Message from the General Chair

Greetings,

Welcome to NAACL HLT 2016! This year's conference is held in San Diego, California, where we have assembled an exciting program of computational linguistics research.

The main program features a wide array of topics, and it includes excellent invited talks by Prof. Regina Barzilay and Prof. Ehud Reiter. In addition, we have six tutorials on the day before the main program, plus fifteen workshops on the following two days. Some of these workshops are back for their 10th or 11th incarnation, while others are brand-new. In parallel, we have a live demonstration track, and a Student Research Workshop that showcases work by the junior members of our research community.

This NAACL HLT meeting takes place only through the hard work of many people who deserve our gratitude.

Thanks to Priscilla Rasmussen for making local arrangements, handling registration, setting up social events, writing visa invitation letters, and solving a myriad of issues. Priscilla, your experience is a great asset to any conference!

The NAACL HLT organizing committee took all the steps to bring you a great conference. Many thanks to Ani Nenkova and Owen Rambow (Program Co-chairs), Mohit Bansal and Alexander M. Rush (Tutorial Co-chairs), Radu Soricut and Adrià de Gispert (Workshop Co-chairs), Jacob Andreas, Eunsol Choi, and Angeliki Lazaridou (Student Research Workshop Co-Chairs) and their faculty advisors Jacob Eisenstein and Nianwen Xue, Aliya Deri (Student Volunteer Coordinator), Julie Medero (Local Sponsorship Chair), Mark Finlayson, Sravana Reddy, and John DeNero (Demonstration Co-chairs), Adam Lopez and Margaret Mitchell (Publications Co-chairs), Jason Riesa (Website Chair), Wei Xu (Publicity Chair), and Jonathan May (Social Media Chair).

Thanks also to the NAACL Board for providing excellent advice, and thanks to previous chairs for their suggestions and timelines.

Sponsors of NAACL HLT 2016 include Baidu and Google (Platinum Sponsors), Amazon, Bloomberg, eBay, Microsoft Research, and UnitedHealth Group (Gold Sponsors), Huawei (Silver Sponsors), Civis Analytics, Facebook, @newsela, and Nuance (Bronze Sponsors), and the University of Washington (Supporter). Thanks for your extremely valuable contributions!

Finally, thanks to the scientists, engineers, authors, and attendees who come to share and learn at this leading venue for computational linguistics research!

Kevin Knight
Information Sciences Institute, University of Southern California
NAACL HLT 2016 General Chair

Message from the Program Co-Chairs

Welcome to San Diego for the 15th Annual Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies!

The conference has grown remarkably in the past five years: we had 698 submissions this year, despite our deadline right after the end-of-the-year holidays. As we worked on organizing the conference program, we made many changes to reflect the growth of the NAACL community, the increasing diversity of topics covered by the field, and the acceleration of the pace of the publication cycle.

We had a record short time between paper submission and author notification—less than two months. We settled on such compressed timeline in order to avoid spreading the reviewing period over the winter holidays, to ensure that papers spend only a short time under submission, and to coordinate submission deadlines with ACL. Our incredible team of area chairs and reviewers ensured that the planned schedule went smoothly.

As the computational linguistics field has expanded, it has become increasingly difficult to recruit a sufficient number of knowledgeable reviewers. We decided to reach out to the largest possible pool of computational linguists and provide convenient ways for the area chairs to control which reviewers they end up working with: we invited all researchers actively working in the area of computational linguistics/language processing to review for the conference. We defined "active researchers" to be those who have published at least five papers in the last ten years in the ACL, NAACL, EMNLP, EACL or COLING conferences. In order to be inclusive of the amazing young researchers who became active in the field only more recently, we also included everyone who had published at least three papers in the same venues for the last five years. This yielded a list of over 1,400 researchers that we invited to serve as reviewers for the conference. Of these, 685 agreed and participated in the review process. This is another record for NAACL HLT 2016, no previous NAACL has had such a large program committee. Among these, the area chairs recognized 120 as best reviewers.

Working with the reviewers were the 42 area chairs. We asked the area chairs to work in pairs, so they can have a back-up in case other obligations need their attention during the review period and to ensure that all decisions about reviewer assignment and paper recommendation are discussed in detail. All area chairs and reviewers submitted a list of keywords that describe their area of expertise (the full list appears in the conference call for papers). The area chairs were paired based on the keyword overlap.

To match reviewers to area chairs, we used a bidding system. For bidding, each area received a list of the 140 reviewers with best matching keyword profiles. If the area chairs did not know the work of a potential reviewer on their bidding list, they looked him or her up on DBLP or Google Scholar before making their final bid. Areas were assigned only reviewers for which the area chairs bid positively. Area chairs were free as usual to recruit additional reviewers they wished to work with.

Submissions were assigned to areas by taking into account the match between the paper keywords and the area chair keywords. Areas were capped at 40 submissions maximum (long and short combined). As in the past, reviewers bid on papers they wanted to review. 69% of the reviews were written by reviewers who had bid indicating that they want to review the paper; 29% of the reviews were written by reviewers who had bid indicating they are ok with reviewing the paper. The remaining 2% of reviews were written by reviewers who did not bid on the paper but were asked by an area chair to review it. Three reviewers were assigned a paper that they did not want to review according to their bid. The average reviewer load was 3 papers, which included a mix of long and short submissions. Only 43 reviewers had more than four papers to review.

Area chairs wrote meta-reviews, for use only by us, justifying their accept/reject recommendation. In making difficult decisions, we drew on these meta-reviews, the reviews themselves, the discussion among the reviewers, and the author response to the initial reviews.

We are happy with our changes to the review process: area chairs had control over the reviewers they worked with, reviewers were assigned papers they wanted to review and the overall reviewing load was low. Needless to say, there is room for further improvements. The reviewing process is crucial to the quality of this conference; only if the community has confidence in the quality of the reviewing process will this conference continue to be a leading conference in our field. Our goal has been to make sure that every single submission receives a complete and fair review and decision, and to make sure that the authors of every single submission understand why their paper was accepted or declined for the conference. We would like to thank our 685 reviewers, and we would especially like to thank our 42 area chairs, who were patient in allowing us to pursue some of the innovative aspects of this year's reviewing cycle.

Eighteen of the 698 initial submissions were withdrawn by the authors or rejected without review because of formatting violations. A total of 396 long and 284 short papers underwent review; 100 long and 82 short papers were accepted, for an acceptance rate of 25% and 29% respectively. In addition, ten TACL papers will be presented at the conference.

This year we decided to have shorter slots for oral presentations, in order to have more of the accepted papers presented as talks. In the program, long papers are allotted 20-minute slots (15 min presentation + 5 min questions). Short papers are allotted 10-minute slots (6 min presentation + 4 min questions).

The best paper award committee consisted of NAACL general and program chairs from the last three years. Not all past chairs could participate in the selection. The final best paper committee included Joyce Chai, Katrin Kirchhoff, Rada Mihalcea, Kristina Toutanova, Lucy Vanderwende and Hua Wu. They selected two best long papers and one best short paper, along with two runner-ups in each category.

Best Short Paper
Improving sentence compression by learning to predict gaze
Sigrid Klerke, Yoav Goldberg and Anders Søgaard

Short Paper, Runners Up
Patterns of Wisdom: Discourse-Level Style in Multi-Sentence Quotations
Kyle Booten and Marti A. Hearst

A Joint Model of Orthography and Morphological Segmentation
Ryan Cotterell, Tim Vieira and Hinrich Schütze

Best Long Papers
Feuding Families and Former Friends: Unsupervised Learning for Dynamic Fictional Relationships
Mohit Iyyer, Anupam Guha, Snigdha Chaturvedi, Jordan Boyd-Graber and Hal Daumé III

Learning to Compose Neural Networks for Question Answering
Jacob Andreas, Marcus Rohrbach, Trevor Darrell and Dan Klein

Long Paper, Runners Up
Multi-way, Multilingual Neural Machine Translation with a Shared Attention Mechanism
Orhan Firat, Kyunghyun Cho and Yoshua Bengio

Black Holes and White Rabbits: Metaphor Identification with Visual Features
Ekaterina Shutova, Douwe Kiela and Jean Maillard

The conference program includes two inspiring invited talks by Regina Barzilay and Ehud Reiter. Both push the boundaries of the field, discussing the potential for real-world impact of language technologies.

Finally we would like to thank all other people who supported us in the past year in our work for NAACL HLT 2016. Last year's program chairs, Anoop Sarkar and Joyce Chai shared their valuable advice and promptly answered the many questions we had throughout the process. The NAACL board chair for 2015 (Hal Daumé III) and 2016 (Emily Bender) were our effective link with the NAACL board. The conference general chair, Kevin Knight, was always available to us when we needed to consult about decisions we were making. The conference business manager, Priscilla Rasmussen, gave us details about the venue and coordinated with us at the final stages of making the conference schedule. The ACL treasurer, Greame Hirst, answered questions about the venue. The conference webmaster, Jason Riesa, put content on the conference webpage as soon as we made it available to him. The publication chairs, Meg Mitchell and Adam Lopez, answered all lingering author questions about formatting for submission and final versions. Many talks to all of them!

We look forward to an exciting conference!

Invited Talk: How can NLP help cure cancer?

Regina Barzilay

Massachusetts Institute of Technology

Abstract

Cancer inflicts a heavy toll on our society. One out of seven women will be diagnosed with breast cancer during their lifetime, a fraction of them contributing to about 450,000 deaths annually worldwide. Despite billions of dollars invested in cancer research, our understanding of the disease, treatment, and prevention is still limited.

Majority of cancer research today takes place in biology and medicine. Computer science plays a minor supporting role in this process if at all. In this talk, I hope to convince you that NLP as a field has a chance to play a significant role in this battle. Indeed, free-form text remains the primary means by which physicians record their observations and clinical findings. Unfortunately, this rich source of textual information is severely underutilized by predictive models in oncology. Current models rely primarily only on structured data.

In the first part of my talk, I will describe a number of tasks where NLP-based models can make a difference in clinical practice. For example, these include improving models of disease progression, preventing over-treatment, and narrowing down to the cure. This part of the talk draws on active collaborations with oncologists from Massachusetts General Hospital (MGH).

In the second part of the talk, I will push beyond standard tools, introducing new functionalities and avoiding annotation-hungry training paradigms ill-suited for clinical practice. In particular, I will focus on interpretable neural models that provide rationales underlying their predictions, and semi-supervised methods for information extraction.

Biography

Regina Barzilay is a professor in the Department of Electrical Engineering and Computer Science and a member of the Computer Science and Artificial Intelligence Laboratory at the Massachusetts Institute of Technology. Her research interests are in natural language processing. She is a recipient of various awards including of the NSF Career Award, the MIT Technology Review TR-35 Award, Microsoft Faculty Fellowship and several Best Paper Awards at NAACL and ACL. She received her Ph.D. in Computer Science from Columbia University, and spent a year as a postdoc at Cornell University.

Invited Talk: Evaluating Natural Language Generation Systems

Ehud Reitter

University of Aberdeen and Arria NLG

Abstract

Natural Language Generation (NLG) systems have different characteristics than other NLP systems, which effects how they are evaluated. In particular, it can be difficult to meaningfully evaluate NLG texts by comparing them against gold- standard reference texts, because (A) there are usually many possible texts which are acceptable to users and (B) some NLG systems produce texts which are better (as judged by human users) than human-written corpus texts. Partially because of these reasons, the NLG community places much more emphasis on human-based evaluations than most areas of NLP.

I will discuss the various ways in which NLG systems are evaluated, focusing on human-based evaluations. These typically either measure the success of generated texts at achieving a goal (eg, measuring how many people change their behaviour after reading behaviour-change texts produced by an NLG system); or ask human subjects to rate various aspects of generated texts (such as readability, accuracy, and appropriateness), often on Likert scales. I will use examples from evaluations I have carried out, and highlight some of the lessons I have learnt, including the importance of reporting negative results, the difference between laboratory and real-world evaluations, and the need to look at worse-case as well as average-case performance. I hope my talk will be interesting and relevant to anyone who is interested in the evaluation of NLP systems.

Biography

Ehud Reiter is a Professor of Computing Science at the University of Aberdeen and also Chief Scientist of Arria NLG. He has worked on natural language generation for the past 30 years, on methodology (including evaluation) and resources as well as algorithms, and is one of the most cited authors in NLG. His 2000 book Building Natural Language Generation Systems is widely used as an NLG textbook. Dr Reiter currently spends most of his time trying to commercialise NLG at Arria (one of the largest specialist NLG companies), which grew out of a startup he cofounded in 2009.

