## ABSTRACT

This paper describes SCANMail, a system that allows users to browse and search their voicemail messages by content through a GUI. Content based navigation is realized by use of automatic speech recognition, information retrieval, information extraction and human computer interaction technology. In addition to the browsing and querying functionalities, acoustics-based caller ID technology is used to proposes caller names from existing caller acoustic models trained from user feedback. The GUI browser also provides a note-taking capability. Comparing SCANMail to a regular voicemail interface in a user study, SCANMail performed better both in terms of objective (time to and quality of solutions) as well as subjective objectives.

## 1. INTRODUCTION

Increasing amounts of public, corporate, and private audio present a major challenge to speech, information retrieval, and human-computer interaction research: how can we help people to take advantage of these resources when current techniques for navigating them fall far short of text-based search methods? In this paper, we describe SCANMail, a system that employs automatic speech recognition (ASR), information retrieval (IR), information extraction (IE), and human computer interaction (HCI) technology to permit users to browse and search their voicemail messages by content through a GUI interface. A CallerId server also proposes caller names from existing caller acoustic models and is trained from user feedback. An Email server sends the original message plus its ASR transcription to a mailing address specified in the user's profile. The SCANMail GUI also provides note-taking capabilities as well as browsing and querying features. Access to messages and information about them is presented to the user via a Java applet running under Netscape. Figure 1 shows the SCANMail GUI.

## 2. SYSTEM DESCRIPTION

In SCANMail, messages are first retrieved from a voicemail server, then processed by the ASR server that provides a transcription. The message audio and/or transcription are then passed to the IE, IR, Email, and CallerId servers. The acoustic and language model of the recognizer, and the IE and IR servers are trained on 60 hours of a 100 hour voicemail corpus, transcribed and hand labeled for telephone numbers, caller names, times, dates, greetings and closings. The corpus includes approximately 10,000 messages from approximately 2500 speakers. About 90% of the messages were recorded from regular handsets, the rest from cellular and speaker-phones. The corpus is approximately gender balanced and approximately 12% of the messages were from non-native speakers. The mean duration of the messages was 36.4 seconds; the median was 30.0 seconds.

### 2.1 Automatic Speech Recognition

The baseline ASR system is a decision-tree based state-clustered triphone system with 8k tied states. The emission probabilities of the states are modeled by 12 component Gaussian mixture distributions. The system uses a 14k vocabulary, automatically generated by the AT&T Labs NextGen Text To Speech system. The language model is a Katz-style backoff trigram trained on 700k words from the transcriptions of the 60 hour training set. The word-error rate of this system on a 40 hour test set is 34.9%.

Since the messages come from a highly variable source both in terms of speaker as well as channel characteristics, transcription accuracy is significantly improved by application of various normalization techniques, developed for Switchboard evaluations [9]. The ASR server uses Vocal Tract Length Normalization (VTLN) [5], Constrained Modelspace Adaptation (CMA) [3], Maximum Likelihood Linear Regression (MLLR) [6] and Semi-Tied Covariances (STC) [4] to obtain progressively more accurate acoustic models and uses these in a rescoring framework. In contrast to Switchboard, voicemail messages are generally too short too allow direct application of the normalization techniques. A novel message clustering algorithm based on MLLR likelihood [1] is used to guarantee sufficient data for normalization. The final transcripts, obtained after 6 recognition passes, have a word error rate of 28.7% – a 6.2% accuracy improvement. Gender dependency provides 1.6% of this gain. VTLN then additively improves accuracy with 1.0% when applied only on the test data and an additional 0.3% when subsequently applied with a VTLN trained model. The use of STC further improves accuracy with 1.2%. Finally CMA and MLLR provide additive gains of 1.5% and 0.6% respectively. The ASR

server, running on a 667 MHz 21264 Alpha processor, produces the final transcripts in approximately 20 times real-time.

## 2.2 Information Retrieval

Messages transcripts are indexed by the IR server using the SMART IR [8, 2] engine. SMART is based on the vector space model of information retrieval. It generates weighted term (word) vectors for the automatic transcriptions of the messages. SMART pre-processes the automatic transcriptions of each new message by tokenizing the text into words, removing common words that appear on its stop-list, and performing stemming on the remaining words to derive a set of terms, against which later user queries can be compared. When the IR server is used to execute a user query, the query terms are also converted into weighted term vectors. Vector inner-product similarity computation is then used to rank messages in decreasing order of their similarity to the user query.

## 2.3 Information Extraction

Key information is extracted from the ASR transcription by the IE server, which currently extracts any phone numbers identified in the message. Currently, this is done by recognizing digit strings and scoring them based on the sequence length. An improved extraction algorithm, trained on our hand-labeled voicemail corpus, employs a digit string recognizer combined with a trigram language model, to recognize strings in their lexical contexts, e.g. <word> <digit string> <word>.

## 2.4 Caller Identification

The CallerID server proposes caller names by matching messages against existing caller models; this module is trained from user feedback. The caller identification capability is based on text independent speaker recognition techniques applied to the processed speech in the voicemail messages. A user may elect to label a message he/she has reviewed with a caller name for the purpose of creating a speaker model for that caller. When the cumulative duration of such user-labeled messages is sufficient, a caller model is constructed. Subsequent messages will be processed and scored against this caller model and models for other callers the user may have designated. If the best matching model score for an incoming message exceeds a decision threshold, a caller name hypothesis is sent to the GUI client; if there is no PBX-supplied identification (i.e. caller name supplied from the owner of the extension for calls internal to the PBX), the CallerId hypothesis is presented in the message header, for either accepting or editing by the user; if there is a PBX identification, the CallerId hypothesis appears as the first item in a user 'contact menu', together with all previously id'd callers for that user. To optimize the use of the available speech data, and to speed model-building, caller models are shared among users. Details and a performance evaluation of the CallerId process are described in [7].

## 2.5 Graphical User Interface

In the SCANMail GUI, users see message headers (callerid, time and date, length in seconds, first line of any attached note, and presence of extracted phone numbers) as well as a thumbnail and the ASR transcription of the current message. Any note attached to the current message is also displayed. A search panel permits users to search the contents of their mailbox by inputting any text query. Results are presented in a new search window, with keywords color-coded in the query, transcript, and thumbnail.

## 2.6 User Studies

User studies compared SCANMail with a standard over-the-phone voicemail access. Eight subjects performed a series of fact-finding, relevance ranking, and summarization tasks on artificial mailboxes of twenty messages each, using either SCANMail or phone access. SCANMail showed advantages for fact-finding and relevance ranking tasks in quality of solution normalized by time to solution, for fact-finding in time to solution and in overall user preference. Normalized performance scores are higher when subjects employ IR searches that are successful (i.e. the queries they choose contain words correctly recognized by the recognizer) and for subjects who listen to less audio and rely more upon the transcripts. However, we also found that SCANMail's search capability can be misleading, causing subjects to assume that they have found all relevant documents when in fact some are NOT retrieved, and that when subjects rely upon the accuracy of the ASR transcript, they can miss crucial but unrecognized information. A trial of 10 friendly users is currently underway, with modifications to access functionality suggested by our subject users. A larger trial of the system is being prepared, for more extensive testing of user behavior with their own mailboxes over time.
