialogue sentence is not a good choice.

PLM is an effective representation extractor for dialogue sentences. From Table 1 and Table 2, we can see that most embedding-based metrics, i.e., Average, Extrema, Greedy, BERTScore and BLEURT, using pretrained embedding to represent the sentences, perform better than word-overlap metrics which uses n-grams as representation. Furthermore, traditional embedding-based metrics with Glove-based embedding, i.e., Average, Extrema, Greedy, perform worse than the embedding-based metrics with PLM-based embedding, i.e., BERTScore and BLEUET. Thus, we can know that using PLM to represent the dialogue sentence is more effective for the evaluation.

Table 1: Performance of our EMS methods and all baselines evaluated on the Persona-Chat Dataset. The BERTScore and BLEURT are built based on the base and large version of the Roberta (Liu et al., 2019).

Metrics	**Pearson's ρ**	**Spearmans's r**
BLEU		
Hybrid	0.0602 (0.100)	0.0623 (0.088)
1-gram	0.2486 (<0.001)	0.2201 (<0.001)
2-gram	0.1991 (<0.001)	0.1891 (<0.001)
3-gram	0.0998 (<0.001)	0.1138 (<0.001)
4-gram	0.0558 (0.127)	0.0622 (0.002)
ROUGE		
1-gram	0.2663 (<0.001)	0.2553 (<0.001)
2-gram	0.1706 (<0.001)	0.1715 (<0.001)
3-gram	0.1062 (0.004)	0.1157 (0.001)
L	0.2777 (<0.001)	0.2619 (<0.001)
METEOR	0.2507 (0.033)	0.2297 (0.020)
Embedding Metrics		
Average	0.1330 (<0.001)	0.1452 (<0.001)
Extrema	0.2354 (<0.001)	0.2272 (<0.001)
Greedy	0.2585 (<0.001)	0.2502 (<0.001)
BERTScore		
Base	0.2943 (<0.001)	0.2781 (<0.001)
Large	0.2782 (<0.001)	0.2619 (<0.001)
BLEURT		
Base	0.3560 (<0.001)	0.3482 (<0.001)
Large	0.3045 (<0.001)	0.2857 (<0.001)
RUBER	0.4581 (<0.001)	0.4570 (<0.001)
MAUDE	0.5619 (<0.001)	0.5631 (<0.001)
EMS	**0.5856** (<0.001)	**0.5921** (<0.001)

Learning-based discriminative metrics outperform training-free metrics. From Table 1 and Table 2, we can observe that all the learning-based discriminative metrics (i.e., RUBER, MAUDE, and our EMS) outperform all other training-free metrics (i.e., BLEU, ROUGE, METEOR, Average, Extrema, Greedy, BERTScore, and BLEURT) in both the Pearson and Spearman correlation with human judgment. Therefore, we conclude the learning-based discriminative metrics are very powerful to evaluate the open-domain dialogue systems.

Our proposed EMS metric performs the best. Our EMS metric achieves the best performance with 0.5856, 0.5921 in Pearson and Spearman correlation with the human judgment on the persona-chat dataset, respectively. Meanwhile, on the dailydialog dataset, EMS obtains 0.5331, 0.5253 in Pearson and Spearman score. These experimental

Table 2: Performance of our EMS methods and all baselines evaluated on the DailyDialog Dataset. The BERTScore and BLEURT are built based on the base and large version of the Roberta (Liu et al., 2019).

Metrics	**Pearson's ρ**	**Spearmans's r**

MAUDE	0.5162 (<0.001)	0.5343 (<0.001)
EMS	**0.5331** (<0.001)	0.5253 (<0.001)

results show our method outperforms all existing baselines, indicating the superiority of our method.

5.2 Analysis

Our model aims to enhance the dialogue evaluation via variational training. Hence, in this subsection, we examine whether variational training can improve the performance by ablation study.

First, we replace the hidden representation ("w/o q") in Eq. 5 by the one from pure BERT, i.e., CLS. From the performance in Table 3, the KL regularization enhances the performance of EMS metric on both two datasets which proves a smooth latent space (via VAE training) is important. Second, as shown in Table 3, without z_p in Eq. 6 ("w/o p") which captures the feasible latent reference information, EMS gains a performance drop. Therefore, it proves the effectiveness of the feasible latent reference information.

Table 3: Performance of the ablation study. Note that ρ and r indicate the Pearson's ρ and Spearmans's r.

Metrics	**Persona-Chat Dataset**		**DailyDialog Dataset**	
	ρ	r	ρ	r
EMS	0.5856	0.5921	0.5331	0.5253
w/o q	0.5732	0.5741	0.5298	0.5221
w/o p	0.5621	0.5618	0.5193	0.5218

Table 4: Two evalution cases from DailyDialog Dataset. _eos_ indicates the end of the current sentence.

Context:	did you get your bus pass? _eos_ i have n't gone to get it yet. _eos_ why have n't you got it? _eos_ i do n't know where to go to get one. _eos_ i know where to get them from.		
Reference:	where do i get it?		
Generated:	what kind of buses are they on?		
Human (1-5)	**BLEU (0-1)**	**MAUDE (1-5)**	**EMS (1-5)**
3.00	0.00	4.99	3.32
Context:	what a beautiful home! _eos_ you'll notice that the window treatments, carpeting, and drapes are all new. _eos_ i like the way the blinds give you privacy from the street. _eos_ follow me into the kitchen. you will love it. _eos_ i love that they put a wine storage area in the kitchen.		
Reference:	the best part is the bedroom and attached bathroom.		
Generated:	i'm sure you will.		
Human (1-5)	**BLEU (0-1)**	**MAUDE (1-5)**	**EMS (1-5)**
3.50	0.00	1.17	2.29

5.3 Case Study

To explain more intuitively, we show two cases of our experiments in Table 4. In the first case, we can observe the golden score from the human is 3.00, however, MAUDE predicts the score as 4.99. We find the MAUDE gives such a high score because there is a keyword ("what kind of buses are they on ?") in the generated response which also exists in the conversational context. In the second case, MAUDE gives an extremely low score, i.e., 1.17, since no repeated words in the generated response and the context. However, our EMS gives scores similar to the Human Score, 3.32 and 2.29 in the first and second case, respectively. It proves that our EMS is more similar to human evaluation.

6 Conclusion and Future Work

In this study, we propose a two-stage automatic evaluation metric, i.e., EMS, which can obtain a smooth latent space that can both capture discourse-level context information and model more feasible latent references for evaluating the open-domain dialogues. Experimental results on two dialogue datasets confirm the superiority of our method for open-domain dialogue evaluation, where both Pearson and Spearman correlations with human judgments outperform all baseline methods.

Owing to the promising performance of the variational training, we pursue to design the training procedures for better representation in latent space. Besides, we will explore more efficient methods to obtain more useful feasible reference information.

Ethics Impact

In this paper, we propose a two-stage automatic evaluation metric EMS for open-domain dialogue systems. The positive impact lies in that it allows quick and effective comparison between different dialogue systems and is crucial for the development of open-domain dialogue tasks. The negative impact may be that in some extreme cases, the system may give high scores to the rude and dirty responses. Hence, in such situation, the training dataset is crucial and should be examined before employed in practice.

A Proof

As well we know, the the mutual information (MI) of X and Y is defined as

$$\begin{aligned} I(X;Y) &= H(X) - H(X \mid Y) \\ &= H(Y) - H(Y \mid X) \end{aligned} \tag{8}$$

where $H(\cdot)$ denotes the entropy.

Obviously, we can get

$$\begin{aligned} H(l \mid c, \{r_k\}_{k=1}^{N}) &= H(l \mid c, r_i, \{r_k\}_{k=1}^{N} \setminus r_i) \\ &\leq H(l \mid c, r_i). \end{aligned} \tag{9}$$

Then, we can compare the MI of using the feasible latent reference information and not as follows

$$\begin{aligned} I(l; c, \{r_k\}_{k=1}^{N}) &= H(l) - H(l \mid c, \{r_k\}_{k=1}^{N}) \\ &\geq H(l) - H(l \mid c, r_i) \\ &= I(l; c, r_i). \end{aligned} \tag{10}$$

where we can observe the MI is enhanced.

Adapting Monolingual Models: Data can be Scarce when Language Similarity is High

Abstract

For many (minority) languages, the resources needed to train large models are not available. We investigate the performance of zero-shot transfer learning with as little data as possible, and the influence of language similarity in this process. We retrain the lexical layers of four BERT-based models using data from two low-resource target language varieties, while the Transformer layers are independently fine-tuned on a POS-tagging task in the model's source language. By combining the new lexical layers and fine-tuned Transformer layers, we achieve high task performance for both target languages. With high language similarity, 10MB of data appears sufficient to achieve substantial monolingual transfer performance. Monolingual BERT-based models generally achieve higher downstream task performance after retraining the lexical layer than multilingual BERT, even when the target language is included in the multilingual model.

1 Introduction

Large pre-trained language models are the dominant approach for solving many tasks in natural language processing. These models represent linguistic structure on the basis of large corpora that exist for high-resource languages, such as English. However, for the majority of the world's languages, these large corpora are not available.

Past work on multilingual learning has found that multilingual BERT (mBERT; Devlin et al. 2019a) generalizes across languages with high zero-shot transfer performance on a variety of tasks (Pires et al., 2019; Wu and Dredze, 2019). However, it has also been observed that high-resource languages included in mBERT pre-training often have a better-performing monolingual model, and low-resource languages that are not included in mBERT pre-training usually show poor performance (Nozza et al., 2020; Wu and Dredze, 2020).

An alternative to multilingual transfer learning is the adaptation of existing monolingual models to other languages. Zoph et al. (2016) introduce a method for transferring a pre-trained machine translation model to lower-resource languages by only fine-tuning the lexical layer. This method has also been applied to BERT (Artetxe et al., 2020) and GPT-2 (de Vries and Nissim, 2020). Artetxe et al. (2020) also show that BERT models with retrained lexical layers perform well in downstream tasks, but comparatively high performance has only been demonstrated for languages for which at least 400MB of data is available.

To test if this procedure is also effective for low- to zero-resource languages, we consider two regional language varieties spoken in the North of the Netherlands, namely Gronings (Low Saxon language variant) and West Frisian.

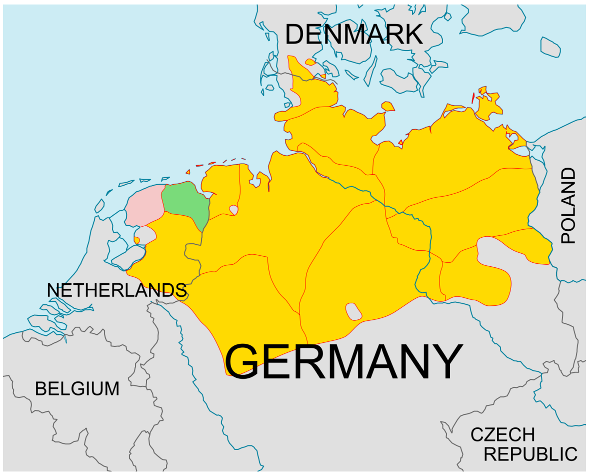

Figure 1: Geographical areas where Gronings (in green) and West Frisian (in red) are spoken. Image modified from https://en.wikipedia.org/wiki/Low_German.

[*] These authors contributed equally.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4901–4907
August 1–6, 2021.

Figure 1 visualizes the geographical areas where these regional language variants are spoken. The regional Low Saxon language is spoken in the north-eastern provinces of the Netherlands and in the North of Germany (shown in yellow). As part of the Low Saxon language, Gronings is spoken in the province of Groningen (highlighted in green). The West Frisian language is spoken in the province of Friesland (shown in red), and it is the second official language of the Netherlands, next to Dutch. Dutch is the national language of the Netherlands, and it is spoken in every province of the Netherlands and in Flanders (North of Belgium).

For both Gronings and West Frisian limited data is available. In addition to unlabeled data, for both target languages we have a small collection of annotated part-of-speech (POS) tagging data, which we use for evaluating zero-shot model transfer. We use three monolingual BERT models (source languages English, German, Dutch) and mBERT to investigate if linguistic structure can be transferred to Gronings and West Frisian by learning new subword embeddings. Our model source and target languages are closely related West Germanic languages (Eberhard et al., 2020). In Table 1, we show parallel sentences in Gronings, West Frisian, Dutch, German, and English to illustrate the lexical similarity between these languages. Additionally, the examples show that there are some lexical and syntactic differences.

We also evaluate to what extent the similarity between each source language of the monolingual models and the target languages is relevant for transferring monolingual representations, and assess the minimum amount of data necessary to adapt these models.

Gronings	Tom is n jong en Mary is n wicht.
West Frisian	Tom is in jonge en Mary is in famke.
Dutch	Tom is een jongen en Mary is een meisje.
German	Tom ist ein Junge und Mary ist ein Mädchen.
English	Tom is a boy and Mary is a girl.
Gronings	Zie haar n bloum ien heur haand.
West Frisian	Se hie in blom yn har hân.
Dutch	Ze had een bloem in haar hand.
German	Sie hatte eine Blume in der Hand.
English	She had a flower in her hand.
Gronings	Dat was n poar joar leden.
West Frisian	Dat wie in pear jier lyn.
Dutch	Dat was een paar jaar geleden.
German	Das war vor ein paar Jahren.
English	That was a couple of years ago.

Table 1: Translations of three sentences in Gronings, West Frisian, Dutch, German, and English.

Our pre-trained models for Gronings and West Frisian (which did not yet exist) are released. Additionally, our code is publicly available for bringing language models to other low-resource languages at https://github.com/wietsedv/low-resource-adapt.

2 Materials

Models We use monolingual BERT-based models of the source languages, and multilingual BERT (mBERT; Devlin et al. 2019a). Specifically, we use BERT (Devlin et al., 2019b) for English, German BERT (gBERT; DBMDZ 2019) for German, and BERTje (de Vries et al., 2019) for Dutch. Each model shares the same architecture as the original base-sized (12 layers) BERT model of Devlin et al. (2019b). The lexical layer weights are shared between the first and last layer of the model to transform discrete tokens into distributed vector representations and vice versa.

Each monolingual model has a vocabulary of 30K capitalized tokens, while mBERT has a vocabulary of 120K tokens shared between the 104 languages it is pre-trained on. These languages include English, German, Dutch and West Frisian, but not Gronings. The monolingual BERT models contain 110M parameters, with 24M being part of the lexical embeddings. Due to its larger vocabulary size, mBERT contains 180M parameters, with 92M part of the lexical embeddings.

Labeled data We use POS-annotated treebanks from the Universal Dependencies (UD) project (Zeman et al., 2020), corresponding to the languages of the monolingual BERT models. For English, we use `GUM` (6.0K sentences; 113.4K tokens) and `ParTUT` (2.1K sentences; 49.6K tokens). In addition, `HDT` (189.9K sentences; 3.4M tokens) and `GSD` (15.6K sentences; 287.7K tokens) are used for German. Finally, `Alpino` (13.6K sentences; 208.5K tokens) and `LassySmall` (7.3K sentences; 98.0K tokens) are used for Dutch. All treebanks are based on various text types from a diverse set of sources. The standard data splits for each of the annotated treebanks are used for training, validation and testing.

We evaluate the performance of our language models on POS-annotated data of Gronings and West Frisian. Manually annotated texts from the

Klunderloa[1] project are used for Gronings (3.8K sentences, 49.0K tokens; fiction, poetry, and songs for children). Annotations follow the UD guidelines. West Frisian is under development in the UD project, and we consider all currently available annotations (1.0K sentences, 15.9K tokens; mainly fiction and news). For both treebanks, 25% is used for development, and 75% is used as a test set.

Unlabeled data The new sub-word embeddings are learned from texts written in Gronings and West Frisian. In total, we have 43MB (8.3M tokens) of plain text available for Gronings. These texts are derived from the Bible, fiction and non-fiction texts, poetry, and Low Saxon Wikipedia. The West Frisian data collection consists of 59MB (10.8M tokens) of plain text extracted from fiction and non-fiction texts, and the multilingual OSCAR corpus (Ortiz Suárez et al., 2020).

Language similarity To quantify language similarity, we use the (lexical-phonetic) LDND measure (Wichmann et al., 2010) on the basis of the 40-item word lists from the ASJP database (Wichmann et al., 2010). While a syntax-based measure may be preferred, this is not available for the included language varieties. We use the LDND as a proxy, given that linguistic distance measures between different linguistic levels are correlated (Spruit et al., 2009). Figure 2 visualizes the relative linguistic distances between the five language varieties using multidimensional scaling (MDS; Torgerson, 1952). If cross-lingual transfer benefits from language similarity, we expect Gronings and West Frisian to profit most from a monolingual Dutch model and least from a monolingual English model, with a German model performing in-between.

Figure 2: MDS plot with the relative positions of English, German, Dutch, Gronings, and West Frisian based on the ASJP-based lexical-phonetic distances.

Table 2: Accuracies for the target languages (columns) with the original and retrained lexical layers (subcolumns), which are averaged per source language.

3 Model Training

Our training procedure consists of two separate fine-tuning steps. The Transformer layers in the three monolingual BERT models and mBERT are fine-tuned for the POS-tagging task. Independently, new lexical layers for each BERT model are trained for the two target languages with a masked language modeling pre-training objective. Afterwards, the retrained lexical layer and the fine-tuned Transformer layers are combined to yield a POS-tagging model that is now adapted to the target language. Optimal checkpoint combinations of retrained lexical layers and fine-tuned Transformer layers are based on their performance on the development data for each target language.

POS-tagging The BERT-based models are fine-tuned for POS-tagging with the UD datasets. The task-specific model consists of BERT's layers with an additional linear classification layer that yields predictions for each of the 16 possible POS tags. During training, the lexical layer of BERT is frozen such that the fine-tuned Transformer layers rely on unchanged token representations from pre-training.

The described model is trained with the Adam optimizer (Kingma and Ba, 2014) with $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1\mathrm{e}{-8}$ and a linearly decreasing learning rate starting at $lr = 1\mathrm{e}{-5}$. Each model is trained until validation loss stops decreasing.

Lexical layer retraining We retrain lexical layers for each BERT model using Gronings and West Frisian data. First, sub-word vocabularies of 10K tokens are created for Gronings and West Frisian using the WordPiece method (Devlin et al., 2019b) where each token occurs at least 100 times in the data. This vocabulary size is chosen conservatively,

Table 3: POS-tagging accuracy for Gronings and West Frisian with subsets of the unlabeled lexical layer retraining data. Results are averaged per source language for each of the two source language datasets.

as we have limited data to train the lexical layer. Preliminary experiments with 30K tokens showed poor performance on the development data.

The Gronings and West Frisian unlabeled documents are split into sequences of 128 tokens. Then, the models are trained with a masked language modeling objective where 15% of the input tokens are masked. The Adam optimizer is used with $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1\text{e}{-8}$ and a linearly decreasing learning rate starting at $lr = 1\text{e}{-4}$. After retraining, we have three (original, Gronings and West Frisian) interchangeable lexical layers for each base model.

4 Results and Discussion

We summarize our results in Table 2 (details per dataset in Appendix A). The monolingual language models perform poorly on Gronings and West Frisian POS-tagging when the original lexical layers are used, even though Gronings is quite similar to Dutch (see Figure 2). mBERT with its original lexical layer achieves better results than the monolingual models, but only West Frisian performance is comparable to the source language performance. Since West Frisian was included in mBERT pre-training, these results suggest that mBERT might serve languages included in pre-training well, whereas it may be less suitable for those not included (e.g., Gronings).

For all monolingual models, task performance greatly improves by retraining the lexical layer for Gronings and West Frisian (Figure 3a). Best results are obtained by (Dutch) BERTje fine-tuned on the `Alpino` dataset (92.4% for Gronings, 95.4% for West Frisian). In contrast, (English) BERT yields the worst performance. We find that performance scores and the linguistic distance from Gronings and West Frisian to the source languages (Figure 2) strongly correlate ($r = -0.85$, $p < 0.05$). This suggests that measures of linguistic distance can guide the optimal choice of monolingual models to transfer to low-resource languages. Retraining mBERT's lexical layer also improves performance, especially for Gronings (Figure 3b), but with smaller gains than for monolingual models.

To estimate how our zero-shot approach compares with supervised learning, we train UDPipe (Straka et al., 2016) with five-fold cross-validation on the Gronings and West Frisian POS-tagging data. UDPipe achieves an accuracy of 91.85 ($\sigma = 0.81$) for Gronings and 90.60 ($\sigma = 0.58$) for West Frisian. These results do not indicate out-of-domain performance, since training and test data are from the same source. Also, labeled data for Gronings comes from a corpus with a specific target audience (i.e. children). Therefore, these results can be seen as an upper-bound. Our adapted models perform on par (Gronings) or better (West Frisian) with no need for labeled data in the target language.

Data size Our zero-shot transfer method relies on the availability of unlabeled Gronings and West Frisian data. Other low-resource languages may have even smaller amounts of data available than we have for West Frisian (59MB) and Gronings (43MB). We therefore assess how little data is sufficient for adequate performance by retraining the lexical layer with subsets of (independently randomly sampled) unlabeled data.

Table 3 shows POS-tagging accuracies for each subset. Results are consistent across both target languages and show that ca. 10MB of data (1.9M tokens) is sufficient to achieve almost optimal performance for the monolingual models. By contrast, mBERT shows a steadier improvement with more data, suggesting that it might further improve if even more data is available than we have for Gronings and West Frisian. BERT's POS-tagging accuracy is very low compared to the other monolingual models and performance decreases with more data. These fluctuations suggest that the retrained lexical layer fits BERT poorly and it is unclear if using more data will impact performance positively.

5 Conclusion

We adapted three monolingual BERT models and mBERT to two low-resource languages, Gronings and West Frisian, by retraining the lexical layers with new vocabularies. We found that the adaptability of mBERT is limited, suggesting that a model trained on a large amount of languages may not facilitate transfer to low-resource languages. Instead, monolingual BERT models are transferable to languages with very little data if the source and target languages are relatively similar. In such case, 10MB of unlabeled data, and no task-specific labeled data, is sufficient to achieve high ($> 90\%$ accuracy) downstream task performance.

A Detailed Results

Table 4 shows results per adapted model per training dataset. Dutch POS-tagging accuracy is still relatively high after lexical layer replacement. Similarly, Table 5 shows the POS-tagging performance with subsets of the lexical layer retraining data per training dataset. Training on the Dutch `Alpino` dataset instead of `LassySmall` results in consistently higher performance for both Gronings and West Frisian.

BATCHMIXUP: Improving Training by Interpolating Hidden States of the Entire Mini-batch

Wenpeng Yin, Huan Wang, Jin Qu and Caiming Xiong
Salesforce Research
`wyin@salesforce.com`

Abstract

Usually, we train a neural system on a sequence of mini-batches of labeled instances. Each mini-batch is composed of k samples, and each sample will learn a representation vector. MIXUP implicitly generates synthetic samples through linearly interpolating inputs and their corresponding labels of random sample pairs in the same mini-batch. This means that MIXUP only generates new points on the edges connecting every two original points in the representation space. We observed that the new points by the standard MIXUP cover pretty limited regions in the entire space of the mini-batch. In this work, we propose BATCHMIXUP—improving the model learning by interpolating hidden states of the entire mini-batch. BATCHMIXUP can generate new points scattered throughout the space corresponding to the mini-batch. In experiments, BATCHMIXUP shows superior performance than competitive baselines in improving the performance of NLP tasks while using different ratios of training data.

1 Introduction

The study of data augmentation techniques has a long history in the NLP community. Typical data augmentations include synonym replacement (Kobayashi, 2018), back-translation (Fadaee et al., 2017), adding data noise (Xie et al., 2017), etc. Mostly, these techniques are combined with the augmentation-free models in pipeline. MIXUP (Zhang et al., 2018) is able to augment the data by linearly combining each two examples by their hidden representations, keeping the whole system trained in end-to-end.

MIXUP has shown effectiveness in a range of NLP tasks (Sun et al., 2020). Nevertheless, it has two drawbacks. First, MIXUP generates new points merely and exactly on the connecting edges of random point pairs; these new points cover pretty limited region in the representation space of the mini-batch. Second, the training of a system equipped with MIXUP is considerably inefficient—generally, MIXUP slows down the training by n times if it generates n new points for each original point pair. In this work, we propose BATCHMIXUP, an improved mixup paradigm that generates new points scattered uniformly throughout the whole representation region of the mini-batch. Specifically, within a mini-batch, each example and its label will first learn a representation vector respectively, BATCHMIXUP then generates n new points (including a new input representations and a new label representation) simultaneously by non-linearly interpolating all the examples in the same mini-batch. The new n points are expected to better identify the space represented by the mini-batch. Finally, the n mixed points will act as one batch to update the model.

Our model BATCHMIXUP, as a batch-wise non-linear MIXUP, shows advantages in two aspects. (i) Compared with the standard MIXUP, BATCHMIXUP further improves the representation learning in solving downstream NLP tasks, yielding better performance. (ii) BATCHMIXUP works much more efficient than the conventional MIXUP and other pair-wise mixup variants.

2 Related Work

MIXUP was originally proposed in the computer vision community. The standard MIXUP (Zhang et al., 2018) interpolates the raw pixels of each two images in a mini-batch. Verma et al. (2019) conducted interpolation in the hidden states of images. Guo et al. (2019b) discovered a limitation of MIXUP, called "manifold intrusion", which is the conflict between the synthetic label of the mixed-up points and the labels of the original examples. They came up with "AdaMixup", an adaptive MIXUP,

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4908–4912
August 1–6, 2021.

where the mixing policies are automatically learned from the data using an additional network and objective function designed to avoid manifold intrusion. Other work tried to explain the work mechanisms of MIXUP from different threads, such as "MIXUP as directional adversarial training" (Archambault et al., 2019), "MIXUP training as the complexity reduction" (Kimura, 2020)

To date, only a couple of previous studies explored the effectiveness of the standard MIXUP in NLP. Guo et al. (2019a) tried two strategies: interpolating word embeddings or sentence embeddings generated by convolutional/recurrent neural networks. Sun et al. (2020) incorporated MIXUP into BERT (Devlin et al., 2019), the state of the art architecture in NLP. To improve the standard MIXUP, Guo (2020) added non-linearity to the MIXUP for text classification tasks. However, that non-linear MIXUP works on word embedding level, which is less applicable to Transformer-style (Vaswani et al., 2017) systems. All the work above are pair-wise mixup, this work is the first work that interpolates all the examples in the same mini-batch to cover the representation space better.

3 The Base Model: MIXUP

Given a pair of samples (x_i, y_i) and (x_j, y_j) from the original mini-batch (x: input, y: the one-hot label), the standard MIXUP (Zhang et al., 2018) generates a synthetic sample as follows.

$$\hat{x}_{ij} = \beta x_i + (1-\beta)x_j \tag{1}$$

$$\hat{y}_{ij} = \beta y_i + (1-\beta)y_j \tag{2}$$

where β is a mixing scalar, sampled from a Beta(α, α) distribution with a hyper-parameter α, for mixing both the inputs and the corresponding targets. The generated synthetic data are then fed into the model for training to minimize the loss function.

From the same mini-batch, the standard MIXUP will sample the β value n times so that totally n new mixed points for a sampled input pair will be generated sequentially. The model, as a result, will be updated n times more than the mixup-free model.

4 Our Model: BATCHMIXUP

BATCHMIXUP mixes all the samples in the same mini-batch on the level of hidden states generated by RoBERTa (Liu et al., 2019).[1]

To start, we first think about how the standard text classifier works: For the labeled input (x_i, y_i), first RoBERTa (optionally with a multilayer perceptron block) generates a representation for x_i ("$v(x_i) \in \mathbb{R}^d$"), then $v(x_i)$ is fed to a logistic regression (LR) layer to classify to y_i. The LR layer has a weight matrix $W \in \mathbb{R}^{c\times d}$ where c is the class size and d is the dimension size of representations. Each row in W, i.e., $w_i \in \mathbb{R}^d$, can be treated as the representation vector of the class y_i. So, LR essentially uses the dot-product to derive the matching score ($s_i \in \mathbb{R}$) between the input x_i and the label y_i: $s_i = (v(x_i))^T \cdot w_i$.

For the same mini-batch of inputs $\{v(x_i)\}$ and labels $\{w_i\}$, BATCHMIXUP deploys the same mixing policy to interpolate the $\{v(x_i)\}$ and $\{w_i\}$.

We denote the whole batch of input representations $\{v(x_i)\}$ as $\mathcal{X} \in \mathbb{R}^{d\times b}$ where b is the batch size and the whole mixing policy for this batch is $\mathcal{M} \in \mathbb{R}^{n\times d\times b}$. To generate a single mixed point $\hat{x}_i \in \mathbb{R}^d$, the BATCHMIXUP uses the following mixing policy $\mathcal{M}[i] \in \mathbb{R}^{d\times b}$ ($i = 1, \cdots, n$) on $\mathcal{X}$, where each element of $\mathcal{M}[i]$ is independently sampled from a Beta(α, α) distribution:

$$\hat{x}_i = \sum_{\text{axis}=1} (\text{softmax}(\mathcal{M}[i]) \circ \mathcal{X}) \tag{3}$$

where $\circ$ is the Hadamard product. Equation 3 can be performed for all i values in [1,n] simultaneously; this means the original batch input $\mathcal{X}$ is transformed into a new batch of mixed input $\hat{\mathcal{X}} \in \mathbb{R}^{n\times d}$.

Similarly, the same mixing policy $\mathcal{M}$ is applied to the batch of label representations, denoted as $\mathcal{Y} \in \mathbb{R}^{d\times b}$ ($\mathcal{Y} = \{w_i\}$):

$$\hat{y}_i = \sum_{\text{axis}=1} (\text{softmax}(\mathcal{M}[i]) \circ \mathcal{Y}) \tag{4}$$

Each ($\hat{x}_i$, $\hat{y}_i$) ($i = 1, \cdots, n$) is a newly mixed point. All $\{(\hat{x}_i, \hat{y}_i)\}$ can be generated in parallel and are scattered throughout the space represented by $\mathcal{X}$.

For training, we minimize the negative-dot-product loss between the mixed input and the mixed label. In testing, an input x_i still compares with all classes $\{y_i\}$ by dot-product between $v(x_i)$ and all $\{w_i\}$ to find the best class.

5 Experiments

In experiments, we check the effectiveness of our approach in NLP tasks with two settings: one is

Table 1: Experimental results on three NLP tasks: textual entailment (RTE (Dagan et al., 2005; Wang et al., 2019)), relation classification (FewRel (Han et al., 2018)) and intent classification (BANKING77 (Casanueva et al., 2020)). We decrease the size of training data from 100% to 1% with random sampling. All numbers are averaged over three random seeds.

full-shot setting that trains on the regular full training data; the other is few-shot setting that train with limited training data. Unfortunately, prior work about mixup never evaluated on few-shot scenarios.

Tasks. We evaluate on the following three tasks.

- **Textual Entailment.** Textual entailment is a task that figures out the truth value of a hypothesis sentence given a premise sentence (Dagan et al., 2005). This is a binary classification ("entailment" or "non-entailment") problem where the input is a sentence pair. We use the GLUE RTE (Wang et al., 2019) benchmark which has 2,490/277/2,999 examples in train/dev/test. The smaller size of this dataset (compared MNLI (Williams et al., 2018) for example) makes it a good testbed for data augmentation techniques.

- **Relation Classification.** FewRel (Han et al., 2018) is a large-scale relation classification dataset. It has 100 relation types, each with 700 labeled examples. The original FewRel relation set was split by 64/16/20 for developing meta-learning techniques which only allow a test instance to search for its relation type within the 20 candidates. This is not a practical setting because (i) in relation detection, an input should search for a label in the entire space of defined relations, (ii) we should always define a "None" type in this problem because most span pairs in the input actually do not have a relation. Since the test relations of FewRel is not publicly available, we use the 64+16=80 relations as the entire relation set, in which 5 relations are treated "None" (So, basically this is a regular "75+None" setting).

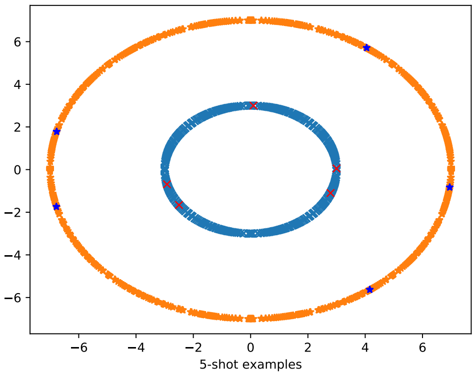
- **Intent Classification ("intent").** We use the benchmark BANKING77[2] (Casanueva et al., 2020), which is single-domain intent detection dataset comprising 13,083 annotated examples over 77 intents (average: 170 examples per intent). Each intent class is described by a short name, such as "get physical card", "lost or stolen card", etc.

Baselines. The augmentation-free system we use for above tasks consists of a RoBERTa[3] encoder

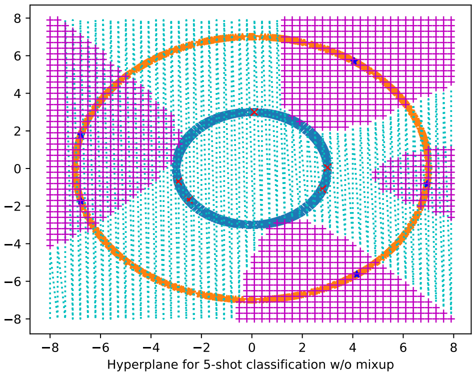
---

[2] `https://github.com/PolyAI-LDN/task-specific-datasets`

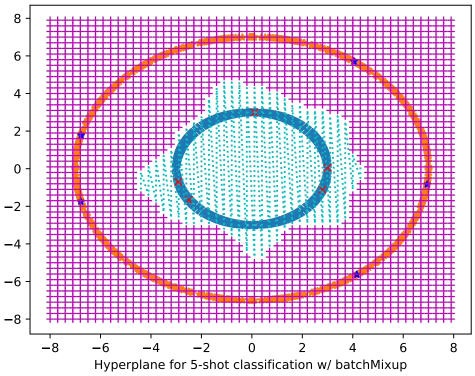
[3] We used the pretrained "RoBERTa-large"



(a) Two classes (orange vs. blue), 5-shot for each



(b) Hyperplane after training w/o mixup; it cannot distinguish the two classes clearly.



(c) Hyperplane after training w/ BatchMixup, it separates the two classes very well

Figure 1: Visualization analysis

and a final logistic regression layer. Based on this RoBERTa system, we compare our system BatchMixup with (i) the standard Mixup (Zhang et al., 2018; Sun et al., 2020), and (ii) non-linear Mixup (Guo, 2020). Both baselines conduct data interpolation in the hidden states output by the RoBERTa.

All systems are implemented through the Huggingface's Transformers package.[4]

Results and Analysis. Table 1 lists the main results. We notice that our approach RoBERTa+BatchMixup consistently outperforms the baselines Mixup and non-linear Mixup. In "1% entailment", none of systems really worked—all system results are around the majority baseline. This is because that the RTE task is very challenging with over limited annotations. With 2.5K × 1%=25 labeled examples, the "RoBETTa" cannot learn any useful representations. This is in line with the observations in (Yin et al., 2020) which showed that few-shot RTE (when $k \in \{1, 3, 5, 10\}$) will make RoBERTa fail. So, we conclude that when a system is close to random guess, adding mixup is not helpful. In this situation, maybe using other conventional data augmentation skills makes more sense as the representation learning of synthetic data and that of the original data are decoupled.

To further study how BatchMixup works, we simulate the classification process with a toy experiment: we generate a large amount of 2-dimensional data in Gaussian distributions for two classes (Figure 1(a)), and randomly sample 5 examples for each class to conduct 5-shot classification. We used a MLP as the classifier, trained 100 epochs. Comparing the final hyperplane of training with BatchMixup with that of training without Mixup, we can observe that BatchMixup can improve the training considerably.

Last but not least, the training of same epochs for "w/ Mixup", "w/ Nonlinear Mixup" takes much longer than our system "w/ BatchMixup". For example, when all systems separately run on a GPU Tesla V100, our system BatchMixup and the baseline "RoBERTa-large" both take about 1.5min to finish one epoch on RTE, but "w/ Mixup" and "w/ Nonlinear Mixup" will take ∼20mins if β is sampled 15 times per point pair.

6 Conclusion

In this work, we proposed a novel Mixup model, named BatchMixup, to improve the text classifier. Different with prior Mixup variants, which always interpolate random two points, our system interpolates all the hidden states in the mini-batch. The mixed points by our system are able to better cover the space expressed by the minibatch. The experiments and visualization analysis both show the effectiveness of our model BatchMixup.

DocNLI: A Large-scale Dataset for Document-level Natural Language Inference

`wyin@salesforce.com`

Abstract

Natural language inference (NLI) is formulated as a unified framework for solving various NLP problems such as relation extraction, question answering, summarization, etc. It has been studied intensively in the past few years thanks to the availability of large-scale labeled datasets. However, most existing studies focus on merely sentence-level inference, which limits the scope of NLI's application in downstream NLP problems. This work presents DocNLI — a newly-constructed large-scale dataset for document-level NLI. DocNLI is transformed from a broad range of NLP problems and covers multiple genres of text. The premises always stay in the document granularity, whereas the hypotheses vary in length from single sentences to passages with hundreds of words. Additionally, DocNLI has pretty limited artifacts[1] which unfortunately widely exist in some popular sentence-level NLI datasets. Our experiments demonstrate that, even without fine-tuning, a model pretrained on DocNLI shows promising performance on popular sentence-level benchmarks, and generalizes well to out-of-domain NLP tasks that rely on inference at document granularity. Task-specific fine-tuning can bring further improvements. Data, code and pretrained models can be found at `https://github.com/salesforce/DocNLI`.

1 Introduction

A fundamental challenge of natural language processing (NLP) lies in the variability of semantic expression, where the same meaning can be conveyed by, or inferred from, different pieces of text (Dagan et al., 2009). This phenomenon gives rise to the many-to-many mapping between textual expressions and meanings. Many NLP problems, such as information extraction, question answering, document summarization and machine translation, desire a system for this variability phenomenon so as to figure out that a particular meaning can be inferred from distinct text strings (Dagan et al., 2009). Natural language inference (a.k.a textual entailment (Dagan et al., 2005)) acts as a unified framework to study those NLP problems by casting the background text as a premise and the text of target meaning as a hypothesis. Then, a good NLI recognizer can be considerably translated to a well-performing system regarding respective NLP tasks.

NLI was first studied in (Dagan et al., 2005). Research in the early stages was mostly driven by the PASCAL Recognizing Textual Entailment (RTE) challenges which are annual competitions with benchmark datasets released. In the past few years, the study of NLI has moved forward rapidly along with the construction of large-scale datasets, such as SNLI (Bowman et al., 2015), the science domain SciTail (Khot et al., 2018) and multi-genre MNLI (Williams et al., 2018), etc.

However, some NLI datasets may not be suitable any more for solving downstream NLP problems since they were commonly crowdsourced in isolation from any end task [2] (Khot et al., 2018). In addition, most NLI datasets and studies paid attention merely to sentence-level inference — both the premises and hypotheses are single (and usually short) sentences. This makes them unsuitable for other open-ended NLP problems. For example, to verify the factual correctness of a document summary, sentence-level NLI systems cannot be of much help (Kryściński et al., 2019). Considering the fact-checking task FEVER (Thorne et al., 2018) as another example, in order to figure out the truth value of a claim against a Wikipedia article, NLI

---

[1] NLI "artifacts" are some label-specific biases (often) in the hypotheses; they can indicate which NLI class a hypothesis belongs to even without looking at the premise.

[2] Except for RTE and SciTail

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4913–4922
August 1–6, 2021.

has to be done on individual sentences instead of using the whole article as the premise. In short, some NLP tasks require the reasoning of NLI to go beyond the sentence granularity, regarding both the premise and the hypothesis.

In this work, we introduce DocNLI, a large-scale dataset for document-level NLI. It is constructed by reformatting some mainstream NLP tasks, including question answering and document summarization, and integrating existing NLI in which the premises may be longer than single sentences. DocNLI has the following characteristics:

- DocNLI is highly related with end NLP tasks. A well-performing system to DocNLI is expected to throw light on addressing other NLP challenges.
- Premises always have more than one sentence; the majority are natural documents such as news articles. Hypotheses cover a variety of lengths, ranging from a single sentence to a document with hundreds of words. By this setting, we hope the systems can learn to deal with future applications that need to infer the truth value of a piece of text regardless of its length.
- In contrast to some existing sentence-level NLI datasets, DocNLI has pretty limited artifacts. We present a novel approach to disconnect the potential artifacts with the NLI task itself; a "hypothesis-only" baseline has difficulties in discovering some spurious correlations.

In experiments, we will show that a RoBERTa (Liu et al., 2019) system pre-trained on DocNLI demonstrates promising performance on conventional sentence-level NLI benchmarks such as MNLI and SciTail, and generalizes well to out-of-domain NLP tasks (e.g., fact-checking and multi-choice question answering) that necessitate document-level inference. Task-specific fine-tuning can further improve the performance and achieve new state of the art for some end tasks.

2 Related Work

To our knowledge, document-level NLI has attracted very little ink in the community, possibly because of the lack of labeled datasets. In this section, we mainly describe some prior NLI datasets that share some spirits with our DocNLI.

End-task driven. As mentioned in Section 1, the RTE series were driven by downstream NLP tasks such as information retrieval, information extraction, question answering, and summarization. MCTest (Richardson et al., 2013) is a question answering task in which a paragraph is given as background knowledge, then each question is paired with a positive answer and some negative answers. The MCTest benchmark released an NLI version of this corpus by treating the whole paragraph as a premise and combining the question and answer candidates as hypotheses. SciTail (Khot et al., 2018) is also derived from the end QA task of answering multiple-choice school-level science questions. Unlike MCTest, the premises in SciTail are single sentences selected by an information retrieval approach. By casting an end NLP task as NLI, a good NLI recognizer therefore can be directly turned into a well-performing system for that NLP task. This can be even more attractive if we can learn a generalizable NLI system to solve some NLP problems that have limited annotations.

Going beyond the sentence granularity. The premises in MCTest are paragraphs, but MCTest has pretty limited size. Demszky et al. (2018) tried to convert the question answering benchmark SQuAD (Rajpurkar et al., 2016) into an NLI format by treating the paragraph as a premise and using a neural network to generate a hypothesis sentence given the question and answer span as inputs. Kryściński et al. (2019) created a (document, sentence) pair data "FactCC" to train a classifier for checking the factual correctness of single sentences in automatically generated summaries. FactCC is specific to the target summarization benchmark dataset, so it is unclear how well FactCC can generalize to other summarization benchmarks and other NLP problems. In addition, only single sentences act as hypotheses. Nevertheless, that literature exactly showed that document-level NLI, especially the inference of document-level hypotheses, is highly desirable. ANLI (Nie et al., 2020) also gather multi-sentence as premises. However, the sentence sizes in ANLI premises are pretty limited and the hypotheses in ANLI are single sentences consistently.

To our knowledge, our DocNLI is the first dataset that uses hypotheses longer than single sentences, and stays closely with end NLP tasks.

3 Data Creation

What kind of document-level NLI dataset is preferred? (i) We want the premise is a paragraph or

	original task	domain	premise length	hypothesis length
ANLI	NLI	various (wiki, news, etc.)	multi-sentence (20∼94 words)	single sentence (4∼18 words)
SQuAD	QA	wiki	paragraph (27∼237 words)	single sentence (6∼22 words)
DUC (2001)	summarization	news	doc. (124∼879 words)	multi-sent (80 ∼100 words)
CNN/Daily Mail	summarization	news	doc. (247∼652 words)	3∼4 sent. (40∼50 words)
Curation	summarization	news	doc. (229∼842 words)	multi-sent (64∼279 words)

Table 1: Data resources that are reformatted into DOCNLI.

even a document, and the hypotheses cover a large range of granularity: from a single sentence to a longer paragraph (e.g., 250 words); (ii) Diverse domains; (iii) No severe artifacts; for example, we do not include the hypotheses that can be easily found "grammatically incorrect" by well-trained language models such as BERT (Devlin et al., 2019).

3.1 Data Preprocessing

Table 1 lists all the resources that we use to create DOCNLI. Briefly, DOCNLI combines and reformats five existing NLP benchmarks: adversarial NLI (ANLI) (Nie et al., 2020), the question answering benchmark SQuAD (Rajpurkar et al., 2016) and three summarization benchmarks (DUC2001[3], CNN/DailyMail (Nallapati et al., 2016), and Curation[4] (Curation, 2020)). Next, we describe how each data resource is integrated into DOCNLI.

ANLI to DOCNLI. ANLI is a large-scale NLI dataset collected via an iterative, adversarial human-and-model-in-the-loop procedure. In each round, the best-performing model from the previous round is selected and then human annotators are asked to write "hard" examples that this model misclassifies. They always choose *multi-sentence paragraphs as premises and write single sentences as hypotheses*. Then a part of those "hard" examples join the training set so as to learn a stronger model for the next round. The remaining "hard" examples act as dev/test sets correspondingly. Totally three rounds were accomplished for ANLI construction. In the end, ANLI has train/dev/test sizes as 162,865/3200/3200 with three classes "entail", "neutral" and "contradict".

We keep premise-hypothesis pairs in ANLI unchanged, but unify the two classes "neutral" and "contradict" into a new class "not_entail".

SQuAD to DOCNLI. SQuAD is a QA dataset in which a multi-sentence paragraph is accompanied by a couple of questions; each question has a text span from the paragraph as its answer. Demszky et al. (2018) converted SQuAD into NLI format by reformatting the question-answer pairs into declarative sentences (QA2D) by neural networks. The resulting sentences containing correct (resp. incorrect) answers are entailed (resp. not_entail) by the paragraph. Human evaluation was conducted to make sure those declarative sentences have high quality on three criteria: grammaticality, naturalness, and completeness. In addition, Demszky et al. (2018) replicated some statistical analyses showing that this QA2D dataset does not have clear artifacts as SNLI or MNLI. In this work, we directly use this QA2D dataset and re-split it into train/dev/test by 50k/7,236/8,275.

Summarization to DOCNLI. Here we introduce the basics of the three summarization datasets (DUC2001, CNN/DailyMail and Curation), and explain how we convert them into DOCNLI in a unified approach.

- The DUC series are some of the earliest benchmarks for studying automatic document summarization. DUC2001 is on generic, single-document summarization in the news domain. There are totally 600 documents along with human-written reference summaries of approximately 100 words. We split those document-summary pairs into train/dev/test by size of 400/50/150.

doc		Petrofac shares surged on Wednesday following reports that the Serious Fraud Office has abandoned a criminal investigation into three businessmen who were accused of paying brides in the energy industry. The SFO had been probing claims that Unaoil - a Monaco-based consultancy that worked with Petrofac, primarily in Kazakhstan between 2002 and 2009 - had paid multimillion pound brides to land contracts in the oil and gas industry. But The Guardian cited sources earlier as saying that the SFO has dropped the investigation into the trio. Compliance industry newsletter MLex was the first to report the news, saying on Tuesday that the probe had been halted after three years. The SFO launched an investigation into Petrofac in May 2017 as part of a wider probe into Unaoil. In February 2019, David Lufkin, Petrofac's former global head of sales, pleaded guilty to 11 counts of bribery linked to contracts worth more than $730m in Iraq and $3.5bn in Saudi Arabia. SFO spokesman Adam Lilley said the Unaoil investigation ”remains active and is ongoing”. “We do not comment on ongoing investigations,” he said. [$\cdots$]

	sent repl.	The Serious Fraud Office has reportedly dropped a criminal investigation into three businessmen who had been accused of conspiring to make corrupt payments to secure contracts in Iraq. A spokesman for the SFO said it was “unable to confirm or deny” that an inquiry had taken place.

Table 2: An example of the Curation summarization dataset shows the original document, and the real summary written by humans. We used "word replacement", "entity replacement" and "sentence replacement" to form three types of "fake" summaries against the document. Texts in red are substitutes.

- CNN/DailyMail was gathered from news articles in *CNN* and *Daily Mail* websites; each article is paired with 3 to 4 sentences of abstractive summary bullets generated by humans. CNN/DailyMail has 286,817/13,368/11,487 article-summary pairs in train/dev/test. The source articles in the training set have 766 words spanning 29.74 sentences on average while the summaries consist of averagely 3.72 sentences.
- Curation is a recent summarization dataset with 40,000 professionally-written summaries of news articles. We split it into train/dev/test as 20K/7K/13K.

All three summarization datasets align the documents with the human-written reference summaries. This enables us to obtain "entail" pairs of (document, reference summary). The remaining challenge lies in how to generate "not_entail" pairs.

We adopt three types of manipulations on the "reference" (also referred as "real") summaries.

- *Word replacement*. We mask eight words whose part-of-speech tags are among {"VERB", "NOUN", "PROPN", "NUM"} by spaCy toolkit[5], then use BERT to predict them. The most likely predicted word is used to replace a masked one. After word replacements, the resulting text is our "fake" summary.
- *Entity replacement*. We use spaCy for named entity recognition (NER). For an entity which is the only one of a specific NER type in the real summary, we search for a different entity with the same type from the document to replace it; otherwise, it will be replaced by the entity of the same type in the real summary. We do this operation for five entities. We skip entity-level manipulation for the instances that have fewer than five detected entities. After entity replacement, we get a "fake" summary.
- *Sentence replacement*. From the real summary, we randomly select a sentence, then forward its left context to CTRL (Keskar et al., 2019), a state-of-the-art controllable text generator, to generate a new sentence which is used to replace the selected sentence. This operation generates a new "fake" summary.

Table 2 illustrates a (document, real summary) pair in the Curation dataset, and the three types of "fake" summaries we generated.

3.2 Mitigating Artifacts in DOCNLI

In Section 3.1, we transformed these NLI, QA and summarization datasets to satisfy the format of DOCNLI. We refer this resulting dataset as *raw*-DOCNLI. In consideration of the common artifacts in some popular sentence-level NLI benchmarks (Gururangan et al., 2018; Poliak et al., 2018; Tsuchiya, 2018), we tried a "hypothesis-only" baseline based on RoBERTa on this *raw*-DOCNLI. Sur-

---

[5] `https://spacy.io`

		entail	not_entail
DocNLI	raw DocNLI	ANLI SQuAD $\{(D, R)\}$	ANLI SQuAD $\{(D, F_i)\}$
	added pairs	$\{(F_i^+, F_i)\}$	$\{(F_i, R)\}$

Table 3: D: a document in summarization benchmarks; R: a real summary; F_i: a fake summary derived from R (i=$1 \cdots n$); F_i^+: Using CTRL to insert a generated sentence between a random pair of consecutive sentences in the F_i, in a way similar to what we described as "sentence replacement" in Section 3.1. DocNLI's training set is the combination of raw-DocNLI and those added pairs; DocNLI's dev and test sets *do not have trivial pairs* $\{(F_i^+, F_i)\}$.

prisingly, this baseline indeed obtains non-trivial performance. This means that RoBERTa can still learn some label-specific biases from the hypotheses, even though we have tried hard to make the "fake" summaries coherent and natural.

Nevertheless, this does not mean we have failed to build a robust DocNLI dataset. The surprising behavior of "hypothesis-only" in *raw*-DocNLI indicates that the BERT classifier can easily recognize the summary is "real vs. fake", but "real vs. fake" is not the same concept as "entail vs. not_entail" defined in the NLI framework. This is because a "fake" one can still be "entail"-ed if the premise has proper information; and a "real" one can also be "not_entail" if the premise does not contain necessary clues for inferring it.

For convenience, we use D as a document, R as the real summary, and $\{F_1, F_2, \cdots, F_n\}$ as the n fake summaries derived from R. To ensure the model can learn exactly what "entail vs. not_entail" is rather than be misled by the manipulations that yield those "fake" text pieces, as Table 3 demonstrates, we prepare the following pairs to extend the *raw*-DocNLI and get our final DocNLI:

- Adding pairs (F_i^+, F_i), $i = 1, \cdots, n$, for class "entail". Here F_i^+ has one more sentence than F_i, inserted by CTRL, as described in "sentence replacement" in Section 3.1 (here we do insertion rather than replacement). The goal is to let the system know that a fake summary can also be a positive hypothesis in NLI, if its premise covers necessary information.
- Adding a single pair (F_i, R) for class "not_entail". This means the original real summary can also be a negative hypothesis if it includes mis-matching information with its premise. F_i is randomly chosen from the set $\{F_1, \cdots, F_n\}$.

	train	dev	test
entail.	466,653	28,890	33,128
not_entail	475,661	205,368	233,958
sum	942,314	234,258	267,086

Table 4: Data sizes of DocNLI.

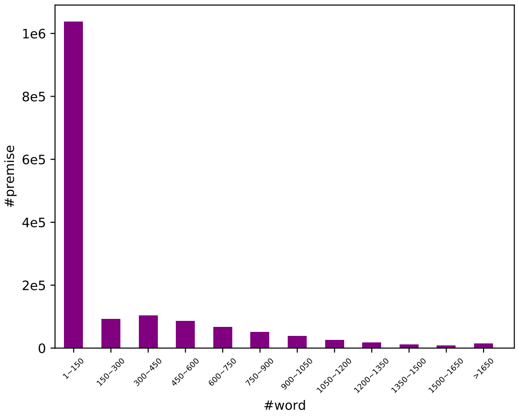

Figure 1: #premise vs. #words in DocNLI

By adding above two sorts of pairs, we want to disconnect the concept of "real vs. fake" from "entail vs. not_entail", letting the system learn the essence of NLI. Both the "real" and "fake" summaries have the same number of instances of being "entail" and "not_entail" in the extended dataset.

It is worth mentioning that since the instances "$(F_i^+, F_i) \rightarrow$ entail" are very trivial to be recognized, we add them in the training set only.

Table 4 lists the sizes of DocNLI for train/dev/test in each class. The training set is roughly balanced, while approximately 12% examples in dev and test belong to "entail". F1 is the evaluation metric.

Figures 1-2 illustrate the length distributions of premises and hypotheses in DocNLI. Because the majority of hypotheses have fewer than 150 words, and real/fake summaries also act as premises in DocNLI, as reported in Table 3, therefore, the majority of premises stay within the length limit of 150 words, shown in Figure 1. Still, there are a large amount of premises whose lengths are within the range of [150, 900] words.

3.3 Human Verification

DocNLI covers examples derived from ANLI, SQuAD and three summarization datasets. Here,

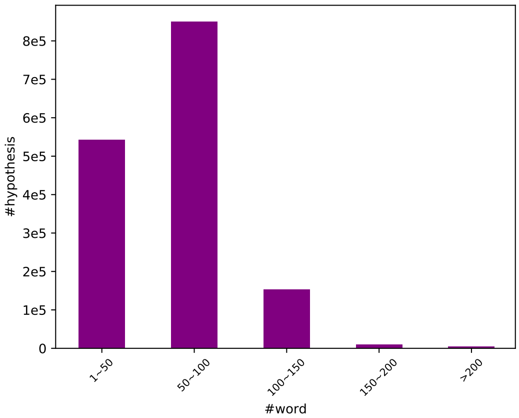

Figure 2: #hypothesis vs. #words in DOCNLI. The hypotheses in our new data DOCNLI are mostly longer than single sentences; this is one key difference with some related datasets.

we only conduct human verification for the pairs derived from summarization, especially for those "fake" summaries, to get some clues to answer two questions: (i) Are those "fake" summaries indeed incorrect given the original document? (ii) Do those "fake" summaries look natural? By "natural" we mean the text should have no major grammar errors, and no unrelated text spans that make the whole text piece look over uncoordinated.

The authors of this work manually checked 200 random "fake" examples, among which none is true given the same document as the "real" summary. This is mainly because we replaced relatively a lot from the original real summaries.

However, some minor grammar issues inevitably exist. Take the following text piece as an example:

"*WeWork Companies LLC (replace: "WeWork") has announced plans to hold a conference call on 2025 for holders of its 7.875% Senior Notes due 26 August to discuss its Notes (replace: "Q2") results. Securities analysts and market-making financial institutions can also register for access. The call is scheduled for 12:00 P.M. (replace: "noon Eastern Time").*"

This example has five entities that are substitutes, all underlined. If a substitute comes from the premise document, we use "(replace: XX)" to denote the entity that was there. The two entities (NER type "date"), in red, replaced each other: "2025" and "26 August", which makes the new text "[· · ·] on 2025 [· · ·]" grammatically incorrect.

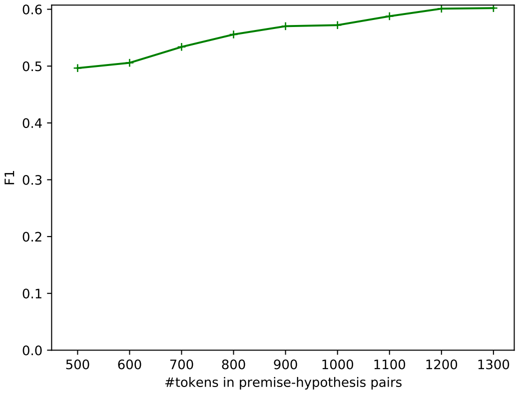

Figure 3: Longformer F1 vs. #tokens in DOCNLI dev set.

	dev	test
Random	19.75	19.91
Hypothesis-only	21.89	22.02
Longformer-base	56.11	54.37
Roberta-large	64.06	61.52

Table 5: F1 scores on DOCNLI.

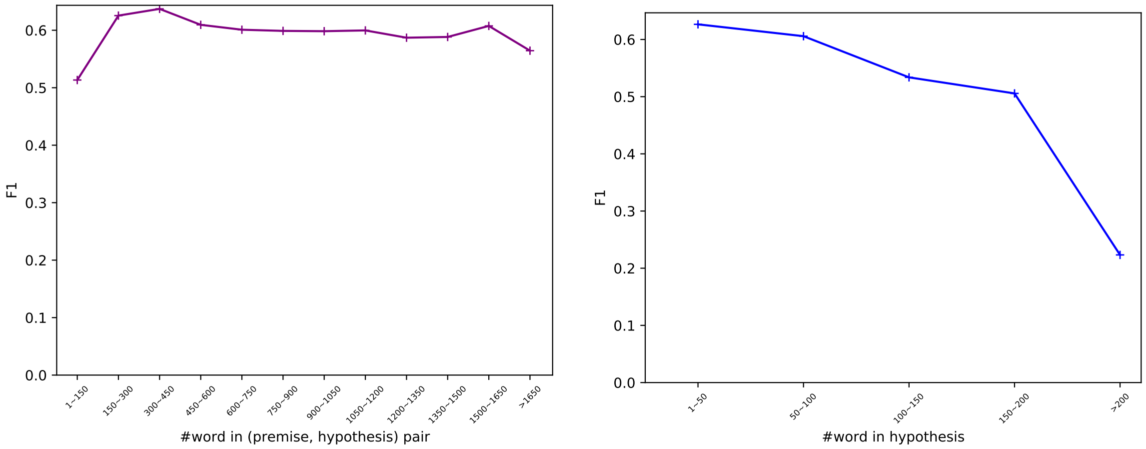
4 Experiments

We study three questions. (**Q**$_1$) How challenging is DOCNLI (especially with regard to different lengths of hypotheses)? (**Q**$_2$) Out-of-domain evaluation, in which we train a system given DOCNLI and test it on downstream NLP tasks that are not covered by the source tasks in DOCNLI construction. (**Q**$_3$) Could a system trained on DOCNLI work well on sentence-level NLI?

4.1 The DOCNLI task is challenging

The state-of-the-art systems on sentence-level NLI problems are largely based on transformers (Vaswani et al., 2017), such as BERT, RoBERTa (Liu et al., 2019), etc. However, they can only handle maximal 512 tokens preprocessed by the WordPiece tokenizer (Wu et al., 2016). This is an issue to build an effective document-level NLI machine. Therefore, for the main experiments, we also report Longformer (Beltagy et al., 2020) – a RoBERTa variant that can handle up to 4096 tokens. Longformer has two versions, one is "Longformer-base", the other is "Longformer-large". We currently only report "Longformer-base" due to memory constraints.

To answer the question (**Q**$_1$), we compare the following systems (we can include more baselines, but most popular approaches either are too weak or



(a) F1 vs. pair length

(b) F1 vs. hypothesis length

Figure 4: Fine-grained F1 scores for different lengths of DocNLI pairs or hypotheses alone.

can only handle short piece of texts):

- **Hypothesis-only.** We train RoBERTa on hypotheses only.
- **RoBERTa-large.** Although we claimed that RoBERTa may not be a good platform to learn DocNLI, here we report it just for reference. Maximal token limit: 512 tokens.
- **Longformer-base.** We use the released Longformer library[6] by (Beltagy et al., 2020), training it on the full training set of DocNLI, with length limit of 1.3K tokens, batch size 1 per GPU, and learning rate 5e-6.

All systems are trained for 5 epochs, and report the best model tuned on dev set. Table 5 lists the F1 results of all systems on DocNLI. We notice that "hypothesis-only" is just slightly higher than random guess, and is much lower than the "RoBERTa-large" system which takes both premises and hypotheses as input: 22.02 vs. 61.52 on test. Surprisingly, "Longformer"'s performance is clearly below that of the RoBERTa, even if it covers more tokens, possibly because we do not have enough computing resources to fully explore the better settings of Longformer. Figure 3 illustrates the impact of taking different numbers of tokens in Longformer, evaluated on dev set. In general, the more tokens the better performance.

We further look at the fine-grained F1 reports on the various lengths of premise-hypothesis pairs and hypotheses alone. Figure 4(a) shows that the system performance for pairs of lengths > 450 does not change clearly. This is probably due to those models' truncation when the (premise, hypothesis) pairs are overlong (note that one word may be split into multiple tokens by the WordPiece tokenizer). Figure 4(b) demonstrates that the task gets increasingly challenging when the hypotheses become longer, which matches our intuition.

Overall, DocNLI is a very challenging task that seeks solutions equipped with a stronger capability of representation learning.

4.2 Applying DocNLI to end NLP tasks

To answer the question (**Q**$_2$), we play DocNLI to see if it can help downstream NLP tasks. As DocNLI is derived from summarization and QA already, we do not consider these two types of NLP tasks any more (since improvements on them are not surprising), especially when their domains are covered in DocNLI. In addition, we have to explore tasks that have NLI-format data available — converting an open NLP task to NLI format is not trivial and is beyond the scope of this work. Therefore, we consider the following two NLP tasks:

FEVER (Thorne et al., 2018). FEVER is a benchmark dataset for fact-checking. Given an declarative sentence (aka. "claim"), the task searches for textual evidences from Wikipedia articles and then decide the truth value of this sentence (i.e., support / refute / not-enough-info).

We use the NLI-version of FEVER, released by (Nie et al., 2019): claims are hypotheses; premises corresponding to "support" or "refute' claims consist of ground truth textual evidence and some other randomly sampled evidence; premises for "not-enough-info" claims are the concatenation of all selected evidential sentences by a previ-

ous SOTA fact-checking system. We combine "refute" and "not-enough-info" as a single class "not_entail", and rename this data as "FEVER-binary". We randomly split FEVER-binary by 203,152/8,209/10,000 for train/dev/test respectively.[7]

MCTest (Richardson et al., 2013). In Related Work, we have introduced MCTest. Briefly, it is a multi-choice QA benchmark in the domain of **fictional story**. The authors of MCTest released an NLI-version MCTest by combining the question and the positive (resp. negative) answer candidate as a positive (resp. negative) hypothesis.

MCTest consists of two subsets. MCTest-160 contains 160 items (70 train, 30 dev, 60 test), each consisting of a document, four questions followed by one correct answer and three incorrect answers and MCTest-500 500 items (300 train, 50 dev, 150 test). *MCTest has pretty limited labeled data; thus, it is a good testbed to investigate* DocNLI *in studying annotation-scarce tasks.* The MCTest has two official metrics: accuracy and NDCG (Normalized Discounted Cumulative Gain). Here we only report accuracy.

In this section, we still use RoBERTa-large and compare our DocNLI with a latest NLI dataset ANLI in which the premises are longer than single sentences, and MNLI, the most widely-used sentence-level NLI dataset. For each data set (i.e., MNLI, ANLI or DocNLI), we try two settings: (i) Using the data for pre-training, then do inference on FEVER-binary or MCTest directly without task-specific fine-tuning; (ii) First pre-training on the data, then fine-tune on FEVER-binary or MCTest.

In Table 6, DocNLI can consistently generalize better than ANLI and MNLI on the two NLP tasks FEVER-binary and MCTest. We notice that the pretrained model on DocNLI demonstrates very strong performance on the two end tasks, even without any fine-tuning on the task-specific examples. Especially for MCTest, both the "DocNLI (pretrain)" and "DocNLI+finetune" surpass the prior state-of-the-art by large margins.

	SciTail	b-MNLI
majority	60.33	66.66

Prior state-of-the-art	97.70	–

Table 7: Train on DocNLI, test on sentence-level NLI benchmarks with or without fine-tuning. The SOTA of SciTail was reported by the DeBERTa model (He et al., 2020).

4.3 Applying DocNLI to sentence-level NLI

To answer the question (**Q**3), we use SciTail and MNLI as target sentence-level NLI tasks. SciTail is from the science domain with two classes "entail" and "not_entail" split 23,596/1,304/2,126 (train/dev/test). MNLI covers a broad range of genres with three classes "entail/neutral/contradict" split 392,702/20k/20k (train/dev/test). Since the gold labels of the test set in MNLI are not publicly available and DocNLI is a binary classification task, we first unify MNLI's "neutral" and "contradict" into "not_entail", then build a new labeled test set by randomly sampling 13k from the original dev set (the remaining examples are the new dev set). So now we have train/dev/test of size 372,702/6,647/13k. We first try some popular Transformer-style models, such as BERT-large, RoBERTa-large and Longformer-base to check how much we can get by training a supervised system on the full training data. Afterwards, we build a classifier by training RoBERTa-large on DocNLI with or without SciTail/MNLI-specific fine-tuning.

Table 7 shows that: (i) The pretrained model on DocNLI indeed can generalize to some extend on both SciTail and MNLI. In particular, it gets

---

[7] Please note that this data released by (Thorne et al., 2018) is different from the one used in FEVER leaderboard.

SciTail accuracy 78.17 which is even higher than some task-specific fully-supervised models such as "ESIM", "De-Att" and "DGEM". The same pretrained system can also get comparable performance with BERT, Longformer and RoBERTa on binary-MNLI; this should be attributed to the strong generalization of ANLI towards MNLI (Nie et al., 2020); (ii) When do task-specific fine-tuning, our model can further improve the performance and get very close to the state-of-the-art in SciTail.

5 Summary

In this work, we collect and release a large-scale document-level NLI dataset DocNLI. It covers multiple genres and multiple ranges of lengths in both premises and hypotheses. We expect this dataset can help to solve some NLP problems that require document-level reasoning such as QA, summarization, fact-checking etc. In experiments, we show that DocNLI can yield a model generalizing well to downstream NLP tasks and some popular sentence-level NLI tasks.

Abstract

Recently, unsupervised parsing of syntactic trees has gained considerable attention. A prototypical approach to such unsupervised parsing employs reinforcement learning and auto-encoders. However, no mechanism ensures that the learnt model leverages the well-understood language grammar. We propose an approach that utilizes very generic linguistic knowledge of the language present in the form of syntactic rules, thus inducing better syntactic structures. We introduce a novel formulation that takes advantage of the syntactic grammar rules and is independent of the base system. We achieve new state-of-the-art results on two benchmarks datasets, MNLI and WSJ.[1]

1 Introduction

Syntactic parse trees have demonstrated their importance in several downstream NLP applications such as machine translation (Eriguchi et al., 2017; Zaremoodi and Haffari, 2018), natural language inference (NLI) (Choi et al., 2018), relation extraction (Gamallo et al., 2012) and text classification (Tai et al., 2015). Based on linguistic theories that have promoted the usefulness of tree-based representation of natural language text, tree-based models such as Tree-LSTM have been proposed to learn sentence representations (Socher et al., 2011). Inspired by the Tree-LSTM based models, many approaches were proposed do not require parse tree supervision (Yogatama et al., 2017; Choi et al., 2018; Maillard et al., 2019; Drozdov et al., 2019). However, (Williams et al., 2018; Sahay et al., 2021) have shown that these methods cannot learn meaningful semantics (not even simple grammar), though they perform well on NLI tasks. Recently, there has been surge in approaches using weak supervision in the form of rules for various tasks such as sequence classification (Safranchik et al., 2020), text classification (Chatterjee et al., 2020; Maheshwari et al., 2020), *etc.* These approaches have demonstrated the importance of external knowledge in both unsupervised and supervised setup. To the best of our knowledge, previous works on syntactic parse tree has not utilized such external information. In this paper, we propose an approach that leverages linguistic (and potentially domain agnostic) knowledge in the form of explicit syntactic grammar rules while building upon a state of the art, deep and unsupervised inside-outside recursive autoencoder (DIORA; (Drozdov et al., 2019)). DIORA is an unsupervised model that uses inside-outside dynamic programming to compose latent representations from all possible binary trees. We extend DIORA and propose a framework that harness grammar rules to learn constituent parse trees. We use context free grammar (CFG) productions for English language (like NP →VP NP, PP →IN NP, *etc*) as rules. Note that the construction of such a rule set is a one time effort and our method is independent of any underlying dataset. The rule sets used are available in our github repository.

Summarily, our main contributions are : (a) a framework (*cf.*, Section 3) that uses (potentially domain agnostic), off-the-shelf CFG to learn to produce constituent parse trees (b) two rule-aware loss functions (*cf.*, Section 3.1) that maximize some form of agreement between the unsupervised model and the rule-based model (c) experimental analysis (*cf.*, Section 4), demonstrating improvements on unsupervised constituency parsing over previous state-of-the art by over **3**% on two benchmark datasets.

2 Background and Related Work

A brief survey of latent tree learning models is covered in (Williams et al., 2018). Several prior works have explored the unsupervised learning of

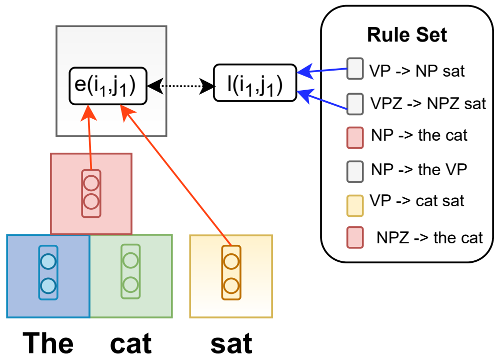

Figure 1: For the input 'The cat sat', DIORA computes $e(i_1, j_1)$ compatibility score for each pair of neighboring constituents. $l(i_1, j_1)$ is computed using triggered rules for each span and it interacts with the compatibility score in our loss function as explained in Section 3.1.

constituency trees (Brill et al., 1990; Ando and Lee, 2000) using dependency parsers (Klein and Manning, 2004) and inside-outside parsing algorithm (Drozdov et al., 2019). Recently, (Drozdov et al., 2019) proposed an unsupervised latent chart tree parsing algorithm, *viz.*, DIORA, that uses the inside-outside algorithm for parsing and has an autoencoder-based neural network trained to reconstruct the input sentence. DIORA is trained end to end using masked language model via word prediction. As of date, DIORA is the state-of-the-art approach to unsupervised constituency parsing.

Exploiting additional semantic and syntactic information that acts as a source of additional guidance rather than the primary objective function has been discussed since 1990s (Sun et al., 1993). Recently, Kim et al. (2019b) proposed to learn CFG rules and their probabilities by the parameterizing terminal or non-terminal symbols with neural networks. However, our approach leverages predefined language CFG rules and provisions for augmenting an existing (state-of-the-art) inside-outside algorithm with such external knowledge.

More specifically, we augment DIORA (Drozdov et al., 2019) with CFG rules to reconstruct the input by exploiting syntactic information of the language. We next provide some technical details of the inside-outside algorithm of DIORA.

2.1 DIORA

DIORA learns constituency trees from the raw input text using an unsupervised training procedure that operates like a masked language model or denoising autoencoder. It encodes the entire input sequence into a single vector analogous to the encoding step in an autoencoder. Thereafter, the decoder is trained to reconstruct and reproduce each input word. We next describe the inside and the outside pass of DIORA, respectively. *Inside Pass:* Given an input sentence with T tokens $x_0, x_1, x_2 \ldots x_{T-1}$, DIORA computes a *compatibility* score e and a *composition* vector $\bar{a}$ for each pair of neighboring constituents i and j. It composes a vector $\bar{a}$ weighing over all possible pairs of constituents of i and j: $\bar{a}(k) = \sum_{i,j\epsilon\{k\}} e(i,j)a(i,j)$ & $\bar{e}(k) = \sum_{i,j\epsilon\{k\}} e(i,j)\hat{e}(i,j)$ The composition vector, $\bar{a}(k)$ is a weighted sum of all possible constituent pairs, k. Here, $\hat{e}$ is a bilinear function of the vectors from neighboring spans, $\bar{a}(i)$ and $\bar{a}(j)$. Composition vector $\bar{a}(k)$ is learnt using a TreeLSTM or multi-layer neural network (MLP).

Outside Pass: The outside pass of DIORA computes an outside vector $\bar{b}(k)$ representing the constituents not in $x_{i:j}$. It computes the values for a target space (i, j) recursively from its sibling $(j+1, k)$ and outside spans $(0, i-1)$ and $(k+1, T-1)$.

Training and Inference: DIORA is trained end to end using masked language model via word prediction. The missing token x_i is predicted from the outside vector $\bar{b}(k)$. The training objective uses reconstruction based max-margin loss to predict the original input x_i:

$$L_{rec} = \sum_{i=0}^{T-1} \sum_{i^*=0}^{N-1} \max(0, 1 - \bar{b}(i).\bar{a}(i) + \bar{b}(i).\bar{a}(i^*))$$

The chart filling procedure of DIORA is used to extract binary unlabeled parse trees. It uses the CYK algorithm to find the maximal scoring tree in a greedy manner. For each cell of the parse table, the algorithm computes the span (i, j) with the maximal net compatibility score, computed recursively by summing the maximum compatibility score $e(a, b)$ for each constituent of the span.

3 Our Approach to Rule Augmentation

Our goal is to learn to produce constituency parse trees using input sentences alone and in the absence of ground truth parse trees. We introduce a rule-augmented unsupervised model that leverages generic (potentially domain agnostic) production rules of the language grammar to infer constituency trees. Since most grammar rules for constituency parsing are generic, designing them can be a one-time effort, while being able to leverage their benefits across domains as background knowledge (as we will see in our experiments in Section 4). As described in Section 2.1, the induction of latent trees in DIORA is based on a CYK-like parsing algorithm that uses the compatibility scores $e(i,j)$ at each cell to merge two constituents in the final tree. We impart supervision through the production rules of English language grammar.

For each sentence, we associate CFG production rules with constituents i and j in a CYK parse table format. We curate a set of domain-agnostic rules of the form $X \to YZ$ and a dictionary of the form $X \to x$, where X, Y, Z are non-terminals while x is a terminal. Concretely, X represents constituent tags such as S, NP, VP, etc., while x represents words in the vocabulary. Using the CYK parsing algorithm on our rule set and each sentence, we first determine which rules are triggered at each cell for a particular sentence. Whenever a rule r is triggered for a span (i,j), we weakly associate label $\delta_{(i,j)}(r) = 1$ otherwise 0. We use these weak labels to guide the rule scores $l(i,j)$ for the constituents. Compatibility score observed for the span (i,j) is defined as :

$$l(i,j) = \frac{\exp\left(\sum_{p=0}^{P} r_p \delta_{(i,j)}(p)\right)}{\sum_{(a,b)\in\{k\}} \exp\left(\sum_{p=0}^{P} r_p \delta_{(a,b)}(p)\right)}$$

where r_p are the *learned* weights associated with each of the production rules and P is the total number of rules. The score sums to 1 over all spans belonging to a particular cell in the CYK parse table. Intuitively, we aim to align $e(i,j)$ and $l(i,j)$ score to maximize the agreement between model and rules. We note that we use rules only to augment the training objective, and our inference procedure is identical to that of DIORA.

3.1 Training Objective

We learn a model that minimizes the overall loss L that is a composition of the reconstruction loss L_{rec} and the rule based agreement loss or L_{rule}: $L = L_{rec} + \lambda L_{rule}$. We propose two alternatives for the loss function L_{rule}.

Cross entropy (CE) - For each cell k in the CYK parse table, this loss (CE) tries *to match the distribution (score)* of $e(i,j)$ induced by DIORA with the distribution $l(i,j)$ induced by the background knowledge:

$$L_{ce} = \sum_{k} \sum_{(i,j)\in\{k\}} -l(i,j)\log(e(i,j))$$

RL and CE refer to the losses from section 3.1. † indicates scores reported by (Williams et al., 2018) for a fully supervised model.

Ranking Loss (RL) - We recall from Section 2.1 that the CYK algorithm finds the maximal scoring tree in a greedy manner based on the highest compatibility score $e(i,j)$ among all spans. Since the final parse tree output by DIORA relies only on the *relative order* of the $e(i,j)$ to decide which span to merge, we propose an alternative rule-based loss that aims *to match the relative order* induced by compatibility scores $e(i,j)$ of DIORA at each cell with the order induced by the scores of the rules $l(i,j)$ at that cell. We achieve this through a pairwise ranking loss defined as

$$L_{rank} = \sum_{\text{k}} \sum_{\substack{(i,j)\\(i',j')}\in\{\text{k}_{trig}\}} \left(\Delta^{l}_{\substack{(i,j),\\(i',j')}} - \Delta^{e}_{\substack{(i,j),\\(i',j')}}\right)^2$$

where $\{\text{k}_{trig}\} = \{(i,j) \in \{k\} | \sum_{p=1}^{P} \delta_{i,j}(p) \neq 0\}$, $\Delta^{f}_{(i,j),(i',j')} = \tanh(f(i,j) - f(i',j'))$ and p is index into the rule set. The set $\{k_{trig}\}$ consists of all spans which have at least one rule triggered in its cell. In cases where our rule set is not extensive enough, we would like our model's compatibility score to rely more on the reconstruction loss, and $\{\text{k}_{trig}\}$ ensures that a sparse rule set does not lead to bad performance.

4 Experiments

We evaluate our rule augmented model and compare it against baselines on the tasks of unsuper-

vised parsing, unsupervised segment recall, and phrase similarity.

4.1 Data

We evaluate our model on two data sets: The Wall Street Journal (WSJ) and MultiNLI. WSJ is an extraction of PennTree Bank (Marcus et al., 2002) containing human-annotated constituency parse trees. MultiNLI consists of Stanford generated parse trees (Manning et al., 2014) as the ground truth. MultiNLI is originally designed for evaluating NLI tasks, but is often also utilized to evaluate constituency parse trees. We train on the complete NLI dataset, which is a composition of the MultiNLI and SNLI train sets. We evaluate model performance on the MultiNLI dev set and WSJ test set (split 23) following the experimental setting and evaluation metrics in (Drozdov et al., 2019). Further details are provided in the appendix. We initialize our model with the trained weights of DIORA and evaluate on unsupervised constituency parsing and segment recall. We also perform the post-processing (PP) of generated trees by attaching the trailing punctuation to the root node, exactly as carried out by (Drozdov et al., 2019).

4.2 Rule Set

We consider two rule-sets: (i) **Set of Handcrafted Rules (HR)** consists of 2500 human created CNF production rules ii) To assess robustness of the rule-augmented method to the preciseness of the rule set, we present comparison by instead using a **set of Automated Rules' (AR)** which consists of the 2500 most frequently occurring CNF production rules extracted from the trees of automatically (using the Stanford CoreNLP parser) parsed SNLI corpus. Further details about these rule sets can be found in the appendix. We also use a train-set specific dictionary containing the POS (part-of-speech) tags of words in the training vocabulary for the terminal CFG productions for CYK parsing.

4.3 Unsupervised Parsing

In Tables 1 and 2, we present comparison between different approaches on the MultiNLI dev set and WSJ test set. We observe that our rule augmented approach outperforms the state of the art with respect to the max-F1 score. registering a maximum increase of 3.4 and 3.1 F1 points over DIORA respectively. The HR trained models outperform DIORA on both datasets, demonstrating that rule creation is indeed a one-time process and independent of domain. We also report parsing scores of a fully supervised model SPINN from (Williams et al., 2018) as an upper bound, and RL-SPINN (Choi et al., 2018), a distantly supervised model.

4.4 Constituency Segment Recall

In Table 3, we present the breakdown of constituent recall across the 6 most common types. Our approach achieves the highest recall across all the types and is the only model to perform effectively on SBAR and NP. Unlike other approaches, our approach consistently close to or the best recall score. We observe that rule augmentation using HR is more beneficial than AR with respect to precise evaluation measures such as Constituency, Segment Recall and Phrase Recall but yields smaller improvements than AR with respect to looser evaluation measures such as max F1 of Unsupervised Parsing. This can be possibly attributed to our observation that the extracted (most frequent) rules from SNLI, have (around 25%) higher coverage on the training set than HR, but appear to be semantically less precise.

Table 4: Phrase similarity scores on CoNLL2000 and CoNLL 2012 tasks.

4.5 Phrase Similarity

We also employed the phrase similarity strategy followed by (Drozdov et al., 2019). Phrase Similarity scores measures the models capability to learn meaningful representation for spans of the text. Generally, most models focus more on generating the tokens representation and then use some ad-hoc arithmetic operations to generate representation for the larger spans of text thus losing the essence of the context that ties the words of the span.

To evaluate on the phrase similarity task we consider two data sets of labeled phrases: 1) CoNLL 2000 (Tjong Kim Sang and Buchholz, 2000), which is a shallow parsed dataset and contains spans of verb phrases, noun phrases, preposition phrases *etc.*, and 2) CoNLL 2012 (Pradhan et al., 2012) which is a named entity dataset containing 19 different entity types. For the evaluation routine, we first generated the phrase representation of labeled spans whose length is greater than one. Cosine similarity is then used to obtain the similarity score of it with respect to all other labeled spans. We then calculate if the label for that query span matches the labels for each of the K most similar other spans in the dataset.In Table 4 we report precision@K for both datasets and various values of K. The baseline numbers are reported using the weights of DIORA provided by the authors.

5 Conclusion

In this work, we leverage linguistically grounded and domain agnostic CFG rules for language to induce parse trees and representations of constituent spans. We show that our approach augmented with generic, linguistically grounded grammatical rules, is easily able to outperform previous methods on constituency parsing and obtain higher segment recall.

Appendix

A Training and evaluation details

We use the multi-layered neural network model provided by the authors of (Drozdov et al., 2019) to initialize our model's weights. We have a learning rate of 10^{-4} and a batch size of 32. Using these settings we train our models for 500000 steps. We use weights $\lambda_{ranking} = 10^{-1}$ and $\lambda_{ce} = 1.0$ for the rule based losses. All other model parameters are same as the ones set in (Drozdov et al., 2019). We run all our experiments on Nvidia RTX 2080Ti GPUs 12 GB RAM over Intel Xeon Gold 5120 CPU having 56 cores and 256 GB RAM. It takes about 2 days to train the model on NLI data.