Monday, June 13, 2016

7:30–8:45 ***Breakfast, Pavilion***

9:00–9:15 *Welcome, Grande Ballroom*
Kevin Knight, Ani Nenkova, Owen Rambow

9:15–10:30 *Invited talk: "How can NLP help cure cancer?"*
Regina Barzilay

10:30–11:00 ***Coffee break, Pavilion***

11:00–12:30 ***Session 1***

1A. Machine translation

11:00–11:20 *Achieving Accurate Conclusions in Evaluation of Automatic Machine Translation Metrics*
Yvette Graham and Qun Liu

11:20–11:40 *Flexible Non-Terminals for Dependency Tree-to-Tree Reordering*
John Richardson, Fabien Cromierès, Toshiaki Nakazawa and Sadao Kurohashi

11:40–12:00 *Selecting Syntactic, Non-redundant Segments in Active Learning for Machine Translation*
Akiva Miura, Graham Neubig, Michael Paul and Satoshi Nakamura

12:00–12:10 *Multi-Source Neural Translation*
Barret Zoph and Kevin Knight

12:10–12:20 *Controlling Politeness in Neural Machine Translation via Side Constraints*
Rico Sennrich, Barry Haddow and Alexandra Birch

1B. Summarization

1C. Dialog

Monday, June 13, 2016 (continued)

12:10–12:20 *Conversational Flow in Oxford-style Debates*
Justine Zhang, Ravi Kumar, Sujith Ravi and Cristian Danescu-Niculescu-Mizil

12:20–12:30 *Counter-fitting Word Vectors to Linguistic Constraints*
Nikola Mrkšić, Diarmuid Ó Séaghdha, Blaise Thomson, Milica Gašić, Lina M. Rojas-Barahona, Pei-Hao Su, David Vandyke, Tsung-Hsien Wen and Steve Young

12:30–2:00 ***Lunch break***

2:00–3:30 ***Session 2***

2A. Language and Vision

2:00–2:20 *Grounded Semantic Role Labeling*
Shaohua Yang, Qiaozi Gao, Changsong Liu, Caiming Xiong, Song-Chun Zhu and Joyce Y. Chai

2:20–2:40 *Black Holes and White Rabbits: Metaphor Identification with Visual Features*
Ekaterina Shutova, Douwe Kiela and Jean Maillard

2:40–3:00 *Bridge Correlational Neural Networks for Multilingual Multimodal Representation Learning*
Janarthanan Rajendran, Mitesh M. Khapra, Sarath Chandar and Balaraman Ravindran

3:00–3:20 *Unsupervised Visual Sense Disambiguation for Verbs using Multimodal Embeddings*
Spandana Gella, Mirella Lapata and Frank Keller

3:20–3:30 *Stating the Obvious: Extracting Visual Common Sense Knowledge*
Mark Yatskar, Vicente Ordonez and Ali Farhadi

2B. Parsing

2:00–2:20 *Efficient Structured Inference for Transition-Based Parsing with Neural Networks and Error States [TACL]*
Ashish Vaswani and Kenji Sagae

2:20–2:40 *Recurrent Neural Network Grammars*
Chris Dyer, Adhiguna Kuncoro, Miguel Ballesteros and Noah A. Smith

2:40–3:00 *Expected F-Measure Training for Shift-Reduce Parsing with Recurrent Neural Networks*
Wenduan Xu, Michael Auli and Stephen Clark

3:00–3:20 *LSTM CCG Parsing*
Mike Lewis, Kenton Lee and Luke Zettlemoyer

3:20–3:30 *Supertagging With LSTMs*
Ashish Vaswani, Yonatan Bisk, Kenji Sagae and Ryan Musa

2C. Named Entity Recognition

2:00–2:20 *An Empirical Study of Automatic Chinese Word Segmentation for Spoken Language Understanding and Named Entity Recognition*
Wencan Luo and Fan Yang

2:20–2:40 *Name Tagging for Low-resource Incident Languages based on Expectation-driven Learning*
Boliang Zhang, Xiaoman Pan, Tianlu Wang, Ashish Vaswani, Heng Ji, Kevin Knight and Daniel Marcu

2:40–3:00 *Neural Architectures for Named Entity Recognition*
Guillaume Lample, Miguel Ballesteros, Sandeep Subramanian, Kazuya Kawakami and Chris Dyer

3:00–3:20 *Dynamic Feature Induction: The Last Gist to the State-of-the-Art*
Jinho D. Choi

3:20–3:30 *Drop-out Conditional Random Fields for Twitter with Huge Mined Gazetteer*
Eunsuk Yang, Young-Bum Kim, Ruhi Sarikaya and Yu-Seop Kim

3:30–4:00 ***Coffee break, Pavilion***

Monday, June 13, 2016 (continued)

4:00–5:00 ***Session 3***

3A. Event detection

4:00–4:20 *Joint Extraction of Events and Entities within a Document Context*
Bishan Yang and Tom M. Mitchell

4:20–4:40 *A Hierarchical Distance-dependent Bayesian Model for Event Coreference Resolution [TACL]*
Bishan Yang, Claire Cardie, and Peter Frazier

4:40–5:00 *Joint Event Extraction via Recurrent Neural Networks*
Thien Huu Nguyen, Kyunghyun Cho and Ralph Grishman

3B. Language Models

4:00–4:20 *Top-down Tree Long Short-Term Memory Networks*
Xingxing Zhang, Liang Lu and Mirella Lapata

4:20–4:40 *Recurrent Memory Networks for Language Modeling*
Ke Tran, Arianna Bisazza and Christof Monz

4:40–5:00 *A Latent Variable Recurrent Neural Network for Discourse-Driven Language Models*
Yangfeng Ji, Gholamreza Haffari and Jacob Eisenstein

3C. Non Literal Language

4:00–4:20 *Questioning Arbitrariness in Language: a Data-Driven Study of Conventional Iconicity*
Ekaterina Abramova and Raquel Fernández

4:20–4:40 *Distinguishing Literal and Non-Literal Usage of German Particle Verbs*
Maximilian Köper and Sabine Schulte im Walde

4:40–5:00 *Phrasal Substitution of Idiomatic Expressions*
Changsheng Liu and Rebecca Hwa

5:00–5:15 ***Break***

5:15–6:00 ***One Minute Madness***

6:00–8:00 ***Posters and Dinner***

Posters

Leverage Financial News to Predict Stock Price Movements Using Word Embeddings and Deep Neural Networks
Yangtuo Peng and Hui Jiang

Grammatical error correction using neural machine translation
Zheng Yuan and Ted Briscoe

Multimodal Semantic Learning from Child-Directed Input
Angeliki Lazaridou, Grzegorz Chrupała, Raquel Fernández and Marco Baroni

Recurrent Support Vector Machines For Slot Tagging In Spoken Language Understanding
Yangyang Shi, Kaisheng Yao, Hu Chen, Dong Yu, Yi-Cheng Pan and Mei-Yuh Hwang

Expectation-Regulated Neural Model for Event Mention Extraction
Ching-Yun Chang, Zhiyang Teng and Yue Zhang

Monday, June 13, 2016 (continued)

Monday, June 13, 2016 (continued)

Cross-lingual Wikification Using Multilingual Embeddings
Chen-Tse Tsai and Dan Roth

Deconstructing Complex Search Tasks: a Bayesian Nonparametric Approach for Extracting Sub-tasks
Rishabh Mehrotra, Prasanta Bhattacharya and Emine Yilmaz

6:00–8:00 ***System Demonstrations***

rstWeb - A Browser-based Annotation Interface for Rhetorical Structure Theory and Discourse Relations
Amir Zeldes

Instant Feedback for Increasing the Presence of Solutions in Peer Reviews
Huy Nguyen, Wenting Xiong and Diane Litman

Farasa: A Fast and Furious Segmenter for Arabic
Ahmed Abdelali, Kareem Darwish, Nadir Durrani and Hamdy Mubarak

iAppraise: A Manual Machine Translation Evaluation Environment Supporting Eye-tracking
Ahmed Abdelali, Nadir Durrani and Francisco Guzmán

Linguistica 5: Unsupervised Learning of Linguistic Structure
Jackson Lee and John Goldsmith

TransRead: Designing a Bilingual Reading Experience with Machine Translation Technologies
François Yvon, Yong Xu, Marianna Apidianaki, Clément Pillias and Pierre Cubaud

New Dimensions in Testimony Demonstration
Ron Artstein, Alesia Gainer, Kallirroi Georgila, Anton Leuski, Ari Shapiro and David Traum

ArgRewrite: A Web-based Revision Assistant for Argumentative Writings
Fan Zhang, Rebecca Hwa, Diane Litman and Homa B. Hashemi

Scaling Up Word Clustering
Jon Dehdari, Liling Tan and Josef van Genabith

Task Completion Platform
A self-serve multi-domain goal oriented dialogue platform: Paul Crook, Alex Marin, Vipul Agarwal, Khushboo Aggarwal, Tasos Anastasakos, Ravi Bikkula, Daniel Boies, Asli Celikyilmaz, Senthilkumar Chandramohan, Zhaleh Feizollahi, Roman Holenstein, Minwoo Jeong, Omar Khan, Young-Bum Kim, Elizabeth Krawczyk, Xiaohu Liu, Danko Panic, Vasiliy Radostev, Nikhil Ramesh, Jean-Phillipe Robichaud, Alexandre Rochette, Logan Stromberg and Ruhi Sarikaya

Student Workshop Posters

An End-to-end Approach to Learning Semantic Frames with Feedforward Neural Network
Yukun Feng, Yipei Xu and Dong Yu

Analogy-based detection of morphological and semantic relations with word embeddings
what works and what doesn't: Anna Gladkova, Aleksandr Drozd and Satoshi Matsuoka

Argument Identification in Chinese Editorials
Marisa Chow

Automatic tagging and retrieval of E-Commerce products based on visual features
Vasu Sharma and Harish Karnick

Combining syntactic patterns and Wikipedia's hierarchy of hyperlinks to extract relations: The case of meronymy extraction
Debela Tesfaye Gemechu, Michael Zock and Solomon Teferra

Cross-Lingual Question Answering Using Profile HMM & Unified Semantic Space
Amir Pouran Ben Veyseh

Data-driven Paraphrasing and Stylistic Harmonization
Gerold Hintz

Detecting "Smart" Spammers on Social Network
A Topic Model Approach: Linqing Liu, Yao Lu, Ye Luo, Renxian Zhang, Laurent Itti and Jianwei Lu

Developing language technology tools and resources for a resource-poor language: Sindhi
Raveesh Motlani

Tuesday, June 14, 2016

7:30–8:45 ***Breakfast, Pavilion***

9:00–10:30 ***Session 4***

4A. Semantic Parsing

9:00–9:20 *Transforming Dependency Structures to Logical Forms for Semantic Parsing [TACL]*
Siva Reddy, Oscar Täckström, Michael Collins, Tom Kwiatkowski, Dipanjan Das, Mark Steedman, and Mirella Lapata

9:20–9:40 *Imitation Learning of Agenda-based Semantic Parsers [TACL]*
Jonathan Berant and Percy Liang

9:40–10:00 *Probabilistic Models for Learning a Semantic Parser Lexicon*
Jayant Krishnamurthy

10:00–10:20 *Semantic Parsing of Ambiguous Input through Paraphrasing and Verification [TACL]*
Philip Arthur, Graham Neubig, Sakriani Sakti, Tomoki Toda, and Satoshi Nakamura

10:20–10:30 *Unsupervised Compound Splitting With Distributional Semantics Rivals Supervised Methods*
Martin Riedl and Chris Biemann

4B. Morphology and Phonology

9:00–9:20 *Weighting Finite-State Transductions With Neural Context*
Pushpendre Rastogi, Ryan Cotterell and Jason Eisner

9:20–9:40 *Morphological Inflection Generation Using Character Sequence to Sequence Learning*
Manaal Faruqui, Yulia Tsvetkov, Graham Neubig and Chris Dyer

9:40–10:00 *Towards Unsupervised and Language-independent Compound Splitting using Inflectional Morphological Transformations*
Patrick Ziering and Lonneke van der Plas

10:00–10:20 *Phonological Pun-derstanding*
Aaron Jaech, Rik Koncel-Kedziorski and Mari Ostendorf

10:20–10:30 *A Joint Model of Orthography and Morphological Segmentation*
Ryan Cotterell, Tim Vieira and Hinrich Schütze

4C. Various

9:00–9:20 *Syntactic Parsing of Web Queries with Question Intent*
Yuval Pinter, Roi Reichart and Idan Szpektor

9:20–9:40 *Visualizing and Understanding Neural Models in NLP*
Jiwei Li, Xinlei Chen, Eduard Hovy and Dan Jurafsky

9:40–10:00 *Bilingual Word Embeddings from Parallel and Non-parallel Corpora for Cross-Language Text Classification*
Aditya Mogadala and Achim Rettinger

10:00–10:20 *Joint Learning with Global Inference for Comment Classification in Community Question Answering*
Shafiq Joty, Lluís Màrquez and Preslav Nakov

10:20–10:30 *Weak Semi-Markov CRFs for Noun Phrase Chunking in Informal Text*
Aldrian Obaja Muis and Wei Lu

10:30–11:00 ***Coffee break, Pavilion***

11:00–12:30 ***Session 5***

Tuesday, June 14, 2016 (continued)

5A. Generation

11:00–11:20 *What to talk about and how? Selective Generation using LSTMs with Coarse-to-Fine Alignment*
Hongyuan Mei, Mohit Bansal and Matthew R. Walter

11:20–11:40 *Generation from Abstract Meaning Representation using Tree Transducers*
Jeffrey Flanigan, Chris Dyer, Noah A. Smith and Jaime Carbonell

11:40–12:00 *A Corpus and Semantic Parser for Multilingual Natural Language Querying of OpenStreetMap*
Carolin Haas and Stefan Riezler

12:00–12:20 *Natural Language Communication with Robots*
Yonatan Bisk, Deniz Yuret and Daniel Marcu

12:20–12:30 *Inter-document Contextual Language model*
Quan Hung Tran, Ingrid Zukerman and Gholamreza Haffari

5B. Sentiment

11:00–11:20 *Ultradense Word Embeddings by Orthogonal Transformation*
Sascha Rothe, Sebastian Ebert and Hinrich Schütze

11:20–11:40 *Separating Actor-View from Speaker-View Opinion Expressions using Linguistic Features*
Michael Wiegand, Marc Schulder and Josef Ruppenhofer

11:40–12:00 *Clustering for Simultaneous Extraction of Aspects and Features from Reviews*
Lu Chen, Justin Martineau, Doreen Cheng and Amit Sheth

12:00–12:20 *Opinion Holder and Target Extraction on Opinion Compounds – A Linguistic Approach*
Michael Wiegand, Christine Bocionek and Josef Ruppenhofer

12:20–12:30 *Capturing Reliable Fine-Grained Sentiment Associations by Crowdsourcing and Best–Worst Scaling*
Svetlana Kiritchenko and Saif M. Mohammad

5C. Knowledge Acquisition

11:00–11:20 *Concept Grounding to Multiple Knowledge Bases via Indirect Supervision [TACL]*
Chen-Tse Tsai and Dan Roth

11:20–11:40 *Mapping Verbs in Different Languages to Knowledge Base Relations using Web Text as Interlingua*
Derry Tanti Wijaya and Tom M. Mitchell

11:40–12:00 *Comparing Convolutional Neural Networks to Traditional Models for Slot Filling*
Heike Adel, Benjamin Roth and Hinrich Schütze

12:00–12:20 *A Corpus and Cloze Evaluation for Deeper Understanding of Commonsense Stories*
Nasrin Mostafazadeh, Nathanael Chambers, Xiaodong He, Devi Parikh, Dhruv Batra, Lucy Vanderwende, Pushmeet Kohli and James Allen

12:20–12:30 *Dynamic Entity Representation with Max-pooling Improves Machine Reading*
Sosuke Kobayashi, Ran Tian, Naoaki Okazaki and Kentaro Inui

12:30–1:15 ***Lunch***

1:15–2:15 ***Panel Discussion: How Will Deep Learning Change Computational Linguistics?***

2:30–3:30 ***Session 6***

6A. Machine Translation II

2:30–2:50 *Speed-Constrained Tuning for Statistical Machine Translation Using Bayesian Optimization*
Daniel Beck, Adrià de Gispert, Gonzalo Iglesias, Aurelien Waite and Bill Byrne

2:50–3:10 *Multi-Way, Multilingual Neural Machine Translation with a Shared Attention Mechanism*
Orhan Firat, Kyunghyun Cho and Yoshua Bengio

3:10–3:30 *Incorporating Structural Alignment Biases into an Attentional Neural Translation Model*
Trevor Cohn, Cong Duy Vu Hoang, Ekaterina Vymolova, Kaisheng Yao, Chris Dyer and Gholamreza Haffari

6B. Relation Extraction

2:30–2:50 *Multilingual Relation Extraction using Compositional Universal Schema*
Patrick Verga, David Belanger, Emma Strubell, Benjamin Roth and Andrew McCallum

2:50–3:10 *Effective Crowd Annotation for Relation Extraction*
Angli Liu, Stephen Soderland, Jonathan Bragg, Christopher H. Lin, Xiao Ling and Daniel S. Weld

3:10–3:30 *A Translation-Based Knowledge Graph Embedding Preserving Logical Property of Relations*
Hee-Geun Yoon, Hyun-Je Song, Seong-Bae Park and Se-Young Park

6C. Semantic Similarity

2:30–2:50 *DAG-Structured Long Short-Term Memory for Semantic Compositionality*
Xiaodan Zhu, Parinaz Sobhani and Hongyu Guo

2:50–3:10 *Bayesian Supervised Domain Adaptation for Short Text Similarity*
Md Arafat Sultan, Jordan Boyd-Graber and Tamara Sumner

3:10–3:30 *Pairwise Word Interaction Modeling with Deep Neural Networks for Semantic Similarity Measurement*
Hua He and Jimmy Lin

3:30–4:00 ***Break***

Tuesday, June 14, 2016 (continued)

4:00–5:00 ***Session 7***

7A. Machine Translation III

4:00–4:20 *An Attentional Model for Speech Translation Without Transcription*
Long Duong, Antonios Anastasopoulos, David Chiang, Steven Bird and Trevor Cohn

4:20–4:40 *Information Density and Quality Estimation Features as Translationese Indicators for Human Translation Classification*
Raphael Rubino, Ekaterina Lapshinova-Koltunski and Josef van Genabith

4:40–4:50 *Interpretese vs. Translationese: The Uniqueness of Human Strategies in Simultaneous Interpretation*
He He, Jordan Boyd-Graber and Hal Daumé III

4:50–5:00 *LSTM Neural Reordering Feature for Statistical Machine Translation*
Yiming Cui, Shijin Wang and Jianfeng Li

7B. Anaphora Resolution

4:00–4:20 *A Novel Approach to Dropped Pronoun Translation*
Longyue Wang, Zhaopeng Tu, Xiaojun Zhang, Hang Li, Andy Way and Qun Liu

4:20–4:40 *Learning Global Features for Coreference Resolution*
Sam Wiseman, Alexander M. Rush and Stuart M. Shieber

4:40–4:50 *Search Space Pruning: A Simple Solution for Better Coreference Resolvers*
Nafise Sadat Moosavi and Michael Strube

4:50–5:00 *Unsupervised Ranking Model for Entity Coreference Resolution*
Xuezhe Ma, Zhengzhong Liu and Eduard Hovy

7C. Word Embeddings I

4:00–4:20 *Embedding Lexical Features via Low-Rank Tensors*
Mo Yu, Mark Dredze, Raman Arora and Matthew R. Gormley

4:20–4:40 *The Role of Context Types and Dimensionality in Learning Word Embeddings*
Oren Melamud, David McClosky, Siddharth Patwardhan and Mohit Bansal

4:40–5:00 *Improve Chinese Word Embeddings by Exploiting Internal Structure*
Jian Xu, Jiawei Liu, Liangang Zhang, Zhengyu Li and Huanhuan Chen

5:00–5:15 ***Break***

5:15–6:00 ***One-Minute Madness***

6:00–8:00 ***Posters, Demos, and Snacks***

Posters

Assessing Relative Sentence Complexity using an Incremental CCG Parser
Bharat Ram Ambati, Siva Reddy and Mark Steedman

Frustratingly Easy Cross-Lingual Transfer for Transition-Based Dependency Parsing
Ophélie Lacroix, Lauriane Aufrant, Guillaume Wisniewski and François Yvon

Geolocation for Twitter: Timing Matters
Mark Dredze, Miles Osborne and Prabhanjan Kambadur

Fast and Easy Short Answer Grading with High Accuracy
Md Arafat Sultan, Cristobal Salazar and Tamara Sumner

Interlocking Phrases in Phrase-based Statistical Machine Translation
Ye Kyaw Thu, Andrew Finch and Eiichiro Sumita

Tuesday, June 14, 2016 (continued)

Eyes Don't Lie: Predicting Machine Translation Quality Using Eye Movement
Hassan Sajjad, Francisco Guzmán, Nadir Durrani, Ahmed Abdelali, Houda Bouamor, Irina Temnikova and Stephan Vogel

Making Dependency Labeling Simple, Fast and Accurate
Tianxiao Shen, Tao Lei and Regina Barzilay

Deep Lexical Segmentation and Syntactic Parsing in the Easy-First Dependency Framework
Matthieu Constant, Joseph Le Roux and Nadi Tomeh

Sentiment Composition of Words with Opposing Polarities
Svetlana Kiritchenko and Saif M. Mohammad

Learning to Recognize Ancillary Information for Automatic Paraphrase Identification
Simone Filice and Alessandro Moschitti

Learning a POS tagger for AAVE-like language
Anna Jørgensen, Dirk Hovy and Anders Søgaard

PIC a Different Word: A Simple Model for Lexical Substitution in Context
Stephen Roller and Katrin Erk

Bootstrapping Translation Detection and Sentence Extraction from Comparable Corpora
Kriste Krstovski and David Smith

Discriminative Reranking for Grammatical Error Correction with Statistical Machine Translation
Tomoya Mizumoto and Yuji Matsumoto

Patterns of Wisdom: Discourse-Level Style in Multi-Sentence Quotations
Kyle Booten and Marti A. Hearst

Right-truncatable Neural Word Embeddings
Jun Suzuki and Masaaki Nagata

MAWPS: A Math Word Problem Repository
Rik Koncel-Kedziorski, Subhro Roy, Aida Amini, Nate Kushman and Hannaneh Hajishirzi

Cross-genre Event Extraction with Knowledge Enrichment
Hao Li and Heng Ji

K-Embeddings: Learning Conceptual Embeddings for Words using Context
Thuy Vu and D. Stott Parker

Learning Composition Models for Phrase Embeddings [TACL]
Mo Yu and Mark Dredze

System Demonstrations

Illinois Math Solver: Math Reasoning on the Web
Subhro Roy and Dan Roth

LingoTurk: managing crowdsourced tasks for psycholinguistics
Florian Pusse, Asad Sayeed and Vera Demberg

Sentential Paraphrasing as Black-Box Machine Translation
Courtney Napoles, Chris Callison-Burch and Matt Post

A Tag-based English Math Word Problem Solver with Understanding, Reasoning and Explanation
Chao-Chun Liang, Kuang-Yi Hsu, Chien-Tsung Huang, Chung-Min Li, Shen-Yu Miao and Keh-Yih Su

Cross-media Event Extraction and Recommendation
Di Lu, Clare Voss, Fangbo Tao, Xiang Ren, Rachel Guan, Rostyslav Korolov, Tongtao Zhang, Dongang Wang, Hongzhi Li, Taylor Cassidy, Heng Ji, Shih-fu Chang, Jiawei Han, William Wallace, James Hendler, Mei Si and Lance Kaplan

SODA: Service Oriented Domain Adaptation Architecture for Microblog Categorization
Himanshu Sharad Bhatt, Sandipan Dandapat, Peddamuthu Balaji, Shourya Roy, Sharmistha Jat and Deepali Semwal

Lecture Translator - Speech translation framework for simultaneous lecture translation
Markus Müller, Thai Son Nguyen, Jan Niehues, Eunah Cho, Bastian Krüger, Thanh-Le Ha, Kevin Kilgour, Matthias Sperber, Mohammed Mediani, Sebastian Stüker and Alex Waibel

Zara The Supergirl: An Empathetic Personality Recognition System
Pascale Fung, Anik Dey, Farhad Bin Siddique, Ruixi Lin, Yang Yang, Yan Wan and Ho Yin Ricky Chan

Kathaa: A Visual Programming Framework for NLP Applications
Sharada Prasanna Mohanty, Nehal J Wani, Manish Srivastava and Dipti Misra Sharma

Why Should I Trust You?": Explaining the Predictions of Any Classifier
Marco Ribeiro, Sameer Singh and Carlos Guestrin

Student Workshop Posters

Effects of Communicative Pressures on Novice L2 Learners' Use of Optional Formal Devices
Yoav Binoun

Explicit Argument Identification for Discourse Parsing In Hindi: A Hybrid Pipeline
Rohit Jain and Dipti Sharma

Exploring Fine-Grained Emotion Detection in Tweets
Jasy Suet Yan Liew and Howard Turtle

Extraction of Bilingual Technical Terms for Chinese-Japanese Patent Translation
Wei Yang, Jinghui Yan and Yves Lepage

Hateful Symbols or Hateful People? Predictive Features for Hate Speech Detection on Twitter
Zeerak Waseem and Dirk Hovy

Non-decreasing Sub-modular Function for Comprehensible Summarization
Litton JKurisinkel, Pruthwik Mishra, Vigneshwaran Muralidaran, Vasudeva Varma and Dipti Misra Sharma

Phylogenetic simulations over constraint-based grammar formalisms
Andrew Lamont and Jonathan Washington

Question Answering over Knowledge Base using Weakly Supervised Memory Networks
Sarthak Jain

Using Related Languages to Enhance Statistical Language Models
Anna Currey, Alina Karakanta and Jon Dehdari

8:00–10:00 ***Bayview Lawn Beach Social***

Wednesday, June 15, 2016

7:30–8:45 ***Breakfast, Pavilion***

9:00–10:15 *Invited talk: "Human-based evaluations of language generation systems"*
Ehud Reiter

10:15–10:45 ***Coffee break, Pavilion***

10:45–12:15 ***Session 8***

8A. Question Answering

10:45–11:05 *A Joint Model for Answer Sentence Ranking and Answer Extraction [TACL]*
Md Arafat Sultan, Vittorio Castelli, and Radu Florian

11:05–11:25 *Convolutional Neural Networks vs. Convolution Kernels: Feature Engineering for Answer Sentence Reranking*
Kateryna Tymoshenko, Daniele Bonadiman and Alessandro Moschitti

11:25–11:45 *Semi-supervised Question Retrieval with Gated Convolutions*
Tao Lei, Hrishikesh Joshi, Regina Barzilay, Tommi Jaakkola, Kateryna Tymoshenko, Alessandro Moschitti and Lluís Màrquez

11:45–12:05 *Parsing Algebraic Word Problems into Equations [TACL]*
Rik Koncel-Kedziorski, Hannaneh Hajishirzi, Ashish Sabharwal, Oren Etzioni, and Siena Dumas Ang

12:05–12:15 *This is how we do it: Answer Reranking for Open-domain How Questions with Paragraph Vectors and Minimal Feature Engineering*
Dasha Bogdanova and Jennifer Foster

8B. Multilingual Processing

10:45–11:05 *Multilingual Language Processing From Bytes*
Dan Gillick, Cliff Brunk, Oriol Vinyals and Amarnag Subramanya

11:05–11:25 *Ten Pairs to Tag – Multilingual POS Tagging via Coarse Mapping between Embeddings*
Yuan Zhang, David Gaddy, Regina Barzilay and Tommi Jaakkola

11:25–11:45 *Part-of-Speech Tagging for Historical English*
Yi Yang and Jacob Eisenstein

11:45–12:05 *Statistical Modeling of Creole Genesis*
Yugo Murawaki

12:05–12:15 *Shallow Parsing Pipeline - Hindi-English Code-Mixed Social Media Text*
Arnav Sharma, Sakshi Gupta, Raveesh Motlani, Piyush Bansal, Manish Shrivastava, Radhika Mamidi and Dipti M. Sharma

8C. Word Embeddings II

10:45–11:05 *Bilingual Learning of Multi-sense Embeddings with Discrete Autoencoders*
Simon Šuster, Ivan Titov and Gertjan van Noord

11:05–11:25 *Polyglot Neural Language Models: A Case Study in Cross-Lingual Phonetic Representation Learning*
Yulia Tsvetkov, Sunayana Sitaram, Manaal Faruqui, Guillaume Lample, Patrick Littell, David Mortensen, Alan W Black, Lori Levin and Chris Dyer

11:25–11:45 *Learning Distributed Representations of Sentences from Unlabelled Data*
Felix Hill, Kyunghyun Cho and Anna Korhonen

11:45–12:05 *Learning to Understand Phrases by Embedding the Dictionary [TACL]*
Felix Hill, KyungHyun Cho, Anna Korhonen, and Yoshua Bengio

12:05–12:15 *Retrofitting Sense-Specific Word Vectors Using Parallel Text*
Allyson Ettinger, Philip Resnik and Marine Carpuat

12:15–1:00 ***Lunch***

1:00–2:00 ***NAACL business meeting, Grande Ballroom A***

2:15–3:45 ***Session 9***

9A. Argumentation and Discourse

2:15–2:35 *End-to-End Argumentation Mining in Student Essays*
Isaac Persing and Vincent Ng