For evaluation, we have reported the tree F-1 score for MNLI dev and WSJ test set. The metric computes the F-1 score for each tree based on the constituent spans induced in the predicted tree against the constituent spans in the ground truth. We further binarize the WSJ test set using the Stanford CoreNLP Parser and report scores on unlabelled binary trees.

We find that training with AR helps us achieve better results on both MNLI as well as on WSJ. This could be because extracted rules from SNLI have wider coverage on the training set than HR resulting in a stronger training signal and better performance. Further, our ranking loss performs better for HR extracted rules, indicating its efficacy with non-extensive rule sets, i.e. in the cases where the training signal is not rich. In such cases when some cells may not have any triggering rules, the ranking loss ensures that the model's decision is guided by the reconstruction loss.

We also find that the generic background knowledge of English grammar (HR) helps the model to better chunk constituents that are rarer (e.g. SBAR), while dataset-specific rules (AR) might benefit its overall tree structures more, leading to higher unlabelled F1 scores.

B Rule sets

In this work we utilise two distinct rule sets - (i) The first rule set (HR) consists of 2500 human created CNF production rules ii) the other set (AR) consisted of 2500 most frequently occurring CNF production rules extracted from the trees of automatically parsed SNLI corpus. All rules in both these sets consist only of non-terminals. The rules in (HR) come from observing human annotated parse trees from the PTB train set and consists of 2500 rules in the Chomsky Normal Form. The rules in (AR) are programatically extracted from the parse trees generated by running the Stanford Parser on the SNLI train set. We only retain the 2500 most frequently occurring productions from the set to match the size of the HR set. We note however that these rules have a higher coverage on the train data. We also provides `rules-AR.txt` and `rules-HR.txt` in the github repository.

In our training procedure, we aim to learn a weight r_p for each production rule p in our train set. Table 5 shows the top 10 most important (i.e. the ones with the highest r_p) rules from the grammar as determined by our models.

C Learnt Trees

In this section we present examples of trees induced by DIORA and our model. The first row of fig. 1 shows an example where our tree matches the ground truth exactly while DIORA does not, and the second row of fig. 1 shows an example where both models do not provide exact matches, but our model is able to capture the syntax better.

Abstract

Multilingual language models have been a crucial breakthrough as they considerably reduce the need of data for under-resourced languages. Nevertheless, the superiority of language-specific models has already been proven for languages having access to large amounts of data. In this work, we focus on Catalan with the aim to explore to what extent a medium-sized monolingual language model is competitive with state-of-the-art large multilingual models. For this, we: (1) build a clean, high-quality textual Catalan corpus (CaText), the largest to date (but only a fraction of the usual size of the previous work in monolingual language models), (2) train a Transformer-based language model for Catalan (BERTa), and (3) devise a thorough evaluation in a diversity of settings, comprising a complete array of downstream tasks, namely, Part of Speech Tagging, Named Entity Recognition and Classification, Text Classification, Question Answering, and Semantic Textual Similarity, with most of the corresponding datasets being created ex novo. The result is a new benchmark, the Catalan Language Understanding Benchmark (CLUB), which we publish as an open resource, together with the clean textual corpus, the language model, and the cleaning pipeline. Using state-of-the-art multilingual models and a monolingual model trained only on Wikipedia as baselines, we consistently observe the superiority of our model across tasks and settings.

1 Introduction

Over the past decades, Natural Language Processing (NLP) has become a powerful technology that may be found behind many AI-based consumer products, such as voice assistants, automatic translators, intelligent chatbots, etc. This undeniable success is somehow tarnished by the fact that most NLP resources and systems are available only for a small percentage of languages (Joshi et al., 2020).

In contrast, most of the languages spoken in the world today, even some with millions of speakers, are left behind, both in the research and in the development of the technology. Recent breakthroughs in deep learning, specifically the Transformer architecture (Vaswani et al., 2017), have revolutionized the entire field and have opened the doors to powerful transfer learning and unsupervised techniques, making it possible for under-resourced languages to benefit -at least, partially- from the formidable advances taking place for English. Transformed-based multilingual pre-trained models (Devlin et al., 2019; Conneau et al., 2020) soon showed an impressive increase of performance also for under-resourced languages, as they considerably reduce the amount of training data needed for a particular task.

The question as to whether training language-specific models was worth the effort, given those impressive results, was more or less quickly resolved, for languages having enough monolingual data to train with (Martin et al., 2020; Virtanen et al., 2019). However, for most languages it is still a challenge to obtain such large amounts of data. Therefore, the question still stands for many of them. There is a huge variation in the potential access to language resources for any given language, going from high-resourced, medium, under or severely under-resourced.

In this paper, we focus on Catalan, a moderately under-resourced language. By comparison, the size of the corpus -purposefully collected and cleaned for this work- is almost half of the one in the Finnish FinBERT (Virtanen et al., 2019) (a comparably sized language), and almost 20 times smaller than the French CamemBERT. Another defining characteristic of Catalan is its affiliation

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4933–4946
August 1–6, 2021. ©2021 Association for Computational Linguistics

to the Romance family, which is abundantly represented in multilingual pre-trained models. Several big languages (French, Spanish, Italian, Portuguese) belong to this family and, thus, are typologically close to Catalan. Presumably, this fact could give a Romance-rich multilingual model an upper hand in its comparison with a Catalan-only model.

This exercise also gives us the opportunity to enrich the number and quality of open-source resources for Catalan. Our contributions can be summarized as follows:

- We compile a clean, high-quality textual Catalan corpus, the largest to date, released with an open license.
- We build a complete end-to-end cleaning pipeline, released as open-source.
- We train a Transformer-based language model for Catalan, also openly released.
- We create new annotated corpora for those tasks for which there was not any, such as Text Classification (TC), Question Answering (QA) and Semantic Textual Similarity (STS). We publicly release them as well. Together with existing Part-Of-Speech (POS) and Named Entity Recognition and Recognition (NERC) datasets, they are part of a new Natural Language Understanding (NLU) benchmark, the Catalan Language Understanding Benchmark (CLUB).

All the code, datasets and the final model are made available to the community in standard formats.[1]

2 Previous Work

While the original motivation for the Transformer was machine translation, it has been successfully applied to a wide range of tasks, excelling at representation learning via unsupervised pre-training. Both in decoder-based language models, as in GPT (Radford and Sutskever, 2018), and in encoder-based masked language models, as pioneered by BERT (Devlin et al., 2019), large Transformer models are pre-trained on big unlabelled corpora. The learned representations can then be applied as a feature extractor or by fine tuning to the downstream task of choice, typically resulting in state-of-the-art performance.

The original BERT also had a multilingual version, mBERT, leveraging monolingual text from the corresponding Wikipedia of different languages. In XLM (Conneau and Lample, 2019), authors introduced a *cross-lingual* language model, explicitly modeling cross-lingual representations (instead of just concatenating text from all languages). This model was scaled up producing XLM-RoBERTa (Conneau et al., 2020), based on RoBERTa (Liu et al., 2019), a variant of BERT with a simplified pre-training objective.

Especially in the case of BERT-like models, which are intended for NLU tasks (rather than generation), the literature has been considerably prolific in terms of language-specific models. While both mBERT and XLM-RoBERTa are considered the state-of-the-art in NLU for numerous languages, several works observed that language-specific models trained from scratch proved to obtain better performance, such as the French CamemBERT (Martin et al., 2020), the Dutch BERTje (de Vries et al., 2019), and the Finnish FinBERT (Virtanen et al., 2019). FinBERT authors made emphasis on text cleaning, claimed to be essential. The same authors proposed WikiBERT (Pyysalo et al., 2020), a set of language-specific baselines based on BERT for as many as 42 languages (including Catalan). Regarding low-resource languages, Basque-specific models have been shown to outperform mBERT (Agerri et al., 2020), although it is worth pointing out that Basque, being a linguistic isolate, is typologically far apart from the rest of languages in the pre-training corpus of mBERT.

The authors of these language-specific models hypothesized different causes behind the increase in performance with respect to the multilingual models:

1. Having a language-specific vocabulary, they avoid the split of words into too many subwords (which, linguistically, are less interpretable);
2. The amount of language-specific data; and
3. Training on more diverse data of the target language (e.g., web crawlings, instead of just Wikipedia)

. In Nozza et al. (2020), they compare the performance of mBERT with a number of language-specific models. They conclude that there is a huge

---

[1] `https://github.com/TeMU-BSC/berta`

variability in the models and that it is difficult to find the best model for a given task, language, and domain.

In this work, we further investigate the issue of whether building language-specific models from scratch is worth the effort, and if so under which circumstances. Unlike previous works, we focus on a moderately under-resourced language, Catalan. In addition to being low-resource, Catalan is close to other Romance languages largely present in the pre-training corpora of multilingual models, and knowledge from these other Romance languages transfers well to Catalan. These two facts call into question whether building language-specific models for these cases is still interesting. We show that a Catalan-specific model is indeed relevant, and we provide tools and recipes for other languages in a similar situation. Besides the model itself, we build the largest Catalan (clean) pre-training corpus to date as well as an extensive evaluation benchmark for NLP tasks in Catalan.

3 Pre-training Corpus

3.1 Data sources

Our new Catalan text corpus, CaText, includes both data from datasets already available in Catalan and data from three new crawlers we recently ran.

From the published datasets, we use (1) the Catalan part of the DOGC corpus, a set of documents from the Official Gazette of the Catalan Government; (2) the Catalan Open Subtitles, a collection of translated movie subtitles (Tiedemann, 2012); (3) the non-shuffled version of the Catalan part of the OSCAR corpus (Suárez et al., 2019), a collection of monolingual corpora, filtered from Common Crawl;[2] (4) the CaWac corpus, a web corpus of Catalan built from the `.cat` top-level-domain in late 2013 (Ljubešić and Toral, 2014), the non-deduplicated version, and (5) the Catalan Wikipedia articles downloaded on 18-08-2020.

Regarding the newly created datasets, we ran three new crawlings: (6) the Catalan General Crawling, obtained by crawling the 500 most popular `.cat` and `.ad` domains; (7) the Catalan Government Crawling, obtained by crawling the `gencat.cat` domain and subdomains, belonging to the Catalan Government; and (8) the ACN corpus with 220k news items from March 2015 until October 2020, crawled from the Catalan News Agency.[3]

3.2 Preprocessing

In order to be able to obtain a high-quality training corpus, we apply strict filters to the raw data, by means of a cleaning pipeline built for the purpose, CorpusCleaner.[4] This pipeline supports 100+ languages[5] and stands out for keeping document boundaries, instead of being sentence-based, which allows modeling long-range dependencies.

Transforms: CorpusCleaner is able to parse data in different formats (WARC files from crawlings, for instance), in a way that document boundaries and metadata are kept whenever possible. It includes the `ftfy` library (Speer, 2019) for fixing encoding errors and applies raw string transformations for normalizing spaces, removing HTML tags, and others.

Filters: The pipeline applies a *cascade of language identifiers* (similarly to Kosmajac and Keselj, 2018), using FastText's (Bojanowski et al., 2017) language identifier and LangId.[6] By cascade, we mean that we first apply the faster language identifiers to discard documents in which we are sure that the target language is not present. We then use the slower (but with better performance) language identifiers only with the remaining documents. After that, we make use of a fast and tokenization-agnostic sentence splitter.[7] In addition, CorpusCleaner includes numerous heuristics (e.g., standard deviation of sentence length in a given document for detecting badly split sentences coming from PDFs, or non-natural text) that apply reasonably well to the languages we have tested so far. Some of these rules have been inspired by Virtanen et al. (2019). Even in the case of document-level corpora, some rules are also applied at sentence-level, to improve document coherency (e.g., remove corrupted sentences in an otherwise high-quality document).

Deduplication: The last stage of the pipeline consists of document-level deduplication, based on n-gram repetitions with Onion (Pomikálek, 2011). In addition, we also deduplicate at the sentence-level with a threshold of occurrences, since most of

[7] `https://github.com/mediacloud/sentence-splitter`

Dataset	Original	Final
1 DOGC	126.65	126.65
2 Cat. Open Subtitles	3.52	3.52
3 Cat. OSCAR	1,355.53	695.37
4 CaWaC	1,535.10	650.98
5 Wikipedia	198.36	167.47
6 Cat. Gen. Crawling	1,092.98	434.82
7 Cat. Gov. Crawling	303.10	39.12
8 ACN	81.28	75.61
Total	4,696.52	2,193.54
Deduplicated (CaText)		1,770.32

Table 1: Number of tokens (in millions) in the different used corpora before and after the filtering process, just before deduplication. The difference between these two columns shows the scale of the clean-up performed by the filters in the pipeline, particularly in the crawled data: OSCAR, CaWaC, Catalan General Crawling and Catalan Government Crawling. The last row the number of tokens after a global document deduplication across all corpora.

the often repeated sentences are not natural linguistic occurrences, but placeholders commonly used by web developers (e.g. copyright notices).

Table 1 shows the composition of the CaText corpus.

Splits and release: We sample 2,000 documents for validation, in order to monitor the training, and 2,000 more for test, as a hold-out set for future analysis. We release the preprocessed corpus CaText[8] with an open license, but respecting the licenses of the original data sources.[9]

3.3 Vocabulary

To build the language model, we use Byte-Level BPE (Radford et al., 2019), as in the original RoBERTa, but learning the vocabulary from scratch using the training set of CaText. Following recent works, we keep casing, and use a vocabulary size of 52k tokens (Scheible et al., 2020).

As shown in Table 2, our tokenization, being language-specific (and having a bigger vocabulary than WikiBERT-ca), generates less subwords per word, which has been shown to be beneficial (Virtanen et al., 2019; Agerri et al., 2020).

Model	Subwords per sentence
BERTa	**33.94**
mBERT	41.14
WikiBERT-ca	38.38
XLM-RoBERTa	38.62

Table 2: Subwords per sentence in the test set of CaText.

We describe the models used in our comparative study in Section 5 and Section 6. Here, we provide some examples of the different tokenization results depending on the used tokenizer:

```
original: coronavirus
BERTa: coronavirus
mBERT: corona ##vir ##us
WikiBERT-ca: corona ##vir ##us
XLM-RoBERTa: ▁corona virus

original: lamentablement
BERTa: lamentablement
mBERT: la ##menta ##blement
WikiBERT-ca: la ##menta ##ble ##ment
XLM-RoBERTa: ▁lamentable ment
```

As the examples show, our Catalan-specific model (BERTa) is more likely to keep the full word, even in the presence of derivative morphemes, such as the adverb 'lamentablement' (*unfortunately*). The fact that it does not split the word 'coronavirus' either reveals that a large part of the training corpus is very recent and includes many references to the COVID-19 pandemic. In the Appendix A we provide more detailed information about vocabulary overlapping between models.

4 CLUB: The Catalan Language Understanding Benchmark

In order to evaluate our model on different downstream tasks, we generate a new benchmark for evaluating NLU capabilities for Catalan, the Catalan Language Understanding Benchmark (CLUB).[10] To build it, we bootstrap from existing resources (such as the Ancora corpus[11]) and create new high quality ones from scratch, adopting (and in some cases improving on) existing guidelines for well known benchmarks. These datasets are publicly available in the Zenodo platform,[12] under the Catalan AI language resources community, where

---

[8] http://doi.org/10.5281/zenodo.4636228

[9] Regarding the two crawlings run in-house, we have also opted to release them with a more open license so they can be used freely (see https://zenodo.org/record/4636228 and https://zenodo.org/record/4636899).

[10] See https://github.com/TeMU-BSC/berta.

[11] https://doi.org/10.5281/zenodo.4762030

[12] https://zenodo.org/

further details about the curation and annotation guidelines for each one are given. In general, we provide as much information as possible following Bender and Friedman (2018) guidelines when relevant. For example, gender and socioeconomic status are considered not as relevant for the kind of semantic annotations created. However, the fact that all commissioned annotators (1) were native speakers of Catalan, (2) were translators, editors, philologists or linguists, and (3) had previous experience in language-related tasks, *is* considered to be important. The curation rationale we follow wis to make these datasets both representative of contemporary Catalan language use, as well as directly comparable to similar reference datasets from the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2019).[13]

For **Part-of-Speech Tagging (POS)** and **Named Entity Recognition and Classification (NERC),** we use annotations from the Universal Dependencies treebank[14] of the well-known Ancora corpus, which uses UPOS tags. We extracted named entities from the original Ancora[15] version, filtering out some unconventional ones, like book titles, and transcribe them into a standard CONLL-IOB format.

For **Semantic Textual Similarity (STS)** (Agirre et al., 2012), we create a new dataset from scratch. We use different similarity measures (Jaccard, Doc2Vec (Le and Mikolov, 2014) and DistilBERT (Sanh et al., 2019) embedding cosine similarity) to pre-select potential sentence pairs from the aforementioned CaText corpus, as well as a final manual review to ensure that the selection represented superficial and deep similarities in subject matter and lexicon. This results in 3,073 pairs for manual annotation. Following the guidelines set in the series of landmark SemEval challenges,[16] we commission 4 native speaker annotators to assess the similarity of the sentence pairs on a scale between 0 (*completely dissimilar*) to 5 (*completely equivalent*), with other possible values, such as 3 (*roughly equivalent, but some important information differs*). Then, for each sentence pair, we compute the mean of the four annotations, and we discard single annotations that deviate by more than 1 from the mean. After this cleaning process, we use the mean of the remaining annotations as a final score. Finally, in order to assess the annotation quality of the dataset, we measure the correlation of each annotator with the average of the rest of the annotators, and average all the individual correlations, resulting in a Pearson correlation of 0.739.[17]

For **Text Classification (TC)**, we use 137k news pieces from the Catalan News Agency (ACN) corpus, mentioned in Section 3.1. As labels in our classification task, we used the article category provided by the metadata, keeping only those categories that had more than 2,000 articles. See the Appendix B for more details on the distribution by label. We call this benchmark TeCla (Text Classification Catalan dataset).[18]

Finally, for extractive **Question Answering (QA)**, we compile two datasets:

- The Catalan translation of XQuAD (Artetxe et al., 2020), a multilingual collection of manual translations of fragments from English Wikipedia articles used mainly for cross-lingual analyses. The Catalan dataset, XQUAD-ca,[19] as the rest of languages, includes a subset of 240 paragraphs and 1,190 question-answer pairs from the development set of SQuAD v1.1 (Rajpurkar et al., 2016), and has no adversarial or unanswerable questions.

- A new dataset, ViquiQuAD, an extractive QA dataset from Catalan Wikipedia)[20] consisting of more than 15,000 questions outsourced from Catalan Wikipedia. We randomly choose a set of 596 articles which were originally written in Catalan, i.e. not translated from other Wikipedias. From those, we randomly select 3,129 short paragraphs to use as contexts and ask annotators to create up to 5 questions that could be answered by quoting directly from the context provided. In the Appendix B, we provide some statistics on our QA datasets and list the types of questions, comparing ViquiQuAD and XQuAD-

ca with XQuAD-en and the French FQuAD (d'Hoffschmidt et al., 2020).

These benchmarks present a well-balanced set of challenges with which to test and compare our model with others. Apart from the diversity in the tasks themselves, for QA we provide an additional test from a different distribution (XQuAD-ca), and the data regime is heterogeneous across datasets (from more than 100k samples in TC to 3k in STS).

5 BERTa: A Model for Catalan

Following other language-specific models, we train a RoBERTa (Liu et al., 2019) base model (110M parameters), omitting the auxiliary Next Sentence Prediction task used in the original BERT, and just using the masked language modeling as the pre-training objective. The model is trained for 48 hours using 16 NVIDIA V100 GPUs of 16GB DDRAM, instead of 32 GB as in most works. For fitting an effective batch size of 2,048 sequences, we use gradient accumulation as implemented in Fairseq (Ott et al., 2019). Otherwise, we use the same hyperparameters as in the original RoBERTa, with a peak learning rate of 0.0005. We feed entire documents[21] instead of stand-alone sentences, fostering the modeling of long-range dependencies. We refer to the resulting model as BERTa.

6 Evaluation

We evaluate BERTa comparing the performances with two well-known multilingual baselines, mBERT and XLM-RoBERTa,[22] and another monolingual baseline, WikiBERT-ca (the Catalan WikiBERT by Pyysalo et al., 2020), on a variety of downstream tasks.

6.1 Fine-tuning

For evaluating our model against the existing baselines, we use common practices in the literature. For doing so, we leverage the Huggingface Transformers library (Wolf et al., 2019). For each task, we attach a linear layer to the models and fine tune with the training set of the specific dataset. For tasks involving tokens classification, we use the first token of the last output layer. Specifically, in the case of the BERT model, we use the `[CLS]` token while for the RoBERTa models we use the `<s>` token. We train each model under the same settings (see Table 3 for dataset splits) across tasks consisting of 10 training epochs, with an effective batch size of 32 instances, a max input length of 384 tokens and a learning rate of $5e^{-5}$. The rest of the hyperparameters are set to the default values in Huggingface Transformers.[23] We select the best checkpoint as per the task-specific metric in the corresponding validation set, and then evaluate it on the test set. We report the results and metrics used in Table 4.

6.2 Impact of fine-tuning data size

To show the impact of the fine-tuning data size on the tasks performances, we incrementally increase the fine-tuning data size and fine-tune on downstream tasks. We choose TC and QA because they have enough data to study the size effect across several magnitudes ranging from a minimum of 10^2 to a maximum of 10^4 examples. In the case of TC, we reduce the fine-tuning data by performing a stratified sampling that preserves the original distribution of examples per label, while for QA we just sample random examples corresponding to a given size. Figures 1, for QA, and 2, for TC, show the results of the studied models in the test set of the corresponding tasks, when progressively increasing the amount of instances in the train set.

6.3 Data contamination

As studied in Brown et al. (2020), data contamination refers to the inclusion of content from test or development sets into the training corpora used for language model pre-training. Consequently, the effect of contamination might have an impact on the downstream tasks performances, distorting them. In our case, we measure the effect of data

---

[21] We truncate those documents exceeding the maximum number of tokens.

[22] In this work, we always use a base model version with 12 layers, for a fair comparison.

[23] `https://github.com/huggingface/transformers/blob/master/src/transformers/training_args.py`

model	NERC	POS	STS	TC	QA (ViquiQuAD)	QA (XQuAD)
BERTa	88.13 (2)	**98.97** (10)	79.73 (5)	**74.16** (9)	**86.97/72.29** (9)	**68.89/48.87** (9)
+ decontaminate	**89.10** (6)	98.94 (6)	**81.13** (8)	73.84 (10)	86.50/70.82 (6)	68.61/47.26 (6)
mBERT	86.38 (9)	98.82 (9)	76.34 (9)	70.56 (10)	86.97/72.22 (8)	67.15/46.51 (8)

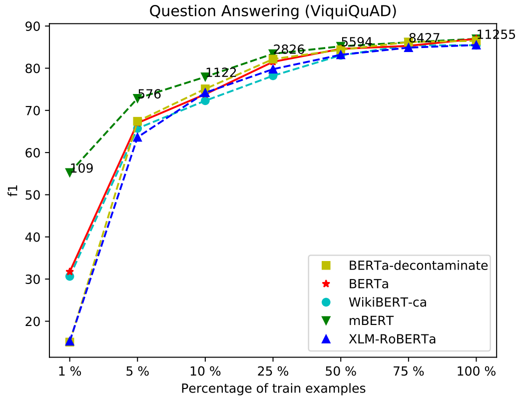
XLM-RoBERTa	87.66 (8)	98.89 (10)	75.40 (10)	71.68 (10)	85.50/70.47 (5)	67.10/46.42 (5)

Table 4: Results for the downstream tasks using different metrics. We use F1 for POS and NERC, accuracy for TC, an average of Pearson and Spearman coefficient for STS and F1/Exact Match for QA. We also report within round brackets the best epoch on the dev set.



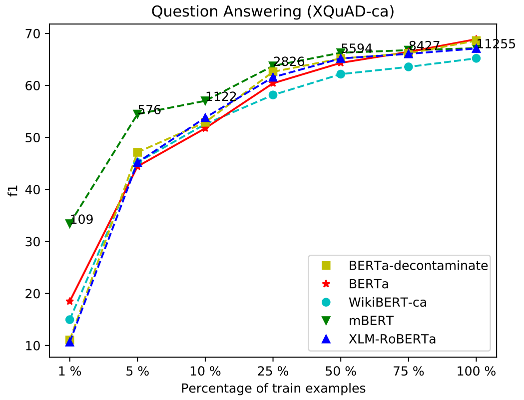


Figure 1: QA performance depending on the number of training examples.

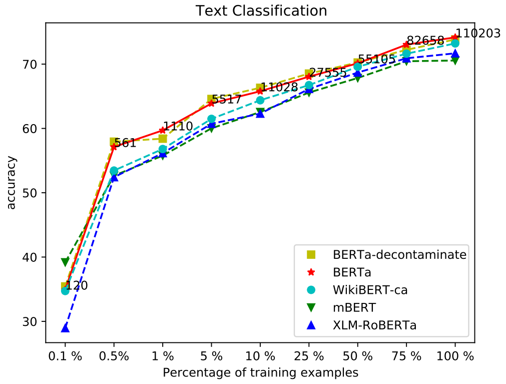

Figure 2: TC performance depending on the number of training examples.

contamination produced by those sentences used during language model training and, after being annotated, as part of our evaluation benchmark. Specifically, the STS, TC, and QA benchmarks (unlike the NERC and POS ones) are indeed contaminated since some examples are built from the Catalan Wikipedia and ACN sources. Actually, about the 0.078% of the training corpora (57,187 out of 73,172,152 sentences) are responsible for contamination. Therefore we train our BERTa model in two settings, one which includes these sentences and the other which does not include them. Note that all the compared models (mBERT, WikiBERT-ca, XLM-RoBERTa) have some degree of data contamination, since all of them include the Catalan Wikipedia as part of their training corpora. We show the results of BERTa along with BERTa-decontaminate in Table 4.

7 Discussion

Downstream tasks: Our model obtains better results in different benchmarking settings, ranging from simpler tasks with large training data sets (TC) to more advanced tasks with medium data (QA) and really complex tasks with small training data (STS).

In the case of NERC, BERTa clearly outperforms the existing baselines. In the case of POS, it also obtains better results, but only by a slight margin, being a considerably easy task, for which the existing models are already extremely competitive. For TC, BERTa also outperforms mBERT and XLM-RoBERTa models (by a larger margin when it has not been decontaminated). For QA, as measured in the ViquiQuAD dataset, only the version of BERTa that has not been decontaminated equals mBERT and is slightly better than XLM-RoBERTa. Note, however, that both mBERT and XLM-RoBERTa are equally *contaminated*, as pointed out in 6.3. When measured in the XQuAD-ca dataset, BERTa outperforms both models. Finally, for STS, BERTa outperforms mBERT and XLM-RoBERTa in 4.79 and 3.95 points respectively.

Interestingly, in the case of the XQuAD test, we are evaluating with a test set from a different distribution (i.e. it does not belong to our original split). Here, BERTa also outperforms all the baselines.

Error analysis and Question Answering: For the QA task, many of the errors detected are due to the inclusion or not of articles and punctuation in the answers. Based on this observation, we adopt the strategy introduced in Lewis et al. (2020) and we ignore initial articles when evaluating. The F1 results improve by at least one percentage point, while the exact match metric increases even more when measured using this MLQA[24] evaluation standard that discounts for initial articles.

Size matters, quality too: One of the goals of our work has been to estimate the effect of corpus size in the results. Although to the best of our knowledge, CaText is one of smallest datasets used to train monolingual language models, we note that this data is roughly 8 times the size of the Catalan Wikipedia, used to train WikiBERT-ca, as well as the Catalan portion of mBERT. Interestingly, XLM-RoBERTa, built on a filtered version of CommonCrawl, contains a portion of Catalan comparable in size to CaText.[25] In the line of FinBERT (Virtanen et al., 2019), we think that BERTa compensates for the relative scarcity of pre-training data with the quality of this data by using a rigorous filtering process. This is supported by the fact that XLM-RoBERTa, with a Catalan portion comparable in size to our corpus, has a consistently lower performance, not only with respect to our model, but also with respect to mBERT, which contains a smaller but cleaner portion of Catalan. While results for WikiBERT-ca seem to indicate that a Catalan model solely trained on the Wikipedia may not be enough in most cases, our results show that a model with sufficient diverse monolingual data that has been curated and cleaned, can outperform large multilingual models. Still, the question of how much data is enough remains unanswered.

Decontamination: We experimentally observe that our model generally benefits from data contamination in terms of performance, with a remarkable difference in the exact match metrics for QA, as shown in Table 4.

A more intricate error analysis on the predictions for QA of both our BERTa models (with and without contamination) sheds light on the issue of decontamination. While the sole difference between these two is the inclusion of these sentences, we observe an improvement in exact match correct answers for the model that has not been decontaminated, and suspect this might be due to the fact that the model has indeed memorized the questions; nonetheless, more investigation is needed in this regard.

This posits the question of whether the metrics obtained in these kinds of benchmarks are only indicative of the actual performance in the tasks with sentences different from those in the pre-training corpus, or otherwise reflect a certain memorization of the evaluation sentences. Still, the decontaminated BERTa outperforms the baselines in all test sets (including the explicitly decontaminated ones) except for ViquiQuAD (in which mBERT is superior to the decontaminated BERTa), hinting that BERTa is better than the other models regardless of the possible effects of their contamination.

Note also that for the TC setting, the monolingual WikiBERT-ca model also beats multilingual models. In this scenario, neither WikiBERT-ca nor the multilingual models have unlabeled data from the training set in their pre-training datasets. It is, therefore, an uncontaminated scenario where a small monolingual model clearly beats the multilingual ones.

Varying fine-tuning data size in downstream tasks: We experiment with different data sizes for the train sets of the QA and TC tasks, as shown in Figure 1.[26] Surprisingly, mBERT starts from a relatively high score, especially for QA, showing remarkably transfer capabilities when only a few examples are available. We point out that in the case of TC, as shown in Figure 2, starting from about 500 examples, BERTa models always remain above the baselines. Overall, all the curves show a constant progression up to 75% of training data and then seems to exhibit a slightly decreasing tendency in the case of multilingual models indicating they are approaching a plateau. Instead, monolingual ones still displays signs of improvement. For TC, Catalan-specific models, especially BERTa, show

[26] This figure shows F1 score. In the Appendix C, we provide the results for the exact match evaluation as well.

a better performance. Having a language-specific vocabulary may be helpful to further exploit increasing fine-tuning data.

8 Conclusions

We have demonstrated that it is worth to build a monolingual model for a moderately under-resourced language, even if it belongs to an over-represented linguistic family in multilingual models, such as the Romance language family. Our model outperforms the multilingual SOTA scores in all downstream tasks, as well as the monolingual scores from WikiBERT-ca, trained on a smaller and less varied corpus. Furthermore, by developing this model, we have contributed to the creation of open-source resources for Catalan, both for training and evaluation, that will encourage the development of technology in this language. We believe our methods can serve both as a recipe and a motivation for other languages in similar situations. In addition, we also release the cleaning pipeline used to build CaText, supporting 100+ languages.

As future work, we suggest further investigating the effect of contamination by explicitly studying the relation between memorization and performance in the exact match evaluation in QA. In addition, we propose conducting experiments for quantifying the effect of the data size, data cleaning, and data diversity (e.g., just Wikipedia vs. crawlings).

Broader impacts

Regarding possible environmental concerns, training new language-specific models is costly[29] and one could argue that it could be avoided if a multilingual baseline performs well enough. However, we observe improvements that justify training from scratch another model. In addition, language-specific models are potentially more efficient, including inference, since their tokenizers generate less tokens.

As far as the model itself is concerned, we hypothesize that the pre-training corpus will have different biases and the model might reproduce them, so users must be aware of this issue. Nevertheless, with this work we contribute to an under-resourced language and open the door to follow similar approaches to other languages in similar situations, which can encourage a less English-centric view in the field of NLP.

How transfer learning impacts linguistic knowledge in deep NLP models?

Abstract

Transfer learning from pre-trained neural language models towards downstream tasks has been a predominant theme in NLP recently. Several researchers have shown that deep NLP models learn non-trivial amount of linguistic knowledge, captured at different layers of the model. We investigate how fine-tuning towards downstream NLP tasks impacts the learned linguistic knowledge. We carry out a study across popular pre-trained models BERT, RoBERTa and XLNet using layer and neuron-level diagnostic classifiers. We found that for some GLUE tasks, the network relies on the core linguistic information and preserve it deeper in the network, while for others it forgets. Linguistic information is distributed in the pre-trained language models but becomes localized to the lower layers post-fine-tuning, reserving higher layers for the task specific knowledge. The pattern varies across architectures, with BERT retaining linguistic information relatively deeper in the network compared to RoBERTa and XLNet, where it is predominantly delegated to the lower layers.

1 Introduction

Contextualized word representations learned in transformer-based language models capture rich linguistic knowledge, making them ubiquitous for transfer learning towards downstream NLP problems such as Natural Language Understanding tasks e.g. GLUE (Wang et al., 2018). The general idea is to pretrain representations on large scale unlabeled data and adapt these towards a downstream task using supervision.

Descriptive methods in neural interpretability investigate what knowledge is learned within the representations through relevant extrinsic phenomenon varying from word morphology (Vylomova et al., 2016; Belinkov et al., 2017a; Dalvi et al., 2017) to high level concepts such as structure (Shi et al., 2016; Linzen et al., 2016) and semantics (Qian et al., 2016; Belinkov et al., 2017b) or more generic properties such as sentence length (Adi et al., 2016; Bau et al., 2019). These studies are carried towards analyzing representations from pre-trained models. However, it is important to investigate how this learned knowledge evolves as the models are adapted towards a specific task from the more generic task of language modeling (Peters et al., 2018) that they are primarily trained on.

In this work, we analyze representations of 3 popular pre-trained models (BERT, RoBERTa and XLnet) with respect to morpho-syntactic and semantic knowledge, as they are fine-tuned towards GLUE tasks. More specifically we investigate i) if the fine-tuned models retain the same amount of linguistic information, ii) how this information is redistributed across different layers and individual neurons. To this end, we use *Diagnostic Classifiers* (Hupkes et al., 2018; Conneau et al., 2018), a popular framework for probing knowledge in neural models. The central idea is to extract feature representations from the network and train an auxiliary classifier to predict the property of interest. The quality of the trained classifier on the given task serves as a proxy to the quality of the extracted representations w.r.t to the understudied property (Belinkov et al., 2020).

We carry layer-wise (Liu et al., 2019a) and neuron-level probing analyses (Dalvi et al., 2019a) to study the fine-tuned representations. The former probes representations from individual layers w.r.t a linguistic property and the latter finds salient neurons in the network that capture the property. Fine-tuning involves adjusting feature weights, therefore it is important to look at the individual neurons to uncover important details, in addition to a more holistic layer-wise view.

Our layer-wise analysis shows: i) that some GLUE tasks rely on core linguistic knowledge and

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4947–4957
August 1–6, 2021.

the model preserves the information deeper in the network, while for others it is retained only in the lower layers ii) interesting cross-architectural differences with knowledge regressed to lower layers in RoBERTa and XLNet as opposed to BERT where it is still retained at the higher layers. Our neuron-wise analysis shows: i) salient linguistic neurons are relocated from the higher to lower layers, reinforcing our layer-wise results, ii) that linguistic information becomes less distributed and less redundant in the network post fine-tuning.

Finally, we show how our analysis entails findings in layer pruning. Dropping higher layers of the models maintains comparable performance to fine-tuning the full network, with linguistic information regressed to the lower layers. Conversely, pruning the lower layers (which hold the core linguistic information) leads to substantial degradation in performance.

In comparison to the related work done in this direction, our findings resonate with Merchant et al. (2020) who found that fine-tuning primarily affects top layers and does not lead to "catastrophic forgetting of linguistic phenomena" in BERT. However, we found that other models like RoBERTa and XLNet, which they did not study, see a substantial drop in accuracy even at the lower layers and start forgetting linguistic knowledge much earlier in the network. In contrast to Mosbach et al. (2020), we study core-linguistic phenomena whereas their study is based on sentence level probing tasks. Differently from both, we carry out a fine-grained neuron analysis which sheds light on how neurons are distributed and relocated post fine-tuning. Our work complements their findings while extending the layer-wise analysis to core-linguistic tasks and additionally looking at the distribution and relocation of neurons after fine-tuning.

2 Methodology

Our methodology is based on the probing framework called as *Diagnostic Classifiers*. We train a classifier using the activations generated from the trained neural network as static features, towards the task of predicting a certain linguistic property. The underlying assumption is that if the classifier can predict the property, the representations implicitly encode this information. We train layer- and neuron-wise probes using logistic-regression classifiers. Formally, consider a pre-trained neural language model $\mathbf{M}$ with L layers: $\{l_1, l_2, \ldots, l_L\}$. Given a dataset $\mathbb{D} = \{w_1, w_2, ..., w_N\}$ with a corresponding set of linguistic annotations $\mathbb{T} = \{t_{w_1}, t_{w_2}, ..., t_{w_N}\}$, we map each word w_i in the data $\mathbb{D}$ to a sequence of latent representations: $\mathbb{D} \overset{\mathbb{M}}{\longmapsto} \mathbf{z} = \{\mathbf{z}_1, \ldots, \mathbf{z}_n\}$. The model is trained by minimizing the following loss function:

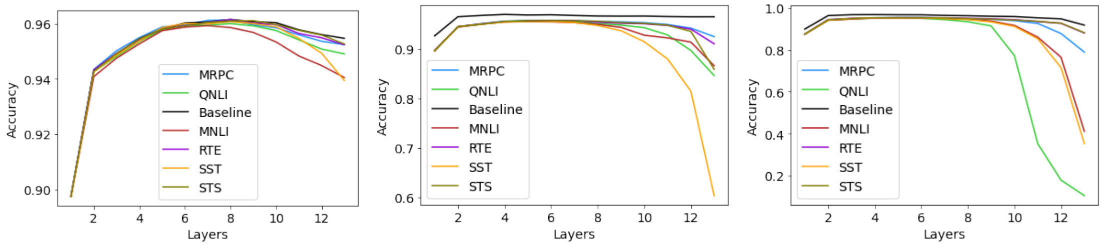
$$\mathcal{L}(\theta) = -\sum_i \log P_\theta(t_{w_i}|w_i) + \lambda_1\|\theta\|_1 + \lambda_2\|\theta\|_2^2$$

where $P_\theta(t_{w_i}|w_i) = \frac{\exp(\theta_l \cdot \mathbf{z}_i)}{\sum_{l'} \exp(\theta_{l'} \cdot \mathbf{z}_i)}$ is the probability that word i is assigned property t_{w_i}. We extract representations from the individual layers for our layer-wise analysis and the entire network for the neuron-analysis. We use the *Linguistic Correlation Analysis* as described in Dalvi et al. (2019a), to generate a neuron ranking with respect to the understudied linguistic property: Given the trained classifier $\theta \in \mathbb{R}^{D \times T}$, the algorithm extracts a ranking of the D neurons in the model $\mathbb{M}$ based on weight distribution. The elastic-net regularization (Zou and Hastie, 2005) – a combination of $\lambda_1\|\theta\|_1$ and $\lambda_2\|\theta\|_2^2$ is used to strike a balance between identifying focused ($L1$) versus distributed ($L2$) neurons. The weights for the regularization terms are tuned using a grid-search algorithm.

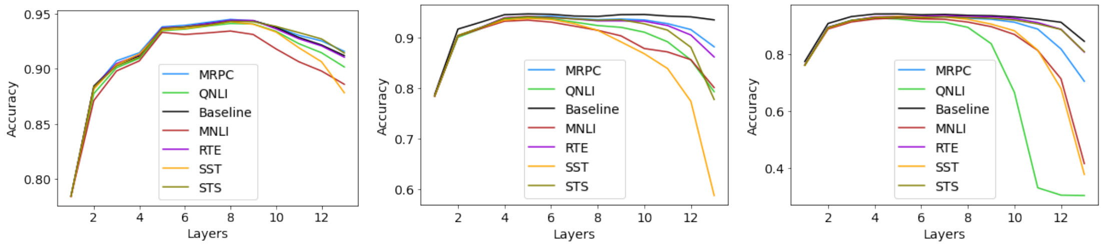
Following Durrani et al. (2020), we extract salient neurons for a linguistic property by iteratively choosing the top N neurons from the ranked list and retrain the classifier using these neurons, until the classifier obtains an accuracy close (within a specified threshold δ) to the *Oracle* – accuracy of the classifier trained using all the features in the network.

3 Experimental Setup

Pre-trained Neural Language Models: We experimented with 3 transformer models: BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b) and XLNet (Yang et al., 2019) using the base versions (13 layers and 768 dimensions). This choice of architectures leads to an interesting comparison between auto-encoder versus auto-regressive models. The models were then fine-tuned towards GLUE tasks of which we experimented with SST-2 for sentiment analysis with the Stanford sentiment treebank (Socher et al., 2013), MNLI for natural language inference (Williams et al., 2018), QNLI for Question NLI (Rajpurkar et al., 2016), RTE for recognizing textual entailment (Bentivogli et al., 2009), MRPC for Microsoft Research paraphrase corpus (Dolan and Brockett, 2005), and STS-B



(a) BERT – POS (b) RoBERTa – POS (c) XLNet – POS



(d) BERT – Chunking (e) RoBERTa – Chunking (f) XLNet – Chunking

Figure 1: Layer-wise Probing Performance. Baseline refers to the performance of the pre-trained models without any finetuning.

for the semantic textual similarity benchmark (Cer et al., 2017). All the models were fine-tuned with the identical settings and we did 3 independent runs.

Linguistic Properties: We evaluated our method on 3 linguistic tasks: POS tagging using the Penn TreeBank (Marcus et al., 1993), syntactic chunking using CoNLL 2000 shared task dataset (Tjong Kim Sang and Buchholz, 2000), and semantic tagging using the Parallel Meaning Bank data (Abzianidze et al., 2017). We used standard splits for training, development and test data.

Classifier Settings: We used a linear probing classifier with elastic-net regularization, using a categorical cross-entropy loss, optimized by Adam (Kingma and Ba, 2014). Training is run with shuffled mini-batches of size 512 and stopped after 10 epochs. The regularization weights are trained using grid-search. For sub-word based models, we use the last activation value to be the representative of the word following Durrani et al. (2019). We computed *selectivity* (Hewitt and Liang, 2019) to ensure that our results reflect the property of representations and not the probe's capacity to memorize. Please see Appendix for details.

4 Analysis

4.1 Layer-wise Probing

First we train layer-wise probes to show how linguistic knowledge is redistributed across the network as we fine-tune it towards downstream tasks. Figure 1 shows results for POS and Chunking tasks.[1] We found varying observations across different GLUE tasks.

Comparing GLUE tasks: We found that linguistic phenomena are more important for certain downstream tasks, for example STS, RTE and MRPC where they are preserved in the higher layers post fine-tuning, as opposed to others, for example SST, QNLI and MNLI where they are forgotten in the higher layers. It would be interesting to study this further by connecting linguistic probes with any causation analysis on these tasks. Such an analysis would shed light on what concepts are used by the network while making predictions and why such information is forgotten for certain tasks. We leave this exploration for future.

Comparing Architectures: We found that pre-trained models behave differently in preserving information post fine-tuning. In the case of BERT, linguistic knowledge is fully preserved until layer 9, after which different task-specific models drop to varying degree, with SST and QNLI showing significant drop compared to others. An exception to this overall trend is MNLI where we start seeing a decline in performance earlier (between layers $5-7$). Contrastingly RoBERTa and XLNet show a depreciation in linguistic knowledge as early as layer 5. Also the drop is much more

---

[1] The observations are consistent for semantic tagging. Please see Appendix for results.

catastrophic in these two models with accuracy dropping by more than 35% in RoBERTa and 70% in XLNet. These results indicate that BERT retains its primarily learned linguistic knowledge and uses only a few of the final layers for fine-tuning, as opposed to XLNet and RoBERTa, where linguistic knowledge is retained only in the lower half of the network. Another cross-architectural observation that we made was that in RoBERTa and XLNet, the fine-tuned models do not ever reach the baseline performance (i.e. accuracy before fine-tuning – See Figure 1) at any layer, although the loss is $< 2\%$. We conjecture this discrepancy is due to the fact that the knowledge is more redundant and polysemous in the case of BERT, compared to XLNet, where it is more localized (also observed in Durrani et al. (2020)). Consequently, during fine-tuning XLNet and RoBERTa are more likely to lose linguistic information that is unimportant to the downstream task. We discuss this further in our neuron-analysis section.

4.2 Neuron-wise Probing

In our second set of experiments, we conducted analysis at a more fine-grained neuron level using *Linguistic Correlation Method* (Dalvi et al., 2019a). We extract the most salient neurons w.r.t a linguistic property (e.g. POS) and compare how the distribution of such neurons changes across the network as it is fine-tuned towards a downstream GLUE task. We use the weights of the trained classifier to rank neurons and select minimal set of salient neurons that give the same classifier accuracy as using the entire network in the baseline model. We found 5% neurons for POS and SEM tagging tasks and 10% for the Chunking tagging were sufficient to achieve the baseline performance.

Information becomes less distributed in the fine-tuned XLNet and RoBERTa models post fine-tuning: Table 1 shows accuracy of the classifier selecting the most (top) and least (bottom) 5% salient neurons on the task of POS tagging.[2] We observed that the bottom neurons in the fine-tuned models show a significant drop in performance, compared to the baseline model in the case of RoBERTa and XLNet. These results show that the information is more redundant in the baseline models as bottom neurons also preserved linguistic knowledge. On the contrary the information becomes more localized and less distributed in the fine-tuned models. The bottom neurons in the fine-tuned BERT changed the least, showing that linguistic information is still redundant and distributed in BERT.

Tasks	BERT		RoBERTa		XLNet

Table 1: POS accuracy – Top vs. Bottom neurons

How do salient neurons spread across the network layers? Previously we investigated how representations in each layer change w.r.t linguistic task. Now we study how the spread of the most salient neurons changes across the fine-tuned models. Figure 2 shows results for the selected GLUE tasks.[3] Notice how the most salient linguistic neurons shift from the higher layers towards the lower layers in RoBERTa and XLNet. This is especially pronounced in the case of *Roberta-SST* and *XLNet-QNLI* (See Figures 1e and 1f), where the number of salient chunking neurons significantly increased in the lower layers and droped in the higher layers, compared to the baseline. These findings reinforces our layer-wise results and additionally show how more responsibility is delegated to the neurons in the lower layers. Contrastingly, BERT did not exhibit this behavior. These results are inline with Durrani et al. (2020), who also found linguistic properties in XLNet to be localized to the lower layers[4] and fewer neurons and mutually exclusive as compared to BERT where neurons are highly polysemous[5] and therefore more redundant. Their finding helps us explain why XLNet forgets linguistic information that is unimportant to the downstream task more catastrophically.

5 Network Pruning

Our layer and neuron-wise analyses showed that core linguistic knowledge is redundant and distributed in the large pre-trained models. But as they are fine-tuned towards a down-stream task,

---

[2] See Appendix for SEM and Chunking tagging.

[3] See Appendix for all tasks and linguistic properties.

[4] Similarly (Wu et al., 2020) reported lower and middle layers of XLNet to have the most salient features.

[5] attend to multiple linguistic phenomenon

(d) BERT – Chunking (e) RoBERTa – Chunking (f) XLNet – Chunking

Figure 2: Distribution of top neurons across layers

it is relocated and localized to lower layers, with higher layers focusing on the task-specific information. In this section, we show that our findings explain patterns in layer pruning. We question **How important is the linguistic knowledge for these downstream NLP tasks?** Following Sajjad et al. (2020) we prune top and bottom (excluding the embedding layer) 6 layers of the network in two separate experiments and compare architectures. Table 2 shows that removing bottom layers of the network in RoBERTa and XLNet leads to more damage compared to BERT. **How do these findings resonate with our analysis?** We showed that BERT retains linguistic information even at the higher layers of the model as opposed to RoBERTa where it is preserved predominantly at the lower layers. Removing the bottom 6 layers in RoBERTa leads to a bigger drop because the network is completely deprived of the linguistic knowledge. Linguistic knowledge is more distributed in BERT and preserved at the higher layers also which leads to a smaller drop as it can still access this information. We leave a detailed exploration on this for future.

Tasks	**SST**	**MNLI**	**QNLI**
		BERT

Table 2: Pruning Layers in the Models

6 Conclusion

We studied how linguistic knowledge evolves as the pre-trained language models are adapted towards downstream NLP tasks. We fine-tuned three popular models (BERT, RoBERTa and XLNet) towards GLUE benchmark and analyzed representations against core morpho-syntactic knowledge. We used probing classifiers to carry out layer and neuron-wise analyses. Our results showed that morpho-syntactic knowledge is preserved at the higher layers in some GLUE tasks (e.g. STS, MRPC and RTE), while forgotten and only retained at the lower layers in others (MNLI, QNLI and SST). Comparing architectures, we found that BERT retains linguistic knowledge deeper in the network. In the case of RoBERTa and XLNet, the information is only preserved in the middle layers. This discrepancy is due to the fact that neurons in BERT are more polysemous and distributed as opposed to XLNet and RoBERTa where they are more localized (towards lower layers) and mutually exclusive. We showed that this difference in architectures, entails different patterns as we prune top or bottom layers in the network. Our code is publicly as part of the NeuroX toolkit (Dalvi et al., 2019b).

Ethics and Broader Impact

For this study, we used existing publicly available data sets while following their terms in the licenses. We do not see any harm or ethical issues resulting from our study and findings. Our study has implications towards the work on interpreting and analyzing deep models.

A Appendices

A.1 Data and Representations

We used standard splits for training, development and test data for the 4 linguistic tasks (POS, SEM, Chunking) that we used to carry out our analysis on. The splits to preprocess the data are available through git repository[6] released with Liu et al. (2019a). See Table 3 for statistics. We obtained the understudied pre-trained models from the authors of the paper, through personal communication.

Task	Train	Dev	Test	Tags
POS	36557	1802	1963	44
SEM	36928	5301	10600	73
Chunking	8881	1843	2011	22

Table 3: Data statistics (number of sentences) on training, development and test sets using in the experiments and the number of tags to be predicted

A.2 Layer-wise Probing

Section 4.1 presented layer-wise probing results for POS and Chunking tagging. Figure 4 show results on Semantic tagging. We see a similar pattern across architectures as in Figure 1.

A.3 Neuron-wise Probing

Section 4.2 presented neuron-wise probing results for for Chunking tagging. Figure 2 show results on POS and SEM tagging. We see a similar pattern across architectures as in Figure 3. As the model is fine-tuned towards downstream, number of salient neurons towards a linguistic property, in the lower layers increase.

A.4 Top versus Bottom Neurons

In Section 4.2 we presented spread how information is more distributed and redundant in in the network as bottom neurons also preserved linguistic knowledge. On the contrary the linguistic information becomes more localized and less distributed post fine-tuning using accuracy of the bottom neurons. Tables 4 and 5 demonstrate the same pattern with respect to Chunking and Semantic tagging tasks, selecting 10% and 5% neurons respectively.

SST	92.1	90.5	91.5	60.7	91.3	34.8
STS	92.1	90.4	91.5	79.5	91.6	83.7

Table 5: SEM accuracy – Top vs. Bottom neurons

A.5 Pruning Layers

In Section 5 we showed how pruning bottom layers in RoBERTa was more harmful in comparison to BERT. We conjectured that this pattern entails from our analysis that in RoBERTa linguistic information is preserved in the initial middle layers as opposed to BERT where linguistic knowledge is distributed deeper in the network. We show that XLNet exhibit similar pattern to RoBERTa in Table 6.

A.6 Control Tasks

While there is a plethora of work demonstrating that contextualized representations encode a continuous analogue of discrete linguistic information, a question has also been raised recently if the representations actually encode linguistic structure or whether the probe memorizes the understudied task. We use *Selectivity* as a criterion to put a "linguistic task's accuracy in context with the probe's capacity to memorize from word types" (Hewitt and Liang,

Tasks	**SST-2**	**MNLI**	**QNLI**

2019). It is defined as the difference between linguistic task accuracy and control task accuracy. An effective probe is recommended to achieve high linguistic task accuracy and low control task accuracy.

A.7 Infrastructure and Run Time

Our experiments were run on NVidia GeForce GTX TITAN X GPU card. Grid search for finding optimal lambdas is expensive when optimal number of neurons for the task are unknown. Running grid search would take $\mathcal{O}(MN^2)$ where $M = 100$ (if we try increasing number of neurons in each step by 1%) and $N = 0, 0.1, \ldots 1e^{-7}$. We fix the $M = 20\%$ to find the best regularization parameters first reducing the grid search time to $\mathcal{O}(N^2)$ and find the optimal number of neurons in a subsequent step with $\mathcal{O}(M)$. The overall running time of our algorithm therefore is $\mathcal{O}(M + N^2)$. This varies a lot in terms of wall-clock computation, based on number of examples in the training data, number of tags to be predicted in the downstream task. Including a full forward pass over the pre-trained model to extract the contextualized vector, and running the grid search algorithm to find the best hyperparameters and minimal set of neurons took on average 8 hours ranging from 3 hours for the Chunking experiment to 12 hours for POS and SEM due to large training data.

A.8 Hyperparameters

We use elastic-net based regularization to control the trade-off between selecting focused individual neurons versus group of neurons while maintaining the original accuracy of the classifier without any regularization. We do a grid search on L_1 and L_2 ranging from values $0 \ldots 1e^{-7}$. See Table 8 for the optimal values for each task across different architectures.

Abstract

We investigate the semantic knowledge of language models (LMs), focusing on (1) whether these LMs create categories of linguistic environments based on their semantic *monotonicity* properties, and (2) whether these categories play a similar role in LMs as in human language understanding, using negative polarity item licensing as a case study. We introduce a series of experiments consisting of probing with diagnostic classifiers (DCs), linguistic acceptability tasks, as well as a novel *DC ranking* method that tightly connects the probing results to the inner workings of the LM. By applying our experimental pipeline to LMs trained on various filtered corpora, we are able to gain stronger insights into the semantic generalizations that are acquired by these models.[1]

1 Introduction

Neural language models (LMs) have become powerful approximators of human language, making it increasingly important to understand the features and mechanisms underlying their behavior (Linzen et al., 2018, 2019). In the past few years, a substantial number of studies have investigated the linguistic capabilities of LMs (Gulordava et al., 2018; Giulianelli et al., 2018; Lakretz et al., 2019; Wu et al., 2020; Ettinger, 2020, i.a.). Such work has focused primarily on *syntactic* properties, while fewer studies have been done on what kind of *formal semantic* features are encoded by language models. In this paper, we focus explicitly on what LMs learn about a semantic property of sentences, and in what ways their knowledge reflects well-known features of human language processing.

As the topic of our studies, we consider **monotonicity**, a semantic property of linguistic environments that plays an important role in human language understanding and inference (Hoeksema, 1986; Valencia, 1991; Van Benthem, 1995; Icard III and Moss, 2014): the monotonicity of a linguistic environment determines whether inferences from a general to a particular term or vice versa are valid in that environment. For example, the fact that the inference from "*Mary didn't write a paper*" to "*Mary didn't write a linguistics paper*" is valid shows us that the position where "*a paper*" occurs is *downward monotone*: the inference is valid when a more general term ("*a paper*") is replaced with a more specific one ("*a linguistics paper*").

To investigate monotonicity we focus on **negative polarity items** (NPIs): a class of expressions such as *any* or *ever* that are solely acceptable in downward monotone environments (Fauconnier, 1975; Ladusaw, 1979). Psycholinguistic research has confirmed this connection between NPIs and monotonicity: humans judge NPIs acceptable in a linguistic environment if they consider that environment to be downward monotone (Chemla et al., 2011). Previous research has established that LMs are relatively successful in processing NPIs (Warstadt et al., 2019), but without investigating *how* they came to these successes.

We raise the following research questions:

RQ1 Do language models encode the monotonicity properties of linguistic environments?

RQ2 To what extent do they employ this information when processing negative polarity items?

We developed a series of experiments, in which we first evaluate the general capacities of LMs in handling monotonicity and NPIs and then investigate the generalization heuristics of the LM by doing experiments with modified training corpora. First, we establish that LMs are able to encode a notion of monotonicity by probing them with diagnostic classifiers (DCs, Hupkes et al., 2018) (§5.1).

---

[1] All code and data can be found at `https://github.com/jumelet/monotonicity-npi-lm`

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4958–4969
August 1–6, 2021.

In our second experiment we demonstrate that our LMs are reasonably successful with NPI licensing using an NPI acceptability task (§5.2). Next, we introduce a novel *DC ranking* method to investigate the overlap between the information that the model uses to make judgments about NPIs and the information that the DCs use to predict monotonicity information, finding that there is a significant overlap (§5.3).

We then investigate two potential confounds that may obfuscate our results. First, we consider whether the signal that is picked up by the monotonicity DC is not simply a proxy that tells the model that an NPI may occur at that position (§5.4). To assess this, we train new LMs on a corpus from which all sentences with NPIs have been removed, re-run the montonicity probing task, and find that even in the absence of NPI information, LMs are still able to encode a notion of monotonicity.

Next, we consider whether an LM bases its NPI predictions on simple co-occurrence heuristics, or if it can extrapolate from a general notion of monotonicity to cases of NPIs in environments in which they have never been encountered during training (§5.5). We again train new LMs on modified corpora, this time removing NPIs only in one specific environment, and repeat the NPI acceptability and DC ranking experiments. The results of this setup demonstrate that LMs indeed use a general notion of monotonicity to predict NPI licensing.

Contributions With this work, we contribute to the ongoing study of the linguistic abilities of language models in several ways:

- With a series of experiments we demonstrate that LMs are able to acquire a general notion of monotonicity that is employed for NPI licensing.
- We present two novel experimental setups: *filtered corpus training* and *DC ranking*, that can be used to assess the impact of specific information during training and compare the information used by DCs with the information used with the model, respectively.
- By using experimental results from psychosemantics to motivate hypotheses for LM behavior, we find that our models reflect behavior similar to human language processing.

In the remainder of this paper, we will first provide some linguistic background that helps to situate and motivate our experiments and results (§2). We then discuss related work on NPI processing in LMs in §3. In §4, we discuss our methods and experimental setup. §5.1 through §5.5 explain and present the results. We conclude in §6 with a general discussion and pointers to future work.

2 Linguistic Background

Monotonicity Monotonicity is a property of a linguistic environment which determines what kind of inferences relating general and particular terms are valid in that environment. If inferences from a general to a particular term are valid, the linguistic environment is said to be *downward monotone* (DM). If inferences are valid the other way around, from a particular to a general term, the linguistic environment is said to be *upward monotone* (UM).

Examples of expressions inducing DM environments are negation and quantifiers like *nobody, no NP*, but also specific types of adverbs and the antecedents of conditional sentences. For instance, (1) below exemplifies that in these environments the inference from a sentence with a general term (*cookies*) to that sentence with a more particular term (*chocolate cookies*) is valid, but not vice versa.

(1) a. Mary did**n't** eat cookies. ⇒
Mary didn't eat *chocolate* cookies.
b. **Nobody** ate cookies. ⇒
Nobody ate *chocolate* cookies.
c. Mary **rarely** ate cookies. ⇒
Mary rarely ate *chocolate* cookies.

Common examples of UM environments are (non-quantified) positive sentences, quantifiers such as *somebody, many NP*, and other kind of adverbs. (2) exemplifies that in these environments the inference from a sentence with a more particular term (*chocolate cookies*) to the same sentence with a general term (*cookies*) is valid, but not vice versa.

(2) a. Mary ate *chocolate* cookies. ⇒
Mary ate cookies.
b. **Everyone** ate *chocolate* cookies. ⇒ Everyone ate cookies.
c. Mary **often** ate *chocolate* cookies. ⇒
Mary often ate cookies.

NPIs NPIs are expressions such as the English words *any, anyone, ever*, whose acceptability depends on whether its linguistic environment is downward monotone (Fauconnier, 1975; Ladusaw, 1979; Dowty, 1994; Kadmon and Landman, 1993; Krifka, 1995; Lahiri, 1998; Chierchia, 2006, 2013).[2] While the conditions for NPI acceptability are complex, a good approximation is that NPIs are acceptable (or *licensed*) in the syntactic scope of *NPI licensors* that induce a DM environment.[3] If we again consider the DM environment of (1-a) and the UM environment of (2-a), it can be seen that English *any* is an NPI, as it is acceptable when inside the syntactic scope of negation (a DM expression) as in (3-a), and not acceptable when they are in an UM environment as in (3-b).

(3) a. Mary didn't eat (any) cookies.
 b. Mary ate (*any) cookies.

Importantly, monotonicity plays a role at the psychological level: human judgments about the monotonicity of a linguistic environment predict their judgments of NPI acceptability in that environment (Chemla et al., 2011; Denić et al., 2021). For example, how plausible someone finds the inference (1-a) predicts how acceptable they find the sentence (3-a). Summing up, NPI licensing has a syntactic component (NPIs must reside in syntactic scope of a licensor) and a semantic component (NPI licensors are DM expressions), that are connected on a psychological level (monotonicity judgments predict NPI acceptability). Our research aims to uncover whether this connection is exhibited by LMs as well.

3 Related work

The literature on interpreting LMs has grown substantially in the last few years (see, e.g. Belinkov and Glass, 2019; Alishahi et al., 2019; Rogers et al., 2021, for survey papers). Several studies investigate how they process NPIs, focused mainly on the *syntactic* aspect of NPI licensing.

Jumelet and Hupkes (2018) conclude that LSTM language models encode information about the dependency between the NPI and the NPI licensor, although this effect diminishes as the distance between the NPI and its licensor grows. Marvin and Linzen (2018) study NPI judgments of LMs on minimally different sentence pairs (with the NPI licensor either in an appropriate syntactic configuration or not) and find that their models are unable to reliably assign higher probability to sentences in which NPIs are correctly licensed. The syntactic aspect of NPI licensing is also examined by Futrell et al. (2019), who demonstrate that LSTM LMs are susceptible to learning spurious licensing relationships, a finding that Warstadt and Bowman (2020) demonstrate to also hold for BERT (Devlin et al., 2019). Wilcox et al. (2019) investigate how explicit syntactic supervision of LMs affects their success with syntactic aspects of NPI licensing. The broad linguistic suites of Warstadt et al. (2020) and Hu et al. (2020) also contain a set of tasks related to NPI licensing, demonstrating that it is one of the most challenging tasks for LMs to handle. Weber et al. (2021) investigated the dynamics of NPI learning during training, and connected this to a multi-task learning paradigm, demonstrating that LMs are able to efficiently leverage information from related licensing environments.

Lastly, Warstadt et al. (2019) examine BERT's ability in determining NPI acceptability. They demonstrate that BERT has significant knowledge of the dependency between NPIs and their licensors, but that this success varies widely across different experimental methods. Our study builds on that of Warstadt et al. (2019). Although they demonstrate that BERT is generally successful with NPI licensing, their results do not reveal whether BERT has constructed a more general category of DM expressions that is independent of collocational cues, nor whether it has understood that this category matters for NPI licensing.

4 Methods

Before getting to the main experimental part of our work, we briefly discuss the training corpus, model architecture and evaluation corpus we consider.

Training Corpus The base training corpus we consider in our experiments is the corpus used by Gulordava et al. (2018). This corpus is a collection of sentences from Good and Featured English Wikipedia articles and consists of over 90M tokens. The vocabulary of the corpus consists of the 50.000 most frequent tokens in this corpus; less frequent tokens are mapped to a special `<unk>` token. We refer to the full training corpus type with the name Full, and to the LMs trained on this corpus as Full LMs. In addition to Full, we use multiple other corpora which are derived from Full by means of filtering. This will allow us to draw conclusions about specific generalization abilities and reliance on collocational cues of LMs; filtered corpora will

---

[2] See however Zwarts, 1995; Giannakidou, 1998; Barker, 2018 for different takes on NPI acceptability generalizations.

[3] An NPI occurs in the syntactic scope of a licensor if the licensor *c-commands* the NPI. An NPI licensor c-commands an NPI if the NPI is the licensor's sister node or one of its sister's descendants in a constituent tree (Reinhart, 1976).

Environment Class	Abbrev.	DM example	UM example
Adverbs	ADV	A lady **rarely** *ever* ...	*A lady sometimes *ever*...
Conditionals	COND	**If** the dancers see *any* ...	*While the dancers see *any*...
Determiner Negation	D-NEG	**No** teacher says that the students had practiced *at all*.	*Some teacher says that the students had practiced *at all*.
Sentential Negation	S-NEG	The dancer was **not** saying that the guy had profited *yet*.	*The dancer was really saying that the guy had profited *yet*.
Only	ONLY	**Only** the boys had *ever* ...	*Even the boys had *ever* ...
Quantifiers	QNT	**Every** senator who had *ever* ...	*Some senator who had *ever* ...
Embedded Questions	QUES	The patients wonder **whether** the lady admires *any* ...	*The patients say that the lady admires *any*...
Simple Questions	SMP-Q	Did the boy *ever* listen**?**	*The boy did ever listen.
Superlatives	SUP	A lady buys the **oldest** dish that the adult had *ever* ...	*A lady buys the old dish that the adult had *ever* ...

Table 1: The nine environment classes of Warstadt et al. (2019), with an example of a minimal DM/UM pair for each class taken from the corpus.

be introduced in the relevant sections.

Model Architecture In our studies, we focus on recurrent language models. More specifically, following Gulordava et al. (2018), we consider two-layer LSTM language models, with an embedding and hidden size of 650. All training runs across our experiments follow the same regime, identical to the regime described by Gulordava et al. (2018): 40 epochs of training with SGD, with a plateau scheduler and an initial learning rate of 20, a batch size of 64, BPTT length of 35, and dropout of 0.1.[4]

Evaluation Corpus To assess monotonicity and NPI licensing knowledge of LMs in our experiments, we leverage the NPI corpus of Warstadt et al. (2019), which consists of a large amount of grammatical and ungrammatical sentences with NPIs. This corpus is divided into 9 distinct **environment classes**, allowing for fine-grained analysis of NPI licensing. Importantly, these nine environment classes come in two versions: a DM version—in which NPIs are grammatically acceptable, and a minimally different UM version—in which they are not. We provide an overview with examples of DM and UM versions of all environment classes in Table 1. The full size of the corpus is 106.000 distinct DM sentences, and the division of environment classes is split roughly uniformly.

5 Experiments and Results

In this section we describe the experimental pipeline in more detail. A graphical overview of our experiments is depicted in Figures 1 and 4. Each experiment description is directly followed by an analysis of its results.

5.1 Experiment 1: Do LMs represent monotonicity information?

In our first experiment, we test whether LMs trained on our Full corpus possess a notion of monotonicity. We train five different LMs and test how well they represent monotonicity properties of different environments by training linear **diagnostic classifiers** (DCs, Hupkes et al., 2018) on top of the hidden states of the LM. To create a corpus of monotonicity sentences for training and testing the DCs, we leverage the corpus of Warstadt et al. (2019), now selecting all DM and UM sentences to build up a balanced corpus of these categories. The nine environment classes in that corpus hence provide a broad spectrum of DM environments and their minimally different UM counterparts.

For training and testing the DCs, we consider the hidden states at the position directly before an NPI occurs (see Figure 1). The reason we train the DCs at this position is because only at this point we are sure that the monotonicity information should surface and be encoded *linearly*. This is due to the fact that the decoder of the LM that transforms a hidden state into a probability distribution is linear as well: if the probability of some token depends on a linguistic feature, this feature must hence be encoded linearly. The DCs are implemented using the `diagNNose` library of Jumelet (2020), and trained using 10-fold cross-validation, Adam optimization (Kingma and Ba, 2015), a learning rate of 10^{-2} and L1 regularization with $\lambda = 0.005$.

We train our monotonicity DCs in two separate ways. First, we divide the entire monotonicity corpus into a 90/10 train/test split, sampled *uniformly* across the different environment classes. This allows us to examine whether DM and UM environments are linearly separable in a way that is applicable to all environment classes. We refer to this classifier as the All-ENV DC.

Second, we move to a more fine-grained type

---

[4] Models are trained on a *GeForce 1080 Ti* GPU, take around 40 hours to train, and consist of 71M parameters.

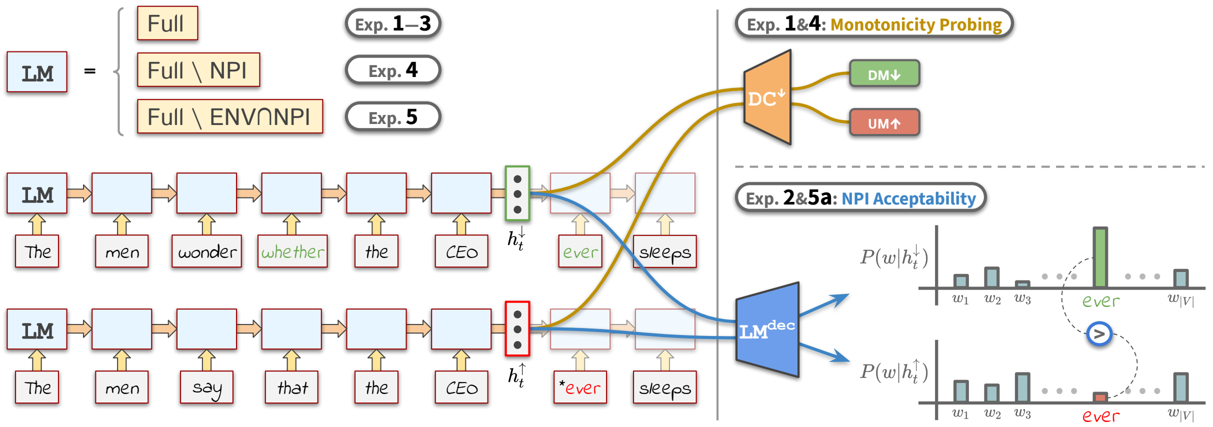

Figure 1: The pipeline of our experimental setup. We start by computing the hidden states $h_t^\downarrow$ (within a DM environment ahead of the NPI) and $h_t^\uparrow$ (within a UM environment). These hidden states are then used for training the monotonicity DC (Exp. 1 & 4), and to compare $P_{\text{LM}}(\text{NPI}|h_t^\downarrow) > P_{\text{LM}}(\text{NPI}|h_t^\uparrow)$ (Exp. 2 & 5a). The task of Experiments 3 and 5a can be found in Figure 4. Experiments 4 and 5 consist of the same tasks as the first three experiments, but differ in the language model that is used.

of analysis. High performance of the All-ENV DC namely does not provide evidence that monotonicity is encoded the same way for each environment: the set of salient hidden units used by the All-ENV DC for classifying monotonicity within the *Adverbs* environment, for example, could be disjoint from the set of units used for the *Only* environment. To investigate this, we train a DC on the hidden states of all-but-one environment class, and test its performance on the excluded class. This provides a measure to what extent the monotonicity representation of DM and UM environments derived from all other environment classes *generalizes* to the held-out class, demonstrating stronger evidence that the model represent monotonicity in the same way across different environments.

Results The results of our first experiment are shown in the top row of Figure 2. The first column contains the average accuracy for the All-ENV DC, and it can be seen that the diagnostic classifier succeeds in this task with high accuracy (97%). This indicates that the uniform split over all environment classes is linearly separable.

Next, we consider the held-out evaluation procedure for each of the nine environment classes. It can be seen that the monotonicity signal generalizes well to five classes (*adverbs, determiner negation, only, sentential negation, and embedded questions*), all with an accuracy above 90%. The other four classes yield a higher standard deviation, indicating that these classes are encoded less consistently across initialization seeds. The accuracy for all held-out DCs is lower compared to the All-ENV DC results, indicating that the All-ENV DC relied partly on information unrelated to a shared notion of monotonicity. The fact that the accuracy of these DCs is still so high, however, indicates that there is a substantial overlap between the way that monotonicity is encoded within the different environments.

5.2 Experiment 2: Do LMs predict the licensing conditions of NPIs?

In the next experiment we investigate the NPI acceptability judgments of the Full LMs on the corpus of Warstadt et al. (2019). This is done by comparing the probability of an NPI conditioned on the model's representation of a DM environment ($h_t^\downarrow$) and a UM environment ($h_t^\uparrow$), where success is defined as follows:

$$P_{\text{LM}}(\text{NPI}|h_t^\downarrow) > P_{\text{LM}}(\text{NPI}|h_t^\uparrow)$$

This is a common evaluation procedure in the interpretability literature (Linzen et al., 2016), and has earlier been applied in the domain of NPI licensing by Jumelet and Hupkes (2018) and Warstadt et al. (2020). Our approach is similar to the Cloze Test of Warstadt et al. (2019), but their setup used (bi-directional) masked LMs, making it possible to directly compare the probabilities of the NPI licensor, instead of comparing the NPI probabilities. Note that we purposefully do not base NPI acceptability on comparing full sentence probabilities: in our view this type of comparison can be distracted by token probabilities not related to the NPI itself.

Environment class

Figure 3: Accuracy on the NPI acceptability task—based on whether the NPI was assigned a higher probability in the DM environment than in its UM counterpart.

We split this procedure out for each of the nine environment classes. The example sentence of the Simple Questions environment in Table 1, for example, is evaluated as follows:

$$P_{\text{LM}}(ever|Did\ the\ boy) > P_{\text{LM}}(ever|The\ boy\ did)$$

Using the full sentence probabilities for this comparison would require taking probabilities into account such as $P_{\text{LM}}(the|Did)$ and $P_{\text{LM}}(boy|The)$, that have no relation to NPI licensing at all.

Results We present the results for this experiment in the top row of Figure 3. The Full models demonstrate a considerable ability at predicting NPI acceptability, with the least performing class (SMP-Q, *Simple Questions*) yielding an accuracy that is still well above chance (0.72). Compared to earlier investigations on the ability of LSTM LMs in NPI licensing, our results indicate that these models are able to obtain a more sophisticated understanding of NPIs than previously thought: both Marvin and Linzen (2018) and Hu et al. (2020) report LSTM performance below chance on NPI acceptability tasks. This might in part be due to the different evaluation procedure we used (conditional vs. full-sentence probability comparison).

5.3 Experiment 3: Is the LM's knowledge of DM environments and of NPI licensing related?

We have now established that our models encode a signal related to monotonicity, and are successful at predicting NPI acceptability. In our third experiment, we assess to what extent the parameters used by the LM to predict NPIs (i.e. the LM's decoder embeddings for NPIs) *overlap* with the information the DCs use to predict the monotonicity properties of a particular environment class. For this we have devised a novel **DC ranking** method, that ranks the LM's decoder weights for all tokens based on their similarity with the DC weights.

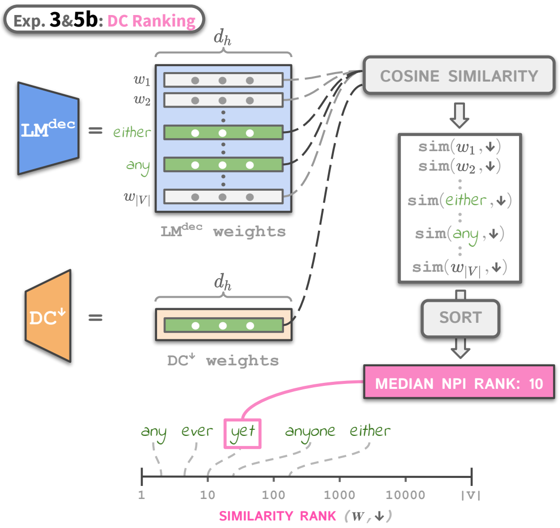

Figure 4: The *DC Ranking* experiment, in which we investigate whether the monotonicity DC and the LM decoder base their predictions on similar cues, by computing and ranking the cosine similarities between the DC weights and the decoder weights of each token.

We present a schematic overview of the method

	All-ENV	ADV	COND	D-NEG	S-NEG	ONLY	QNT	QUES	SMP-Q	SUP
Full (exp. 3)	9	14	1121	16	28	449	206	82	14124	1248
Full \ ENV∩NPI (exp. 5b)	10	35	6634	622	1152	1418	1509	297	28670	3288

Figure 5: Results on the median NPI rank task. A low median rank indicates that the monotonicity DC uses the same representational information as the NPI decoder.

in Figure 4. The LM's decoder weight matrix can be interpreted as a collection of vectors corresponding to each token in the model's vocabulary. The monotonicity DC is a binary classifier, so its weights are represented by a single vector. The LM's decoder vectors are of the same dimensionality as the weight vector of the monotonicity DC, which allows us to compute the similarity between each decoder vector and the monotonicity DC. For each of the 50.000 tokens in the LM's vocabulary, we calculate the cosine similarity between the decoder weights corresponding to that token and the DC's weights. We then sort these similarity scores, which results in a ranking of tokens that are most similar to the DC.

As we are interested in finding the connection of the monotonicity DC and the LM's NPI processing in general, we compute the **median rank** over a set of 11 NPIs.[5] A low median NPI rank indicates that the LM uses the same cues for NPI prediction as the monotonicity DC, demonstrating a clear connection between NPI licensing and monotonicity.

Contrary to Experiment 1, we no longer make use of the hold-one-out training procedure, that gave insights to what extent a general monotonicity signal generalizes to a held-out environment class. Instead, we train a separate diagnostic classifier for each environment class using a train/test split made up of DM and UM environments within that class. This results in a classifier that represents the class-specific decision boundary between minimal pairs of DM and UM items and allows us to investigate to what extent these decision boundaries align with the weights of the LM decoder. Next to the environment-specific DCs we also report the DC ranking outcome for the All-ENV DC that has been trained on all environments.

Results The results of this experiment are presented in the top row of Figure 5. The first column (All-ENV) contains the result for the DC trained on all environment classes, and the median NPI rank of 9 demonstrates that the monotonicity DC aligns very closely with the NPI decoder weights of the LMs. This median rank should be interpreted within the context of the model vocabulary size: it can range upwards to 50.000, so a rank that is close to 0 signifies a tight connection between the probing task and the tokens of interest.

Moving on to the environment-specific results, it can be seen that the results vary considerably between the environment classes. The worst scoring class is again that of Simple Questions. This makes sense, as the licensing conditions for question constructions do not depend on the presence of a specific licensing token such as *not*, but on the overall structure of the whole sentence. The other environment classes lead to scores far closer to 0, indicating that for these classes monotonicity classification is closely aligned to NPI processing.

Interestingly, the median rank of the All-ENV DC is lower than the ranks of all other DCs. This shows that the model has aligned its representation of NPIs to an aggregate of the monotonicity representations in the different environment classes. This allows the model to flexibly deal with NPIs in a wide range of licensing environments.

5.4 Experiment 4: Are NPIs important for learning monotonicity information?

With Experiment 3 we established that NPI processing and monotonicity are related in our LMs. Now, we investigate to what extent their representations are entangled during training. More specifically, we investigate if the signal from the presence of NPIs is indispensable for the LM to develop a notion of monotonicity, or if instead the success in categorizing monotonicity environments can be learned independently of NPIs.

We address this question by testing whether LMs

---

[5] We consider the following 11 single-token NPI expressions: *dared, any, anybody, anymore, anyone, anything, anywhere, ever, nor, whatsoever,* and *yet*. These are all the single-token NPIs taken from a list of NPIs that is described in §5.4.

can still classify the monotonicity properties of environments when they are completely deprived of NPIs during training. To do so, we train new language models on a modified corpus that does not contain any NPIs at all. To arrive at this corpus, we remove all sentences that contain at least one NPI expression from the Full corpus. We identify these expressions based on a comprehensive list of NPI expressions in English collected by Hoeksema (2012) and the list of NPIs in English compiled by Israel (2011). From this list, we manually removed expressions that have both NPI and non-NPI uses (e.g. *a thing, a bit*). The 40 NPI expressions that resulted from this procedure can be found in Appendix A. We train 5 models on this corpus and refer to them by the name Full\NPI.

In this experiment, we run the monotonicity probing procedure of Experiment 1 on the Full\NPI models. We posit that if the notion of monotonicity can be learned independently of NPIs, there should be no significant drop in performance compared to the results of the Full LMs.

Results We report the results of this experiment in the bottom row of Figure 2. Again it can be noted that the All-ENV DC, trained and tested uniformly over all environment classes, obtains a high accuracy on the task (0.95). Furthermore, none of the held-out environment DCs lead to significant drops in performance compared to the Full LMs. Based on this we conclude that even in the absence of NPI cues, LMs are still able to build up a shared robust notion of monotonicity.

5.5 Experiment 5: How robust is the connection between monotonicity and NPI processing?

This research aims to uncover whether LMs possess a robust connection between monotonicity and NPI licensing. Our findings indicate that this connection is present in our models. A major confound that has not yet been addressed, however, is the extent to which our models rely on collocational cues when judging the acceptability of an NPI. To test this, we examine whether an LM's connection between NPIs and monotonicity *generalizes* to novel environment classes in which NPIs have never been encountered during the training phase of the LM.

We have created nine modified corpora in which sentences with NPIs within a specific environment have been removed. For these different corpora, we again consider the nine NPI-licensing environments of Warstadt et al. (2019). For each environment class we create a new corpus by removing all sentences from the Full corpus in which an NPI expression from Appendix A is preceded by an expression belonging to that class, somewhere earlier in the sentence.[6] Note that we only remove the sentences in which the environment actually licenses an NPI; sentences in which the environment occurs without an NPI are retained. So for the *adverbs* environment, for example, we remove sentences like "*Mary rarely ate any cookies*" but not "*Mary rarely ate cookies*". For each of these nine corpora we train 3 new LMs. Models trained on these corpora are referred to by the name Full\ENV∩NPI.

We run the NPI acceptability task of Experiment 2 and the DC ranking method of Experiment 3 on the nine types of Full\ENV∩NPI models. A model with a robust connection between monotonicity and NPI processing should be able to learn for NPIs in the held-out environment that (i) the environment belongs to the class of environments in which NPIs are licensed, and that (ii) determining NPI acceptance should be done based on representational cues that are similar for monotonicity prediction.

Results We report the results of this experiment next to the previous results of the Full model. First, we consider the NPI acceptability task, which is reported in the bottom row of Figure 3. Note that each cell in this row now corresponds to a specific model type: the ADV result, for instance, corresponds to the accuracy of the Full\ENV∩NPI models in which sentences with NPIs within adverbial environments have been removed. Our results show that the performance drops slightly for all environment classes, which can be attributed to a model's dependence on collocational cues. However, the models are still able to adequately generalize from the other environments, in which NPIs still are encountered, to the held-out environment. This demonstrates the semantic generalization capacities of the LM: it infers that the held-out environment in which NPIs have never been encountered shares some relevant properties with the other eight environment classes in which NPIs still occur.

The results for the DC ranking experiment are shown in the bottom row of Figure 5. Similar to the NPI acceptability results, the performance of the Full\ENV∩NPI models has dropped slightly compared to the Full models. However, if the models

---

[6] For Simple Questions we remove a sentence if an NPI occurs in a sentence that ends with a question mark.

would no longer pick up on the connection between monotonicity in the held-out environment and NPI licensing at all, these median ranks should drop to chance, i.e. around the halfway mark of the vocabulary size (25.000). It can be seen that this is only the case for the Simple Questions environment, that was already performing poorly for the Full models. Based on this we conclude that although models depend partly on collocational cues for their connection between monotonicity and NPIs, they are still able to encode a robust connection that generalizes to novel DM environments.