2:35–2:55 *Cross-Domain Mining of Argumentative Text through Distant Supervision*
Khalid Al-Khatib, Henning Wachsmuth, Matthias Hagen, Jonas Köhler and Benno Stein

2:55–3:15 *A Study of the Impact of Persuasive Argumentation in Political Debates*
Amparo Elizabeth Cano-Basave and Yulan He

3:15–3:35 *Lexical Coherence Graph Modeling Using Word Embeddings*
Mohsen Mesgar and Michael Strube

3:35–3:45 *Using Context to Predict the Purpose of Argumentative Writing Revisions*
Fan Zhang and Diane Litman

9B. Misc Semantics

2:15–2:35 *Automatic Generation and Scoring of Positive Interpretations from Negated Statements*
Eduardo Blanco and Zahra Sarabi

2:35–2:55 *Learning Natural Language Inference with LSTM*
Shuohang Wang and Jing Jiang

2:55–3:15 *Activity Modeling in Email*
Ashequl Qadir, Michael Gamon, Patrick Pantel and Ahmed Hassan Awadallah

3:15–3:35 *Clustering Paraphrases by Word Sense*
Anne Cocos and Chris Callison-Burch

Wednesday, June 15, 2016 (continued)

3:35–3:45 *Unsupervised Learning of Prototypical Fillers for Implicit Semantic Role Labeling*
Niko Schenk and Christian Chiarcos

9C. Text Categorization

2:15–2:35 *Hierarchical Attention Networks for Document Classification*
Zichao Yang, Diyi Yang, Chris Dyer, Xiaodong He, Alex Smola and Eduard Hovy

2:35–2:55 *Dependency Based Embeddings for Sentence Classification Tasks*
Alexandros Komninos and Suresh Manandhar

2:55–3:15 *Deep LSTM based Feature Mapping for Query Classification*
Yangyang Shi, Kaisheng Yao, Le Tian and Daxin Jiang

3:15–3:35 *Dependency Sensitive Convolutional Neural Networks for Modeling Sentences and Documents*
Rui Zhang, Honglak Lee and Dragomir R. Radev

3:35–3:45 *MGNC-CNN: A Simple Approach to Exploiting Multiple Word Embeddings for Sentence Classification*
Ye Zhang, Stephen Roller and Byron C. Wallace

3:45–4:15 ***Coffee break, Pavilion***

4:15–5:45 ***Best paper awards***

4:15–4:35 *Improving sentence compression by learning to predict gaze*
Sigrid Klerke, Yoav Goldberg and Anders Søgaard

4:35–5:05 *Feuding Families and Former Friends: Unsupervised Learning for Dynamic Fictional Relationships*
Mohit Iyyer, Anupam Guha, Snigdha Chaturvedi, Jordan Boyd-Graber and Hal Daumé III

5:05–5:35 *Learning to Compose Neural Networks for Question Answering*
Jacob Andreas, Marcus Rohrbach, Trevor Darrell and Dan Klein

5:35–5:45 ***Closing remarks***

Achieving Accurate Conclusions in Evaluation of Automatic Machine Translation Metrics

Yvette Graham
School of Computing
Dublin City University
graham.yvette@gmail.com

Qun Liu
ADAPT Research Centre
Dublin City University
qliu@computing.dcu.ie

Abstract

Automatic Machine Translation metrics, such as BLEU, are widely used in empirical evaluation as a substitute for human assessment. Subsequently, the performance of a given metric is measured by its strength of correlation with human judgment. When a newly proposed metric achieves a stronger correlation over that of a baseline, it is important to take into account the uncertainty inherent in correlation point estimates prior to concluding improvements in metric performance. Confidence intervals for correlations with human judgment are rarely reported in metric evaluations, however, and when they have been reported, the most suitable methods have unfortunately not been applied. For example, incorrect assumptions about correlation sampling distributions made in past evaluations risk over-estimation of significant differences in metric performance. In this paper, we provide analysis of each of the issues that may lead to inaccuracies before providing detail of a method that overcomes previous challenges. Additionally, we propose a new method of translation sampling that in contrast achieves genuine high conclusivity in evaluation of the relative performance of metrics.

1 Introduction

In empirical evaluation of Machine Translation (MT), automatic metrics are widely used as a substitute for human assessment for the purpose of measuring differences in MT system performance. The performance of a newly proposed metric is itself measured by the degree to which its automatic scores for a sample of MT systems correlate with human assessment of that same set of systems. A main venue for evaluation of MT metrics is the annual Workshop for Statistical Machine Translation (WMT) (Bojar et al., 2015) where large-scale human evaluation takes place, primarily for the purpose of ranking systems competing in the translation shared task, but additionally to use the resulting system rankings for evaluation of automatic metrics. Since 2014, WMT has used the Pearson correlation as the official measure for evaluation of metrics (Macháček and Bojar, 2014; Stanojević et al., 2015). Comparison of the performance of any two metrics involves the comparison of two Pearson correlation point estimates computed over a sample of MT systems, therefore. Table 1 shows correlations with human assessment of each of the metrics participating in the Czech-to-English component of WMT-14 metrics shared task, and, for example, if we wish to compare the performance of the top-performing metric, REDSYSSENT (Wu et al., 2014), with the popular metric BLEU (Papineni et al., 2001), this involves comparison of the correlation point estimate of REDSYSSENT, $r = 0.993$, with the weaker correlation point estimate of BLEU, $r = 0.909$, with both computed with reference to human assessment of a sample of 5 MT systems.

When a new metric achieves a stronger correlation with human assessment over a baseline metric, such as the increase achieved by REDSYSSENT over BLEU, it is important to consider the uncertainty surrounding the difference in correlation. Confidence intervals are very rarely reported in metric evaluations, however, and when attempts have been made,

Table 1: WMT-14 Czech-to-English metrics shared task Pearson correlation (r) point estimates for metrics with human assessment (5 MT systems), reported confidence intervals (CI), and corresponding upper confidence limits (UCL).

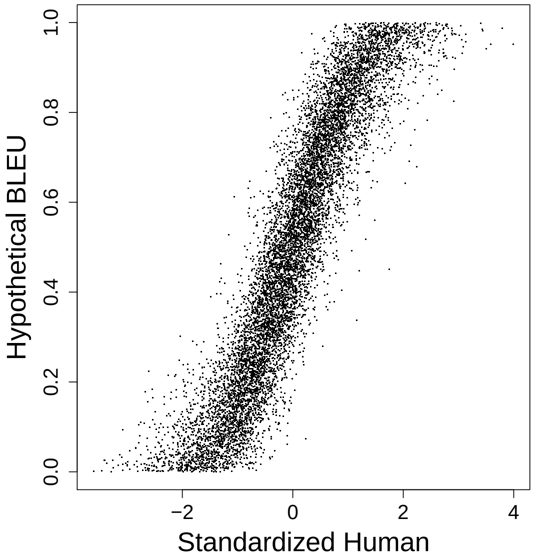

Figure 1: 10k simulated Bleu scores correlating with human assessment at $r = 0.91$ as in Bleu evaluation of Czech-to-English in WMT-14.

the most appropriate method has unfortunately not been applied. For example, although WMT constitutes a main authority on MT evaluation, and have made the best attempt to provide confidence intervals for metric correlations we could find, when we closely examine results of WMT-14 Czech-to-English metrics shared task, reproduced here in Table 1, a discrepancy can be identified. For the nine top-performing metrics participating in the shared task, upper confidence interval limits are reported to exceed 1.0.

Confidence intervals reported in the metrics shared task unfortunately also risk inaccurate conclusions about the relative performance of metrics for other less obvious reasons and risk conclusions that over-estimate the presence of significant differences. False-positives are problematic in metric evaluations because, if a given metric is mistakenly concluded to significantly outperform a competing metric, it is possible that had a larger sample of MT systems been employed in the evaluation, that the reverse conclusion should in fact be made. We demonstrate how this can occur for metrics, showing that in reality in current metric evaluation settings, it is only possible to identify a very small number of significant differences in performance. A main cause is the small number of MT systems employed in evaluations, and we propose a new sampling technique, hybrid super-sampling, that overcomes previous challenges and facilities the evaluation of metrics with reference to a practically unlimited number of MT systems.

2 WMT-style Evaluation

Alongside the correlation sample point estimates achieved by metrics, WMT reports confidence intervals for correlations that unfortunately risk over-estimation of significant differences in metric performance, reasons for which we outline below (Macháček and Bojar, 2013; Macháček and Bojar, 2014; Stanojević et al., 2015).

2.1 Sampling Distribution Assumptions

As shown in Table 1, confidence intervals are reported for metric correlations using ± notation. The use of the ± notation implies that the sampling distribution is symmetrical. Since the sampling distribution of the Pearson correlation, r, is skewed, however, this means that, for a non-zero correlation, it is not possible for the portion of the confidence interval that lies above the correlation sample point estimate and the portion that lies below it to be equal. Ad-

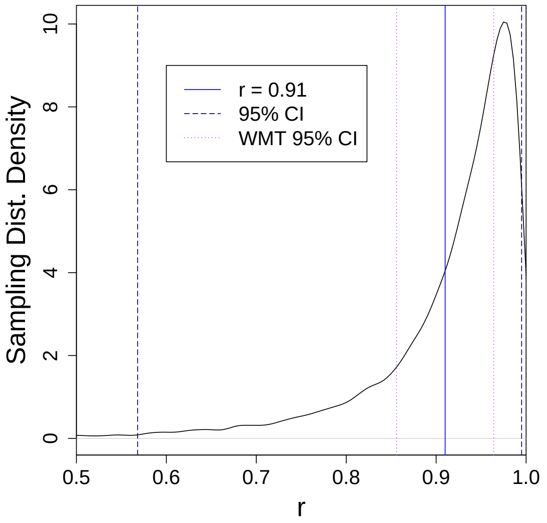

Figure 2: Sampling distribution of $r = 0.91$ and N = 5 for correlation of BLEU with human assessment for hypothetical "population" of MT systems in Figure 1.

ditionally, since the correlation sample statistic, r, cannot take on values greater than 1.0, the closer r is to 1.0 the more extreme the skew of its sampling distribution becomes.[1]

To demonstrate how the skew of the sampling distribution of r impacts on upper and lower confidence interval limits for metrics, in Figures 1 and 2, we simulate a possible population and sampling distribution for BLEU's correlation with human assessment, $r = 0.91$, achieved in WMT-14 Czech-to-English shared task, where the sample size, n, was 5 MT systems. Figure 1 depicts a hypothetical "population" of 10,000 MT systems and BLEU scores, where hypothetical BLEU scores for systems correspond with human assessment scores in such a way that a correlation of 0.91 is achieved. Figure 2 depicts the sampling distribution for r yielded by repeatedly drawing sets of 5 systems at random from the larger "population" of 10,000 systems, where the negative skew can be clearly observed. Figure 2 also depicts the 95% confidence interval (CI), within which 95% of sampled correlations lie, where the width of the lower portion of confidence interval is substantially wider than the upper portion, and the overly conservative confidence interval reported for BLEU in WMT-14, where upper and lower portions of the confidence interval are incorrectly assumed to be equal in size.

2.2 Application of Bootstrap Resampling

A conventional approach to bootstrap resampling for the purpose of computing confidence intervals for a correlation sample point estimate is to create a correlation coefficient pseudo-distribution by sampling (at random with replacement) human and automatic scores for n MT systems from the set of n systems for which we have genuine metric and human scores. Instead, however, reported confidence intervals are the result of creating pseudo-distributions of human assessment scores for systems. The method unfortunately does not produce accurate confidence intervals for correlation sample point estimates, as confidence intervals produced in this way can unfortunately only inform us about the certainty surrounding human assessment scores for systems rather than the more relevant question of the certainty surrounding the correlation point estimates achieved by metrics. Confidence intervals computed in this way are substantially narrower than confidence intervals computed using the standard Fisher r-to-z transformation, that can also be directly applied to correlations of metrics with human assessment without application of randomized methods.

Table 2[2] includes reported confidence intervals of metric correlations for English-to-Czech in WMT-15, and those computed using the standard Fisher r-to-z transformation, where confidence intervals of the latter are substantially wider. An extreme example occurs for metric DREEM, where the difference between its original reported lower confidence interval limit and the correlation point estimate is 0.006, more than 34 times narrower than that computed with the Fisher r-to-z transformation, 0.206.

2.3 Difference in Dependent Correlations

When reporting the outcome of an empirical evaluation, along with sample point estimates, such as the mean or, in the case of metrics, correlation, we only

[1] It should be noted that the assumption of symmetry of the sampling distribution of r is not explicitly made in any WMT report.

[2] WMT confidence intervals have been recomputed from the published data set to remove the previously described error with respect to the symmetry of r's sampling distribution.

ever have access to a *sample* of the actual data that would be needed to compute the corresponding true value for the *population*. Confidence intervals provide a way of estimating the range of values within which we believe with a specified degree of certainty that the corresponding true value lies. Generally speaking, they can also provide a mechanism for drawing conclusions about significant differences in sample statistics. If, for example, mean scores are used to measure system performance, and the confidence intervals of a pair of systems do not overlap, a significant difference in sample means and subsequently system performance can be concluded.

Although confidence intervals for individual correlations do provide an indication of the degree of certainty with which we should interpret reported correlation sample point estimates, they unfortunately cannot be used in the above described way to conclude significant differences in the performance of metrics, however. All we can gain from confidence intervals for *individual* correlations with respect to significance differences is the following: if the confidence interval of a correlation sample point estimate does not include zero, then it can be concluded (with a specified degree of certainty) that this *individual* correlation is significantly different from *zero*. Confidence intervals for individual metric correlations with human assessment do not inform us about the certainty surrounding a *difference* in correlation with human assessment, the relevant question for comparing performance of competing MT metrics.

When computing confidence intervals for a difference in correlation, it is important to consider the nature of the data. For MT metric evaluation, data used to compute correlation point estimates for a given pair of metrics is *dependent*, as it includes three variables (Human, Metric$_a$, Metric$_b$), and, for each MT system that is a member of the sample, there is a value corresponding to each of these three variables. Besides the two correlations we are interested in comparing, r(Human, Metric$_a$) and r(Human, Metric$_b$), there is a third correlation to consider, therefore, the correlation that exists directly between the metric scores themselves, r(Metric$_a$, Metric$_b$). Graham and Baldwin (2014) provide detail of Williams test, a test of significance of a difference in *dependent* correlations, suitable for evaluation of MT metrics. Confidence intervals are more informative than the binary conclusions that can be inferred from p-values produced by significance tests, however, and Zou (2007) presents a method of constructing confidence intervals for differences in *dependent* correlations also suitable for evaluation of MT metrics. We provide an implementation of Zou (2007) tailored to metric evaluation at `https://github.com/ygraham/MT-metric-confidence-intervals`.

Table 3 includes confidence intervals for differences in dependent correlations (Zou, 2007) for the seven top-performing German-to-English metrics in WMT-15. Besides providing an indication of the degree of certainty surrounding a given difference in correlation for a pair of metrics, confidence intervals that do not include *zero* can now be used to infer a significant difference in performance for a pair of metrics. For example, the 95% confidence interval for the difference in correlation between the top-performing metric, UpfCobalt (r = 0.981) and MeteorWsd (r = 0.953), [0.005, 0.123], in Table 3, does not include zero and subsequently implies a significant difference in performance.

Figure 3 depicts the contrast in conclusions for

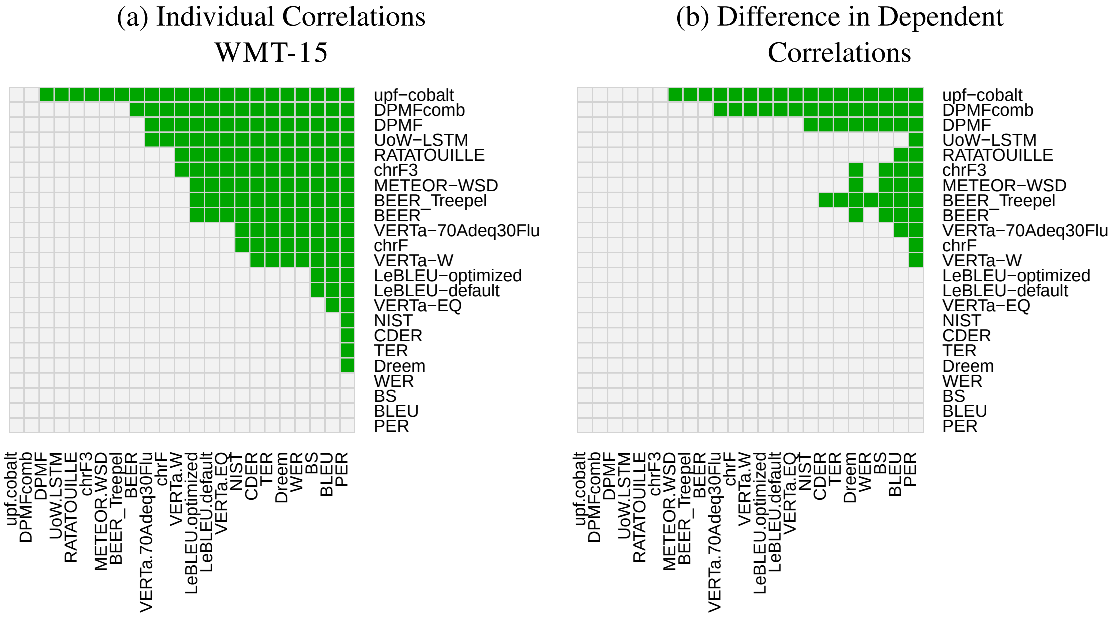
Table 3: Pairwise 95% confidence intervals for differences in correlation for seven top-performing metrics for German-to-English in WMT-15 (13 MT systems), confidence intervals not including zero imply a significant difference and are highlighted in bold.



(a) Individual Correlations WMT-15

(b) Difference in Dependent Correlations

Figure 3: Conclusions of significant differences in correlation for WMT-15 German-to-English metrics (13 MT systems) drawn from the (a) non-overlap of individual correlation confidence intervals originally reported in WMT and from (b) confidence intervals of a difference in dependent correlations not including zero, green cells imply a significant win for the metric in that row over the metric in that column.

WMT-15 German-to-English metrics drawn from (a) a likely interpretation of confidence intervals originally reported in WMT, where the non-overlap of individual correlation confidence intervals of a pair of metrics is used to infer a significant difference, and (b) those drawn from the non-overlap of confidence intervals for differences in dependent correlations with zero (Zou, 2007), highlighting the over-estimation of significant differences in metric performance risked by current WMT confidence intervals. For example, for German-to-English with interpretation (a) a total of 91 significant differences are implied that are not identified according to our corresponding approach. For instance, the non-overlap of confidence intervals of the top-performing metric, UPFCOBALT, with those of all but one other metrics in the original report risks the interpretation of a significant increase in performance for that metric with all but one other competing metrics, but with the more appropriate method of Zou (2007), however, confidence intervals of this metric's difference in correlation with four of those competing metrics in fact include zero, with no significant difference identified. It is worth noting that original WMT reports *do not* state that the confidence intervals they provide *should* be interpreted in the way we have done here, where the non-overlap of individual correlation confidence intervals of a pair of metrics implies a significant difference, but this is nonetheless a very likely interpretation.

3 Accurate and Conclusive Metric Evaluations

Results of past metric evaluations have been highly inconclusive with relatively few significant differences in performance possible to identify for metrics.[3] The lack of conclusivity in metric evaluations is mainly caused by the small number of systems used to evaluate metrics. For example, in the original experiments used to justify the use of automatic metric BLEU, reported correlations with human assessment were for a sample size of as small as 5, comprising three automatic systems and two human translators (Papineni et al., 2001). WMT have improved on this for some language pairs at least, as in the past four evaluations sample sizes have ranged from 5 (Czech-to-English WMT-14) to 22 systems (German-to-English WMT-12/WMT-13). Even at the maximum sample size of 22 systems, however, correlation point estimates are computed with a high degree of uncertainty.

3.1 Hybrid Super-Sampling

In an ideal world, MT metric evaluations would employ a much larger sample of systems than those relied upon in past evaluations, subsequently yielding correlation sample point estimates that can be relied on with more certainty. Although not immediately obvious, data sets currently used to evaluate MT metrics potentially contain data for a very large number of systems. If we consider the fact that, given the output of as little as two MT systems, there exists a very large number of possible ways of combining their translated segments to form a hybrid system, this opens up the evaluation of metrics to a vastly larger pool of systems. For example, even if we restrict the creation of hybrid systems to combinations of *pairs* of the n MT systems competing in a translation shared task (as opposed to hybrids created by sampling translations from *several* different MT systems at once), the number of potential hybrid systems is exponential in size of the test set, m:

$$n(n-1)/2 \cdot 2^m \tag{1}$$

For instance, even for a language pair for which human scores are available for as few as 5 MT systems, by *super-sampling* translations from every pair of competing systems, this results in 10 x $2^{3,000}$ hybrid systems. Including all possible hybrid systems is of course not necessary, and to make the approach feasible, we sample a large but manageable subset of 10,000 MT systems.

Obtaining automatic metric scores for this larger number of MT systems is feasible for any metric that is expected to be useful in practice, since automatic metrics must already be highly efficient to be used for optimizing systems. Obtaining human assessment of this large set of hybrid systems may seem

[3] Due to space limitations, it was only possible to include confidence intervals for differences in correlation for a subset of German-to-English WMT-15 metrics (Figure 3). Confidence intervals for the the remaining metrics and language pairs are available at `https://github.com/ygraham/MT-metric-confidence-intervals` for which very few significant differences in performance are identified.

		12 Systems		10k Systems

Table 4: Correlations and confidence intervals of pseudo document-level metrics (averaged segment-level metrics) with human assessment evaluated on original 12 MT systems and 10k hybrid super-sample (WMT-12 Spanish-to-English). Metrics with a different rank order in the original sample and hybrid super-sample evaluations are marked with • and confidence intervals that do not include zero are in bold.

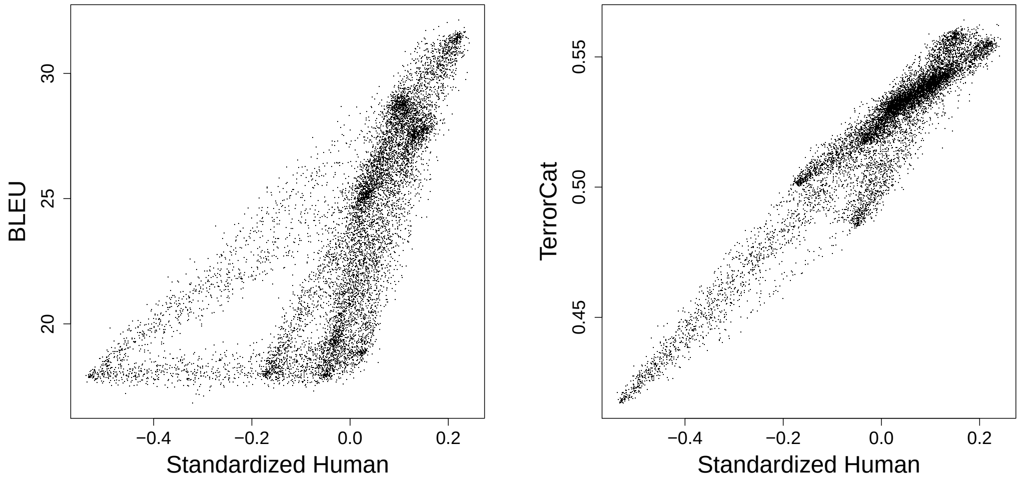

Figure 4: Human, TerrorCat and Bleu scores for 10k super-sampled hybrid MT systems for WMT-12 Spanish-to-English.

more challenging, but the method of human evaluation we employ facilitates the straight-forward computation of human scores for vast numbers of systems directly from the original human evaluation of only n systems. Graham et al. (2013) provide a human evaluation of MT that elicits adequacy assessments of translations, independent of other translations on a fine-grained 100-point rating scale. After score standardization to iron-out differences in individual human assessor scoring strategies, the overall human score for a MT system is simply computed as the mean of the ratings attributed to its translations, and this facilitates the straight-forward computation of a human score for any hybrid system from the original human evaluation of n systems.

To demonstrate, we replicate a previous year's WMT metrics shared task, constructing a hybrid super-sample of 10,000 MT systems each with a corresponding metric and human score. Since we do not have access to all document-level metrics that participated in the original shared task, we use segment-level metric scores as *pseudo document-level metrics* by taking the average of segment-level scores of the segments that comprise the test set document. This allows retrospective computation of automatic metric scores for the large set of 10k hybrid MT systems. For the purpose of comparison, in addition to averaged segment-level metrics, we also include document-level BLEU and an analysis of the correlation it achieves in the context of hybrid super-sampling. Human evaluation scores were computed using the mean of a minimum of 1,500 crowd-sourced human ratings per system, where strict quality-controlling of crowd-sourced workers was applied.

Table 4 shows correlations achieved by metrics when evaluated on the original 12 and 10k systems, as well as confidence intervals of the difference in correlation achieved by each metric with that of the next best performing metric in each case.[4] As expected, confidence intervals for differences in correlation are substantially reduced for the larger sample of metrics. Importantly, the change in rank order of metrics when evaluated with reference to a sample of 10k MT systems, as opposed to 12, highlights the risk of concluding an increase in performance from evaluations that include only a small sample of systems.

Figure 4 plots super-sampled human and automatic metric scores for BLEU providing insight into how BLEU scores correspond with human assessment. Worryingly for the range of systems with scores below 20 BLEU points, the plot shows an almost horizontal band of systems spread across a wide range of quality according to human assessors despite extremely similar BLEU scores. The top-performing automatic metric, TERRORCAT, on the other hand, impressively sustains its high correlation with human assessment when evaluated on as many as 10k MT systems, evidence that this metric is indeed highly consistent with human assessment of Spanish-to-English.

Due to space limitations, it is not possible to include pairwise confidence intervals for all pairs of metrics, and instead we include in Figure 5 a heatmap of significant differences in performance, where a significant win is inferred for the metric in a given row over the metric in a given column if the confidence interval of the difference in correlation for that pair did not include zero. Results show the super-sampled evaluation facilitates not only the identification of an outright best-performing metric, TERRORCAT, it also yields an almost total-order ranking of metrics, as significant differences are possible to identify for all but one pairs of competing metrics. Finally, we repeated the metric evaluation with ten distinct super-samples of 10k MT systems with all replications resulting in precisely the same ranking of metrics as shown in Table 4.

4 Conclusion

Analysis of evaluation methodologies applied to automatic MT metrics was provided and the risk of over-estimation of significant differences in metric performance identified. Confidence intervals for differences in dependent correlations were recommended as appropriate for evaluation of MT metrics. Hybrid super-sampling was proposed, evaluating metrics with reference to a substantially larger sample of MT systems, achieving genuinely highly conclusive metric rankings.

[4] It should be noted, since participating teams did not intend segment-level metric scores to be averaged as we have done here, correlations are for demonstrative purposes and do not reflect performance of participating teams.

Abstract

A major benefit of tree-to-tree over tree-to-string translation is that we can use target-side syntax to improve reordering. While this is relatively simple for binarized constituency parses, the reordering problem is considerably harder for dependency parses, in which words can have arbitrarily many children. Previous approaches have tackled this problem by restricting grammar rules, reducing the expressive power of the translation model.

In this paper we propose a general model for dependency tree-to-tree reordering based on flexible non-terminals that can compactly encode multiple insertion positions. We explore how insertion positions can be selected even in cases where rules do not entirely cover the children of input sentence words. The proposed method greatly improves the flexibility of translation rules at the cost of only a 30% increase in decoding time, and we demonstrate a 1.2–1.9 BLEU improvement over a strong tree-to-tree baseline.