6 Conclusion

Based on a series of experiments, we have established the following: (1) LMs categorize environments into DM and UM; (2) LMs are overall successful with NPI licensing; (3) LMs employ similar representational cues when processing NPIs and predicting monotonicity; (4) their categories of DM and UM environments can be learned independently of NPI occurrence; and (5) their connection between monotonicity and NPI processing is robust and not solely dependent on co-occurrence heuristics. This demonstrates that LMs have quite sophisticated knowledge of NPI licensing, which may be similar to that of humans and constitutes a vital step towards better understanding the linguistic generalization capacities of LMs.

These results raise the question: what do LMs learn about the DM and UM environments which they succeed in finding? Do they actually learn the inferential properties of those environments, or do they rely on some other property that DM environments have in common to categorize them as such? A direction for future work would be to develop methods to probe the inferential capacities of LMs and explore how they align with the DM and UM categories they construct.

Another direction for future work would be to incorporate the recent advancements on probing-based interpretability methods in our experimental pipeline (Hewitt and Liang, 2019; Voita and Titov, 2020). Our DC Ranking method aligns the performance of a probe with that of the language model itself, which is related to the approaches of Saphra and Lopez (2019), Elazar et al. (2021), and Lovering et al. (2021). Placing our methodology more firmly in this body of work will allow for stronger conclusions to be drawn regarding the semantic knowledge of current language models.

Acknowledgments

We thank Oskar van der Wal and Lucas Weber for their valuable feedback. We thank Jack Hoeksema for providing us with the list of NPIs. MD and JS were funded by the European Research Council under the European Unions Seventh Framework Programme (FP/20072013)/ERC Grant Agreement n. STG 716230 CoSaQ.

A Filtered NPIs

We here present the full list of NPIs that were used for filtering sentences from the Full corpus, resulting in the Full\NPI corpus. The method for selecting these expressions is described in Section 5.4.

A damn, any, any longer, any old, anybody, anymore, anyone, anything, anything like, anytime soon, anywhere, anywhere near, as yet, at all, avail, by much, can possibly, could possibly, ever, in any, in days, in decades, in minutes, in years, just any, just yet, let alone, much help, nor, or anything, set foot, squat, such thing, that many, that much, that often, the slightest, whatever, whatsoever, yet.

This resulted in a reduction of 75.062 sentences out of the 3.052.726 sentences in the original Full corpus (2.46%).

Slot Transferability for Cross-domain Slot Filling

Abstract

Cross-domain slot filling focuses on using labeled data from source domains to train a slot filling model for target domains. It is of great significance for transferring a dialogue system into new domains. Most of the existing work focused on building a cross-domain transfer model. From the perspective of slots themselves, this paper proposes a model-agnostic Slot Transferability Measure (STM) for evaluating the transferability from a source slot to a target slot, specifically, the degree that labeled data of the source slot is helpful to train the slot filling model for the target slot. We also give a STM-based method for a model to select helpful source slots and their labeled data for a given target slot. Experimental results on multiple existing models and datasets show that our method significantly outperforms state-of-the-art baselines in cross-domain slot filling. The code is available at `https://github.com/luhengtong/STM-for-cdsf.git`.

1 Introduction

As an important task in task-oriented dialog systems, slot filling aims to identify task-related slot information in user utterances. When a task (or domain) has a large amount of labeled data, most existing slot filling models can achieve desired performance. However, there is usually little or even no labeled data for a new task. How to train the slot filling model in the new task (target task) with the labeled data of one or more existing tasks (source tasks) is of great significance for the rapid expansion of the application of task-oriented dialog systems.

Existing work can be mainly classified into two categories. The first is to establish implicit semantic alignment between slot representations of the source task and the target task, the model trained with the source task data is directly used for the target task (Bapna et al., 2017; Lee and Jha, 2019; Shah et al., 2019). The second is to use a two-stage strategy (Liu et al., 2020), which treats all slot values as entities. First, it trains a generic entity recognition model using source task labeled data to identify all candidate slot values in the target task. Then, the candidate slot value is classified into the target task slot by comparing the similarity between its representation and the target task slot information.

Most of the existing work has focused on building cross-task transferable models that leverage the association information between source tasks and target tasks, and the model is always trained using the labeled data of all the source tasks without distinction. However, not all the source task data will have transferable value to the target task, and the value of different source tasks data to a particular target task may be different. For example, flight-ticket-reservation task and train-ticket-reservation task have high similarity so that the labeled data of the former will be helpful to the latter. While the flight-ticket-reservation task and the weather-inquiry task have great difference so that the labeled data of the former has no or only little value to the latter, and even has a negative effect on the target model. Furthermore, even though the source task is similar to the target task, not every source slot will be useful for all the slots of the target task. For example, the labeled data for leaving-time slot in flight-ticket-reservation task may be helpful for the slot filling of leaving-time in train-ticket-reservation task, but not useful for the train-type slot. Therefore, finding valuable source slots that can provide transferable information for slot filling in target slot and then training a model based on the labeled data of these slots can make better use of the data in source tasks. This is the starting point of this paper which is different from the existing work.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 4970–4979
August 1–6, 2021.

In achieving this goal, we firstly propose slot transferability measure (STM) and give a method to calculate the STM. By comparing the STM between the target slot and each source slot, we can select different set of source slots for different target slot. Only the labeled data of these source slots are used to train the slot filling model for the target slot. To be more specific, we fuses distribution similarity of the slot value representations and of the slot value context representations between target slot and source slot as STM between two slots. All source slots are sorted according to their STMs with the target slot. Labeled data of the source slot with the highest STM are used to train the model, and then the labeled data of the source slot with the second highest STM is added to train the model. The process continues until the model gains no improvement on validation set of target slots. Those source slots and their labeled data are used to build the final slot filling model for the target slots.

Our main contributions are three-fold as follows.

1. We propose a metric called STM to measure the transferability between two slots. To our best knowledge, it is the first study on the transferability between two slots. The STM is model-agnostic.

2. We also propose a STM-based method to select source slots and their labeled data for training slot filling model for target slots.

3. Experimental results on several existing models and datasets show that this method brings consistent performance improvement for cross-domain slot filling.

2 Related work

As a key component of dialog system, the slot filling task has been studied extensively. Traditional supervised learning methods have made great achievements with a large amount of labeled data (Liu and Lane; Mesnil et al., 2015; Hakkani-Tür et al., 2016; Kurata et al., 2016; Liu and Lane, 2016; Goo et al., 2018; E et al., 2019). However, there is little or even no labeled data for a new task, the cross-domain slot filling task which uses labeled data in source tasks to training model for target task is gaining increasing attention (Yazdani and Henderson, 2015; Bapna et al., 2017; Zhu and Yu, 2018; Lee and Jha, 2019; Shah et al., 2019; Liu et al., 2020; Zhu et al., 2020). There are mainly two streams of methods in previous work.

The first is to establish implicit semantic alignment of the slot representations between the source task and the target task (Bapna et al., 2017; Lee and Jha, 2019; Shah et al., 2019; Liu et al., 2020). Bapna et al. (2017) proposed the Concept Tagging model (CT), which unified the slot filling model on the source tasks and the target task by combining the slot representations modeled by slot description information, and then conducting BIO 3-way classification. Based on CT, Lee and Jha (2019) proposed the Zero-Shot Adaptive Transfer model (ZAT), which introduced an attention layer in building representations of slot description; Meanwhile, Shah et al. (2019) proposed the Robust Zero-shot Tagger (RZT) model, which used a small number of sample slot values of the target slot to constrain the slot filler to avoid the negative transfer caused by the misalignment of slot names.

The second is a coarse-to-fine approach, which first identifies all candidates of slots and then classifies them into corresponding slots. Liu et al. (2020) proposed a Coarse-to-fine approach (Coach). They first predicted whether the tokens are slot value candidates, and then identified their specific slot types based on the similarity between the tokens and the representation of each slot description. In addition, Coach utilized a template regularization method which clusters the representations of semantically similar utterance into a similar vector space. It greatly improves the robustness of the model.

Most of these efforts focus on building a cross-task transferable model by exploiting the correlation information between source and target tasks. All source data is used to train the transfer model no matter if the data is helpful for target slot filling. On the contrast, this paper proposes a new method to select parts of source slots and their labeled data for model training.

3 Methodology

This section describes the cross-domain slot filling method proposed in this paper. First, we propose the concept of slot transferability and its measurement STM in Section 3.1. Then we describe the method of finding source slots for target slot based on the STM in Section 3.2. Finally, we introduce how this method can be deployed and implemented on existing models in Section 3.3. The STM is model-agnostic and will be validated on multiple existing models.

3.1 Slot Transferability Measure

Given slots s_a and s_b, the transferability from s_a to s_b refers to the degree of that the slot filling information of s_a can be used for slot filling of s_b, denoted as $\mathrm{STM}(s_a, s_b)$.

Let $p_v(s_i)$ be the distribution of slot value representation of slot $s_i(i = \{a, b\})$, $p_c(s_i)$ be the distribution of slot value context representation of slot $s_i(i = \{a, b\})$. We define the transferability from slot s_a to slot s_b as Equation (1):

$$\mathrm{STM}_\beta(s_a, s_b) = 1 - \tanh\left(\frac{(1+\beta^2)sim(p_v(s_a), p_v(s_b))sim(p_c(s_a), p_c(s_b))}{\beta^2 sim(p_v(s_a), p_v(s_b)) + sim(p_c(s_a), p_c(s_b))}\right) \tag{1}$$

where $sim(p, q)$ denotes the similarity between distribution p and q. The β parameter determines the weight of similarity between distributions of slot value context representations. $\beta > 1$ favors similarity between distributions of slot value context representations, $\beta < 1$ lends more weight to similarity between distributions of slot value representations. The larger the $\mathrm{STM}_\beta(s_a, s_b)$, the higher the transferability from slot s_a to slot s_b.

Maximum Mean Discrepancy (MMD) is employed to calculate $sim(p, q)$. MMD is usually used as a loss function in transfer learning (Tzeng et al., 2014; Zhang et al., 2015; Long et al., 2015, 2016, 2017; Yan et al., 2017). It minimizes the difference between different domains to obtain the domain-invariant features. It serves as test statistics to determine if two distributions are the same, as well as measure the similarity between two distributions. The smaller the MMD is, the higher the similarity between distributions is. Let $\mathcal{F}$ be a class of functions $\mathcal{F} : X \to R$. Let $X = \{x_1, ..., x_m\}$ and $Y = \{y_1, ..., y_n\}$ be samples composed of independent and identically distributed observations drawn from distribution p and q, respectively. MMD is defined as Equation (2), and the square of the MMD can be empirically estimated by Equation (3) (Borgwardt et al., 2006):

$$\mathrm{MMD}^2[\mathcal{F}, p, q] = \sup_{f \in \mathcal{F}}(E_p[f(x)] - E_p[f(y)]) \tag{2}$$

$$\mathrm{MMD}^2[\mathcal{F}, X, Y] = \frac{1}{m(m-1)}\sum_{i \neq j}^{m} k(x_i, x_j) + \frac{1}{n(n-1)}\sum_{i \neq j}^{n} k(y_i, y_j) - \frac{2}{mn}\sum_{i,j=1}^{m,n} k(x_i, y_j) \tag{3}$$

where k is the kernel function. Gaussian kernel functions are usually used as. Therefore, the similarity between the distributions of slot value representations of slots s_a and s_b, and the similarity between distributions of slot value context representation of slots s_a and s_b are Equations (4) and (5) respectively:

$$sim(p_v(s_a), p_v(s_b)) = \mathrm{MMD}^2[\mathcal{F}, \Omega_{va}, \Omega_{vb}] \tag{4}$$

$$sim(p_c(s_a), p_c(s_b)) = \mathrm{MMD}^2[\mathcal{F}, \Omega_{ca}, \Omega_{cb}] \tag{5}$$

where Ω_{vi} and Ω_{ci} is the sample set of the slot values representation distribution and the sample set of the slot value context representation distribution corresponding to slots $s_i(i = \{a, b\})$.

Given labeled data $D_{sa} = \{(x^{(i)}, y^{(i)})\}_{i=1}^{N_a}$ for slot s_a , where $x^{(i)} = (x_1^{(i)}, x_2^{(i)}, \cdots, x_l^{(i)})$ is a sequence of words, $y^{(i)} = (y_1^{(i)}, y_2^{(i)}, \cdots, y_l^{(i)})$ is the corresponding label sequence. Since $x^{(i)}$ contains the slot value of slot s_a, there is either "B-s_a" (the slot value is a word) or "B-s_a" and "I-s_a" (the slot value includes several words) in the label sequence. We first extract all slot value words from labeled dataset D_{sa}, and have the sample set Ω_{va} of the slot value representation of slot s_a, as shown in Equation (6):

$$\Omega_{va} = \left\{E(x_j^{(i)}) \mid if\ I_{va}(x_j^{(i)}, s_a)\right\}_{i=1, j=1}^{i=N_a, j=l} \tag{6}$$

where E is a word embedding mapping, and I_{va} indicates whether $x_j^{(i)}$ is the slot value of slot s_a defined as Equation (7):

$$I_{va}(x_j^{(i)}, s_a) = \begin{cases} 1, & if\ y_j^{(i)} = B\text{-}s_a \\ & or\ y_j^{(i)} = I\text{-}s_a \\ 0, & otherwise \end{cases} \tag{7}$$

Then we extract the slot values context. N words before and after the slot values are extracted to form the sample set Ω_{ca} as shown in Equation (8):

$$\Omega_{ca} = \left\{E(x_k^{(i)}) \mid if\ I_{ca}\ (x_k^{(i)}, s_a)\right\}_{i=1, k=1}^{i=N_a, k=l} \tag{8}$$

where E is a word embedding mapping, and I_{ca} indicates whether $x_k^{(i)}$ is the slot value context for slot s_a defined as Equation (9):

$$I_{ca}(x_k^{(i)}, s_a) = \begin{cases} 1,\ if\ x_k^{(i)} \neq B\text{-}s_a\ and\ x_k^{(i)} \neq I\text{-}s_a \\ \quad and\ (y_{k+N}^{(i)} = B\text{-}s_a\ or\ y_{k-N}^{(i)} = I\text{-}s_a \\ \quad or\ y_{k-N}^{(i)} = B\text{-}s_a) \\ 0,\ otherwise \end{cases} \tag{9}$$

Similarly, we can obtain Ω_{vb} and Ω_{cb}. Based on Ω_{va}, Ω_{ca}, Ω_{vb} and Ω_{cb}, we can calculate

$sim(p_v(s_a), p_v(s_b))$ and $sim(p_c(s_a), p_c(s_b))$ based on Equations (4) and (5) and then calculate $\text{STM}_\beta(s_a, s_b)$ based on Equation (1).

Slot transferability has the following two properties:

Symmetry STM is symmetric. Let the transferability from s_b to s_a be $\text{STM}_\beta(s_b, s_a)$, we have:

$$\text{STM}_\beta(s_a, s_b) = \text{STM}_\beta(s_b, s_a) \tag{10}$$

Relativity When comparing the STM between two slot pairs, it is meaningful only their source slot or target slot is the same. When $\text{STM}_\beta(s_a, s_b) < \text{STM}_\beta(s_c, s_b)$, the transferability from s_a to s_b is higher than that from s_c to s_b, or when $\text{STM}_\beta(s_a, s_b) < \text{STM}_\beta(s_a, s_c)$, the transferability from s_a to s_b is higher than that from s_a to s_c. The comparison between $\text{STM}_\beta(s_a, s_b)$ and $\text{STM}_\beta(s_c, s_d)$ is meaningless.

3.2 Selection of source slots based on STM

Given a slot set $S = \{s_1, \cdots, s_{ns}\}$ from source tasks and the target slot s_t. Each source slot s_a has a labeled dataset $D^T_{sa} = \{(x^{(i)}, y^{(i)})\}_{i=1}^{N^T_{sa}}$, and the target slot s_t is given a labeled dataset $D^V_{st} = \{(x^{(i)}, y^{(i)})\}_{i=1}^{N^V_{st}}$ for validation. We select a slot set S_t for training the target slot filling model from S basing on the following steps.

1. For each slot s_i in the source slot set, we calculate the transferability $\text{STM}_\beta(s_i, s_t)$.
2. After sorting $[s_1, \cdots, s_{ns}]$ from big to small basing on $\text{STM}_\beta(s_i, s_t)$, we get $[s_{(1)}, \cdots, s_{(n)}]$, the slots sequence according to the order of transferability from highest to lowest.
3. First, we select a slot filling model M and define the union of training data corresponding to the first h slots (h is initialized to 1) in the sorted list $[s_{(1)}, \cdots, s_{(ns)}]$ as $D^{ACC}_h = D^T_{(1)} \cup D^T_{(2)} \cup \cdots \cup D^T_{(h)}$. After replacing the B-$*$ and I-$*$ tags on D^{ACC}_h and D^V_d with the labels B and I, we train the model M with D^{ACC}_h and then test the trained model on D^V_{st} to get the corresponding F1 value, which is denoted as $f_h = M(D^{ACC}_h, D^V_{st})$. Then $h = h + 1$, till F1 gets to its maximum, then $S_t = [s_{(1)}, \cdots, s_{(h)}]$.

3.3 Model training

Given a set of source tasks $T = \{T_1, \cdots, T_n\}$, a target task T_{tgt} and the slot set $S_i = \{s_1, \cdots, s_{N_i}\}$ corresponding to task T_i. We define the set of all source task slots as $S_{union} = S_1 \cup \cdots \cup S_n$, and the set of target task slots as S_{tgt}. For an existing cross-domain slot filling model M_{base}, we deploy our approach on the model by following these steps.

Firstly, the training set and validation set corresponding to the target task and the source task are divided into the training set and validation set corresponding to each slot according to whether the slots contained in each sample. Then select the corresponding source slot set S_{ti} for each slot s_{ti} in the target task slot set from all the source tasks set S_{union}. We combine the source slot set corresponding to all target task slots to get the source slot set for the target task $S_{tgt} = S_{t1} \cup \cdots \cup S_{tN_{tgt}}$ and then replace the labels corresponding to all slots in the source task training set that are not in S_{tgt} with labels O. Finally, the source slot set S_{tgt} and the training data after replacement are used to train the model M_{base}.

4 Experiments

In this section we describe the dataset used for evaluation, the baseline models used for comparison, and more details of the experimental settings.

4.1 Datasets

To evaluate the effectiveness of our approach, we conduct experiments on SNIPS (Coucke et al., 2018). In order to further evaluate the generalization ability of our approach, we also construct a cross-task slot filling dataset called MultiWoz-Slot (MWS) based on the multi-domain task-oriented dialog dataset MultiWoz (Budzianowski et al., 2018; Eric et al., 2020). Table 1 displays some statistics about the two datasets. Details about the two datasets and how the MWS dataset is constructed are described as follows.

SNIPS SNIPS is a public SLU dataset that contains 7 tasks (intents) and 39 slots, and each task contains approximately 2000 training samples. As shown in Table 1, the data contains a total of 14,484 samples, the vocabulary size is 12,134, the average length of the sample utterance is 9, and the average number of slots in each sample is 2.6.

Multiwoz-Slot MultiWoz is a public multidomain task-oriented dialogue dataset that contains 7

Table 1: Some statistics about SNIPS and MWS. The upper script on task indicates the task id. The upper script on slot indicates the task it belongs.

tasks and 24 slots. Since the (hospital, police) tasks have little conversation data and only appear in the training data, we use user-side utterance for just five tasks (attractions, hotel, restaurant, taxi, train) to construct the MWS dataset, which contains 14 slots. When constructing the training, validation and test data of a task in MWS, we extract the user-side utterance containing the task separately from the conversations in the training set, validation set and test set of Multiwoz. Since the training set of the target task is generally used as the final test set in the cross-domain slot filling task, we combine the validation set and test set as validation set for each task. Table 1 shows the number of slots and the number of sample of training set and validation set included in each task in MWS. As shown in Table 1, the data contains a total of 39,839 samples, and the vocabulary size is 3,314, the average length of the sample utterance is 15, and the average number of slots in per sample is 1.7.

Compared to SNIPS, MWS has smaller vocabulary size and the number of slots in each task. However, MWS has more samples in each task, so when it is used as a cross-domain slot filling dataset, its source tasks have more sufficient training samples, and the correlation between these tasks is stronger.

4.2 Models

We conduct our experiments on the following models.

Concept Tagger (CT) A cross-domain slot filling model proposed by Bapna et al. (2017), which uses the information of the slot descriptions to establish implicit alignment between target slots and source slots.

Robust Zero-shot Tagger (RZT) A model proposed by Shah et al. (2019), which uses the slot value sample of slots to improve the robustness of the model on the target task based on the CT model.

Coarse-to-fine Approach (Coach) A two-stage cross-domain slot filling method proposed by Liu et al. (2020), which splits the cross-domain slot filling task into two stages: coarse-grained BIO 3-way classification and fine-grained slot type classification, and uses slot descriptions in the second stage to help recognize unseen slots.

Coach+TR A variant of Coach proposed by Liu et al. (2020), which further uses template regularization on the basis of Coach to improve the performance of the model on similar or the same slots, is the state-of-the-art model.

4.3 Implementation Details

We deploy the proposed method on above slot filling models CT, RZT, Coach, and Coach+TR.

β is set to 1. A two-layer BiLSTM (Schmidhuber and Hochreiter, 1997) model is used for selecting source slots for all models. 300 dimensions Glove (Pennington et al., 2014) vector is used for word embedding. The hidden layer dimension is set to 300, the learning rate is 0.001. We train the model 30 epochs and select the model with the best performance on the validation set as the final model.

Table 2: The main result of the four models (CT, RZT, Coach, Coach +TR) trained using original data (All data) and data selected by our method (STM_1). Scores in each row are F1 of target task.

In order to make a fair comparison, we use the same settings with Liu et al. (2020) to construct the cross-domain slot filling model. We concatenate the 100-dimensional character-level representation and the 300-dimensional word-level representation as word representation. We set the hidden layer dimension of all the BiLSTM encoders to 300 and set the dropout rate to 0.3. We use Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.0005. The samples of each task in SNIPS are divided into two parts: 500 samples as validation set, and the remaining samples as training set. When a task is set as a target task, its training set is used as a test set. We evaluate on two datasets respectively. For each test, we choose one task as the target task and set the other tasks as the source tasks.

5 Result and Discussion

In this section, we describe and analyze the experimental results. Firstly, the main results of the experiment are described in Section 5.1. Then, we analyze the impact of some factors on STM in Section 5.2.

5.1 Main Results

Quantitative Analysis Table 2 shows the main result of the four models. For each model, the first column is F1 of the model trained by all labeled data available, i.e., the original way for using the model. The second column is F1 of the model trained by labeled data selected by method proposed in the paper. As can be seen from the Table 2:

1. Our method improves the average F1 (average on all target tasks) of all four models on two datasets consistently, e.g. our method improves the average F1 of coach+TR by 4.4 points on MWS, and by 3.17 points on SNIPS.

2. Our method improves the performance of all four models on most target tasks, even improves several of them by more than 10 points.

Qualitative analysis We perform a qualitative analysis of the STM on the MWS dataset. Figure 1 shows the thermal diagram of slot transferability between any two slots in MWS. Each cell in the figure represents the value of STM_1 between the slot labeled in the horizontal axis and the vertical axis. The higher the brightness, the higher the transferability. The figure is symmetric because the STM_1 is symmetric. It can be found that the slot with high transferability to each other are roughly divided into 7 categories, as shown in Table 3. After observing the data, we find that there are mainly three kinds of slots in the same category. The first type is the slot with high coincidence degree of slot value set. For example, ”attraction-name” and ”taxi-dest” have some common values, such as ”adc theatre”, ”all saints church”, ”county folk museum” and so on. The second kind of slots is that the slot values appear in similar context. For example, ”attraction-name” and ”hotel-name” have some common context words, such as ”about”, ”for”, ”at” and so on. The third kind of slots are the slots with higher coincidence degree, as well as similar context of slot values, such as ”attraction-area” and ”hotel-area”. These phenomena are consistent with the definition of STM.

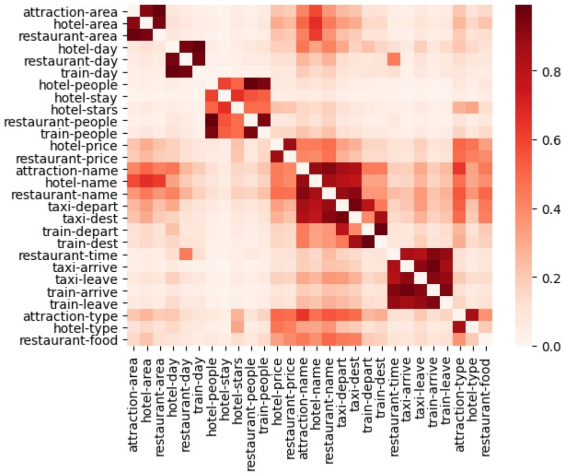

Figure 1: the thermal diagram of slot transferability between any two slots in MWS.

Category	Slots
1	*attraction-area*, *hotel-area*, *restaurant-area*
2	*hotel-day*, *restaurant-day*, *train-day*
3	*hotel-people*, *hotel-stars*, *hotel-stay*, *restaurant-people*, *train-people*
4	*hotel-price*, *restaurant-price*
5	*attraction-name*, *hotel-name*, *restaurant-name*, *taxi-depart*, *taxi-dest*, *train-depart*, *train-dest*
6	*restaurant-time*, *taxi-arrive*, *taxi-leave*, *train-arrive*, *train-leave*
7	*attraction-type*, *hotel-type*, *restaurant-food*

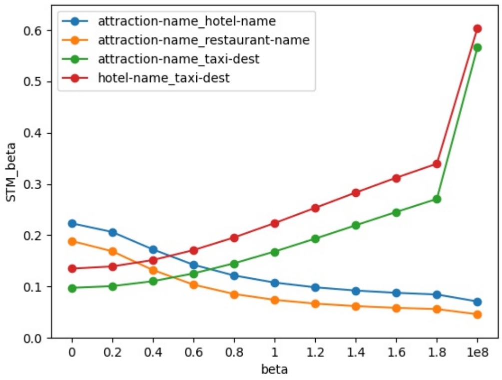

Figure 2: The impact of β on STM.

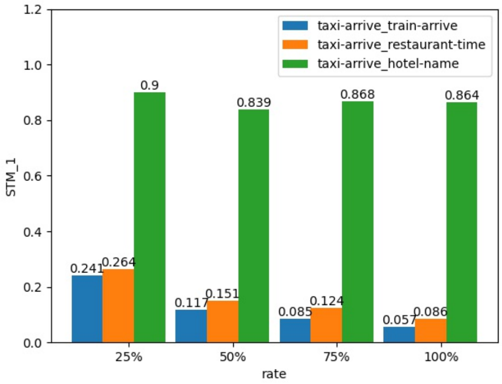

Figure 3: The impact of sample number on STM.

5.2 The impact of some factors on STM

There are three main factors in the calculation of STM_{beta}. The following is an experimental analysis of the impact of the three factors on STM.

The impact of β on STM β parameter determines the weight of similarity between distributions of slot value context representations . We randomly select four slot pairs which are (attraction-name, hotel-name), (attraction-name, restaurant-name), (attraction-name, taxi-dest), and (hotel-name, taxi-dest). In the first two groups, the slot values appear in similar context, but the sets of slot values almost have no intersection. In the last two groups, the sets of slot values set have high consistency, but the contexts of slot values are not similar. β is range from 0 and $+\infty$. When $\beta = 0$, STM_β only measures the similarity of distributions between slot values representations of the two slots, and when $\beta = +\infty$, STM_β only measures the similarity of distributions between the slot value context representation of the two slots. As shown in Figure 2, the STM_β of the first two groups increased with the increase of β, while the STM_β of the last two groups decreased with the increase of β. Therefore, when β increases, the effect of slot value similarity on STM_β becomes greater, and the effect of slot value context similarity on STM_β becomes smaller.

The impact of sample number on STM In order to measure the impact of sample number on STM_β, we randomly selected three slot pairs which are (taxi-arrive, train-arrive), (taxi-arrive, restaurant-time) and (taxi-arrive, hotel-name) for comparative experiment. We select 25%, 50%, 75% and 100% samples from the validation set used to calculate STM_β on the three groups of slots. The experimental results are shown in Figure 3. According to the figure, although the absolute values of STM_β of the three slot pairs changed, their relative relations didn't change. That is, sam-

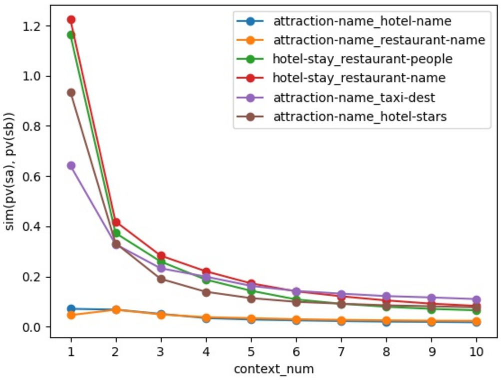

Figure 4: The impact of N on $sim(p_c(s_a), p_c(s_b))$.

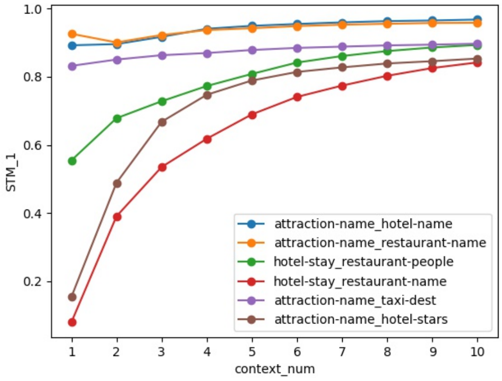

Figure 5: The impact of N on STM.

ple size will affect the value of STM_β. However, for the same source slot, the relationship between STM_β to different target slots does not change.

The impact of N on STM When calculating slot transferability, we fuse distribution similarity of the slot value representations and of the slot value context representations. We select one word before and after slot value as slot value context. In order to measure the impact of slot context window size N on slot transferability, (attraction-name, hotel-name), (attraction-name, restaurant-name), (attraction-name, taxi-dest), (attraction-name, hotel-stars), (hotel-stay, restaurant-people) and (hotel-stay, restaurant-name) are randomly selected for comparing. The first two groups have similar context, the middle two have similar slot values sets, and the last two have low similarity in both slot values and context. N is range from 1 and 10. We observe the change of context representation distribution similarity $sim(p_c(s_a), p_c(s_b))$ and STM_1 among 6 groups of slots. As shown in Figure 4 and Figure 5, the similarity among context representation distributions increases with the increase of context window size N, and the context similarity among 6 groups of slots tends to be the same. In addition, STM increases with the increase of window size N, and the distinction of STM between different types of slot pairs decreases. We conjecture this is due to the fact that the context we extracted contains too much slot-independent context when the window size N becomes large.

5.3 Running time analysis

The method proposed in Sec 3.2 does increase the running time. However, there are two sides of running time. Selecting slots by a Bi-LSTM cost some times, while training the model with selected (less) data saves times. We don't calculate the save minutes in training, however, we find the increase of time consumption in slots selection is small, it is acceptable considering the performance improvements it brings. Since the process in Sec 3.2 is offline and once for a new domain, and the model used in Sec 3.2 is a simple Bi-LSTM model, it increases only a little time. To be more detailed, we conducted experiments on one Titan V GPU, the average running time of the method in Sec 3.2 is 80 minutes for a new domain.

6 Conclusions and Future Work

In this paper, we propose a metric STM to measure the slot transferability of the slots across task, and the calculation of this metric is model-agnostic. Based on this metric, we also propose a cross-domain slot filling method to improve the performance of the existing models by selecting the source slots with high transferability for the target slots. The results on several existing models and datasets show that our method can bring consistent performance improvement to the slot filling models of the target tasks, which show the effectiveness of the STM. We also further explore the impact of some factors on STM. In the future, we hope to use STM to further guide the improvements of models.

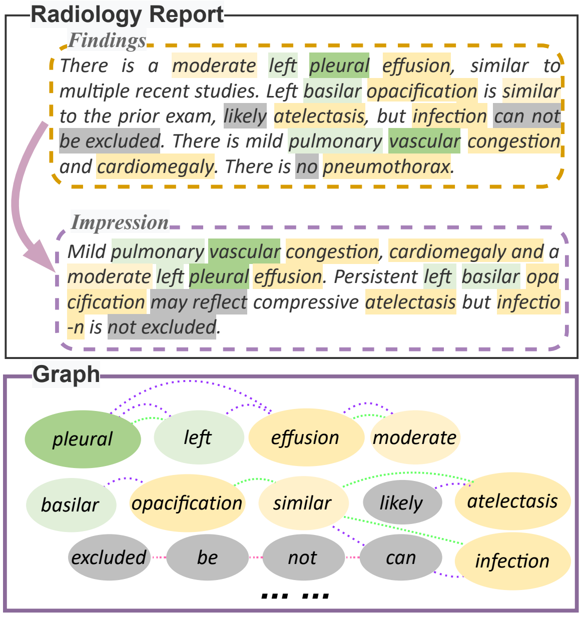
Abstract

Radiology reports play a critical role in communicating medical findings to physicians. In each report, the impression section summarizes essential radiology findings. In clinical practice, writing impression is highly demanded yet time-consuming and prone to errors for radiologists. Therefore, automatic impression generation has emerged as an attractive research direction to facilitate such clinical practice. Existing studies mainly focused on introducing salient word information to the general text summarization framework to guide the selection of the key content in radiology findings. However, for this task, a model needs not only capture the important words in findings but also accurately describe their relations so as to generate high-quality impressions. In this paper, we propose a novel method for automatic impression generation, where a word graph is constructed from the findings to record the critical words and their relations, then a Word Graph guided Summarization model (**WGSUM**) is designed to generate impressions with the help of the word graph. Experimental results on two datasets, OPENI and MIMIC-CXR, confirm the validity and effectiveness of our proposed approach, where the state-of-the-art results are achieved on both datasets. Further experiments are also conducted to analyze the impact of different graph designs to the performance of our method.[1]

1 Introduction

A radiology report usually contains a findings section (FINDINGS) describing detailed medical observations and an impression section (IMPRESSION) summarizing the most critical observations. In practice, the IMPRESSION is an essential part and plays an important role in delivering critical findings to clinicians. Therefore, summarizing FINDINGS helps to locate the most prominent observations so that the automatic process of doing so greatly eases the workload of radiologists. Recently, many methods are proposed for automatic impression generation (AIG) (Hassanpour and Langlotz, 2016; Zhang et al., 2018; Gharebagh et al., 2020), which are mainly based on the sequence-to-sequence architecture with specific designs for the characteristics of this task. For example, MacAvaney et al. (2019) employed clinical terms within the FINDINGS as key information to enhance AIG. Based on this work, Gharebagh et al. (2020) further proposed to identify the importance of these clinical terms and selected the most salient ones to facilitate the recognition of significant content



There is a moderate left pleural effusion, similar to multiple recent studies. Left basilar opacification is similar to the prior exam, likely atelectasis, but infection can not be excluded. There is mild pulmonary vascular congestion and cardiomegaly. There is no pneumothorax.

Mild pulmonary vascular congestion, cardiomegaly and a moderate left pleural effusion. Persistent left basilar opacification may reflect compressive atelectasis but infection is not excluded.

Figure 1: An example radiology report including its FINDINGS and IMPRESSION, and a word graph constructed from the FINDINGS. Different colored edges in the graph represent different types of relations. The curved arrow indicates the AIG task to generate the IMPRESSION from the FINDINGS.

---

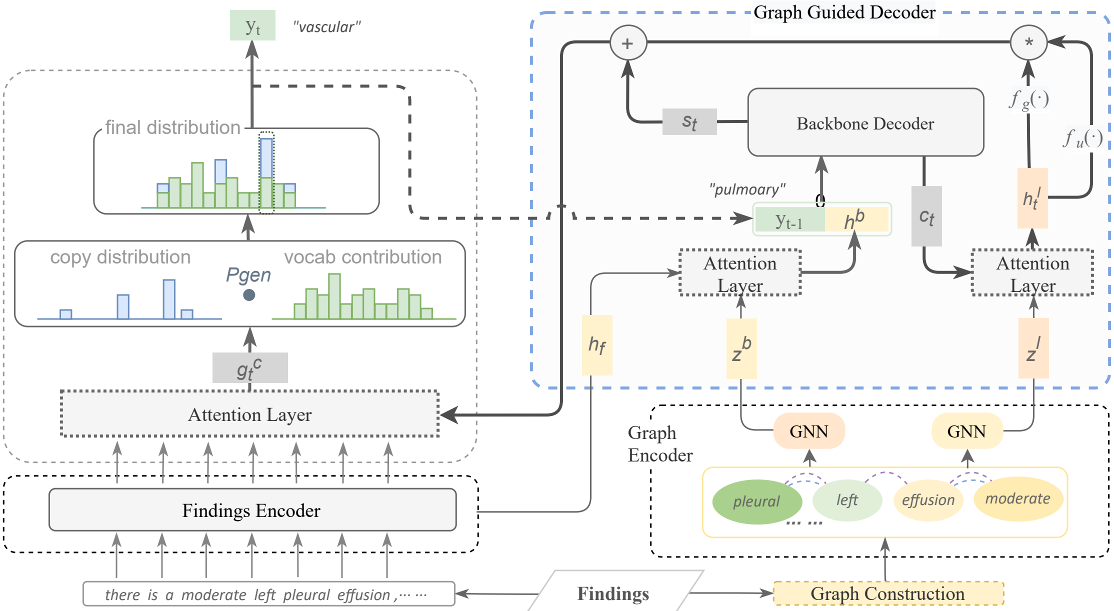

Figure 2: The overall architecture of our proposed method with an example input and sample outputs at the $t-1$ and t step. The FINDINGS Encoder and the Graph Encoder are shown in different grey dashed boxes with their details omitted. The Graph Guided Decoder is illustrated in the blue dashed box.

so as to improve the performance. Although these efforts are able to find the important words to promote AIG, less attention is paid to the important aspect on leveraging the relation information among them. For example, in Figure 1, the observation word "*effusion*" and its modifier word "*moderate*" have a relation (which describes the severity of the symptoms) in between them, where such relation needs to appear in the IMPRESSION. Therefore, to better generate IMPRESSION, in addition to using important words, it is required to recognize the relations among such words in the FINDINGS and describe their corresponding relations for AIG.

In this paper, we propose to enhance AIG via a summarization model integrated with a word graph by leveraging salient words and their relations in the FINDINGS. In detail, the word graph is constructed by identifying the important words in the FINDINGS and building connections among them via different typed relations. To exploit the word graph, a Word Graph guided Summarization model (**WGSUM**) is designed to perform AIG, where the information from the word graph is integrated into the backbone decoder (e.g., LSTM (See et al., 2017) or Transformer (Liu and Lapata, 2019)) from two aspects, including enriching the decoder input as extra knowledge, as well as guiding the decoder to update its hidden states. Experimental results illustrate that WGSUM outperforms all baselines on two benchmark datasets, where the state-of-the-art performance is observed on all datasets in comparison with previous studies. Further analyses also investigate how different types of edges in the graph affects the performance of our proposed model.

2 The Proposed Method

We follow the standard sequence-to-sequence paradigm for AIG. In doing so, we regard the FINDINGS as the source sequence $\mathbf{X} = \{x_1, ..., x_i, ..., x_N\}$, where N is the number of tokens in the FINDINGS, and the goal of the task is to generate a target sequence (i.e., the IMPRESSION) $\mathbf{Y} = \{y_1, ...y_i, ..., y_L\}$, where L is the number of tokens in the IMPRESSION. An overview of our method is shown in Figure 2 where the details are illustrated in following subsections.

2.1 The Overall Structure

The model used in our method contains three major components, i.e., the FINDINGS encoder, the graph encoder, and the graph guided decoder with their details and the training objective described below.

FINDINGS Encoder Given a FINDINGS, denoted by $\mathbf{X}$ with N tokens, LSTM or the standard encoder from Transformer is applied to model the sequence and its output is the hidden state $\mathbf{h}^x$. The process is formulated as

$$\mathbf{h}^x = f_{fe}(x_1, ..., x_i, ..., x_N) \quad (1)$$

where $f_{fe}(\cdot)$ refers to the FINDINGS encoder.

Graph Encoder For the node V and adjacency matrix $\mathbf{A}$ in the graph G constructed from the FINDINGS, we utilize graph neural networks[2] (GNN) to encode them, because GNNs are powerful in encoding graph-like information (Chen et al., 2020; Zheng and Kordjamshidi, 2020; Tian et al., 2021a,b). In detail, two encoders are employed to extract features from G, where one is used to construct the background information and the other is used to generate the dynamic guiding information. The process is thus formalized as

$$\mathbf{z}^b = f_{gb}(V, \mathbf{A}) \tag{2}$$

$$\mathbf{z}^l = f_{gl}(V, \mathbf{A}) \tag{3}$$

where $f_{gb}(\cdot)$ and $f_{gl}(\cdot)$ refer to two graph encoders, with $\mathbf{z}^b$ and $\mathbf{z}^l$ the intermeidate states used to generate the static background information and the dynamic guiding information, respectively.

Graph Guided Decoder In our model, $\mathbf{z}^b$ and $\mathbf{z}^l$ from the graph encoders are integrated into the backbone decoder (e.g., LSTM and Transformer decoder.) and perform a decoding process via

$$P_{\text{vocab}} = f_d(\mathbf{h}^x, \mathbf{z}^b, \mathbf{z}^l) \tag{4}$$

where $f_d(\cdot)$ represents the decoder.

Objective Since the FINDINGS and the IMPRESSION are highly related, a pointer generator (PG) is also introduced to our model by

$$P(y_t \,|\, \mathbf{X}, y_{<t}) = p_{\text{gen}} P_{\text{vocab}}(y_t) + (1 - p_{\text{gen}}) \sum_{i:x_i = y_t} a_i^t \tag{5}$$

where $\mathbf{a}_i^t$ is the distribution over source tokens at step t, which is obtained by performing the attention mechanism on the source tokens; p_{gen} and $(1 - p_{gen})$ are the weights of predicting the next token from the vocabulary or the source tokens, respectively. The model is then trained to maximize the negative conditional log-likelihood $P(\mathbf{Y}|\mathbf{X}, G)$ by of $\mathbf{Y}$ given $\mathbf{X}$ and G:

$$\theta^* = \arg\max_{\theta} \sum_{t=1}^{L} \log p\left(y_t \mid y_1, ..., y_{t-1}, \mathbf{X}, G; \theta\right) \tag{6}$$

where θ are the parameters of the model.

2.2 Graph Construction

In FINDINGS, the most critical content that the radiologists need to summarize is the abnormality which usually includes the corresponding specific observations as well as their modifying words. Therefore, in our study, we first extract 5 types of entities from FINDINGS: *anatomy*, *observation*, *anatomy modifier*, *observation modifier*, and *uncertainty*, where these entities are able to cover most of the key words that need to appear in IMPRESSION. In addition, Gharebagh et al. (2020) has shown that fine-grained words are more effective than the entire ontology. Inspiring by this idea, we regard words from these entities as nodes in our graph. To avoid confusion, the repeated words are treated as one single node in each FINDINGS even though they are not presented in the same entity. Besides modifying relation, some other relations are also important for IMPRESSION generation, such as relations between *anatomy* and *observation*. For example, in Figure 1, the relation between "*pleural*" (*anatomy*) and "*effusion*" (*observation*), which can be obtained for the detailed abnormality in the IMPRESSION. To capture these types of relations, we leverage dependency trees which have been widely used to model word-word relations in many studies (Tian et al., 2020a,b; Pouran Ben Veyseh et al., 2020; Chen et al., 2021). Thus, we define three types of edges for our word graph. Note that, each FINDINGS has its corresponding word graph:

- **Type** I: this is the type using the natural order of words in an entity. In detail, we connect words if they are adjacent in the same entity. In Figure 1, the pink dashed lines serve as the type I edge. For example, "*endotracheal tube*" is an entity, so that "*endotracheal*" is connected to "*tube*".
- **Type** II: this is the type using the relations among entities within the same category (e.g., observation and its modifier, and anatomy and its modifier). As shown in Figure 1, given an *observation*,"*effusion*" and a *observation modifier* "*moderate*", the relation is constructed by connecting them with a green dash line.
- **Type** III: this is the type using the relations among entities across different categories (e.g., observation and anatomy). Different from the previous two types, this type is able to provide the global relation information while the previous two types emphasize the local information. In detail, we construct a dependency tree using stanza in the Universal Dependencies (UD) format (Nivre et al., 2020). As shown in Figure 1, given "*effusion*" and its head "*left*", they are connected with a purple dash line.

---

[2] It can be any type (e.g., graph convolutional networks (GCN) and graph attention networks (GAT)).

Then the nodes and edges in graph are recorded by a node list V and an adjacency matrix $\mathbf{A}$ which are then used as the input of graph encoder.

2.3 Graph Guided Decoder

We utilize graph to generate two different kinds of information and they are working on two aspects: enriching decoder input by static background information $\mathbf{h}^b$ and controlling decoder hidden state by dynamic guiding information $\mathbf{h}^l$, which are introduced in following parts.

Background Information Since the graph can be considered as a condensing of source sequence (i.e., FINDINGS) which contains the most important information, it is appropriate to serve as a static background information to enrich the decoder inputs. The first output $\mathbf{z}^b$ of graph encoder is used to construct the background information. For the hidden state $\mathbf{z}_i^b$ in $\mathbf{z}^b$ of each node, we can obtain attention weights by:

$$e_i^b = \mathbf{p}_b^\top \tanh(\mathbf{W}_b \mathbf{z}_i^b + \mathbf{W}_h \mathbf{h}_f) \tag{7}$$

$$\mathbf{a}^b = \text{softmax}(\mathbf{e}^b) \tag{8}$$

where $\mathbf{W}_b$,$\mathbf{W}_h$ and $\mathbf{p}_b$ are learnable parameters. For LSTM, we define $\mathbf{h}_f$ as the final hidden state, and for Transformer, we calculate the mean of all hidden states as $\mathbf{h}_f$. The attention distribution $\mathbf{a}^b$ can be viewed as a probability distribution over nodes in graph. Next, $\mathbf{a}^b$ is used to produce a weighted sum of the nodes and then we obtain the static background information:

$$\mathbf{h}^b = \sum_i a_i^b \mathbf{z}_i^b \tag{9}$$

For clarity, we simplify Equation (7), (8) and (9) as a function AttCon$(\cdot)$. Therefore, $\mathbf{h}^b$ can be obtained by:

$$\mathbf{h}^b = \text{AttCon}(\mathbf{z}^b, \mathbf{h}_f) \tag{10}$$

In our model, the background information $\mathbf{h}^b$ is directly concatenated to the decoder input. For each decoder input $\mathbf{y}_{t-1}$ at step t, it is expanded as $\mathbf{y}'_{t-1} = [\mathbf{y}_{t-1}, \mathbf{h}^b]$.

DATA	OPENI			MIMIC-CXR		
	TRAIN	VAL	TEST	TRAIN	VAL	TEST
REPORT #	2,400	292	576	122,014	957	1,606
AFL	37.89	37.77	37.98	55.78	56.57	70.67
AFS	5.75	5.68	5.77	6.50	6.51	7.28
AFE	18	17	18	27	28	36
AIL	10.43	11.22	10.61	16.98	17.18	21.71
AIS	2.86	2.94	2.82	3.02	3.04	3.49

Table 1: The statistics of the two benchmark datasets (random split for OPENI and official split for MIMIC-CXR) in the training, validation, and test sets, where the number of reports, the averaged sentence-based (AFS, AIS) and word-based length (AFL, AIL) of IMPRESSION and FINDINGS, and the averaged number of edges in graph (AFE) are reported.

Dynamic Guiding Information Since $\mathbf{h}^b$ remains unchanged and works as the global static knowledge during the decoding process, to make the guidance more flexibly, the other information $\mathbf{z}^l$ from graph encoder in Equation (3) is used to generate dynamic guiding information $\mathbf{h}_t^l$ for each decoding step t. For different backbone decoders, there is a little difference in generating $\mathbf{h}_t^l$. For LSTM decoder, each cell updates its information by two states and one input: cell state $\mathbf{c}_{t-1}$, hidden state $\mathbf{s}_{t-1}$ and input $\mathbf{y}'_{t-1}$, which is formulated as:

$$[\mathbf{c}_t, \mathbf{s}'_t] = \text{LSTM}(\mathbf{c}_{t-1}, \mathbf{s}_{t-1}, \mathbf{y}'_{t-1}) \tag{11}$$

where $\mathbf{c}_t$ usually contains rich contextual information and it is appropriate to compute guiding information $\mathbf{h}_t^l$.[3]

$$\mathbf{h}_t^l = \text{AttCon}(\mathbf{z}^l, \mathbf{c}_t) \tag{12}$$

For Transformer, the general decoder only has one hidden state $\mathbf{s}'_t$ which is the output of the last layer. In this part, we regard the output of the penultimate layer as another hidden state $\mathbf{c}_t$ which is then used to generate dynamic information $\mathbf{h}_t^l$ by:

$$\mathbf{h}_t^l = \text{softmax}(\mathbf{c}_t(\mathbf{z}^l)^\top)\mathbf{z}^l \tag{13}$$

After obtaining the dynamic guidance $\mathbf{h}_t^l$ from the LSTM decoder or Transformer decoder, it is then utilized to update decoder hidden state $\mathbf{s}'_t$ by:

$$\mathbf{s}_t = \mathbf{s}'_t + f_g(\mathbf{z}^l) \cdot f_u(\mathbf{z}^l) \tag{14}$$

where $f_g(\cdot)$ and $f_u(\cdot)$ are fully connected layers.

Vocabulary Distribution To incorporate the FINDINGS information for final prediction, we calculate the attention context vector $\mathbf{g}_t^c$ by the same way as Equation (7), (8) and (9) using sequence encoder hidden state $\mathbf{h}^x$ as well as the updated $\mathbf{s}_t$:

$$\mathbf{g}_t^c = \text{AttCon}(\mathbf{h}^x, \mathbf{s}_t) \tag{15}$$

Then both $\mathbf{g}_t^c$ and decoder hidden state $\mathbf{s}_t$ are used to calculate vocabulary distribution at step t:

$$P_{vocab} = \text{softmax}\left(\mathbf{Q}' \tanh\left(\mathbf{Q}\left[\mathbf{s}_t; \mathbf{g}_t^c\right]\right)\right) \tag{16}$$

where $\mathbf{Q}'$ and $\mathbf{Q}$ are learnable weights.

---

[3] We also try to use hidden state $\mathbf{s}'_t$ from LSTM to calculate $\mathbf{h}_t^l$, but the performance is not better than that of $\mathbf{c}_t$.

3 Experiment Settings

3.1 Dataset

We conduct our experiments on the following two datasets of radiology reports: **OpenI** (Demner-Fushman et al., 2016) and **MIMIC-CXR** (Johnson et al., 2019). The former is collected by Indiana University with 3,268 reports after pre-processing. The latter contains a larger amount of data, where we obtain 124,577 after pre-processing. In our experiments, the original Impressions written by the radiologists are considered as the ground truth. For both datasets, we follow Zhang et al. (2018) and Gharebagh et al. (2020) to exclude the following types of reports: (a) incomplete reports; (b) reports whose Findings have less than 10 words; and (c) reports with Impression words less than 2. For the dataset splits, OpenI is partitioned into train/validation/test set by 2400:292:576 randomly in our experiments. For MIMIC-CXR, we apply two splits, one is the official split as the dataset published by Johnson et al. (2019), and the other is a random split with a ratio of 8:1:1, which is the same as Gharebagh et al. (2020). The statistics of the datasets are shown in Table 1.

3.2 Baseline and Evaluation Metrics

To compare the performance of our proposed models, we use the following models as our baselines:

- **PG-LSTM** (See et al., 2017): This is Pointer Generator Network (PGN) with copy mechanism where both encoder and decoder are vanilla LSTMs without graph information.
- **PG-Trans** (Liu and Lapata, 2019): This is also a PGN with both the encoder and decoder replaced with the transformer.

Besides, we also compare our model with those in previous studies, including extractive summarization models, e.g., **LexRank** (Erkan and Radev, 2004), **TransformerEXT** (Liu and Lapata, 2019), as well as abstractive summarization models, e.g., **CAVC** (Song et al., 2020), **CGU** (Lin et al., 2018) and **OntologyABS** (Gharebagh et al., 2020). In our experiments, we use ROUGE metrics (Lin, 2004) to evaluate the generated Impressions. We only report F_1 scores of ROUGE-1 (R-1), ROUGE-2 (R-2) and ROUGE-L (R-L), where R-1, R-2 are unigram and bigram overlap measuring the informativeness and R-L is the longest common sub-sequence overlap aiming to assess fluency. In addition, to evaluate the factual consistency (FC), CheXbert (Smit et al., 2020)[4] is utilized to detect 14 observations related to diseases in reference impressions and generated impressions. Then precision, recall and F1 score are used to evaluate the performance.

3.3 Implementation Details

We employ stanza (Zhang et al., 2020)[5], a python-based natural language processing library, to recognize named entities and get the syntactic analysis. Then we use the extracted entities and dependency tree to construct graph for each Findings. We im-

---

[4] FC only apply to MIMIC-CXR since the CheXbert is designed for MIMIC-CXR and we obtain Chexbert from `https://github.com/stanfordmlgroup/CheXbert`

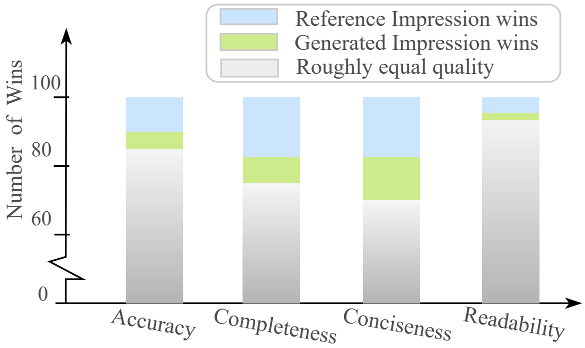

Figure 3: Experts evaluation results of 100 sampled test examples. For each of the metrics, more than 80% of the generated Impressions are at least as good as the reference Impressions.

plement our model based on Zhang et al. (2018)[6] and Liu and Lapata (2019)[7]. Since the quality of text representation plays an important role in model performance (Mikolov et al., 2013; Song et al., 2017, 2018; Peters et al., 2018; Song and Shi, 2018; Devlin et al., 2019; Joshi et al., 2020; Song et al., 2021), we try two powerful Findings encoders, namely, LSTM and Transformer, which have achieved state-of-the-art results in many natural language processing tasks. For WGSum (LSTM+GAT)), we employ 2-layer GAT with hidden size of 200 as our graph encoder, 2-layer Bi-LSTM encoder for findings sequence with hidden size of 100 for each direction and 1-layer LSTM for decoder with hidden size of 200. The dropout is set to 0.5 for embedding layer. We use Adam optimizer (Kingma and Ba, 2014) with the learning rate of 0.001. For WGSum(Trans+GAT), the graph encoder is a 2-layer GAT with hidden size 512 and the Findings encoder is a 6-layer Transformer with 512 hidden size and 2,048 feed-forward filter size. The decoder is also a 6-layer Transformer with hidden size 512.

4 Results and Analyses

4.1 Effect of word graph

To illustrate the validity of the word graph, we conduct experiments with the aforementioned baselines on the two benchmark datasets. Besides, we also try two different types of GNNs: GCN (Kipf and Welling, 2016) and GAT (Veličković et al., 2017) respectively. The results are shown in Table 2 and there are several observations drawn from different aspects. First, we can observe that for our word graph, the encoder GAT is more effective than GCN where GAT can bring more significant improvements on the two datasets. The main reason might be that GAT is more powerful in updating node representation via self-attention. Second, integrating the word graph into the two different PGNs gains better performance on both the datasets, which confirms the usefulness of the word graph. Third, for OpenI, the LSTM-based models outperform much more than the Transformer-based models, while on MIMIC-CXR, the Transformer-based models are more effective. The main reason could be that the LSTM is able to obtain prominent performance in the small dataset and the Transformer is more powerful under a large amount of data. Fourth, on the FC metrics on MIMIC-CXR, our proposed methods also outperform the Base model, indicating that the generated Impressions from our methods are more accurate and reasonable, which is because the word graph can provide both key word and relation information for the generation process so that the decoder tends to produce words with correct relations.

[7] `https://github.com/nlpyang/PreSumm`

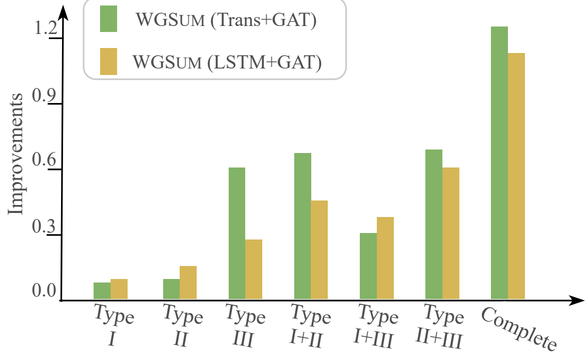

Figure 4: The improvements (R-1) of WGSum with different graph edges on MIMIC-CXR dataset.

4.2 Comparison with Previous Studies

In this subsection, we compare our models with existing studies on the two datasets and report all results (i.e., ROUGE scores) in Table 3. We can get several observations. First, the abstractive models are apparently more effective than the extractive models in AIG, owing to the characteristics of Findings and Impression in radiology reports. Second, our models with the word graph show the effectiveness of both key words information and their relations in this task when being compared to the previous models that only leverage medical term information, e.g., OntologyABS only uses ontology information in database RadLex[8]. Third, our methods achieve the best performance among all previous models, which demonstrates that using background knowledge and dynamic guidance information to control the decoding process is an appropriate design to improve the quality of the generated Impressions.

4.3 Expert Evaluation

Since the limitation of ROUGE metrics, we further conduct an expert evaluation for a better understanding of the generated Impressions. We randomly select 100 generated Impressions along with their corresponding reference Impressions and Findings from MIMIC-CXR. To avoid potential bias, we randomly order the predicted and reference Impressions. We extend Gharebagh et al. (2020) metrics to four metrics: Accuracy, Completeness, Conciseness and Readability. Three medical experts are employed to score each Impression on these metrics. Figure 3 presents the results of human evaluation. We can observe that although reference Impressions written by the radiologists are still better, there are still over 80% of generated Impressions have roughly equal or better quality. About 85%, 75%, 70%, and 94% of generated Impressions are equal to human written Impressions on the four metrics (Accuracy, Completeness, Conciseness, and Readability). In addition, there are even 5%, 7%, 12%, 2% of generated Impressions surpassed the reference Impressions on these metrics.

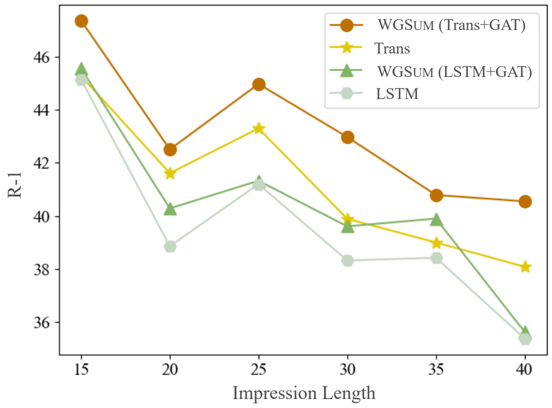

Figure 5: The performance (R-1) of generated Impressions from WGSum (Trans+GAT), PG-Trans, WGSum (LSTM+GAT) and PG-LSTM on the MIMIC-CXR test set. Each group contains Impressions of different length intervals.

4.4 Analyses

We conduct further analyses on Graph Edge, Impression Length, and Case Study.

Graph Edge As we introduced before, our graph contains three types of edges, i.e., entity interval edge (Type I), entity modifier edge (Type II), and edge from dependency tree (Type III). To show the effect of different edges, we conduct experiments for WGSum (LSTM+GAT) and WGSum (Trans+GAT) with different edges on MIMIC-CXR. The improvements from these different edge combinations are shown in Figure 4. First, we can observe that models incorporating word graph outperform the baselines no matter with what type of edge, indicating the effectiveness of our innovation in combining the entity words and their relations into the word graph. Second, regardless of WGSum (LSTM+GAT) or WGSum (Trans+GAT), Type III edge can bring the most significant improvements, while Type I brings little improvements. The main reason might be that the dependency tree contains more comprehensive and accurate relations for the entity words from Findings. Third, WGSum (Trans+GAT) usually obtains bet-

Figure 6: Examples of the generated IMPRESSIONS from two models (i.e., the PG-TRANS and the WGSUM (TRANS+GAT), respectively) , as well as the reference IMPRESSIONS.

ter improvements than WGSUM (LSTM+GAT) in most cases.

IMPRESSION Length Another factor that could affect the model performance is the number of tokens in the IMPRESSION. To test the effect of IMPRESSION length, we categorize all generated IMPRESSIONS in the MIMIC-CXR test set into 6 groups (within [15,40] with the interval of 5) and compare the R-1 score for each group. The results are shown in Figure 5. There are several observations. First, when IMPRESSION gradually increases in the length, the performance of all models shows a downward trend, which indicates that long IMPRESSION generation is difficult for all models. Second, TRANSFORMER-based methods are more effective than LSTM based models, especially for long IMPRESSION. The main reason might be that the Transformer is more powerful in dealing with longer sequences via its self-attention mechanism. Third, both WGSUM (TRANS+GAT) and WGSUM (LSTM+GAT) show their superiority when being compared to their baselines and obtain better results in almost all of the groups.

Case Study To further analyze the effect of our proposed model, we perform qualitative analysis on some cases with their reference and generated IMPRESSIONS from different models. Figure 6 shows three cases from MIMIC-CXR where different colors on text refer to varied key information. It is found that in the first case, when referring to the corresponding FINDINGS our model generates more complete IMPRESSION than the reference, e.g., *"et tube terminates 3 .9 cm above the carina"* is a helpful text piece but does not appear in reference IMPRESSION. In addition, compared to the reference IMPRESSIONS written by radiologists, our method covers almost all of the key information in the generated IMPRESSIONS. For example, the key information *"moderate bilateral pleural effusions"*,*"mild pulmonary edema"* and *"small opacity in the right media "* in the three examples are not generated in PG-TRANS model, but they are necessary for describing the clinical condition.

5 Related Work

Our work focuses on summarizing the FINDINGS of radiology reports to generate the IMPRESSION, which is essentially an abstractive summarization task. For abstractive summarization, there exists a serious problem known as hallucination (Maynez et al., 2020), in which the generated summary contains fictional content. This problem also exists in AIG and would lead to misdiagnosis for the patient. To tackle this problem, in the general domain, many attempts have been made in terms of guiding information to control the generation process and output the high-quality summary (Li et al., 2018; Hsu et al., 2018; Pilault et al., 2020; Huang et al., 2020; Haonan et al., 2020). For the IMPRESSION generation task in the medical domain, there also exist several solutions. Zhang et al. (2018) encodes a section of the radiology report as the background information to guide the decoding process. MacAvaney et al. (2019) employs the entire ontological terms extracted from FINDINGS as the medical terms, and then enhances the summarizer by selecting the salient information. Gharebagh et al. (2020) further splits ontological terms into words and then incorporates these words into summarization by a separate encoder. Compared to these studies, our model offers an alternative solution to robustly enhancing guidance with a word graph for summarizing the FINDINGS of radiology reports without requiring external resources. To our best knowledge, this is the first work employing word relation information for AIG.

6 Conclusion

In this paper, we propose a novel method for AIG, where a word graph is constructed from the FINDINGS by identifying the salient words and their relations and a graph-based model WGSUM is designed to generate IMPRESSIONs with the help of the word graph. In doing so, the information from the word graph guides the decoding process with the help of background information and dynamic guiding information. Experimental results on two benchmark datasets show the validity of our proposed method, which obtains the state-of-the-art performance on both datasets. Further analyses on the effect of edge types demonstrate that our model can generate IMPRESSION with accurate medical items.

Abstract

The attention-based encoder-decoder framework is widely used in many natural language generation tasks. The attention mechanism builds alignments between target words and source items that facilitate text generation. Previous work proposes supervised attention that uses human knowledge to guide the attention mechanism to learn better alignments. However, well-designed supervision built from ideal alignments can be costly or even infeasible. In this paper, we build a Generalized Supervised Attention method (GSA) based on quasi alignments, which specify candidate sets of alignments and are much easier to obtain than ideal alignments. We design a Summation Cross-Entropy (SCE) loss and a Supervised Multiple Attention (SMA) structure to accommodate quasi alignments. Experiments on three text generation tasks demonstrate that GSA improves generation performance and is robust against errors in attention supervision.

1 Introduction

The encoder-decoder framework has been applied to various natural language generation (NLG) tasks, such as neural machine translation (Cho et al., 2014; Luong et al., 2015; Vaswani et al., 2017; Liu et al., 2016), text generation (Wiseman et al., 2017; Puduppully et al., 2019), text summarization (Liu and Lapata, 2019; Lin et al., 2018), image captioning (Anderson et al., 2018), dialogue systems (Liu et al., 2018), and so on. The attention mechanism (Bahdanau et al., 2015) plays a significant role in the framework, which automatically extracts the alignments between the target and the source for predicting the next target output. One disadvantage of the vanilla attention mechanisms is that the automatic weights do not necessarily encode prior knowledge, such as the alignments between input and output (Jain and Wallace, 2019). To alleviate this problem, supervised attention was considered (Liu et al., 2016; Mi et al., 2016; Kamigaito et al., 2017; Nguyen et al., 2018; Nguyen and Nguyen, 2018), which shows that human knowledge is helpful for guiding the learning process of attention models.

Previous work on supervised attention assumes access to ideal alignments. Unfortunately, obtaining ideal alignments is infeasible or extremely costly, for most NLG tasks. For example in Figure 1, for the AMR-to-text generation task, given the AMR graph for sentence "*From among them, pick out 50 for submission to an assessment committee to assess.*", the ideal alignment of the last word "*assess*" is node (10). As the names of (8) and (10) are the same, it is not easy to pick (10) exactly. On the other hand, it is much easier to obtain a candidate set containing both (8) and (10) and be rather confident that the ideal alignment is in the set. For different tasks, both EM-based algorithms (Brown et al., 1993; Pourdamghani et al., 2014) or rule-based methods (Flanigan et al., 2014) can be used to obtain such ambiguous alignments. However, little work has discussed making use of ambiguous labels for supervised attention.

We investigate the *generalized supervised attention* (GSA), where the supervision signal aligns a target word to multiple *possible* source items (named the *quasi alignment*), although only a subset of the items are the *true* alignment targets. The multiple source items are named *candidate set* of the quasi alignment. A generalized supervised attention framework is built for various text generation tasks with alignment relationships between target words and source items. One challenge for generalized supervised attention is that the standard Cross-Entropy (CE) loss (Liu et al., 2016)

Target Sentence:

From among them, pick out 50 for submission to an assessment committee to assess.

Alignments of target word assess:

Ideal alignment	(10)
Quasi alignments	(8), (10)
Relevant alignments	(4), (10), (12), (14)

Figure 1: Example of an AMR graph and the alignments between the graph and the target sentence. Ideal alignment points to the most related source node to "assess". Quasi alignments point to the source nodes with the same name. Relevant alignments point to more source items with weak relation to "assess".

can be limited because it is not suitable for quasi alignments. We design a new loss function named Summation Cross-Entropy (SCE) to replace the Cross-Entropy loss given a set of quasi alignments. SCE considers multiple candidates as a whole and is more robust against spurious candidates than traditional CE.

Supervised attention and automatically learned attention can be complementary. In Figure 1, the relevant alignments (4), (10), (12), (14) are useful for predicting "*assess*", but such alignments cannot be captured by simple rules and may require human annotation in order to be used for attention supervision. It is therefore more practical to rely on automatic attention to uncover such alignments. To balance supervised attention and automatic attention, we design a Supervised Multiple Attention (SMA) module for GSA. In SMA, there are multiple attention channels with the same structure but different parameters. One of them is used for supervised attention and the others are used for pure automatic attention (named unsupervised attention below) that are not influenced by the attention supervision. SMA can be seen as an extension of multi-head attention introduced in the Transformer (Vaswani et al., 2017).

We evaluate GSA on three real-world tasks: data-to-text generation (Koncel-Kedziorski et al., 2019), AMR-to-text generation (Mager et al., 2020), and text summarization (Yan et al., 2020). The results demonstrate that our method improves the performance in general. We also examine the robustness of our method against alignment errors. Our code will be released at `https://github.com/LiuYixian/Supervised_attention`.

2 Related Work

Previous work (Liu et al., 2016; Mi et al., 2016; Kamigaito et al., 2017; Nguyen et al., 2018; Nguyen and Nguyen, 2018) have studied supervised attention. Their work is based on well-designed alignments. However, no work has considered ambiguous labels, which are practically more common. We study the quasi alignments as the attention supervision and design the Summation Cross-Entropy to deal with the ambiguity in quasi alignments.

Learning with ambiguous labels has been widely studied, in which the true label is not precisely annotated but in a candidate label set. In cross-lingual Part-of-Speech, annotations are derived for low resource languages from cross-language projection, which results in partial or uncertain labels. To solve this problem, Täckström et al. (2013) proposed a partially observed conditional random field (CRF) (Lafferty et al., 2001) method, Wisniewski et al. (2014) made a history-based model, and Buys and Botha (2016) proposed an HMM-based model. SCE is designed for training attention weights using ambiguous labels. Xu et al. (2020) also study learning from ambiguous labels (called *partial label learning*) in classification tasks. Their method is based on constructing similar and dissimilar pairs of samples. However, supervised attention is not a traditional classification problem. The label spaces are various in different samples, making it difficult to construct similar pairs. Thus, the method is not suitable for GSA.

3 Basic Model

3.1 Encoder-decoder Model with Attention

Encoder-decoder models, including RNN models (Cho et al., 2014; Luong et al., 2015) and the Transformer model (Vaswani et al., 2017), are used for a variety of NLP tasks. The encoder extracts information from the source data into a memory bank, and the decoder makes use of the memory bank to generate the target sentence.

Let $\mathbf{x} = \{x_1, \dots, x_m\}$ denote a sequence of source items, and $\mathbf{y} = \{y_1, \dots, y_n\}$ a target sentence. The encoder converts the source data $\mathbf{x}$ into a memory bank $\mathbf{H} = \{\mathbf{h}_1, \dots, \mathbf{h}_m\}$, where each vector $\mathbf{h}_i$ represents the contextual embedding of x_i. At the t-th time step of the decoder, the model obtains the feature vector $\mathbf{s}_t$. The meaning of $\mathbf{s}_t$ varies in different decoders. For an RNN decoder, it is the hidden state of the RNN at time t. The attention mechanism computes the contextual feature $\mathbf{c}_t$ of $\mathbf{s}_t$ over $\mathbf{H}$, which is used to predict the next target word.

The objective function of generation is the negative log conditional likelihood loss:

$$\ell(\mathbf{x}, \mathbf{y}) = -\log P(\mathbf{y}|\mathbf{x}) \tag{1}$$

3.2 Supervised Attention (SA) with Cross-Entropy (CE) Loss

Supervised attention (SA) was first introduced by Liu et al. (2016) and Mi et al. (2016) for neural machine translation. They obtain attention supervision between source and target words with off-the-shelf aligners. SA is a multi-task learning approach, where the objective function is the summation of the loss of sequence generation (*generation loss*) and the disagreement between attention distribution and attention supervision (*attention loss*) as follows:

$$\text{Ł} = \ell(\mathbf{x}, \mathbf{y}) + \lambda \sum_t \Delta(\boldsymbol{\alpha}_t, \hat{\boldsymbol{\alpha}}_t) \tag{2}$$

where $\boldsymbol{\alpha}_t$ is the computed attention and $\hat{\boldsymbol{\alpha}}_t$ is the attention supervision.

$\ell(\mathbf{x}, \mathbf{y})$ is the generation loss in Eq. (1), and λ is a positive hyper-parameter that balances the two losses. $\hat{\boldsymbol{\alpha}}_t$ is the target attention distribution and Δ measures the disagreement between the attention distribution and the target distribution. Liu et al. (2016) assume that every target word is aligned to at least one source word. If a target word is aligned to k source words, the corresponding elements in $\hat{\boldsymbol{\alpha}}_t$ are $\frac{1}{k}$ and the other elements are 0. They apply the Cross-Entropy loss as the attention loss function:

$$\Delta(\boldsymbol{\alpha}_i, \hat{\boldsymbol{\alpha}}_i) = -\sum_{j=1}^{m} \hat{\alpha}_{i,j} \times \log \alpha_{i,j} \tag{3}$$

4 Generalized Supervised Attention (GSA)

The overall architecture of GSA is shown in Figure 2. We will first introduce quasi alignments, and introduce a Summation Cross-Entropy loss function and a Supervised Multiple Attention structure.

4.1 Quasi Alignments

We consider *quasi alignments* as shown in Figure 1, in which a target word is allowed to be aligned to a candidate set in the source items, although only a subset of the candidates are the *true* alignment targets. The supervision signal provided by the quasi alignments is $\bar{\boldsymbol{\alpha}}_t = \{\bar{\alpha}_{t,1}, \dots, \bar{\alpha}_{t,m}\}$, where $\bar{\alpha}_{t,i} = 1$ if x_i and y_t should be aligned with considerable probability. If $|\bar{\boldsymbol{\alpha}}_t| = 1$ and $\hat{\boldsymbol{\alpha}}_t$ is a one-hot alignment vector, y_t is only aligned to x_i. If $|\bar{\boldsymbol{\alpha}}_t| > 1$, $\hat{\boldsymbol{\alpha}}_t$ expresses a discrete uniform distribution over the candidate set. Such candidate items usually include some irrelevant items that should not be aligned to y_t, but it is costly to pick out the correct subset from these candidates. Therefore, we retain all these candidates and expect the training process to determine the better alignment automatically. If $|\bar{\boldsymbol{\alpha}}_t| = 0$, no item is found for y_t.

In our experiments, we obtain the quasi alignments using simple rule-based methods, which differ for different tasks, as will be discussed in Section 5.

4.2 Summation Cross-Entropy (SCE) Loss

Quasi alignments form candidate sets containing the potential aligned source items but do not indicate the true ones among them. Intuitively, we want our attention loss to penalize attention probabilities outside the candidate set but allow an arbitrary attention distribution within the set. To this end, we design the SCE loss function to maximize the total of attention probabilities in the candidate set.

$$\Delta(\boldsymbol{\alpha}_t, \bar{\boldsymbol{\alpha}}_t) = \begin{cases} 0, \text{ if } \bar{\boldsymbol{\alpha}}_t = \mathbf{0} \\ -\log(\langle \boldsymbol{\alpha}_t, \bar{\boldsymbol{\alpha}}_t \rangle), \text{ else} \end{cases} \tag{4}$$

where $\langle \cdot, \cdot \rangle$ stands for the inner product. The SCE loss is the negative logarithm of the likelihood summation of all candidate items.

Theoretically, SCE loss can be derived from a generative model. Assume that one target word should be aligned to only one true source item. For the t-th target word, we define a random variable as the true aligned source item, $P(z_t = i) = \alpha_{t,i}$. Given z_t, we re-define the candidate set as

$$\bar{\boldsymbol{\alpha}}_t = \{\bar{\alpha}_{t,1}, \dots, \bar{\alpha}_{t,m}\}, \text{ where } \bar{\alpha}_{t,z_t} = 1. \tag{5}$$

In this way, the candidate set contains z_t. Considering that z_t is a hidden variable, the likelihood

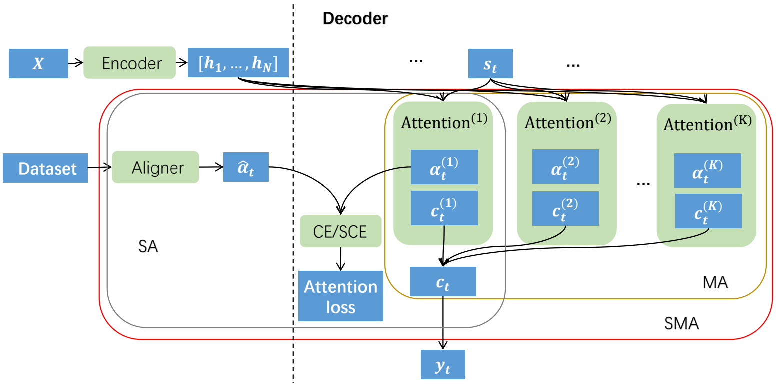

Figure 2: The overall architecture of GSA.

of the candidate set can be defined as

$$P(\bar{\boldsymbol{\alpha}}_t) = \sum_i P(z_t = i) P(\bar{\boldsymbol{\alpha}}_t | z_t = i) \quad (6)$$

$$= \sum_i \alpha_{t,i} \mathbb{I}(\bar{\alpha}_{t,i} = 1) \quad (7)$$

$$= \langle \boldsymbol{\alpha}_t, \bar{\boldsymbol{\alpha}}_t \rangle \,. \quad (8)$$

We assume that it is a certain event that we obtain a candidate set containing the true alignment given z_t. $P(\bar{\boldsymbol{\alpha}}_t | z_t)$ is a distribution over candidate sets, in which only the candidate set that contains all the words identical to x_{z_t} has probability 1 and all the other candidate sets have probability 0. Thus, $P(\bar{\boldsymbol{\alpha}}_t | z_t = i) = \mathbb{I}(\bar{\alpha}_{t,i} = 1)$. Therefore, optimizing the SCE loss is to maximize the likelihood of the candidate set.

By comparing Eq. (3) and Eq. (4), CE loss optimizes the summation of log-likelihood of target alignments, while SCE loss optimizes the log of summation of the likelihood of target alignments. If a target word is not aligned to any source items, the attention loss is 0. If it is aligned to only one source item, SCE reduces to CE (de Boer et al., 2005). If it is aligned to multiple items, then the SCE loss penalizes the attention probabilities outside the candidate set and uniformly increases the attention probabilities within the set. Note that this behavior is different from that of CE, which would encourage uniform attention over all the candidates in the set and hence produce different updates to the attention probabilities of different candidates during training.

4.3 Multiple Attention (MA) and Supervised Multiple Attention (SMA)

The motivation of supervised attention is to incorporate prior knowledge of alignments between source and target items into the attention mechanism. One problem of supervised attention is that alignments are typically established between similar items, but ideally, the decoder should also attend to some other informative source items (Figure 1), which are not necessarily similar to the target word. Besides, the automatic aligner may make errors and align the target word to irrelevant source items. Therefore, the unsupervised automatic attention mechanism is still a useful supplement to supervised attention.

We define a multiple channel attention (MA) structure, which is closely related to multi-head attention (Vaswani et al., 2017). There are K attention channels with the same structure but different parameters in MA, which work concurrently and their output contextual feature vector are combined into one contextual feature vector.

$$\mathbf{c}_t^{(k)} = \text{attn}(\mathbf{s}_t, \mathbf{H}; \theta_{\mathbf{k}}) \text{ for } k = 1, \ldots, K \quad (9)$$

$$\mathbf{c}_t = G(c^{(1)}, \ldots, c^{(K)}), \quad (10)$$

where G is a combination function. Multi-head attention (Vaswani et al., 2017) can be regarded as a special case of the MA structure. One head of multi-head attention is an attention channel in Eq. (9). The contextual features are combined by a stacking action followed with a linear function. We do not use the standard multi-head attention because the structure of multi-head attention is strict and it is not proper for all generation tasks.

To balance supervised attention and unsupervised attention, SMA has the same structure as MA, and we compute the attention loss of the first channel only, leaving the other channels still unsupervised. The objective of SMA model is:

$$Ł = \ell(\mathbf{x}, \mathbf{y}) + \lambda \sum_t \Delta(\boldsymbol{\alpha}_t^{(1)}, \hat{\boldsymbol{\alpha}}_t) \quad (11)$$

A proposed generation model with attention can be easily modified by the SMA structure. If the original attention is one-headed, we add a new attention channel with the same structure parallel to the original one, and compute the attention loss for the new attention. The contextual features of the two attention channels are averaged in Eq. (10). If the original attention is multi-headed, we do not change the structure, and compute supervised attention loss for the first head.

5 Experiments

We apply GSA to three tasks: data-to-text generation, AMR-to-text generation, and text summarization. For each task, we choose one of the best published approaches as our basic model and modify it with GSA. In the three tasks, the relations between the source and the target are diverse. For text summarization, the source items contain more information than the target words. For data-to-text generation, the source items only contain key contents. For AMR-to-text generation, the source and the target contain the same information. We report the details of model structures and hyper-parameters in the appendix.

5.1 Data-to-text Generation

Task and Model : We consider the Abstract GENeration DAtaset (AGENDA) (Ammar et al., 2018), which contains pairs of a literature abstract and a knowledge graph extracted from the abstract. The nodes in the knowledge graphs are entity types, such as “Task” and “Method”. The edges are the relations between different entities, including “COMPARE”, “PART-OF”, and so on. We use the training, development, and test splits of 38,720/1000/1000, as Ammar et al. (2018) does.

We use GraphWriter[1] (Koncel-Kedziorski et al., 2019) on this task. The encoder of this model is a graph transformer and the decoder is an RNN decoder with attention and copying mechanism. More detail is introduced in the appendix.

Aligner: The source items of this task include entities and relations, as shown in Figure 3. We use our string matching aligner to extract the alignments from target words to the source entities and extend our aligner for the alignments of relations, such as aligning target words “*use*” and “*apply*” to source relation “USED-FOR”. For the details of the aligner for source relations, please refer to the appendix.

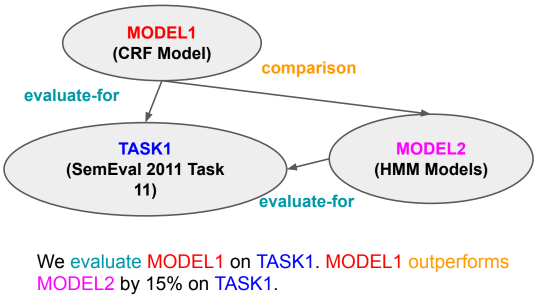

Figure 3: Example of alignments of the AGENDA dataset. The upper is part of the graph data and the lower is the corresponding sentence. The words with the same color should have quasi alignments.

Experimental Settings: We experiment with 4 different approaches in this experiment: *unsupervised attention* (UA), SA-CE, SA-SCE, SMA-SCE. The unsupervised approach means the original method without supervision on attention. As the decoder applies multi-head attention, we design the SA approach, in which the attention distributions of all heads are averaged to compute the attention loss. In this way, we consider the multi-head attention as a supervised attention channel. The SMA approach is designed as in Section 4.3, in which only the first head is a supervised attention channel. In SCE and CE approaches, we used SCE and CE loss function to supervise the attention, respectively.

5.2 AMR-to-text Generation

Task and Model : Abstract meaning representation (AMR) (Banarescu et al., 2013) is a semantic graph representation that is independent of the syntactic realization of a sentence. In the graph, nodes represent concepts and edges represent semantic relations between the concepts. AMR-to-text generation is to generate sentences from AMR graphs. We use the AMR dataset LDC2015E86, which contains 16,833 training samples, 1368 development samples, and 1371 test samples.