1 Introduction

Translation is most commonly performed by splitting an input sentence into manageable parts, translating these segments, then arranging them in an appropriate order. The first two steps have roughly the same difficulty for close and distant language pairs, however the reordering step is considerably more challenging for language pairs with dissimilar syntax. We need to be able to make linguistic generalizations, such as learning to translate between SVO and SOV clauses and converting post-modifying prepositional and pre-modifying postpositional phrases (Quirk et al., 2005). Such generalizations often require syntactically motivated long-distance reordering.

The first approaches to reordering were based on linear distortion (Koehn et al., 2003), which models the probability of swapping pairs of phrases over some given distance. The linear distance is the only parameter, ignoring any contextual information, however this model has been shown to work well for string-to-string translation. Linear reordering was improved with lexical distortion (Tillmann, 2004), which characterizes reordering in terms of type (monotone, swap, or discontinuous) as opposed to distance. This approach however is prone to sparsity problems, in particular for distant language pairs.

In order to improve upon linear string-based approaches, syntax-based approaches have also been proposed. Tree-to-string translation has been the most popular syntax-based paradigm in recent years, which is reflected by a number of reordering approaches considering source-only syntax (Liu et al., 2006; Neubig, 2013). One particularly interesting approach is to project source dependency parses to the target side and then learn a probability model for reordering children using features such as source and target head words (Quirk et al., 2005).

While tree-to-tree translation (Graehl and

Proceedings of NAACL-HLT 2016, pages 11–19,

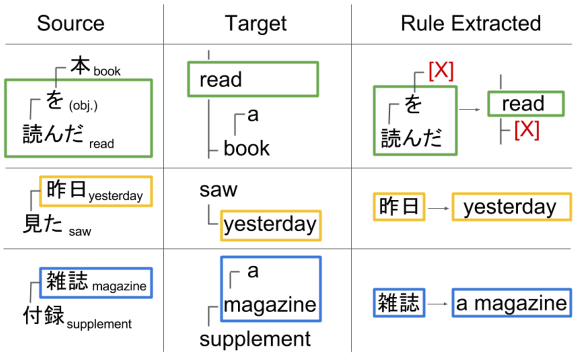

Figure 1: Examples of tree-to-tree translation rules extracted from an aligned and parsed bitext. Colored boxes represent aligned phrases and [X] is a non-terminal.

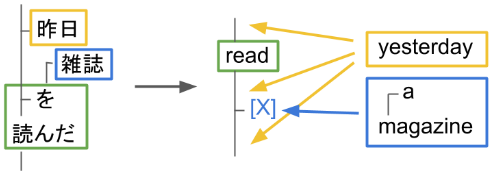

Figure 2: Combination of translation rules, demonstrating non-terminal substitution and multiple possible insertion positions for a non-matching input phrase (‘昨日’).

Knight, 2004; Cowan and Collins, 2006; Chiang, 2010) has been somewhat less popular than tree-to-string translation, we believe there are many benefits of considering target-side syntax. In particular, reordering can be defined naturally with non-terminals in the target-side grammar. This is relatively simple when the target structure of rules is restricted to ‘well-formed’ dependencies (Shen et al., 2008), however in this paper we consider more general rules with flexible non-terminal insertion positions.

2 Dependency Tree-To-Tree Translation

Dependency tree-to-tree translation begins with the extraction of translation rules from a bilingual corpus that has been parsed and word aligned. Figure 1 shows an example of three rules that can be extracted from aligned and parsed sentence pairs. In this paper we consider rules similar to previous work on tree-to-tree dependency MT (Richardson et al., 2014).

The simplest type of rule, containing only terminal symbols, can be extracted trivially from aligned subtrees (see rules 2 and 3 in Figure 1). Non-terminals can be added to rules (see rule 1 in Figure 1) by omitting aligned subtrees and replacing on each side with non-terminal symbols. We can naturally express phrase reordering as the source/target-side non-terminals are aligned.

Decoding is performed by combining these rules to form a complete translation, as shown in Figure 2. We are able to translate part of the sentence with non-ambiguous reordering (‘read a magazine’), as we can insert ‘雑誌 → a magazine’ into the rule ‘[X] を 読んだ → read [X]’.

We cannot however decide clearly where to insert the rule ‘昨日 → yesterday’ as there is no matching non-terminal in the rule containing its parent in the input sentence (‘読んだ’). We use the term *floating* to describe words such as ‘yesterday’ in this example, i.e. for an input subtree matched to the source side of a rule, children of the input root that are not contained in the source side of the rule as terminals and cannot be inserted using fixed-position non-terminals in the rule.

Previous work deals with this problem by either using simple glue rules (Chiang, 2005) or limiting rules in a way to avoid isolated floating children (Shen et al., 2008). For example, it is possible to disallow the first rule in Figure 1 when translating a sentence such as that in Figure 2 with uncovered children (in this case the word ‘yesterday’). This method greatly reduces the expressiveness and flexibility of translation rules.

In our generalized model, we allow any number of terminals and non-terminals and permit arbitrarily many floating children in each rule. To our knowledge this is the first study to take this more comprehensive approach.

Note that in the case of constituency-based tree-to-tree translation it is possible to binarize the input tree and therefore gluing floating children becomes simpler, as we only have to choose between pre-insertion and post-insertion. In the dependency case it is in general much more dif-

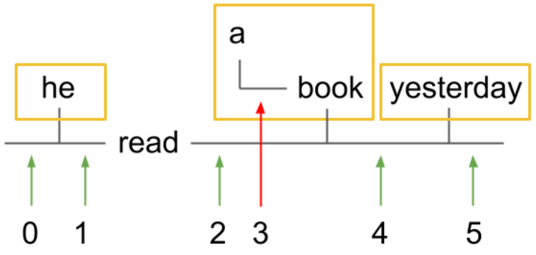

Figure 3: Possible insertion positions for flexible non-terminals with target-side head 'read'. Allowed positions are shown in green and disallowed positions are shown in red. We do not allow insertion position 3 because it could allow a non-projective dependency structure.

ficult because we must order an arbitrarily large group of children sharing a common head.

3 Flexible Non-Terminals

In this paper we propose flexible non-terminals in order to create generalized tree-to-tree translation rules that can overcome the problems described in the previous section. Rather than fixed insertion positions for child nodes, we instead consider multiple possible insertion positions and give features to each position. These are stored in a compact representation allowing for efficient decoding.

We define *flexible non-terminals* as non-terminals with multiple possible insertion positions and associated features. During decoding we select the most promising insertion position for each non-terminal.

3.1 Rule Augmentation

As is standard practice in phrase-based SMT, before translation we filter translation rules to those relevant to the input sentence. At this time, for each accepted rule we check the input sentence for floating children, and flexible non-terminals are added for each floating child.

We allow all insertion positions between the children (along with their descendants) of the target-side head for each floating child, including insertion before the first child and after the last child. We do not allow insertion positions between deeper descendants of the head to avoid non-projective dependencies. See Figure 3 for an example of allowed/disallowed positions.

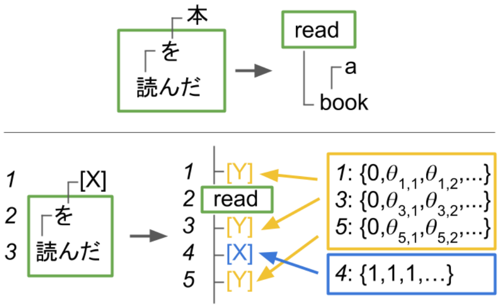

Figure 4: Example of translation rule with flexible non-terminals generated from the first parallel sentence in Figure 1. [X] has a fixed position (4) but [Y] can have multiple positions (1, 3, 5). Each position has an associated set of features shown in curly brackets, where $\theta_{i,j}$ is the jth feature for insertion position i. The first feature (0 or 1) shows whether the insertion position is unambiguous.

Features are then set for each insertion position and these are used to determine the best insertion position during decoding (see Section 3.2). Figure 4 shows an example of the proposed rule augmentation.

3.2 Features

In previous work reordering is mostly decided by the combination of a standard distortion model and language model to score possible insertion positions. We instead consider the following four features and combine them during decoding to find the most appropriate insertion positions for floating children. All features are real numbers between 0 and 1.

3.2.1 Insertion Position Features

We first define a set of features to estimate the likelihood of each insertion position for some given non-terminal. The features for inserting the translation f of a source phrase into the target-side e of a rule at insertion position i are defined as follows, for surface forms (S) and POS tags (P):

- Reordering probability:
  $P_S(i \mid f, e)$, $P_P(i \mid f, e)$

- Marginalized over target-side:
  $P_S(i \mid f)$, $P_P(i \mid f)$
- Marginalized over source-side:
  $P_S(i \mid e)$, $P_P(i \mid e)$

The probabilities $P(i \mid X)$ are calculated by counting insertions of X in each position i across the whole training corpus (aligned and parsed bitext). The exact formula is given below, for position i (X is one of $\{f\}$, $\{e\}$ or $\{f, e\}$):

$$P(i \mid X) = \frac{count(i, X)}{\sum_j count(j, X)} \qquad (1)$$

Instead of applying smoothing, in order to reduce sparsity issues we use both the full probability $P(i \mid f, e)$ and also probabilities marginalized over the source/target phrases. We also consider both probabilities trained on surface forms (S) and POS tags (P).

While traditional models use linear distance for i, this is impractical for long-distance reordering. Instead we restrict insertion types i to one of the following 6 types: first-pre-child, mid-pre-child, final-pre-child, first-post-child, mid-post-child, and final-post-child. These correspond to the first (first), last (final) or central (mid) children on the left (pre) or right (post) side of the parent word. We found this was more effective than using either linear distance or a binary (pre/post) position type.

3.2.2 Relative Position Feature

We also consider a relative position, or 'swapping' feature, inspired by the swap operation of classic lexical distortion (Tillmann, 2004).

Let T be the children of the root word of the target-side of a rule. We also include in T a pseudo-token M splitting the left and right children of the target-side root to differentiate between pre-insertion and post-insertion.

We first learn a model describing the probability of the translation of input phrase I appearing to the left ($P_L(I, t)$) or right ($P_R(I, t)$) of word t in the target-side of a translation rule. The probabilities are calculated by counting occurrences of I being translated to the left/right sides of t over the aligned and parsed training bitext.

The relative position feature is calculated by considering the relative position of the translation of I with all the target-side root children T. For each insertion position i, let $T_{i,L}$ be the $t \in T$ to the left of position i and $T_{i,R}$ the $t \in T$ to the right of position i. Then we have:

$$P(i \mid I, T) = \prod_{t \in T_{i,R}} P_L(I, t) \prod_{t \in T_{i,L}} P_R(I, t) \qquad (2)$$

3.2.3 Left/Right Attachment Preference

We also set an attachment direction preference feature for each rule, specifying whether we prefer to insert the rule as a left child or right child of the root of a parent rule.

The attachment preference is determined by the position of the target-side of the rule in the target-side of the parallel sentence from which it was extracted. For example, in Figure 1 the rule '昨日 → yesterday' was extracted from a parallel sentence in which 'yesterday' was a right-side child of its head ('saw'), so we set the attachment preference to 'right'. In cases when we cannot determine the attachment preference (for example 'read' in the first rule in Figure 1), because it is the sentence root), we arbitrarily choose 'right'.

3.2.4 Unambiguous Insertion Preference

In cases where we have a single unambiguous insertion position for a non-terminal (e.g. [X] in Figure 4), we set an additional binary feature to the value 1 (otherwise 0) to specify that this position is unambiguous. We found that a large positive weight is almost always given to this feature, which is to be expected as we would prefer to use fixed non-terminals if possible. We set all features related to insertion position choice to the maximum value (1).

3.3 Decoding

The flexible non-terminals that we are proposing can lead to some interesting challenges when it comes to decoding. A naive approach is to expand each translation rule containing flexible non-terminals into a set of 'simple' rules with fixed non-terminals, and then apply classic decoding with cube-pruning.

However, this can be quite inefficient in practice. Due to the combinatorial aspect, a single rule can expand into a very large number of simple rules. It is common for our translation rules to have more than four flexible non-terminals, each with more than four possible insertion positions. Such rules will already generate hundreds of simple rules. In the most extreme cases, we may encounter rules having more than ten flexible non-terminals, leading to the generation of many millions of simple rules. This explosion of rules can lead to impractical decoding time and memory usage.

It is therefore important to make use of the compact encoding of many simple rules provided by the concept of flexible non-terminals in the decoding process itself. We use the decoding approach of right-hand lattices (Cromières and Kurohashi, 2014), an efficient way of encoding many simple rules. The idea is to encode the translation rules into a lattice form, then use this lattice to decode efficiently without the need to expand the flexible non-terminals explicitly.

Figure 5 shows how the concept of flexible non-terminals can be efficiently encoded into lattice form. The top half shows a target-side tree translation rule with flexible non-terminals X1, X2, X3 and X4 allowed to be inserted at any position that is a child of the word ‘a’, with the constraint that X1 comes before X2 and that X2 comes before X3. X5 is another flexible non-terminal that will be a child of the word ‘f’. The lower half shows a lattice compactly encoding all the possible combinations of non-terminal positions. Each path from the top-left to the bottom right in this lattice represents a choice for the insertion positions of the non-terminals. For example, the path marked with a dotted line represents the flattened sequence ‘b c X1 X2 a X3 X4 d e f X5 g’. The lattice form has only 48 edges, while an explicit enumeration of all combinations of insertion positions for the flexible non-terminals would force the decoder to consider ${}^{8}C_4 \times 3 \times 12 = 2520$ edges.

The insertion position features described above are added to the edges of the lattice. They are combined alongside the standard set of features, such as word penalty and language model score, using a standard log-linear model. The weights for the reordering features are tuned together with the standard features.

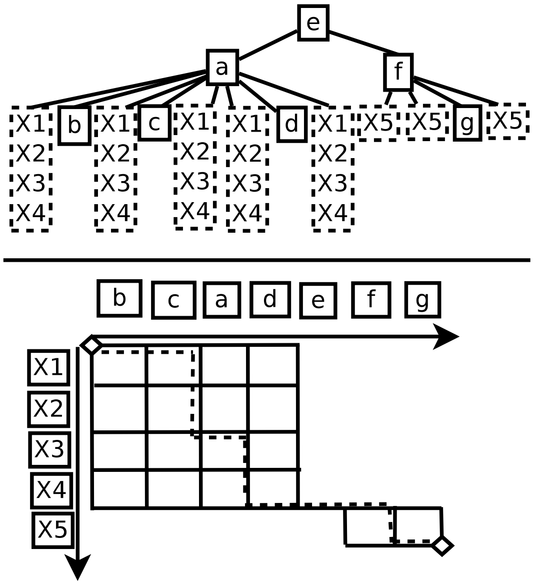

Figure 5: Example showing how a rule containing many flexible non-terminals is encoded into lattice form for decoding.

4 Experiments

4.1 Data and Settings

We performed translation experiments on four distant language pairs, Japanese–English (JA–EN), English–Japanese (EN–JA), Japanese–Chinese (JA–ZH) and Chinese–Japanese (ZH–JA), from the Asian Scientific Paper Excerpt Corpus (ASPEC)[1]. The data was split into training, development and test folds as shown in Table 1.

Our experiments were conducted using a state-of-the-art dependency tree-to-tree framework KyotoEBMT (Richardson et al., 2014).

Table 2: Automatic evaluation of translation quality (BLEU and RIBES). Results marked with † are significantly higher than the baseline system and those marked with ‡ are significantly higher than the proposed system with no insertion position features (‘Flexible’). Significance was calculated with bootstrapping for $p < 0.05$.

Experiments were performed with the default settings by adding the proposed non-terminal reordering features to the rules extracted with the baseline system. We used lattice-based decoding (Cromières and Kurohashi, 2014) to support multiple non-terminal insertion positions and default tuning using, k-best MIRA (Cherry and Foster, 2012). Dependency parsing was performed with: KNP (Kawahara and Kurohashi, 2006) (Japanese), SKP (Shen et al., 2012) (Chinese), NLParser (Charniak and Johnson, 2005) (English, converted to dependencies with hand-written rules). Alignment was performed with Nile (Riesa et al., 2011) and we used a 5-gram language model with modified Kneser-Ney smoothing built with KenLM (Heafield, 2011).

4.2 Evaluation

As our baseline (‘Baseline’), we used the default tree-to-tree settings and features of KyotoEBMT, allowing only fixed-position non-terminals. We dealt with floating children not covered by any other rules by adding glue rules similar to those in hierarchical SMT (Chiang, 2005), joining floating children to the rightmost slots in the target-side parent. For reference, we also show results using Moses (Koehn et al., 2007) with default settings and distortion limit set to 20 (‘Moses’).

The proposed system (‘Flexible’) adds flexible non-terminals with multiple insertion positions, however we do not yet add the insertion choice features. This means that the insertion positions are in practice chosen by the language model. Note that we do not get a substantial hit in performance by adding the flexible non-terminals because of their compact lattice representation. The systems ‘+Pref’, ‘+Pref+Ins’ and ‘+Pref+Ins+Rel’ show the results of adding insertion choice position features (left/right preference, insertion position choice, relative position choice).

We give translation scores measured in BLEU (Papineni et al., 2002) and RIBES (Isozaki et al., 2010), which is designed to reflect quality of translation word order more effectively than BLEU. The translation evaluation is shown in Table 2.

5 Discussion and Error Analysis

The experimental results showed a significantly positive improvement in terms of both BLEU and RIBES over the baseline tree-to-tree system. The baseline system uses fixed non-terminals and is competitive with the most popular string-to-string system (Moses).

The extensions of the proposed model (adding a variety of features) also all showed significant improvement over the baseline, and approximately half of the extended settings performed significantly better than the core proposed model. It is unclear however which of the extended settings is the most effective for all language pairs. There are a number of factors such as parse quality, corpus size and out-of-vocabulary occurrence that could affect the potential value of these features. Furthermore, Japanese is strongly left-branching (head-final), so the left/right preference distinction is likely to be less useful than for English and Chinese, which contain both left-branching and right-branching structures.

Compared to the baseline, the flexible non-terminals gave around a 1.2–1.9 BLEU improvement at the cost of only a 30% increase in decoding time (approximately 2.04 vs. 2.66 seconds per sentence). This is made possible by the compact non-terminal representation combined with lattice decoding.

5.1 Non-Terminal Matching Analysis

We found that roughly half of all our translation rules were augmented with flexible non-terminals, with one flexible non-terminal added per rule on average. This led to roughly half of non-terminals having flexible insertion positions. The decoder chose to use ambiguous insertion positions between 30%–60% of the time (depending on language pair), allowing for many more new translation hypotheses than the baseline system. For detailed results, see Table 3.

5.2 Translation Examples

The following translation is an example of an improvement achieved by using the proposed flexible non-terminals. There were multiple word order errors in the baseline translation that impeded understanding, and these have all been corrected.

- **Input:** 磁場入口と出口の温度差により生ずる磁性流体の圧力差と流速を測定した。
- **Reference:** The pressure difference and the flow velocity of the magnetized fluid caused by the temperature difference between the inlet and outlet of the magnetic field were measured.
- **Baseline:** We have measured the pressure difference and flow rate of a magnetic fluid generated by an entrance of a magnet and an exit temperature, and the difference between.
- **Proposed:** The pressure difference and the flow rate of a magnetic fluid generated by the temperature difference between the magnetic field inlet and exit were measured.

There are also cases where the proposed model decreases translation quality. In the example below, the proposed system output was selected by the decoder since it had a higher language model score than the baseline output, despite having incorrect word order. The incorrect translation was made available by the increased flexibility of the proposed model, and selected because the LM feature had a higher impact than the insertion position features.

- **Input:** このソフトウエアのR5バージョンの特徴，利用マニュアルと設計文書をまとめた。
- **Reference:** The characteristics of R5 version of this software, instruction manual, and design document were summarized.
- **Baseline:** The R5 version of this software features, the manual for the utilization and design documents are summarized.
- **Proposed:** This software design documents of R5 version features, the manual for the utilization and summarized.

6 Conclusion and Future Work

In this paper we have proposed flexible non-terminals for dependency tree-to-tree translation. We plan to continue working on feature design for insertion position choice, and in the future would like to consider using neural networks for learning these features. We believe that it is important to continue to explore approaches that exploit more general target-side syntax, faithful to the tree-to-tree translation paradigm.

Flexible non-terminals allow multiple insertion positions to be expressed compactly and selected with features based on both source and target syntax. We have shown that a significant improvement in BLEU and RIBES scores can be gained by using the proposed model to increase the generality of dependency tree-to-tree translation rules.

Abstract

Active learning is a framework that makes it possible to efficiently train statistical models by selecting informative examples from a pool of unlabeled data. Previous work has found this framework effective for machine translation (MT), making it possible to train better translation models with less effort, particularly when annotators translate short phrases instead of full sentences. However, previous methods for phrase-based active learning in MT fail to consider whether the selected units are coherent and easy for human translators to translate, and also have problems with selecting redundant phrases with similar content. In this paper, we tackle these problems by proposing two new methods for selecting more syntactically coherent and less redundant segments in active learning for MT. Experiments using both simulation and extensive manual translation by professional translators find the proposed method effective, achieving both greater gain of BLEU score for the same number of translated words, and allowing translators to be more confident in their translations[1].

1 Introduction

In statistical machine translation (SMT) (Brown et al., 1993), large quantities of high-quality bilingual data are essential to achieve high translation accuracy. While in many cases large corpora can be collected, for example by crawling the web (Resnik and Smith, 2003), in many domains or language pairs it is still necessarily to create data by hand, either by hiring professionals or crowdsourcing (Zaidan and Callison-Burch, 2011). In these cases, *active learning* (§2), which selects which data to annotate based on their potential benefit to the translation system, has been shown to be effective for improving SMT systems while keeping the required amount of annotation to a minimum (Eck et al., 2005; Turchi et al., 2008; Haffari et al., 2009; Haffari and Sarkar, 2009; Ananthakrishnan et al., 2010; Bloodgood and Callison-Burch, 2010; González-Rubio et al., 2012; Green et al., 2014).

Most work on active learning for SMT, and natural language tasks in general, has focused on choosing which *sentences* to give to annotators. These

San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

methods generally assign priority to sentences that contain data that is potentially useful to the MT system according to a number of criteria. For example, there are methods to select sentences that contain phrases that are frequent in monolingual data but not in bilingual data (Eck et al., 2005), have low confidence according to the MT system (Haffari et al., 2009), or are predicted to be poor translations by an MT quality estimation system (Ananthakrishnan et al., 2010). However, while the selected sentences may contain useful phrases, they will also generally contain many already covered phrases that nonetheless cost time and money to translate.

To solve the problem of wastefulness in full-sentence annotation for active learning, there have been a number of methods proposed to perform *sub-sentential annotation of short phrases* for natural language tasks (Settles and Craven, 2008; Bloodgood and Callison-Burch, 2010; Tomanek and Hahn, 2009; Sperber et al., 2014). For MT in particular, Bloodgood and Callison-Burch (2010) have proposed a method that selects poorly covered n-grams to show to translators, allowing them to focus directly on poorly covered parts without including unnecessary words (§3). Nevertheless, our experiments identified two major practical problems with this method. First, as shown in Figure 1 (a), many of the selected phrases overlap with each other, causing translation of *redundant* phrases, damaging efficiency. Second, it is common to see *fragments* of complex phrases such as "one of the preceding," which may be difficult for workers to translate into a contiguous phrase in the target language.

In this work, we propose two methods that aim to solve these two problems and improve the efficiency and reliability of segment-based active learning for SMT (§4). For the problem of overlapping phrases, we note that by merging overlapping phrases, as shown in Figure 1 (b), we can reduce the number of redundant words annotated and improve training efficiency. We adopt the idea of *maximal substrings* (Okanohara and Tsujii, 2009) which both encode this idea of redundancy, and can be calculated to arbitrary length in linear time using enhanced suffix arrays. For the problem of phrase structure fragmentation, we propose a simple heuristic to count only *well-formed syntactic constituents* in a parse tree, as shown in Figure 1 (c).

To investigate the effect of our proposed methods on learning efficiency, we perform experiments on English-French and English-Japanese translation tasks in which we incrementally add new parallel data, update models and evaluate translation accuracy. Results from both simulation experiments (§5) and 120 hours of work by professional translators (§6) demonstrate improved efficiency with respect to the number of words annotated. We also found that human translators took more time, but were more confident in their results on segments selected by the proposed method.

2 Active Learning for Machine Translation

In this section, we first provide an outline of the active learning procedure to select phrases for SMT data. In this paper, we regard a "phrase" as a word sequence with arbitrary length, which indicates that full sentences and single words both qualify as phrases. In Algorithm 1, we show the general procedure of incrementally selecting the next candidate for translation from the source language corpus, requesting and collecting the translation in the target language, and retraining the models.

Algorithm 1 Active learning for MT

```
1: Init:
2:   $SrcPool$ ← source language data including candidates for translation
3:   $Translated$ ← translated parallel data
4:   $Oracle$ ← oracle giving the correct translation for an input phrase
5: Loop Until $StopCondition$:
6:   $TM \leftarrow TrainTranslationModel(Translated)$
7:   $NewSrc \leftarrow SelectNextPhrase(SrcPool, Translated, TM)$
8:   $NewTrg \leftarrow GetTranslation(Oracle, NewSrc)$
9:   $Translated \leftarrow Translated \bigcup \{\langle NewSrc, NewTrg \rangle\}$
```

In lines 1-4, we define the datasets and initialize them. $SrcPool$ is a set with each sentence in source language corpus as an element. $Translated$ indicates a set with source and target language phrase pairs. $Translated$ may be empty, but in most cases will consist of a seed corpus upon which we would like to improve. $Oracle$ is an oracle (e.g. a human translator), that we can query for a correct translation for an arbitrary input phrase.

In lines 5-9, we train models incrementally. $StopCondition$ in line 5 is an arbitrary timing when to stop the loop, such as when we reach an accuracy goal or when we expend our translation budget. In line 6, we train the translation model using $Translated$, the available parallel data at this point. We evaluate the accuracy after training the translation model for each step in the experiments. In line 7, we select the next candidate for translation using features of $SrcPool$, $Translated$ and TM to make the decision.

In the following sections, we discuss existing methods (§3), and our proposed methods (§4) to implement the selection criterion in line 7.

3 Selection based on n-Gram Frequency

3.1 Sentence Selection using n-Gram Frequency

The first traditional method that we cover is a sentence selection method. Specifically, it selects the sentence including the most frequent uncovered phrase with a length of up to n words in the source language data. This method enables us to effectively cover the most frequent n-gram phrases and improve accuracy with fewer sentences than random selection. Bloodgood and Callison-Burch (2010) demonstrate results of a simulation showing that this method required less than 80% of the data required by randomly selected sentences to obtain the same accuracy.

However, as mentioned in the introduction, the selected full sentences include many phrases already covered in the parallel data. This may cause an additional cost for words in redundant segments, a problem resolved by the phrase selection approach detailed in the following section.

3.2 Phrase Selection using n-Gram Frequency

In the second baseline approach, we directly select and translate n-gram phrases that are the most frequent in the source language data but not yet covered in the translated data (Bloodgood and Callison-Burch, 2010). This method allows for improvement of coverage with fewer additional words than sentence selection, achieving higher efficiency by reducing the amount of data unnecessarily annotated. Bloodgood and Callison-Burch (2010) showed that by translating the phrases selected by this method using a crowdsourcing website, it was possible to achieve a large improvement of BLEU score, outperforming similar sentence-based methods.

However, as mentioned in the introduction, this method has several issues. First, because it uses short phrases, it often selects phrases that are not linguistically well-formed, potentially making them difficult to translate concisely. Second, it also has problems with redundancy, with no device to prevent multiple overlapping phrases being selected and translated. Finally, the previous work limits the maximum phrase length to $n = 4$, precluding the use of longer phrases. However, using a larger limit such as $n = 5$ is not likely to be a fundamental solution, as it increases the number of potentially overlapping phrases, and also computational burden. In the next section we cover our proposed solutions to these problems in detail.