We use the model[2] of Mager et al. (2020) on this task, which is a GPT-2 (Radford et al., 2019) model with fine-tuning.

Aligner: We apply lemma matching to build the attention supervision as shown in Figure 1. There is a quasi alignment between a source item and target

Table 1: Main test result of GSA.

word if they have the same lemma[3].

Experimental Settings: We experiment with 4 different approaches: UA, SA-CE, SA-SCE, SMA-SCE. We apply GSA to the multi-head attention in the last Transformer layer of the decoder.

5.3 Text Summarization

Task and Model : We use the CNN/DailyMail dataset (Nallapati et al., 2016). This dataset contains 287,226 training samples, 13,368 validation samples, and 11,490 test samples. We use ProphetNet (Yan et al., 2020) on this task, which builds a pre-training and fine-tuning method for text generation. Both the encoder and the decoder are Transformers. ProphetNet is pre-trained on a large-scale dataset (160GB).

Aligner: We obtain the quasi alignments with lemma matching as in Section 5.2. A target word is aligned to a source item if they have the same lemma. Some words, such as "*is*" and "*do*", appear very frequently and are likely to cause wrong alignments. We use the inverse document frequency (IDF) (Robertson, 2004) scores to downweight these words. More details about IDF applied here are shown in the appendix.

Experimental Settings: The model has a Transformer decoder. We set the experiments similarly to Section 5.2. The basic model is proposed by Yan et al. (2020). We cannot fully reproduce their reported result (ROUGE-1/2/L of 44.2/21.17/41.30) by running their public model[4]. Thus, we report our results.

5.4 Main Results

The test results of GSA on the three tasks are shown in Table 1. For data-to-text generation, the basic model with unsupervised attention (UA) gives 14.30 BLEU, 18.80 METEOR, and 27.94 ROUGE-L. All the supervised attention approaches outperform UA. SCE outperforms CE and SMA outperforms SA. SMA-SCE achieves the best performance in BLEU, METEOR, and ROUGE-L. For AMR-to-text generation, the basic model (UA) gives a BLEU of 28.39 and a chrF++ of 58.16. All the supervised attention approaches outperform the unsupervised attention approach, demonstrating the strength of supervised attention. SMA and SCE approaches obtain higher BLEU scores compared with SA and CE, respectively. SMA-SCE achieves the best performance. For text summarization, the basic model (UA) gives a ROUGE-2 of 20.89. All the supervised attention approaches beat UA. SCE outperforms the CE. However, different from the above two tasks, the SA approaches are better than SMA. SA-SCE gives the best performance. We discuss the variation in performance of SMA compared with SA in the following.

Approach	A.C.	M.C.	M.S.
Data2text	13.21%	9.41%	2
AMR2text	46.64%	27.11%	2.93
Text Sum.	83.53%	78.10%	8.98

Table 2: Alignment coverage (A.C.), multi-alignment coverage (M.C.), and average multi-alignment size (M.S.) of attention supervision.

Approach	SA-SCE	SA-CE
variance	0.1332	0.0561
entropy	0.4214	0.8364

Table 3: Normalized variance and entropy of attention probability over the candidate set.

To analyze the variations of the performance of GSA in different tasks, we compute the alignment coverage (A.C.), multi-alignment coverage (M.C.), and average multi-alignment size (M.S.) of different tasks (Table 2). A.C. is the percentage of target words with at least one alignment. M.C. is the percentage of target words with at least two alignments over all the aligned target words. M.S. is the average number of alignments of target words with at

(b) SCE approach attention

Figure 4: Comparison of the test attention of SCE structure.

least two alignments.

For data-to-text and AMR-to-text generation, SMA outperforms SA. On the other hand, SA performs better than SMA for text summarization. One possible reason is that the summarization dataset has much higher alignment coverage and multi-alignment coverage and the alignment accuracy may also be higher; consequently, supervised attention works so well that automatic attention becomes unnecessary or even distracting.

5.5 Significance Test

To assess the evidence of significance, we perform significance tests on GSA. The p-value is calculated using the one-tailed sign test with bootstrap resampling on the test set of all three tasks following Chollampatt et al. (2019):

- For data-to-text, we compare the Rouge-L score of SMA-SCE to the result of SA-CE.
- For AMR-to-text, we compare the BLEU score of SMA-SCE to the result of SA-CE.
- For summarization, we compare the Rouge-L score of SA-SCE to the result of SA-CE.

The p-value results are shown in Table 4, which show that the improvements are significant.

Task	Data-to-Text	Amr-to-Text	Summarization
P-value	6.5489e-12	5.5795e-10	3.925e-5

Table 4: Significance test for GSA.

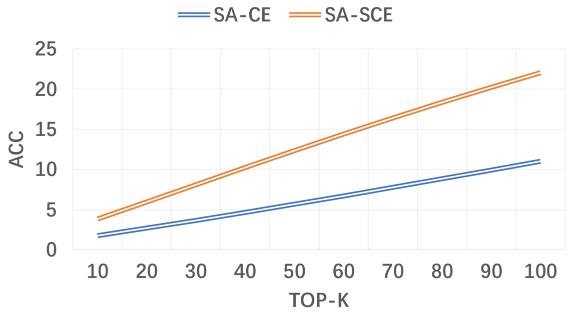

Figure 5: Top-K accuracy of SA-CE and SA-SCE in text generation.

5.6 SCE Analysis

Variance We compute the variance of attention probability in the candidate set for the text summarization task. For every generated token, we get the candidate set containing the input tokens with the same lemma as the generated token. If the candidate set contains more than one token, we compute the normalized variance and entropy of the attention scores in the candidate set. Normalized variance means that we divide every attention score by their summation and compute the variance of the normalized attention scores. Then we average the values of normalized variance and entropy in the test set. As shown in Table 3, the normalized attention variance of SCE is larger than that of CE and the entropy of SCE is smaller. It implies that CE homogenizes the attentions over the candidate set, while SCE concentrates the attentions on certain tokens. It echos Section 4.2 that CE encourages uniform attention while SCE fixes the issue.

Attention Accuracy We design an automatic evaluation method to investigate whether our SCE method can find the *correct* alignment from the quasi alignment set in an unsupervised way. For a token whose length is greater than 5[5] in the generated result, if it is matched (by lemma matching) with more than one input token, we study the generated token and the candidate set containing the matched input tokens. Specifically, we consider the local context window of length 7 around the tokens in the candidate set. The correct alignment is defined as the input token whose context window shares the most tokens with the same window around the generated token. We find the alignment selected by this automatic method almost fits the human judgment. An example is shown in Table 5.

Generated	wayne was in atlanta for a performance
Matching 1	early sunday in atlanta . no one
Matching 2	been made , atlanta police spokes woman
Matching 3	parking lot in atlanta ' s buckhead
Matching 4	wayne was in atlanta for a performance

Table 5: Automatic method to find the correct alignment.

	SA-CE	SA-SCE	SMA-SCE
BLEU	31.01	**31.19**	30.88
chrF++	59.64	**60.08**	59.86

Table 6: GSA annotated by ISI aligner for AMR-to-text generation.

The *top-K accuracy* indicates the rate that the attention score corresponding to the correct alignment is among the largest K scores. Figure 5 shows the top-K accuracy of CE and SCE for text summarization. We can find that our SA-SCE method gets higher top-K accuracy than SA-CE. That means our SCE method could find the correct alignment token and pay more attention to it without supervision.

Case Study An example of text summarization is shown in Figure 4. The figure displays a fragment of a test output sentence and the corresponding source fragment. The abscissas indicate the input text, and the ordinates denote the output summary. Figure 4(a) shows the attention of the CE approach, and 4(b) shows the attention of SCE. Both SCE and CE select the correct alignment in this example. However, the SCE approach provides higher attention probability on the correct alignment. As shown in Table 2, most output words can be flexibly aligned to more than one source word. Consider the attention probabilities of the word "*police*" framed by green squares. For one output word, there are two similar input "*police*" shown in the figure, with the first one being correct and the other one being incorrect. CE gives a probability of 0.07 for the correct alignment and 0.04 for the incorrect one. SCE approaches give the probability of 0.1 for the correct alignment and 0.03 for the incorrect one. According to section 4.2, SCE loss reduces the effect of incorrect alignments in the candidate set, which promotes the true source word.

5.7 More Powerful Supervision

In the main experiments, we apply a simple and general-purpose string matching aligner. For certain tasks, there are more powerful aligners available. To study the impact of better aligners, we in-

---

[5] In order to filter out high-frequency words like 'a', 'the', and 'and'.

vestigate the performance of GSA on AMR-to-text generation with the ISI aligner proposed by Pourdamghani et al. (2014), which is specially designed for the AMR-to-text task. The result is shown in Table 6. The improvement over the result in Table 1 proves that a more accurate aligner helps the supervised attention method for text generation. Besides, we can also find the result of SA-SCE better than that of SA-CE, which shows that SCE also works well while using a more accurate aligner.

We also analyze the alignments by the ISI aligner following the metrics of Table 2. The alignment coverage is 64.75%; the multi-alignment coverage is 52.17%; and the multi-alignment size is 3.11. It shows that the better aligner also produces ambiguous alignments. Therefore, SCE outperforms CE.

5.8 Robustness Analysis

We test the robustness of GSA by corrupting the attention supervision by changing correct alignments into incorrect ones. For every N target words with alignments, we change the alignments of one target word to a random and different source item. Then, we test GSA on data-to-text and AMR-to-text tasks based on the corrupted attention supervision. N ranges in $\{2, 3, 5, 10, 20\}$, which correspond to error rates of $\{50\%, 33\%, 20\%, 10\%, 5\%\}$, respectively.

The results are shown in Table 7. For AMR-to-text generation, we test the SMA-SCE approach. We observe that the supervised attention approach with a 20% error rate is still better than UA. Only with a 33% error rate does the supervised attention approach underperform the unsupervised attention. For data-to-text generation, we test the SMA-SCE approach. We observe that the SMA-SCE approach with even a 33% error rate is still better than UA. These results demonstrate the robustness of our supervised attention. On the other hand, in both experiments, the performance almost always decreases with more errors, demonstrating the importance of correct supervision.

Although GSA is shown to be robust to alignment errors, an overly high error rate would prevent the attention mechanism from finding the true alignments and make the supervised attention approaches worse than UA. Thus, reducing the mistake error rate is the most important when designing the aligner. More analyses about errors in attention supervision are in the appendix.

Error Rate	Data-to-text			AMR-to-text
	BLEU	METEOR	ROUGE-L	BLEU
0%	15.51	19.88	29.00	29.30
5%	14.93	19.68	28.44	29.01
10%	14.49	19.00	28.49	28.89
20%	14.36	18.99	28.41	28.80
33%	14.30	19.18	28.20	28.08
UA	14.30	18.80	27.94	28.39

Table 7: Robustness analysis.

6 Conclusion

We studied generalized supervised attention (GSA) for text generation tasks, considering quasi alignments instead of true alignments, which are much more difficult to obtain in practice. A Summation Cross-Entropy (SCE) loss function was designed to deal with quasi alignments, and a Supervised Multiple Attention (SMA) structure was used to balance supervised attention and unsupervised attention. Experiments on three generation tasks demonstrated that generalized supervised attention produces competitive results and is robust against errors in attention supervision.

Appendix

A Model detail

A.1 Graph-to-text generation

In the basic model, multi-head attention is utilized to compute the contextual feature in every time step, over all the source items, including entities and relations. The copying mechanism uses basic attention just over the entities with different parameters from the multi-head attention.

The graph transformer encoder has 6 block layers. The number of attention heads is 4. The dimensions of embedding and hidden states are 500. The decoder is a one-layer LSTM recurrent networks. The decoder attention is multi-headed. In the decoding process, beam search with beam size of 4 is applied. In GSA model, the supervised attention weight is 0.5. The weight is tuned on the validation set by the BLEU score.

A.2 AMR-to-text generation

We use GPT-2 medium as the baseline generation model. It has 24 transformer block layers and 16 attention heads. The dimensions of word embeddings and hidden states are 1024. In the decoding process, the beam size is 15. The supervised attention weight for the lemma matching aligner is 0.001, and for the ISI aligner is 0.01. The weight is tuned on the validation set by the BLEU score.

A.3 Text Summarization

The baseline model is based on an encoder-decoder structure with Transformer. It has 12 block layers with 1024 hidden sizes. The beam size of decoding is 5. The supervised attention weight is 0.1. The weight is tuned on the validation set by the BLEU score.

B Aligner for Relations in Graph-to-text Generation

There are seven different relations as mentioned in the main paper. A relation can be represented by different words in the target text. For example, "use" and "apply" both suggest the relation "USED-FOR". We build a corresponding keyword list (shown in Table 8) for each relation. In the source data, each relation is of the form "a-R-b", where "a" and "b" are two entities, and "R" is the relation type. To find the alignments, we first look for the cooccurrence of "a" and "b" in the abstract with the shortest distance between them. Then, we examine the words between "a" and "b" as well as four preceding words and align the words that appear in the corresponding keyword list to both the forward and backward directions of that relation.

C IDF Score in Text Summarization

The IDF score of a word w is computed as:

$$\mathrm{IDF}(w) = -\log \frac{1}{M} \sum_{i=1}^{M} \mathbb{I}(w \in X^{(i)}) \qquad (12)$$

where $\mathbb{I}(\cdot)$ is the indicator function, M is the number of training samples, and $X^{(i)}$ is the target sentence of the i-th sample in the training set.

In the training step, the IDF scores of target words are used to downweight the attention loss:

$$\text{Ł} = \mathrm{LOSS}(\mathbf{x}, \mathbf{y}) + \lambda \sum_{t} \big(\mathrm{IDF}(w_t) \cdot \Delta(\boldsymbol{\alpha}_t, \hat{\boldsymbol{\alpha}}_t)\big), \qquad (13)$$

where w_t is the t-th word in sentence $\mathbf{y}$.

In the loss function, the attention loss of a target word is scaled by its IDF score. The IDF scores are only applied in this experiment because the alignments of these high-frequency words are rare in previous experiments.

D Alignment Error Analysis

The performance of supervised attention is influenced by the quality of the aligner. There are three types of alignment errors.

- Missing: a target word is not aligned to any source item.
- Redundancy: a target word is aligned not only to the correct source items but also to irrelevant items.
- Mistake: a target word is only aligned to some irrelevant items but not aligned to correct source items.

Missing errors reduce the alignment coverage over the target sentences. They decrease the number of target words that receive attention supervision but will not make supervised attention worse than the unsupervised baseline.

Redundancy errors, which are related to the candidate set from the flexible alignments, are handled by our SCE loss. In the worst case, a target word is aligned to all the source items, and the attention loss of this word becomes 0, resulting in no supervision. Thus, redundancy errors will not make supervised attention worse than the unsupervised baseline either. A case study is provided in the appendix showing that our method is not confused by the redundancy errors.

We empirically analyze mistake errors in section 4.5. Although supervised attention is shown to be robust to mistake errors, an overly high error rate would prevent the attention mechanism from finding the correct alignments and make the supervised attention approaches worse than the baseline. Thus, reducing the mistake error rate is the most important when designing the aligner.

Abstract

The high subjectivity and costs inherent in peer reviewing have recently motivated the preliminary design of machine learning-based acceptance decision methods. However, such approaches are limited in that they: a) do not explore the usage of both the reviewer and area chair recommendations, b) do not explicitly model subjectivity on a per submission basis, and c) are not applicable in realistic settings, by assuming that review texts are available at test time, when these are exactly the inputs that should be considered to be missing in this application. We propose to utilise methods that model the aleatory uncertainty of the submissions, while also exploring different loss importance interpolations between area chair and reviewers' recommendations. We also propose a modality hallucination approach to impute review representations at test time, providing the first realistic evaluation framework for this challenging task.

1 Introduction

An analysis (Langford and Guzdial, 2015) of the NeurIPS 2014 experiment shows that 60% of the selected accepted papers were rejected by a second, independent review committee. Such significant reviewer disagreement makes the task of the area chair harder, and may even invite questioning of their decision. Software tools have been piloted in an effort to aid the human reviewers with a computational recommendation on aspects like absence of bias and proper statistical reporting in scientific submissions (Sizo et al., 2019).

Natural Language Understanding (NLU) could also offer decision *support* to the area chair, as argued in (Ghosal et al., 2019; Stappen et al., 2020). Such systems jointly model the entire or part of the article and one (Kang et al., 2018; Wang and Wan, 2018; Ghosal et al., 2019), or a variable number of potentially contradicting reviews (Stappen et al., 2020). We adopt the latter, review-aggregating approach, that resembles the editorial process more.

1.1 Contributions

In this short paper, we offer solutions to three particularities of this task that the above approaches do not address: a) Often, the recommendations given by the area chair and the reviewers are in disagreement. Whereas previous studies have used either the former (Kang et al., 2018; Wang and Wan, 2018; Ghosal et al., 2019) or a soft label average of the latter (Stappen et al., 2020) for supervision, we show that both signals comprise complementary information. b) Whereas soft labels de-emphasise subjective articles with disagreeing reviews during training (Stappen et al., 2020), we manage to outperform the latter study by explicitly modelling *aleatory uncertainty* as an auxiliary prediction task. c) A model that aims to support the editorial decision process should only assume the availability of human review text during training, and be able to make recommendations in their absence. Inspired by missing modality hallucination methods (Hoffman et al., 2016; Tang et al.; Pérez et al., 2020)), we propose a *realistic* system that uses all available data for training, but imputes review representations at test time based on the abstract text.

1.2 Purpose & Ethical Statement

We sincerely believe that human peer reviews should continue to be the main component of the paper acceptance selection process, and this work in no way attempts to replace the human reviewers; instead, we believe an NLU model can serve as an additional reviewer, aiding an area chair's decision-making process by slot-filling a missing reviewer, or providing a data-driven, tie-breaking perspective to the editor in cases of borderline reviews. The motivation behind this proposal is that NLU models trained on large-scale data, can learn to robustly

August 1–6, 2021.

cancel out individual human biases – in a similar way neural networks are robust to non-systematic label noise (Rolnick et al., 2017). Admittedly, such a model can still learn and reflect systematic biases, but we leave an approach to this problem by means of methods that learn with biased data (Kim et al., 2019) for future work.

2 Related work

Kang et al. (2018) compiled the PeerRead dataset of submissions, and proposed NLU baselines for binary acceptance decision and score prediction such as novelty and technical correctness. Wang and Wan (2018) explored the acceptance task by modelling the abstract via a memory mechanism (Weston et al., 2015), along with one review. Ghosal et al. (2019) improved performance on the PeerRead dataset by utilising sentiment information using the VADER tool (Hutto and Gilbert, 2014) and universal sentence embeddings (Cer et al., 2018). Unfortunately, PeerRead is imbalanced in that the NeurIPS rejected submissions are not included, despite the fact that 90% of the accepted submissions with reviews in PeerRead are from NeurIPS. Furthermore, around 80% of the submissions are from arxiv, thus having no reviews attached to them.

Stappen et al. (2020) worked on the largest such dataset – the Interspeech 2019 submission corpus – and fused the variable number of text reviews per submission. On incorporating reviewer disagreement information, they showed the simple label average to be better than the adapted version proposed in (Ando et al., 2018), and also approached the score prediction tasks via deep quantile regression (Rodrigues and Pereira, 2020). Direct modelling of a label disagreement value, instead of using soft labels, has been utilised in areas such as affective computing (Han et al., 2017) and medical image modelling (Raghu et al., 2019). Alternatively, Kendall and Gal (2017) devised a method for aleatory uncertainty modelling that is learnt from the data, instead of requiring ground truth disagreement "labels". Both Han et al. (2017); Kendall and Gal (2017) have shown regularisation benefits of learnt uncertainty prediction.

3 Submission-level modelling

Following Wang and Wan (2018); Stappen et al. (2020), we focus on abstract x_i^{abs} and review texts $x_{i,r}^{rev}$ (numbering R_i) for the i-th submission, the acceptance classification labels given by the area chair y_i^{ac}, as well as by the reviewers $y_{i,r}^{rev}$. We use a model $\mathcal{M}$ that: a) learns abstract h_i^{abs} and review h_i^{rev} representations using corresponding *modules*, b) fuses the aforementioned into a submission representation h_i^{sub}, and generates the class probability distribution $\hat{y}_i$ via a *prediction module* and softmax. We then calculate the cross entropy (CE) loss with the *true* probability distribution y_i^{true}:

$$\mathcal{L}_{pred} = CE(\hat{y}_i, y_i^{true}). \tag{1}$$

The most straightforward way to do this is by using a *hard label*, i. e., assuming $y_i^{true} \equiv y_i^{ac}$, with all the probability concentrated at the final recommendation given by the area chair. This way, however, we withhold information about the reviewer uncertainty for the particular submission. Stappen et al. (2020) have successfully used the simple *soft label*:

$$y_i^{true} \equiv \frac{1}{R_i} \sum_{r=1}^{R_i} y_{i,r}^{rev}. \tag{2}$$

The value of soft labels becomes clear when one considers that, in their absence, true acceptance probabilities of .51 and .89 would receive the same treatment. Occasionaly, the area chair may disagree with the reviewers' aggregate decision, which motivates the interpolation of the two factors:

$$\mathcal{L}_{pred} = \lambda^{soft} \mathcal{L}_{pred}^{soft} + \lambda^{hard} \mathcal{L}_{pred}^{hard}, \tag{3}$$

where $\mathcal{L}_{pred}^{*}$, λ_* refers to prediction loss and regularisation parameter for either hard or soft labels.

3.1 Modelling recommendation subjectivity

We add a second "head" in our prediction module that outputs a predictive uncertainty estimate $\hat{\sigma}_i$. We now require a supervision signal to train it, either by: a) treating label disagreement as ground truth uncertainty (**GTU**), or b) learning a heteroscedastic loss attenuation score (**HLA**). Inspired by (Han et al., 2017; Raghu et al., 2019), we define our approach to GTU as a multi-task loss:

$$\mathcal{L}_{pred}^{GTU} = \gamma^{pred} \mathcal{L}_{pred} + \gamma^{unc} MSE(\hat{\sigma}_i, \sigma_i), \tag{4}$$

where σ_i is the standard deviation among reviewer recommendations; MSE is mean squared error.

For HLA we use the method proposed in (Kendall and Gal, 2017), where $\hat{\sigma}_i$ is the standard deviation of a normal distribution centred at the mean denoted by the main head logits. By sampling T logits, and calculating a corresponding

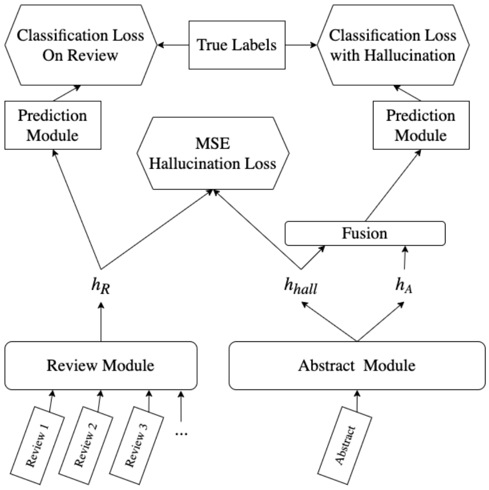

Figure 1: The peer review machine support system, including the hallucination mechanism. In a first training stage, only the *Classification Loss on Review* is used, to learn review representations. In the second training stage, the *MSE Hallucination Loss* and the *Classification Loss with Hallucination* are used.

class distribution $\hat{y}_i^t$, the loss function becomes:

$$\mathcal{L}_{pred}^{HLA} = \frac{1}{T}\sum_{t=1}^{T} CE(\hat{y}_i^t, y_i^{true}). \quad (5)$$

A larger $\hat{\sigma}_i$ relaxes the loss value for a sample that is difficult to predict correctly.

3.2 Imputing reviews at test time

Figure 1 depicts an overview of our architecture. Inspired by modality hallucination studies (Hoffman et al., 2016; Pérez et al., 2020), we use the abstract module to predict both the abstract h_i^{abs} and a review hallucination h_i^{hall} representation; *we do not generate review text*. In the first training stage, we train a model to predict based *only* on the review texts to learn meaningful h_i^{rev} representations. In the second stage, we use the true h_i^{rev} only as an auxiliary supervision target for training the h_i^{hall} representations by minimising MSE. Thus, we avoid *teacher forcing* (Bengio et al., 2015) by training the model to predict based only on the hallucinated representations, also available at test-time. The total loss, then, is:

$$\mathcal{L}_{hall} = \zeta^{hall} MSE(h_i^{rev}, h_i^{hall}) + \zeta^{pred}\mathcal{L}_{pred}. \quad (6)$$

4 Experiments

Small available dataset size is a limitation known to the community working on this domain (Kang et al., 2018; Ghosal et al., 2019) – we use the largest database of its kind (Stappen et al., 2020), i. e., the 2 179 preprocessed academic submissions, 5 842 reviews, with corresponding acceptance decisions and reviewer scores from the submission system of Interspeech 2019, shared with us by the technical chairs of the conference. After data cleaning and removal of corrupt entries, the accepted and rejected classes are well-balanced: 50.2 % acceptances, and 49.8 % rejections. The dataset is shuffled and split into 80-10-10 train-validation-test set percentages. We monitor the validation performance in terms of Macro-averaged F1 score, and also report the Macro-averaged Area Under Receiver Operator Characteristic (AU-ROC), averaged across 20 trials. We use the Adam optimiser (Kingma and Ba, 2014) with learning rate of 1e-3, and represent words using FastText (Bojanowski et al., 2017). Our abstract and review modules comprise a stacked 1D convolutional network with kernel sizes 4-4, interleaved by max pooling with rates 2-2, followed by a recurrent layer with gated recurrent unit cell and 100 hidden units, and attentional sequence pooling. The prediction module consists of two dense layers of 50-2 units, with a ReLu activation between them.

4.1 To model the reviewer or the area chair?

The interpolation weights λ^{soft}, λ^{hard} for the prediction error (cf. Eq. 3) are dataset-based and should be set based on validation performance. We experiment with a grid, ranging from $[1.0, 0.0]$ to $[0.0, 1.0]$ using a step of 0.2. $\lambda^{soft} \equiv 0.0$ *denotes the simple hard label case.* The results using the GTU loss are summarised in Table 1.

We find that the area chair and the reviewers' recommendations carry *complementary* information, and the best results of this study are at $\lambda^{soft} \equiv 0.8$. Interestingly, the agreement/accuracy between the editorial labels and the reviewer soft averages (rounded to 0 or 1) is 78.901%. The disagreements occur on close-to-borderline papers, in which cases the additional supervision is the most informative.

4.2 Are soft labels enough?

A comparison among the different loss functions, without hallucination, is summarised in Table 2. We report the best soft loss interpolation per case.

λ^{soft}	Metric	No Review		With Review	
		Mean	±	Mean	±
0.0	AU-ROC	.589	.026	.683	.065
	F1	.559	.019	.625	.061
0.2	AU-ROC	.590	.021	.724	.031
	F1	.558	.023	.651	.030
0.4	AU-ROC	**.608**	.027	.750	.029
	F1	**.565**	.033	.673	.030
0.6	AU-ROC	.605	.026	.745	.050
	F1	.553	.027	.668	.040
0.8	AU-ROC	.601	.034	**.776**	.044
	F1	.512	.066	**.694**	.043
1.0	AU-ROC	.564	.047	.730	.084
	F1	.396	.102	.629	.108

Table 1: Results with **GTU**, for classification with and without reviews, for different relative weightings or (soft) reviewer ratings / (hard) editorial decisions.

Loss	Metric	No Review		With Review	
		Mean	±	Mean	±
BL	AU-ROC	-	-	.550	.130
	F1	-	-	.652	.100
Soft	AU-ROC	.597	.022	.772	.029
	F1	.558	.024	.683	.024
GTU	AU-ROC	**.608**	.027	**.776**	.044
	F1	**.565**	.033	**.694**	.043
HLA	AU-ROC	.578	.044	**.776**	.020
	F1	.407	.082	*.688*	.020

Table 2: Results on using the abstract with or without the reviews, using different kinds of losses. **BL** denotes the baseline by Stappen et al. (2020).

In the case of *GTU* we found that the choice of $\gamma^{unc} \equiv \gamma^{pred} \equiv 0.5$ works best. The additional complexity of explicit uncertainty modelling is shown to be beneficial when compared to the simple soft labels, and GTU is better than the self-learnt uncertainty method HLA. Our model implementation with soft-hard loss mixing is also shown to greatly outperform a baseline (**BL**), i. e., the best result found in (Stappen et al., 2020).

We also performed statistical significance testing, using Welch's unequal variances t-test. No significance was found in improvement brought by uncertainty-aware methods compared to hard labels in the abstract-only experiments. However, GTU with hallucinated review representations is significantly better than abstract-only with $p < 0.1$ for AU-ROC and $p < 0.05$ for F1, and HLA with $p < 0.05$ for both measures. In the experiments using both abstract and reviews, the simple soft labels as well as HLA are both significantly better than hard labels in terms of AU-ROC with $p < 0.05$. GTU was significantly better than hard labels with $p < 0.1$ for F1 and $p < 0.05$ for AU-ROC.

Loss	Metric	Abstract		Hallucination	
		Mean	±	Mean	±
Hard	AU-ROC	.589	.026	**.592**	.022
	F1	.559	.019	**.562**	.024
Soft	AU-ROC	.611	.035	**.612**	.029
	F1	.535	.030	**.544**	.028
GTU	AU-ROC	.601	.025	**.608**	.030
	F1	.512	.054	**.532**	.076
HLA	AU-ROC	.557	.034	**.636**	.033
	F1	.358	.042	**.575**	.091

Table 3: We report the review hallucination results; for the uncertainty-aware methods, we used $\lambda^{soft} \equiv 0.8$.

4.3 Can we impute reviews?

Table 3 summarises the improvement brought by hallucinated reviews over the abstract-only case. Even though we only report a specific hard-soft interpolation weight $\lambda \equiv 0.8$, we observe this improvement universally. The HLA method with hallucination achieves both the best performance in this experiment, and the largest relative improvement (t-test, $p < .05$) upon the abstract-only case, as shown in Table 4. Lacking the true reviews, we have high label variance for the same abstract input, i. e., high aleatory uncertainty. HLA (Kendall and Gal, 2017) is designed for such cases, and guides the learning of hallucinated review representations through regularisation, allowing for a significant fraction of the performance gap to be covered. Hard-labels with hallucination is the method that performs relatively closest to its ceiling performance, but this can be explained by the ceiling being comparatively low in the hard-labels case.

The additional label uncertainty information, whether explicit or learnt, informs not just the classification capacity of the model, but also its ability to generate review representations. These hallucinated representations should be placed in embedding space such that they inform the model regarding the label, however not in an overconfident manner, given that the actual reviews are missing – this is exactly where knowledge of uncertainty contributes. In terms of a final method recommendation: we recommend the learnt attenuation based HLA, due to its better performance along with modality hallucination and the fact that it does not require the presence of multiple reviewer recommendations even at training-time.

4.4 Can we learn model disagreement?

The Pearson Correlation Coefficient (PCC) between the predicted uncertainty and the standard deviation of reviewer recommendations is .25 and

Loss	Metric	+ Relative	- Relative
Hard	AU-ROC	+0.5	-13.3
	F1	+0.5	-10.1
Soft	AU-ROC	+0.2	-19.7
	F1	+1.7	-19.8
GTU	AU-ROC	+1.2	-21.5
	F1	+3.8	-23.3
HLA	AU-ROC	+12.4	-17.9
	F1	+37.8	-16.4

Table 4: Relative improvements (in %) brought by hallucinated reviews compared to using only the abstract, and relative reductions compared to the performance ceiling in the case the reviews are available at test time. In cases where the true reviews cannot be assumed to be present in test/deployment, our hallucination approach allows for improvement of results compared to excluding reviews altogether.

.08 for GTU and HLA respectively in the abstract plus review case. The former indeed learns on actual disagreement labels, although high uncertainty prediction fidelity may not be necessary for high predictive performance, shown by the competitive HLA. When using only abstracts, PCC drops to .08 and .04 respectively, whereas by using hallucination we observe .08 and .05, indicating that the true review representations are required for good uncertainty prediction.

5 Conclusion

We have proposed a machine learning framework for automatic peer review support that makes better use of the available information, and is also realistic with respect to the limitations set by the task[1]. We have found that the the area chair and reviewer recommendations comprise independent supervision signals that should be used *in conjunction* to train the system. Furthermore, in order to relax the penalty for mispredicting subjective submissions, it is not enough to use a simple soft label average of the reviewer recommendations; one has to directly model an aleatory uncertainty score as an auxiliary task, either using ground truth "uncertainty labels", or through learnt attenuation of the loss. Finally, we utilise review representation hallucinations at test-time to best utilise available review texts in a realistic manner, and find that this approach works well with and *benefits* from the regularisation introduced by direct uncertainty modelling.

Even with the application of our review representation hallucination, the performance gap from the ceiling set by using the true review representations is still high. We intend to approach the task via self-supervision methods (He et al., 2020) that focus on multimodal data (Nagrani et al., 2020). Requesting additional reviewers based on inference-time uncertainty, similar to (Raghu et al., 2019), is another promising future work step, as is an analysis of the uncertainties predicted by our model using the different losses. Finally, we have shown in our study that only a representation of the abstract is required as the input both for acceptance and hallucination modelling. Since previous work (Ghosal et al., 2019) has shown that modelling an article based on the entire paper can be beneficial, we also intend to explore the impact of using such a highly expressive article representation for hallucinating review representations.

Automatically Select Emotion for Response via Personality-affected Emotion Transition

Abstract

To provide consistent emotional interaction with users, dialog systems should be capable to automatically select appropriate emotions for responses like humans. However, most existing works focus on rendering specified emotions in responses or empathetically respond to the emotion of users, yet the individual difference in emotion expression is overlooked. This may lead to inconsistent emotional expressions and disinterest users. To tackle this issue, we propose to equip the dialog system with personality and enable it to automatically select emotions in responses by simulating the emotion transition of humans in conversation. In detail, the emotion of the dialog system is transitioned from its preceding emotion in context. The transition is triggered by the preceding dialog context and affected by the specified personality trait. To achieve this, we first model the emotion transition in the dialog system as the variation between the preceding emotion and the response emotion in the **V**alence-**A**rousal-**D**ominance (VAD) emotion space. Then, we design neural networks to encode the preceding dialog context and the specified personality traits to compose the variation. Finally, the emotion for response is selected from the sum of the preceding emotion and the variation. We construct a dialog dataset with emotion and personality labels and conduct emotion prediction tasks for evaluation. Experimental results validate the effectiveness of the personality-affected emotion transition.[1].

1 Introduction

Emotional intelligence can be considered a mental ability to reason validly with emotional information, and the action of emotions to enhance thought (Mayer, 2004). Hence, to create dialog systems with emotional intelligence during communication, it is necessary to enable the machine to understand the emotion of users, select appropriate response emotions and express in conversation.

Existing works either focus on rendering specified emotions in responses (Zhou et al., 2018; Colombo et al., 2019), or understanding the emotion of users and respond empathetically (Zandie and Mahoor, 2020; Zhong et al., 2020; Lin et al., 2019); but how to automatically select the emotion for response is seldom discussed. Wei et al. (2019) proposes to learn appropriate emotional responses from massive anonymous online dialogues. However, trained on conversations from different speakers, the dialog system ignores the individual difference of expressing emotions. This may lead to inconsistent emotional interactions and disinterest users as they may feel they are still talking to rigid machines.

In a dialog system, automatically selecting the emotion for response is to decide an emotion to be expressed facilitating the emotional response generation. Emotion selection can be modeled as the emotion transition (Thornton and Tamir, 2017), which refers to how the preceding emotion changes to the next, of the dialog system reacting to the dialog context. To achieve it like humans, it requires long-term patterns of thought, and behavior associated with an individual (Ball, 2000). Mehrabian (1996a) shows that the personality, *e.g.*, the big-five personality model (Costa and McCrae, 1992) also can be represented as temperament in the **V**alence-**A**rousal-**D**ominance (VAD) space for emotions (Mehrabian, 1996b).[2] The finding suggests that different personalities make different impacts on emotional expressions. Inspired by these works, we propose a personality-affected emotion

---

[1] Our dataset is released at: github.com/preke/PELD

[2] It is Pleasure-Arousability-Dominance (PAD) in the original paper, PAD and VAD share the same meaning in the context of text understanding, we will use VAD for consistency henceforth.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 5010–5020
August 1–6, 2021. ©2021 Association for Computational Linguistics

transition model to endow personality to the dialog system, enabling it to select emotions that react to the dialog context affected by its given personality.

In our method, we model the emotion transition of the dialog system as the variation in the VAD space from its preceding emotion to the next emotion in the response to users. We first obtain the preceding emotion of the dialog system from the dialog context and project it into the VAD space as an emotion vector. Simultaneously, we endow a personality trait, a 5-dimension vector representing the strength of each dimension in the big-five personality traits, to the dialog system. Then, we design neural networks to encode the dialog context and the personality traits into the VAD space to compose the variation of emotion. Finally, the emotion for response is selected based on the sum of the preceding emotion and the variation.

To facilitate related researches, we construct the **P**ersonality **E**motion**L**ines **D**ataset (PELD), which includes 6,510 dialogue triples of daily conversations with emotion labels and annotated personality traits. The emotion labels and personality annotations are adopted from other researches (Poria et al., 2018; Zahiri and Choi, 2017; Jiang et al., 2019) analyzing the script of a famous TV series *Friends*[3]. We conduct emotion prediction tasks on the PELD dataset to evaluate the effectiveness of our method. The results suggest that the personality-affected emotion transition does contribute to better accuracy in emotion selection. To summary, our contributions are as follows:

- We raise the problem of automatically select the emotion for response in conversation and propose a new perspective to solve it through personality-affected emotion transition.
- We construct a dialog script dataset with emotion and personality labels and analyze the patterns of emotion transitions in our dataset to facilitate related researches.
- We evaluate the effectiveness of our proposed method on emotion prediction tasks and analyze the effects of personality and emotion transition respectively.

2 Related Works

Our research is related to the emotional dialog systems, and the personality influence on emotion expression in psychology and Human-Computer Interaction (HCI). So, we review existing works in the two aspects as follows.

2.1 Emotional Dialog Systems

The concept of the emotional dialog system first occurred in (Colby, 1975), where a rule-based emotion simulation chatbot was proposed. Microsoft introduced the Xiaoice (Zhou et al., 2020), an empathetic social chatbot that is able to recognize users' emotional needs, in 2014. Related researches become popular recently since Zhou et al. (2018) proposed the Emotional Chatting Machine to exploit the deep learning approach in building a large-scale emotionally aware conversational bot. Most existing works focus on incorporating specified emotion factors into neural response generation. Shantala et al. (2018) trains emotional embeddings based on context and then integrated them into response generation. Colombo et al. (2019) controls the emotional response generation with both categorical emotion representations and continuous word representations in VAD space (Mohammad, 2018). Moreover, Asghar et al. (2018) proposes an affectively diverse beam search for decoding. Besides, reinforcement learning is also adopted to encourage response generation models to render specified emotions. Li et al. (2019) combines reinforcement learning with emotional editing constraints to generate meaningful and customizable emotional replies. (Sun et al., 2018) also uses an emotion tag to partially rewarding the model to express specified emotion.

However, it is impractical to always specify response emotions for dialog systems in real application scenarios. To simulate the emotional interaction among humans, Wei et al. (2019) designs an emotion selector to learn the proper emotion for responses from massive dialogue pairs. But the emotional expression is subjective, for the same post, different users may have different emotions in their responses. So, the pattern learned only from online dialogues ignores the user information and turns to be impractical.

2.2 Personality Effects on Emotions

Emotion is a complex psychological experience of an individual's state of mind as interacting with people or environmental influences (Han et al., 2012). The **P**leasure-**A**rousal-**D**ominance (PAD) (Mehrabian, 1996b) or **V**alence-**A**rousal-**D**ominance (VAD) emotion temperament model

---

[3] https://en.wikipedia.org/wiki/Friends

shows three nearly orthogonal dimensions providing a comprehensive description of emotional states. Based on this, several psychologists studied the relationship between human emotional factors and personality factors. However, most of them are rule-based models (Johns and Silverman, 2001) and probabilistic models (André et al., 1999). Mehrabian (1996a) utilized the five factors of personality (Costa and McCrae, 1992) to represent the VAD temperament model through linear regression analysis. This finding is widely used to design robots having non-verbal emotional interaction with users (Han et al., 2012; Masuyama et al., 2018), where the pre-defined personalities of robots affect their propensity of simulated emotion transitions.

To integrate the analysis above into Artificial Intelligence, some researchers in HCI borrow the idea and design facial emotional expressions for humanoid robots. Ball (2000) utilizes models of emotions and personality encoded as Bayesian networks to generate empathetic behaviors or speech responses to users in conversation. Han et al. (2012) employed five factors of personality to a 2D (pleasure-arousal) scaling model to represent a robotic emotional model. Masuyama et al. (2018) introduces an emotion-affected associative memory model for robots expressing emotions. While in NLP, though the VAD space is adopted to model emotions in some researches (Mohammad, 2018; Colombo et al., 2019; Asghar et al., 2018), the personality influence on emotion in dialogues is still an open problem.

3 Methodology

3.1 Problem Definition

We research on enabling the dialog system to automatically select emotions for response through the personality-affected emotion transition.

Formally, a dyadic emotional conversation between the user and the dialog system contains the dialog context $C = \{U_1, U_2, ..., U_{n-1}\}$ including all the preceding $n - 1$ utterances from both the user and the dialog system, the preceding emotion E_i expressed in $U_i \in C$ which is the last utterance from the dialog system, and the response emotion E_r for the dialog system to facilitate generating the next emotional response U_n to the user. We specify a personality trait P_n to the dialog system and enable it to select response emotion E_r through the personality-affected emotion transition model F_{ET}:

$$E_r = F_{ET}(E_i|P_n, C) \tag{1}$$

where E_r is transitioned from E_i. The transition is triggered by the preceding dialog context C and affected by the specified personality trait P_n. In the following content, we will introduce how we model this process in detail.

3.2 Preliminaries

3.2.1 Emotions in the VAD space

Assuming in the problem above, emotions in all emotional utterances can be categorized into the six basic emotions: *Anger*, *Disgust*, *Fear*, *Joy*, *Sadness*, and *Surprise* (Ekman and Davidson, 1994). We project the basic emotions into the Valence-Arousal-Dominance (VAD) space as Table 1 refer to the analysis result in (Russell and Mehrabian, 1977)[4]. The VAD space indicates emotion intensity in three different dimensions, where the valence measures the positivity/negativity, arousal the excitement/calmness, and dominance the powerfulness/weakness. As for the utterances with no explicit emotion, we use the *Neutral* with (0.00, 0.00, 0.00) as the VAD vector.

Basic Emotions	(Valence, Arousal, Dominance)
Anger	(-0.51, 0.59, 0.25)
Disgust	(-0.60, 0.35, 0.11)
Fear	(-0.62, 0.82, -0.43)
Joy	(0.81, 0.51, 0.46)
Neutral	(0.00, 0.00, 0.00)
Sadness	(-0.63, -0.27, -0.33)
Surprise	(0.40, 0.67, -0.13)

Table 1: Emotions in the VAD Space.

3.2.2 Personalities in the VAD space

Meanwhile, the big-five personality traits (OCEAN, shown in Table 2) are widely used for psychological analysis. Mehrabian (1996a) proposed a temperament model shown in Equation 2 derived through linear regression to show the VAD scales of personality traits, where O, C, E, A, N are the strength of the big-five personality traits.

---

[4] *fear* and *Joy* correspond to *Terrified* and *Happy* in the reference table.

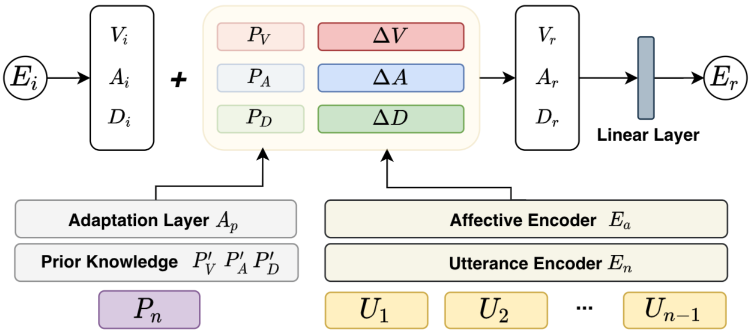

Figure 1: The Model Illustration

$$\begin{aligned} P_V &= 0.21E + 0.59A + 0.19N \\ P_A &= 0.15O + 0.30A - 0.57N \\ P_D &= 0.25O + 0.17C + 0.60E - 0.32A \end{aligned} \tag{2}$$

3.3 Personality-affected Emotion Transition

Based on the problem definition and the preliminaries above, we design the Personality-affected Emotion Transition model as illustrated in Figure 1. Our model mainly include three modules: the personality effect on emotions in the left lower part, the context encoding in the right lower part, and the emotion transition in the top half in Figure 1. We will introduce these three modules in detail as follow.

3.3.1 Personality Effect on Emotions

In our model, the personality of the dialog system is specified as a 5-dimensional vector $P_n = [O, C, E, A, N]$ representing the strength in Openness, Conscientiousness, Extraversion, Agreeableness, and Neuroticism, respectively.

The temperament of personality in the VAD space (shown in Equation 2) is widely used as weighting parameters for emotion transition of robots in HCI works (Han et al., 2012; Masuyama et al., 2018). However, the numeric coefficients in Equation 2 are summarized from analysis of questionnaire results from 72 participants (Mehrabian, 1996a), which are not suitable to directly adopted as hyper-parameters in the model design. Hence, we choose to adopt the analysis results in Equation 2 as prior knowledge and learn suitable coefficients for personality by neural networks. First, we still calculate P'_V, P'_A, P'_D from the personality P_n by Equation 2; then we use P'_V, P'_A, P'_D as initialized input for an adaptation layer A_p to learn the weighting parameters P_V, P_A, P_D that suitable for the training data.

Factor	Description
Openness	Openminded, imaginative, and sensitive.
Conscientiousness	Scrupulous, well-organized.
Extraversion	The tendency to experience positive emotions.
Agreeableness	Trusting, sympathetic, and cooperative.
Neuroticism	The tendency to experience psychological distress.

Table 2: The OCEAN personality traits and description (Costa and McCrae, 1992)

3.3.2 Context Encoding

The dialog context acts as a set of parameters that may influence a person to speak an utterance while expressing a certain emotion (Poria et al., 2018). In the VAD space, the emotion transition is regarded as the variation from one point (the preceding emotion) to another point (the next emotion). Thus, we generate the emotion transition variations $\Delta V, \Delta A, \Delta D$ from the semantic representations of the preceding dialog context C.

$$\begin{aligned} &R_c = E_n(U_1) \oplus E_n(U_2) ... \oplus E_n(U_{n-1}) \\ &\Delta V, \Delta A, \Delta D = E_a(R_c) \end{aligned} \tag{3}$$

We fine-tune the pre-trained RoBERTa[5] (Liu et al., 2019) encoder, a famous pre-trained language model whose performance is widely validated in many natural language understanding tasks, to first extract the semantic representations $E_n(U_1), ..., E_n(U_{n-1})$ of all $n-1$ utterances in C. Then, we concatenate the semantic representations of utterances to obtain the overall context semantics R_c. Finally, $\Delta V, \Delta A, \Delta D$ are calculated by feeding R_c into an affective encoder E_a, which extract the affective information from R_c in the aspect of V, A, D, respectively.

---

[5] Here we adopt the pre-trained RoBERTa-base model.

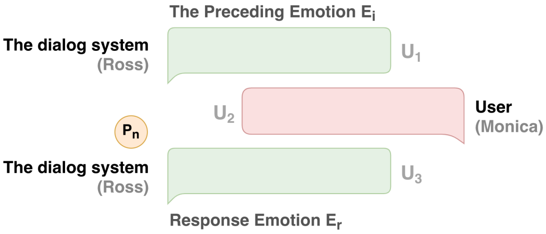

Figure 2: A triple example in PELD. The dyadic conversation between Ross and Monica (two main roles in *Friends*, P_n is the personality of Ross. The dialog system is set as Ross and talk with the user set as Monica in this example.

3.3.3 Emotion Transition

After we obtain the weighting parameters P_V, P_A, P_D and the emotion transition variation $\Delta V, \Delta A, \Delta D$, the emotion for response is generated by the sum of the VAD vectors of the preceding emotion and the weighted variation, as shown in Equation 4.

$$\begin{aligned} V_r &= V_i + P_V \cdot \Delta V \\ A_r &= A_i + P_A \cdot \Delta A \\ D_r &= D_i + P_D \cdot \Delta D \\ E_r &= F_c(V_r, A_r, D_r) \end{aligned} \tag{4}$$

where the V_i, A_i, D_i are the VAD vectors of E_i, and the V_r, A_r, D_r are the emotion transition results in the VAD space. To alleviate the errors of using the numeric value in calculated VAD vectors, we add a linear layer F_c to transform V_r, A_r, D_r into a probability distribution on the discrete emotion categories. The output E_r is the emotion with the largest probability.

4 The PELD Dataset

4.1 Dataset Construction & Statistics

To facilitate related researches, we construct the **P**ersonality **E**motion**L**ines **D**ataset (**PELD**), an emotional dialog dataset with personality traits for speakers. As labeling online conversation on social media with speakers' personalities is time-consuming and may cause privacy issues, we turn to research on the dialogue script of a famous TV series *Friends*. This classic script is widely analyzed in many dialog researches (Li et al., 2016; Li and Choi, 2020; Jiang et al., 2019).

In PELD, each sample is represented as a dialog triple ($C = \{U_1, U_2, U_3\}, \{E_i, E_r\}, P_n$), shown in Figure 2) as a dyadic conversation. E_i and E_r are emotions expressed in U_1 and U_3, respectively. The utterances and their emotion labels are mainly adopted from the dialogues in the MELD (Poria et al., 2018) and the EmoryNLP dataset (Zahiri and Choi, 2017), two famous datasets analyzing emotional expressions in *Friends*. To keep consistency, each dialog triple in PELD is constructed within the same dialogue in the original datasets.

Roles	Personality Traits (O,C,E,A,N)
Chandler	[0.648, 0.375, 0.386, 0.58, 0.477]
Joey	[0.574, 0.614, 0.297, 0.545, 0.455]
Monica	[0.713, 0.457, 0.457, 0.66, 0.511]
Phoebe	[0.6, 0.48, 0.31, 0.46, 0.56]
Rachel	[0.635, 0.354, 0.521, 0.552, 0.469]
Ross	[0.722, 0.489, 0.6, 0.533, 0.356]

Table 3: Personalities of *Friends* main roles in PELD.

The personality traits in our dataset are adopted from the personality annotations in 711 different dialogues (Jiang et al., 2019). Refer to the annotations, a role may exhibit different aspects of its personality in different dialogues. We only keep the personality traits of the six main roles in *Friends* for confidence as these annotations are most frequent. For each of the main roles, we average their annotated personality traits in all the dialogues by $P_n = \frac{1}{K}\sum_{i=1}^{K} P_i$ for simplification, where K is the number of annotations. The averaged results are shown in Table 3.

We split the PELD into **Train**, **Valid**, and **Test** set with portion around 8:1:1. The total number of utterances in PELD (10,648) is less than the sum of the original MELD (13,708) and the EmoryNLP (9,489), as not all dialogues are suitable to construct triples including main roles. The overall statistics of the dataset is shown in Table 4.

Similar to existing emotional conversation datasets (Li et al., 2017; Busso et al., 2008), PELD also suffers the emotion imbalance issue. Utterances labeled as *Neutral* are the majority, while *Fear* and *Disgust* only take a small portion. Though it reflects the real emotion distribution in daily conversation, it also brings challenges to machine learning models to identify and generate emotions. We tried several automatic methods for data augmentation like synonym substitution, back-translation, or the EDA proposed in (Wei and Zou, 2019). But most of the synthetic samples are either odd or the same as the original samples. The

Basic Statistics	**Train**	**Valid**	**Test**	**Total**

Phoebe	782	87	103	972
Rachel	921	112	123	1156
Ross	928	87	108	1123

Table 4: Basic Statistics in PELD.

reason might be there are limited options for short sentences as utterances in conversation to replace synonyms, add or delete words.

Another way to alleviate the imbalance issue is to expand the granularity of emotion to sentiment. As mentioned in **3.2**, in the VAD space, the Valence dimension of emotions measures the positivity and negativity, we can categorize the emotions into sentiments according to the values of Valance; i.e., positive emotions: *Joy* and *Surprise*; negative emotions: *Anger*, *Disgust*, *Fear*, and *Sadness*. Thus, the distribution of sentiments in PELD is also shown in Table 4. Besides, dialog triples of six main roles (each triple corresponds to a main role with the personality trait) are averagely distributed in all train, valid, and test sets in PELD.

4.2 Emotion Transitions in PELD

After constructed PELD, we further explore the dataset in the aspect of emotion transitions. As the triples in PELD are constructed for analyzing the emotion transitions between E_i in U_1 and the E_r in U_3. Table 5 shows the emotion and sentiment distributions in the U_1 and U_3, respectively. Besides, we also count the sentiments of emotions in U_1 and U_3 denoted as S_1 and S_3. We can see that for both emotion and sentiment, the distributions in U_1 and U_3 are similar, which means the transition of emotions and sentiments are equitable in PELD triples. Besides, the proportions of all emotions and sentiments are also similar to the overall statistics of PELD, which suggests that the emotions and sentiments in PELD are also average distributed in the triples.

Since emotion transitions are affected by the personality traits as discussed above, we exhibit the emotion transition patterns for different roles with different personality traits in Figure 3. Although the emotion transitions are also correlated to the dialog context, we can still find patterns through these transition matrixes[6].

In general, among the six transition matrixes, all the first columns are in deeper colors, which indicates most transitions occur from other emotions to *Neutral* as it is the majority emotion in PELD. Besides, blocks with deeper color also more likely to occur around or in the diagonals of the transition matrixes; it suggests the preceding emotions tend to transition to the same or similar emotions. As for individual roles, 0.59 of the *Anger* from Rachel remains the same in dialog triples, while for other roles, most *Anger* emotions are transferred to *Neutral* and *Anger*. Besides, most *Surprise* from Ross transfers to the *Neutral*, *Joy*, and *Surprise*, but most *Surprise*s of the other five roles tend to transfer to only *Surprise* and *Neutral*.

Moreover, to highlight the individual differences of emotion transitions among the six main roles in detail, we also show the standard deviations (Std) of each row in the emotion transition matrixes of the six main roles, as shown in Figure 4. The red bar chart shows the Std of the infinite norms of rows in the emotion transition matrix, which indicates the diversity of the most probable emotions from the same emotion in emotion transfers of different roles. While the blue bar chart shows the Std of the L2-norms, which generally describes the difference in how different roles transfer from one emotion to other emotions.

Both charts show similar patterns of emotion transitions. *Anger*, *Surprise*, and *Disgust* vary the most in different roles, while people are more common when process *Neutral* and *Joy* emotions in

---

[6] Here, we analyze the personality-affected emotion transition based on roles rather than the numeric traits in Table 2 to avoid numeric observation errors.

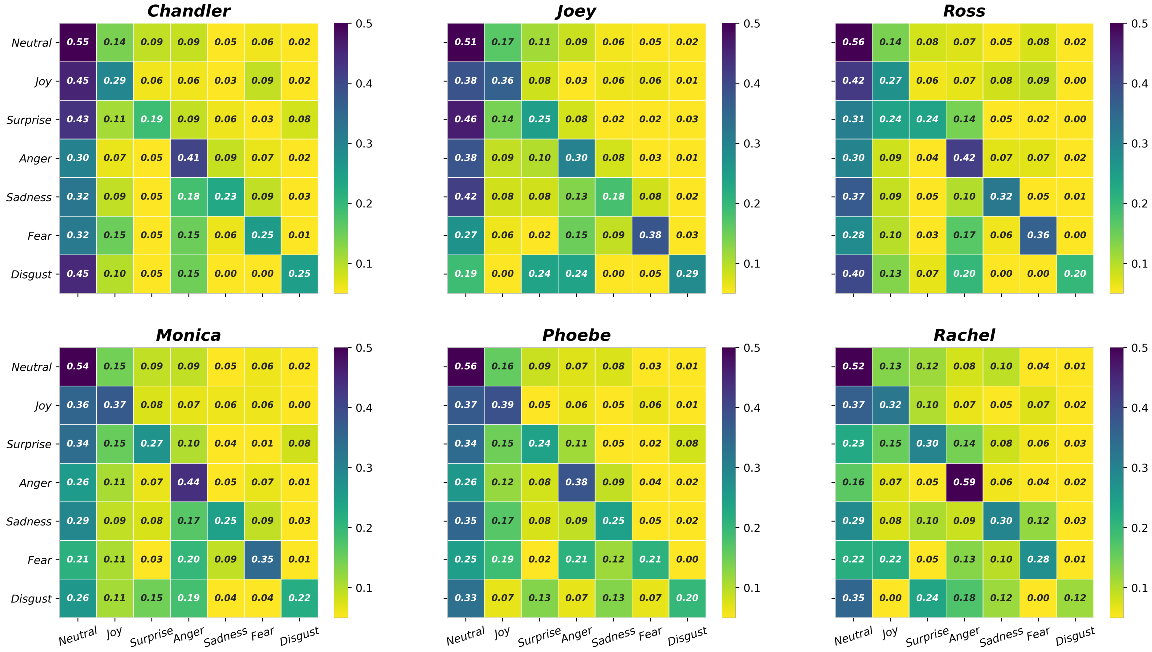

Figure 3: Emotion transition matrixes of the six main roles in PELD. Each row in a matrix shows the ratios of the current emotion E_i is transferred to the next emotion E_r.

conversation. Besides, negative emotions (*Anger*, *Sadness*, *Fear*, and *Disgust*) are relatively higher than positive emotions and *Neutral* on average. So, we can infer that the personality traits influence more in the emotion transfers from negative emotions.

5 Experiment

5.1 Evaluation Tasks

To validate the effectiveness of our proposed emotion generation model, we set two evaluation tasks: Emotion Prediction and Sentiment Prediction on PELD. Emotion Prediction requires the model to predict the emotion in the upcoming utterance based on the preceding dialog context in a dyadic conversation scenario; while Sentiment Prediction has the same setting except to predict the sentiment in the upcoming utterance.

For both tasks, we evaluate the prediction performance by F-scores of single emotion or sentiment. Besides, the overall performance is also measured from two aspects with the macro averaged (**m-avg**) and the weighted averaged (**w-avg**) F-scores. A higher m-avg indicates the model performs relatively better predicting all categories, while a higher w-avg indicates the model predicts emotions or sentiments with larger proportions in the dataset better.

Tri.Emos	**Neutral**	**Joy**	**Surprise**	**Anger**	**Sadness**	**Fear**	**Disgust**
E_i	2910	1242	597	751	438	457	115
E_r	2771	1123	634	858	493	487	144
Tri.Sentis	**Neutral**	**Positive**		**Negative**			
S_i	2910	1839		1761			
S_r	2771	1757		1982

5.2 Ablation Study Setting

Although plenty methods (Majumder et al., 2019; Ghosal et al., 2020, 2019) has been proposed to analyze emotions in dialogues of *Friends*, most of their targets are to recognize the emotions of utterances in conversation. Compared with emotion recognition, the problem setting of selecting emotion is different and it is more difficult to select the appropriate emotion in response without knowing the response content. So, instead of comparing with other emotion recognition models, we turn to conduct ablation studies to evaluate the effectiveness of different parts of our model design. The ablation study compares the performances of the following models:

RoBERTa: RoBERTa (Liu et al., 2019) is a famous pre-trained language model designed for natural language understanding. Its performance

Methods	Anger	Disgust	Fear	Joy	Neutral	Sadness	Surprise	m-avg	w-avg
RoBERTa	0.218	0.000	0.107	0.214	0.453	0.122	0.126	0.177	0.287
RoBERTa-P	0.178	0.000	0.047	**0.265**	0.517	0.110	0.053	0.167	0.352
PET-VAD	0.190	**0.081**	0.115	0.188	0.474	0.000	**0.179**	0.175	0.309
PET-CLS	**0.320**	0.070	**0.140**	0.198	**0.528**	**0.155**	0.098	**0.203**	**0.424**

Table 6: Results for Emotion Prediction.

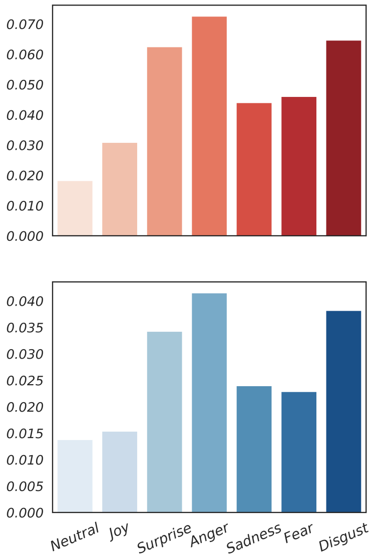

Figure 4: The standard deviations of the infinity norm (red) and the L2-norm (blue) of each row in emotion transition matrixes of the six main roles in PELD.

is widely validated in many downstream tasks. We here use pre-trained RoBERTa, corresponding to the E_n in our model, to encode the preceding dialog context to obtain the semantic representation as input, then directly predict the emotion for response through a classification head.

RoBERTa-P: We concatenate the personality vector of the speakers with the dialog context representation by RoBERTa as the feature, then predict the response emotion. This method is to evaluate whether personality influences the expression of emotions.

PET-VAD: As emotions can be represented by both discrete category labels or vectors in the VAD spaces. PET-VAD is set to compare the different usages of emotion VAD vectors in our model. During training, PET-VAD regressions the VAD vectors of target emotions by minimizing the Mean Squared Error (MSE) between generated vectors and the VAD vectors of ground truth emotions. The prediction output of PET-VAD is the closest neighbor emotions of generated VAD vectors measured by MSE.

PET-CLS: This is our method Personality-affected Emotion Transition with a classifier after obtaining the VAD vector of generated emotion. PET-CLS predicts emotions in the upcoming utterances as described in Section 3.

For RoBERTa, RoBERTa-P, and PET-CLS directly outputting discrete emotions, we adopt the Focal loss (Lin et al., 2017) to relieve the imbalanced emotion prediction.

6 Results and Analysis

In this section, we report and analyze the experimental results on the Test set of PELD in our ablation study. All results are chosen by the best performance on the Valid set within 50 epochs training.

6.1 Results for Emotion Prediction

The results on the Emotion Prediction task are reported in Table 6. First of all, as a seven-classes prediction task also suffered from the imbalance issue, the overall performance is moderately low, which also indicates the difficulty of the task. As for the averaged F-scores, PET-CLS improves both the w-avg and m-avg by a large margin from all other methods, which verifies our personality-affected emotion transition method.

In detail, all models perform better on emotions with larger portions (*Neutral* and *Joy*), as they are more probable to occur in the response emotion. Moreover, PET-VAD and PET-CLS achieve moderately higher F-score on the minority emotions (*Anger*, *Sadness*, *Disgust*, *Fear*, and *Surprise*), which shows that the emotion transition process is more important generating these minority emotions. It also verifies the finding in Section 4.2.

Methods	Negative	Neutral	Positive	m-avg	w-avg
RoBERTa	0.415	0.430	0.323	0.389	0.390
RoBERTa-P	0.401	**0.505**	0.176	0.361	0.430
PET-CLS	**0.492**	0.474	**0.327**	**0.431**	**0.445**

Table 7: Results for Sentiment Prediction.

On the other hand, although PET-VAD is based on the designed personality-affected emotion transition, most single emotion F-scores of PET-VAD are lower than RoBERTa or RoBERTa-P. We discuss the possible reasons as follows. One reason might be that the imbalance emotion issue cannot be alleviated in directly regression the emotion VAD vectors. Another reason might be that the value of emotion VAD vectors in Table 1 are estimated rather than precisely calculated, and the distance among different emotions in the theoretical VAD space is not similar to those in the emotion distribution in daily conversation.

6.2 Results for Sentiment Prediction

As predicting the emotions for the upcoming responses is difficult due to the multiple imbalanced categories, we also report the results on the Sentiment Prediction task in Table 7. Besides, different from the analysis above, which categorizes emotions by their portions in PELD, sentiment is another aspect of emotion analysis. As the sentiments are not directly described in the VAD spaces, we only report the results for RoBERTa, RoBERTa-P, and the PET-CLS. Besides, we only change the output size of PET-CLS from 7 (for emotions) to (3 for sentiments) and preserve the emotion transition process in this task.

In general, we can see that the prediction F-scores of sentiments are higher than emotion predictions. Besides, the prediction of negative emotions is much easier than predicting positive emotions in all three methods. It may because although the numbers of sentiments are similar, the categories of negative emotions (*Anger*, *Sadness*, *Fear*, and *Disgust*) are more than positive emotions (*Joy* and *Surprise*). Equipped with our model design, PET-CLS outperforms both RoBERTa and RoBERTa-P excepted for the neutral sentiment. It suggests that the personality-affected emotion transitions also facilitate sentiment prediction. However, only concatenating the personality vectors with context representation, RoBERTa-P improves the F-scores of Neutral but decreases the Positive and Negative. Hence, direct concatenation limits the effect of personality information in sentiment prediction.

7 Conclusion and Future Work

In this work, we raise the problem of automatically selecting the emotion for response considering the individual differences in conversation and propose a new perspective to solve it through personality-affected emotion transition. Besides, we construct a dialog script dataset PELD with emotion and personality labels to facilitate related researches. We also validate our personality-affected emotion transition model in emotion prediction experiments.

Facial expressions, voices, gestures, and environment information are also vital in emotional interaction, but they are not captured in the purely text-based dialog systems. Besides, as seen from statistics in PELD, the most common emotion in the dialog scripts is still Neutral. One possible reason is that other subtle affective information is not captured in the text. Therefore, our future works will continue to investigate the personality effects on emotions in the multi-modality scenario.

Highlight-Transformer: Leveraging Key Phrase Aware Attention to Improve Abstractive Multi-Document Summarization

Shuaiqi LIU, Jiannong Cao, Ruosong Yang, and Zhiyuan Wen
Department of Computing, The Hong Kong Polytechnic University
{cssqliu, csjcao, csryang, cszwen}@comp.polyu.edu.hk

Abstract

Abstractive multi-document summarization aims to generate a comprehensive summary covering salient content from multiple input documents. Compared with previous RNN-based models, the Transformer-based models employ the self-attention mechanism to capture the dependencies in input documents and can generate better summaries. Existing works have not considered key phrases in determining attention weights of self-attention. Consequently, some of the tokens within key phrases only receive small attention weights. It can affect completely encoding key phrases that convey the salient ideas of input documents. In this paper, we introduce the Highlight-Transformer, a model with the highlighting mechanism in the encoder to assign greater attention weights for the tokens within key phrases. We propose two structures of highlighting attention for each head and the multi-head highlighting attention. The experimental results on the Multi-News dataset show that our proposed model significantly outperforms the competitive baseline models.

1 Introduction

Abstractive Multi-Document Summarization (MDS) offers the challenge of generating a comprehensive summary of multiple related documents. It requires summarization models to capture the salient content from input documents. Compared with the previous RNN-based models for abstractive MDS, the Transformer-based models (Gehrmann et al., 2018; Liu et al., 2018; Liu and Lapata, 2019a; Li et al., 2020b) employ the self-attention mechanism to capture the dependencies in input documents, and they can generate better summaries.

Calculating attention weights is a crucial step in the self-attention mechanism. Input documents usually contain some key phrases that convey the salient ideas of input documents. However, existing works have not considered key phrases in determining attention weights of self-attention. Key phrases usually comprise multiple tokens, which should be highly related and serve as a complete grammatical unit in input documents. When testing Transformer-based models, we observe some of the tokens within key phrases only receive small attention weights, which can affect completely encoding key phrases and the salient ideas they convey.

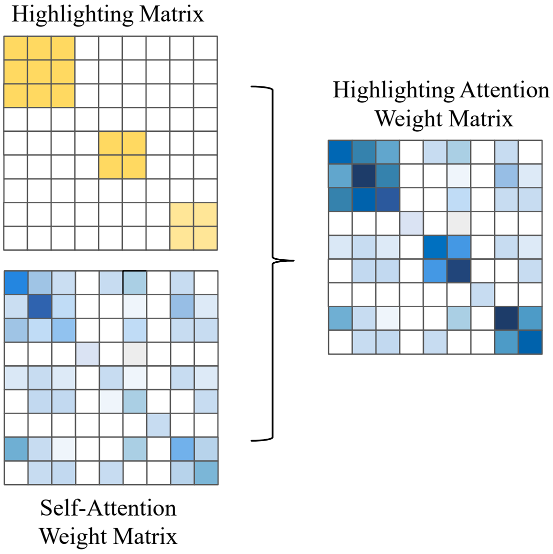

Figure 1: The highlighting mechanism assigns greater attention weights for tokens within key phrases indicated by the highlighting matrix.

In this paper, we propose the Highlight-Transformer, an abstractive summarization model with the highlighting mechanism in the encoder. As depicted in Figure 1, the highlighting mechanism assigns greater attention weights for tokens within key phrases. Furthermore, the highlighting mechanism mainly comprises three parts: the highlighting matrix, the highlighting attention, and the multi-head highlighting attention.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 5021–5027
August 1–6, 2021.

Our work is inspired by previous studies in education and psychology that indicate key phrases are important for people to understand (Rello et al., 2014; Hargreaves and Crabb, 2016) and summarize (Benzer et al., 2016; Chou, 2012) the given documents. Highlighting key phrases can help people with dyslexia improve comprehension (Rello et al., 2014; Hargreaves and Crabb, 2016). Their findings can be instructive to improve the self-attention mechanism.

We build a highlighting matrix for each input token sequence to indicate key phrases' positions in the attention weight matrix and phrases' importance values. We propose two structures of highlighting attention for each head to adjust attention weights according to the phrase importance. After comparing the effects of adopting the highlighting attention in the different numbers of heads and layers, we discover that adopting it in a subset of heads surpass adopting it in all heads. Experimental results on the Multi-News dataset (Fabbri et al., 2019) exhibit that our proposed model significantly improves the ROUGE scores (Lin, 2004) of generated summaries.

Our contribution is threefold:

- We present the highlighting mechanism that assigns greater attention weights for the tokens within key phrases.
- We propose the multi-head highlighting attention and two structures of highlighting attention for each head to combine attention weights with the phrase importance.
- Our proposed model significantly outperforms the competitive baseline models on the Multi-News dataset.

2 Related Work

Previous encoder-decoder models (Rush et al., 2015; Nallapati et al., 2016; Paulus et al., 2018; Chopra et al., 2016) equipped with the attention mechanism (Bahdanau et al., 2015) have achieved great performance on abstractive summarization. However, they were found to miss some important content in input documents (Li et al., 2018; Xu et al., 2020). How to retain the key information of input documents in the generated summaries has received increasing attention in the past few years. Some previous works focus on improving the copy mechanism. Gehrmann et al. (2018) utilize the attention masks to restrict copying phrases from the selected parts of an input document. Xu et al. (2020) explicitly guide the copy process with the centrality of each source word. Several papers also explore the potential of enhancing the encoder. Li et al. (2018, 2020a) extend the pointer-generator-based models (See et al., 2017) with a separate LSTM-based encoder to get the keywords' representation and then combine it with the sentence representation. In this work, we explore the potential of leveraging phrase importance as guidance to adjust attention weights in the multi-head self-attention of the Transformer encoder.

3 Model

In this section, we present the Highlight-Transformer, a model with the highlighting mechanism. We introduce its three main components: the highlighting matrix, the highlighting attention for each head, and the multi-head highlighting attention. We focus on the encoder part, and our decoder follows the CopyTransformer model used in (Gehrmann et al., 2018; Fabbri et al., 2019). Each input example of our proposed model includes the source articles, the articles' key phrases, and the phrases' importance values. The automatic key phrases extraction method we used will be introduced in section 4.1.

3.1 Highlighting Matrix

The first step of the highlighting mechanism is to build a highlighting matrix for each input example. It can indicate key phrases' positions in the attention weight matrix and the phrases' importance values. The concatenated source articles can be represented as an input sequence $(t_1, ..., t_n)$ containing n tokens. We use $(p_1, ..., p_k)$ and $(v_1, ..., v_k)$ to denote key phrases and their importance values. For each input example, We build the highlighting matrix $H \in \mathbb{R}^{n\times n}$ with the same shape as the self-attention weight matrix. Assuming a phrase p_r contains b tokens in the input sequence $p_r = (x_a, ..., x_{a+b})$, the phrase's importance value v_r is added to the elements $H_{i,j}$, where $i = a, \ldots, a+b, j = a, \ldots, a+b$, in the highlighting matrix. The phrases can be overlapping or nested, and the token t_i may be contained in c phrases $(p_r, ..., p_{r+c})$, whose importance values are $(v_r, ..., v_{r+c})$. The element H_{ii} is assigned as the sum of the c phrases' importance values.

3.2 Highlighting Attention

The highlighting attention is the key component in our proposed model for adjusting attention weights according to the phrase importance. For the head *m*, the Transformer model (Vaswani et al., 2017) adopts the scaled dot-product attention that operates on a query Q, a key K, and a value V:

$$\mathrm{Attention}(Q, K, V) = W^m V \tag{1a}$$

$$W^m = \mathrm{softmax}(\frac{QK^T}{\sqrt{d_k}}) \tag{1b}$$

where $W^m \in \mathbb{R}^{n \times n}$, and d_k is the dimensionality of key. In the encoder layers, queries, keys, and values come from the output of the previous layer.

The highlighting matrix H can be used to determine which elements in the attention weight matrix should be increased. We propose two structures of highlighting attention, namely the weighted highlighting attention and the additive highlighting attention, to adjust attention weights according to the phrase importance.

The weighted highlighting attention mainly modifies Equation (1b) to calculate the attention weight matrix W^m for the head *m*. The highlighting matrix H is multiplied by a scalar α, named the brightness factor. The product will be added to the input of the softmax function.

$$W^m = \mathrm{softmax}(\frac{QK^T}{\sqrt{d_k}} + \alpha H) \tag{2}$$

Since the softmax function applies the exponential function to each input element and divides them by the sum of all these exponentials, the above additive operation can be identical to calculating the weighted average.

$$\mathrm{softmax}(z_i + b_i) = \frac{e^{b_i} e^{z_i}}{\sum_{j=1}^{n} e^{b_j} e^{z_j}} \quad i = 1, \ldots, n \tag{3}$$

The additive highlighting attention is also designed to adjust the attention weight matrix W^m. In Equation (4a), the product of the highlighting matrix H and the scalar α is normalized by the softmax function[1] and added to the original attention weight matrix W_a^m calculated by Equation (1b). And then, elements in W_b^m will be normalized to ensure the sum of the attention weights equals one along the dimension where the softmax conducts.

$$W_b^m = W_a^m + \mathrm{softmax}(\alpha H_m) \tag{4a}$$

$$W_{:,\,j}^m = \frac{W_{b\ :,\,j}^m}{||W_{b\ :,\,j}^m||_1} \quad j = 1, \ldots, n \tag{4b}$$

3.3 Multi-Head Highlighting Attention

In our proposed model, the encoder with d_{model} consists of N layers and h heads. Each encoder layer has two sub-layers: the multi-head highlighting attention layer and the position-wise fully connected feed-forward network. We proposed the multi-head highlighting attention mechanism, which employs the highlighting attention on p highlighted heads and the scaled dot-product attention on the rest of $(h - p)$ normal heads.

$$\begin{aligned} &\mathrm{MultiHead}(Q, K, V) = \mathrm{Heads} W^o \\ &\mathrm{Heads} = \mathrm{Concat}(\mathrm{Head}_1, ..., \mathrm{Head}_h) \\ &\mathrm{Head_i} = \mathrm{Attention}(Q, K, V) \end{aligned} \tag{5}$$

where the projection is a parameter matrix $W^o \in \mathbb{R}^{hd_v \times d_{model}}$. The matrix Head_i is calculated by Equation (1a). The attention weight matrix W of the highlighted heads can be calculated by Equation (2) or (4), and that of the normal heads can be calculated by Equation (1b). The results on all heads will be concatenated and then projected through a feed-forward layer.

4 Experiments

4.1 Data Preparation

We train and evaluate our model on a MDS dataset named Multi-News (Fabbri et al., 2019), in which each example includes multiple news articles about the same event and a human-written summary collected from the website newser.com.

Following the setting in (Fabbri et al., 2019), we truncate each input article to 500/S tokens for the example with S news articles and concatenate the truncated articles into a single document. For each example, we first filter out stopwords and select candidate phrases from these truncated source articles. And then, we use the library named scikit-learn to calculate the candidate phrases' tf-idf values (Salton and Buckley, 1988) as their importance values. These candidate phrases are sorted in descending order of their importance values. We only select the top-10 bigrams or trigrams as key phrases

---

[1] Since the number of key phrases is limited, and the highlighting matrix can be sparse, we mask the zero elements and only conduct the softmax operation on the nonzero elements.

in each example since we observe longer phrases are sparse and more likely to be compressed in summary. Each input example of our proposed model includes the source articles, key phrases together with their L2 normalized tf-idf values.

4.2 Experimental Setting

We adopt a 4-layer encoder and a 4-layer decoder to build our proposed model, in which each layer has eight attention heads. Both the word embedding size and hidden size are set as 512. The maximum size of the vocabulary is set as 50000. Besides, we implement our model with the framework named OpenNMT-py (Klein et al., 2017).

The optimizer is Adam (Kingma and Ba, 2015) with learning rate 2, β_1=0.9, and β_2=0.998. Learning rate warmup is adopted to linearly increase the learning rate over the first 8,000 steps and then decrease it as the setting in (Vaswani et al., 2017). In addition, the brightness factor α in the highlighting attention also progressively decreases at the end of each epoch. Following the setting in (Fabbri et al., 2019), we also apply label smoothing (Szegedy et al., 2016) with smoothing factor 0.1 and dropout (Srivastava et al., 2014) with probability 0.2.

During testing, we use beam search with a beam size of 5. We also use trigram blocking to reduce repetitions. Our models are trained and evaluated on one NVIDIA Tesla P100 GPU.

4.3 Baselines

We compare our proposed Highlight-Transformer model with the following extractive and abstractive summarization methods.

LexRank and TextRank (Erkan and Radev, 2004; Mihalcea and Tarau, 2004) are two graph-based ranking methods that can be used for extractive summarization.

A **tf-idf**-based extractive summarization method (Christian et al., 2016) is evaluated to compare with introducing tf-idf score into our abstractive method.

BertExt (Liu and Lapata, 2019b) stacks inter-sentence Transformer layers on top of the pre-trained BERT (Devlin et al., 2019). We fine-tune this model on the Multi-News training set.

PG and PG-MMR are the pointer-generator (PG) network based summarization models reported by (Lebanoff et al., 2018).

Hi-MAP (Fabbri et al., 2019) extends the PG network into a hierarchical network. The attention distribution of tokens is multiplied by the MMR score of the sentence to which they belong.

Method	R-1	R-2	R-SU
LexRank	38.27	12.70	13.20
TextRank	38.44	13.10	13.50
tf-idf	38.68	12.09	13.54
BertExt	44.27	15.09	17.44
PG	41.85	12.91	16.46
PG-MMR	40.55	12.36	15.87
Hi-MAP	43.47	14.89	17.41
BertAbs	42.21	15.14	16.33
SAGCopy	43.98	15.21	17.65
CopyTransformer	43.57	14.03	17.37
Highlight (Weighted)	**44.62**	**15.57**	**18.06**
Highlight (Additive)	44.29	15.46	17.73

Table 1: Evaluation results on the Multi-News test set.

Highlight (Weighted)	R-1	R-2	R-SU
1/4 Heads 1/2 Layers	**44.62**	**15.57**	**18.06**
1/2 Heads 1/2 Layers	44.25	15.37	17.84
All Heads 1/2 Layers	44.18	15.12	17.70
1/4 Heads All Layers	44.32	15.16	17.82
1/2 Heads All Layers	44.41	15.50	17.84
All Heads All Layers	44.21	15.11	17.72

Table 2: Evaluation results on highlighting different numbers of heads and layers.

SAGCopy (Xu et al., 2020) adds the word centrality score to the linearly transformed hidden state when calculating the copy distribution.

BertAbs (Liu and Lapata, 2019b) adopts the pre-trained BERT as the encoder. A decoder with six Transformer layers is initialized randomly. We fine-tune this model on the Multi-News training set.

CopyTransformer (Gehrmann et al., 2018; Fabbri et al., 2019) adds the copy mechanism (See et al., 2017) to a 4-layer Transformer model. The decoder of our model follows its architecture.

4.4 Results and Discussion

We report the ROUGE F_1 (Lin, 2004) scores, including the overlap of unigrams (R-1), bigrams (R-2), and skip bigrams with a max distance of four words (R-SU). The results of LexRank, TextRank, PG, PG-MMR, Hi-MAP, and CopyTransformer follow Fabbri et al. (2019).

As shown in Table 1, the Highlight-Transformer significantly outperforms these baseline models on all metrics, which proves the effectiveness of the highlighting mechanism. Compared with the additive highlighting attention, the weighted high-

	Win	Lose	Tie	Kappa
Informativeness	46.5%	21.5%	32.0%	0.664
Fluency	29.5%	26.0%	44.5%	0.639
Non-Redundancy	27.5%	25.5%	47.0%	0.624

Table 3: Human evaluation results. “Win” represents the generated summary of our proposed model is better than that of CopyTransformer in one aspect.

	R-1	R-2	R-SU
Highlight-Transformer	**44.62**	**15.57**	**18.06**
w/o brightness	44.38	15.44	17.90
w/o highlight attn	43.57	14.03	17.37
w/o self-attention	42.54	14.40	16.54

Table 4: Ablation study on the Multi-News test set. ”brightness” denotes the brightness factor α and ”highlight attn” denotes the highlighting attention.

lighting attention is more favorable.

We also compare the effects of adopting the weighted highlighting attention in different numbers of heads and layers in the encoder of our proposed model. The results on the test set of Multi-News are summarized in Table 2. It reveals that adopting it in a quarter of the heads and half of the layers achieves the best performance. We discover that adopting highlighting attention in a subset of heads surpasses adopting it in all heads. Besides, applying the multi-head highlighting attention on all layers of the encoder is also not optimal.

Multi-head attention in the Transformer model (Vaswani et al., 2017) is designed for jointly attending to information from different representation sub-spaces. Voita et al. (2019) find the heads in Transformer model trained on the neural machine translation dataset have specialized functions and focus on different types of information. Adopting the highlighting attention in all heads and layers will affect the Transformer-based model to encode other types of useful information and lead to performance degradation.

In addition to automatic evaluation, we performed a human evaluation to compare the generated summaries in terms of informativeness (the coverage of information from input documents), fluency (content organization and grammatical correctness), and non-redundancy (less repetitive information). We randomly selected 50 samples from the test set of the Multi-News dataset. Four annotators are required to compare two models’ generated summaries that are presented anonymously. We also assess their agreements by Fleiss’ kappa (Fleiss, 1971). The human evaluation results in Table 3 exhibit that the Highlight-Transformer significantly outperforms the CopyTransformer in terms of informativeness and is comparative in terms of fluency and non-redundancy.

The ablation study aims to validate the effectiveness of individual components in our proposed model. In Table 4, ”w/o highlight attn” refers to the CopyTransformer model used in (Gehrmann et al., 2018; Fabbri et al., 2019). The results confirm that incorporating the highlighting attention is beneficial for multi-document summarization, and the decreasing brightness factor α also benefits our model’s performance. Besides, we tried replacing the self-attention weight matrices in a quarter of the heads and half of the layers with the highlighting matrices. The performance degradation reveals that it is important to combine the attention weights with the phrase importance instead of directly replacing the attention weights.

5 Conclusion

In this paper, we introduce the Highlight-Transformer, a novel summarization model with the highlighting mechanism in the encoder. The highlighting mechanism assigns greater attention weights for the tokens within key phrases, and it comprises three main parts: the highlighting matrix, the highlighting attention, and the multi-head highlighting attention. Specifically, a block diagonal highlighting matrix is built for each input token sequence to indicate key phrases’ positions and phrases’ importance values. For each head, we propose and compare two structures of highlighting attention. Furthermore, we also compare the effects of adopting the weighted highlighting attention in different numbers of heads and layers in the encoder of our proposed model. The experimental results exhibit the effectiveness of our proposed model. We intend to incorporate more phrase-level and sentence-level information into Transformer-based summarization models and evaluate them on different datasets in future work.

Phrase-Level Action Reinforcement Learning for Neural Dialog Response Generation

Abstract

Defining a sophisticated action space for a dialog agent is essential for efficient training with reinforcement learning (RL). Recent work introduces discrete latent variables to use as an action space; however, a limitation is that a global vector can contain entangled information such as dialog act, sentence structure, and content. This sacrifices the flexibility of the response generation. In this paper, we propose phrase-level action reinforcement learning (PHRASERL), which allows the model to flexibly alter the sentence structure and content with the sequential action selection. Our model first learns to generate useful phrases during the supervised pre-training, and then further trained to form a response by rearranging the phrases with reinforcement learning. Experiments on the MultiWOZ dataset show that our model achieves competitive results with state-of-the-art models on automatic evaluation metrics, indicating that our phrase-level action space has improved flexibility and is effective for solving task-oriented dialogs.

1 Introduction

Dialog policy optimization is key research to efficiently solving real-world tasks (Rastogi et al., 2020; Budzianowski et al., 2018; Lewis et al., 2017). In neural response generation, which has made remarkable progress in recent years (Vinyals and Le, 2015; Li et al., 2016a; Serban et al., 2017; Bao et al., 2019), many methods that apply reinforcement learning (RL) have been proposed (Li et al., 2016b; Peng et al., 2018; Saleh et al., 2019; Zhao et al., 2019). In those studies, one major issue was how to define an action space. Early research proposed a method in which each word of the response is an action (Li et al., 2016b). However, this has a shortcoming that the generated responses deviate from natural human language (Zhao et al., 2019). A possible reason is that the action space is huge, making it difficult to optimize with RL. Moreover, rewarding only the task accomplishment can cause biased improvement, which leads the model to ignore the comprehensibility of the generated response (Wang et al., 2020a).

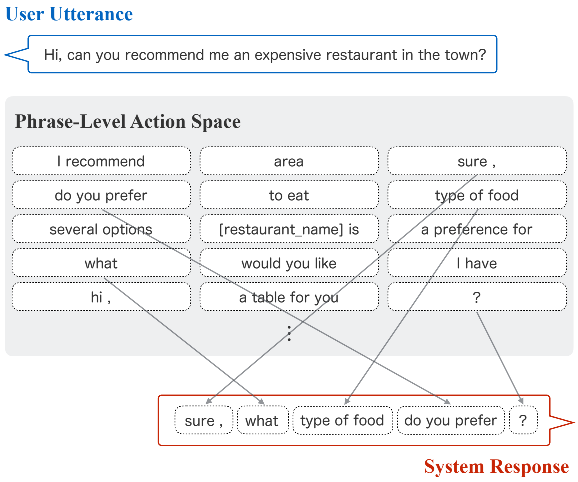

Figure 1: Demonstration of phrase-level action. The model generates useful phrases and rearrange them to form a response.

To overcome such issues, LaRL (Zhao et al., 2019) was proposed, which used a discrete global vector to represent dialog acts. In this method, reinforcement learning is performed only on those discrete latent variables, thus the policy optimization is achieved without affecting the language generation. However, LaRL depends on a single vector from the beginning to the end during the response generation, even though a response may often contain more than one dialog act and contents (Wang et al., 2020b). Due to this, a static, global vector tends to be an entangled representation of multiple dialog acts, sentence structure, and contents. Therefore, using a global vector for action space sacrifices the flexibility of the response generation.

To improve the flexibility of the surface realiza-

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 5028–5038
August 1–6, 2021.

tion, we propose phrase-level action reinforcement learning (PHRASERL), in which the model performs action selections in fine-grained semantic units. PHRASERL is based on neural hidden semi-Markov model (HSMM) decoder (Wiseman et al., 2018) which generates typed text-segments from hidden states, and we use them as an action space. This disentangles the generation process: the policy learns to structure a response as a sequence of hidden states, while each hidden state is trained to represent content or a type of phrase. Intuitively, as described in figure 1, our model learns to generate useful phrases during the supervised pre-training, and it is further trained with reinforcement learning to reorder the phrases and form a response.

Experiment results on the task-oriented MultiWOZ dataset (Budzianowski et al., 2018) show that our best performing model outperforms LaRL by far and achieves competitive results with the state-of-the-art models in automatic evaluation. Furthermore, PHRASERL can maintain a high BLEU score, suggesting that the model is flexible in its output response depending on the context. Finally, we study the phrase generation from hidden states in a case study, and show that the hidden state-action space is capable of generating (1) informative response, (2) grammatical sentence, and (3) diverse intentions, which can be considered as requirements for an effective action space. Our code is available at `https://github.com/Alab-NII/PhraseRL`.

2 Related Work

A classical approach for realizing task-oriented dialog systems is the frame-based dialog system (Chen et al., 2017). This model generates a response in a pipeline fashion, by splitting the generation process into three modules: natural language understanding, dialog management, and natural language generation. Natural language understanding converts user utterances to a semantic frame which is considered a dialog state, and a popular method is slot filling (Mrkšić et al., 2017; Ramadan et al., 2018). The estimated dialog state is then passed on to dialog management to determine the next action, which is formulated as a partially-observable Markov decision process (POMDP) (Young, 2006). The action space is represented with hand-crafted dialog acts (Budzianowski et al., 2018; Stolcke et al., 2000) or meaning representations (Balakrishnan et al., 2019). Finally, a natural language generator generates a response, which is often realized with recurrent neural networks (Zhou et al., 2016; Tran and Nguyen, 2017). Our proposed model spans between dialog management and natural language generation, however, our model does not require any hand-crafted representation.

Past works that applied reinforcement learning to dialog models have shown a huge performance improvement in task success (Lewis et al., 2017; He et al., 2018). Li et al. (2016b) proposed a dialog generation method by using deep reinforcement learning with words as action spaces. Although the rewards were carefully designed, it is reported that these models tend to generate incomprehensible responses. Zhao et al. (2019) solved the problem by using discrete latent variables as the action space. Wang et al. (2020a) have extended LaRL and applied hierarchical reinforcement learning technique to decouple the dialog policy and natural language generation. The model is composed of two policy networks; one is the high-level policy which acts on latent dialog act and another is the low-level policy that acts on words. The low-level policy is prone to degeneration, so the paper proposes to use language model discriminator as a reward provider. These models either use words or a global latent variable as an action space, however, our work stands between the two by using phrases for the action space.

3 Preliminaries

In this section, we first explain the characteristics and formulation of the HSMM. We then describe the neural HSMM decoder, which will be the backbone of our proposed method.

3.1 Hidden Semi-Markov Model (HSMM)

In our work, we consider sentences as a sequence of phrases, and the probabilistic model that can represent this is the hidden semi-Markov model (HSMM). The difference between a standard hidden Markov model (HMM) and HSMM is shown in figure 2. While an HMM gives one observation from a hidden state, an HSMM gives a sequence of observations per hidden state. Therefore, if we consider words as observations, hidden states will be phrases.

To represent a variety of sentences with a limited number of hidden states, HSMM is expected to assign the same sequence of hidden states for similar sentences. Figure 3 is an example. As it can

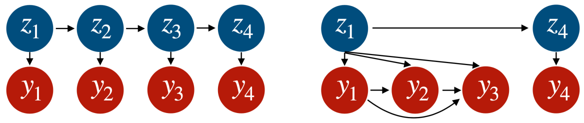

Figure 2: The difference between Hidden Markov Models (left) and Hidden Semi-Markov Models (right)

[what]$_8$ [time]$_{23}$ [would you like]$_{11}$ [to leave ?]$_{34}$
[what]$_8$ [kind of food]$_{23}$ [would you like]$_{11}$ [to eat ?]$_{34}$

Figure 3: An example of sentence segmentation in HSMM. The number represents the index of a hidden state.

be seen, each hidden state has a type; for instance, hidden state #8 and #11 outputs the same phrase, while #23 outputs noun phrases and #34 outputs verb phrases for end of questions. In this way, text-segments assigned to a certain hidden state will be having a similar property.

For our model, we specifically use *conditional* HSMMs which takes a source input x. For each timestep $t \in \{1, \cdots, T\}$, we denote the observations as $y_1 \cdots y_T$ and the discrete hidden states as $z_t \in \{1, \cdots, K\}$. We additionally introduce two latent variables; the length of the current observation sequence, denoted as $l_t \in \{1, 2, \cdots, L\}$, and a binary variable which represents whether the sequence is finished at timestep t, denoted as f_t. The maximum number of hidden states K and observation length L are tunable parameters. An HSMM will be represented with a joint distribution of the observations and the described latent variables:

$$\begin{aligned} p(y,z,l,f|x;\theta) = & \prod_{t=0}^{T-1} p(z_{t+1},|z_t,x)^{f_t} \\ & \times \prod_{t=0}^{T-1} p(l_{t+1}|z_{t+1})^{f_t} \\ & \times \prod_{t=1}^{T} p(y_{t-l_t+1:t}|z_t,l_t,x)^{f_t}. \end{aligned} \tag{1}$$

In other words, an HSMM will be the product of three probabilities: state transition distribution, length distribution, and emission distribution.

3.2 Neural HSMM Decoder

We now introduce a neural HSMM decoder (Wiseman et al., 2018). Figure 4 shows the overview of the decoder model. The aforementioned three distributions can be obtained using trainable parameters. We define the embeddings of the x as

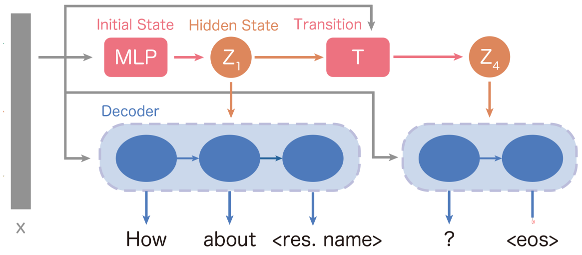

Figure 4: Model overview of neural HSMM decoder.

$\boldsymbol{x} \in \mathbb{R}^d$ and the hidden state z as $\boldsymbol{z} \in \mathbb{R}^d$.

State Transition Distribution For the state transition function $p(z_{t+1}|z_t, x)$, we use $K \times K$ matrix, where sum of each row is 1. We define the state transition matrix as

$$p(z_{t+1}|z_t, x) \propto \boldsymbol{A}\boldsymbol{B} + \boldsymbol{C}(\boldsymbol{x})\boldsymbol{D}(\boldsymbol{x}), \tag{2}$$

where $\boldsymbol{A} \in \mathbb{R}^{K \times m_1}$ and $\boldsymbol{B} \in \mathbb{R}^{m_1 \times K}$ represents state embeddings, and where $\boldsymbol{C} : \mathbb{R}^d \rightarrow \mathbb{R}^{K \times m_2}$ and $\boldsymbol{D} : \mathbb{R}^d \rightarrow \mathbb{R}^{m_2 \times K}$ is a non-linear function parameterized with neural networks. m_1 and m_2 are tunable parameters.

Length Distribution Wiseman et al. (2018) have found that parameterizing length distribution leads to hidden states that specialize in specific output lengths. To avoid that, we simply used uniform distribution for every length probability $p(l_{t+1}|z_{t+1})$.

Emission Distribution For the emission distribution $p(y_{t-l_t+1:t}|z_t, l_t, x)$, we use the product of the token probability. Therefore, the emission distribution is obtained with

$$\begin{aligned} & p(y_{t-l_t+1:t}|z_t = k, l_t = l, x) = \\ & \prod_{i=1}^{l_t} p(y_{t-l_t+i}|y_{t-l_t+1:t-l_t+i-1}, z_t = k, x) \\ & \times p(\langle eop \rangle | y_{t-l_t+1:t}, z_t = k, x) \times \mathbf{1}_{\{l_t = l\}}, \end{aligned} \tag{3}$$

where $\langle eop \rangle$ stands for end-of-phrase token which indicates the end of emission for each hidden state. We use gated recurrent unit (GRU) to compute the token probabilities:

$$\boldsymbol{v}_i = \boldsymbol{W}\mathrm{ReLU}\left(\mathrm{GRU}\left(\left[\boldsymbol{y}'_{i-1}, \boldsymbol{z}^k\right], \boldsymbol{h}_{i-1}\right)\right), \tag{4}$$

where $\boldsymbol{y}'_{i-1}$ is the embeddings of the generated previous token and $\boldsymbol{z}^k$ is the embeddings of the hidden state k. Finally, the probability of the token w will be

$$p(y_{t-l_t+i} = w|z_t = k, l_t = l, x) = v_{i,w}. \tag{5}$$

Training We assume z, l, f of an HSMM is unobservable, so we maximize the marginal likelihood of the emission y given only input x by training. The marginal likelihood of y in HSMMs can be efficiently computed using a dynamic programming algorithm such as backward-algorithm (Murphy, 2002). Using variables β, β^*, the backward-algorithm can be expressed as

$$\begin{aligned} \beta_t(j) &= p(y_{t+1:T}|z_t = j, f_t = 1, c) \\ &= \sum_{k=1}^{K} \beta^*_t(k) p(z_{t+1} = k|z_t = j) \end{aligned} \tag{6}$$

$$\begin{aligned} \beta^*_t(k) &= p(y_{t+1:T}|z_{t+1} = k, f_t = 1, c) \\ &= \sum_{l=1}^{L} [\beta_{t+l}(k) p(l_{t+1} = l|z_{t+1} = k) \\ &\qquad p(y_{t+1:t+l}|z_{t+1} = k, l_{t+1} = l)], \end{aligned} \tag{7}$$

where $\beta_T(j) = 1$. Finally, from the definition $f_0 = 1$, the log-marginal likelihood of y will be:

$$\ln p(y|x;\theta) = \ln \sum_{k=1}^{K} \beta^*_0(k) p(z_1 = k). \tag{8}$$

Here, we compute $p(z_1 = k)$ with a linear layer. Since equations (6) and (7) are differentiable, we can optimize θ by maximizing the log-marginal likelihood $\ln p(y|x;\theta)$ with backpropagation.

4 Proposed Method

The original neural HSMM decoder (Wiseman et al., 2018) was proposed as a data-to-text generation method, so the model needs modification to be applied to dialog response generation. Particularly, we investigate what the HSMM should condition on, in other words, we determine the input x. However, we need to carefully design x because of a known problem of the neural HSMM decoder, which will be explained first. Afterward, we discuss how to improve the response quality by applying reinforcement learning.

4.1 Conditional Source for Neural HSMM Decoder

The neural HSMM decoder is based on the assumption that the output phrases from each hidden state to be independent of each other. However, if the source $\boldsymbol{x}$ is informative enough to capture the interdependence between the phrases, the RNN decoder may fully depend on the source $\boldsymbol{x}$ and ignore the hidden state $\boldsymbol{z}$ for the generation. We will call this problem the *interdependence problem*. To avoid this, we must use weak source input that does not contain enough information to precisely predict the target response.

For our work, we use contextual information (e.g. dialog history, belief state, database results) as a conditional source x. A common practice to embed contextual information is to use a GRU and a linear layer to encode, and as a result, we obtain continuous embeddings $\boldsymbol{x}$. However, continuous embeddings can result in the interdependence problem, since they can theoretically contain infinite information.

To weaken the encoder, we reduce the resolution of the input embeddings $\boldsymbol{x}$ by using discrete embeddings. We define it as an array of N-way categorical variables: $\boldsymbol{x} = \{\boldsymbol{x}_1, \boldsymbol{x}_2, \cdots, \boldsymbol{x}_M\}$, where each $\boldsymbol{x}_n$ is a N-sized binary vector and M is the number of variables. To obtain this, straight-through Gumbel-softmax (Jang et al., 2017) is applied to the conditional source encoded by a GRU and a linear layer. In our experiments in section 6, we will compare the results of these discrete embeddings with continuous embeddings.

4.2 Response Generation with Reinforcement Learning

To rearrange the invented hidden states of a neural HSMM decoder, we apply reinforcement learning, which we named this method as *phrase-level action reinforcement learning* (PHRASERL). Here, we consider a Markov decision process of input context as state $x \in \mathcal{S}$, hidden states (which represents phrases) as action space $z \in \mathcal{A}$, and task-success rate as rewards $r \in \mathcal{R}$. We define the timestep of hidden state selection as $t' = \{1, 2, \cdots, T'\}$. We consider the combined initial state selection and state transition as policy $\pi : \mathcal{S} \mapsto \mathcal{A}$ and apply REINFORCE algorithm (Williams, 1992). For each reward $r_{t'}$ in time step t', we use discounted reward $G_{t'} = \sum_{k=0}^{T'} \gamma^k r_{t'+k}$ during training. Now, the policy gradient will be:

$$\nabla J(\pi) = \mathbb{E}\left[\sum_{t'=1}^{T'} \nabla_\pi \log \pi(z_{t'}|x) G_{t'}\right]. \tag{9}$$

Note that we do not train the GRU for the emission distribution; we only further train the hidden state transition. For embedding the contexts, we used the pre-trained encoder and did not further update during this RL step.

5 Experimental Settings

5.1 Task Description

For the experiments, we use MultiWOZ dataset (Budzianowski et al., 2018). MultiWOZ is a large-scale task-oriented dialog dataset, which contains seven types of domains such as booking restaurants, hotels, and train seats. We specifically use Dialogue-Context-to-Text Generation task proposed in the original paper. In this task, a model is given an oracle belief state, and the model's goal is to generate an appropriate and informative response. For the evaluation, we use BLEU, Inform Rate, and Success Rate. We also compute the total score, which is used in previous works to compare models in MultiWOZ dataset. Total score is calculated with $\mathrm{BLEU} + (\mathrm{Inform} + \mathrm{Success})/2$.

5.2 Model Details

Duplicated Hidden States While increasing the number of hidden states allows for a more expressive latent model, the computational complexity of the neural HSMM decoder will increase linearly depending on the number of hidden states K. In order to increase the number of hidden states without making the computation heavier, we use the same emission distribution for multiple hidden states as proposed in Wiseman et al. (2018). For instance, if we set the base state as 80 and duplicated 5 times, K will be 400 and we use $z \bmod 80$ for the input into the computation of emission distribution. This way, the model can utilize a large number of hidden states in the state transition, while the model only needs to run the GRU feed-forward for a smaller number of times to compute emission distribution.

Training Details We first train the neural HSMM decoder with supervised learning, and later we further train with reinforcement learning as explained in section 4.2. To embed the context information x, we use a MLP layer for encoding oracle belief state and a GRU for encoding dialog history. For comparison, we trained both continuous and discrete embeddings, which we denote each model as CONT and DISC respectively. To train with reinforcement learning, we use the MultiWOZ RL setup proposed in (Zhao et al., 2019). For the rewards, we use $r_{\text{success}} + r_{\text{inform}} + r_{\text{BLEU}}$.

The average loss is computed with the validation dataset after every epoch, and early stopping is performed after 5 consecutive epochs without improvement. When we determine the number of hidden states, we tested every 10 states from 40 to 120 for base states, and 1, 3, 5, 7 for duplication. In consequence, $K = 400$ (80 base states, duplicated 5 times) produced the best results, and the following evaluations are based on these results. For the vocabulary set, we substituted the words that occurred less than 30 times in the dataset with an unknown tag ($\langle unk \rangle$). We used beam search with a beam size of 5 for the decoding. For more details, refer to Appendix A.

5.3 Baseline and State-of-the-Art Models

Our model is compared with the following models:

- **Baseline** (Budzianowski et al., 2018) is proposed in the original MultiWOZ paper. The model is based on Seq2Seq with attention on the context words.

- **Word-Level RL** further trains the pre-trained baseline on reinforcement learning with the action space of words. It is known that this model often encounters a degeneration problem, in which the generated sentence will diverge from natural human sentences.

- **Latent Action Reinforcement Learning (LaRL)** (Zhao et al., 2019) introduces a discrete latent variable between the encoder and decoder to represent a dialog act. Similar to our model, it first trains on supervised pre-training, then it further trains the dialog policy with reinforcement learning.

- **Hierarchical Disentangled Self-Attention Network (HDSA)** (Chen et al., 2020) introduces hierarchical dialog act. The model is composed of 3 transformer layers which each layer corresponds to each hierarchy of the dialog act. The model switches the self-attention based on the dialog act, which is called the disentangled self-attention.

- **SOLOIST** (Peng et al., 2020) is a transformer-based auto-regressive language model for task-oriented dialog, pre-trained on large and diverse dialog corpora. The model is fine-tuned on MultiWOZ task.

- **MarCo** (Wang et al., 2020b) extends the idea of HDSA and considers a hierarchical dialog

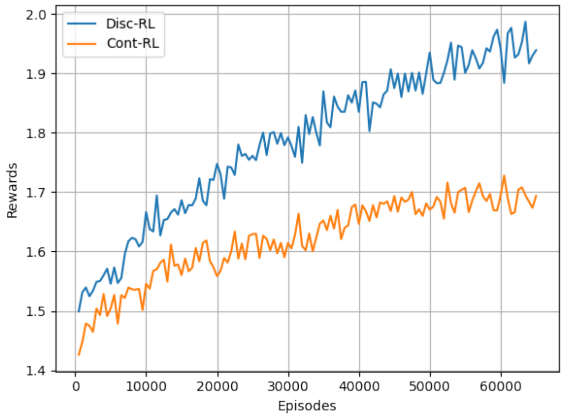

Figure 5: Average rewards for every 500 episodes of our proposed models. DISC-RL and CONT-RL indicates discrete and continuous embeddings, respectively. The maximum reward is 3.0.

act. The difference is that it co-generates the dialog act sequence and the response jointly.

- **HDNO** (Wang et al., 2020a) decouples the dialog policy and natural language generation by applying hierarchical RL. This model uses language model as a reward provider to maintain grammaticality.

Among these models, Word-Level RL, LaRL, and HDNO use reinforcement learning and, therefore, are considered as the main competitors to our PHRASERL. Also, note that HDNO uses rewards from external modules to avoid degeneration, but PhraseRL does not use them in this experiment.

6 Results and Analysis

6.1 Automatic Evaluations

Table 1 shows the results of the automatic evaluation of our models. We firstly see that applying reinforcement learning greatly improves the scores, indicating that hidden states had been an effective action space. We also see that discrete embeddings outperform continuous embeddings in every score. This shows that the model can improve generation performance by alleviating the interdependence problem with weaker encoders. It also can be observed that the discrete embeddings are significantly effective within reinforcement learning models. This can also be seen in the reward graph shown in figure 5, where discrete embeddings have a sharper reward increase compared to continuous embeddings. A possible reason behind this is that discrete embeddings led the phrase generation to be less diverse and strongly typed, which made the agent easier to learn the relation between a hidden state and the generated phrases.

We also compare our best model (DISC-RL) with the past works, and the results are shown in table 2. Our model achieved competitive results with the recently proposed state-of-the-art models, which also is near-human performance.

Comparing with LaRL, our model significantly outperforms in BLEU score even after applying RL. A possible reason for LaRL's low BLEU score is that it cannot fully express the diverse human sentences in a discrete global vector. On the other hand, PHRASERL can broaden the range of expression by dividing the action space into finer semantic units, which enables it to learn more human-like responses. Additionally, the improvement in Inform Rate and Success Rate can also be attributed to the ability of PHRASERL to flexibly select content.

Nevertheless, if we compare with state-of-the-art models without using RL, our model has a lower BLEU score. This suggests that using fixed phrases and arranging them have a drawback in regard to generating grammatical responses, since it lacks word-level flexibility. However, it is surprising to see that it still achieves a competitive score even with such disadvantage.

6.2 Model Analysis

Although our PHRASERL was able to maintain a high BLEU score, this can only be because the model was rewarded with the BLEU score during the training. We also trained the model without using the BLEU score for rewards and the results are shown in table 3. Although there is a slight decrease, it is still largely outperforming the Word-Level RL and LaRL. This indicates that our PHRASERL is resistant to degeneration to some extent, even without adding external modules for rewarding grammaticality as in HDNO. Further improvements can be expected by applying external rewards for avoiding degeneration, though this remains as future work.

Table 4 shows the generated phrases from randomly selected hidden states. By observing the outcome of DISC, we can notice that the common property of the generated phrases are interpretable: state 303 outputs ”verb phrases for the end of question”, state 239 outputs ”beginning of the question”, state 103 outputs ”features of a facility”, state 70 outputs ”back-channeling words”, and state 325

	BLEU (%)	Inform (%)	Success (%)	Total
CONT	15.3	56.7	42.9	65.2
DISC	15.7	71.5	46.3	74.6
CONT-RL	16.7	86.2	67.2	93.5
DISC-RL	**18.0**	**95.6**	**79.3**	**105.4**

Table 1: Evaluation results of MultiWOZ test dataset of our models. RL indicates additional training on reinforcement learning. The total score is computed with BLEU + (Inform + Success) / 2.

	RL	BLEU (%)	Inform (%)	Success (%)	Total
Human	-	-	91.0	82.7	-
Baseline (Budzianowski et al., 2018)	-	18.9	71.3	61.0	85.0
HDSA (Chen et al., 2020)	-	23.6	82.9	68.9	99.5
SOLOIST (Peng et al., 2020)	-	18.3	89.6	79.3	102.8
MarCo (Wang et al., 2020b)	-	20.0	92.3	78.6	105.5
Word-Level RL (Zhao et al., 2019)	✓	1.4	80.5	79.1	81.2
LaRL (Zhao et al., 2019)	✓	12.8	82.8	79.2	93.8
PHRASERL (Ours)	✓	18.0	95.6	79.3	105.4
HDNO (Wang et al., 2020a)	✓	18.9	96.4	84.7	109.5

Table 2: Evaluation results of MultiWOZ test dataset compared with previous works. Our PHRASERL is the result of DISC-RL. The results were obtained from corresponding papers.

outputs ”noun phrases for domains”. This indicates that the hidden states in Disc are strongly typed. Although phrases of CONT also seems to be typed, some states such as state 138 have multiple types. This is due to the interdependence problem because the RNN can recognize which type to use depending on the conditional input x.

6.3 Case Study

To verify that the hidden states are a valid and flexible action space, we qualitatively validate the generated phrases. Figure 6 shows the generated phrases from user input and possible responses that can be formed by reordering the phrases. The possible responses were generated from hidden states that were reordered by hand. We consider three criteria for a valid and flexible action space in MultiWOZ dataset: the model must be able to (1) inform appropriate content (e.g. restaurant name, departure time), (2) generate grammatical sentences, and (3) generate diverse dialog acts.

Content Appropriate contents for this case would be the area of the restaurant ([value_area]), price range ([value_pricerange]), name of the restaurant ([restaurant_name]), and type of food ([value_food]). These entities appear at least once in the generated phrases, and the model can select the content by acting on the hidden states. Furthermore, as shown in the third and fourth examples of possible responses, the model can use a similar hidden state sequence for generating similarly structured responses, but it can still tweak the content depending on their strategy.

We further investigated if the contents are sufficiently provided with the hidden states. We counted the number of cases in the test set where all the entities in the golden response were contained in the generated phrases. As a result, 83.6% of the cases had sufficient information in the generated phrases, which we consider enough because the model may have other response options. Therefore, we can conclude that the first condition has been met.

Grammar Although there remains the possibility of generating ungrammatical sentences, the possible responses in figure 6 show that an appropriate sequence of hidden states will allow generating fluent responses.

Dialog Act As shown in the bottom section in figure 6, the four response samples have different intentions. For instance, the first response asks the type of food to the user, while the second response recommend a restaurant and ask for a booking. Particularly, a second example contains two different dialog acts (recommend and offer booking), but the model can choose to finish with the first sentence to just recommend. This shows that our PHRASERL have disentangled representation for each dialog acts. Therefore, we can conclude that the model can flexibly select from several intentions.

Finally, in table 5, we show an example response

	BLEU (%)	Inform (%)	Success (%)	Total
$r_{\text{success}} + r_{\text{inform}} + r_{\text{BLEU}}$	18.0	95.6	79.3	105.4
$r_{\text{success}} + r_{\text{inform}}$	17.1	95.7	78.9	104.4

Table 3: Evaluation results of DISC-RL with different rewards in MultiWOZ test set.

CONT

i recommend [restaurant_name] . can i book a table for you ?
there are no [value_pricerange] restaurant -s . would you like to try a different area ?
there are no [value_pricerange] restaurant -s . would you like to try a different price range ?
```

Figure 6: A case study for generated phrases of DISC. In the second section, we show the number of hidden states that output the same phrase. The third section shows possible responses which were generated from inputting sequence of hidden states ordered by hand. The colors indicate the corresponding phrases.

from MultiWOZ test dataset. We first see that CONT is not generating a grammatical response. This may be due to the interdependence problem that tries to output various sentences in the same hidden state sequence. On the other hand, the rest of our models can generate a grammatical and in-context response. We also observe that while models without RL generate plausible responses, RL models provide a more informative response by including hotel names and phone numbers. The reason is that the model often receives rewards by conveying those information.

7 Conclusion and Future Work

In conclusion, this paper proposes a phrase-level action reinforcement learning for neural response generation. A neural HSMM decoder is introduced to learn hidden states that output typed phrases, and we used them as the action space for reinforcement

Context	i am looking for a place to stay in the [value_area] of the city . i would prefer a [value_count] star hotel please .
Human Response	there are several guesthouses available . do you have a price preference ?
Baseline	i have [value_count] hotel -s in the [value_area] . would you like to book a room ?
CONT	yes , i have [value_count] a few in the [value_area] . would you like a hotel or guesthouse ?
DISC	sure , there are [value_count] options . is there a particular price range ?
CONT-RL	i have the [hotel_name] in the [value_area] . the phone number is [hotel_phone] .
DISC-RL	[hotel_name] is in the [value_area] . would you like me to book it for you ?

Table 5: Example responses from baseline and our models. ⟨unk⟩ represents unknown word of the model.

learning. Our experiments on MultiWOZ dataset have shown that the model is capable of generating flexible outputs with RL, achieved competitive results to state-of-the-art models. A possible future direction is to apply hierarchical reinforcement learning, where the high-level policy determines the dialog act of the entire response, while low-level policy designs the syntax of the response.

Abstract

Automatic speech recognition (ASR) in Sanskrit is interesting, owing to the various linguistic peculiarities present in the language. The Sanskrit language is lexically productive, undergoes euphonic assimilation of phones at the word boundaries and exhibits variations in spelling conventions and in pronunciations. In this work, we propose the first large scale study of automatic speech recognition (ASR) in Sanskrit, with an emphasis on the impact of unit selection in Sanskrit ASR. In this work, we release a 78 hour ASR dataset for Sanskrit, which faithfully captures several of the linguistic characteristics expressed by the language. We investigate the role of different acoustic model and language model units in ASR systems for Sanskrit. We also propose a new modelling unit, inspired by the syllable level unit selection, that captures character sequences from one vowel in the word to the next vowel. We also highlight the importance of choosing graphemic representations for Sanskrit and show the impact of this choice on word error rates (WER). Finally, we extend these insights from Sanskrit ASR for building ASR systems in two other Indic languages, Gujarati and Telugu. For both these languages, our experimental results show that the use of phonetic based graphemic representations in ASR results in performance improvements as compared to ASR systems that use native scripts.[1]

1 Introduction

Sanskrit is a language with fairly advanced disciplines of phonetics (*Śikṣā*), prosody (*Chandas*), and grammar (*Vyākaraṇa*). The language has a rich oral tradition and it tends to follow a phonemic-orthography resulting in systematic grapheme-phoneme correspondences. Connected speech leads to phonemic transformations in utteracnes, and in Sanskrit this is faithfully preserved in writing as well (Krishna et al., 2018). This is called as Sandhi and is defined as the euphonic assimilation of sounds, *i.e.*, modification and fusion of sounds, at or across the boundaries of grammatical units (Matthews, 2007, p. 353). Phonemic orthography is beneficial for a language, when it comes to designing automatic speech recognition Systems (ASR), specifically for unit selection at both the Acoustic Model (AM) and Language Model (LM) levels.

Regardless of the aforementioned commonalities preserved in both the speech and text in Sanskrit, designing a large scale ASR system raises several challenges. The Unicode encoding for the native scripts in Sanskrit, both in Roman and Devanāgari, does not preserve the correspondence with the phonemic encoding. Further, mapping the graphemes in Unicode to the corresponding phonemes either leads to ambiguity and redundancy or often requires multi-grapheme combinations.

The language is lexically productive, which results in long compound words with multiple components in usage. This results in the speakers segmenting the compounds at arbitrary lexeme boundaries of the compound, as it need not always be possible to utter the compound in one breath and also to convey the meaning clearly. Similarly, such arbitrary segmentations at the word boundaries are possible in utterance of long text sequences where multiple lexical items are fused together via Sandhi. These segmentations are accompanied with the corresponding Sandhi based transformations, resulting in a new phonetic sequence different from the original sequence. Finally, Sanskrit might be one of those rare natural languages where the number of non-native proficient speakers are

August 1–6, 2021.

manifold in comparison to the native speakers (Krishna et al., 2020). This makes the ASR task further challenging, as the speakers are prone to carry their influence from their corresponding mother tongues into the Sanskrit utterances as well.

While there exist several computational models for processing Sanskrit texts (Kulkarni, 2013; Kumar et al., 2010; Shukla et al., 2010; Kulkarni et al., 2010a; Goyal et al., 2012; Kulkarni et al., 2010c; Mishra et al., 2013; Saluja et al., 2017; Anoop and Ramakrishnan, 2019; Krishna et al., 2021), large scale systems for processing of speech in Sanskrit, are almost non-existent. First, we present a new dataset, with 78 hours of speech covering about 46,000 sentences, for ASR in Sanskrit. Keeping the rich and long cultural heritage the language carries, we prepare our dataset to be diverse both chronologically and in terms of the domain coverage. Further, the dataset contains utterances from 27 different speakers, representing 6 different native languages. The dataset splits have disjoint speakers, with 12 in the training and 5 each in the validation, test and out-of-domain test data sets. Further, we explicitly mark the segmentation decisions made by a speaker to segment long compound words and fused phrases and include the corresponding transformations due to sandhi.

Using this dataset, we propose a new, large-vocabulary Sanskrit ASR system, which, to the best of our knowledge, is the first such system for Sanskrit. The phonemic orthography followed in Sanskrit has influenced our design choices in terms of unit selection at the level of the acoustic and language models. We investigate three different encoding schemes used to model LM tokens, namely, word-based encoding, byte pair encoding (BPE) and a new vowel split encoding inspired by existing linguistic theories of syllabic structure popularly used within text-to-speech systems (Kishore and Black, 2003; Mishra et al., 2013). Further, to address the redundancy issues in Unicode representations, we make use of the Sanskrit Library Phonetic (SLP1) encoding scheme proposed by Scharf and Hyman (2011). SLP1 is designed such that it preserves the phonemic orthography. Building on the study by Scharf and Hyman (2011), we focus on two graphemic representations only, *viz.*, native script (Devanagari) and SLP1.

Finally, we extend our insights to model ASR systems for two more Indian languages, *viz.*, Telugu and Gujarati. We extend the SLP1 to include graphemes relevant for these languages which are missing from Sanskrit. We report the performance of these ASR systems on two publicly available ASR datasets.

Our main contributions in this work are:
1) We present (in Section 2) a new, large vocabulary Sanskrit ASR system and the first ever ASR-based study for Sanskrit using a new, large and diverse, labeled speech corpus वाक्सञ्चयः (/Vāksañcayaḥ/).
2) We investigate (in Sections 3 and 4) different modeling choices for both acoustic models and language models in Sanskrit ASR systems, along with different graphemic representations. We propose a new word segmentation technique based on splitting at vowels that can be used with both the acoustic model and the language model.
3) We also contextualize our findings for Sanskrit by providing comparisons on ASR systems built for two other Indian languages, *viz.*, Gujarati and Telugu.

2 A new Sanskrit Speech Corpus: वाक्सञ्चयः(/Vāksañcayaḥ/)

Our corpus वाक्सञ्चयः (/Vāksañcayaḥ/), has more than 78 hours of data with an overall vocabulary size of 91,000 words and recordings of about 46,000 sentences, each with a sampling rate of 22 KHz. The contents span over 3 time periods categorised into pre-classical literature (1,500 BCE - 100 BCE), classical literature (300 CE - 800 CE) and modern literature (900 CE to now). The corpus is intended to address the challenges in interfacing the speech and the text covered by the disciplines of phonetics (*Śikṣā*), and grammar (*vyākaraṇa*). Hence, we confine our corpora to those written only in prose (Gadya)[2]. In the Sanskrit literature, frequency of commonly used words changes

Dataset	Speakers	Hours	Utterances
Train	12	56	34,309
Validation	5	8	3,337
Test	5	10	5,531
Out-of-domain Test	5	5	2,618

Table 1: Overview of Sanskrit speech corpus.

[2] We do not include verses in our current dataset, as modelling ASR systems for verses would require additional resources on both the acoustic model and the language model fronts.

from one topical domain to another, specifically one *Śāstra* (branch of learning) to another (Adiga et al., 2018). Our corpus contain samples from diverse domains, including philosophy, literature, commentary on poetry and grammar. It also includes contemporary recordings such as stories, live lectures, spiritual discourse and radio program/podcast, so that collecting a wide range of Sanskrit vocabulary.

The recordings were primarily collected with the help of volunteers, recording their speech by using the Recorder app on Android phones and the Audacity platform, and from various sources available online.[3] oTranscribe[3] was used to transcribe the audio files. We had a total of 9 volunteers for recording and 18 unique speakers for the content collected online. Each of these speakers are proficient Sanskrit speakers, with at least an undergraduate or equivalent degree in Sanskrit. These speakers are native speakers of one of the 6 following Indic languages, Hindi, Kannada, Malayalam, Marathi, Tamil and Telugu. In Table 1, we provide the details of the training/validation/test splits for our corpus, वाक्सञ्चयः (/Vāksañcayaḥ/). The speakers in all these 4 splits, train, validation, test, and out-of-domain test sets are disjoint. The out-of-domain test dataset is a stratified sampled dataset, consisting of speech samples from 5 unique speakers. Two of these were added to include utterances in Sanskrit from speakers with more pronounced influence of their native languages (in Hindi and Tamil). The domain of the training dataset primarily is a speech collection of readings from various well known texts. Further, the speech in the training data is in accordance with the traditional phonetic prescriptions of Sanskrit (Śikṣā). Hence, the remaining three in the out-of-domain test set were added to include utterances from different speech domains, extempore discourse, lecture and radio program, differing from the speech domain in the training set. The radio program is studio produced, while the other two are live recorded.

2.1 Challenges in Sanskrit ASR

In this section, we describe various linguistic phenomena that are important to consider when preparing datasets and building ASR systems for Sanskrit with the help of illustrative examples.

Word Length: The tokens in Sanskrit texts can be very long owing to "Sandhi" and the lexically productive process of compounding (``Samāsa"). For instance, consider a compound word, वागर्थप्रतिपत्तये(/vāgarthapratipattaye/). It forms a 19 letter word in SLP1 (vAgarTapratipattaye), and is formed by combining the three Sanskrit stems वाक्, अर्थ, प्रतिपत्ति (/vāk, artha, pratipatti/), as per the rules of Sandhi and Samāsa. In Figure 1, we present the distribution of the number of characters (in SLP1 format) per word across the three languages that we experimentally analyse in this work, *viz.*, Sanskrit, Telugu and Gujarati. The plots are normalized with respect to the size of the vocabulary. The average word length is much higher in Sanskrit (10.75) compared to Gujarati (7.79) and Telugu (9.35). Table 2 compares the distribution of number of characters (*wrt* SLP1) per word in the training vocabulary of three ASR datasets. More than 26% of the words in Sanskrit have length exceeding 12 characters.

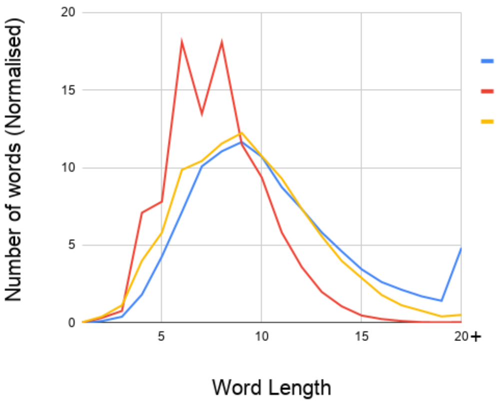

Figure 1: Distribution of Number of characters (in SLP1 representation) per word across Sanskrit, Telugu and Gujarati

Char count(N)	Sanskrit	Telugu	Gujarati
$N \leq 6$	13.79%	21.27%	34.11%
$6 < N \leq 12$	59.56%	61.60%	61.82%
$N > 12$	26.65%	17.13%	4.07%

Table 2: Distribution of number of characters (*wrt* SLP1) per word in three ASR datasets

Sandhi: Sandhi can occur between successive words in a sentence or between the lexemes in a compound, or between the morphemes of the

---

a) nityaśśabdārthasambandhaḥ
b) nityaḥ śabdārthasambandhaḥ
c) nityaḥ śabdārtha sambandhaḥ
d) nityaśśabdārtha sambandhaḥ

Figure 2: a) Utterance of a sequence without any pause b) Sandhi split at word boundary c) Sandhi based segmentation d) utterance splits without sandhi

same word. While recognising longer sequences due to sandhi and compounding is a challenge in itself, the external sandhi gives rise to the issue of arbitrary points of segmentation performed by speakers at the time of utterance. Figure 2a shows text-sequence where the sequence contains a word *nityaḥ* and a compound *śabdārthasambandhaḥ* fused together via Sandhi. Further, *śabdārthasambandhaḥ* is a compound with *śabda*, *artha* and *sambandha* as its components. While it is expected to be uttered without any pause after considering *Samhitā* (Aṣṭādhyāyī-1-4-109), a speaker may choose to segment at the lexical boundaries as shown in Figure 2c and Figure 2d. However in doing so, a proficient speaker would prefer a sequence similar to Figure 2a or 2b, rather than Figure 2c or 2d. This is because, the former two, though result in phonetic transformations, preserve the syntactic and semantic validity of the sequence. However, the latter do not preserve the syntactic and semantic validity of the sequence. Similarly, there are cases where there can be phonetic transformations between the bound morphemes and the free morpheme of a word. These transformations do not result in any modification to the word, other than phonetic variations. However, this makes it challenging for an ASR system. The case of Diphthongs is the quite prevalent under these cases.

In Diphthongs, which can occur both at internal or external sandhi, the independent vowel can only occur at the start of a word. Any vowel appearing in the middle of a word either gets converted to a dependent vowel or a diphthong. When a word ending with "ए(/ē/) or ओ(/ō/)" and followed by any vowel, then ending will be changed to either "अय्(/ay/) or अव्(/av/) respectively" or "अ(/a/)". For example विष्णो+ इह(/viṣṇo+iha/) will get converted to विष्णइह(/viṣṇaiha/) or विष्णविह(/viṣṇaviha/).

Unicode encoding: The Unicode encoding for the native scripts in Sanskrit, similar to several indian languages, does not preserve the correspondence with the phonemic encoding. Further, mapping the graphemes in Unicode to the corresponding phonemes either suffers from ambiguity and redundancy or often requires multi-grapheme combinations. For instance, consider the word वागर्थाविव(/vāgarthāviva/) in Sanskrit.Here the graphemes in Devanagari 'व ◌ा ग र ◌् थ ◌ा व ◌ि व'and Roman (v ā g a r t h ā v i v a) do not exhibit a one-to-one mapping with the phonemes. For instance, a single grapheme (e.g., ग) may correspond to 2 phonemes while two graphemes (e.g., र ◌् in devanagari, 't h' in roman) may correspond to a single phoneme.

3 Unit Selection Alternatives for AM and LM

In this section, we discuss different alternatives for identifying units of the language model and the acoustic model that we subsequently employ in our experimental evaluation and analysis.

3.1 Alternatives for Graphemic Representation

The Unicode standard for native scripts of Sanskrit : Devanagari, Gujarati and Telugu faces challenge for computational language processing due to redundancy in mappings between phonemes and graphemes as previously discussed. So for Sanskrit, we use Sanskrit Library Phonetic encodings (SLP1) designed by Scharf and Hyman (2011). This encoding gives unique one-to-one mapping to the phoneme. However Gujarati possesses extra native characters such as ઍ(/e/), ઑ(/o/) . Telugu also possesses extra characters such as ఎ(/e/), ఒ(/o/), and ఱ(/r̲/). So we extend SLP1 to fit to the character set of Gujarati and Telugu in our experiments.

3.2 Alternatives for Sub-word units

One possibility for deriving subword units for the language modeling is to segment words in Sanskrit based on Sandhi rules. However, Sandhi splitting can change some phonemes corresponding to the words in almost all cases. Consider the word रामायेदम् = रामाय+ इदम् (/rāmāyedam/ = /rāmāya/+/idam/), wherein the vowel ए (/e/) is changed into अ+ इ (/a/+/i/) after performing Sandhi-based splitting. This leads to a mismatch between the speech transcript and the speech audio, potentially creating further complications for

ASR.

3.2.1 BPE-based Word Segmentation

Byte pair encoding (BPE) is a simple data compression algorithm that iteratively replaces the frequently occurring subword units with a single unused byte (Gage, 1994). This technique was first adopted to model rare words using subword units in neural machine translation (Sennrich et al., 2016). Interestingly, BPE has been explored for learning new vocabulary for poetry to prose conversion in Sanskrit (Krishna et al., 2019). We consider the benefits of using BPE as a subword unit for Sanskrit ASR.

While BPE is a purely data-driven segmentation strategy, we next present a linguistically motivated segmentation approach that might be aligned with finding syllable units for ASR that are more phonetically compliant. We refer to this technique as *vowel segmentation.*

3.2.2 Vowel Segmentation

Splitting the tokens based on vowels and adjacent consonants is inspired by the identification of metres in Sanskrit prosody, where the metre of a verse is identified by using syllable segmentation, followed by identification of syllable weights and it's combinations (Melnad et al., 2013). The syllable weight of a syllable can either be laghu (light)(represented by the symbol ।) or guru (heavy)(represented by the symbol ऽ). Syllables with short vowels generally form Laghu and those with loing vowels form a Guru. Also, when a short vowel is followed by a conjunct consonant or Anusvāra (nasal sound /ṃ/) or Visarga (voiceless glottal fricative /ḥ/), the short vowel now becomes Guru. E.g., the *Laghu-Guru* mapping of "अन्यानि संयाति(/anyāni saṃyāti/)" is "ऽऽ। ऽऽ।". In prior work involving Indian languages for TTS, Kishore et al. (2002) proposed various syllabification rules for words. Herein (with a few exceptions), if a vowel is followed by 3 or more consonants, only the first following vowel is grouped with the preceding vowel to form the subword unit.

Our proposed algorithm for vowel segmentation (VS) is outlined in Algorithm 1. We propose segmenting words at vowel boundaries to extract the units for which alignment with speech is learnt within the ASR system. For acoustic models, an effective unit of a word for ASR would arguably be the syllable (Lee et al., 2013). Representing a word in terms of syllables demands the mapping of a word from graphemes to phonemes. To create syllable units, phonemes are then combined together based on the *sonority sequencing principle* (Clements, 1990). Absence of accurate syllabifiers for Indian languages restricts the use of syllables as units for learning alignment. Our approach produces units which can be viewed as a rough approximation to a syllable. A syllable is composed of three parts *viz.,* onset, nucleus and coda, where nucleus has the highest sonority and is always a vowel. In our approach, the onset is always one or zero consonants and the coda is zero or *n-1* consonants if the nucleus is followed by *n* consonants. It is also observed in the pronunciation of conjunct consonant by professional speakers that the beginning part of conjunct consonant gets associated more with the preceding vowel than the following. We consider nasal Anusvāra (◌ं), Chandrabindu (◌ॅ or ◌ँ), and Visarga (◌ः) to be part of the consonant set. For example, in Sanskrit, the units for a word उद्यानः (udyāna , park) will be 'उद् या नः(/ud yā na /)' and subword units of the Telugu word తల్లితండ్రులు(/tallitaṃḍrulu/) will be 'తల్ లి తండ్ రు లు(/tal li taṃḍ ru lu/)'.

ALGORITHM 1: Vowel segmentation algorithm for Indian languages

```
Input: word in Indian language
Output: Vowel segments in output
output = "";
for each graphemic unit $c_i$ in word do
    if $c_i$ is V then
        if $c_{i+1}$ is V then
            output += $c_i$ + " ";
        else if $c_{i+1}$ is C and $c_{i+2}$ is C then
            output += $c_i$;
        else if $c_{i+1}$ is C and $c_{i+2}$ is V then
            output += $c_i$ + " ";
    else
        if $c_{i+1}$ is V then
            output += $c_i$;
        else if $c_{i+1}$ is C and $c_{i+2}$ is C then
            output += $c_i$;
        else if $c_{i+1}$ is C and $c_{i+2}$ is V and
          $c_{i+2}$ is first vowel of the word then
            output += $c_i$;
        else if $c_{i+1}$ is C and $c_{i+2}$ is V then
            output += $c_i$ + " ";
```

3.3 Vocabulary size as a function of graphemic unit

For each choice of graphemic unit (*viz.* native script and SLP1) described in Section 3.1, we study three different units for the acoustic modeling (AM) in ASR, *viz.,* graphemic unit and vowel segmentation for Sanskrit and also phonemic unit across the two other representative Indian languages *viz.*, Gujarati and Telugu. Whereas, for language modeling (LM), we study word, BPE and VS based units. In Figure 3, we report the vocabulary size based on each of these *three* different unit selections and contrast the sizes with that of two extreme hypothetical systems - one that considers the entire word as a single unit for AM and the other that treats the phoneme as a single unit for AM. Note that while phonetic dictionaries are available for Telugu and Gujarati, our dataset for Sanskrit does not have an accompanying phonetic dictionary. We present the variation in vocabulary size as a function of the graphemic unit (native script vs. SLP1). In both Gujarati and Telugu, we point out that the number of SLP1 graphemic units almost coincide with the number of phonemes, while the native script-based graphemes are much larger in number compared to phonemes.

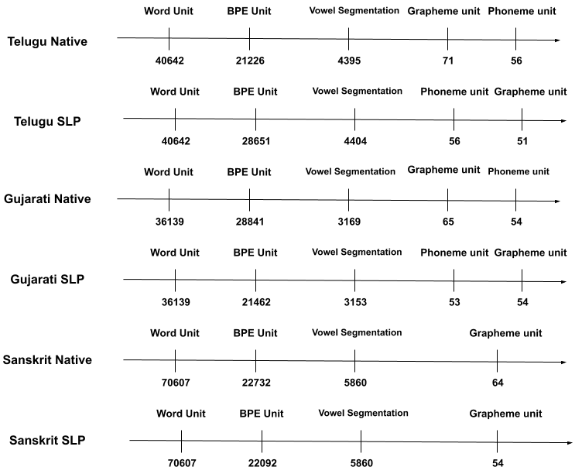

Figure 3: Variation in vocabulary size as a function of the Graphemic unit (native script vs. SLP1) depicting the vocabulary sizes of the whole word units, vowel segment units, BPE units, phonemes and graphemes for ASR data across the three languages including our new Sanskrit ASR data

We can also roughly estimate the extent of data sparsity in terms of vocabulary size in each setting - larger the vocabulary size, higher is the chance of data sparsity. We note that data sparsity is minimal for graphemes and highest for a hypothetical system where whole words are the unit of selection.

4 Experiments and Results

Description of Datasets: In addition to reporting ASR results on the carefully created वाक्सञ्चयः (/Vāksañcayaḥ/) dataset (described in Section 2), we also contrast through experimental analysis on two other Indian languages, *viz.*, Telugu and Gujarati. For Telugu and Gujarati, we used the publicly available speech corpora released by Microsoft (Srivastava et al., 2018) that contains 36.2/8.7 hours and 33.2/5.8 hours of training/test speech in Telugu and Gujarati, respectively. We use a new train-test split for the Gujarati and Telugu datasets because the original split had overlapping spekaers in their train and test. Our new split ensures that the train-test split have disjoint speakers. Transcript of this corpora was cleaned for orthographic errors. Corpora in these two languages were accompanied by pronunciation lexicons, which we used to build phoneme-based ASR systems to compare against our grapheme-based systems.

Experimental Setup: We use the Kaldi toolkit (Povey et al., 2011) for all our ASR experiments. Our acoustic model is implemented using Time Delay Neural Networks (TDNNs) (Peddinti et al., 2015) containing 14 layers. We use 40-dimensional MFCCs as our input features along with 100-dimensional i-vector based speaker embeddings (Saon et al., 2013). We used ngram language models with Kneser-Ney smoothing implemented using the SRILM toolkit (Stolcke, 2002). The language models were trained using both training transcripts from the speech data, as well as additional textual data derived from the Leipzig Corpora Collection for Gujarati and Telugu (Goldhahn et al., 2012) and the Digital Corpus of Sanskrit (Hellwig, 2010) for Sanskrit. The word vocabulary sizes in the lexicons for Sanskrit, Telugu and Gujarati are 76K, 43K and 48K, respectively.

Results: Tables 3, 4 and 5, present the WERs from ASR systems built using different choices of AM and LM units using both the graphemic representations (Native and SLP1) for Sanskrit, Gujarati and Telugu, respectively. From Table 3, we

Sr.	Script	LM Unit	AM Unit	WER
1	Native	Word	Gr.	40.06
2	SLP1	Word	Gr.	40.57
3	Native	VS	Gr.	22.55
4	SLP1	VS	Gr.	22.59

Table 4: WERs on Gujarati test set. (Gr.=Grapheme , Phn.= Phoneme)

Script	LM Unit	AM Unit	WER
Native	Word	Phn.	21.12
Native	Word	Gr.	21.25
Native	BPE	Gr.	26.68
SLP1	Word	Gr.	**20.75**
SLP1	Word	Phn.	20.92
SLP1	Word	Gr. + VS	22.13
SLP1	BPE	Gr.	25.07
SLP1	BPE	Gr. + VS	26.3
SLP1	VS	Gr.	33.68
SLP1	VS	Gr. + VS	36.57

Table 5: WERs on Telugu test set. (Gr.=Grapheme , Phn.= Phoneme)

see that BPE units[4] and vowel segment units are far superior compared to words as an LM unit for Sanskrit. This is unsurprising given that Sanskrit has a high rates of OOV (44.16%). However, as shown in Tables 4 and 5 the configurations with word based LMs performs the best for Gujarati and Telugu respectively. Gujarati and Telugu have lower OOV rates of 18.63 % and 15.26 %.

Table 6 shows the distribution of words with 1-4 continuous consonants in all three languages. For Telugu, even though the number of conjunct consonants with $N = 2$ is higher than in Sanskrit, we found on inspecting the audio data that such conjunct consonants are often not enunciated clearly. For example స్వాతన్త్ర్యమ్(/svāta**ntry**am/) is pronounced as స్వాతన్త్రమ్(/svāta**ntr**am/). However, in Sanskrit, conjunct consonants having 5 consonants together such as कार्त्स्न्यम् (/kā**rtsny**am/) are enunciated very clearly and all consonants appear articulated in its pronunciation.

Due to the morphological richness (Kulkarni et al., 2015), inflections and compounds, Sanskrit always has the highest number of rare words. In the training dataset used in the Sanskrit ASR experiments with the vocab size of 70.5K, more than 87.25% words have a frequency less than 3, where as in Telugu and Gujarati training dataset, this is 76.76% and 77.26%, respectively. Clear articulation of conjunct consonants and higher rare word rates makes the BPE and VS based models performs better in Sanskrit than other two languages along with the impact of OOVs.

We observe that use of SLP1 as a graphemic representation schemes performs best for all the three languages. SLP1 is designed to capture the phonemic-graphemic correspondences present in Indic languages. We also find that ASR performance using phonemes is comparable to graphemes for Gujarati and Telugu. In Sanskrit, we observe that purely grapheme-based acous-

N	Sanskrit	Telugu	Gujarati
1	77.30%	75.77%	89.37%
2	21.41%	23.27%	10.06%
3	1.26%	0.96%	0.56%
4	0.03%	0%	0%

Table 6: Number of continuous consonants (N) distribution in three ASR datasets

---

[4] Vocabulary size of 32K is used for BPE which is closest to the vowel split (29,147 entries) for Sanskrit. Performance for varying number of subword units for BPE is presented in Appendix B.

tic models outperform grapheme+vowel segment-based acoustic models. With the consistent mapping between graphemes and phonemes and the absence of schwa deletion, it is intuitive that grapheme-based models would be most appropriate for Sanskrit. Even though for Sanskrit in some cases Devanagari as a graphemic representation outperforms the SLP1 (Sr. 1,3,9,11 in Table 3), the model that uses SLP1 script always outperforms the other in terms of character error rate.

In Sanskrit the pause given between the sub-words of a compound word and in between two words varies depending on the fluency of the speaker and the complexity of the text, which can deteriorate the WER. The utterance for 'महान् प्राकारः' /mahān prākāraḥ/ may get recognised as 'महान्प्राकारः' /mahānprākāraḥ/, where two correctly recognised words will be evaluated as one *deletion* and one *substituion* by the evaluation model. Similarly if the audio of 'शोभमानमासीत्' /śobhamānamāsīt/ gets recognised as 'शोभमानम् आसीत्' /śobhamānam āsīt/, then it will be considered as one *insertion* followed by one *substituion*. After negating these two particular errors, we will get 17.79% as the *modulo substitution deletion* WER for our best model of Sanskrit (Sr. 6 of Table 3). The character error rate 3.10% for the best model in Sanskrit also ensures the performance of the model and the quality of the dataset, where as the CER for the best model of Gujarati and Telugu are 5.49% and 5.60% respectively, much higher than Sanskrit.

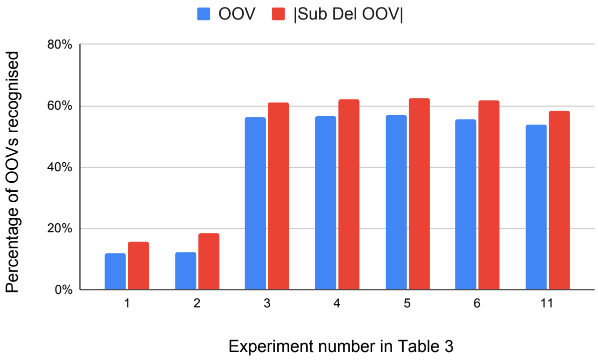

Figure 4: Percentage of OOVs recognised for Sanskrit by the ASR system for the experiments listed in Table 3

OOV Analysis: The OOVs at word level are 44.16%, 15.26% and 18.63% for Sanskrit, Telugu and Gujarati, respectively. Figure 4 depicts the percentage of OOVs recovered by different ASR experimental setup described in Table 3, also giving *modulo substitution deletion* OOVs. As we move from word based LM Unit to BPE and VS, system is able to recognize more than 57% of OOVs. For Telugu and Gujarati OOVs recognition rate is 53.67% and 48.61% respectively for their best performing models.

#	WER	Speech Description
1*	37.79%	Tamil influenced accents
2*	37.60%	Hindi influenced accents
3*	46.27%	Radio Program
4	46.62%	Extempore Discourse
5	51.52%	Live Lecture

Table 7: Test results for the Out-of-domain Dataset (* readings from books and transcripts)

Out-of-domain test set. Table 7 presents results on the out-of-domain test set described in Section 2. It shows the WERs we can expect from our models when the speakers and content largely vary in domain from our dataset. This test set was sampled for specific speakers and content that qualify as being out-of-domain. These test utterances were evaluated using our best performing Sanskrit ASR models. Speakers #1 and #2 were included, as their utterances show more pronounced influence of their native languages, Tamil and Hindi respectively. It is observed that speaker #1, does not often attempt to distinguish between the pronunciation of the phoneme pairs such as /ta/ and /da/, /ka/ and /ga/, *etc.* This is in congruence with the orthography followed in Tamil, the speaker's native language. Speaker #2's reading was influenced by schwa deletion, *i.e.*, the phenomena of deleting vowel markers accompanying consonants at certain contexts (elaborated in the supplementary material) which is dominant in Hindi. For example, गतवान् /gatavān/ is pronounced as /gatvān/ by this speaker and the ASR system correctly predicts it as /gatvān/. Here, the acoustic model clearly dominates the language model. Speaker #3's utterances are the Sanskrit translation of the Indian government's public outreach program known as 'मन की बात' /man kī bāt/. This widely differs from the training speech dataset and vocabulary of the LM that is used. Similar observation can be made for speakers #4 and #5, albeit for different reasons. Speaker #4 in the discourse tends to use rare words, especially domain-specific proper nouns and derivational verbs, both of which are scarce in our LM vocabulary. Speaker #5 tends to deviate from conventional speech patterns, by providing emphasis on specific words, for the purpose of pedagogy.

5 Conclusion

We presented a new Sanskrit speech corpus वाक्सञ्चयः (/Vāksañcayaḥ/) along with a new large-vocabulary ASR system. We explored different unit selection alternatives for both AM and LM, along with a new segmentation approach. We observe that SLP1, when used as the script instead of the native scripts generally results in better performances for Gujarati and Telugu. For Sanskrit, SLP1 based model results in better character error rate and BPE based model with SLP1 giving the best result. Similarly, we observe that vowel split based segmentation consistently yields better performance than word based model and close to results of the best model. Our current dataset and the model are specifically designed to handle data in prose. The inclusion of poetry data would require substantial changes to the system, which we plan to address in the near future. For instance, the poetry data would greatly benefit from insights from Sanskrit prosody. More importantly, the degree of free word orderness in prose and poetry greatly varies in Sanskrit, so much so that an n-gram LM will not be effective (Krishna et al., 2018).

Acknowledgments

We would like to thank Prof. K. Ramasubramanian, IIT Bombay, for supporting the creation of Sanskrit speech corpus. We express our gratitude to the volunteers who have participated in recording readings of classical Sanskrit texts and helping make this resource available for the purpose of research.

A Differences between Sanskrit and other Indic languages for ASR

Many Indian languages are known to be derived from Sanskrit (Kulkarni et al., 2010b) and their scripts derived from the Brahmi script (Salomon, 1996; Sproat, 2003), which leads to grapheme-based similarites amongst them. In Figure 5, we illustrate through an example, the spectrum of mapping the native character/grapheme (units) in words across languages; at one end of the spectrum is राम(/rām/) in Hindi mapped to రామ(/rāma/) in Telugu as an example where direct correspondence with the native character exists. Going further in the spectrum are examples for which direct character correspondence does not exist. सीता(/sītā/) in Hindi going to ಸೀತೆ(/sīte/) in Kannada is an instance where there is a change in the ending vowel.

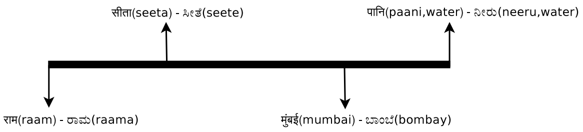

Figure 5: Spectrum of mapping native character/grapheme (units) in words across Indian languages

Schwa Deletion The schwa deletion phenomenon plays a crucial role in the north Indian languages. Every consonant by itself includes a short /a/ vowel sound (referred to as “schwa”) unless otherwise specified. For example, the letter ‘त’ in Hindi is pronounced as /ta/. This sound can be associated with any other vowel sound by the use of “Mātras”. Mātras are dependent forms of vowels. Schwa is the default vowel for a consonant and hence does not require any explicit Mātra to represent it. Schwa deletion is a phenomenon where implicit schwas of a word are deleted during pronunciation. For example, in Hindi, the proper noun, ‘अर्जुन (/arjun/, the name of a person) has schwa deletion after the consonant ‘न’ and is pronounced as Arjun. This phenomenon is not observed in the South Indian languages. For instance, in Kannada it is pronounced as ‘Arjuna’. There is no implicit schwa deletion in Sanskrit as well as in the traditional use of South Indian languages such as Kannada. North Indian languages observe schwa deletion not only at the end of the word, but also in the middle of a word in some cases. For example, the word ‘गलती’ (/galtī/ meaning mistake) in Hindi observes implicit schwa deletion after the consonant ‘ल’ (/la/).

ASR becomes challenging because of this phenomenon since the occurrence of schwa deletion is not always explicitly specified in the orthography. For example, the name रामबाबु (/rāmbābu/) has two basic words concatenated to form a name. In Hindi, this name has an implicit schwa deleted at म (consonant sounding ’ma’) of राम (/rām/). While constructing phonetic representations for ASR, such deletions introduce ambiguities in pronunciation which could be alleviated by enforcing more consistency between graphemes and phonemes. This same word रामबाबु written in Telugu would be phonetically represented as రామ్బాబు (/rāmbābu/) instead of రామబాబు (/rāmabābu/) which is intuitive. Note that in the former case, there is an addition of ‘◌్(*halant*: an explicit schwa deletion marker) at మ(/ma/). This forces the consonants మ(/ma/) and బ(/ba/) to combine and form a conjunct. In the latter case there is a grapheme consistency across both Hindi and Telugu languages but there is a variation in their pronunciation due to the schwa deletion phenomenon. In contrast, in the case of Sanskrit, since pronunciation is strictly governed by the शिक्षा(/śikṣā/) (Manomohan and Pāṇini, 1938), a treatise on phonetics, schwa deletion is not observed.

B BPE Experiment Details

In Sanskrit a noun can have 24 to 92 inflections (depending on base word’s gender and alternate forms) and a verb can have 90 to 180 inflections. Derivative nouns (*Taddhitas*) and verbs (passive (*Karmaṇi*), *san, ṇic, yaṅ,* etc) are also used often in Sanskrit literature. Due to this morphological richness and frequently occurring compound words, vocab size can be reduced by properly selecting repetitive stems and suffices using BPE by specifying the number of merge operations. Therefore we experimented varying number of subword unit with vocabulary sizes of 2K, 4K, 8K, 16K, 32K and 64K (K=1000). Table 8 shows the varying BPE configuration on our best configuration, i.e graphemes as AM unit and BPE as LM unit. However, the performance of these configurations are comparable irrespective of their BPE vocabulary size.

BPE with vocabulary size of 32,000 stands closes to that of VS, with a vocabulary size of 29,147. Even in this configuration, BPE outperforms VS, as BPE reports a WER of 21.94 as

Sr.	Vocabulary Sizes	WER
1	32K	21.94
2	16K	21.96
3	8K	21.83
4	4K	**21.79**
5	2K	22.41

Table 8: WERs for Sanskrit on different vocabulary sizes with Graphemes as AM unit and BPE as LM unit using script SLP1 (on the best configuration model).

against 22.58 (Table 3 serial no. 4) of VS. However, the BPE configuration with a vocabulary size of 4K reports the lowest WER, which is 0.15% points lower in comparison to BPE with 32K vocabulary size. But the CER for 32K vocabulary size is 3.10% which is outperforming the BPE with vocabulary size of 4K which has a CER of 3.29%.

Abstract

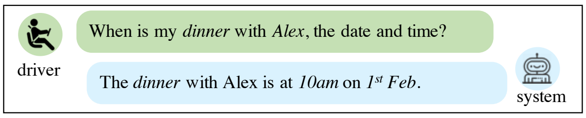
End-to-End task-oriented dialogue systems generate responses based on dialog history and an accompanying knowledge base (KB). Inferring those KB entities that are most relevant for an utterance is crucial for response generation. Existing state of the art scales to large KBs by softly filtering over irrelevant KB information. In this paper, we propose a novel filtering technique that consists of (1) a pairwise similarity based filter that identifies relevant information by respecting the n-ary structure in a KB record. and, (2) an auxiliary loss that helps in separating contextually unrelated KB information. We also propose a new metric – multiset entity F1 which fixes a correctness issue in the existing entity F1 metric. Experimental results on three publicly available task-oriented dialog datasets show that our proposed approach outperforms existing state-of-the-art models.

1 Introduction

Task oriented dialog systems interact with users to achieve specific goals such as restaurant reservation or calendar enquiry. To satisfy a user goal, the system is expected to retrieve necessary information from a knowledge base and convey it using natural language. Recently several end-to-end approaches (Bordes and Weston, 2017; Wu et al., 2018; He et al., 2020b; Madotto et al., 2018) have been proposed for learning these dialog systems.

Inferring the most relevant KB entities necessary for generating the response is crucial for achieving task success. To effectively scale to large KBs, existing approaches (Wen et al., 2018; Wu et al., 2018) distill the KB by softly filtering irrelevant KB information based on the dialog history. For example, in Figure 1 the ideal filtering technique is expected to filter just the row 1 as the driver is requesting information about *dinner* with *Alex*. But existing techniques often filter some irrelevant KB information along with the relevant KB information. For example, in Figure 1 row 3 may also get filtered along with row 1.

#	Date	Event	Invitee	Time
1	*1st Feb*	*dinner*	*Alex*	*10am*
2	7th Feb	dentist appointment	-	2pm
3	8th Feb	dinner	Ana	7pm



When is my *dinner* with *Alex*, the date and time?

The *dinner* with Alex is at *10am* on *1st Feb*.

Figure 1: An example dialog between a driver and a system along with the associated knowledge base.

Our analysis of the best performing distillation technique (Wu et al., 2018) revealed that embeddings learnt for entities of the same type are quite close to each other. This may be due to entities of the same type often appearing in similar context in history and KB. Such embeddings hurt the overall performance as they reduce the gap between relevant and irrelevant KB records. For example, in Figure 1 row 3 may not get distilled out if *Alex* and *Ana* have similar embeddings.

In this paper, we propose Constraint based knowledge base Distillation NETwork (CDNET), which (1) uses a novel pairwise similarity based distillation computation which distills KB at a record-level, and (2) an auxiliary loss which helps to distill contextually unrelated KB records by enforcing constraints on embeddings of entities of the same type. We noticed the popular entity F1 evaluation metric has a correctness issue when the response contains multi instances of the same entity value. To fix this issue, we propose a new metric called multiset entity F1. We empirically show that CDNET performs either significantly better than or comparable to existing approaches on three publicly available task oriented dialog datasets.

2 Related Work

We first discuss approaches that are closely related to our work. Wu et al. (2018) perform KB distillation but fails to capture the relationship across attributes in KB records. It represents a KB record with multiple attributes as a set of triples (*subject, predicate, object*). This breaks direct connection between record attributes and requires the system to reason over longer inference chains. In Figure 1, if *event* field is used as the key to break the record into triples, then the distillation has to infer that *(dinner, invitee, Alex)*, *(dinner, date, 1st Feb)* and *(dinner, time, 10am)* are connected. In contrast, CDNET performs KB distillation by maintaining the attribute relationships. Wen et al. (2018) perform distillation using the similarity between dialog history representation and each attribute representation in a KB record, whereas CDNET uses word based pairwise similarity for distillation.

We now briefly discuss approaches that improve other aspects of task oriented dialogs. He et al. (2020c) and He et al. (2020b) model KBs using Relational GCNs (Schlichtkrull et al., 2018).Raghu et al. (2019) provide support for entities unseen during train. Reddy et al. (2019) improve the ability to reason over KB by respecting the relationships between connected attributes. Qin et al. (2019) restricts the response to contain entities from a single KB record. (Qin et al., 2020) handle multiple domains using shared-private networks and He et al. (2020a) optimize their network on both F1 and BLEU. We are the first to propose a pairwise similarity score for KB distillation and a embedding constraint loss to distill irrelevant KB records.

3 CDNET

CDNET [1] has an encoder-decoder architecture that takes as input (1) the dialog history $\mathcal{H}$, modelled as a sequence of utterances $\{u_i\}_{i=1}^{k}$ and each utterance u_i as sequence of words $\{w_i^j\}$, and (2) a knowledge base $\mathcal{K}$ with M records $\{r_m\}_{m=1}^{M}$ and each record r_m has N key-value attribute pairs $\{(k^n, v_m^n)\}_{n=1}^{N}$. The network generates the system response $Y = (y_1, \ldots, y_{\mathbb{T}})$ one word at a time.

3.1 CDNET Encoder

Context Encoder: The dialog history $\mathcal{H}$ is encoded using a hierarchical encoder (Sordoni et al., 2015). Each utterance representation $\mathbf{u}_i$ is computed using a Bi-GRU (Schuster and Paliwal, 1997). We denote the hidden state of the j^{th} word in i^{th} utterance as $\mathbf{w}_i^j$. The context representation $\mathbf{c}$ is generated by passing $\mathbf{u}_i$s through a GRU.

KB Encoder: We encode the KB using the multi-level memory proposed by Reddy et al. (2019) as its structure allows us to perform distillations over KB records. The KB memory contains two-levels. The first level is a set of KB records. Each KB record is represented as sum of its attributes $\mathbf{r}_m = \sum_n \Phi^e(v_m^n)$, where Φ^e is the embedding matrix. In the second level, each record is represented as a set of attributes. Each attribute is a key-value pair, where the key $\mathbf{k}^n$ is the attribute type embedding and the value $\mathbf{v}_m^n$ is the attribute embedding.

3.2 KB Distillation

The KB distillation module softly filters irrelevant KB records based on the dialog history by computing a distillation distribution (P_d) over the KB records. To compute $P_d = [d_1, \ldots, d_M]$, we first score each KB record r_m based on the dialog history $\mathcal{H}$ as follows:

$$s_m = \sum_{w \in \mathcal{H}} \sum_{v_m^n \in r_m} \text{CosSim}(\Phi^e(w), \Phi^e(v_m^n)) \quad (1)$$

where CosSim is the cosine similarity between two vectors. The distillation likelihood d_m

---

[1] `https://github.com/dair-iitd/CDNet`

for each record r_m then is given by $d_m = \exp(s_m)/\sum_{q=1}^{M}\exp(s_q)$.

Defining distillation distribution over the KB records rather than KB triples has two main advantages: (1) attributes (such as invitee, event, time and date in Figure 1) in a KB record are directly connected and thus easy to distill, (2) it helps to distill the right records even when the record keys are not unique. In Figure 1, row 3 would be distilled even though it shares the same event name.

3.3 CDNET Decoder

Following Wu et al. (2018), we first generate a sketch response which uses entity type (or sketch) tag in place of an entity. For example, *The @meeting with @invitee is at @time* is generated instead of *The dinner with Alex is at 10pm*. When an entity tag is generated, we choose an entity suggested by the context and KB memory pointers.

Sketch RNN: We use a GRU to generate the sketch response. At each time t, a generate distribution P_g is computed using the decoder hidden state $\mathbf{h}_t$ and an attended summary of the dialog context $\mathbf{g}_t$. The summary $\mathbf{g}_t = \sum_i \sum_j a_{ij}\mathbf{w}_i^j$, where a_{ij} is the Luong attention (Luong et al., 2015) weights over the context word representations ($\mathbf{w}_i^j$).

Context Memory Pointer: At each time t, generate the copy distribution over the context P_{con} by performing a multi-hop Luong attention over the context memory. The initial query $\mathbf{q}_t^0$ is set to $\mathbf{h}_t$. $\mathbf{q}_t^0$ is then attended over the context to generate an attention distribution $\mathbf{a}^1$ and a summarized context $\mathbf{g}_t^1$. We represent this as $\mathbf{g}_t^1 = \text{Hop}(\mathbf{q}_t^0, \mathbf{x})$. In the next hop the same process is repeated by updating the query $\mathbf{q}_t^1 = \mathbf{q}_t^0 + \mathbf{g}_t^1$. The attention weights after H hops is used for computing the context pointer P_{con} as follows:

$$P_{con}(y_t = w) = \sum\nolimits_{ij:w_i^j = w} a_{ij}^H \qquad (2)$$

KB Memory Pointer: At each time t, we generate the copy distribution over the KB P_{kb} using (1) Luong attention weight β_m^t over the KB record r_m and (2) Luong attention weight γ_n^t over attribute keys in a record $\mathbf{k}^n$ and (3) the distillation weight d_m over the KB record r_m. The KB pointer P_{kb} is computed as follows:

$$P_{kb}(y_t = w) = \frac{\sum_{mn:v_m^n = w} d_m \beta_m^t \gamma_n^t}{\sum_{mn} d_m \beta_m^t \gamma_n^t} \qquad (3)$$

The two copy pointers are combined using a soft gate α (See et al., 2017) to get the final copy distribution P_c as follows,

$$P_c(y_t) = \alpha P_{kb}(y_t) + (1-\alpha)P_{con}(y_t) \qquad (4)$$

3.4 Loss

We guide the distillation module using two auxiliary loss terms: entity constraint loss $\mathcal{L}_{ec}$ and distillation loss $\mathcal{L}_d$. Often entities of the same type (e.g., *Ana* and *Alex*) have embeddings similar to each other. As a result, records with similar but unrelated entities are incorrectly assigned a high distillation likelihood. To alleviate this problem, we make the cosine similarity between two entities of the same type to be as low as possible. This is captured by the constraint loss $\mathcal{L}_{ec}$ given by,

$$\mathcal{L}_{ec} = \sum_{(e_a, e_b)\in\mathcal{E}} \text{CosSim}(\Phi^e(e_a), \Phi^e(e_b)) \qquad (5)$$

where $\mathcal{E}$ is a set of entity pairs in the KB that belong to the same entity type.

The distillation likelihood d_m of a KB record r_m depends on the similarity between entities in the record and the words mentioned in the dialog context. We compute the distillation loss by defining reference distillation distribution d_m^* as $s_m^*/\sum_{q=1}^{M} s_q^*$, where s_m^* is the number of times any attribute in r_m occurs in $\mathcal{H}$ and in the gold response. The distillation loss is given by,

$$\mathcal{L}_d = -\sum\nolimits_{m=1}^{M} d_m^* \log(d_m) \qquad (6)$$

The overall loss function $\mathcal{L} = \mathcal{L}_g + \mathcal{L}_c + \mathcal{L}_{ec} + \mathcal{L}_d$, where $\mathcal{L}_g$ and $\mathcal{L}_c$ are the cross entropy loss on P_g and P_c respectively. Detailed equations are described in Appendix B.

4 Experimental Setup

Datasets: We evaluate our model on three datasets – CamRest (Wen et al., 2017), Multi-WOZ 2.1 (WOZ) (Budzianowski et al., 2018) and Stanford Multi-Domain (SMD) Dataset (Eric et al., 2017).

Baselines: We compare CDNET against the following baselines: MLM (Reddy et al., 2019), DSR (Wen et al., 2018), GLMP (Wu et al., 2018), Entity Consistent (Qin et al., 2019), EER (He et al., 2020c), FG2Seq (He et al., 2020b), TTOS (He et al., 2020a) and DFNet (Qin et al., 2020).

Table 2: Performance of CDNet and baselines on the CamRest, SMD and Multi-WOZ 2.1 datasets.

Training Details: CDNet is trained end to end using Adam optimizer (Kingma and Ba, 2014). The embedding dimensions of the hidden states of encoder and decoder GRU are set to 200 and 100 respectively. Word embeddings are initialized with pre-trained 200d GloVe embeddings (Pennington et al., 2014). Words not in Glove are initialized using Glorot uniform distribution (Glorot and Bengio, 2010). The dropout rate is set to 0.2 and teacher forcing ratio set to 0.9. The best hyper-parameter setting for each dataset and other training details are reported in the Appendix A.

Evaluation Metrics: We measure the performance of all the models using BLEU (Papineni et al., 2002), our proposed multiset entity F1 and for completeness the previously used entity F1 (Wu et al., 2018).

MultiSet Entity F1 (MSE F1): The entity F1 is used to measure the model's ability to predict relevant entities from the KB. It is computed by micro averaging over the set of entities in the gold responses and the set of entities in the predicted responses. This metric suffers from two main problems. First, when the gold response has multiple instances of the same entity value, it is accounted for just once in the set representation. For example, in Table 1 the entity value *11am* occurs twice in the gold response but accounted for just once in the *set* representation. As a result the recall computation does not penalize the prediction *pred-1* for missing an instance of *11am*. Second, the existing metric fails to penalize models that stutter. For example, in Table 1 the precision of *pred-2* is not penalized for repeating the entity value *8th*. We propose a simple modification to the entity F1 metric to fix these correctness issues. The modified metric, named MultiSet Entity F1, is computed by micro averaging over the *multiset* of entities rather than a *set*. As multisets allow multiple instances of same entity values, it (1) accounts for the same entity value mentioned more than once in the gold by penalizing recall for missing any instances and (2) accounts for models that stutters by penalizing the precision.

5 Results

The results are shown in Table 2. On CamRest and SMD, CDNet outperforms existing models in both MSE F1 and BLEU. On WOZ, CDNet achieves best only in MSE F1. We observed that the responses generated by CDNet on WOZ were appropriate, but did not have good lexical overlap with the gold responses. To investigate this further, we perform a human evaluation of the responses predicted by CDNet, FG2Seq and EER.

Human Evaluation: We conduct a human evaluation to assess two dimensions of generated responses: (1) *Appropriateness*: how useful are the responses for the given dialog context and KB, and (2) *Naturalness:* how human-like are the predicted responses. We randomly sampled 75 dialogs from each of the three datasets and requested two judges

Table 4: Ablation study of CDNET on the CamRest and SMD datasets.

to evaluate on a Likert scale (Likert, 1932). The results are summarized in Table 3. CDNET outperforms both FG2Seq and EER on *appropriateness* across all three datasets. Despite having a lower BLEU score on WOZ, CDNET performs in-par with the other two baselines on *naturalness*.

Ablation Study: We perform an ablation study by defining three variants. Table 4 shows the MSE F1 and BLEU for the two settings on CamRest and SMD datasets. (1) We remove the entity constraint loss $\mathcal{L}_{ec}$ from the overall loss $\mathcal{L}$. (2) We replace our pairwise similarity based score s_m used for KB distillation with the global pointer score ($s_m = \mathbf{r}_m^T.\mathbf{c}$) proposed by (Wu et al., 2018). We refer to this setting as naive distillation. (3) We replace our pairwise similarity based score s_m with the entry-level attention proposed by (Wen et al., 2018). We see that both our contributions: pairwise similarity scorer for computing distillation distribution and the entity constraint loss contribute to the overall performance.

Discussion: We now discuss the effect of the entity constraint loss $\mathcal{L}_{ec}$ on the KB entity embeddings. Figure 3 shows the t-SNE plot (Van der Maaten and Hinton, 2008) of entity embeddings of CDNET and GLMP where entities of the same type are represented using the same colour. We see that entities of the same type (e.g. *father* and *boss* of the type *invitees*) are clustered together in embedding space of GLMP, while they are distributed across the space in CDNET. This shows that the entity constraint loss has helped reduce the embedding similarity between entities of the same type and ensures KB records with similar but unrelated entities are filtered by the KB distillation. Visualization of distillation distribution helping identify relevant KB entities is shown in Appendix C.

6 Conclusion

We propose CDNET for learning end-to-end task oriented dialog system. CDNET performs KB distillation at the level of KB records, thereby respecting the relationships between the connected attributes. CDNET uses a pairwise similarity based score function to better distill the relevant KB records. By defining constraints over embeddings of entities of the same type, CDNET filters out contextually unrelated KB records. We propose a simple modification to the entity F1 metric that helps fix correctness issues. We refer to the new metric as multiset entity F1. CDNET significantly outperforms existing approaches on multiset entity F1 and *appropriateness*, while being comparable on *naturalness* and BLEU. We release the code for further research.

A Training Details:

All the hyper parameters are finalised after a grid search over the dev set. We sample learning rates (LR) from $\{2.5 \times 10^{-4}, 5 \times 10^{-4}, 10^{-4}\}$. The Disentangle Label Dropout (DLD) rate (Raghu et al., 2019) is sampled from $\{0.0, 0.05, 0.10, 0.15, 0.20\}$. The number of hops H in the response decoder is sampled from $\{1, 3, 5\}$. We ran each hyperparameter setting 10 times and use the setting with the best validation entity F1. The best performing hyperparameters for all datasets are listed in Table 5.

Dataset	Hops	DLD	LR	Val MSE F1
CamRest	1	0%	0.0005	68.6
SMD	3	5%	0.00025	60.4
WoZ 2.1	3	0%	0.00025	34.3

Table 5: Best performing hyperparameters along with the best validation Entity F1 (Val Ent. F1) achieved for the three datasets.

All experiments were run on a single Nvidia V100 GPU with 32GB of memory. CDNET has an average runtime of 3 hours (6 min per epoch), 10 hours (20 min per epoch) and 24 hours (36 min per epoch) on CamRest, SMD and WOZ respectively. CDNET has a total of 2.8M trainable parameters (400K for embedding matrix, 720K for context encoder, 240k for the sketch RNN and 1440k for the Memory pointers).

B Detailed Equations

In this section, we describe the details of context encoder, CDNETdecoder and the loss.

B.1 Context Encoder

Given a dialog history $\mathcal{H}$ we compute the utterance representation $\mathbf{u}_i$ and context representation $\mathbf{c}$ as follows:

$$\mathbf{u_i} = \text{BiGRU}(\Phi^e(w_i^1), \ldots, \Phi^e(w_i^{\tau_i})) \quad (7)$$

$$\mathbf{c} = \text{GRU}(\mathbf{u}_1, \ldots, \mathbf{u}_k) \quad (8)$$

where τ_i is the number of words in utterance u_i and w_i^j is the j^{th} word in the i^{th} utterance.

B.2 CDNET Decoder

Let $\mathbf{h_t}$ and y_t be the hidden state and the predicted word at time t respectively. The hidden state is computed as follows,

$$\mathbf{h}_t = \text{GRU}(\Phi^e(y_{t-1}), \mathbf{h}_{t-1}) \quad (9)$$

Now, we compute multi-hop Luong attention over the words representations $\mathbf{w}_i^j$ in the context memory. We set the initial query $\mathbf{q_t^0}$ to $\mathbf{h_t}$ and then apply Luong attention as follows:

$$a_{ij}^1 = \frac{\exp(W_1 \tanh(W_2[\mathbf{w}_i^j, \mathbf{q}_t^0]))}{\sum\limits_{ij} \exp(W_1 \tanh(W_2[\mathbf{q}_t^0, \mathbf{w}_i^j]))} \quad (10)$$

where W_1, W_2 are trainable parameters. We then compute the summarized context representation $\mathbf{g}_t^1$ and the next hop query as follows:

$$\mathbf{g}_t^1 = \sum\limits_{ij} a_{ij}^1 \mathbf{w}_i^j \quad (11)$$

$$\mathbf{q}_t^1 = \mathbf{q}_t^0 + \mathbf{g}_t^1 \quad (12)$$

We repeat this for H hops. The attention vector after H hop is represented $\mathbf{a}^H$. The generate distribution P_g is given by:

$$P_g = \text{Softmax}(W_3[\mathbf{h}_t, \mathbf{g}_t^1] + b_1) \quad (13)$$

where W_3 and b_1 are trainable parameters. The context copy distribution P_{con} is computed as follows:

$$P_{con}(y_t = w) = \sum\nolimits_{ij:w_i^j = w} a_{ij}^H \quad (14)$$

The KB copy distribution P_{kb} is given by,

$$\beta_m^t = \text{Softmax}(W_4 \tanh(W_5[\mathbf{g}_t^H, \mathbf{h}_t, \mathbf{r}_m])) \quad (15)$$

$$\gamma_n^t = \text{Softmax}(W_6 \tanh(W_7[\mathbf{g_t}^H, \mathbf{h}_t, \mathbf{k}^n])) \quad (16)$$

$$P_{kb}(y_t = w) = \frac{\sum_{mn:v_m^n = w} d_m \beta_m^t \gamma_n^t}{\sum_{mn} d_m \beta_m^t \gamma_n^t} \quad (17)$$

where W_4, W_5, W_6 and W_7 are trainable parameters. Now we compute the gate α to combine P_{con} and P_{kb} to get a final copy distribution P_c as follows:

$$\mathcal{K}_t = \sum_m d_m \beta_m^t \mathbf{r}_m \quad (18)$$

$$\alpha = \text{Sigmoid}(W_8[\mathbf{h}_t, \mathbf{g}_t^H, \mathcal{K}_t]) \quad (19)$$

$$P_c = \alpha P_{kb}(y_t) + (1 - \alpha) P_{con}(y_t) \quad (20)$$

where W_8 is a trainable parameter.

B.3 Loss

We compute the cross entropy loss over the generate P_g and copy P_c distribution as follows:

$$\mathcal{L}_g = -\sum_{t=1}^{T} \log(P_g(y_t)) \quad (21)$$

$$\mathcal{L}_c = -\sum_{t=1}^{T} \log(P_c(y_t)) \quad (22)$$

C Distillation Visualisation

We show the visualisation of how the KB distillation distribution helps the decoder rectify the incorrect KB memory pointer inference in Figure 4. Figure 5 shows how the KB distillation distribution helps increase the confidence associated with the correct entity in the KB.

D Datasets

We present statistics of SMD, CamRest and WOZ in Table 6.

	SMD	CamRest	WOZ
Train Dialogs	2425	406	1839
Val Dialogs	302	135	117
Test Dialogs	304	135	141

Table 6: Statistics of the three datasets.

E Domain-Wise Results

Table 7 and Table 8 show the domain wise entity F1 scores of SMD and WOZ datasets respectively. We note that CDNET either has the best or the second-best performance in domain wise scores.

F Qualitative Example

Table 9 shows responses predicted by CDNET, EER and FG2Seq for an example from the WOZ dataset.

G Human Evaluation

Figure 6 shows a screenshot of the task used for collecting human judgements.

Abstract

Proposal of large-scale datasets has facilitated research on deep neural models for news summarization. Deep learning can also be potentially useful for spoken dialogue summarization, which can benefit a range of real-life scenarios including customer service management and medication tracking. To this end, we propose DIALOGSUM, a large-scale labeled dialogue summarization dataset. We conduct empirical analysis on DIALOGSUM using state-of-the-art neural summarizers. Experimental results show unique challenges in dialogue summarization, such as spoken terms, special discourse structures, coreferences and ellipsis, pragmatics and social common sense, which require specific representation learning technologies to better deal with.

1 Introduction

Text summarization is the task of automatically generating a concise, salient, coherent and fluent summary of a given set of documents (Radev et al., 2002). Thanks to the advance in neural network models and the availability of large-scale labeled datasets, recent research has achieved promising progress on summarizing monologic texts such as news articles (Paulus et al., 2018; Gehrmann et al., 2018; Liu and Lapata, 2019; Liu et al., 2020), patents (Pilault et al., 2020) and academic papers (Koncel-Kedziorski et al., 2019).

However, dialogue, as an important channel for achieving communicative intents (Bender and Koller, 2020), has received significantly less attention from the summarization research community. One main reason is the paucity of a suitable summarization dataset built on dialogue texts. Most existing research uses the AMI meeting corpus (Carletta et al., 2005), which consists of 137 dialogues obtained from virtual multi-party meeting recordings. However, research on the corpus is limited to its small scale. SAMSum (Gliwa et al., 2019) is a recently released *written* online dialogue summarization dataset, which contains 16k online chats with corresponding summaries. However, it focuses on conversations via messenger apps, which are rather short (around 94 tokens per conversation) and their language style and topics also differ from *spoken daily dialogues*.

(a) Dialogue from DIALOGSUM:
#Person_1#: Good morning. I wonder whether you have got an answer from your superior.
#Person_2#: Yes, we had a meting about it yesterday afternoon.
#Person_1#: What's the answer?
#Person_2#: We decided that we could agree to your price, but we are a bit worried about the slow delivery.
#Person_1#: Let me see. I quoted your delivery in three months, didn't I?
#Person_2#: Yes, but we hope that the wool could reach us as soon as possible.
#Person_1#: I thought you would. So I rang Auckland last night. As you are our biggest customer, they agreed to ship the order on the first vessel available that will leave Auckland next month.
#Person_2#: Good, if you agree we‘ll draft the agreement right away and sign it then.
#Person_1#: By all means.

Summary from DIALOGSUM: #Person_1# and #Person_2# agree to sign an agreement ***since*** #Person_1# could speed up the delivery as #Person_2# hopes.

(b) Dialogue from SAMSum:
…
Leo: BTW what are those pics?
Ryan: Pics from Italy!!! :):):):))))))))))
Leo: Yeah. They seem nice. (‘A`)
Ryan: That's all???? I need more reactions!!!!!!!!!!
Leo: I'm tied to this office and working like a slave. AM I SUPPOSED TO SAY \"I AM SO JEALOUS!!!!!!!!\"?😬😬😬
…

Summary from SAMSum: Ryan is in Italy while Leo is working hard and wishing he could win the lottery.

Figure 1: An example from DIALOGSUM dataset compared with an example from SAMSum dataset.

A comparison between the real-life scenario dialogue and online chat is shown in Figure 1. Online-chat messages contain unique tokens (e.g., “BTW”), emoticons (e.g., “:)”) and emojis (e.g., “😬”). In contrast, daily conversations have a different

Datasets	Lan. style	Domain	Scenario	Dialogs	Data size	#Tokens/dial.	#Tokens/turn	#Comp. rate
AMI	spoken	single	meeting	137	100hrs (video)	4,757	16.5	0.07
SAMSum	written	multiple	online	16,369	1.5M (token)	94	8.4	0.30
DIALOGSUM	spoken	multiple	daily life	13,460	1.8M (token)	131	13.8	0.18

Table 1: Comparison between DIALOGSUM and other public dialogue summarization datasets. Lan. stands for language. Dial. stands for dialogue. # stands for the average result. Comp. stands for compression. The compression rate is the ratio of the length of the summary divided by the length of the original text.

and more formal style. In addition, real-life dialogues have more diverse task-oriented scenarios and topics compared to online chit-chats. For example, online-chat messages in SAMSum are about leisure and social chats, but real-life dialogues contain business negotiation (Figure 1(a)). Intuitively, automatically summarizing such dialogues can help a business find common needs or complaints from customers. With the rise of personal assisting chatbots, summarizing dialogues from different aspects of daily life can also be useful for personal record management and other applications.

We introduce Real-Life Scenario Dialogue Summarization (DIALOGSUM), a large-scale summarization dataset for dialogues. Dialogue data for DIALOGSUM are collected from three public dialogue corpora, namely Dailydialog (Li et al., 2017), DREAM (Sun et al., 2019) and MuTual (Cui et al., 2020), as well as an English speaking practice website. These datasets contain face-to-face spoken dialogues that cover a wide range of daily-life topics, including schooling, work, medication, shopping, leisure, travel. Most conversations take place between friends, colleagues, and between service providers and customers. We clean and preprocess the dialogue data into a unified format, and ask annotators to summarize them from an observer perspective. Topics are also manually labeled for each dialogue. An example of DIALOGSUM is shown in Figure 1(a), where the summary expresses the main content in a business conversation.

The contribution of DIALOGSUM can be stated from two perspectives. First, from the perspective of downstream applications, summarizing daily spoken dialogues can be useful for both business and personal uses. Dialogue summaries can also be useful for personal assistants to keep track of important events as such business negotiation. Second, from the method perspective, DIALOGSUM has a larger scale of long dialogue data, which can facilitate the study of dialogue summarization using neural network models. The number of dialogues in DIALOGSUM is orders of magnitude larger than in AMI, which can be useful for training large neural network models for dialogue summarization. The average length of dialogues in DIALOGSUM is 39.8% longer than in SAMSum. To our knowledge, we are the first to release a large-scale real-life scenario dialogue summarization dataset.

We empirically investigate the performance of state-of-the-art neural summarization models on DIALOGSUM, comparing the characteristics of the spoken daily dialogue summarization dataset with standard news summarization benchmarks and the online chat summarization benchmark SAMSum. Experimental results show that DIALOGSUM is more amenable to abstractive summarizers, while being relatively more challenging compared to the existing summarization datasets. We find that main difficulties arise from discourse structures in multi-turn dialogues, as well as the need for book-keeping both entities and events mentioned in turns of utterances. We release our dataset at `https://github.com/cylnlp/DialogSum`.

2 The DIALOGSUM Dataset

2.1 Dialogue Data Preparation

Data Collection DailyDialog is a dataset consisting of 13k multi-turn dialogues, obtained from websites that aim to help English learners to practice English speaking. DREAM and MuTual are dialogue understanding datasets, consisting of 6k and 9k speech transcripts, respectively, both collected from online English listening exam materials. In order to further increase the diversity of data, we crawl additional dialogues from another English speaking practice website[1] which aims to provide English learners with conversation examples in real life practical circumstances, such as business negotiation and banking services.

Although dialogues of DIALOGSUM are from different sources, they all share important characteristics that are in line with what we expect. First, as mentioned earlier, these dialogues are under rich

---

Source	Num. dial.	Tokens	% in DIALOGSUM
DailyDialog	7837	980,398	58.22
DREAM	2028	301,098	16.94
MuTual	1870	260,139	13.89
Crawled	1725	238,902	12.82

Table 2: Proportions of dialogue sources in DIALOGSUM.

real-life scenarios. Unlike chitchats, these conversations have clear communication patterns and intents, making them more suitable and valuable to serve as summarization sources (Carletta et al., 2005). Moreover, their multi-turn dialogue lengths are within a reasonable scale and are longer than chitchats[2], which comforts the purpose of automatic summarization. Greater lengths also indicate these dialogues contain more events and discourse relations between them. Properly selecting vital events and identifying their relations make summarizing these dialogues more challenging.

Data Cleaning and Pre-Processing We delete non-English characters, correct typos and grammatical errors, and further filter out duplicated data based on text similarity. After deduplicating, proportions of the data sources are summarized in Table 2. Because of different data processing methods and annotation procedures, original dialogues in DailyDialog, DREAM and MuTual are in different formats. We follow previous work (Li et al., 2017; Zhang et al., 2018; Budzianowski et al., 2018; Dinan et al., 2019) and preprocess them into a bi-turn dialogue flow, merging continuous turns of the same speaker into one utterance. Also, we add tags (e.g. `#Person_1#` and `#Person_2#` in Figure 1(a)) before each dialogue turn, to distinguish speakers. The final DIALOGSUM dataset contains 13,460 dialogues, which are divided into training (12,460), validation (500) and test (500) sets.

2.2 Annotation

We ask annotators to write dialogue summaries based on following criteria: the summary should (1) convey the most salient information of the dialogue and; (2) be brief (no longer than 20% of the conversation length) and; (3) preserve important named entities within the conversation and; (4) be written from an observer perspective and; (5) be written in formal language.

Human Annotated Summary	R1	R2	RL
Summary1 to Summary2	52.90	26.01	50.42
Summary1 to Summary3	53.85	27.53	51.65
Summary2 to Summary3	53.30	26.61	50.44
Average	53.35	26.72	50.84

Table 3: ROUGE scores between three human annotated summaries in test set.

We require our annotators to pay extra attention to the following aspects.

Tense Consistency: Annotators should take the moment that the conversation occurs as the *present* time, and choose a proper tense to describe events *before* and *after* the ongoing conversation.

Discourse Relation: If summarized events hold important discourse relations, particularly causal relation, annotators should preserve the relations if they are also in the summary.

Emotion: Different from newspaper and academic articles, social conversations in DIALOGSUM are often implied with emotions. Therefore, we ask annotators to explicitly describe important emotions related to events in the summary.

Intent Identification: Rather than merely summarizing the consequences of dialogues, annotators should also describe speakers' intents in summaries, if they can be clearly identified.

In addition to the above, annotators should use person tags to refer to different speakers if real names cannot be detected from the conversation. Annotators are also asked to write a short (around 3 tokens) topic for each dialogue. Appendix A shows the list of topics.

2.3 Quality Control

To ensure quality, before formal annotation, we ask annotators to annotate training samples until they pass our examination and meet our requirements. After annotation, we check summaries by cross-validation between different annotators twice. During the checking process, bonus is paid to checkers who find unqualified summaries, and penalty is given to annotators whose annotation is found with mistakes. In case of appeal, we make the final decision. After the second checking, we sample 10% summaries and manually check the samples ourselves. If errors are found in an annotation batch, we ask corresponding annotators to self-check and re-annotate the whole batch and repeat this checking and sampling processes.

To further control the quality, and to analyze inter-annotator agreement, for each dialogue in the

Table 4: Corpora statistics and extractive methods on CNN/DailyMail, NY Times, XSum, SAMSum and DIALOGSUM. Part of results is from Narayan et al. (2018). All results are computed on test sets. For DIALOGSUM, the results are the average of multi-reference results.

test set, we provide three summaries written and checked by different annotators. For each test dialogue, we compare its and compute their pair-wise ROUGE (Lin, 2004) scores. Table 3 reports their averaged F_1 scores of ROUGE-1 (R1), ROUGE-2 (R2) and ROUGE-L (RL). We see R2 is relatively low while RL is high, which suggests that annotators' usage of language is variable, but the main content and logical order are mostly the same.

2.4 Characteristics of DIALOGSUM

We empirically compare DIALOGSUM with existing news summarization datasets and SAMSum. CNN/DailyMail (Hermann et al., 2015), NY Times (Sandhaus, 2008) and XSum (Narayan et al., 2018) are large-scale summarization datasets from the news domain, written in a monologic structure. XSum is a dataset designed specifically for abstractive summarization.

First, we compare the percentages of novel n-grams in the reference summary against the source document/dialogue. This intuitively reflects the level of abstraction of annotated summaries. As shown in Table 4, except for XSum, which is designed to be highly abstractive, dialogue-based summarization datasets contain more novel n-grams in the summaries. We also find that the percentage of novel unigrams in DIALOGSUM is 26%, 6% lower than in SAMSum, but novel bigrams, trigrams and 4-grams are about the same as SAMSum. We believe that the relatively lower novel unigram proportion in DIALOGSUM compared to SAMSum is because of our pre-processing and annotation criteria. SAMSum's summaries include real names, third-person singular pronouns, which can be diverse across the dialogues. In contrast, DIALOGSUM uses tags such as `#Person_1#` to refer to persons whatever they are subjective, objective, or possessive. This constrains the proportion of novel unigrams to be lower.

Second, we compare the datasets using several extractive summarization methods. Following previous summarization work (Liu, 2019; Pilault et al., 2020), we report R1, R2 and RL here. LEAD creates summaries by selecting the first n sentences from source texts. LONGEST is designed for dialogue summarization (Gliwa et al., 2019). It selects the n longest utterances as a summary, which gives better ROUGE scores than LEAD on SAMSum. EXT-ORACLE creates summaries by choosing n sentences that have the highest ROUGE against reference summaries. It can be viewed as an upper bound for extractive summarization. We report results of LEAD-3, LONGEST-3 and EXT-ORACLE-2 on SAMSum, and LEAD-2, LONGEST-2 and EXT-ORACLE-2 on DIALOGSUM, where n is searched for each dataset in range of 1 to 6.

The results are shown in Table 4. In terms of LEAD, DIALOGSUM sees the lowest R1 and R2 except for XSum, showing that it is in nature a highly abstractive summarization dataset. SAMSum is less abstractive than DIALOGSUM by all ROUGE scores, which is likely because the compression rate of SAMSum (0.30) is higher than DIALOGSUM (0.18) (Table 1). The higher compression ratio suggests the summary contains denser information in the original text. The same conclusion can be found by using the LONGEST method. By using the EXT-ORACLE method, we find that DIALOGSUM is the most challenging dataset for extractive summarizers except for XSum, which is carefully designed for evaluating abstractive summarizers.

3 Experiments

We experiment with several abstractive summarization baselines to further understand the characteristics and challenges of DIALOGSUM. Following Gliwa et al. (2019), we concatenate utterances of a dialogue as the input. For pretrained models, we only finetune them on corresponding datasets.

Model	**CNNDM**			**XSum**			**SAMSum**			**DIALOGSUM**		
	R1	R2	RL	R1	R2	RL	R1	R2	RL	R1	R2	RL
Transformer	40.21	17.76	37.09	29.41	9.77	23.01	37.20	10.86	34.69	35.91	8.74	33.50
UNILMV2$_{\text{BASE}}$	43.16	20.42	40.14	44.00	21.11	36.08	50.53	26.62	48.81	47.04	21.13	45.04
BART$_{\text{LARGE}}$	**44.16**	**21.28**	**40.90**	**45.14**	**22.27**	**37.25**	**53.12**	**27.95**	**49.15**	47.28	21.18	44.83

Table 5: Results of abstractive models on CNNDM, XSum, SAMSum and DIALOGSUM. For DIALOGSUM, we give the average of multi-reference results.

3.1 Models

Transformer We take Transformer (Vaswani et al., 2017) as a non-pretrained abstractive baseline. For dialogue summarization, we follow Gliwa et al. (2019), using the same hyper-parameters for news summarization[3], but changing the minimum length to 15. We train the 6-layer Transformer model with Adam (Kingma and Ba, 2014) for 100,000 steps. Copy attention mechanism is applied and the dropout rate is set to 0.1.

UNILMV2 UNILMV2 (Bao et al., 2020) is a recently released pretrained language model for autoencoding and partially autoregressive language modeling. Here we use UNILMV2$_{\text{BASE}}$ as a strong abstractive model. For dialogue summarization, we train the model with Adam for 100,000 steps with 2,000 warmup steps and learning rate is set to $1.5e^{-5}$.

BART BART (Lewis et al., 2020) is an encoder-decoder Transformer model pretrained on a large corpus using a denoising autoencoder task. We use the large version of BART and finetune it with 5,000 training steps/200 warmup steps for dialogue summarization. Learning rate is set to $3e^{-5}$.

3.2 Results

Table 5 presents the experimental results. In general, we find that non-pretrained abstractive models outperform LEAD (Table 4), and the best results are achieved by pretrained models, despite the fact that BART$_{\text{LARGE}}$ and UNILMV2$_{\text{BASE}}$ are pretrained on monologic texts.

Extractive Summary vs Abstractive Summary Transformer gives similar results on CNNDM and better results on XSum, SAMSum and DIALOGSUM compared to LEAD, and pretrained models show better performance than EXT-ORACLE on all datasets except for CNNDM. In particular, pretrained models outperform Transformer by $13.07 \sim 14.24\%$ RL on XSum, $14.12 \sim 14.46\%$ RL on SAMSum, and $11.33 \sim 11.54\%$ on DIALOGSUM, while only $3.05 \sim 3.81\%$ on CNNDM. We believe that it is because CNNDM is a highly extractive dataset (Section 2.4). The key to summarizing CNNDM is to correctly understand intersentence relations within long documents, and extract important sentences. In contrast, XSum, SAMSum and DIALOGSUM are more abstractive, which require a model to paraphrase. And the strong generation capability of pretrained models can bring great improvements on them. We also see that, for abstractive datasets, model performance decreases as document length grows (Avg. length: SAMSum - 93.8, DIALOGSUM - 131.1, Xsum - 431.1) and compression rate decreases (Comp. rate: SAMSum - 0.30, DIALOGSUM - 0.18, XSum - 0.05). This explains why SAMSum is the easiest dataset.

Spoken vs Written All three models perform better on dialogue summarization datasets, compared with XSum. This can be potentially because XSum is naturally highly abstractive, and thus more challenging. We also compare improvement brought by pretrained models that are trained on large written texts.

Still in Table 5, the improvement on DIALOGSUM is the least. BART$_{\text{LARGE}}$ outperform Transformer by 15.73% R1 on XSum, 15.92% R1 on SAMSum, but 11.37% R1 on DIALOGSUM. It demonstrates that SAMSum has overall more written style than DIALOGSUM, and also suggests that dialogue and monologue are different. This can be explained by the design of written app-chat annotation in SAMSum (Gliwa et al., 2019).

DIALOGSUM vs SAMSum As shown in Table 5, model performance is steadily lower on DIALOGSUM than SAMSum. As stated, DIALOGSUM is more abstractive, open-domain, and spoken analogous. One more possible reason for the lower performance on DIALOGSUM is the longer input size. To better quantify the difference between these two dialogue summarization datasets, we further evaluate Transformer trained on DIALOGSUM when tested on the SAMSum, and vice versa. As

Trans. Test	R1	R2	RL
S2D	31.72(-5.48)	6.25(-4.61)	29.72(-4.97)
D2S	31.74(-4.17)	5.93(-2.81)	29.79(-3.71)

Table 6: Difference between DIALOGSUM (D) and SAMSum (S). Trans. stands for Transferred.

Summary	Fluency	Cons.	Relevance	Coherence
Summary 1	5	5	4.96	5
Summary 2	5	5	4.98	5
Summary 3	5	5	5	5
Avg.	5	5	4.98	5
Transformer	4	2.08	2.3	3.84
UNILMV2$_{\text{BASE}}$	4.8	3.84	4.06	4.34

Table 7: Human evaluation on human annotated summaries and model generated Summaries. Cons. stands for Consistency. Summary 1 - Summary 3 correspond to three summaries of a dialogue.

shown in Table 6, the performance of Transformer drops greatly when traiend on DIALOGSUM and tested on SAMSum, and vice versa. This shows that the two datasets have substantial differences. In addition, Transformer trained on DIALOGSUM performs better than on SAMSum, and shows lower performance drop, suggesting that DIALOGSUM can provide more generalization ability for training dialogue summarization models.

4 Human Evaluation

To better understand DIALOGSUM, we take a deeper investigation into the outputs of Transformer and UNILMV2 on DIALOGSUM by conducting human evaluation from multiple aspects.

Fluency, Consistency, Relevance and Coherence First, following Kryscinski et al. (2019, 2020), we implement human evaluation from four dimensions. *Fluency* evaluates the quality of individual generated sentences, *Consistency* evaluates the factual alignment between the source text and generated summary, *Relevance* evaluates the importance of summary content, and *Coherence* evaluates the collective quality of all sentences.

We randomly select 50 dialogues and their summaries from DIALOGSUM test, and ask a judge to give scores in scale from 1 to 5 along the four mentioned dimensions. The higher, the better. The judge also gives scores to human-annotated summaries to evaluate their quality. As shown in Table 7, human annotated summaries receive the best scores from all dimensions. UNILMV2$_{\text{BASE}}$ has steadily better scores than Transformer, but lower than human. Model-generated summaries have the highest scores on Fluency, while lowest on Consistency. It suggests that although model-generated summaries are grammatical and fluent, they still contain factual errors.

Model	Human Scores				ROUGE Scores		
	-1	0	1	Avg.	R1	R2	RL
Transformer	80%	17%	3%	-0.77	34.35	7.01	31.13
UNILMV2	43%	37%	20%	-0.23	43.78	17.91	40.97

Table 8: Human evaluation on discourse relations, with corresponding ROUGE scores on the sub-test set. Avg. stands for the averaged score here.

Discourse Relation Reasonable summaries should convey important relations between main events, and identifying discourse relations and using proper phrases to express them in summaries can be challenging for summarization systems (Xu et al., 2020). Take Figure 1 (a) for example, the human annotated summary connects two main events (underlined) using "*since*" to express their causal relation explicitly. However, the causal relation between those two events are not explicitly expressed in the dialogue, and the distance between them is long. Multiple turns usually correspond to more complicated discourse structure and relation. Also, similar with Chen and Yang (2020), we find that model performance decreases when the number of dialogue turns grows (See Appendix B).

To better evaluate model ability to disambiguate discourse relations in DIALOGSUM, we first collect discourse connectives from Penn Discourse Treebank (Miltsakaki et al., 2004), and check whether these connectives are included in summaries in the testset. If the three reference summaries of a dialogue all contain connectives, we assume that the dialogues have strong discourse signals. We choose 70 dialogues from DIALOGSUM in this way.

We then ask linguists who specialize in discourse to evaluate model outputs and give scores from $\{-1, 0, 1\}$, where 1 means that the generated descriptions of main events are reasonable and contain correct discourse connectives, 0 means that the descriptions are good but contain no discourse connectives and -1 means that the description is either incorrect or contains incorrect connectives. We ask the linguists to focus only on clauses or phrases that are essential to discourse relations, and ignore syntactic errors. We report the distribution of annotated scores in Table 8.

We can see that the most summaries generated by Transformer are scored as -1, and their average score is -0.77, close to -1. This means that Transformer is not only incapable of identifying discourse relations but also incapable of generating the main events correctly. UNILMV2 has a relatively smooth distribution over three categories and a better average score of -0.23, which is closer to 0, suggesting that UNILMV2 can mostly choose important events amongst the conversation. But the -1 still holds most proportion and its average result is still far from 1, indicating its incapability of understanding relations between events.

Compared to the full test set, the model performance on this sub-set generally decreases ($1.56 \sim 3.26\%$ lower of R1, $1.73 \sim 3.22\%$ of R2, $2.37 \sim 4.07\%$ of RL), which also suggests complicated discourse relations between events make summarization more difficult. The results indicate that further research is necessary for better representing dialogue discourse structures in order to obtain more reliable summarization systems.

Coreference Information To evaluate model's ability to distinguish different interlocutors, we ask a judge to evaluate whether interlocutors' names and their conversation actions/contents are correctly associated in the 50 randomly selected data, and give scores from $\{-1, 0, 1\}$, where 1 means that all names and actions/content in the summary are associated correctly, 0 means partial incorrectly, and -1 means all incorrectly. Here, we only focus on coreference information in generated summaries, and ignore other errors, such as incorrect syntax or failing to summarize salient information.

We report the distribution of annotated scores in Table 9. Most Transformer generated summaries are annotated as -1 and the average result is close to -1, suggesting that Transformer cannot generate clauses that express the same relation between arguments and predicates in original dialogues. The UNILMV2$_{\text{BASE}}$ has more 0-scored summaries, and the result is much higher, yet closer to 0, which indicates that although UNILMV2$_{\text{BASE}}$ can generate summaries containing correct clauses, but still have much inconsistency. The performance of both models indicates that Transformer is only capable of extracting important word-level information from dialogues in DIALOGSUM, while UNILMV2$_{\text{BASE}}$ shows better performance on clause-level — it can identify the speakers and partially preserve coreference information, consistent with findings of Levesque et al. (2012) that pretraining is useful for coreference resolution. However, it is far from human annotations.

Model	Human Scores				ROUGE Scores		
	-1	0	1	Avg.	R1	R2	RL
Transformer	66%	28%	6%	-0.6	35.68	8.49	32.77
UNILMV2	4%	56%	40%	0.36	47.46	21.33	44.93

Table 9: Human evaluation on models' ability of preserving coreference information on DIALOGSUM, with corresponding ROUGE scores. Avg. stands for the averaged score here.

Summary	Human Scores	
	-1	1
Summary 1	7.7%	92.3%
Summary 2	20.5%	79.5%
Summary 3	17.9%	82.1%
Avg.	15.4%	84.6%
Transformer	84.6%	15.4%
UNILMV2	30.8%	69.2%

Table 10: Human evaluation on models' ability of identifying interlocutors' intents.

Intent Identification As stated in Section 2.2, we ask annotators to include important intents of interlocutors in their summaries, addition to the consequences of dialogues. The intent here refers to the motivation of a speaker to initiate a conversation, e.g. "*want to do an annual physical*" (c.f. Figure 2, DIALOGUE-A). This can make summaries more comprehensive and readable. Therefore, we conduct corresponding human evaluation on whether interlocutors' intents are described in summaries in the 50 randomly selected data.

We first ask a judge to evaluate whether the intent is important to a dialogue, and we select 39 dialogues that contain important intents. Then, we ask the judge to give scores from $\{-1, 1\}$, where 1 means that intents are identified correctly, -1 means incorrectly. Note that we only focus on intent identification in the summary, and other errors should be ignored. We also ask the judge to evaluate human annotated summaries.

The distribution of annotated scores is shown in Table 10. We see that most summaries generated by Transformer are scored as -1, which means that Transformer is incapable of generating summaries that correctly convey speakers' intents. UNILMV2$_{\text{BASE}}$ shows much better performance, however, it is still below human performance.

5 Challenges in DIALOGSUM

Compared to written texts, spoken dialogues can be more difficult for models to understand, and

DIALOGUE - A:	**DIALOGUE - B:**
#Person_1#: Hello, so how are we feeling today? **#Person_2#:** Things are going well for me, doctor. **#Person_1#:** Am I correct in thinking that you are here for your annual physical? **#Person_2#:** Yes, I am applying for new health insurance, and I need a physical examination to qualify. **#Person_1#:** Your basic physical exam will include lungs, heart, blood levels, and eyes, ears, and nose. **#Person_2#:** I've been having a little trouble breathing. Would you look into that, please? **#Person_1#:** We can do an allergy test, and later I can send you for an asthma test. **#Person_2#:** I would appreciate it. When you give me a blood test, what are you looking for? **#Person_1#:** I am going to check your cholesterol, blood sugar, and white blood cell count. **#Person_2#:** I am expecting the tests to go well. I have been taking good care of myself.	**#Person_1#:** Good morning. What can I do for you? **#Person_2#:** I'm in Room 309. I'm checking out today. Can I have my bill now? **#Person_1#:** Certainly. Please wait a moment. Here you are. **#Person_2#:** Thanks. Wait…What's this? The 30 dollar for? **#Person_1#:** Excuse me… The charge for your laundry service on Nov. 20th. **#Person_2#:** But I didn't take any laundry service during my stay here. I think you have added someone else's. **#Person_1#:** Ummm… Sorry, would you mind waiting a moment? We check it with the department concerned. **#Person_2#:** No. As long as we get this straightened out. **#Person_1#:** I'm very sorry. There has been a mistake. We'll corrected the bill. Please take a look. **#Person_2#:** Okay, here you are. **#Person_1#:** Goodbye.
SUMMARY – A1: #Person_2# wants to do an annual physical examination to apply for new health insurance and says #Person_2#'s breathing is not good. #Person_1# explains the items and will do tests on #Person_2#'s breathing. **SUMMARY – A2:** #Person_1# explains the checking items in #Person_2#'s annual physical examination and will do test to look into #Person_2's breathing. **SUMMARY – A3:** #Person_2# is going through an annual physical examination to apply for new health insurance, and #Person_2# asks #Person_1# to look into the breathing.	**SUMMARY – B1:** #Person_2# is checking out and asks #Person1# for the bill. #Person1# gives #Person_2# a wrong bill at first then corrects it. **SUMMARY – B2:** #Person_1# helps #Person_2# correct a mischarged bill on laundry service and helps #Person_2# check out. **SUMMARY – B3:** #Person_2# finds #Person_2# being mischarged. #Person_1# corrects the bill and #Person_2# pays for it.
UniLMv2: #Person_2# comes to #Person_1#'s annual physical to apply for new health insurance. #Person_1# will do an allergy test, an asthma test, and a blood test.	**UniLMv2:** #Person_2# is checking out. #Person_1# finds #Person_2# has added someone else's laundry service . #Person_1# apologizes and will correct the bill.
Transformer: #Person_2# goes to #Person_1# for an annual physical examination. #Person_1# will send #Person_1# for an asthma test and what #Person_2# eats.	**Transformer:** #Person_2# checks out with #Person_2#'s assistance and thinks they'll be very sorry for the laundry service.

Figure 2: Case study on DialogSum. Dialogue-A - a doctor and a patient dialogue, Dialogue-B - a customer and a hotel service dialogue.

to summarize (Goo and Chen, 2018). Therefore, we conduct error analysis and case studies on DialogSum to quantitatively and qualitatively discuss such challenges.

5.1 Error Analysis

We make error analysis on the 50 selected model-generated summaries (Section 4). Table 11 summarizes the five most frequent error types and their error rates. In general, UniLMv2$_{\text{BASE}}$ shows better performance than Transformer, but its error rates are still high. In particular, incorrect **coreference** (c.f. Section 4) sees the highest error rates for both models, indicating that models can be confused because of interactive information flow. Compared with Transformer, UniLMv2$_{\text{BASE}}$ can greatly avoid errors regarding unfactual information (-52%) and syntactic (-50%). However, it still suffers from coreference issues, and tends to generate redundant summaries.

Error Type	Transformer	UniLMv2$_{\text{BASE}}$
Incorrect Coref.	94%	60%
Missing Salient Inf.	64%	32%
Redundant Inf.	62%	44%
Unfactual Inf.	74%	22%
Syntactic Error	72%	22%

Table 11: Error analysis of model performance on DialogSum. Coref. stands for coreference, and Inf. stands for Information.

5.2 Case Study

We demonstrate two dialogues and their human-annotated/system-generated summaries in Figure 2.

First, a big challenge posed by spoken dialogues is that their **information flow** is different from monologic text, which is intuitively reflected in the dialogue **discourse structures** (Wolf and Gibson, 2005). For example, two utterances can be closely related even where there is a large distance between them. Such phenomena are common in spoken dialogues such as negotiations and procedures (e.g., medical consultation and police reports). Due to the unique structure of the spoken dialogue, important information is rather dispersed than well-structured monologues and written-dialogues.

Regular greetings can be useless to written dialogue summaries (e.g. SAMSum), which is reflected by that LEAD is worse than LONGEST on SAMSum (Table 4). In contrast, LEAD outperforms LONGEST by over 3% on DIALOGSUM. This is because, for spoken dialogues, such utterances sometimes express and indicate essential intents of speakers (c.f. Section 4). **Farewells** also express the dialogue consequence and future plan of the speakers (e.g. dialogues in Figure 2). Besides, **interruptions** appear frequently in the middle of conversations (Figure 2, DIALOGUE-B). These interruptions make other speaker's utterances incomplete, adding redundant information, and can also destroy coherent discourse structures, making dialogues more difficult to encode. These characteristics also make information in DIALOGSUM dialogues more dispersed than existing datasets.

Second, **coreference** and **ellipsis** are frequent in spoken dialogues (Grosz et al., 1995; Quan et al., 2019). It is a natural behavior of communication that humans obey as a rhetorical principle for saving words and avoiding repetitions. Although it can be trivial for humans, their understanding can be challenging to a neural model. For example, to correctly generate "*mischarged/wrong*" in SUMMARY-B1-SUMMARY-B3, models need to understand "*I think you have added someone else's (laundry service on my bill)*", where "*my bill*" refers to "`#Person_2#`*'s bill*".

Third, **pragmatics** and **social common sense** give a unique challenge for spoken language understanding and has a significant impact on summarization. From the last two sentences of DIALOGUE-B, human could understand that the "*Here you are*" is actually "*make a payment*", and "*Goodbye*" indicates that the event "*check out*" is finished. It requires commonsense knowledge to fully understand such dialogues. Beside, dialogues are summarized from a *different* perspective (compared with speakers' perspective), which suggests that summarizing dialogues needs to go beyond summarizing dialogue contents, but also dialogue actions at the **pragmatic** level. For example, "*explains*" in SUMMARY-A1 and SUMMARY-A2 summarizes multiple dialogue actions of `#Person_1#`, "*agree*" in Figure 1 (a) summarizes actions of both speakers. It requires model to not only summarize *what speakers are saying*, but also *what they are doing*.

6 Conclusion

We presented DIALOGSUM, a large-scale dialogue summarization dataset, investigating its characteristics and challenges empirically. Experiments with typical models show that DIALOGSUM is highly abstractive, and poses unique challenges in discourse and complex co-references. From these observations, we made discussion on the uniqueness of spoken dialogue summarization, listing several key problems to consider in future modeling. To our knowledge, we are the first to release a large-scale dataset for real-life scenario dialogue summarization.

7 Ethics Consideration

As mentioned, we collect our data from DailyDialog, DREAM and MuTual that all are public for academic use. The additional data are from www.tingroom.com, which are available to the public as well. The sources of our dialogue data are freely accessible online without copyright constraint to academic use.

We hired annotators who have degrees in English Linguistics or Applied Linguistics. Before formal annotation, we annotated 50 samples randomly extracted from the dataset, and calculated our average annotation time so we could set a fair salary for annotators' training annotation. During the training annotation process, they were paid as well. We also calculated the average annotation time for each dialogue during training, based on which we determined the final salary was around 9.5 dollars per hour. This hourly salary was the same for manual checking. All of our annotators took this annotation as a part-time job.

Acknowledgments

Yue Zhang is the corresponding author. We would like to thank the anonymous reviewers for their comments, and Xuefeng Bai, Ming Shen and Bonnie Webber for insightful discussion and proofreading. Also, we would like to thank Leyang Cui for sharing original dialogue data of MuTual dataset. Our sincere appreciation goes to annotators who have contributed to building this dataset. This work receives funding support from the Westlake University and Bright Dream Joint Institute for Intelligent Robotics, and a research grant from Rxhui Inc.

A Dialogue Topics

We use k-means (Likas et al., 2003) to cluster the dialogue topic with GloVe embedding (Pennington et al., 2014), where $k = 20$. Figure 3 presents the proportion of clustering results. Table 12 presents the cluster topics with corresponding id, which is assigned by human.

B Dialogue Turns

The number of conversation turns can have a direct impact on neural models. Multi-turn dialogues correspond to more complicated information flow and discourse structure. Following Chen and Yang (2020), we split test data based on dialogue turns, with a step size of 3, and show model performance on different dialogue turns.

The results are shown in Figure 4. The performance of Transformer and UNILMV2$_{\text{BASE}}$ decreases when number of turns grows, suggesting that more interactions between interlocutors and complicated discourse structures bring challenge. This phenomenon is also observed by (Chen and Yang, 2020) for SAMSum.

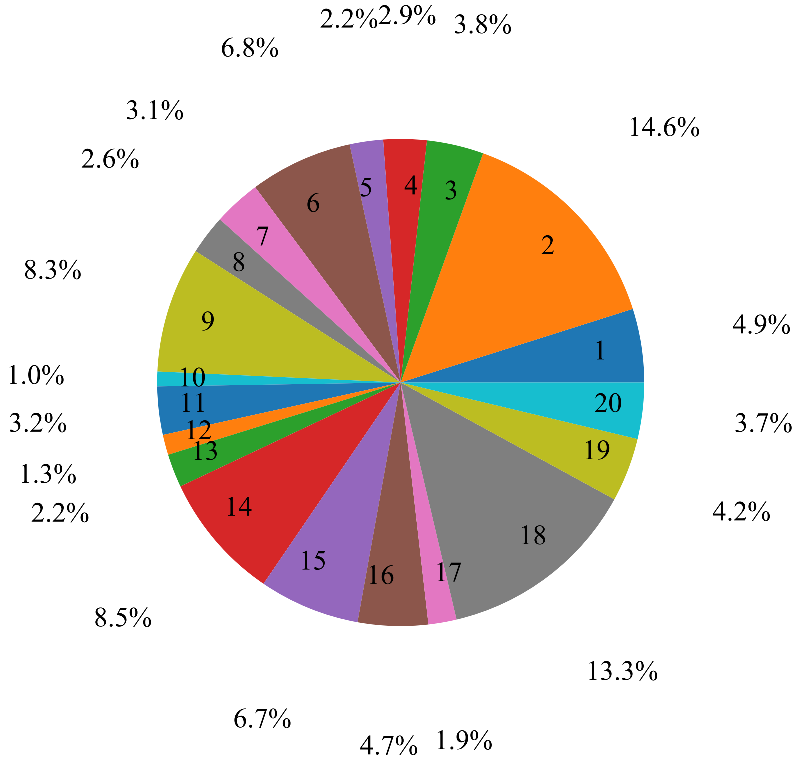

Figure 3: Proportion of dialogue topics.

ID	topic	ID	topic	ID	topic	ID	topic
1	interpersonal relation	6	education	11	personal and business appoinment	16	transportation
2	work and career	7	hobby	12	housing and apartment	17	in-store shopping
3	causal chitchat	8	interview	13	consultation	18	health and medicine
4	hotel and restaurant service	9	vacation plan	14	personal life	19	entertainment
5	sales	10	climate	15	economics	20	food ordering

Abstract

Existing neural end-to-end dialogue models have limitations on exactly interpreting the linguistic structures, such as ellipsis, anaphor and co-reference, etc., in dialogue history context. Therefore, it is hard to determine whether the dialogue models truly understand a dialogue or not, only depending on the coherence evaluation of their generated responses. To address these issues, in this paper, we proposed to directly measure the capability of dialogue models on understanding the entity-oriented structures via question answering and construct a new benchmark dataset, DEQA, including large-scale English and Chinese human-human dialogues. Experiments carried on representative dialogue models show that these models all face challenges on the proposed dialogue understanding task. The DEQA dataset will release for research use.

1 Introduction

Driven by the growth of interest in social chatbot, online customer service and virtual mobile assistant, social dialogue systems have received increasing research attention (Cui et al., 2017; Zhou et al., 2018; Hancock et al., 2019). The current dominant method has been sequence-to-sequence models, trained over large dialogue data end-to-end. Such models use neural network architectures such as Transformer (Vaswani et al., 2017) to encode a user utterance and a dialogue history before generating a system utterance (Adiwardana et al., 2020; Roller et al., 2020; Bao et al., 2020). A major advantage is the use of standard and general model architecture, which facilitates end-to-end training process over large scale dialogue text (Shang et al., 2015; Zhang et al., 2018, 2019, 2020).

Dialogue		
U_1:	Well, you know how important a clean house is to your grandma.	
U_2:	Yes, I hear about it every time she comes here.	
	What do you hear about?	Q_1
	A clean house.	A_1
U_1:	She was the head janitor at St. Mary's Hospital for thirty years, after all.	
U_2:	I think she misses that job and wants to take it out on us.	
U_1:	You know, maybe she is just a neat freak.	
	Who is just a neat freak?	Q_2
	Grandma.	A_2
U_2:	I think she just likes to make us miserable.	
U_1:	You could be right.	

(a)

Co-reference Chain (OntoNotes style)			
Chain 1 (IDENT)		Chain 3 (IDENT)	
1.6-8	a clean house	1.12-12	grandma
2.5-5	it	2.8-8	she
Chain 2 (IDENT)		3.1-1	she
3.4-9	head janitor at St. Mary's Hospital	4.3-3	she
		5.4-4	she
4.5-6	that job	6.3-3	she

(b)

Table 1: (a) Sample of English dialogue in the proposed dataset. U_1 and U_2 are two interlocutors in the dialogue. Q_i and A_i (i=1,2) are clarification requests and the corresponding answers. (b) Co-reference chain annotation in OntoNotes 5.0 style.[1]

Despite showing effectiveness in empirical evaluation, existing work has a few important limitations. First, it is difficult to visualize or interpret the representation of dialogue state from a dense neural network encoder. In particular, there is not explicit representation of entities, semantic relations or discourse structures. Second, the performance of a dialogue system is evaluated directly by the quality of the generated responses. However, relatively little work has been done on evaluating how a system response is determined, which can be important because a proper response can be generated by simply relying on superficial and spurious patterns in dialogues, and we want to find out the cause of

---

[1] IDENT denotes the entities in a co-reference chain are identical. "1.6-8" indicates that "a clean house" is from the 6th to 8th tokens in the 1st utterance.

problematic responses for identifying model limitations. ; To address such limitations, it can be useful to directly measure the quality of *dialogue understanding* by asking a dialogue model to identify important structures in dialogue histories. In this paper, we focus on entity level understanding, evaluating references to entities in a dialogue history context. Such references can include explicit anaphora and implicit mentions by using zero pronouns. Take Table 1 (a) as an example, where the dialogue history consists of 7 utterances and the second utterance contains a pronoun "*it*". At this point, we can measure system understanding of the dialogue state by checking whether the system can resolve the anaphora concerning "*a clean house*".

Our goal is to provide a large-scale benchmark and to evaluate the performance of social chatbot systems on dialogue understanding concerning entities. One way to define the task is to cast it as a co-reference resolution problem (Yin et al., 2017; Kong et al., 2019; Quan et al., 2019), where a benchmark can be constructed by manually labeling co-reference information on a dialogue dataset, as shown in Table 1 (b). However, such a benchmark does not fully meet our goal because a separate model is necessary for achieving co-reference resolution, and it may be challenging to seamlessly integrate such a co-reference module into a dialogue model being tested.

We take a different method, checking dialogue understanding of dialogue systems by inserting clarification requests (Schlangen, 2004; Stoyanchev and Johnston, 2015) into dialogues, and evaluating the response of dialogue systems on such requests. One example is shown in Table 1 (a), where we break a dialogue in the middle, adding clarification requests. For example, for the question "*Who is just a neat freak?*", the correct system response should be "*Grandma*", which reflects that the model has correct understanding of the dialogue context.

The advantage is three fold. First, this method allows the evaluation of a dialogue system without using an external probe task, by directly evaluating system generated responses. This makes our benchmark directly useful for evaluating arbitrary social dialogue models. In contrast to open-ended responses in chit-chats, responses for the proposed clarification requests are factual thus facilitating automatic evaluation. Second, it allows easier crowdsourcing for dataset construction as compared with co-reference resolution, which requires strict training of manual labelers for understanding linguistic concepts. It is thus useful for acquiring large-scale datasets. Such observation is consistent with recent work on other NLP tasks (FitzGerald et al., 2018; Roit et al., 2020). Third, this method allows easy extension to dialogue understanding beyond the entity reference level, such as event co-references, semantic relations and discourse level understanding. No new labeling standards are necessary for adding a new task.

According to the above observations, we create a large scale benchmark, open domain Dialogue Entity via Question Answering (DEQA), which consists of one English dataset and one Chinese dataset, of 8,415 and 6,203 dialogues, respectively. Each dialogue contains one or more questions similar to the one in Table 1. We choose to evaluate representative multi-turn neural dialogue systems, including models using Transformer (Vaswani et al., 2017) and DialoGPT (Zhang et al., 2020). Results show that the prevalent models of multi-turn dialogue generation face challenges in the co-reference questions. We will release the dataset at Github [2] for research use.

2 Dataset

We present the task (Section 2.1), the linguistic structures to evaluate (Section 2.2), the dataset construction (Section 2.3), the dataset characteristics (Section 2.4) and the evaluation metrics (Section 2.5) below.

2.1 Task Definition

Given a multi-turn dialogue, the task is to answer questions concerning one or more turns of the dialogue history. In particular, the model needs to answer questions about the anaphor and ellipsis phenomenons that appear in the context. It is worth noting that most of the answers can be extracted from the given context, but some answers may not explicitly appear in the context. These questions are called *summary questions*. The dialogue model should also have the capability on answering these summary questions.

We have already seen one example of English dialogue in Table 1. Table 2 shows a sample Chinese dialogue in the annotated dataset and its English translation. For the second utterance "我也想吃。。。(I also want to eat...)", the corresponding question is "你也想吃什么？(What do

---

[2] `https://github.com/adamszhu/DEQA`

	Chinese Dialogue	**English Translation**
U_1:	我想吃炸鸡。。。	I want to eat fried chicken...
U_2:	我也想吃。。。	I also want to eat... (literal translation)
U_1:	昨天买的炸鸡被我家猫吃了。	The fried chicken I brought yesterday was eaten by my cat.
U_2:	哈哈，是时候教育它了	Haha, it's time to teach it a lesson.
U_1:	不舍得啊	Unwilling to do that.
U_2:	我来替你啊	I can do it for you.

Table 2: Sample of Chinese dialogue in the annotated dataset.

you want to eat too?)" This question refers to the first utterance and the phrase "炸鸡(fried chicken)" should be extracted as the answer of the question. For the fourth utterance "哈哈，是时候教育它了。(Haha, it's time to teach it a lesson.)", there is a pronoun "它(it)" which should be resolved. A question "教育谁？（Teach whom a lesson?）" which refers to the fourth utterance is then raised. According to the third utterance, the answer of the question is "你的猫(your cat)". Note that in the proposed task, some answers should be summarized from the whole dialogue rather than only one utterance.

2.2 Linguistic Structures

In our dataset, a question is raised towards one ellipsis or anaphor phenomenon in a given dialogue. The role of a raised question can be seen as a "label" of a pronoun or zero pronoun. Correspondingly, the answer to the question is thus the antecedent of the pronoun or zero pronoun. Ellipsis, anaphor and co-reference are used frequently in natural language expression, especially in human-human dialogues (Quan et al., 2019). The examples in dialogues include:

- Ellipsis
  1) Zero anaphora (Noun phrase ellipsis)
  U_1: "你喜欢邦乔维的音乐吗？" ("*Do you like music of Bon Jovi?*")
  U_2: "是的(*Yes*)，我(*I*)喜欢(*like*)。"

The noun phrase "邦乔维的音乐" ("*music of Bon Jovi*") is omitted in the second utterance.

  2) Verbal phrase ellipsis
  U_1: "*I like the V6 engine of Audi S4.*"
  U_2: "*So do I.*"

Here, "*do*" is a trigger word which indicates the ellipsis of verbal phrase "*like the V6 engine of Audi S4*".

- Anaphor
  1) Personal pronoun
  U_1: "*Do you know Kelly Clarkson?*"
  U_2: "*Yes, she is my idol.*"

"*she*" is a personal pronoun which refers to "*Kelly Clarkson*".

  2) Demonstrative pronoun
  U_1: "*Have you ever made some family albums?*"
  U_2: "*Yes, these are my treasures.*"

Here, "*these*" refers to "*family albums*".

- co-reference
  U_1: "*There is a concert of Taylor Swift next month.*"
  U_2: "*Let us sing with Swifty together!*"

In this case, "*Swifty*" and "*Taylor Swift*" are co-reference.

2.3 Data Annotation

The English dialogue data are sourced from the DailyDialogue dataset (Li et al., 2017). The Chinese dialogue data are collected by ourself from Douban[3], a Chinese online forum. We randomly sample a subset of dialogues from the above two dataset respectively, and then annotate these dialogues in question answering.

For annotation, the first step is to identify ellipsis, anaphor and co-reference phenomenons of utterances in dialogue data. For each utterance, annotators determine whether the meaning of the utterance is complete when ignoring the dialogue context. If the meaning of an utterance is determined as incomplete, we can further identify ellipsis. Both zero anaphora and verbal phrase ellipsis are determined, and the anaphor can include both the personal and demonstrative pronouns. However, utterances such as "是(Yes)", "不是(No)", "好的(OK)" are not identified as ellipsis.

The second step is to raise questions to the identified zero anaphora, personal pronouns, demonstrative pronouns and corefered entities. We require that the questions are not simply obtained

---

[3] `https://www.douban.com/`

	English	Chinese
Total # of dialogues	8,415	6,203
Total # of questions	11,904	10,387
Training set	6,603	4,962
Dev set	832	621
Test set	830	620

Table 3: Statistics of the annotated dialogue dataset. # denotes "number".

by adding interrogative words in the original utterances. The third step is to give answers of each question, which may be an entity, a phrase, a chunk, a clause or a fragment of an utterance. Table 3 presents the statistics of the annotated dialogue dataset. In the end, we have 11,904 questions being labeled in 8,415 English dialogues, and 10,387 in 6,203 Chinese dialogues.

2.4 Characteristics

The characteristics of the annotated dialogue dataset include:

1) The dialogues are real human-human conversations;

2) Each dialogue is annotated with one or more questions and each question is related to at least an utterance of a dialogue;

3) The answer of a question may appear in one or more utterances of the dialogue. It means that an answer may be a composition of fragments that are from different utterances rather than a continuous span of an utterance. We analyze the types of answers in the annotated dataset below.

First, Table 4 shows the number and percentage of different types of answers.

	English		Chinese	
	#	%	#	%
Entity	4,765	40.03	5,810	55.94
Phrase	2,298	19.30	2,203	21.21
Clause	87	0.73	755	7.26
Fragment	4,754	39.94	1,619	15.59

Table 4: Statistics of the answer types in the annotated dataset. # denotes "number" and % denotes percentage.

We can see that most of the answers are entity, phrase and fragment. The proportion of the clause type in the Chinese dialogue data is about ten times that in the English dialogue data. The proportion of the fragment type in English is larger than that in Chinese.

Second, we give the statistics of the status of an answer that appears in a dialogue. Here, in Table 5, "Seq" and "Skip"denote the tokens of an answer are sequential and skipping in an utterance, respectively. "Cross" indicates that the tokens of an answer are from different utterances. "Summary" means that the tokens of an answer written by the annotator is not strictly from the dialogue.

	English		Chinese	
	#	%	#	%
Seq	11,055	92.87	9,831	94.65
Skip	145	1.22	206	1.98
Cross	146	1.23	195	1.88
Summary	552	4.68	147	1.49

Table 5: Statistics of the status of an answer that appears in a dialogue. # denotes "number" and % denotes percentage.

2.5 Evaluation Metrics

The Exact match and F1 are used to evaluate the performance of models.

Exact match (EM): the number of answers predicted by a model and exactly matched the gold answers divides to the total number of gold answers in test set.

F1: F1 is computed by precision(p) and recall(r), where $p = N_{matched}/N_{predAns}$ and $r = N_{matched}/N_{goldAns}$. For a predicted answer, the precision(p) equals to the number of tokens that match to the gold answer($N_{matched}$) divided by the number of tokens in the predicted answer($N_{predAns}$), and the recall equals to the number of tokens that match to the gold answer divided by the number of tokens in the gold answer($N_{goldAns}$). For the Chinese dialogue data, to avoid the error of automatic Chinese word segmentation, the F1 score is calculated in the character level. Note that punctuation is ignored in calculating the EM and F1 scores.

3 Models

We evaluate representative neural end-to-end models for response geenration, which share a similar backbone of encoder-decoder structure (with the exception of DialoGPT, which has only a decoder). Below we give the common structure (Section 3.1) and then introduce the characteristic of each model (Section 3.2).

3.1 Model Structure Overview

We first give an overview of the structures of representative dialogue models. Most existing models adopt an encoder-decoder structure. As shown in Figure 1, the models consist of an utterance encoder, a context encoder and a decoder. Given a

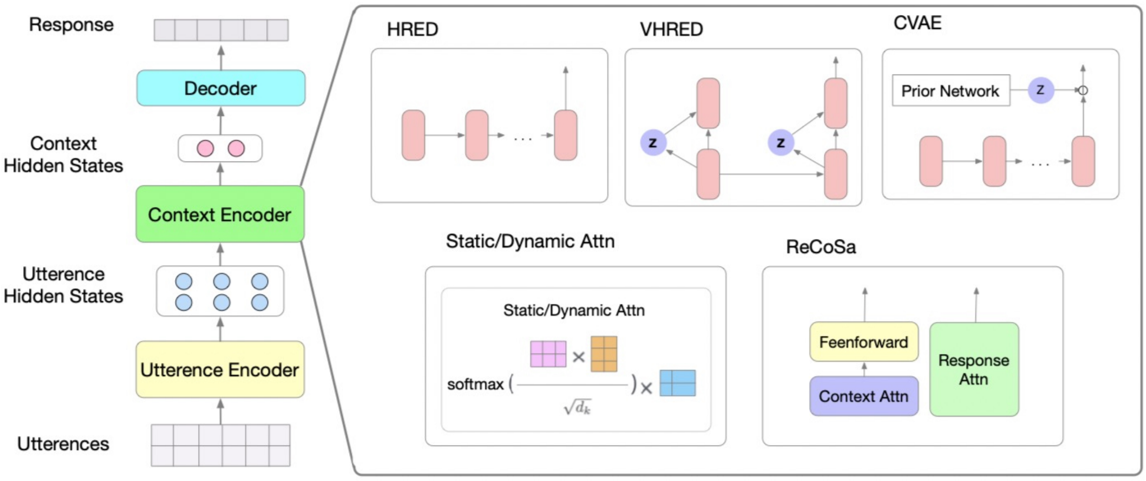

Figure 1: Model structure overview.

dialogue state, all the utterances in the current state, including past QA pairs, and a clarification request (question) are encoded as one input. The target is to generate the "gold" answer a_j from the input. The formalization of the process is:

$$y = \arg\max p(a_j|u_1, u_2, ..., q_i, \hat{a}_i, ..., u_k, q_j)$$

where $u_1, u_2, ..., u_k$ are dialogue utterance. q_i and $\hat{a}_i$ denote the i-th question and the predicted answer, respectively.

3.2 Representative Models

We choose the following 8 multi-turn dialogue generation models.

HRED: (Serban et al., 2016) is a hierarchical RNN-based encoder-decoder framework to sequentially model multi-turn dialogue and generate responses. It consists of two directional RNNs. One RNN is modeling the tokens in an utterance. The other RNN is modeling the utterances in a dialogue context.

vHRED: (Serban et al., 2017) is proposed to alleviate the generation of vague and generic response, which is caused by the gradient vanishing of HRED model, by introducing a hidden variable z. Therefore, vHRED is a variational enhanced HRED model.

CVAE: (Zhao et al., 2017) uses a prior network to model the gold response into a hidden variable z, which is as a condition in training step to improve the generation diversity.

Static/Dynamic Attention: the mechanisms (Zhang et al., 2018) alternatively model the contextual representations of multi-turn dialogue history using two types of attentions rather than using RNN.

ReCoSa: (Zhang et al., 2019) models the dialogue history in various granularity, e.g. context and response, using interactive attention and self-attention, respectively.

Transformer: (Vaswani et al., 2017) is used as a representative pretrained encoder-decoder model for dialogue generation.

DialoGPT: DialoGPT (Zhang et al., 2020) is a generative pretrained Transformer decoder for dialogue generation. To further conclude the characteristics of these models, Table 6 presents an overview of the characteristics of the chosen representative dialogue generation models in the proposed dialogue understanding task.

3.3 Implementation Details

For the training of the HRED, vHRED, CVAE and ReCoSa models, we use a bidirectional GRU (Cho et al., 2014) to encode the dialogue context and the input message. For the training of the static and dynamic attention models (Zhang et al., 2018), to be consistent to the setting in the original paper, a unidirectional GRU is utilized for contextual encoding of dialogue history. A fixed size of contextual window of dialogue utterances is used for modeling

	HRED	vHRED	CVAE	Static	Dynamic	ReCoSa	Transformer	DialoGPT

$c = \sum_i \alpha_i O_i$	$c_t = \sum_i \alpha_{i,t} O_{i,t}$

Table 7: Implementation details of integrating the static and dynamic attentions into Transformer-based dialogue model.

the dialogue history[4].

For adding the Static attention into the Transformer model, the query q is the representation of a question. For the integration of Dynamic attention into the Transformer model, the query q_t denotes the decoded answer fragment in time step t. The key k_i denotes the output of encoding the i-th utterance in the dialogue context. The detailed modeling process is shown in Table 7. Please refer (Vaswani et al., 2017) for the definitions of q,k and d.

The dimension of the word and character embedding, which are initialized with GloVe[5], equals to 300. The RNN model is implemented with GRU. The size of hidden variable in vHRED and CVAE models is 300. For the ReCoSa model, the number of attention head equals to 6 and the number of self-attention layers is 3. Dropout is used in all models. For the experiments on English dialogue data, we use the 840B version of GloVe embedding. In experiments of Chinese dialogue data, to avoid the impact of different Chinese word segmentation tools, we use the character-level GloVe embedding, which is trained on Chinese Weibo corpus (Shang et al., 2015). Noted that the character embedding is fixed in the training process of these dialogue generation models.

4 Results

Table 8 shows the results of the representative models on the proposed DEQA dataset. Overall, the model performances are below 20% in EM and below 40% in F1, which shows that the task is challenging for existing dialogue models. The results are relatively low compared to the same English benchmark on response generation task(Feng et al., 2020), which are in the range of 0.594 to 0.728 in averaged greedy matching and 0.548 to 0.746 in frequency-based similarity. The averaged greedy matching and frequency-based similarity are used to evaluate the coherence and informativeness of a generated response, respectively (Feng et al., 2020).

4.1 Results of Different Models

1) Attention-based models such as Static, Dynamic and ReCoSa, outperform the HRED, vHRED and CVAE models in EM score in both English and Chinese dialogue data and F1 score in Chinese data. It shows that attention/self-attention from an output token to the dialogue history context can be useful for capturing co-reference information.

2) Comparing the results in Table 8, the pretraining models outperform the representative dialogue models on both English and Chinese dialogue data, which demonstrates the superiority of the pretraining scheme on dialogue understanding. The results are consistent with results on the Winograd Scheme challenge (Ruan et al., 2019; Sakaguchi et al., 2020), which demonstrate that pretraining can be useful for co-reference resolution.

3) The CVAE model gives the best F1 score in Chinese dialogue data. Comparing the results of HRED and vHRED, we find that the use of latent variable may not improve the performances on the proposed task. Comparing the results of vHRED and CVAE, we can speculate that the improvements of performance may be from the introducing of prior information in context encoder.

4) The integration of static attention into Transformer model can further improve the performance

---

[4] Note that we also verified the performance of non-fixed window size (e.g., a sliding window) but the performance of the above models all decrease.

[5] `https://nlp.stanford.edu/projects/glove/`

Model	English		Chinese	
	EM	F1	EM	F1
HRED	6.048	13.642	3.762	8.161
vHRED	5.882	14.954	2.871	7.239
CVAE	4.636	17.094	5.509	16.893
Static	6.048	18.132	7.052	14.873
Dynamic	6.214	17.602	6.856	14.408
ReCoSa	6.016	13.390	6.485	14.604
Transformer	9.959	23.221	17.723	33.306
+Static	10.133	24.155	**21.980**	**40.024**
+Dynamic	8.375	23.153	15.941	31.492
DialoGPT	**16.560**	**37.140**	19.307	33.798

Table 8: Results of the representative dialogue models on the proposed task.

on Chinese dialogue data. In addition, comparing the results of "Transformer" and "Transformer+Static", it indicates that the fine-grained encoding process can further improve the performance of the Transformer-based dialogue model.

4.2 Results on Different Answer Types

To further understand the main challenges, we split the test set into four subsets according to the answer types. Table 9 and 10 show the results of the models in English and Chinese dialogue data, respectively. Overall, the performance trends of DialoGPT and Transformer with static attention are consistent to the results in Table 8, which show the strong capability of pretraining models on the proposed task. Comparing each type of answers, we find that the difficulty of generating the answers in types of entity, phrase, clause and fragment is increasing in both English and Chinese dialogue data. One common reason is that the generation quality declines with the increasing of text length (Liu et al., 2018; Tan et al., 2020)[6]. In addition, the F1 score in English dialogue data is not monotonically decreasing as EM score. It is because the average number of tokens in English entities is close to 1, which leads to a lower F1 score than that in English phrases. It also reveals the reason that the EM and F1 scores in Entity type are closer than that in Phrase type.

5 Related Work

Conversational QA Recent research on conversational question answering (**ConvQA**) had been driven by two challenges, namely CoQA (Reddy et al., 2018) and QuAC (Choi et al., 2018). Rather than understanding the meaning of a given passage/document through the form of conversational question answering, the proposed task focuses on measuring the capability of understanding the dialogue itself. Besides the two challenges, several conversational machine reading/comprehension datasets were proposed (Elgohary et al., 2018; Dinan et al., 2018; Huang et al., 2018; Saeidi et al., 2018). The most common characteristic of these datasets are that their questions are open-domain and sequentially (or contextually) related, which shows a recent recognition in the research community that understanding the semantics of a complete conversation, including historical question and answer contexts, is crucial for these tasks. Our work is similar in spirit, but concentrating on clarification requests.

Clarification Request in Dialogue Clarification requests (**CR**) in dialogue are mainly motivated by acoustic understanding and semantic understanding (Schlangen, 2004; Stoyanchev and Johnston, 2015). They are used mainly as a way to establish mutual knowledge or grounding in communication (Gabsdil, 2003; Rieser and Moore, 2005). Purver et al. (2003) proposed to classify the forms of clarification requests into 8 categories, including non-reprise clarifications, reprise sentences, reprise sluices, reprise fragments, gaps, gap fillers, conventional and other. Rodríguez and Schlangen (2004) further summarized the surface forms, intonations and functions of clarification requests in spoken dialogue systems. Ginzburg (2016) detailed the semantics of dialogue and the fundamental problems to tackle for the semantic analysis in dialogue. In their work, a clarification request is defined to be a core function for dialogue systems to maintain the coherence of a dialogue.

This line of work coincides with our motivation that asking questions for clarification is a natural way to help understanding the meaning and maintaining coherence in dialogues. Therefore, the abilities of generating clarification requests to users and correctly responding to such requests from users are crucial to dialogue systems. Different from the above work, we build the DEQA, a Dialogue Entity via Question Answering dataset and investigate computational models for measuring the ability of machines on understanding the semantics of a dialogue via question answering.

---

[6] The average numbers of tokens in the answer types of entity, phrase, clause and fragment are 1.22, 2.15, 9.07, 5.48 in English dialogue data and 1.95, 3.28, 6.86 and 5.77 characters in Chinese dialogue data.

6 Conclusion

We proposed a novel evaluation task for co-reference resolution in dialogue understanding with a new benchmark dataset, DEQA. By asking a dialogue model to identify entity-oriented linguistic structures in dialogue history context, it directly measures the quality of dialogue understanding through response generation. Empirical comparisons show that the chosen representative dialogue models face challenges on the proposed benchmark dataset and clause and fragment types of co-references are paticularly challenging even for pretrained models. We will release the dataset for research use and further annotate the dataset with the questions that are related to more complex linguistic structures in future work.

Ethics Statement

Our research is only oriented to semantic tasks and does not rely on any user information. To protect the privacy, intellectual property rights, and the rights of annotators, we took the following operations:

Privacy As we used crawler technology to get some raw data from Douban. It should be noted that to ensure the privacy of users, we directly deleted all User IDs and pictures during the crawling process, and only retained the text of the conversation. Then, we manually verify that all data has not leaked privacy.

Intellectual property rights Redistributing Douban's data may violate intellectual property rights. So we are now applying to Douban for permission to redistribute the data. We will release the dataset as soon as possible after obtaining permission. Before that, we first release the data of Dailydialog on the Github page and indicate that we are applying for the permission of Douban data.

Reasonable Compensation Regarding salary, Chinese annotation is easier than English for our Chinese annotators. Each piece of Douban data is paid about 1 yuan(about 16 cents), and DailyDialogue annotators are paid about 2 yuan (about 31 cents) per piece of data. Then we estimated the hourly salary of the annotator. The Chinese dataset annotator who is new to the task can complete about 70 annotations in an hour on average, so their hourly salary is at least 70 yuan(about 11 dollars) per hour.

The English dataset annotator completes an average of about 40 annotations per hour. The hourly salary is 80 yuan (about 12.5 dollars)per hour.

Beyond Metadata: What Paper Authors Say About Corpora They Use

Nikolay Kolyada[1] **Martin Potthast**[2] **Benno Stein**[1]

Abstract

The growing ecosystem of data sharing in science has put dataset search into the focus. To make data sharing and reuse more feasible, new retrieval tools and services are being developed. Currently, dataset retrieval relies almost exclusively on metadata provided by the publishers. To extend this knowledge source our work studies the task of "dataset review mining" in scientific publications. For the field of Natural Language Processing we collect metadata about datasets from established resources such as the ELRA and LDC catalogs, and then extract review statements about the datasets from ACL Anthology Corpus publications, compiling the Webis-Dataset-Reviews-21 corpus. By analyzing the reviews we identify different categories of what paper authors write about data. To the best of our knowledge, this is the first analysis of this kind in the field of Natural Language Processing, albeit similar analyses have been carried out in the social and medical sciences. Our corpus and the underlying code are shared alongside this paper.[1,2,3]

1 Introduction

Recently, Google introduced its Dataset Search service (Brickley et al., 2019).[4] Around 30 million datasets have been indexed to date,[5] hosted at web pages and repositories all across the web. Although data sharing and dataset search has long been a best practice in natural language processing, Google's service has accelerated and standardized data sharing across scientific communities, since only those datasets are indexed, for which a certain metadata description prescribed by Google is provided.

Chapman et al. (2020) and Koesten et al. (2017) survey the state of the art in dataset search and analyze how it differs from classical information retrieval. Approaches to dataset search from related fields, such as databases, semantic web, entity-based search, and tabular search are reviewed, but neither solves the task comprehensively. From a user's perspective, searching for datasets entails two steps: (1) its retrieval using standard keyword search, and (2) examining the search results to identify the datasets suitable to one's needs. The second step strongly differs from web search, since a (large) dataset cannot be easily reviewed in the browser; merely it's metadata is available—as well as the descriptions found on the download page. We argue that a crucial piece of information is missing to inform the examination of dataset search results: dataset user experience.

Unlike for commercial products in online shops, for datasets, there are hardly any platforms where users share their experiences using them. On the few that do exist, the amount of published reviews cannot be compared with that of commercial products. In any case, due to the specificity of most datasets, few people actually use them. Their feedback is typically found only as part of their reports and scientific publications. However, here, authors are at liberty to provide testimonials and criticisms that can be more thorough and extended in comparison to commercial product reviews.

To assess this potential source of information about datasets, and to eventually harness it for dataset search, this paper takes the first step in this direction by compiling and analyzing Webis-Dataset-Reviews-21, a corpus of dataset reviews from a large corpus of scientific publications, namely the ACL Anthology. Compiling a list of datasets in the field of Natural Language Processing and Computational Linguistics using authoritative sources including catalogs of the European

Language Resources Association (ELRA) and its LRE Map, the Linguistic Data Consortium (LDC), and others, we extract from the ACL Anthology's 57,608 papers 466,567 sentences mentioning a dataset. Exploring these mention statements, we organize them in a taxonomy, assessing their usefulness for dataset retrieval.

2 Related Work

Dataset review mining can be seen as part of the task of dataset retrieval, as well as that of extracting information from scientific documents. The demand for dataset search has increased with more data being published across scientific communities, by industry, and by government bodies. Multiple initiatives facilitate data sharing and encourage scientists to do so, such as Zenodo,[6] and DataCite[7] (Rueda et al., 2016), which also provide digital object identifiers (DOIs) for datasets, and a platform for publishing them. Several open software frameworks implement data collection management. Currently, most common are CKAN (Solr), Socrata, and OpenDataSoft. Chapman et al. (2020) show that most of the search features implemented rely exclusively on metadata. Brickley et al. (2019) observe that this restricts the effectiveness of dataset retrieval engines as metadata quality varies significantly. Notwithstanding this shortcoming, specialized dataset search engines still dramatically improve dataset discovery and sharing.

Several commonly used schemas and formats for dataset metadata exist, such as the JavaScript Object Notation for Linked Data (JSON-LD), and the Dataset schema[8] based on W3C DCAT (Erickson et al., 2013). The latter has become a de-facto standard, as it is used by Google Dataset Search to index data collections found in the open web. Many data publishers meanwhile adopted these standards of making metadata about their published datasets machine-readable, and data portal software platforms, such as CKAN, integrate this functionality by default. In addition, improvements on tracking citations of data are being actively developed. Projects, like Semantic Scholar, Microsoft Academic Graph,[9] and Google Dataset Search, along with Google Scholar, couple data and publications to improve data discovery.

The task of extracting structured information from scientific publications has been tackled many times. Gupta and Manning (2011) extract key aspects of scientific papers, including focus, technique, and domain from the ACL Anthology. Mesbah et al. (2018), Luan et al. (2018), and Jain et al. (2020) propose approaches to identify entities and their relations in scientific documents. Gábor et al. (2016) creates an annotated corpus for concepts and semantic relations based on the ACL Anthology. Duck et al. (2016) employed text mining to process dataset and software mentions in biological and medical publications from PubMed Central. Boland et al. (2012) identify references to datasets in social science publications. Closely related to our work, *software* mentions in scientific documents can be mined using a Grobid library module,[10] e.g., to give research software more credit.

In 2019, a shared task focusing on the tasks of dataset review mining and extraction of scientific methods and fields was organized by the Coleridge Initiative.[11] The training data provided was based on the Inter-university Consortium for Political and Social Research (ICPSR) data catalog,[12] comprising around 10,000 datasets used in the social sciences and a labeled corpus of 5,000 publications matched with mentioned datasets. The best-performing solution by The Allen Institute for Artificial Intelligence (AI2) implements a set of rule-based candidate citations by exact string matching mentions and datasets as a first step. An ad-hoc named entity recognition model has been trained based on matches identified. Mention labels were generated by string matching mentions in the provided annotations against the full text of papers. Then, candidate datasets were scored based on TF-IDF-weighted token overlap between the mention text and the dataset title, linking them using a binary classifier.

Färber et al.'s (2021) work is perhaps the most closely related one to our paper. It recognizes datasets along with scientific methods in a corpus of 510,000 publications. The TSE-NER approach by Mesbah et al. (2018) was used to identify methods and datasets in order to integrate this data into the Microsoft Academic Knowledge Graph (MAKG). Moreover, identified dataset references has been classified into used vs. not-used based on the textual context.

3 Collecting the Metdata of NLP Datasets

The two major steps to construct the Webis-Dataset-Reviews-21 corpus are the compilation of a collection of metadata of datasets used in the field of Natural Language Processing, and the extraction of mentions of these datasets from the ACL Anthology. To tackle the first step, we crawl authoritative NLP dataset catalogs, collect their metadata, clean and normalize it, merge duplicates, and format this compilation according to the specification of https://schema.org/Dataset.

The catalogs crawled are shown in Table 1. Although these catalogs may not list all existing datasets in Natural Language Processing, they certainly contain many of the most prominent and the most commonly used ones in the field. Nevertheless, there are bound to be many datasets in the "long tail": Their identification will require tailored named entity recognition approaches along the lines of the ones employed in aforementioned shared tasks. Our current collection of dataset metadata contains 13,372 entries in total.

The metadata enclosed in the catalogs are based on different schemas. In order to render them amenable for subsequent processing, we went about cleaning, normalizing, and unifying them across catalogs. Duplicates were identified and merged into a normalized schema: For each dataset, we collect properties relating to its source, original title, acronym, DOI, description, year, creator, and URL, as well as additional properties, such as language, format, size, and metadata about the associated paper, if available. Our final, unified metadata catalog of NLP datasets forms part of the Webis-Dataset-Reviews-21 corpus.

Catalog	**Datasets**

Linguistic Data Consortium (LDC)[15]	950
Big Bad NLP Database[16]	791
NLP Progress[17]	90
Σ	13,372

Table 1: NLP resources crawled for dataset metadata.

4 Mining Dataset Reviews

The second step of constructing our corpus was mining for dataset reviews from the ACL Anthology in the form of sentences that mention a dataset found in our unified catalog. We extract dataset mentions from the anthology's papers, annotate them, and develop a taxonomy with regard to the information a dataset mention provides about the data. We further analyze common patterns used by authors to describe the data.

4.1 Preprocessing the ACL Anthology

The ACL Anthology[18] compiles all papers published in the fields of computer linguistics and natural language processing published between the late 1960s up to today and makes them available open access. We used a collection of papers from that includes the papers up until 2020, 57,606 PDF files in total, omitting ones not written in English.

To enable text processing the papers, we use the Grobid (GRO, 2008–2021) library for parsing scientific publications given as PDF and extracting structured XML/TEI-encoded documents.[19] In the subsequent review mining step, we decided to analze only the publications' body sections (including the introduction), as a pilot study showed datasets mentioned in the abstract or references sections hardly contain any information about them. Harnessing the annotations provided by Grobid, we resolve references and footnotes within the text of a paper and add the titles of cited items to the document full text. If a paper contains exact references in a form of DOI or URL to the corpora used, we consider this information as additional features in the mention extraction step. Information about paper sections and paragraphs within the body are preserved as well.

4.2 Dataset Mentions Extraction

For the dataset mention extraction, we exploit the fact that most datasets in natural language processing research have proper names and/or distinct acronyms. This is unlike in the social sciences, where many datasets rather have descriptions for names (e.g., "national census data on population development 2020", which then gets shortened adhoc by the authors while writing their paper). By contrast, for NLP dataset, their creators often conceive of catchy acronyms (e.g., "WordNet") that

TimeML	2,584	614	384
PubMed	2,437	585	648

Table 3: Number of mentions and papers for top 20 datasets mentioned in the ACL Anthology publications.

are then picked up by paper authors. Therefore, we get by with basic string matching to extract 466,567 mentions of 2,986 unique datasets out of the 13,371 ones in our catalog.[20] At the same time, with this basic approach, we introduce a baseline for the task of dataset mention extraction, which, in practice, has a similar recall compared to that of a full-text search performed over an indexed collection of papers.

We define a dataset review as "an assessment from the person who used the data" (be it praise or criticism). Reviews are often spread across sentences around a dataset mention, but are usually confined to within the same paragraph or section. We employ a co-reference resolution model (Clark and Manning, 2016) to extract further discussion of a dataset from adjacent sentences around a dataset mention. Tables 2 and 3 overview relevant corpus statistics.

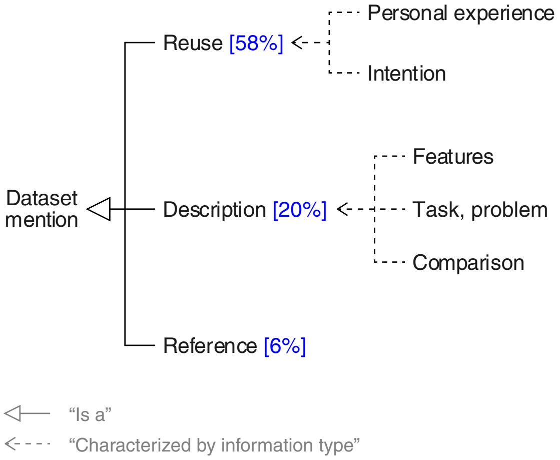

Figure 1: Taxonomy of dataset mentions. The type "personal experience" corrsponds to a dataset review, and implies reuse of the data.

4.3 A Taxonomy of Dataset Mentions

We manually reviewed a random sample of 1,000 dataset mentions and derived a taxonomy of three classes as shown in Figure 1: reuse, description, and reference. We primarily distinguish between "active" cases of reuse of a dataset from "passive" descriptions and references. Statements of dataset reuse include cases where data is used as a basis for experiments, training models, and synthesis of new or sub-datasets. For instance:

(1) *"Second, we reuse the RCV1-V2, using a version that contained a selected 5,000 term vocabulary."*

Descriptions and references rather give details about a dataset or compare it:

(2) *"For instance, two words are said to be synonyms if they belong in the same synset in the WordNet."*;

(3) *"MovieQA is a challenging dataset for movie understanding. The dataset consists of 14,944 multiple choice questions about 408 movies."*

Altogether, 58% of the sample are reuse mentions, 20% descriptions, and 6% references. The remaining mentions are ambiguous and/or incorrect.

From the reuse mentions, 63% share a "personal experience" which we operationalize as a form of dataset review. Projected to the entire set of dataset mentions, this potentially results in about 150,000 such cases. For instance:

(4) *"When only WordNet, not BabelNet, is used for identifying lexico-semantic relations, per-*

---

[20] In future work, we plan on investigating if the recall of mentioned datasets can be increased with heuristic matching approaches as well as citation-based ones; cursory attempts, however, showed especially the former to introduce a lot of noisy mentions, which is why we omitted them in this analysis.

formance increases slightly, which we attribute to noise that comes with using BabelNet.";

(5) *"The TimeBank and the data used in the two TempEval challenges are important, as they have annotations describing not just dates and times, but also events and temporal relations between these entities."*;

(6) *"While AQuA may prove useful for training, it is inappropriate as an evaluation set."*

Unsurprisingly, commonly used datasets, such as Wikipedia, WordNet, the Penn Treebank, the Brown Corpus, and GigaWord receive the most mentions with over 5,000 each. The majority are mentioned only a few times; only 25% of the datasets are mentioned more than 10 times. Altogether, description mentions provide information about the data, its features, and common tasks it is used for. Reuse mentions conveying a personal experience provide information about suitability of the dataset for the paper's envisioned task, as well as details about the data.

5 Conclusion

We compiled a comprehensive list of NLP-related datasets and extracted their mentions from the ACL Anthology. Analyzing the mentions, three basic categories can be distinguished, namely reuse, descriptions, and references. The former two categories of mentions are considered to be useful as a source of information on a dataset in the task of dataset retrieval, enabling dataset search engines to display more in-depth information about a dataset on a search results page, as well as informing their retrieval models. Other future directions include improving the extraction of mentions, e.g., via "few-shot" domain-specific named entity recognition, as well as, expanding to other fields of research.

Abstract

Quality Estimation (QE) is the task of automatically predicting Machine Translation quality in the absence of reference translations, making it applicable in real-time settings, such as translating online social media conversations. Recent success in QE stems from the use of multilingual pre-trained representations, where very large models lead to impressive results. However, the inference time, disk and memory requirements of such models do not allow for wide usage in the real world. Models trained on distilled pre-trained representations remain prohibitively large for many usage scenarios. We instead propose to directly transfer knowledge from a strong QE teacher model to a much smaller model with a different, shallower architecture. We show that this approach, in combination with data augmentation, leads to light-weight QE models that perform competitively with distilled pre-trained representations with 8x fewer parameters.

1 Introduction

Quality Estimation (QE) aims to predict the quality of the output of Machine Translation (MT) systems when no gold-standard translations are available. It can make MT useful in real-world applications by informing end-users on the translation quality. We focus on sentence-level QE, usually formulated as a regression task where quality is required to be predicted on an continuous scale, e.g. 0-100.

The high performances achieved in the most recent shared task on sentence-level QE (Specia et al., 2020) have been attributed to the use of strong pre-trained language models, namely BERT (Devlin et al., 2018) and its multilingual variants, especially XLM-Roberta (Conneau et al., 2020a). These models have an extremely large number of parameters and, since they are required at training and inference time, they are very disk and RAM-hungry, also making inference slow. This poses challenges for real-time inference, and prohibits deployment on client machines with limited resources.

Making models based on pre-trained representations smaller and more usable in practice is an active area of research. One approach is Knowledge Distillation (KD), aiming to extract knowledge from a top-performing large model (the *teacher*) into a smaller (in terms of memory print, computational power and prediction latency) yet well-performing model (the *student*) (Hinton et al., 2015; Gou et al., 2020). KD techniques have been used to make BERT and similar models smaller. For example, DistilBERT (Sanh et al., 2019) and TinyBERT (Jiao et al., 2020) follow the same general architecture as the teacher BERT, but with a reduced number of layers. However, these student models are also based on Transformers and, as such, they still have too large memory and disk footprints. For instance, the number of parameters in the multilingual DistilBERT-based TransQuest model for QE (Ranasinghe et al., 2020) is 135M.

In this paper, we propose **to distill the QE model directly**, where the student architecture can be completely different from that of the teacher. Namely, we distill a large and powerful QE model based on XLM-Roberta into a small RNN-based model. Existing work along these lines has applied KD mainly to classification tasks (Tang et al., 2019; Sun et al., 2019). We instead explore this approach in the context of **regression**. In contrast to classification, where KD provides useful information on the output distribution of incorrect classes, for regression the teacher predictions are point-based estimates, and as such have the same properties as gold labels. Therefore, it is not obvious whether teacher-student learning can be beneficial. The few existing works on KD for regression (Chen et al., 2017; Takamoto et al., 2020) use the teacher loss to minimise the impact of noise in the teacher

predictions on the student training. However, this approach requires access to gold labelled examples to train the student, which in our case are very limited in number.

Our approach allows for much larger **unlabelled student training datasets**, built only from source-MT pairs and labelled by the teacher model. We study the performance of student models under different training data regimes: standard training with gold labels, training with teacher predictions on the same data, training with teacher predictions on augmented in-domain and out-of-domain data, as well as augmented data filtered based on uncertainty of teacher predictions. Interestingly, we find that (i) training with teacher predictions results in better performance than training with gold labels; and (ii) student models trained with augmented data perform competitively with DistilBERT-based TransQuest predictors with 8x fewer parameters.

2 Approach

Figure 1 summarises our approach, with the following main components:

Teacher-student training. We use predictions from a SoTA QE model to train a light-weight student with a different architecture. Specifically, as the teacher model we use the recently proposed TransQuest QE system (Ranasinghe et al., 2020) that fine-tunes multilingual pre-trained representations from XLM-Roberta-Large (Conneau et al., 2020a) to predict a continuous sentence-level quality score. For the student model, we rely on the BiRNN QE architecture proposed by Ive et al. (2018).[1] The BiRNN model encodes both source and translation sentences independently using two bi-directional Recurrent Neural Networks (RNNs). The two resulting sentence representations are concatenated as the weighted sum of their word vectors, generated by an attention mechanism. For predictions at sentence-level, the weighted representation of the two input sentences is passed through a dense layer with sigmoid activation to generate the quality estimates. Table 1 shows the number of parameters, memory and disk space requirements, as well as inference speed for the teacher model (TQ$_{\text{XLM-R-Large}}$), student model (BiRNN) and TransQuest system built on DistilBERT (TQ$_{\text{DistilBERT}}$). We refer the reader to Appendix A for the details on the architecture and implementation for these models.

In classification tasks, KD benefits learning as it uses information on the output distribution and has an effect akin to label smoothing (Tang et al., 2020). In regression, teacher labels are instead point-wise estimates just like the gold labels. Existing work on KD for regression uses teacher loss to minimise the impact of noise in the teacher predictions on student training (Takamoto et al., 2020). However, this approach is not suitable for QE as we have access to a very limited number of gold-labelled examples. We propose a simple strategy that relies directly on teacher predictions for training the student model.

Data augmentation. The power of QE models based on pre-trained representations is due to the rich knowledge that comes from training Transformer-based language models on very large amounts of data. Typically, much smaller datasets are available for downstream tasks, which suffice for fine-tuning but that are hardly suitable for training a neural model from scratch. We exploit the teacher-student framework to produce additional training data. Specifically, we first generate MT outputs for a set of sentences in the source language and domain of interest using the same MT system that was used for generating the test data. Second, we use the teacher model described above to pro-

---

[1] The implementation of our student models is available at `https://github.com/sheffieldnlp/deepQuest-py`.

duce predictions. These predictions are then used as labels for training the student.

Noise filtering. The benefits of data augmentation can be hampered by noise in teacher predictions. In a classification setting, where the student loss is computed with respect to the output distribution of the teacher model, this issue is ameliorated by the example re-weighting effect where teacher predictions with higher confidence have an overall higher impact on learning (Furlanello et al., 2018). Previous work has used teacher loss to address this issue for regression (Chen et al., 2017). However, this strategy is not suitable for data augmentation as it requires both gold labels and teacher predictions.

As an alternative, we propose a mechanism to filter-out noisy examples in the augmented dataset based on uncertainty quantification. Recent work has shown that ensembles produce accurate uncertainty estimates (Lakshminarayanan et al., 2017). We exploit this idea by training a set of additional teacher models independently on the same training data using random initialisation, and using the variance of their predictions as an indicator of predictive uncertainty.[2] Intuitively, examples with very high variance would correspond to noisy teacher predictions. We filter out from the student training data the instances where the variance is more than one standard deviation away from its mean value. This is expected to have a higher impact on the results in the out-of-domain setting where the performance of the teacher model is less stable and teacher predictions can contain more noise.

3 Experiments

MLQE Dataset. For training the teacher and for evaluation, we use the MLQE dataset (Fomicheva et al., 2020), same as in the WMT2020 QE Shared Task (Specia et al., 2020). This dataset contains sentences extracted from Wikipedia translated to and from English for a total of six language pairs: English–German (En-De),[3] English–Chinese (En-Zh), Romanian–English (Ro-En), Estonian–English (Et-En), Sinhala–English (Si-En) and Nepali–English (Ne-En). Each translation was produced with a SoTA Transformer-based NMT model and manually annotated for quality using an annotation scheme inspired by the Direct Assessment methodology (Graham et al., 2013). The scores are produced on a continuous scale indicating perceived translation quality in 0-100. For each language pair, this dataset contains partitions for training (7K), dev (1K), and test (1K).

Language	Sentences
Estonian	25,176
Romanian	372,690
Sinhala	139,406
Nepalese	85,343
English	1,563,519

Table 2: Number of sentences extracted from Wikipedia for data augmentation.

Distilled dataset. Monolingual data for data augmentation was sampled from Wikipedia following the procedure described in Fomicheva et al. (2020) to preserve the domain of the MLQE dataset. Specifically, we sampled documents from Wikipedia for English, Estonian, Romanian, Sinhalese and Nepalese and selected the top 100 documents containing the largest number of sentences that are: (i) in the intended source language according to a language-id classifier and (ii) have the length between 50 and 150 characters. Table 2 shows the total amount of sentences in the monolingual Wikipedia dataset collected for data augmentation.

To test the impact of data domain on the performance of the student QE models, we also collect out-of-domain data for the Et-En language pair. The out-of-domain data is sampled from Common Crawl. We use the version of Common Crawl distributed by the WMT2018 News Translation Task[4]. The total amount of sentences in this dataset is 100,779,314.

To translate the data, we used the same MT models that generated the test data, built with fairseq (Ott et al., 2019) and made available by the WMT2020 QE Shared Task organisers.[5] Sentences that were part of the training data for the MT models or part of the MLQE dataset were excluded. We generate quality predictions for the remaining sentences using the teacher models, as

---

[2] Here we use ensemble only as a way of estimating the error in the predictions and leave distillation based on ensemble predictions to future work.

[3] We skip this language pair as the performance of the teacher model for it is too weak.

Table 4: Pearson correlation on the test partition of the MLQE dataset for BiRNN student models trained with different amounts of distilled Wikipedia data.

Models. As teachers, we use pre-trained models from TransQuest (TQ$_{\text{TEACHER}}$), one of the winning submissions in the WMT2020 QE Shared Task, which we fine-tuned on the MLQE dataset. For noise filtering, we train five teacher models with random initialisation. As students, we use BiRNN models from DeepQuest (Ive et al., 2018). We also compare our results against the Predictor-Estimator model (Kim et al., 2017; Kepler et al., 2019), the baseline at the WMT2020 QE Shared Task, and TransQuest models using multilingual DistilBERT.[6]

4 Results

Table 3 shows the Pearson correlation with human judgments on the test partition of the MLQE dataset for different models and specifies the type of data used for training.[7] The correlation for the student models (BiRNN$_{\text{STUDENT}*}$) does not reach the performance of TQ$_{\text{TEACHER}}$. Smaller models may lack representation power for modeling cross-lingual tasks such as QE. Also, distillation for regression is more challenging, as discussed in Section 2. However, **training on the in-domain distilled data** (BiRNN$_{\text{STUDENT+AUG}}$) **allows to obtain performances comparable to DistilBERT** (TQ$_{\text{DistilBERT}}$) **with much lighter models** (see Table 1).[8] Furthermore, this approach results in a substantial improvement over shallow models trained on gold data (BiRNN and Predictor-Estimator) for all of the language pairs. The student performance for each language pair is strongly related to the performance of the teacher. Thus, the Ro-En student achieves the highest correlation results, whereas correlation for En-Zh is weak.

We further analyse what is the impact of different data selection strategies on the results. **First**, we sample random subsets of training instances from the Wikipedia distilled dataset and evaluate the performance of the student model trained with this data. We run the training 3 times with different random splits for training and validation and report the mean and confidence intervals. Table 4 shows the results for all languages where we have enough Wikipedia data (for Et-En we only have 25K in total). The largest boost in correlation is observed when going from 10K to 50K.

Second, we compare student models trained on these subsets of distilled data of different sizes, i.e. using data extracted from Wikipedia (in-domain), against data splits of the same size extracted from Common Crawl (out-of-domain). For the out-of-domain data we apply the noise filtering strategy described in Section 2. Figure 2 shows the results

---

[6] Multilingual DistilBERT is available at `https://huggingface.co/distilbert-base-multilingual-cased`. We follow the same training procedure as for the teacher model described in detail in Appendix A.

[7] TQ$_{\text{TEACHER}}$, TQ$_{\text{DistilBERT}}$ and Predictor-Estimator use contextual representations trained on large amounts of additional data, which are then fine-tuned for the QE task.

[8] This is true for all language pairs except Et-En and En-Zh. For Et-En we have a considerably smaller amount of in-domain data available for training, whereas for En-Zh the teacher model appears to be too weak to be useful for KD.

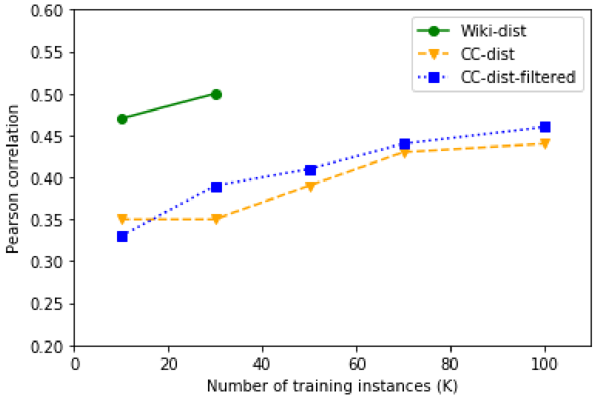

Figure 2: Pearson correlation results on the MLQE test set for the student models trained with different amounts of distilled data in-domain (Wiki-dist), out-of-domain (CC-dist) and out-of-domain with noise filtering (CC-dist-filtered), for Et-En.

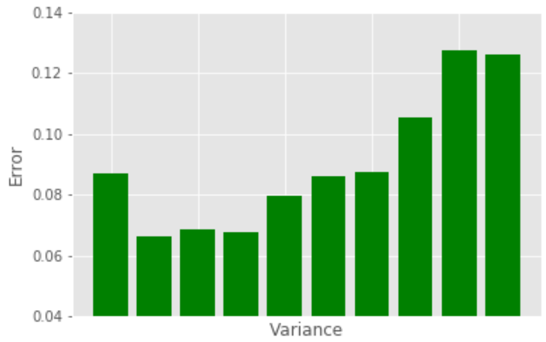

Figure 3: Variance in the predictions of 6 teacher models trained with different random seed against predictions error on the test partition of Ro-En MLQE dataset.

for Et-En, where our largest in-domain set has 25K sentences. We observe that using in-domain data appears to be much more effective than sampling larger amounts of generic data. Noise filtering gives some improvement in the results but its effect appears to be marginal compared to the effect of training with in-domain data.

Figure 3 provides an illustration of the relation between the variance in the predictions of multiple teacher models and prediction error for Ro-En language pair on the in-domain data. We group the sentences in the test partitions of MLQE dataset in 10 bins according to the variance between the predictions of the different teacher models in the ensemble. We then calculate the average prediction error in each bin, where the error is the absolute difference between model predictions and human judgements. As shown in Figure 3, higher variance in the predictions indeed corresponds to larger prediction error.

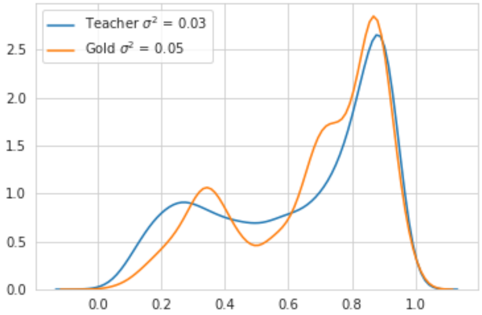

Figure 4: Distribution of teacher scores (blue) and gold labels (orange) on the training partitions of Et-En MLQE dataset.

Interestingly, from Table 3 we see that **training with distilled data brings benefits even without data augmentation** for some of the language pairs. The correlation for Et-En improves from 0.37 to 0.45 by training on teacher predictions (BiRNN$_{\text{STUDENT}}$) instead of gold labels (BiRNN) on the same MLQE dataset. To gain an intuition for this improvement, Figure 4 shows the distribution of teacher predictions and human scores on the train partition of MLQE dataset. We hypothesize that teacher predictions having a smoother distribution with reduced variance makes learning easier. As shown in Appendix B, we observe this trend for all language pairs in the dataset.

5 Conclusions

In this paper, we showed that knowledge distillation, through a teacher-student approach that directly distills QE predictions, can be effective in building a light-weight QE model with similar performance to a SoTA architecture trained on distilled yet large pre-trained representations. We also introduced a noise filtering approach that leverages the uncertainty of an ensemble of teacher models to determine which training instances should be discarded when training the student models, which can be beneficial especially for data augmentation from out-of-domain sources. This results in QE models 4x smaller in disk space with 8x fewer parameters, and 3x faster in inference speed.

A Teacher and student models

Teacher model For the teacher model, we use the transformer-based MonoTransQuest (Ranasinghe et al., 2020) architecture of the TransQuest framework with XLMR-large (Conneau et al., 2020b) as the underlying pre-trained representation model. XLMR is Transformer (Vaswani et al., 2017) based masked language model (with 24 Transformer blocks and the vocabulary size of 250K) trained on one hundred languages using approximately two terabytes of CommonCrawl data. MonoTransQuest takes as input the concatenation of the original sentence and its translation separated by the the special $[SEP]$ token. The learned representation of the special $[CLS]$ token is considered as the joint representation of the original and translated sentence. The joint representation is then fed to the final $softmax$ layer to predict the quality score of the translation. For distillation we use the models that were made available for download by the authors.[9] For training the additional teacher models for data filtering we follow the training settings in Ranasinghe et al. (2020): we used a batch size of 8, Adam optimiser with learning rate 2e-5, and a linear learning rate warm-up over 10% of the training data. During the training process, the parameters of XLM-R model, as well as the parameters of the subsequent layers, are updated. All the models were trained for 3 epochs.

Student model For the student model, we rely on the BiRNN QE architecture proposed by Ive et al. (2018). Our implementation of this architecture is available for download.[10] The light-weight architecture (15 layers) of this model is as follows: both source and target sentences are independently encoded by a dedicated embedding layer followed by a bi-directional Recurrent Neural Network (RNN). The two resulting sentence representations are then concatenated as a weighted sum of their word vectors, generated by an attention mechanism. The resulting representation is then passed through an output dense layer with sigmoid activation to generate the quality estimates. We use the BiRNN model in its default configuration: both source and target embeddings are of size 300, each encoder has a hidden size of 50. The vocabulary size is limited to the 30k most common words. The model is trained with early stopping with a patience of 5.

Abstract

Coreference resolution has been mostly investigated within a single document scope, showing impressive progress in recent years based on end-to-end models. However, the more challenging task of cross-document (CD) coreference resolution remained relatively under-explored, with the few recent models applied only to gold mentions. Here, we introduce the first end-to-end model for CD coreference resolution from raw text, which extends the prominent model for within-document coreference to the CD setting. Our model achieves competitive results for event and entity coreference resolution on gold mentions. More importantly, we set first baseline results, on the standard ECB+ dataset, for CD coreference resolution over predicted mentions. Further, our model is simpler and more efficient than recent CD coreference resolution systems, while not using any external resources.[1]

1 Introduction

Cross-document (CD) coreference resolution consists of identifying textual mentions across multiple documents that refer to the same concept. For example, consider the following sentences from the ECB+ dataset (Cybulska and Vossen, 2014), where colors represent coreference clusters (for brevity, we omit some clusters):

1. ***Thieves*** ***pulled off*** *a two million euro jewellery heist in central Paris on Monday after* ***smashing*** ***their*** *car through the store's front window.*

2. ***Four men*** ***drove*** *a 4x4 through the front window of the store on Rue de Castiglione, before* ***making off*** *with the jewellery and watches.*

Despite its importance for downstream tasks, CD coreference resolution has been lagging behind the impressive strides made in the scope of a single document (Lee et al., 2017; Joshi et al., 2019, 2020; Wu et al., 2020). Further, state-of-the-art models exhibit several shortcomings, such as operating on gold mentions or relying on external resources such as SRL or a paraphrase dataset (Shwartz et al., 2017), preventing them from being applied on realistic settings.

To address these limitations, we develop the first end-to-end CD coreference model building upon a prominent within-document (WD) coreference model (Lee et al., 2017) which we extend with recent advances in transformer-based encoders. We address the inherently non-linear nature of the CD setting by combining the WD coreference model with agglomerative clustering that was shown useful in CD models. Our model achieves competitive results on ECB+ over gold mentions and sets baseline results over predicted mentions. Our model is also simpler and substantially more efficient than existing CD coreference systems. Taken together, our work seeks to bridge the gap between WD and CD coreference, driving further research of the latter in realistic settings.

2 Background

Cross-document coreference Previous works on CD coreference resolution learn a pairwise scorer between mentions and use a clustering approach to form the coreference clusters (Cybulska and Vossen, 2015; Yang et al., 2015; Choubey and Huang, 2017; Kenyon-Dean et al., 2018; Bugert et al., 2020). Barhom et al. (2019) proposed to jointly learn entity and event coreference resolution, leveraging predicate-argument structures. Their model forms the coreference clusters incrementally, while alternating between event and entity coreference. Based on this work, Meged et al. (2020) improved results on event coreference by leverag-

August 1–6, 2021.

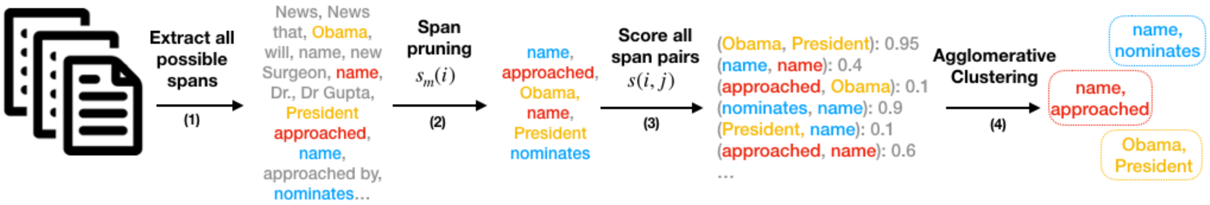

Figure 1: A high-level diagram of our model for cross-document coreference resolution. (1) Extract and score all possible spans, (2) keep top spans according to $s_m(i)$, (3) score all pairs $s(i,j)$, and (4) cluster spans using agglomerative clustering.

ing a paraphrase resource (Chirps; Shwartz et al., 2017) as distant supervision. Parallel to our work, recent approaches propose to fine-tune BERT on the pairwise coreference scorer (Zeng et al., 2020), where the state-of-the-art on ECB+ is achieved using a cross-document language model (CDLM) on pairs of full documents (Caciularu et al., 2021). Instead of applying BERT for all mentions pairs which is quadratically costly, our work separately encodes each (predicted) mention.

All above models suffer from several drawbacks. First, they use only gold mentions and treat entities and events separately.[2] Second, pairwise scores are recomputed after each merging step, which is resource and time consuming. Finally, they rely on additional resources, such as semantic role labeling, a within-document coreference resolver, and a paraphrase resource, which limits the applicability of these models in new domains and languages. In contrast, we use no such external resources.

Within-document coreference The *e2e-coref* WD coreference model (Lee et al., 2017) learns for each span i a distribution over its antecedents.

Considering all possible spans as potential mentions, the scoring function $s(i,j)$ between span i and j, where j appears before i, has three components: the two mention scores $s_m(\cdot)$ of spans i and j, and a pairwise antecedent score $s_a(i,j)$ for span j being an antecedent of span i.

Each span is represented with the concatenation of four vectors: the output representations of the span boundary (first and last) tokens ($x_{\text{FIRST(i)}}, x_{\text{LAST(i)}}$), an attention-weighted sum of token representations $\hat{x}_i$, and a feature vector $\phi(i)$. These span representations (g_i) are first fed into a mention scorer $s_m(\cdot)$ to filter the λT (where T is the number of tokens) spans with the highest scores. Then, the model learns for each of these spans to optimize the marginal log-likelihood of its correct antecedents. The full description of the model is described below:

$$\begin{aligned} g_i &= [x_{\text{FIRST(i)}}, x_{\text{LAST(i)}}, \hat{x}_i, \phi(i)] \\ s_m(i) &= \text{FFNN}_m(g_i) \\ s_a(i,j) &= \text{FFNN}_a([g_i, g_j, g_i \circ g_j]) \\ s(i,j) &= s_m(i) + s_m(j) + s_a(i,j) \end{aligned}$$

3 Model

The overall structure of our model is shown in Figure 1. The major obstacle in applying the *e2e-coref* model directly in the CD setting is its reliance on *textual ordering* – it forms coreference chains by linking each mention to an antecedent span appearing before it in the document. This linear clustering method cannot be used in the multiple-document setting since there is no inherent ordering between the documents. Additionally, ECB+ (the main benchmark for CD coreference resolution) is relatively small compared to OntoNotes (Pradhan et al., 2012), making it hard to jointly optimize mention detection and coreference decision. These challenges have implications in all stages of model development, as elaborated below.

Pre-training To address the small scale of the dataset, we pre-train the mention scorer $s_m(\cdot)$ on the gold mention spans, as ECB+ includes singleton annotation. This enables generating good candidate spans from the first epoch, and as we show in Section 4.3, it substantially improves performance.

Training Instead of comparing a mention only to its previous spans in the text, our pairwise scorer $s_a(i,j)$ compares a mention to all other spans across all the documents. The positive instances for training consist of all the pairs of highest scoring

---

[2] Few works (Yang et al., 2015; Choubey and Huang, 2017) do use predicted mentions, by considering the intersection of predicted and gold mentions for evaluation, and thus not penalizing models for false positive mention identification. Moreover, they used a different version of ECB+ with known annotation errors, as noted in Barhom et al. (2019).

mention spans that belong to the same coreference cluster, while the negative examples are sampled (20x the number of positive pairs) from all other pairs. The overall score is then optimized using the binary cross-entropy loss as follows:

$$L = -\frac{1}{|N|}\sum_{x,z \in N} y \cdot log(s(x,z))$$

where N corresponds to the set of mention-pairs (x, z), and $y \in \{0, 1\}$ to a pair label. Full implementation details are described in Appendix A.1. Notice that the mention scorer $s_m(\cdot)$ is further trained in order to generate better candidates at each training step. When training and evaluating the model in experiments over gold mentions, we ignore the span mention scores, $s_m(\cdot)$, and the gold mention representations are directly fed into the pairwise scorer $s_a(i, j)$.

Inference At inference time, we score all spans; prune spans with lowest scores; score the pairs; and finally form the coreference clusters using an agglomerative clustering (using average-linking method) over these pairwise scores, following common practices in CD coreference resolution (Yang et al., 2015; Choubey and Huang, 2017; Kenyon-Dean et al., 2018; Barhom et al., 2019). Since the affinity scores $s(i, j)$ are also computed for mention pairs in different documents, the agglomerative clustering can effectively find cross-document coreference clusters.

4 Experiments

4.1 Experimental setup

Following most recent work, we conduct our experiments ECB+ (Cybulska and Vossen, 2014), which is the largest dataset that includes both WD and CD coreference annotation (see Appendix A.2). We use the document clustering of Barhom et al. (2019) for pre-processing and apply our coreference model separately on each predicted document cluster.

Following Barhom et al. (2019), we present the model's performance on both event and entity coreference resolution. In addition, inspired by Lee et al. (2012), we train our model to perform event and entity coreference jointly, which we term "ALL". This represents a useful scenario when we are interested in finding all the coreference links in a set of documents, without having to distinguish event and entity mentions. Addressing CD coreference with ALL is challenging because (1) the search space is larger than when treating separately event and entity coreference and (2) models need to make subtle distinctions between event and entity mentions that are lexically similar but do not corefer. For example, the entity *voters* do not corefer with the event *voted*.

We apply RoBERTa$_{LARGE}$ (Liu et al., 2019) to encode the documents. Long documents are split into non-overlapping segments of up to 512 wordpiece tokens and are encoded independently (Joshi et al., 2019). Due to memory constraints, we freeze output representations from RoBERTa instead of fine-tuning all parameters. For all experiments, we use a single GeForce GTX 1080 Ti 12GB GPU. The training takes 2.5 hours for the most expensive setting (ALL on predicted mentions), while inference over the test set takes 11 minutes.

4.2 Results

Table 1 presents the combined within- and cross-document results of our model, in comparison to previous work on ECB+. We report the results using the standard evaluation metrics MUC, B^3, CEAF, and the average F1 of these metrics, called CoNLL F1 (main evaluation).

When evaluated on gold mentions, our model achieves competitive results for event (81 F1) and entity (73.1) coreference. In addition, we set baseline results where the model does not distinguish between event and entity mentions at inference time (denoted as the ALL setting). The overall performance on ECB+ obtained using two separate models for event and entity is negligibly higher (+0.6 F1) than our single ALL model.

Our model is the first to enable end-to-end CD coreference on *raw* text (predicted mentions). As expected, the performance is lower than that using gold mentions (e.g 26.6 F1 drop in event coreference), indicating the large room for improvement over predicted mentions. It should be noted that beyond mention detection errors, two additional factors contribute to the performance drop when moving to predicted mentions. First, while WD coreference systems typically disregard singletons (mentions appearing only once) when evaluating on *raw* text, CD coreference models do consider singletons when evaluating on *gold* mentions on ECB+. We observe that this difference affects the evaluation, explaining about 10% absolute points out of the aforementioned drop of 26.6. The effect of singletons on coreference evaluation is further

Table 1: Combined within- and cross-document results on the ECB+ test set, for event, entity and the unified task, that we term ALL. Our results (in italics) are close to state-of-the-art (in bold) for event and entity over gold mentions, while they set a new benchmark result over predicted mentions and for the ALL setting. The run-time complexity in (Zeng et al., 2020; Caciularu et al., 2021) is substantially more expensive because they apply BERT and CDLM for every mention-pair with their corresponding context (sentence and full document).

	Gold		Predicted	
	WD	CD	WD	CD
Event	**86.6**	81.0	**59.6**	54.4
Entity	**81.2**	73.1	**39.7**	35.7
ALL	**83.9**	76.7	**46.3**	43.4

Table 2: Results (CoNLL F1) of our model, on within-document (WD) vs. cross-document (CD), using gold and predicted mentions. For all settings, results on WD are higher, indicating the need in addressing typical challenges of CD coreference resolution.

	Gold	Δ	**Predicted**	Δ
Event	76.0	**–5.0**	48.2	**–6.2**
Entity	70.9	–2.2	34.4	–1.3
ALL	74.1	–2.6	41.4	–2.0

Table 3: CoNLL F1 results of our model without document clustering , using gold and predicted mentions.

explored in (Cattan et al., 2021). Second, entities are annotated in ECB+ only if they participate in event, making participant detection an additional challenge. This explains the more important performance drop in entity and ALL.

Table 2 presents the CoNLL F1 results of within- and cross-document coreference resolution for both gold and predicted mentions on ECB+. For all settings, results are higher in within-document coreference resolution, showing the need in addressing typical challenges of CD coreference resolution.

Table 3 shows the results of our model without document clustering. Here, the performance drop and error reduction are substantially larger for event coreference (-6.2/12%) than entity coreference (-1.3/2%) and ALL (-2/3.5%). This difference is probably due to the structure of ECB+ which poses a lexical ambiguity challenge for events, while the document clustering step reconstructs almost perfectly the original subtopics, as shown in (Barhom et al., 2019).

Further, the higher results on event coreference do not mean that the task is inherently easier than entity coreference. In fact, when ignoring singletons in the evaluation, as done on OntoNotes, the performance of event coreference is lower than entity coreference (62.1 versus 65.3 CoNLL F1) (Cattan et al., 2021). This happens because event singletons are more common compared to entity singletons (30% vs. 17%), as shown in Appendix A.2.

Finally, our model is more efficient in both training and inference since the documents are encoded using just one pass of RoBERTa, and the pairwise scores are computed only once using a simple MLP. For comparison, previous models compute pairwise scores at each iteration (Barhom et al., 2019; Meged et al., 2020), or apply a BERT-model to every mention pairs with their sentence (Zeng et al., 2020) or full document (Caciularu et al., 2021).[3]

---

[3] For a rough estimation, our model runs for 2 minutes while Barhom et al. (2019)'s model runs for 37 minutes on similar hardware.

	F1	Δ
Our model	58.1	
− pre-train of mention scorer	54.9	−3.2
− dynamic pruning	54.1	−4.0
− negative sampling	56.7	−1.4

Table 4: Ablation results (CoNLL F1) of our model on the development set of ECB+ event coreference.

4.3 Ablations

To show the importance of each component of our model, we ablate several parts and compute F1 scores on the development set of the ECB+ event dataset. The results are presented in Table 4 using predicted mentions without document clustering.

Skipping the *pre-training* of the mention scorer results in a 3.2 F1 points drop in performance. Indeed, the relatively small training data in the ECB+ dataset (see Appendix A.2) might be not sufficient when using only end-to-end optimization, and pre-training of the mention scorer helps generate good candidate spans from the first epoch.

To analyze the effect of the dynamic pruning, we froze the mention scorer during the pairwise training, and kept the same candidate spans along the training. The significant performance drop (4 F1) reveals that the mention scorer inherently incorporates coreference signal.

Finally, using all negative pairs for training leads to a performance drop of 1.4 points and significantly increases the training time.

4.4 Qualitative Analysis

We sampled topics from the development set and manually analyzed the errors of the ALL configuration. The most common errors were due to an over-reliance on lexical similarity. For example, the event “*Maurice Cheeks was* ***fired***” was wrongly predicted to be coreferent with a similar, but different event, “*the Sixers* ***fired*** *Jim O’Brien*”, probably because of related context, as both coached the Philadelphia 76ers. On the other hand, the model sometimes struggles to merge mentions that are lexically different but semantically similar (e.g “*Jim O’Brien* ***was shown the door***”, “*Philadelphia* ***fire*** *coach Jim O’Brien*”). The model also seems to struggle with temporal reasoning, in part due to missing information. For example, news articles from different days have different relative reference to time, while the publication date of the articles is not always available. As a result, the model missed linking “*Today*” in one document to “*Saturday*” in another document.

5 Conclusion and Discussion

We developed the first end-to-end baseline for CD coreference resolution over predicted mentions. Our simple and efficient model achieve competitive results over gold mentions on both event and entity coreference, while setting baseline results for future models over predicted mentions.

Nonetheless, we note a few limitations of our model that could be addressed in future work. First, following most recent work on cross-document coreference resolution (§2), our model requires $\mathcal{O}(n^2)$ pairwise comparisons to form the coreference cluster. While our model is substantially more efficient than previous work (§4.2), applying it on a large-scale dataset would involve a scalability challenge. Future work may address the scalability issue by using recent approaches for hierarchical clustering on massive datasets (Monath et al., 2019, 2021). Another appealing approach consists of splitting the corpus into subsets of documents, constructing initial coreference clusters (in parallel) on the subsets, then merging meta-clusters from the different sets. We note though that it is currently impossible to test such solutions for more extensive scalability, pointing to a need in collecting larger-scale datasets for cross-document coreference. Second, to improve overall performance over predicted mentions, future work may incorporate, explicitly or implicitly, semantic role labeling signals in order to identify event participants for entity prediction, as well as for better event structure matching. Further, dedicated components may be developed for mention detection and coreference linking, which may be jointly optimized.

Acknowledgments

We thank the anonymous reviewers for their helpful comments. The work described herein was supported in part by grants from Intel Labs, Facebook, the Israel Science Foundation grant 1951/17, the Israeli Ministry of Science and Technology, the German Research Foundation through the German-Israeli Project Cooperation (DIP, grant DA 1600/1-1), and from the Allen Institute for AI.

Ethical Considerations

Dataset As mentioned in the paper, we use the ECB+ dataset, available at `http://www.newsreader-project.eu/results/data/the-ecb-corpus/`.

Model Our cross-document coreference model does not contain any intentional biasing or ethical issues. As mentioned in the paper (§4.1), we conduct our experiments on a single 12GB GPU, and both training and inference times are relatively low.

A Appendix

A.1 Implementation Details

Our model includes 14M parameters and is implemented in PyTorch (Paszke et al., 2019), using HuggingFace's library (Wolf et al., 2020) and the Adam optimizer (Kingma and Ba, 2014). The layers of the models are initialized with Xavier Glorot method (Glorot and Bengio, 2010). We manually tuned the standard hyperparameters, presented in Table 5 on the event coreference task and keep them unchanged for entity and ALL settings. Table 6 shows specific parameters, such as the maximum span width, the pruning coefficient λ and the stop criterion τ for the agglomerative clustering, that we tuned separately for each setting to maximize the CoNLL F1 score on its corresponding development set.

Hyperparameter	Value
Batch size	32
Dropout	0.3
Learning rate	0.0001
Optimizer	Adam
Hidden layer	1024

Table 5: Shared hyperparameters across the different models.

	Max span width	λ	τ
Event	10	0.25	0.75
Entity	15	0.35	0.75
ALL	15	0.4	0.75

Table 6: Specific hyperparameters for each mention type; λ is the pruning coefficient and τ is the threshold for the agglomerative clustering.

A.2 Dataset

ECB+[4] is an extended version of the EventCorefBank (ECB) (Bejan and Harabagiu, 2010) and EECB (Lee et al., 2012), whose statistics are shown in Table 7. The dataset is composed of 43 *topics*, where each topic corresponds to a famous news event (e.g Someone checked into rehab). In order to introduce some complexity and to limit the use of lexical features, each topic is constituted by a collection of texts describing two different event instances of the same event type, called *subtopic*. For example, the first topic corresponding to the event *"Someone checked into rehab"* is composed of event mention of the event *"Tara Reid checked into rehab"* and *"Lindsay Lohan checked into rehab"* which are obviously annotated into different coreference cluster. Documents in ECB+ are in English. Since ECB+ is an *event-centric* dataset, entities are annotated only if they participate in events. In this dataset, event and entity coreference clusters are denoted separately.

	Train	**Validation**	**Test**
# Topics	25	8	10
# Documents	594	196	206
# Mentions	3808/4758	1245/1476	1780/2055
# Singletons	1116/814	280/205	632/412
# Clusters	1527/1286	409/330	805/608

Table 7: ECB+ statistics. The slash numbers for # Mentions, # Singletons and # Clusters represent event/entity statistics. As recommended by the authors in the release note, we follow the split of Cybulska and Vossen (2015) that use a curated subset of the dataset.

Abstract

In this paper, we aim to improve abstractive dialogue summarization quality and, at the same time, enable granularity control. Our model has two primary components and stages: 1) a two-stage generation strategy that generates a preliminary *summary sketch* serving as the basis for the final summary. This summary sketch provides a weakly supervised signal in the form of pseudo-labeled interrogative pronoun categories and key phrases extracted using a constituency parser. 2) A simple strategy to control the granularity of the final summary, in that our model can automatically determine or control the number of generated summary sentences for a given dialogue by predicting and highlighting different text spans from the source text. Our model achieves state-of-the-art performance on the largest dialogue summarization corpus SAMSum, with as high as 50.79 in ROUGE-L score. In addition, we conduct a case study and show competitive human evaluation results and controllability to human-annotated summaries.

1 Introduction

Text summarization aims to produce an abridged version of the input text by distilling its most critical information. In particular, abstractive – as opposed to extractive – summarization requires generative models with a high level of semantic understanding, as the output words do not necessarily appear in the source text. While it is more challenging, it gives more flexibility to a summary compared to extractive summarization models (Zhang et al., 2018). Significant research efforts have been focused on summarization of single-speaker documents such as text documents (Liao et al., 2018), News (Hermann et al., 2015; Nallapati et al., 2016; See et al., 2017) or scientific publications (Qazvinian and Radev, 2008; Nikolov et al., 2018). However, dialogue summarization has not received much attention despite the prevalence of dialogues (text messages, email, social media, etc.) and the vast application potential of dialogue summarization systems.

Since dialogue language is inherently different from written text, it poses a unique set of challenges (Zechner, 2001): 1) *Distributed information across multiple speakers.* The most important information is usually scattered across several conversation turns from different speakers, while in articles it mostly presents in titles or the first few sentences. 2) *Boundary detection.* In each turn pauses do not always match linguistic sensible segments; it is difficult to identify various critical information across turns due to surrounding non-content noise and disfluency. 3) *Modeling interactions between speakers.* The speaker interaction plays an important role as it would imply the current dialog state and the status of the next speaker. If we directly apply neural abstract summarization models which mostly encode the whole input only as a source sequence, the flow of the dialogue would be overlooked (Pan et al., 2018). Previous methods (Goo and Chen, 2018; Liu et al., 2019) rely on explicit annotations to capture the logic of the dialogue, however, such annotations are not always available in datasets and additional labeling is cumbersome.

To solve these challenges, we propose CODS, a COntrollable abstractive Dialogue Summarization model equipped with sketch generation. We first automatically create a summary sketch that contains user intent information and essential key phrases that may appear in summary. It identifies the interaction between speakers and salient information in each turn. This summary sketch is prefixed to the human-annotated summary while fine-tuning a generator, which provides weak supervision as the final summary is conditioned on the

Morgan	Hey Suzanne, what's up?
Suzanne	Nothing special, it's just one of many boring days at work. But's better now tho!
Morgan	Are you working at all ?
Suzanne	I'm trying but you aren't helping me, at all. I'm just taking a well-deserved break.
Morgan	I miss you Suzie
Suzanne	I miss you too Morgan
Morgan	Do you feel like going to a concert next week? maroon 5 is playing at the hulu theater at madison square garden .. as it happens , I've got two tickets. do you want to go ?
Suzanne	Really? OMG! That's wonderful !. Thank you sweetheart!
Morgan	Oh, nothing. I just want you to be happy :)

Turn	**Intent**	**Key Phrase**
1	what	-
2	abstain	"s just one of many boring days at work"
3	confirm	"working at all"
4	abstain	"m just taking a well-deserved break"
5,6	abstain	-
7	confirm	"feel like going to a concert next week", "maroon 5", "is playing at the hulu theater at madison square garden"
8	why	-
9	abstain	-

Summary: 1) Suzanne is at work and is having a break now. 2) Morgan invites Suzanne to a concert of Maroon 5 which takes place next week at the Hulu Theatre at Madison Square Garden. 3) Suzzanne agrees.

Figure 1: An input and output example. Given the dialogue, we first construct a summary sketch with intent and key phrase information for each turn, and then split the dialogue into several segments (marked with dashed lines on the left hand side) for model controllability and interpretability.

generated summary sketch. In addition, we propose a length-controllable generation method specifically for dialogue summarization. Desired lengths of summaries strongly depend on the amount of information contained in the source dialogue and granularity of information the user wants to understand (Kikuchi et al., 2016). We first segment the dialogue into different segments by matching each summary sentence linearly to its corresponding dialogue context. Then we train our model to generate only one sentence for each dialogue segment. This strategy makes use of the distributed information of the dialogue and make the generated summaries more trackable.

We base our model on BART-xsum (Lewis et al., 2019), which is first pre-trained with unsupervised denoising objectives, and further fine-tuned on the News summarization corpus XSUM (Narayan et al., 2018). We evaluate our approach on SAMSum (Gliwa et al., 2019), the largest dialogue summarization dataset. Experimental results show that CODS achieves state-of-the-art dialogue summarization performance on several automatic metrics. The main contributions of this work[1] are: 1) We propose a two-stage strategy that uses artificial summary sketch as weak supervision, 2) we introduce a text-span based conditional generation approach to control the granularity of generated dialogue summaries without human-written summaries at different detail levels, and 3) we conduct comprehensive case study and human evaluation to show that CODS can achieve consistent and informative summary, especially for controllable summary, where existing models either cannot do it or do it poorly.

2 Methodology

Our model is based on pre-trained generative language models (Section 2.1). Given an input dialogue history, our model first generates a summary sketch that serves as additional weakly supervised signal for the final summary (Section 2.2). Then it predicts the text span cutoffs over the entire dialogue and generates summaries accordingly (Section 2.3). We define the conversational history input as $D = \{X_1, X_2, \dots, X_N\}$, where each X_i has a sequence of words, N is the total numbers of dialogue turns, and the input may contain more than two speakers. We intend to generate M-sentence dialogue summary $Y = \{Y_1, \dots, Y_M\}$ that is suppose to be briefer than the overall dialogue history.

2.1 Generative Pre-trained Language Models

As a first, our model needs transform a conversational history input into a dialogue summary. Re-

---

[1] Our code is released at `https://github.com/salesforce/ConvSumm`

cently, self-supervised pretrained language models have been employed as encoders and decoders since they (Radford et al., 2019; Yang et al., 2019; Dong et al., 2019) have achieved remarkable success across many NLP tasks. For general text summarization, this has also been the case with models such as BART (Lewis et al., 2019) and PEGASUS (Zhang et al., 2019a). However, there are no results reported for self-supervised pretrained language models applied to dialogue summarisation, and people have argued that there is an intrinsic difference of linguistic patterns between human conversations and written text (Wolf et al., 2019b; Wu et al., 2020a; Wu and Xiong, 2020). We would like to answer the question which generative language model is the best base model for dialogue summarization tasks.

2.2 Sketch Construction

Conversational data, unlike news or scientific publications, includes lots of non-factual sentences such as chit-chats and greetings. Removing these least critical information in the dialogues could potentially help the model better focus on the main content. Based on this hypothesis, we combine a syntax-driven sentence compression method (Xu and Durrett, 2019) with neural content selection.

Another potentially useful attribute for the conversational data is each dialogue turn inherently encodes user intent. However, unlike task-oriented dialogue systems, which have explicit annotated intents (e.g., book flight and check account), dialogue summarization data rarely have such labels. Thus we use a few heuristics with Snorkel (Ratner et al., 2019) to programmatically label each turn with a predefined interrogative pronoun category. The generated intents and the compressed dialogues together constitutes the summary sketch as weakly-supervised signals.

To the best of our knowledge, in general, there is no non-task-oriented established label set. Thus we draw upon the FIVE Ws principle, which often mentioned in journalism and research investigation, in that a passage can only be considered as complete if it answers these questions starting with such interrogative words (Hart). We adapt this principle to the dialogue scenario and identify a set of interrogative pronouns to support diverse enough user intents of all utterances, serving as the dialogue's logic. For example, in Figure 1, Morgan asked Suzanne "Do you feel like going to a concert next week?" One can expect that Suzanne will confirm her willingness in the next utterance. We define such dialogue intent categories including why, what, where, confirm, and abstain. More information for each category is shown in the Appendix (A.1).

To compress and remove noisy sub-sentences in the dialog, we first use a trained constituency parser (Kitaev and Klein, 2018) to parse each utterance. Then we compare the parsed phrases with the ground-truth summary to find their longest common sub-sequence (lcs), we set a threshold to filter and remove non-meaningful words (e.g., stop words) in lcs. Note that there are circumstances where the whole utterance is noisy and removable. Overall, we construct a summary sketch by concatenating utterance index, user intent label, and compressed utterance within the entire dialogue history into a string, ending with a special token, "TL;DR". Take Figure 1 as an example, the summary sketch is "1 what 2 abstain 's just one of ... square garden 8 why 9 abstain TL;DR". We train our model first to generate this summary sketch and then generate the final summary in an autoregressive way. We use TL;DR token to distinguish sketch and final summary during inference time.

2.3 Controllability

Due to the success of controllable language modeling (Keskar et al., 2019), the ability to control text summarization in the News domain has gradually been attracting attention (Fan et al., 2018; Liu et al., 2018) The high-level intuition for our solution is that if we can control a generative model only to generate one sentence as output for a partially-highlighted input, we can control the number of output sentences by choosing how to highlight the input. We highlight each dialogue split using the special token $< hl >$. For example, in Figure 1, we generate the first summary sentence for the first segment from turn one to four, and the second and third from turn five to seven and turn eight to nine, respectively (separated by the dashed lines). This way, we can not only gain the summary controllability but also make the generation more interpretable.

The next challenge is, during training, we have to find a mapping between each sentence in a reference summary to its corresponding dialogue split. In other words, how do we know where to insert the highlighting tokens? We do so by training a dialogue-turn-level binary classifier (detailed below) that predicts whether each turn is a cutting point (i.e., dialogue segmentation). Our observation is that sentences within a reference summary usually have a strong temporal dependency, that is, people summarize the dialogue almost linearly. We use a simple approach to find the cutting points: the highest similarity score between conversations and each summary sentence. The cutting point

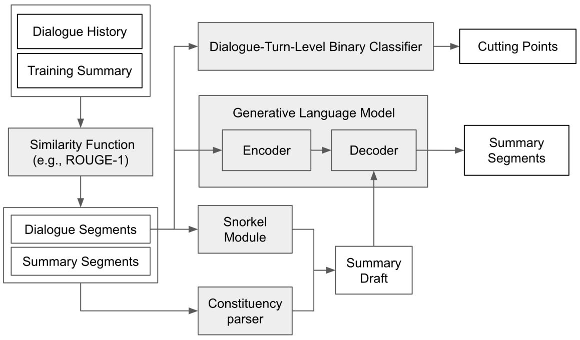
$$t_m = \arg\max_t \text{SIM}(X_{c_m:t}, Y_m), \qquad (1)$$

where SIM could be any similarity functions (we use ROUGE-1), and c_m is the accumulated turn index ($c_1 = 1$ and $c_m = t_{m-1}$) that indicates which part of a dialogue has been covered. Note that for a summary with M sentences, we only need to decide $M - 1$ cutting points. With the pseudo labels (t_m) provided by this heuristic, we formulate the dialogue segmentation problem into a binary classification problem. Specifically, we train a classifier C, which takes dialogue history as input and predicts whether each dialogue turn is a cutting point. We prefix each dialogue turn with a separation token as input to the classifier.

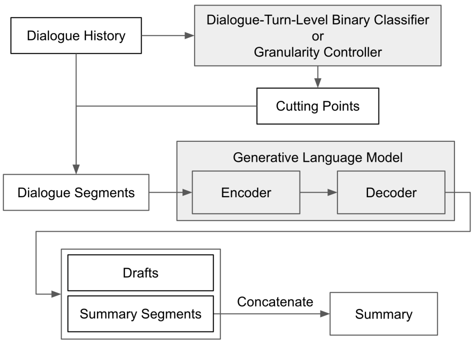
$$\begin{aligned} H &= C([x_{sep}, X_1, x_{sep}, X_2, \ldots]) \in \mathbb{R}^{N \times d_{emb}}, \\ \hat{P} &= \text{Sigmoid}(W_1(H)) \in \mathbb{R}^N. \end{aligned} \qquad (2)$$

The classifier output H is the representations of those separation tokens, and each of them is a d_{emb} dimension vector. $W_1 \in \mathbb{R}^{d_{emb} \times 1}$ is a trainable linear mapping. The $\hat{P}$ is the predicted segment probability that is trained with binary cross-entropy loss. We use a BERT-base model (Devlin et al., 2018) as classifier and the i-th cutting point is triggered if $\hat{P}_i > 0.5$. This prediction means that our model can automatically determine how many sentences should be generated in the final summary. If no cutting point is triggered, we generate a one-sentence summary. If one cutting point is triggered, we will have a two-sentence summary, and so forth.

Finally, we can control the number of output summary sentences by controlling the dialogue split. Specifically, we first decide the expected number of output sentences (e.g., K), and then we choose the top $K-1$ indexes with highest probabilities in segmentation probability $\hat{P}$. We use these $K - 1$ indexes as cutting points. We can also generate one-sentence summary by clipping the whole dialogue with one pair of highlighting tokens at the beginning and the end of a dialogue (we call this setting as CODS-1).



(a)



(b)

Figure 2: (a) Training and (b) inference block diagrams of CODS. Grey boxes are trainable functions.

2.4 Overall Generation

The overall training and inference block diagrams are shown in Figure 2. CODS follows a standard encoder-decoder framework. During training, we use dialogue segmentation to add highlighting tokens for each summary sentence. We take the highlighted dialogue history as input and train our model to generate its corresponding summary sketch and summary sentence. For example in Figure 1, the first summary sentence, we input the whole dialogue with added highlighting tokens both at the beginning of the first turn and at the end of the fourth turn, and generate output that contains the corresponding summary sketch "1 what 2 abstain ... well-deserved break" and the first summary sentence "Suzanne is at work and is having a break now." The entire model is trained using cross-entropy loss for the generated tokens. During inference, we first use the trained binary classifier to predict cutting points. Then, we use the predicted segmentation to add highlighting tokens into a dialogue. Finally, after generating multiple summary sentences separately, we concatenate them to be the final summary.

3 Experiments

3.1 Dataset

We perform experiments on the recently released SAMSum dataset (Gliwa et al., 2019) [2], which is the most comprehensive resource for abstractive dialogue summarization tasks. It contains 16K natural messenger-like dialogues created by linguists fluent in English with manually annotated summaries. This dataset is more challenging than the previous corpus (McCowan et al., 2005) in the following aspects: 1) Unlike previous datasets consisting of only hundreds of dialogue-summary pairs, it has larger data size (16369 samples); 2) 75% of the conversations are between two interlocutors, the rest are between three or more people; 3) the conversations cover diverse real-life topics, and the summaries are annotated with information about the speakers. We preprocess the data by the following steps: 1) concatenate adjacent utterances of the same speaker into one utterance; 2) clean the dialogue text by removing hashtags, URLs and Emojis; 3) label each utterance with its corresponding interrogative pronoun category with a weak supervision approach (Ratner et al., 2019); 4) parse each utterance with a constituency parser and find the longest common sub-sequence between the phrases and summary to be the key phrases.

3.2 Evaluation Metrics and Baselines

We use the standard ROUGE metric (Lin, 2004) as automatic evaluation metrics, including ROUGE-1, ROUGE-2, and ROUGE-L. Following previous work (Gliwa et al., 2019), we use py-ROUGE[3] library with stemming. We compare our model with baselines reported in Gliwa et al., 2019: Longest-3 is a commonly-used extractive summarization baseline which takes the top three longest sentences as summary. The pointer generator and Fast abs are RNN-based methods with copy-attention mechanism or policy gradient. The Transformer is a random-initialized self-attention architecture with multi-head attention. The DynamicConv is a

---

[2] The conversations in SAMSum may contain offensive words, please use the dataset carefully.

[3] `pypi.org/project/pyROUGE/`

lightweight convolutional model that can perform competitively to self-attention. All of these models are not pre-trained.

Besides, we investigate four pre-trained generative language models to see which works the best for the dialogue summarization task. DialoGPT is a GPT model pre-trained on open-domain Reddit data. UniLM is pre-trained using three types of language modeling tasks: unidirectional, bidirectional, and sequence-to-sequence prediction on English Wikipedia and BookCorpus. PEGASUS masks important sentences from input and is trained to generate the missing parts, similar to an extractive summary approach. BART is trained by corrupting text with an arbitrary noising function and learning to reconstruct the original text. We use default parameters listed in the respective open-source repositories to fine-tune on the dialogue summarization task. We show the training details in the Appendix.

3.3 Results

In Table 1 of ROUGE results, we find that the methods that are pre-trained or with pre-trained embeddings perform better than those that are not. For instance, DynamicConv achieves a 3 – 4% improvement by adding GPT-2 embeddings. This further confirms the impact of language model pre-training on downstream tasks. Among the pre-trained generative language models examined, PEGASUS and BART are the two top performance models with ROUGE-1 higher than 50. DialoGPT, the model pre-trained on conversational data, does not achieve satisfactory results, implying that Reddit data has limited knowledge to be transferred to dialogue summarization tasks. CODS achieves the highest ROUGE score compared with other models, notably 50.79% ROUGE-L.

To understand the individual contribution of each component in our model, we also conduct an ablation study by removing summary sketch generation (BART+Ctrl) or controllability (BART+Sketch). In both cases we observe a performance drop, except a slight improvement on ROUGE-1 for BART+Ctrl. This suggests that the sketching step helps generate a more fluent summary even with lower unigram matching. Furthermore, recognizing the limitation of ROUGE scores in their ability to fully capture the resemblance between the generated summary and the reference, in Table 2, we follow (Fabbri et al., 2020) to compare model performances with additional metrics, including ROUGE-Word Embedding (Ng and Abrecht, 2015), BERTScore (Zhang et al., 2019b), MoverScore (Zhao et al., 2019), Sentence Mover's Similarity (SMS) (Clark et al., 2019), BLEU (Papineni et al., 2002), and CIDEr (Vedantam et al., 2015). As shown in Table 2, CODS consistently outperforms PEGASUS and BART. More information about these evaluation metrics are shown in the Appendix.

	Length Ratio	Consistent	Informative
Longest-1	0.27	**0.70**	0.23

CODS	**0.24**	**0.69**	**0.53**
Gold	0.27	0.74	0.55

Table 3: Human evaluation results on test set for both controllable summary and standard summary.

3.4 Analysis

3.4.1 Human Evaluation by Crowdsourcing

We leverage human judgement to evaluate the generated summaries via crowdsourcing, especially for granularity-controlled generation, since we do not have human-written reference summaries of various lengths (number of sentences). We ask workers to rate the summaries in two aspects on a scale from -1 (worst) to 1 (best): factual consistency and informativeness. *Factual consistency* acts as a precision measure, assessing whether the information provided in summary contains factual errors which are against the source dialogue; *Informativeness* is a recall-oriented measure, examining whether critical information in a dialogue is mentioned in summary. We also show the length ratio between a summary and a dialogue, where a lower ratio means a higher compression rate. For the crowdsourcing evaluation, we randomly select 6% dialogues from the test set, each of which is annotated by three workers. More details about human evaluation process are in the Appendix [4].

To show the proposed controllable generation's strengthens and quality, we provide two additional baselines, Longest-1 and BART-1. The longest-1 method is an extractive baseline that outputs the longest dialogue turn as the final summary. The BART-1 is a strong abstractive baseline where we train a BART-based summarization model with the

Table 5: Case analyses by manually examining CODS generated summaries.

number of summary sentences in the training set as its start-of-sentence token during decoding. Similar to the approach from Liu et al., 2018, we can use different start-of-sentence tokens to control the BART output.

In general, it is preferable to have a factually consistent and informative summary that is succinct (low length ratio, high compression rate) at the same time. As shown in the first row of Table 3, CODS-1 achieves the highest informative score among all generated one-sentence summaries, indicating the strength of the proposed controllable method in producing succinct yet informative dialogue summaries. The Longest-1 method has a higher consistent score because its summary is directly copied from the original dialogue, preventing any factual mistakes. The second row of Table 3 shows that CODS, when automatically determining the granularity of the summary, produces summaries that are more succinct (lower length ratio), more factually consistent, and more informative, compared to the BART model.

3.4.2 Case Study

CODS outperforms the baseline models in both ROUGE scores and human evaluation metrics. We now further inspect its textual quality. In Table 4, we show an example from the SAMSum test set with summaries generated by different models. In this example, CODS and CODS-1 can both produce a near-perfect summary even compared to the human-written reference summary. On the other hand, the summary generated by BART includes overly detailed information (e.g., bank account). We show some more examples in the Appendix and all the predictions (including CODS-1 and CODS-2) in the supplementary file.

We also manually examine 100 summaries generated from CODS against the reference summaries in the test set. Specifically, we analyze each of the three following problematic cases, where summarization models frequently make mistakes, reported by Gliwa et al., 2019, and provide sample summaries in Table 5. 1) *Associating names with actions*: CODS performs well in dealing with speakers' names. It accurately associates "her dad" with "Ann's dad," also "Fiona tries to help her" with "Ann and Fiona." 2) *Extract information about the arrangement after discussion*: Even speakers hesitate about the flower's color to be yellow, pink or red in the middle of the discussion, CODS still correctly determines the right color after several turns. 3) *Decide important information in dialogues*: CODS fails to capture some of the important facts (marked as red) mentioned in reference summary. We conjecture the reason could be that 1) some of the important facts are located in the same part of the highlighted turns, and 2) those information is missed by the key phrase extraction. Simultaneously, we force the model to generate only the most important one under the constraint of controllability. The improvement of CODS on the first two summarization difficulties can be partially attributed to the clear logic in the sketch when input to the model.

4 Related Work

Neural Text Summarization There are two main paradigms for text summarization: extractive and abstractive. Inspired by the success of applying seq2seq models on neural machine translation, Rush et al., 2015 and Nallapati et al., 2016 introduce the neural seq2seq model on abstractive text summarization, with an attention-based encoder and a neural language model decoder. To solve the problem of out-of-vocabulary words and to capture salient information in source documents, See et al., 2017 propose a pointer-generator network that copy words from source to target. Many subsequent works (Gehrmann et al., 2018; Paulus et al., 2018) further demonstrate its effectiveness with reinforcement learning. Recently, Liu and Lapata, 2019 apply BERT on text summarization and propose a general framework for both extractive and abstractive models. Zhang et al., 2019c pre-train hierarchical document encoder for extractive summarization. Lewis et al., 2019 introduces BART, a denoising autoencoder for pretraining sequence-to-sequence models. BART significantly outperforms the best previous work in terms of ROUGE metrics.

Dialogue Summarization Regarding to the datasets in dialogue summarization, initial abstractive dialogue summarization work (Oya et al., 2014; Mehdad et al., 2014; Banerjee et al., 2015) are conducted on the AMI meeting corpus (McCowan et al., 2005), with only 141 summaries. Goo and Chen, 2018 propose to use the topic descriptions (high-level goals of meetings) in AMI as reference summaries and use dialogue acts as training signals. Pan et al., 2018 build the Dial2Desc dataset by reversing a visual dialogue task, aligning image dialogues with the image caption as a summary. Liu et al., 2019 collect their dataset from the logs in the DiDi customer service center. It is restricted to task-oriented scenario, where one speaker is the user and the other is the customer agent, with limited topics and it is also connected to the goal of dialogue state tracking task (Wu et al., 2019a, 2020b). Recently, Gliwa et al., 2019 introduce the SAMSum corpus, with 16k chat dialogues with manually annotated summaries. It is the first comprehensive abstractive dialogue summarization dataset spanning over various lengths and topics. Chen and Yang, 2020 propose a multi-view sequence-to-sequence model by extracting different views of structures from conversations. Both their method and ours leverage rich conversation structure information. Evaluating on SAMSum, our model CODS outperform theirs by 3 points in terms of ROUGE scores, indicating our utilized dialogue features are more effective.

Length-controllable Generation The most prevalent method for length control generation is using a special length embedding. Kikuchi et al., 2016 first propose length control for abstractive summarization by using length embedding as an additional input for the LSTM. Fan et al., 2018 train embeddings that correspond to each different output length and prepend that length marker at the beginning of the decoder. Liu et al., 2018 incorporates the length embedding into initial state of a CNN-based decoder. Takase and Okazaki, 2019 extends the positional encoding in

Transformer model by considering the remaining length explicitly at each decoding step. Saito et al., 2020 propose to control the summary length with prototype extractor. However, the retrieve-and-rewrite process is restricted by the extraction quality, leaving its performance limited by extractive solutions' capabilities. The aforementioned works all focus on structured text summarization (e.g. news document). We are the first to propose generate length-controllable summary on dialogues by highlighting arbitrary numbers of dialogue spans.

5 Conclusion

The dialogue summarization task is challenging but with vast application potential. We propose CODS, a state-of-the-art dialogue summarization model with granularity controllability. CODS uses a weakly-labeled summary sketch for its two-stage generation, and text-span conditional generation for a controllable summary. Our model surpasses existing models on the largest dialogue summarization dataset. We show with human evaluation that our model can generate factually consistent and informative summaries. We also point out several error cases to shed light on future research direction of controllable dialogue summarization.

A Appendix

A.1

We define dialogue intent categories as follows: *WHY:* asks the reason of the state mentioned in the previous turn, e.g., “why” or “why not”; *WHAT:* requests more details about the aforementioned object, the sentence usually starts with “what’s” or “what about”; *WHERE:* the location of the event; *WHEN:* the time of the event, e.g. ,“when” or “what time”; *CONFIRM:* expects the other speaker to establish the correctness of a certain case, the sentence usually starts with patterns like “are you”, “will you” or “has he”; *ABSTAIN:* the utterance does not belong to any of the previous categories. It occurs when speakers continue to state or comment without seeking for more information from the others.

A.2

- DialoGPT: A GPT model pretrained on 147M conversation-like data extracted from Reddit comments. We use the model with 117M parameters. `github.com/microsoft/DialoGPT`
- UniLM: A multi-layer Transformer network optimized for three language modeling objectives: unidirectional, bidirectional and sequence-to-sequence prediction. It is initialized with BERT$_{\text{LARGE}}$, then pre-trained using English Wikipedia and BookCorpus. Same as BERT$_{\text{LARGE}}$, it contains 340M parameters. `github.com/microsoft/unilm`
- PEGASUS: They pretrain a Transformer-based encoder-decoder models with a new self-supervised objective - gap-sentence generation - on the C4 corpus. We use the PEGASUS of 568M parameters. `github.com/google-research/pegasus`
- BART: Transformer-based encoder-decoder model trained by corrupting text with an arbitrary noising function and learning a model to reconstruct the original text. We use BART$_{\text{LARGE}}$ model which contains 400M parameters. `huggingface.co/transformers/model_doc/bart.html`
- CODS: It’s based on BART$_{\text{LARGE}}$ model which contains 400M parameters.

Wendy: just be patient for once .
Norbert: im always patient .
Wendy: at the register now .
Norbert: alright .</td></tr>
<tr><td>Summary</td><td>Wendy is shopping, but she needs to hurry up to catch the tour.</td></tr>
</table>

Table 7: Example key phrases in summary sketch.

A.3 Sketch Construction

Previous methods (Goo and Chen, 2018; Pan et al., 2018) heavily rely on explicit intent annotations in datasets. We label user intent automatically for each utterance with the Snorkel library in a weak supervision approach. For each interrogative pronoun category, we first manually identify its most frequent key words and patterns (can be found in our source code). Then we use the labeling functions in Snorkel to label all the utterances.

For the utterance compression, we do LCS on the phrases generated from the constituency parser. In the example of 1, *s just one of many boring days at work* the parsed constituent overlapping with ‘at work’ in the summary, so we keep this phrase. However, in other examples, not all overlapped words are meaningful (e.g. stop words). We thus filter the LCS results and only keep important key phrases. Then we train our model to predict these key phrase spans in each turn. We show three examples of our generated key phrases in summary sketches on evaluation set (see Table 6, 7, 8)

A.4 Training Details

We use huggingface (Wolf et al., 2019a) implementation to fine-tune a BART model. We use the large

<table>
<tr><td colspan="2">Phil: is brandon in ?
Clara: not yet .
Phil: has he called to say he’d be late ?
Clara: no , he hasn’t .
Phil: it’s not the first time , ist it ?
Clara: no , it isn’t .
Phil: when he arrives , tell him to come to me .
Clara: no , it isn’t .
Phil: please prepare a report on the absenteeism and lateness . i expect it by friday on my desk .
Clara: it will be ready .</td></tr>
<tr><td>Summary</td><td>Brandon is late again. Clara will prepare a report on the absenteeism and lateness for Phil by Friday.</td></tr>
</table>

Table 8: Example key phrases in summary sketch.

version fine-tuned on the XSUM (Narayan et al., 2018) dataset with 12 self-attention encoder and decoder layers. We truncate input dialogue to a maximal length 512 with training batch size 4. We train the model with Adam optimizer (Kingma and Ba, 2014) with 0.1 proportion for linear learning rate warmup. We early stop on validation set ROUGE-1 score, and it is trained for around 40,000 steps on one NVIDIA V100 GPU. During inference, we do beam search decoding with beam size 4.

A.5 Evaluation Metrics

Information obtains from (Fabbri et al., 2020):

- ROUGE measures the number of overlapping textual units between the generated summary and a set of reference summaries.
- ROUGE-WE extends ROUGE by taking cosine similarity of Word2Vec embeddings into account.
- BERTScore computes similarity scores by aligning generated and reference summaries on a token-level based on the output of the BERT-based model. Token alignments are computed greedily with the objective of maximizing the cosine similarity between contextualized token embeddings. We report the F1 score.
- MoverScore measures semantic distance between a summary and reference text by making use of the Word Mover's Distance operating over n-gram embeddings pooled from BERT representations.
- Sentence Mover's Similarity (SMS) extends Word Mover's Distance to view documents as a bag of sentence embeddings as well as a variation which represents documents as both a bag of sentences and a bag of words.
- BLEU is a corpus-level precision-focused metric which calculates n-gram overlap between a candidate and reference utterance and includes a brevity penalty. It is the primary evaluation metric for machine translation.
- CIDEr computes 1-4-gram co-occurrences between the candidate and reference texts, down-weighting common n-grams and calculating cosine similarity between the ngrams of the candidate and reference texts.

A.6 Human Evaluation

We use roughly 6% of the test set data in SAMSum for human evaluation and we do some filtering based on the annotation of the "gold summary". Specifically, we filter those annotations if a "gold summary" has been annotated as "-1" (the meaning of each score is shown below), implying that the annotators may not pay attention to the scoring. The final results reported in Table 3 is the mean from three different annotators.

The "gold summary" is actually not perfect and it might contain some noisy annotation, this is the reason why some workers may give 0 even if it is collected from humans. Below is the scoring instruction we sent to our workers:

- Factual Consistency (Precision): The rating measures whether the information provided in a summary is correct. Score -1 if a summary contains a serious factual error. Score 0 if a summary has some minor factual errors. Score 1 if everything in a summary is factually correct.
- Informative (Recall): The rating measures whether all the important information in a dialogue is included in a summary. Score -1 if a summary misses serious key points. Score 0 if a summary misses a few key points. Score 1 if a summary covers all key points.

<table>
<tr><td colspan="2">Paul: what color flowers should i get
Cindy: any just not yellow
Paul: ok , pink ?
Cindy: no maybe red
Paul: just tell me what color and what type ok ?
Cindy: ugh , red roses !</td></tr>
<tr><td>Gold</td><td>Paul will buy red roses following Cindy’s advice.</td></tr>
<tr><td>BART</td><td>Paul wants to get red roses. Cindy doesn’t want pink or yellow roses.</td></tr>
<tr><td>CODS</td><td>Paul wants to buy red roses.</td></tr>

Abstract

Much of modern-day text simplification research focuses on sentence-level simplification, transforming original, more complex sentences into simplified versions. However, *adding* content can often be useful when difficult concepts and reasoning need to be explained. In this work, we present the first data-driven study of content addition in text simplification, which we call *elaborative simplification*. We introduce a new annotated dataset of 1.3K instances of elaborative simplification in the Newsela corpus, and analyze how entities, ideas, and concepts are elaborated through the lens of contextual specificity. We establish baselines for elaboration generation using large-scale pre-trained language models, and demonstrate that considering contextual specificity during generation can improve performance. Our results illustrate the complexities of elaborative simplification, suggesting many interesting directions for future work.

1 Introduction

Text simplification aims to help audiences read and understand a piece of text through lexical, syntactic, and discourse modifications, while remaining faithful to its central idea and meaning (Siddharthan, 2014). It remains an important task, improving text accessibility for children (De Belder and Moens, 2010; Kajiwara et al., 2013), language learners (Yano et al., 1994; Petersen and Ostendorf, 2007; Pellow and Eskenazi, 2014; Paetzold, 2016), and those with language impairments (Carroll et al., 1998; Rello et al., 2013). Text simplification can also be a useful pre-processing step for other NLP tasks such as machine translation (Chen et al., 2012; Štajner and Popovic, 2016) and summarization (Vanderwende et al., 2007; Silveira and Branco, 2012).

Original Text

Results, she said, "could help the team better understand ancient Egyptian health" and, correspondingly, modern-day health. For instance, some mummies still have arteries in their mummified remains, Miller-Thomas said. And, sometimes, scientists can tell if those arteries had hardened.

Simplified Text

The scans could help the team understand about ancient Egyptians' health. For example, some mummies still have arteries. **An artery is a tube that moves blood through the body.** **The artery could show if the person had been healthy or not.**

Figure 1: Elaborative simplification with two elaborations of varying contextual specificity.

With the introduction of large, parallel corpora (Zhu et al., 2010; Woodsend and Lapata, 2011; Coster and Kauchak, 2011; Xu et al., 2015), text simplification research has rapidly advanced in recent years, especially in sentence simplification (Alva-Manchego et al., 2020). However, document simplification involves rich linguistic phenomena that cannot be easily characterized by sentence-level transformations of text, e.g., the omission and addition of content (Petersen and Ostendorf, 2007; Siddharthan, 2014).

This paper presents the first data-driven, dedicated study of *elaborative simplification*, which involves inserting elaborations in the form of definitions, explanations or clarifications to improve readability by providing readers with necessary additional context. Effective elaborations must provide background in a *contextual* manner, adding relevant information to the surrounding text.

Figure 1 shows an example. The original text snippet explains that scientists study mummy arteries to see whether they are hardened. In the corresponding simplified text, we see two elaborations inserted – one, in green, simply defines an artery, and the second, in blue, states the implication of hardened arteries. The content of both elaborations is semantically absent from the original text.

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 5123–5137
August 1–6, 2021.

Our goal is to provide resources and directions toward understanding and generating naturally occurring elaborations. We present an annotated dataset of 1.3K instances of elaborative simplification in the Newsela corpus (Xu et al., 2015). We automatically identify candidate elaborations from simplified documents, and have human annotators verify candidates. We find that many elaborations require multi-hop reasoning, inference, commonsense reasoning, and relevant information retrieval, making it an interesting testbed for a bevy of related tasks.

The previous example highlights two elaborations on opposite ends of the spectrum – the first requires little context, while the second is highly contextualized, drawing a conclusion from content presented in the original text. To this end, we characterize elaborations by annotating their *contextual specificity*, i.e., the extent to which the added content is specific to the current topic under discussion.

We reveal that our dataset contains a fairly balanced distribution of contextual specificity. Qualitatively, while inserting definitions may help provide background about entities, highly contextualized elaborations interpreting or clarifying content can help readers understand the larger implications or significance of ideas presented in the original text. We propose the primary task of generating elaborations given document context. We present baselines for elaboration generation mainly using GPT-2 (Radford et al., 2019), and discuss some of the challenges, especially with respect to the contextual specificity of added content.

We find that generation quality can be improved by selecting an elaboration with an appropriate predicted contextual specificity level. However, existing methods struggle to effectively incorporate input context to generate elaborations. We hope that this study will motivate advancement in elaborative simplification.

In summary, our main contributions include:

1. Introduction of elaborative simplification, a previously understudied phenomenon in text simplification;
2. A new, annotated dataset of 1.3K naturally occurring elaborations in the Newsela corpus and their contextual specificity;
3. Analysis of the challenges of elaborative simplification for pre-trained language models through performance of our baselines.

We make our annotations and code available at `https://github.com/nehasrikn/elaborative-simplification`.

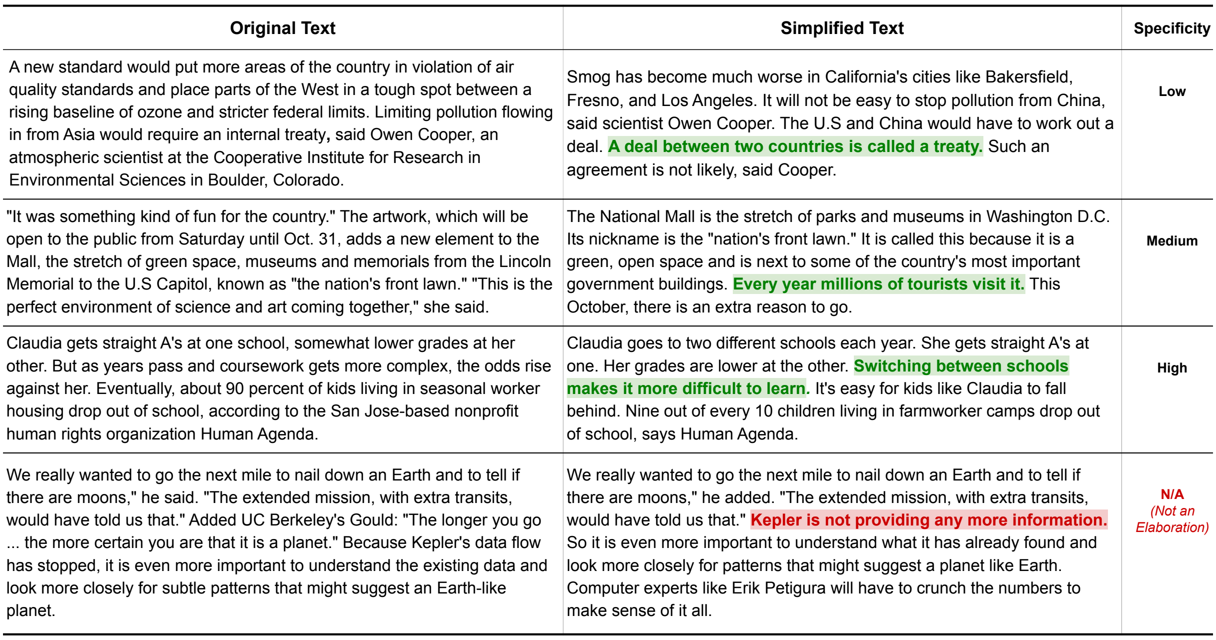
2 Data and Annotation

Elaborative simplification involves the *insertion* of content to make simplified text easier to understand. We present an annotated dataset of 1.3K elaborations from the Newsela corpus (Xu et al., 2015), which contains English news articles manually simplified by professional editors. We describe the scope of our elaborative simplification study (§2.1), strategies for trusted annotators to extract elaborations (§2.2) and rate contextual specificity (§2.3), and scaling up annotation through crowdsourcing with rigorous quality control (§2.4).

2.1 What is an elaboration?

We consider a sentence an elaboration if it contains new content (e.g. statements about entities, actions, or concepts) present in the simplified document, but semantically missing from the original document. Note that while elaborations can contain multiple sentences, we define our label at the sentence level. Past simplification research has focused on operations such as substitution and deletion, but simplifying a piece of text that may contain unknown or difficult concepts could involve inserting simple explanations as well. As we highlight in §6, others have shown that audiences such as new language learners benefit from elaboration or explanation insertion (and conversely, that unfamiliar concepts negatively impact reading comprehension), though computational approaches till date have been largely limited to definition retrieval.

Scope. We intentionally choose to study *how* concepts are elaborated, posing a scenario where an author has the freedom to specify where to elaborate, and our system generates an appropriate elaboration. We do this for two main reasons: first, understanding how to elaborate can be utilized in a system where users specify what to elaborate on, in the spirit of personalized simplification (Paetzold and Specia, 2016; Bingel et al., 2018). Second, determining *when* to elaborate is arguably pragmatically more complex, in that the need for elaboration often relies on the writer's belief about their readers' background, knowledge, and reading ability, as well as their own judgments on how often to elaborate. For example, in the extreme case, inserting an elaboration after every sentence could prove



Original Text	Simplified Text	Specificity
A new standard would put more areas of the country in violation of air quality standards and place parts of the West in a tough spot between a rising baseline of ozone and stricter federal limits. Limiting pollution flowing in from Asia would require an internal treaty, said Owen Cooper, an atmospheric scientist at the Cooperative Institute for Research in Environmental Sciences in Boulder, Colorado.	Smog has become much worse in California's cities like Bakersfield, Fresno, and Los Angeles. It will not be easy to stop pollution from China, said scientist Owen Cooper. The U.S and China would have to work out a deal. **A deal between two countries is called a treaty.** Such an agreement is not likely, said Cooper.	**Low**
"It was something kind of fun for the country." The artwork, which will be open to the public from Saturday until Oct. 31, adds a new element to the Mall, the stretch of green space, museums and memorials from the Lincoln Memorial to the U.S Capitol, known as "the nation's front lawn." "This is the perfect environment of science and art coming together," she said.	The National Mall is the stretch of parks and museums in Washington D.C. Its nickname is the "nation's front lawn." It is called this because it is a green, open space and is next to some of the country's most important government buildings. **Every year millions of tourists visit it.** This October, there is an extra reason to go.	**Medium**
Claudia gets straight A's at one school, somewhat lower grades at her other. But as years pass and coursework gets more complex, the odds rise against her. Eventually, about 90 percent of kids living in seasonal worker housing drop out of school, according to the San Jose-based nonprofit human rights organization Human Agenda.	Claudia goes to two different schools each year. She gets straight A's at one. Her grades are lower at the other. **Switching between schools makes it more difficult to learn.** It's easy for kids like Claudia to fall behind. Nine out of every 10 children living in farmworker camps drop out of school, says Human Agenda.	**High**
We really wanted to go the next mile to nail down an Earth and to tell if there are moons," he said. "The extended mission, with extra transits, would have told us that." Added UC Berkeley's Gould: "The longer you go ... the more certain you are that it is a planet." Because Kepler's data flow has stopped, it is even more important to understand the existing data and look more closely for subtle patterns that might suggest an Earth-like planet.	We really wanted to go the next mile to nail down an Earth and to tell if there are moons," he added. "The extended mission, with extra transits, would have told us that." **Kepler is not providing any more information.** So it is even more important to understand what it has already found and look more closely for patterns that might suggest a planet like Earth. Computer experts like Erik Petigura will have to crunch the numbers to make sense of it all.	**N/A** *(Not an Elaboration)*

Figure 2: Example candidate elaborations. Rows 1–3 contain verified elaborations. Row 4 contains a rejected candidate. We include the original and simplified text regions, highlighting the candidate elaboration, and its corresponding level of contextual specificity in Column 3.

useful for children or readers with no background knowledge about the document content, but may be unnecessary for adults or those with sufficient knowledge.

Task. We introduce the primary task of elaboration generation: given some document context C consisting of text from the original and/or simplified documents, generate an elaboration E.

2.2 Extracting Elaborations

Detecting elaborative simplification requires crafting a way to reliably extract sentences containing new content in simplified documents. Asking humans to read and annotate every sentence in each document is prohibitively costly. To streamline this process, we first obtain candidate elaboration sentences with automatic sentence alignment, then use human annotation to extract true elaborations.

Candidate extraction. Each set of articles in the Newsela corpus consists of multiple simplified articles ranging from grades 3–12. We choose the article written for the lowest grade level as our simplified document (we leave investigating simplified documents across higher grade levels as future work). Using the approach from Zhong et al. (2020), we then align sentences from the original and simplified documents by thresholding the cosine similarity of sentence vector representations using Sent2Vec (Pagliardini et al., 2018). We then consider sentences in the simplified document that are not aligned with any sentence in the original document as *candidate elaborations*. Of the 54,892 sentences across the 1,042 simplified documents (on average, 52 sentences per document), 6,207 were extracted as candidate elaborations.

Human verification. Before crowdsourcing, we conducted a pilot study of elaboration verification with two sets of annotators: (1) Expert annotators (one graduate student, one undergraduate, both native speakers of English) who studied the data extensively; (2) 13 trusted undergraduate volunteer annotators at our university, also native English speakers. They received detailed instructions, but no face-to-face training. This allowed us to gauge task scalability and to gather feedback to design our crowdsourcing protocol. The 13 annotators each annotated a subset of 50 randomly selected documents (a total of 301 candidate elaborations) from our corpus. Each candidate elaboration was annotated by 2 to 4 annotators.

For each original-simplified document pair, we provided annotators with the entirety of both documents. We asked them to identify whether each candidate elaboration truly contained semantically new content, and to provide a rationale for their annotation. We *aggregated* the annotations for each candidate elaboration by taking the mode of all responses. The expert annotation consisted of 150 of these candidate elaborations under the same setup. Figure 2 shows some examples of verified and rejected candidate elaborations.

Agreement. Cohen's Kappa among the two expert annotators is 0.75, indicating substantial agreement (Artstein and Poesio, 2008). Cohen's Kappa between expert annotations and aggregated student annotations is also substantial, at 0.67. Krippendorff's alpha among the 13 student annotators is 0.37. As in complex NLP annotations (Nye et al., 2018), although there is subjectivity among individual annotators due to the complicated nature of the task, their aggregated judgment can be of as high quality as trained expert annotators.

2.3 Contextual Specificity

At first glance, it seemed that elaborative simplification might simply involve retrieving definitions (Paetzold and Specia, 2016) or crafting informative post modifiers (Kang et al., 2019). However, while annotating candidate elaborations, we noticed that elaborations in our corpus took a variety of forms.

To better understand content addition, we conducted an extensive study of elaborations and found that often times, clarification or analysis sentences specific to document context are inserted to aid comprehension or facilitate connections between content in the original text. Notably, elaborations vary in their *contextual specificity*, i.e., the degree to which an elaboration is specific to the context.[1] For example, while simple definitions can be inserted into several different documents mentioning the same entity (low contextual specificity), some elaborations containing clarifications, commonsense reasoning applied to document content, or explicit inference are more contextually specific, as illustrated in Figure 2.

This formulation is inspired by prior work in text specificity (Li et al., 2016; Ko et al., 2019) which is related to how a sentence "stands on its own" or sentence "decontextualization" as in Parikh et al. (2020). As we discuss in §2.4, contextually specific elaborations tend to have slightly lower sentence specificity, thus depending on the surrounding context to enhance understanding.

We ask the pair of experts from the previous pilot to annotate 116 randomly chosen verified elaborations for contextual specificity. Each expert was again given the entirety of the original and simplified documents with the highlighted elaboration, and asked to label its contextual specificity on a scale of 1–3 (low/medium/high). Their Fleiss' Kappa showed moderate agreement (Landis and Koch, 1977) with $\kappa = 0.57$. Spearman's correlation between the two annotators is 0.72. To enable collection, study, and modeling of this linguistic knowledge at scale, we gather contextual specificity ratings during crowdsourcing.

2.4 Crowdsourcing

Annotating elaboration verification and contextual specificity requires careful reading and thoughtful reasoning over text. For the pilot described in §2.2, we provided thorough instructions and example documents and annotations. While these trusted annotators delivered high quality, reliable annotations, they ultimately cannot annotate a dataset of the scale supervised systems require. To remedy this, we use Amazon Mechanical Turk to collect labels at scale, albeit with slightly more noise. Our rationale is that models can tolerate this during training, and we ensure cleaner validation and test sets through expert annotations.

Task setup. We ask workers to annotate elaboration verification and contextual specificity in a single task (HIT). For each candidate elaboration, we provide crowdworkers with the text region from the simplified document containing the elaboration, and the aligned text region from the original document. We ask crowdworkers to categorize each candidate as a true elaboration, not an elaboration, or indicate that the snippets were unrelated. If true elaboration is selected for a candidate, we asked them to rate its contextual specificity[2]. From feedback during our expert pilots, we determined that providing entire documents was often distracting, proving necessary only in rare cases where content was drastically rearranged. Instead, we display text regions of 5–7 sentences from both the simplified and original documents. The simplified text region contains the candidate elaboration and surrounding sentences, and the original text region contains sentences that are aligned with neighboring sentences

---

[1] We draw a distinction between contextual specificity and contextual relevance (as in Kang et al. (2019)).

[2] During crowdsourcing we utilized a 5-point scale, but aggregated the labels to a 3-point scale because the two scores on either end of the scale are not distinctive (i.e., are subjective).

of the elaboration in the simplified text region. We compose HITs that consist of ∼4 candidates from the same article.

Quality control. To ensure high quality annotations, we ask crowd workers to provide a rationale for each rating decision, as in §2.2. These rationales provide insight into worker interpretations of our task, allowing us to actively curate annotations to only include reliable annotations in our dataset. For example, using this method, we were able to remove annotations where crowd workers inflated specificity ratings due to coreferent entity mentions (i.e *"It is a tube that moves blood"* as opposed to *"An artery is a tube that moves blood").*

In addition, we require all crowd workers to reside in the US, UK, Canada, Australia, or New Zealand, and to have completed $\geq$ 100 HITs with an acceptance rate of 95%. Each elaboration is annotated by 5 different crowdworkers. Through active monitoring and small batches of HIT releases, we identified a set of workers that we trust and invite back to the task. Initially, we pay \$0.15 – \$0.23/HIT, and retroactively pay trusted workers at the rate of \$8/hr after work time information is obtained.

Agreement between trained and crowdsourced annotators. For both tasks, we aggregate crowdsourced labels by taking the mode of all responses[3]. Cohen's Kappa of elaboration verification between crowdworkers and experts is 0.37 (fair). To measure contextual specificity agreement between crowdworkers and experts, we use Krippendorff's alpha with an ordinal distance metric, aggregating Turker and expert responses using the mode to obtain an agreement value of α = 0.47, indicating moderate agreement (Artstein and Poesio, 2008). We attribute the disparity between inter-expert agreement and expert-crowdworker agreement to the challenge and subjectivity of this task, especially amongst untrained crowd workers. Though crowdsourcing our data does result in a slightly noisier training set, we are able to collect data for supervised learning and analysis at scale.

Dataset analysis. Using Mechanical Turk, we annotated 4,178 out of the 6,207 candidate elaborations from 1,042 documents. We obtained 1,299 verified elaborations, establishing an approximate 32% conversion rate from candidate to verified elaborations. Note that since candidate elaborations are obtained automatically, this does not accurately reflect the true elaboration rate per document, but rather a lower bound. On average, the elaborations in are corpus are 7–13 tokens long.

	Low	Medium	High	**Total**
Train	303	349	397	**1049**
Valid	71	39	24	**134**
Test	42	34	40	**116**
Total	406	423	470	**1299**

Table 1: Dataset distribution by contextual specificity.

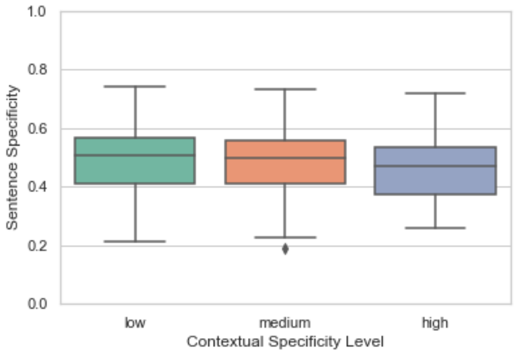


Figure 3: Sentence specificity distribution of elaborations across contextual specificity levels.

To ensure finetuning and evaluation quality, we use the expert-annotated subset of our data for the test set, and sought additional expert annotations for the validation set as well. Table 1 shows our dataset size across splits, stratified by contextual specificity. Our dataset contains a relatively uniform distribution of specificity levels, confirming our qualitative analysis that the contextual specificity of added content is diverse.

Sentence Specificity. As mentioned in §2.3, we explore the nature of sentence specificity of elaborations by running the sentence specificity predictor from Ko et al. (2019) on all standalone elaborations across all splits in our dataset. Sentence specificity predictions range on a continuous scale from 0 (very general) to 1 (highly detailed). Figure 3 shows the sentence specificity distribution across contextual specificity levels. The correlation between contextual and sentence specificity is $\tau = -0.11$, and is statistically significant. This negative correlation illustrates some of the intuition behind contextual specificity – only when highly contextualized elaborations are inserted into documents do they facilitate document understanding.

---

[3] Using the mean as an aggregation function resulted in noisier labels.

3 Elaboration Generation

We frame elaborative simplification as a natural language generation task, and describe a process mimicking editors elaborating as they compose a simplified document from the beginning (i.e. elaborations may be generated based only on the preceding simplified/original context) [4]. Elaboration generation is a challenging test for a model's ability to produce relevant and effective elaborations ranging in contextual specificity given snippets of context from documents in our corpus. We investigate the abilities of pre-trained language models to generate elaborations, establishing baselines in §3.1 and incorporating contextual specificity in §3.2. We find that selecting elaborations of appropriate levels of predicted contextual specificity can help improve elaboration generation results.

3.1 Baseline Elaboration Generation

We generate elaborations using GPT-2 (Radford et al., 2019), a large-scale pre-trained language model which has been shown to be effective in a range of generation tasks, including in recent efforts to elicit world and commonsense knowledge (Zhou et al., 2020; Shwartz et al., 2020).

Formally, we generate elaborations by conditioning on some document context, C. In this baseline setting, we generate sequences via greedy decoding. We utilize context from the original document (C_o) and from the simplified text (C_s). To understand the role that context plays in elaboration generation, we elicit elaborations from the language model by providing it one of the following: **(1)** 2 sentences prior to the gold elaboration in the simplified document (C_{2s}), **(2)** a concatenation of 2 sentences prior to the gold elaboration from the simplified document and the corresponding aligned region in the original document ($C_{2s} + C_o$), **(3)** 4 sentences prior to the gold elaboration in the simplified document (C_{4s}).

Finetuning. We finetune GPT-2 on the set of simplified documents written for the lowest grade level in the Newsela corpus, as well as on our dataset of verified elaborations excluding the test set. We found that such fine-tuning substantially improves generation quality (c.f. Appendix B.1).

3.2 Specificity-guided Generation

As discussed in §2.3, elaborations in our corpus are notably diverse in terms of their contextual specificity. Producing elaborations of appropriate contextual specificity is important, e.g., inserting an unnecessary definition instead of explaining a central concept can be ineffective or detrimental to readers' understanding. Rows 1-2 in Figure 4 show examples where the elaboration generated by the model in §3.1 does not match the level of contextual specificity of the gold elaboration, motivating our exploration of including contextual specificity and its prediction to aid elaboration generation.

Contextual specificity prediction. We build a model to classify the level of contextual specificity of an elaboration as low, medium, or high to incorporate downstream during generation. We leverage BERT (Devlin et al., 2019) for this task. Appendix A explores this auxiliary task further to understand modern NLP models' ability to capture this linguistic information.

We train the model on (E, s) pairs, where E is an elaboration, and s is its labeled contextual specificity. We feed E as input to BERT, and then feed the `[CLS]` token embedding into an output layer for classification. We freeze the BERT parameters since fine-tuning yielded unstable results. We utilize `bert-base` from the HuggingFace library (Wolf et al., 2019). After tuning on the validation set, we train for 5 epochs, using a batch size of 32 and a learning rate of 2e-3. We use the default dropout rate of 0.1 for self-attention layers, but refrain from adding dropout on our linear layer.

This contextual specificity model achieved an accuracy of 56.8 ± 1.5, a macro-averaged F1 score of 55.3 ± 1.6, a Spearman correlation of 47.5 ± 2.6, and a mean absolute error of 0.552 ± 0.01, averaged across 15 randomly initialized runs. This performance is better or on par with other models that incorporate document context in different ways (Appendix A). We find contextual specificity prediction to be a challenging task for BERT. Prediction of *expected* contextual specificity (i.e prediction from context alone, without the elaboration) was particularly difficult, and we leave building stronger models in this setting to future work.

Generation. We investigate the importance of contextual specificity in generating effective elaborations by comparing sequences generated in 3 ways:

---

[4] We explored elaboration generation as a post-processing task after document simplification (Appendix B.2). From preliminary results, we find it to be a more nuanced task which we leave for future work.

1. **Greedy:** Generate elaborations via greedy decoding. This setting was discussed in §3.1.
2. **Top-k:** Sample a sequence from the language model using top-k sampling (Fan et al., 2018), without considering contextual specificity.
3. **Contextual specificity-informed sampling**, shorthand **Contextual:** Sample sequences using top-k sampling until we have 3 elaborations of low, medium, and high contextual specificity, as predicted by the contextual specificity model, and select the sequence with predicted contextual specificity matching the gold specificity level.

In practice, one would ideally use a contextual specificity model trained *without* the elaboration itself (i.e., *Context-Only* models in Appendix A) to predict the appropriate level of contextual specificity of a generated elaboration. However, since we leave to future work to build a strong model presented with this setup, we instead utilize the gold specificity label and explore the upper bound with our generation experiments.

We use sampling-based decoding strategies to achieve contextual specificity diversity because we find that while beam-based decoding methods may result in sequences with diverse *content*, they do not necessarily result in sequences with diverse *contextual specificity*.

3.3 Experimental Settings

We use GPT-2 medium from the HuggingFace library (Wolf et al., 2019) to finetune and generate elaborations. We finetune GPT-2 on documents simplified for the lowest-grade level in the Newsela corpus for 3 epochs with a learning rate of 1e-5 and a batch size of 32. For sampled sequences, we use top-k sampling with $k = 40$, and a temperature of $t = 0.45$, tuned on validation data.

4 Generation Evaluation

As elaboration generation is a new task, we include BLEU scores for completeness and emphasize human evaluation, which provides important insight early on in the study of a new phenomenon.

4.1 Automatic Evaluation

We report BLEU (Papineni et al., 2002), a standard metric in generation tasks. Table 2 shows corpus BLEU-1 and BLEU-2 scores on our test set. As illustrated in Table 2, the best models, as reflected by BLEU, are those finetuned on the Newsela simplified corpus, with four sentences from the simplified document before the gold elaboration as context.

	Greedy		Top-k		Contextual	
Context	B-1	B-2	B-1	B-2	B-1	B-2
C_{2s}	20.8	6.77	20.4	6.12	21.4	7.26
$C_{2s} + C_o$	18.7	5.66	17.2	4.32	19.0	5.31
C_{4s}	20.8	5.54	19.7	6.06	**22.4**	**7.56**

Table 2: BLEU-1 and BLEU-2 scores for elaborations generated by GPT-2, finetuned on the Newsela simplified document corpus. Results for our best model, which we conduct human evaluation on, are in bold.

System	Greedy	Top-k	Contextual
% selected	53.2	44.9	58.0

Table 3: Percentage of annotations for which users selected elaborations generated by each model.

While BLEU captures lexical overlap between generated and gold elaborations, it is also criticized due to poor correlation with human judgments (Liu et al., 2016; Novikova et al., 2017; Chaganty et al., 2018), as it fails to capture semantic similarity or reward multiple plausible hypotheses. During manual inspection of these sequences, we find that elaborations produced after finetuning GPT-2 can be semantically plausible, coherent, and elaboration-like. Content that is pertinent and new, but that does not overlap with the content in the gold elaboration is not rewarded. In some cases, staying true to the content of the gold elaboration is likely unnecessary, as long as the contextual specificity is comparable (see row 4 in Figure 4). To that end, we also perform a human evaluation study of generated elaborations, given that the purpose of elaborations is largely to make simplified text easier to understand for readers.

4.2 Human Evaluation

We set up our human evaluation similar to Panthaplackel et al. (2020), providing a pair of expert evaluators elaborations generated by our C_{4s} model (see Table 2) in each of the three setups (greedy, top-k, contextual), and ask them to select the sequence they thought was most coherent, topical, semantically plausible, and elaboration-like. We allow selection of multiple sequences if they are equally good, and no selection if all sequences are poor. We report human evaluation results as the percentage for which evaluators chose the sequence as higher

Simplified Text	Generated Elaborations
It also has a high amount of smoking for a big city, according to a health department report. In Philadelphia, smoking is more common among the poor than people who aren't poor, said Giridhar Mallya. He works for the Philadelphia Department of Public Health. Being poor can be very hard on a person's mind. **It is not easy to relax, or to feel positive**. ***Contextual Specificity**: High*	**Greedy:** "It's not just the money," he said. **Top-k:** Mallya said the study showed that the poorest people in the city smoke a lot more than the richest people. **Contextual:** It can make them feel guilty.
Workers at the Danish zoo said they had no choice but to kill the giraffe. The reason why is complicated. They said its genes were too much like the genes of other giraffes. All plants and animals have genes. They play a big part in what animals and plants look and act like. Genes are passed down from parents. **They determine eye color, hair color, athletic ability, health and more.** ***Contextual Specificity**: Low*	**Greedy:** The scientists found that the giraffe's genes were very similar to those of other giraffes. **Top-k:** Scientists have known for years that the giraffe's genes were more like those of other giraffes. **Contextual:** The genes are passed down from generations.
Because they look like a poisonous butterfly, they are left alone by predators. Looking like another species works just fine for them. While they avoid getting eaten, the male and the masculine-colored female are still at risk. For a long time, biologists have studied how animals try to look like other animals. It teaches them a lot about natural selection. Natural selection is sometimes called "survival of the fittest." **It means that animals that can change will survive.** ***Contextual Specificity**: Low*	**Greedy:** It is a way of thinking about how animals live. **Top-k:** It means that the more an animal looks like another animal, the more likely it is to survive. **Contextual:** It's a way of thinking about how organisms adapt to change.
The newly found cat is probably part of a separate branch of the cat family, said Tseng. The modern snow leopard is most likely part of the same branch. Both are able to live high in the Tibetan mountains. Big cats present serious problems for paleontologists. **They have existed millions of years longer than people have.** ***Contextual Specificity**: High*	**Greedy:** They are slow and slow to change. **Top-k**: Paleontologists study ancient animals. **Contextual**: They are difficult to study.
Reporters and photographers watched. The big cat crept out of the cage. He looked around, and then ran off down a dirt road. The panther disappeared into the forest. **Wildlife workers were setting him free**. ***Contextual Specificity**: High*	**Greedy:** The news was not good. **Top-k:** Then, it disappeared into the darkness. **Contextual:** The news of the escape made people angry.

Figure 4: Examples of generated elaborations with the different decoding strategies described in §3. Exs. 1–3 are cases where selecting a contextually-appropriate generated elaboration was effective. Ex. 4 is a relevant, sound elaboration with no content overlap with the gold elaboration, hence not rewarded by automatic metrics. Ex. 5 is a difficult case where context is essential – the generated elaboration is not pertinent to document context.

Low	Medium	High
Cushing died in a battle in the War of 1812.	He was captured and taken to a prison.	Cushing was a hero, his supporters said.
A government shutdown is when there are no government services.	A large minority of Germans thought American lawmakers behaved badly, said a poll released Tuesday.	Many lawmakers and their supporters blame the news coverage of their actions.
Football is the national and most popular sport in the United States.	In 2010, just 1 percent of its subscribers played fantasy sports.	The league is also popular with high school and college students looking to build a fan following.

Figure 5: Example generated elaborations of varying contextual specificity.

quality. Two annotators each annotated all 116 examples in our test set, resulting in 232 evaluations total. Table 3 shows these results. We calculate human agreement via Cohen's kappa with MASI distance (Passonneau, 2006), obtaining $\kappa = 0.51$, indicating moderate agreement (Artstein and Poesio, 2008). This round of evaluation confirmed that incorporating contextual specificity is helpful, consistent with our findings with BLEU.

5 Analysis and Discussion

We observe that GPT-2, finetuned on simplified text from the Newsela corpus, is able to adopt elaborative style (i.e short sentences of 7–13 tokens with limited vocabulary), see Figure 4. We find that the model can be effective at generating simple definitions and reasoning. However, the content contained in the elaborations is often not anchored in the document itself – generated sequences seem relevant to the snippet of context provided, but less so when placed in the larger document (see row 5 of Figure 4).

Original Text. We observe that our best model involves context only from the simplified document. We attribute the drop in performance of models with C_o as a part of input largely to the crude incorporation of content from the original document, which is stylistically starkly different from simplified text, most notably in terms of length and vocabulary complexity. Since one of the main sources of relevant content during simplification is the original document, better methods to incorporate text or information from the original document is an important direction for future work.

Effectiveness of contextual specificity. Decoding with top-k sampling allowed GPT-2 to generate low, medium, and high contextualization sequences. A few examples of generated elaborations with varying contextual specificity that were conditioned on the same context are shown in Figure 5.

For most of our models, we do see an improvement when appropriately contextually specific sequences are chosen (rows 1–3 in Figure 4), suggesting the importance and need for further improvement of contextual specificity models.

While our methods take contextual specificity into account, they do not consider factuality or larger document relevance. An improved decoding scheme considering these could promote sequences that better align with larger document context.

Retrieval. Elaborations of medium to high contextual specificity often involve external knowledge not readily available from the simplified or original text. For example, generating factually correct details about a certain event or entity with little to no background on the event the document is referring to can prove challenging for pre-trained language models. To that end, generating truly effective elaborations of medium to high contextual specificity may require some type of retrieval module.

6 Related Work

Text simplification has been studied extensively (Siddharthan, 2014), especially at the sentence level. Recent progress has largely been driven by adapting monolingual translation for sentence simplification (Wubben et al., 2012; Wang et al., 2016; Xu et al., 2016; Zhang and Lapata, 2017; Dong et al., 2019; Kriz et al., 2019). This paradigm, while effective at transforming text, does not suffice when *new* content needs to be generated. A recent survey (Alva-Manchego et al., 2020) identifies explanation generation in simplification as an understudied area in dire need of new resources and methods. We tackle content addition, framed as explanation generation during simplification, and name it broadly as *elaborative simplification*.

The need for elaborative simplification is highlighted in prior hand-coded analysis (Yano et al., 1994), which showed that language learners and other audiences benefit from insertion of relevant elaborations and explanations, and that new or unfamiliar concepts negatively impact reading comprehension (Kintsch and Vipond, 1985). However, existing computational approaches are limited to the retrieval of definitions (Damay et al., 2006; Kandula et al., 2010; Eom et al., 2012; Paetzold and Specia, 2016), or constrained tasks such as post-modifier generation (Kang et al., 2019).

7 Conclusion

We presented the first data-driven study of elaborative simplification, i.e., content insertion during text simplification. We constructed a new corpus of 1.3K verified elaborations, observing a spectrum of contextual specificity and rich types of added content. We developed baselines for elaboration generation using pre-trained language models and found that considering contextual specificity could improve generation quality. We discussed some of the challenges of generating elaborations, and call for techniques to address elaborative simplification.

Acknowledgments

We thank Greg Durrett for reviewing an early draft of this paper, and Joel Tetreault and the UT Austin Computational Linguistics group for valuable feedback and discussions. This work was partially supported by NSF Grant IIS-1850153. We also acknowledge the Texas Advanced Computing Center (TACC) at UT Austin for providing the computational resources for many of the results within this paper.

A Contextual Specificity Prediction

We further explore the auxiliary task of contextual specificity prediction introduced in §3.2, prompted by the observation of diverse elaborations in our corpus. Formally, the task involves predicting the contextual specificity s of an elaboration E as low, medium, or high, given some document context C.

A.1 Methods

As described in §3.2, we use BERT (Devlin et al., 2019) for this classification task. We do so in two settings based on surrounding text and/or the actual elaboration. Settings which include the elaboration can aid generation models by utilizing generated hypothesis elaborations and surrounding text to select sequences that are appropriately contextually specific. Settings that operate off context alone capture the *expected* level of specificity. In addition to the E-only model presented in §3.2, we explore combinations of E, C_o (original document context) and C_{4s} (4 sentences prior to the gold elaboration from the simplified document).

With elaboration. We feed the input sequence into BERT and use `[CLS]` token representation of the sequence, projecting it using a weight matrix $W \in \mathbb{R}^{dx3}$. Input sequences with the elaboration consist of `[CLS]` C `[SEP]` E, where C is either C_o or C_{4s}, or both. When both types of context are used, we learn a representation for a separation token `[CONTEXT_SEP]` to distinguish between the two, and use $C = C_o$ `[CONTEXT_SEP]` C_{4s}.

Context only. While contextual specificity clearly involves the elaboration itself, context-only models help us understand whether it is predictable from context alone, and simulate a realistic setting during simplification, when these models may be incorporated before the actual elaborative text is generated. Input to these models is crafted similarly, but excluding E from the sequence.

A.2 Experiments and Analysis

We train on (E, s) pairs, and utilize `bert-base` from the HuggingFace Transformers library. We feed the sequence representation from the `[CLS]` token embedding into an output layer for classification [5]. For each setting, we train for 5 epochs, using a batch size of 32, and a learning rate of 2e-3. We use the default dropout rate of 0.1 for self-attention layers, but refrain from adding dropout on our linear layer.

Results. We use the same four metrics to evaluate our results – two classification metrics (accuracy, macro-averaged F1), and two regression metrics (Spearman's correlation and mean absolute error), and we again report mean performance over 15 different, randomly initialized runs. Results are shown in Table 4, and suggest that this is a challenging task, even for powerful pre-trained language models. The best predictor of contextual specificity, in terms of correlation and MAE, is context in the form of 4 sentences before the elaboration combined with the elaboration itself. However, the elaboration-only model performs the best in terms of accuracy and F1.

Original Text Presence. In all settings in which the aligned snippet of text from the original document was fed in as partial or complete input to the model, we see a reduction in performance. Compared to text from the simplified document, text from the original document is stylistically distinct. Consequently, when jointly fed in as context with simplified text, the input is largely incoherent, potentially impacting the model. We leave studying more effective ways of incorporating context from the original document to future work.

Qualitative Analysis. In cases where linguistic cues explicitly indicate the level of contextual specificity, our model performs well—i.e when definitions are inserted as *"A is B"* or reasoning is inserted as *"A but B"* or *"The reason for A is B"*. However, predicting the contextual specificity of more nuanced sentences may require an improved method of modeling surrounding context. For example, when the elaboration contains a definition of a term from a different sentence using coreferent mentions, our model predicts a higher level of contextual specificity. In general, our model over-predicts highly contextualized elaborations, and under-predicts lower levels of contextual specificity. Medium contextual specificity was hardest for our models to predict accurately.

Amount of context. To understand the impact of the amount of context on performance, we vary the number of sentences ($\{2, 4, 6\}$) before the elaboration to feed into our best performing model involving context ($C_s + E$). Table 5 shows these results. We see that merely increasing the amount of con-

---

[5] We tried finetuning our contextual specificity prediction models on our elaboration dataset, but found that our dataset was too small to yield stable results.

	Context	Acc.	F1	Correlation	MAE
Context Only	$C_o + C_{4s}$	45.2 ± 3.0	43.1 ± 2.8	27.8 ± 4.9	0.729 ± 0.05
	C_{4s}	46.4 ± 2.9	44.9 ± 3.0	32.4 ± 4.4	0.679 ± 0.04
	C_o	37.9 ± 4.6	36.1 ± 5.4	20.2 ± 1.0	0.813 ± 0.07
With Elaboration	E	$\mathbf{56.8 \pm 1.5}$	$\mathbf{55.3 \pm 1.6}$	47.5 ± 2.6	0.552 ± 0.01
	$C_o + C_{4s} + E$	50.5 ± 3.8	48.3 ± 4.0	40.4 ± 5.8	0.628 ± 0.05
	$C_{4s} + E$	55.3 ± 3.3	54.0 ± 2.5	$\mathbf{50.8 \pm 4.1}$	$\mathbf{0.545 \pm 0.03}$
	$C_o + E$	43.7 ± 1.8	41.7 ± 2.0	26.7 ± 3.6	0.749 ± 0.03

Table 4: Contextual Specificity Prediction results, including accuracy, macro-averaged F1, Spearman's correlation, and Mean Absolute Error, reported across 15 runs. We bold our best results. The performance differences between (1) $C_{4s} + E$ vs E, (2) $C_o + C_{4s}$ vs C_{4s}, and (3) $C_o + C_{4s} + E$ vs. $C_{4s} + E$ are not statistically significant.

	Acc.	F1	Corr	MAE
C_{2s}	53.6 ± 1.8	51.2 ± 3.1	$\mathbf{51.7 \pm 6.8}$	0.566 ± 0.05
C_{4s}	$\mathbf{55.3 \pm 3.3}$	$\mathbf{54.0 \pm 2.5}$	50.8 ± 4.1	$\mathbf{0.545 \pm 0.03}$
C_{6s}	53.9 ± 4.0	52.0 ± 3.6	44.3 ± 5.5	0.591 ± 0.04

Table 5: Mean performance of $C_s + E$ model over 15 runs with varying amounts of pre-elaboration context.

text fed to the model does not translate to stronger results – considering overall performance, 4 sentences before the elaboration from the simplified document performed best.

B Elaboration Generation

B.1 GPT-2 Finetuning

We explore generation with GPT-2 across varying finetuning settings – (1) zero shot (no finetuning, only relying on GPT-2's pre-training), (2) finetuning on the set of simplified documents in the Newsela corpus (excluding documents from the test set), and (3) finally on our elaboration corpus. We utilize the same 3 decoding schemes described in § 3.2 across these different finetuning settings. We used a temperature of $t = 0.7$ for the zero shot setting, and $t = 0.45$ for finetuned settings. For finetuning on our elaboration corpus, we trained for 3 epochs with a batch size of 8 and a learning rate of 1e-3. We report BLEU-1 and BLEU-2 as described in § 4.1. As BLEU metrics for setting 2 are already included in Table 2, we report metrics for zero-shot generation (Table 6), and for generation after finetuning on our elaboration corpus (Table 7). Comparatively, finetuning GPT-2 on the set of simplified Newsela documents yielded the best performance, and we attribute this to there being strictly more data in that setting as opposed to our corpus of verified elaborations.

	Pre-trained GPT-2					
	Greedy		Top-k		Contextual	
Context	B-1	B-2	B-1	B-2	B-1	B-2
C_{2s}	12.48	2.71	9.82	2.04	11.93	2.66
$C_{2s} + C_o$	12.21	2.58	9.80	2.08	10.86	2.82
C_{4s}	13.46	3.35	11.78	2.43	13.80	3.89

Table 6: BLEU-1 and BLEU-2 for generation after finetuning on our elaboration corpus.

	Fine-tuned GPT-2: Elaboration Corpus					
	Greedy		Top-k		Contextual	
Context	B-1	B-2	B-1	B-2	B-1	B-2
C_{2s}	20.9	6.82	19.11	5.32	19.38	5.47
$C_{2s} + C_o$	11.89	2.78	12.72	2.77	14.2	3.05
C_{4s}	20.17	5.87	16.89	4.09	18.97	5.16

Table 7: BLEU-1 and BLEU-2 for the zero-shot generation setting.

B.2 Generation with BART

In addition to GPT-2, we experimented with BART (Lewis et al., 2020), a pre-trained sequence to sequence model. The encoder-decoder nature of BART allows us to explore elaborative simplification as a post-processing/post-editing scenario, where the model can receive context both preceding *and* following the elaboration in the simplified text.

We finetune `bart-base` available via the HuggingFace Transformers library, and feed in four different types of context (1) C_{2s}, (2) C_{4s}, (3) C_{2s+}, (4) C_{4s+}. The latter two context settings utilize two and four sentences before and after the elaboration (without the elaboration itself). In all settings, the gold elaboration was the target. We finetune for 3 epochs, with a batch size of 2, and a learning rate of 1e-4, and generate elaborations via greedy decoding. Results are shown in Table 8.

We find that BART is able to adopt elaborative

	C_{2s}	C_{2s+}	C_{4s}	C_{4s+}
B-1	18.9	21.5	20.2	20.1
B-2	5.05	6.68	6.02	6.18

Table 8: BLEU-1 and BLEU-2 for greedy generation with BART.

style, generating short sequences with limited vocabulary, however we observe that the smaller size of our corpus affected BART's ability to generate coherent, diverse elaborations. In addition, we note that framing elaborative simplification as a post-processing task is a more difficult, nuanced setting – the generated elaboration to be inserted must maintain the flow of the text and blend with the content present subsequent sentences. Elaborative simplification in this setting is another interesting, rich direction for future work.

Could you give me a hint?
Generating inference graphs for defeasible reasoning

Abstract

Defeasible reasoning is a mode of reasoning where conclusions can be overturned by taking into account new evidence. A commonly used method in cognitive science and logic literature is to handcraft argumentation supporting inference graphs. While humans find inference graphs very useful for reasoning, constructing them at scale is difficult. In this paper, we automatically generate such inference graphs through transfer learning from a related NLP task that shares the kind of reasoning that inference graphs support. Through automated metrics and human evaluation, we find that our method generates meaningful graphs for the defeasible inference task. Human accuracy on this task improves by 20% by consulting the generated graphs. Our findings open up exciting new research avenues for cases where machine reasoning can help human reasoning.[1]

1 Introduction

Defeasible inference (Rudinger et al., 2020) is a mode of reasoning in which given a premise **P** (Rob went for a hike), a hypothesis **H** (Rob saw an elephant, it was pink) may be weakened or overturned in light of new evidence i.e., an update **U** (Rob often has hallucinations). Given the non-monotonic nature of this reasoning, humans find it challenging to master this task (Morgan, 2004). This problem has been widely studied in classical AI through logic (Israel, 1980; McCarthy, 1981), and in cognitive science through argumentative models (Pollock, 1987). A prominent approach is to support defeasible inference through argumentations by constructing an *inference graph* (Pollock, 2009).

Despite their prominence (Bentahar et al., 2010), argumentative models are not scalable because an inference graph needs to be handcrafted for every example. Recently, Rudinger et al. (2020) proposed two auxiliary tasks related to defeasible inference: (i) an NLI task to predict whether an update **U** would weaken or strengthen a hypothesis **H**, and (ii) a generative task to generate an update **U** given a premise **P** and a hypothesis **H**. However, this only addresses a part of the problem because their inference is still not supported by the line of reasoning that a human typically uses to solve this task, namely mediators (e.g., hallucinations can be deceptive) and contextualizers (some elephants can have mutated gene which makes them look different) that are inherently embedded in an inference graph, limiting their utility for humans (figure 1).

In this paper, we adopt the concept of an inference graph for defeasible reasoning from cognitive science and provide a computational model to make their generation scalable. Training such a model would require a large amount of annotated inference graphs, which will be too expensive to obtain. Instead, our solution is to draw a parallel to a related reasoning task in NLP (Tandon et al., 2019), where the reasoning is supported by a graph that we find has similarities with the kind of reasoning that an inference graph supports. We train a model that can learn from the NLP task and effectively transfer it to generate inference graphs. Such transfer learning is made possible due to the powerful seq-to-seq neural language models that did not exist before.

The contributions of this paper are the answers to the following two research questions:

RQ1 Can we automate the construction of the argumentation supporting inference graphs? In §2, we show that we can effectively construct meaningful graphs using transfer learning.

RQ2 Can our generated graphs help improve hu-

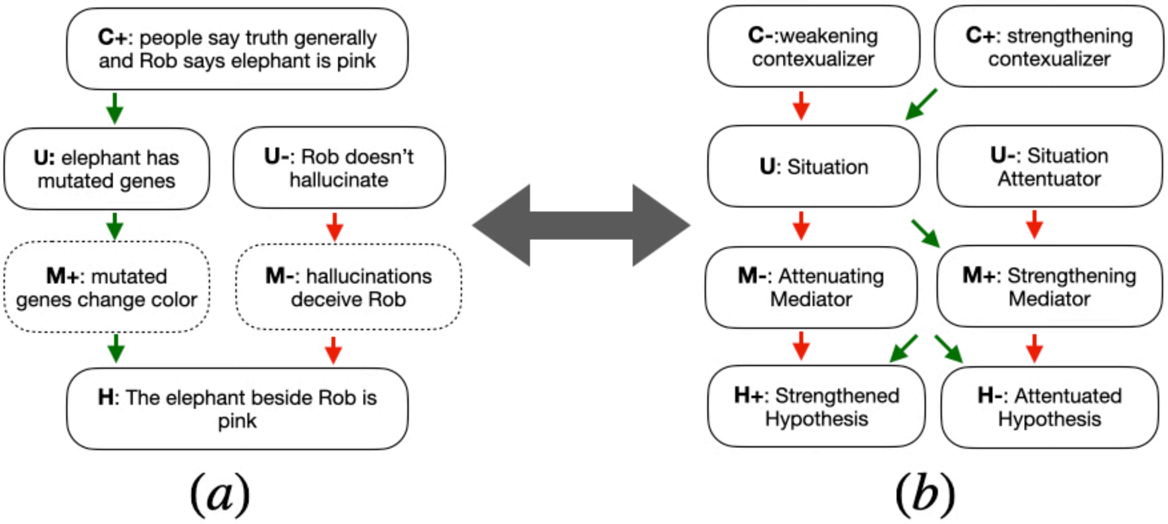

Figure 1: (**a**) An example of an Inference Graph adapted from Pollock (2009) and (**b**) Structure of an Influence Graph adapted from WIQA (Tandon et al., 2019) dataset. The adapted influence graph incorporates the contextualizers, mediators, hypotheses and situations, making them useful for defeasible reasoning.

man performance? In §3, we show that humans leverage generated graphs to improve their performance on a previously reported benchmark.

2 RQ1: Generating argumentation supporting Inference Graphs

We start by drawing parallels to a counterfactual reasoning task in NLP - the WIQA (Tandon et al., 2019) task. WIQA consists of a set of procedural passages, each accompanied by a human-curated *influence graph*. The influence graph captures the causal influences between the events in the context of the process described by the passage. We draw a connection between inference graphs (Pollock, 2009) and influence graphs (Tandon et al., 2019) by drawing parallels between their reasoning structures. In essence, each inference graph from Pollock (1987) can be instantiated via an influence graph from Tandon et al. (2019) by interpreting the nodes in both the graphs as follows (Figure 1):

i. **Contextualizers (C):** these nodes set the context around a situation and connect to the **P** in some way.

ii. **Updates (U):** these nodes are new situations that emerge which might overturn an inference.

iii. **Hypothesis (H):** Hypothesis nodes describes the outcome/conclusion of the situation.

iv. **Mediators (M):** Mediators are nodes that help bridge the knowledge gap between a situation and a hypothesis node by explaining their connection explicitly.

Figure 1 presents an example to highlight the similarities between the two graphs by labeling an example node adapted from (Pollock, 2009), and the structure of the influence graph from (Tandon et al., 2019) with the four node types that we defined above. A green edge indicates that the source node has a positive influence on the target node, and a red edge indicates a negative influence. Further, each node can either act as a *strengthener* (+) or a *weakener* (-) for the hypothesis. Consequently, these graphs can support similar type of reasoning e.g., the effect of **U** on **H** and how this can change in light of external influences (**C**) is captured by graph paths **C+** to **U** and from **U** via a mediator node (**M+/M-**) to **H**. Inspired by these similarities, we hypothesize that influence graphs can be used to supplement defeasible reasoning.

2.1 Influence Graphs Generation

To obtain an influence graph for each defeasible query, we perform a zero-shot transfer from WIQA (Tandon et al., 2019), a corpus of 2100 (passage, influence graphs) pairs.[2].

Training : We treat influence graph generation as a sequence-to-sequence mapping task. We leverage WIQA to derive parallel data $\{(\mathbf{seq}^i_{ip}, \mathbf{seq}^i_{op})\}_{i=1}^N$ for the task. Let $(\mathbf{T}_i, \mathbf{G}_i)$ be a sample in WIQA,

---

[2] Dataset details in the Appendix §E.

where $\mathbf{T}_i$ is the passage text (e.g. describing how viruses spread), and $\mathbf{G}_i$ is the corresponding influence graph (e.g., Figure 2). To create tokens of the input sequence $\mathbf{seq}^i_{ip}$, the model trains best with explicit markers:[3]

$$\mathbf{seq}^i_{ip} = \text{Premise: } \mathbf{T}_i \mid \text{Update: } \mathbf{U}_i \mid \text{less/ more: } \mathbf{H}_i \quad (1)$$

where $\mathbf{T}_i$ is the passage text (e.g. steps describing how viruses spread) and $\mathbf{U}_i$ and $\mathbf{H}_i$ are nodes of $\mathbf{G}_i$ (these are phrases as shown in Figure 2).

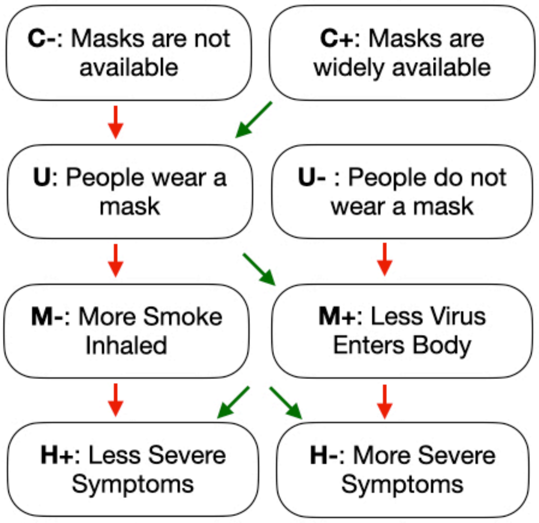

Figure 2: An example of an influence graph similar to ones in WIQA that we train on.

The output $\mathbf{seq}^i_{op}$ is set to a DOT-string representation of the corresponding influence graph $\mathbf{G}_i$, as such a representation was shown to be effective at extracting high-quality graphs (Madaan and Yang, 2021) from free-form text using language models (examples in the appendix). Thus, each passage-graph pair $(\mathbf{T}_i, \mathbf{G}_i)$ from WIQA is mapped to an input-output pair $\mathcal{D} = (\mathbf{seq}^i_{ip}, \mathbf{seq}^i_{op})$. We use this corpus to fine-tune an autoregressive language model $\mathcal{L}$ for graph generation. Essentially, the fine-tuned $\mathcal{L}$ allows us to efficiently sample an influence graph for a given input sequence $\mathbf{seq}^j_{ip}$ by drawing samples from $\mathbf{G}_j \sim P_\theta(y \mid \mathbf{seq}^j_{ip})$ using greedy sampling, where θ denotes the parameters of the language model.

Zero-shot Transfer to Defeasible Inference : We use the model $\mathcal{L}$ trained on WIQA to generate inference graphs on the defeasible inference dataset by Rudinger et al. (2020). We obtain an influence graph for each defeasible input (**P**, **H**, **U**) by converting it to an input sequence that can be fed to $\mathcal{L}$ by filling the template (1). This conversion from (**P**, **H**, **U**) to template (1) is done by setting the premise $\mathbf{P}$ as the context passage $\mathbf{T}$, the update $\mathbf{U}$ as the node $\mathbf{U}$, and the attenuated and strengthened outcomes are simulated by prefixing the hypothesis $\mathbf{H}$ with the tokens *Less* and *More* respectively. This input is then passed to the $\mathcal{L}$ to generate an influence graph.

Results on Influence Graph Generation We use T5-11B (Raffel et al., 2020) fine-tuned on $\mathcal{D}$ derived from WIQA (§2.1) as our graph generation language model ($\mathcal{L}$). All the graphs generated by our model were in valid DOT format. We use the standard generation metrics BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) to evaluate $\mathcal{L}$ on the test split of WIQA. Each node N_i in the reference graph is compared with the corresponding generated node $\hat{N}_i$ using $\texttt{BLEU}(N_i, \hat{N}_i)$ (Node-BLEU). Further, node-edge-node pairs (neighbors) (N_i, N_j) and $(\hat{N}_i, \hat{N}_j)$ are compared using Rel-BLEU $= \texttt{HM}(\texttt{BLEU}(N_i, \hat{N}_i), \texttt{BLEU}(N_j, \hat{N}_j))$ where $\texttt{HM}$ is the harmonic mean. These metrics are averaged over the graph (i.e., across the nodes and the edges), and further averaged across the corpus. We perform these experiments across two different language models: GPT-2-MEDIUM (Radford et al., 2019) and T5-11B. Finally, we calculate the overlap in the edge structures of the reference and generated graphs match as Edge-MATCH%. We report the numbers in Table 1, and include a random baseline for reference. A random baseline will correctly generate the nodes **S**, **H+**, and **H-** as they are part of the query ($\frac{3}{8}$ nodes). As neither of these nodes are connected to another, the random baseline will likely not generate any node pair correctly (Rel-BLEU $\sim$ 0). Since two unique graph structures are possible (Tandon et al., 2019), a random baseline would get Edge-match $\sim$ 50%. Table 1 shows that our T5-based model is able to generate syntactically valid (high edge-match) and semantically meaningful graphs. Additionally, we find that our generated graphs are helpful to humans on a downstream task, as described next.

3 RQ2: Do generated graphs help humans at defeasible reasoning?

Human Evaluation Rudinger et al. (2020) performed a human evaluation on 2000 defeasible queries, where given (**P**, **H**, **U**), the task was to label the nature of the effect of $\mathbf{U}$ on $\mathbf{H}$ as *Intensifies*

---

[3] An example shown in Appendix §A.

Model	Random	GPT-2-MEDIUM	T5-11B
Node-BLEU	37.5	46.05	**50.94**
Rel-BLEU	0.0	19.34	**33.01**
Edge-match%	50.0	92.86	**97.63**

Table 1: Results on automated metrics showing that our T5-11B model is able to generate very accurate graph structure and meaningful nodes that sufficiently match the reference nodes.

or *Attenuates*. Three human judges labeled each query, and the majority label was then compared with the ground-truth to ascertain the accuracy. In their setup, human judges were collectively right on 1745 samples (correct pool) and wrong on 255 samples (wrong pool). We create a challenging pool of 510 queries for the human judges by combining the 255 queries in the wrong pool with 255 queries sampled from the correct pool, giving a baseline accuracy of 50% for this eval pool. Each query in this pool is supplemented with a generated influence graph (§2).[4] We found that our generated influence graphs showed high-levels of redundancy in contextualizers and mediators, with about 46% of the generated influence graphs repeating these nodes. We found that humans find it simpler to follow positive chains of influence, so to reduce their cognitive load, we post-process each influence graph to only retain the strengthening contextualizer (Figure 1), the situation (**U**), the strengthening mediator (**M+**), and the hypothesis (**H**).

In order to establish comparable gains, we replicate the evaluation setup of Rudinger et al. (2020) by using use the same Amazon Mechanical Turk template and the instruction set, and the same pool of 230 qualified annotators that Rudinger et al. (2020) selected based on a paid qualification test, in which the workers were asked to answer SNLI queries of varying levels of difficulty. We paid slightly above $15 per hour for the tasks.

For each query, in addition to answering the defeasible question, three judges were asked to evaluate the augmented influence graphs on two aspects:

i) **Is the influence graph useful?** The judges were allowed to select from the following:

  (a) *helpful*: the graph was crucial in helping towards answering the question

  (b) *relevant but not helpful*: the graph had the right topic (relevant to the question) but did not help in answering the question.

  (c) *irrelevant or misleading*: the graph was irrelevant to the question or misled the human judge to a wrong answer.

ii) **Why is the influence graph useful?** The judges were given an option to highlight the most useful aspect of the generated influence graph. They were allowed to tag one or more of the following aspects as the most helpful: i) Extraneous node, ii) Mediating node, and iii) Structure of the graph.

We summarize the key findings below.

Finding 1: influence graphs are helpful and relevant As Table 2 shows, a large majority of the human judges found the influence graphs to be helpful or relevant. We calculate the inter-annotator agreement for this question using majority-agreement $= \frac{1}{N}\sum_{i=1}^{N} \texttt{ma}_i$ where $\texttt{ma}_i$ indicates a majority agreement for the i^{th} sample (i.e., at least 2 out of 3 judges agreed on the label for the sample). The majority-agreement (`ma`) on these labels was 0.83. The judges marked about 25% of the graphs as relevant but not helpful. The graphs in such cases were on topic but not helpful in answering the query, thereby distinguishing the cases when the graph was crucial in reaching the correct answer. Finally, we note that the graphs provided as hints could have been helpful in two ways: by helping the human annotators arrive at the answer, or by reinforcing their mental picture that helped them in making the right decision. Future research in this direction is needed to study these aspects in depth.

Helpful	47.25
Relevant but not helpful	25.09
Irrelevant or misleading	10.58
No majority agreement	17.05

Table 2: Helpfulness of the augmentations.

Finding 2: Mediators are the most helpful for defeasible queries For every sample, we asked the human judges to mark which parts of the graph was the most helpful (as shown in Figure 6 in Appendix §D.1). The judges could select more than one aspect of the graph if they found multiple useful aspects. Table 3 shows the percentage of human

---

[4] Discussion on IRB exemption in Section §B.

judges that selected the particular graph aspect as most helpful. We observe that 49.48% of the judges who found the graphs useful indicated the mediator node as the most helpful. This indicates that while there may be other events that impact $\mathbf{U}$ and $\mathbf{H}$, the mediating events are the most informative in determining the type of link between them.

Aspect	% marked useful
Mediator	49.48
Extraneous	32.03
Structure	12.81
None helpful	5.68

Table 3: Most useful aspects of an influence graph.

Finding 3: Machine generated influence graphs help humans in defeasible reasoning Table 4 shows that performance improves across all three tasks when the defeasible query is augmented with an influence graph. On our challenging set of 510 queries, the overall accuracy jumps nearly 20 points from 0.50 to 0.698. Figure 3 highlights that 113 queries that were previously given the wrong answers were marked correctly when augmented with the influence graphs.

Dataset	Human (Rudinger et al., 2020)	Human (ours)
SNLI	0.461 ± 0.11	0.553 ± 0.11
SOCIAL	0.628 ± 0.07	0.814 ± 0.06
ATOMIC	0.418 ± 0.06	0.657 ± 0.06
overall	0.500 ± 0.04	$\mathbf{0.698 \pm 0.04}$

Table 4: Human performance (accuracy) on the three tasks with and without generated influence graphs along with Wilson's score intervals for $\alpha = 95\%$. We tested the statistical significance of these results using the McNemar's test (McNemar, 1947) and found the results to be statistically highly significant ($p < 1e - 6$).

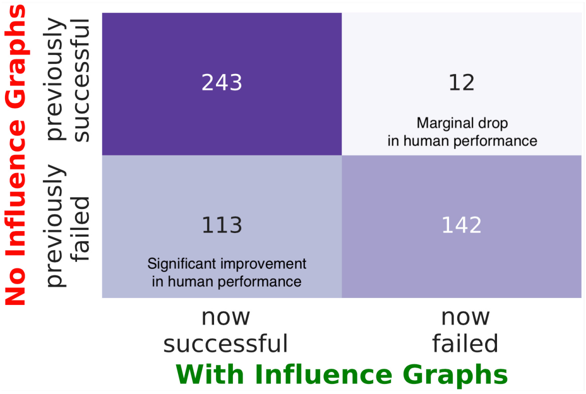

Figure 3: Human performance before and after the human judges were provided with the influence graph.

4 Discussion and Conclusion

Our work takes the idea of using inference graphs for defeasible inference and scales up its usability by automatically generating and augmenting them to a downstream defeasible task that both humans and machines are known to find difficult. We identify that the contextualizer and mediator nodes are crucial to defeasible inference, and show that our generated graphs generate these critical nodes effectively. Humans perform significantly better (20% absolute improvement) across diverse defeasible datasets and overwhelmingly attribute their success to the mediator nodes – giving insights into what helps and why. In this case study, we show that machines can fill the gaps in human knowledge when for defeasible reasoning. While we establish that humans are helped by these graphs, a further investigation on how (and if) the graphs reinforced their beliefs, and what additional information in the graphs was beneficial to their understanding is essential. Furthermore, a deeper understanding of the trade-offs (time spent in answering these questions with and without the graphs) also forms important future work.

A Sample input-output sequence for training $\mathcal{L}$

We now present a sample input-output sequence used to train out $\mathcal{L}$ for graph generation. The input-output sample ($\mathbf{seq_{ip}}, \mathbf{seq_{op}}$) is presented below. As mentioned in Section

1. As described in section 2.1, each input sequence $\mathbf{seq_{ip}}$ is formatted in a special template to be fed to the language model (Template (1)). We show an example of the same next for a sample from our training data. **`Premise:`** `Sunlight shines on plants. Cells with chlorophyll in them ... other parts of the plant.` | **`Situation`** `: more minerals are absorbed` | **`Less`** `: LESS sugar and oxygen being produced` | **`More`** `: MORE sugar and oxygen being produced`

2. Each output graph is encoded in as a DOT string. The output DOT sequence $\mathbf{seq_{op}}$ corresponding to the input shown above is: `strict digraph "C+ : less minerals in the soil [OR] less root system" -> "S : more minerals are absorbed" [label=hurts]; "C- :more minerals in the soil [OR] a better root system" -> "S : more minerals are absorbed" [label=helps]; "S : more minerals are absorbed" -> "M- : less conversion into sugars [OR] less oxygen produced" [label=hurts]; "S : more minerals are absorbed" -> "M+ : more conversion into sugars" [label=helps]; "S- : less minerals absorbed [OR] less root system" -> "M+ : more conversion into sugars" [label=hurts]; "M- : less conversion into sugars [OR] less oxygen produced" -> "H- : LESS sugar and oxygen being produced" [label=helps]; "M- : less conversion into sugars [OR] less oxygen produced" -> "H+ : MORE sugar and oxygen being produced" [label=hurts]; "M+ : more conversion into sugars" -> "H+ : MORE sugar and oxygen being produced" [label=helps]; "M+ : more conversion into sugars" -> "H- : LESS sugar and oxygen being produced" [label=hurts];`

B IRB Exemption

Our study was not an experimentation on humans (posed no identifiable risk to the human judges), did not collect any identifying information, and ensured it involved only adults. As per the IRB guidelines, this falls under the purview of human research, and we are not publishing individual workers' answers but rather the data is tallied up, much like a "benign behavioral intervention." This exempts us from IRB (category 3 of Federal Regulations for Protection of Human Research Subjects https://www.hhs.gov/ohrp/regulations-and-policy/regulations/45-cfr-46/).

C Infrastructure and hyperparameters

To train the T5-11B model, comprising of 11 billion parameters, we used v3-8 TPUs. The average time to train was 7 hours for about 10 epochs. We used the same hyperparameters as provided with the T5 checkpoint at `gs://t5-data/pretrained_models/11B`. We used maximum block size of 512 tokens, and max generation length set to 512. For decoding, we sample according to predicted distribution. We train the GPT-2 model on a Nvidia GTX 2080 Ti, and training the model takes about 30 minutes per epoch.

We use the medium (355M) variant of GPT-2 (Radford et al., 2019) with 24 layers, 1024 hidden size, 16 attention heads.

D Details of our Mechanical Turk Setup

We follow the same instructions for humans as (Rudinger et al., 2020)[5], and only additionally provided instructions for the inference graph. We used a pool of 230 annotators that were previously qualified and selected to do the defeasible inference task, thus providing a fair comparison to their setup. Eventually 12 workers out of these 230 workers

---

[5] We are grateful to the authors of (Rudinger et al., 2020) for sharing their mechanical turk setup template with us.

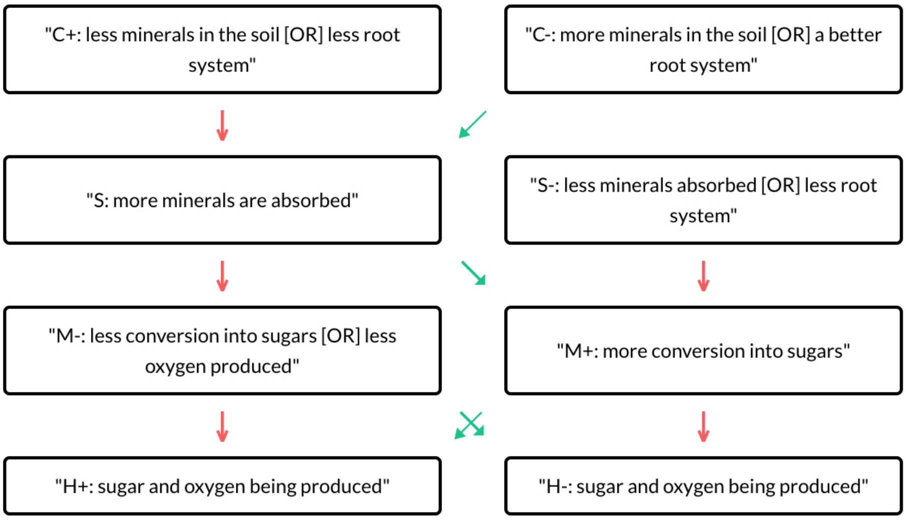

Figure 4: The influence graph corresponding to dot code shown in $\mathbf{seq_{op}}$

worked on our HITs. The graph we showed to humans was a subgraph of the inference graph, where the selected path has the relevant content from the inference graph to avoid showing redundant opposite edges. These redundant edges are useful in training a model as the model must jointly predict all the nodes, but this is redundant for humans. Figure 5 shows this subgraph.

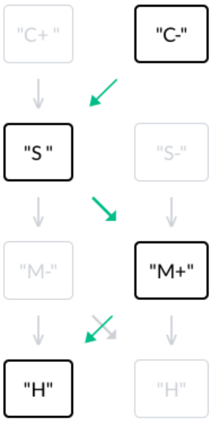

Figure 5: Part of the generated influence graph that is presented in the hit.

D.1 A sample HIT

We now show a sample HIT in Figure 6. We had two set of annotations in every HIT.

D.2 Examples that helped humans

Next, we show two examples (Figure 7, Figure 8) where humans were previously unsuccessful on this answer (in the original setup of (Rudinger et al., 2020)), and were successful now having looked at the inference graphs. The humans marked that the mediator nodes and the contextualizer nodes provide useful information.

Abstract

Social spambots, an emerging class of spammers attempting to emulate people, are difficult for both human annotators and classic bot detection techniques to reliably distinguish from genuine accounts. We examine this human emulation through studying the human characteristics (personality, gender, age, emotions) exhibited by social spambots' language, hypothesizing the values for these attributes will be unhuman-like (e.g. unusually high or low). We found our hypothesis mostly disconfirmed — *individually,* social bots exhibit very human-like attributes. However, a striking pattern emerged when consider the full distributions of these estimated human attributes: social bots were extremely similar and average in their expressed personality, demographics, and emotion (in contrast with traditional bots which we found to exhibit more variance and extreme values than genuine accounts). We thus consider how well social bots can be identified only using the 17 variables of these human attributes and ended up with a new state of the art in social spambot detection (e.g. $F1 = .946$). Further, simulating the situation of not knowing the bots *a priori*, we found that even an unsupervised clustering using the same 17 attributes could yield nearly as accurate of social bot identification ($F1 = 0.925$).

1 Introduction

A *social spambot* is "a computer algorithm that automatically produces content and interacts with humans on social media, trying to emulate and possibly alter their behavior" (Ferrara et al., 2016). Previous studies have shown that standard spambot detection algorithms as well as human annotators, while quite effective at detecting standard spam (e.g. sales advertisements), fail to accurately distinguish these human emulating *social spambots* from genuine Twitter accounts (Cresci et al., 2017).

In light of the goal of social spambots to emulate human behavior, we test the assumption that social spambots should not behave differently than human accounts and that a shared set of traits *should* be common among both groups. Thus, in this study we attempt to characterize and classify social spambots, in comparison to genuine Twitter accounts and traditional spambot accounts, by real human traits and states. We estimate demographics (age and gender), personality traits (openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism), sentiment (positive and negative), and emotions (anger, anticipation, disgust, fear, joy, sadness, surprise, and trust) using a variety of pre-trained models. First and foremost, we describe the distributions of these 17 human attributes, and then we evaluate them as features in relatively simple spambot detection classifiers (random forest) and compare to more sophisticated state of the art detection methods.

Contributions Our contributions: (1) We characterize social spambots in terms of estimated human traits: demographics, personality, sentiment, and emotion. We show that social spambots express limited gender, age, and emotional variation while being much higher in positive sentiment and neurotic language than genuine users. (2) We show that traditional bots exhibit wider variance and more extreme estimated human traits. (3) We use these 17 human traits in a social spambot detection model, achieving state of the art classification results, in addition to outperforming human annotators.

2 Related Work

Bots and bot detection methods have received increased attention due to their role in spreading information, both real and fake, on social media platforms (Shao et al., 2018; Caldarelli et al., 2020). Particular focus has been given to their role in

Findings of the Association for Computational Linguistics: ACL-IJCNLP 2021, pages 5148–5158
August 1–6, 2021.

the 2016 U.S. Presidential election (Bessi and Ferrara, 2016; Badawy et al., 2018), but bots have been discovered discussing other political events such as the Syrian war (Abokhodair et al., 2015) and Brexit (Bastos and Mercea, 2019). Additionally, the spread of misinformation from bots has been linked to multiple public health issues such as vaccines (Broniatowski et al., 2018; Yuan et al., 2019), e-cigarettes (Allem et al., 2017), and marijuana (Allem et al., 2020). There is also growing evidence that bots are spreading information about COVID-19 (Himelein-Wachowiak et al., 2021; Ferrara, 2020; Al-Rawi and Shukla, 2020). The prevalence of bots in online discourse around elections and public policy has lead some researchers to begin outlining government policy for dealing with bots (Pedrazzi and Oehmer, 2020).

Bots have had such far reaching societal impact that research has grown significantly over the last decade (Cresci, 2020), with government agencies sponsoring competitions to identify the influence of bots (Subrahmanian et al., 2016). Although much bot research was done in the context of traditional (non-social or content generating) spambots, interest in social spambots has emerged more recently mostly focused on content, online behavior, or network attributes, rather than the human-likeness of the bots (Zhang et al., 2016). For example, Kudugunta and Ferrara (2018) applied deep neural architectures to the task of classifying social spambots from a single tweet. Using an adversarial learning approach Cresci et al. (2019b) generated evolved versions of current social spambots and, subsequently, attempted to classify them as bot or human. They again show that previous methods, which have been successful in identifying traditional bots, fail to detect the evolved social bots, including their own previous state-of-the-art method. Other studies have used anomaly detection (Miller et al., 2014) as well as sentiment based methods (Dickerson et al., 2014).

Our work is aligned with a growing set of methods to to embed language processing within the social and human contexts they are applied (Lynn et al., 2019). Most similar is the work on language generation or dialog agents (i.e. chatbots). While not directly related to spambot detection, such work has attempted to produce agents with empathy (Rashkin et al., 2019), trust (Novick et al., 2018) and emotion (Zhou and Wang, 2018; Huber et al., 2018) as well as general personalizations (Li et al., 2016; Zhang et al., 2018; Mazaré et al., 2018). As researchers build machines imbued with more sophisticated human attributes, we can expect similar machines to be used for spamming purposes.

3 Data Sets

We sought to use a variety of Twitter bot corpora in order to cover multiple contexts in which bots have been used. These contexts included social and non-social spambots (i.e., content generators and fake followers). In total, we use two social spambot data sets and four traditional bot data sets, each of which is briefly described below. While the focus of the current paper is social spambots, we investigate the human traits of traditional bots to show (1) that our methods generalize across different types of bots and (2) show that social spambots are indeed more sophisticated than traditional bots.

Spambot Data We use the two social spambot data sets derived from Cresci et al. (2017). The first data set, *SSB1* (Social SpamBots #1), is identical Cresci et al's test data: 464 social spambots, who advertised products on *Amazon.com*, plus 464 genuine accounts (718,975 total tweets). As a second data set, *SSB2*, we use an additional 2,913 genuine users from Cresci et al that were not part of *SSB1*, as well as 2,913 randomly selected social spambot accounts that Cresci found to be promoting a VIP version of the *Talnts* app. Because the number of tweets from the genuine accounts was much larger than that of the social spambots, we randomly sampled the genuine tweets, so that the tweet set was evenly split (2,621,684 total tweets). Appendix A contains a selection of social bot tweets to demonstrate how realistic they seem.

Traditional spambots We apply human trait estimates to four open source bot data sets, which consist of non-social bots (i.e., traditional / content generating bots and fake followers), in order to determine if these features generalize across data sets and bot types. All data sets are available through the Bot Repository [1]. We briefly summarize the data sets here (see source papers for more details) which contain both genuine and bot accounts. Yang et al. (2020): A data set of self-identified Twitter bots and verified accounts. Cresci et al. (2019a): Twitter accounts with suspicious financial tweets promoting low-value stocks. Cresci et al. (2015):

---

Fake Twitter followers created to inflate the number of followers of popular accounts. Lee et al. (2011): A collection of content polluting Twitter accounts discovered via honeypot traps.

4 Estimating Human Traits

For each user in our data sets we estimate the following traits from their tweets: age, gender, personality, sentiment, and emotion.

Age / Gender. We applied a predictive lexicon to produce real valued age and gender estimates (Sap et al., 2014). This lexicon was built over Twitter, Facebook, and blog users with labeled age and gender, and produced prediction accuracies (Pearson r) of .831 (age) and .919 (gender).

Personality. We used a language based personality model to estimate the Big Five personality traits: openness to experience, conscientiousness, extraversion, agreeableness and neuroticism (Park et al., 2015). This model was built over 1-3grams and a set of 2,000 LDA (Latent Dirichlet Allocation; Blei et al. 2003) topics and resulted in prediction accuracies (Pearson r) of .43 (openness), .37 (conscientiousness), .42 (extraversion), .35 (agreeableness) and .35 (neuroticism). Park et al. showed that these prediction accuracies are higher than correlations between self-report personality and personality ratings by friends.

Sentiment. We used the positive/negative sentiment categories from the NRC Word-Emotion Association Lexicon, a crowd sourced, word level lexicon (Emolex; Mohammad and Turney 2013).

Emotion. To estimate emotion we used the NRC Hashtag Emotion Lexicon (Mohammad and Kiritchenko, 2015), which has categories based on Plutchik's eight basic emotions: anger, anticipation, disgust, fear, joy, sadness, surprise and trust (Plutchik, 1980). This is an automatically created, word-level lexicon based on tweets with emotion hashtags, i.e. *#anger*, *#anticipation*, etc.

5 Methods

Features For both the *SSB1* and *SSB2* data sets we extract all features needed to estimate the human traits. The age, gender, sentiment, and emotion lexica all use unigrams. For personality, we extract 1-3grams and a set of 2,000 LDA topics. These topics have been used across a number of studies on age, gender, and personality (Schwartz et al., 2013; Park et al., 2016) and were built over the MyPersonality data set (Kosinski et al., 2015).

5.1 Social Spambot Classification

Here the *SSB1* and *SSB2* data sets are used to train and test our model, respectively. In order to keep modeling simple, we built a random forest classifier, utilizing extremely randomized trees (Geurts et al., 2006), as implemented in by scikit-learn (Pedregosa et al., 2011). Modeling parameters are listed in Appendix D .

Comparisons We compare our model accuracies to human annotators and current state of the art methods, which are evaluated on our test set (*SSB2*) and reported in Cresci et al. (2017).

Human Annotators: a crowd sourcing task to test whether humans are able to distinguish social spambots from genuine accounts (Cresci et al., 2017).

BotOrNot: a supervised method trained to identify social spambots (Davis et al., 2016). The model uses over 1,000 different features including tweet content, sentiment and user meta data.

Ahmed et al.: an unsupervised graph clustering of features such as URLs, hashtags, mentions, and retweets (Ahmed and Abulaish, 2013).

Cresci et al.: uses DNA-inspired techniques to model behavior of Twitter users in an unsupervised fashion (Cresci et al., 2016).

5.2 Traditional Spambot Classification

In order to access the generalizability of our features, we evaluate a similar classification task using three open source bot data sets, which we briefly describe below (see the source papers for more details). In the previous task we had dedicated train and test data sets, in order to directly compare against the results in Cresci et al. (2017). Here, we do not have a consistent baseline therefore use a 10-fold cross validation setup, and use a model built on the top 1,000 most frequent unigrams as a comparison. Again, we use an extremely randomized trees classifier; see Appendix E for full modeling and language processing details.

5.3 Unsupervised Classification

Finally, we apply an unsupervised clustering to our data in order to label each account as bot or human. We apply spectral clustering (Von Luxburg, 2007) to all 17 features (age, gender, personality, emotion, and sentiment) as well as the 5 personality dimensions and a baseline of 1,000 unigrams. The spectral clustering algorithm is implemented in scikit-learn with default settings. To simulate a more practical setting, where the human-to-bot ratio is not 50/50, we apply the clustering method to a 90/10 human-to-bot ratio. We fix the number of human accounts to the maximum number in both *SSB1* and *SSB2* (i.e., 2,913 and 464, respectively), and randomly sample bots so as to make a 90/10 human-to-bot ratio. For the 50/50 and 90/10 ratio we set the number of clusters to 2 and 10, respectively. We use 10 clusters on the unbalanced data since spectral clustering assumes equal cluster sizes. To chose the label for the bot cluster, we calculate the standard deviation of each human traits for each cluster, average the standard deviations within each cluster, and label the cluster with the minimum average standard deviation as "bots".

6 Results

Demographic, personality, sentiment, and emotion distributions are shown in Figures 1 and 2. The age estimates for the spambots (red) are tightly clustered (age mean = 28.9, standard deviation = 2.58), when compared to the genuine accounts (blue; mean = 23.8, standard deviation = 5.14). A similar pattern holds for gender – mean (standard deviation) gender is -.50 (.53) and .26 (1.17) for spambots and genuine accounts, respectively. The other traits show patterns similar to age and gender: social spambots have little variation in personality, sentiment, and emotion. Of note are neuroticism and positive sentiment distributions.

		human traits	.862	.865	.862

Table 2: Traditional bot cross validation classification results for 1,000 unigrams and 17 human traits.

Classification results are presented in Table 1. The first four lines ("Past Work") contain results evaluated in Cresci et al. 2017 and are included here for context, while the current study's results are presented in the final five lines. Personality out performs all other single feature sets (age/gender, sentiment and emotion) across all of our evaluation metrics, while emotion performs the worst. Combining all features gives the best classification performance, significantly ($p < 0.01$) above the state of the art in Cresci et al. 2016.

Next, we evaluate estimated human traits for distinguish bots in a number of additional open source bot data sets. Since existing models were largely unavailable for these, we compare to a a much larger model built on the 1,000 most frequent unigrams. Cross validation classification results are in Table 2. The 17 human traits perform almost as well as the 1,000 unigram features, outperforming unigrams in the Lee et al. (2011) data set. The unigram models use (1) features which vary across each data set (i.e., the frequency of each unigram is calculated *within* each data set) and (2) a much larger number of features (1,000 vs. 17). This strongly suggests that the human traits are both generalizable across data sets and also bot types.

Finally, Table 3 shows the results of the unsupervised clustering task. Here, we see that even without providing the means for the models to learn the ideal ranges of attributes (i.e. from training data), the social bots primarily come out in one class with the genuine accounts in the other, even when we sample for a higher ratio of genuine-to-bot accounts (90/10).

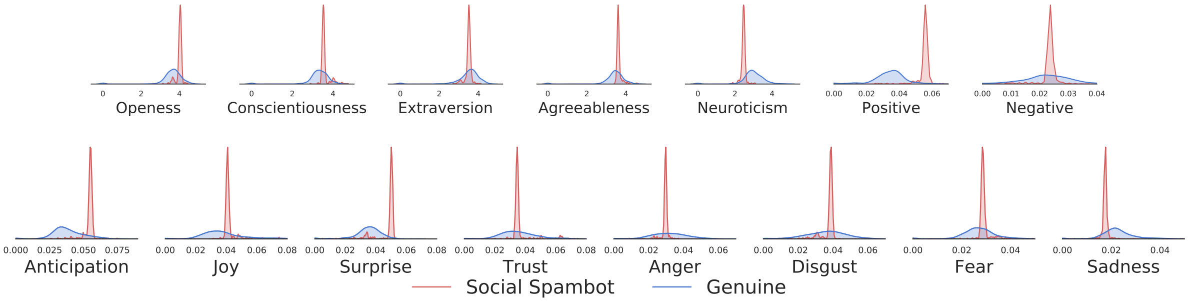

Figure 2: Personality and Emotion distributions of genuine (blue) and social spambot (red) accounts in the *SSB2* data set. Social spambots exhibited reasonable values but with little variance.

7 Ethics Statement

All bot data used in this study are publicly available. This study was reviewed by an academic institutional review board and found to be exempt, non-human subjects data. Still, ethical considerations should be raised when estimating demographics and personality from social media. These include privacy issues, biases in training data, the impact of misclassifications on downstream tasks, and outdated definitions of social constructs such as binary gender. While imperfect, we believe that these estimates are non-obtrusive and allow researchers to study average differences in estimated demographics as expressed in public language.

Further consideration was taken into account given the effectiveness of this approach for bot detection. Notably there is likely a continued arms race between bot creators and bot detectors: as natural language generation methods and bots become more advanced so too will detection methods. When published, it should be assumed that bot creators will try to reverse engineer the methods. Under open security principles, we hope the results of this study promote better detection, but caution that the effectiveness of the approach may ween over time.

8 Conclusion

In this study we showed that social spambots, while difficult for humans to detect, suffer from a lack of variation across all of our measures: age, gender, personality, sentiment, and emotion. Not only did social spambots seem to lack variation in most human traits, their mean values often aligned with the means of genuine accounts (with the exceptions of high mean positive sentiment and low neuroticism – both still with little variance).

The bots' lack of variation across any trait suggests they are "clone"-like. This could explain the inability of human annotators to properly identify them: *individual* social spambot accounts may look human (e.g., 29 years old and slightly male) but the range of humanness is limited. On the *population level*, most social spambots appear to be a clone of the same "human". This contrasts with traditional bots, whose traits were more varied and often with extreme, inhuman values (e.g., negative ages; see Appendix C), suggesting a "robot"-like interpretation of traditional bots.

The consistency of the estimated human traits was strong enough that we were able to build simple yet highly predictive classifiers using only the 17 estimates as features, outperforming human annotators and significantly more accurate than the state of the art in Cresci et al. (2017). On additional data sets spanning other types of bots (e.g., fake followers, spamming accounts, and self identifying bots), the human traits performed on par with much larger models (1,000 unigrams). Finally, simulating where bot training data is non-existant, we showed a simple unsupervised clustering based on the 17 attributes identified social bots nearly as accurately, suggesting human trait based approaches may be able to identify new bots in the wild.

A Spambot Sample Tweets

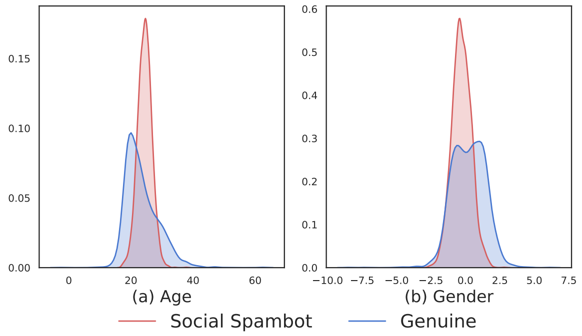
We include a set of random tweets from each social spambot data set, in order to show that these accounts are not immediately identifiable as bots.

	Tweet
SSB1	• To your favorite song, anything you want to do.. • Best week for a long time • Seriously 90210 ended on the best note. I was in waaay too many tears. What do I do with my life now?
SSB2	• I don't read other science fiction. I don't read any at all. - Jack Vance • Better to be a geek than an idiot. • I like my money right where I can see it – hanging in my closet. - Carrie Bradshaw

Table 4: Sample of random social spambot tweets, presented here to highlight the fact that the tweet authors are not immediately identifiable as non-human.

B Social Spambots: Training Data

Here we plot the distributions of our 17 features for the social spambots and genuine users in our training data (see main paper for test data). Demographic data (age and gender) are plotted in Figure 3. We see a similar pattern to the test data, though less pronounced: social spambot distributions are considerably more peaked than the genuine users. Also, note that genuine users have a bimodal gender distribution, corresponding to the female/male splot, whereas the spambot distribution is unimodal. Figure 4 shows the distributions for personality, sentiment and emotion. Again, we see patterns similar to the test data, though less pronounced. The train spambots are also more positive than the genuine users, though the emotional stability split, seen in the test data, is not as pronounced.



(a) Age (b) Gender

Figure 3: Demographic (age and gender) distributions of genuine and social spambot accounts in the training data.

C Human Traits: Traditional vs Social Spambots

We estimates the human traits of a set of 1,000 traditional spambots from Cresci et al. (2017), sampled from a larger set of data released in Yang et al. (2013). In Figure 5 we compare age and gender distributions to those of genuine Twitter users and social spambots. Here we see distinct distributions for each type of account, with traditional spambots having a much wider distribution. In the case of age, we see that traditional bots have non-human predictions (i.e., negative numbers), whereas the predicted age of social spambots is within a reasonable human range. The gender distribution of the traditional spambots do not show a female/male split (i.e., no distinct bimodal distribution). Thus, we have two distinct patterns: (1) traditional bots exhibit a wide range of characteristics, though often non-human and uninterpretable; and, (2) social bots exhibit a very narrow band of characteristics, though this band is within a normal human range, or at least within the range of predicted values for genuine accounts.

In Figure 6 we present the distributions for personality, sentiment, and emotion for all three classes of Twitter users: genuine accounts, traditional spambots and social spambots. First, we see three distinct distributions for each class of Twitter users across all characteristics. Similar to the age and gender plots, when comparing emotions to genuine users, the traditional bots often have a larger spread and are multi-modal. For personality and sentiment, we see a different pattern. Here the traditional bots are more spread than the social bots but still fairly limited when compared to genuine users. While the social spambots have a consistently different pattern when compared to genuine users, we see slightly more variation when comparing traditional bots to genuine users. That said, when comparing across all traits we see three fairly distinct classes of Twitter users.

D Experimental Setup for Classifying Social Bots

We used the following settings in our extremely randomized trees classifier: *bootstrap* is False, *class_weight* is None, *criterion* is gini, *max_depth* is None, *max_features* is sqrt, *max_leaf_nodes* is None, *min_impurity_split* is 1^{-7}, *min_samples_leaf* is 100, *min_samples_split* is 2, *min_weight_fraction_leaf* is 0, *n_estimators* is 1000,

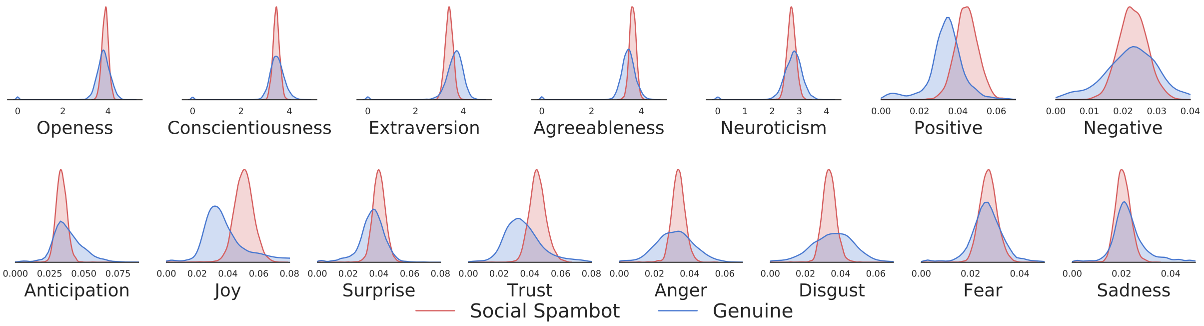


Figure 4: Personality, Sentiment and Emotion distributions of genuine accounts and social spambots in the training data.

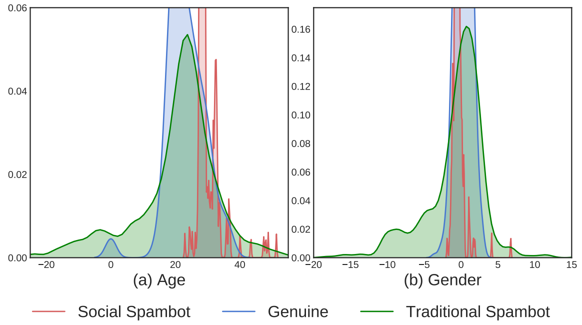

Figure 5: Demographic distributions of traditional spambots, genuine accounts and social spambots. Zoomed to highlight traditional spambots, see Figure 1 in the main paper for genuine accounts and social spambots.

n_jobs is 5, *oob_score* is False, *random_state* is None, and *warm_start* is False.

E Experimental Setup for Classifying Traditional Bots

We use our 17 human trait features in a classification task where we attempt to distinguish traditional bots from genuine human accounts. To do this we use four open source data sets: Yang et al. (2020), Cresci et al. (2019a), Cresci et al. (2015), and Lee et al. (2011). These data sets are all available at the Bot Repository[2], which is a centralized repository for open source bot data sets. Due to privacy reasons, the majority of the data sets on this repo do not contain tweet level data, which we need to estimate the human traits. Therefore, we limit our analysis to three data sets which have tweets available on the Bot Repository: Cresci et al. (2019a), Cresci et al. (2015), and Lee et al. (2011). For the fourth data set in our task, Yang et al. (2020), we use the Twitter API[3] to download available tweet histories from the *botwiki* and *verified* described in the paper (see Yang et al. (2020) for more details).

For each of these data sets we first apply an English filter, since our human trait estimators are trained on English social media data. We use use the langid Python package (Lui and Baldwin, 2012) to restrict to English only tweets. We then extract 1-3grams and a set of 2,000 LDA topics for each account, which are then used to estimate the human traits (age, gender, personality, emotion, and sentiment). See main paper for details on feature extraction. Since we are not using the original tweet set as reported in the above papers (due to English filtering or re-download the tweets from the Twitter API), we build a comparison model using the 1,000 most frequent unigrams. Finally, we restrict our analysis to accounts which have posted at least 500 words across their English tweet histories. To classify each account as human or bot we run 10-fold cross validation using stratified folds. We use an extremely randomized trees classifier as implement in scikit-learn using the following parameters using the settings listed in the social bot detection modeling. Two models are build, one for each of the following feature sets: (1) 1,000 most frequent 1-3grams and (2) 17 human traits.

Additional Acknowledgements

We wish to thank the anonymous reviewers as well as colleagues Joao Sedoc, Johannes Eichstaedt, and David Yaden for their valuable feedback on this work. Dr. Schwartz's effort was funded in part by the Defense Advanced Research Projects Agency (DARPA), via grant #W911NF-20-1-0306 to Stony Brook University. The conclusions and opinions