4 Phrase Selection based on Maximal Phrases and Parse Trees

4.1 Phrase Selection based on Maximal Phrases

To solve both the problem of overlapping phrases and the problem of requiring limits on phrase length for computational reasons, we propose a method using the idea of *maximal substrings* (Okanohara and Tsujii, 2009). Maximal substrings are formally defined as "a substring that is *not* always included in a particular longer substring." For example, if we define p_i as a phrase and $occ(p_i)$ as its occurrence count in a corpus, and have the following data

$$\begin{aligned} p_1 &= \text{"one of the preceding"}, & occ(p_1) &= 200,000 \\ p_2 &= \text{"one of the preceding claims"}, & occ(p_2) &= 200,000 \\ p_3 &= \text{"any one of the preceding claims"}, & occ(p_3) &= 190,000 \end{aligned}$$

p_1 = "one of the preceding" always co-occurs with the longer p_2 = "one of the preceding claims" and thus is not a maximal substring. On the other hand, p_2 does not always co-occur with p_3, and thus p_2 will be maximal. This relationship can be defined formally with the following semi-order relation:

$$p_1 \preceq p_2 \Leftrightarrow \exists\alpha,\beta : p_1 = \alpha p_2 \beta \wedge occ(p_1) = occ(p_2). \quad (1)$$

Demonstrating this by the previous example, $p_1 = \alpha p_2 \beta$, α = "", β = "claims" hold, meaning p_1 is a sub-sequence of p_2, and p_2 is a sub-sequence of p_3 in a similar manner. Since p_1 is a sub-sequence of p_2 and $occ(p_1) = occ(p_2) = 200,000$, $p_1 \preceq p_2$ holds. However, although p_2 is a sub sequence of p_3, because $occ(p_2) = 200,000 \neq 190,000 = occ(p_3)$, the relation $p_2 \preceq p_3$ does not hold. Here, we say p has *maximality* if there does not exist any q other than p itself that meets $p \preceq q$, and we call such a phrase a *maximal phrase*.

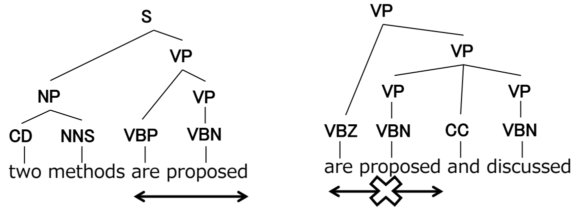
To apply this concept to active learning, our proposed method limits translation data selection to only maximal phrases. This has two advantages. First, it reduces overlapping phrases to only the maximal string, allowing translators to cover multiple high-frequency phrases in the translation of a single segment. Second, maximal phrases and their occurrence counts can be enumerated efficiently by using enhanced suffix arrays (Kasai et al., 2001) in linear time with respect to document length, removing the need to set arbitrary limits on the length of strings such as $n = 4$ used in previous work.

However, it can be easily noticed that while in the previous example p_2 is included in p_3, their occurrence counts are close but not equivalent, and thus both are maximal phrases. In such a case, the naïve implementation of this method can not remove these redundant phrases, despite the fact that it is intuitively preferable that the selection method combines phrases if they have almost the same occurrence count. Thus, we also propose to use the following semi-order relation generalized with parameter λ:

$$p_1 \overset{*}{\preceq} p_2 \Leftrightarrow \exists \alpha, \beta : p_1 = \alpha p_2 \beta \wedge \lambda \cdot occ(p_1) < occ(p_2). \quad (2)$$

where λ takes a real numbered value from 0 to 1, which we set to $\lambda = 0.5$ in this research.

This removes the restriction that the two phrases under comparison be of exactly equal counts, allowing them to have only approximately the same occurrence count. We redefine maximality using this semi-order $\overset{*}{\preceq}$ as *semi-maximality*, and call maximal phrases defined with $\overset{*}{\preceq}$ *semi-maximal phrases* in contrast to normal maximal phrases. By using semi-maximal phrases instead of maximal phrases, we can remove a large number of phrases that are included in a particular longer phrase more than half the time, indicating that it might be preferable to translate the longer phrase instead.



(a) “are proposed” is counted (b) “are proposed” is not counted

Figure 2: Phrase counting based on parse trees

4.2 Phrase Selection based on Parse Trees

In this section, we propose a second phrase selection method based on the results from the syntactic analysis of source language data. This method first processes all the source language data with a phrase structure parser, traverses and counts up all the subtrees of parse trees as shown in Figure 2, and finally selects phrases corresponding to a subtree in frequency order.[2] We propose this method because we expect the selected phrases to have syntactically coherent meaning, potentially making human translation easier than other methods that do not use syntactic information.

It should be noted that because this method counts all subtrees, it is capable of selecting overlapping phrases like the methods based on n-grams. Therefore we also experiment with a method using together both subtrees and the semi-maximal phrases proposed in Section 4.1 to select both syntactic and non-redundant segments.

5 Simulation Experiment

5.1 Experimental Set-Up

To investigate the effects of the phrase selection methods proposed in Section 4, we first performed a simulation experiment in which we incrementally retrain translation models and evaluate the accuracy after each step of data selection. In this experiment, we chose English as a source language and French and Japanese as target languages. To simulate a realistic active learning scenario, we started from given parallel data in the general domain and sequentially added additional source language data in a specific target domain. For the English-French translation task, we adopted the Europarl corpus

[2] The method does not distinguish between equivalent word sequences even if they have different tree structures

Lang Pair	Domain	Dataset	Amount
En-Fr	General (Base)	Train	1.89M Sent. En: 47.6M Words Fr: 49.4M Words
	Medical (Target)	Train	15.5M Sent. En: 393M Words Fr: 418M Words
		Test	1000 Sent.
		Dev	500 Sent.
En-Ja	General (Base)	Train	414k Sent. En: 6.72M Words Ja: 9.69M Words
	Scientific (Target)	Train	1.87M Sent. En: 46.4M Words Ja: 57.6M Words
		Test	1790 Sent.
		Dev	1790 Sent.

Table 1: Details of parallel data

from WMT2014[3] as a base parallel data source and EMEA (Tiedemann, 2009), PatTR (Wäschle and Riezler, 2012), and Wikipedia titles, used in the medical translation task, as the target domain data. For the English-Japanese translation task, we adopted the broad-coverage example sentence corpus provided with the Eijiro dictionary[4] as general domain data, and the ASPEC[5] scientific paper abstract corpus as the target domain data. For pre-processing, we tokenized Japanese corpora using the KyTea word segmenter (Neubig et al., 2011) and filtered out the lines of length over 60 from all the training parallel data to ensure accuracy of parsing and alignment. We show the details of the parallel dataset after pre-processing in Table 1.

For the machine translation framework, we used phrase-based SMT (Koehn et al., 2003) with the Moses toolkit (Koehn et al., 2007) as a decoder. To efficiently re-train the models with new data, we adopted inc-giza-pp,[6] a specialized version of GIZA++ word aligner (Och and Ney, 2003) supporting incremental training, and the memory-mapped dynamic suffix array phrase tables (MMSAPT) feature of Moses (Germann, 2014) for on-memory construction of phrase tables. We train 5-gram models over the target side of all the general domain and target domain data using KenLM (Heafield, 2011). For the tuning of decoding parameters, since it is not realistic to run MERT (Och, 2003) at each retraining step, we tuned the parameters to maximize the BLEU score (Papineni et al., 2002) for the baseline system, and re-used the parameters thereafter. We compare the following 8 segment selection methods, including 2 random selection methods, 2 conventional methods and 4 proposed methods:

sent-rand: Select sentences randomly.

4gram-rand: Select n-gram strings of length of up to 4 in random order.

sent-by-4gram-freq: Select the sentence including the most frequent uncovered phrase with length of up to 4 words (baseline 1, §3.1).

4gram-freq: Select the most frequent uncovered phrase with length of up to 4 words (baseline 2, §3.2).

maxsubst-freq: Select the most frequent uncovered maximal phrase (proposed, §4.1)

reduced-maxsubst-freq: Select the most frequent uncovered semi-maximal phrase (proposed, §4.1)

struct-freq: Select the most frequent uncovered phrase extracted from the subtrees (proposed, §4.2).

reduced-struct-freq: Select the most frequent uncovered semi-maximal phrase extracted from the subtrees (proposed, §4.1 and §4.2).

To generate oracle translations, we used an SMT system trained on all of the data in both the general and target-domain corpora. To generate parse trees, we used the Ckylark parser (Oda et al., 2015).

5.2 Results and Discussion

Comparison of efficiency: In Figure 3, we show the evaluation score results by the number of additional source words up to 100k and 1M words. We can see that in English-French translation, the accuracy of the selection methods using parse trees grows more rapidly than other methods and was significantly better even at the point of 1M additional words. In the case of English-Japanese translation, the gains over 4-gram frequency are much smaller, but the proposed methods still consistently perform as well or better than the other methods. Besides, in all the graphs we can see the improvement of reduced-maxsubst-freq and reduced-struct-freq over maxsubst-freq and struct-freq respectively, demonstrating that avoiding selecting redundant segments is helpful in improving efficiency.

[5] http://lotus.kuee.kyoto-u.ac.jp/ASPEC/

[6] https://github.com/akivajp/inc-giza-pp

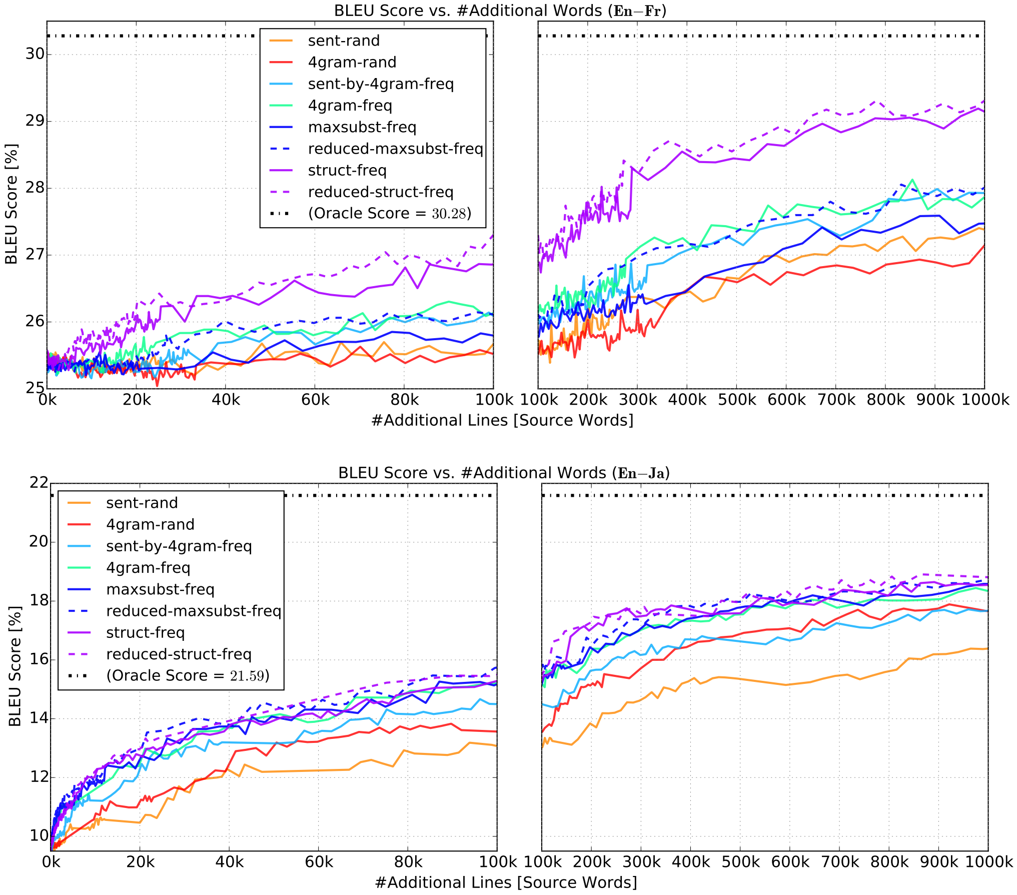

Figure 3: BLEU score vs. number of additional source words in each method

Length of selected phrases: Due to the different criteria used by each method, there are also significant differences in the features of the selected phrases. In Table 2, we show the details of the number of all selected phrases, words and average phrase length until the stop condition, and at the point of 10k additional source words. Here we see the tendency that the selection methods based on parse trees select shorter phrases than other methods. This is caused by the fact that longer phrases are only counted if they cover a syntactically defined phrases, and thus longer substrings that do not form syntactic phrases are removed from consideration.

Phrase coverage: This difference in the features of the selected phrases also affects how well they can cover new incoming test data. To demonstrate this, in Table 3 we show the 1-gram and 4-gram coverage of the test dataset after 10k, 100k and 1M words have been selected. From the results, we can see that the reduced-struct-freq method attains the highest 1-gram coverage, efficiently covering unknown words. On the other hand, it is clear that methods selecting longer phrases have an advantage for 4-gram coverage, and we see the highest 4-gram coverage in the sent-by-4gram-freq method.

6 Manual Translation Experiment

6.1 Experimental Set-Up

To confirm that the results from the simulation in the previous section carry over to actual translators, we further performed experiments in which professional translators translated the selected segments. This also allowed us to examine the actual amount of time required to perform translation, and how confident the translators were in their translations.

We designed a web user interface as shown in Figure 4, and outsourced to an external organization

		All Selected Phrases			First 10k Words

Confidence level:

● 3: sure about the translation
○ 2: not so sure about the translation
○ 1: not sure at all

Figure 4: Example of the human translation interface

that had three professional translators translate the shown phrases. As is standard when hiring translators, we paid a fixed price per word translated for all of the methods. Because showing only the candidate phrase out of context could cause difficulty in translation, we follow Bloodgood and Callison-Burch (2010) in showing a sentence including the selected phrase,[7] highlighting the phrase, and requesting that the translator translate the highlighted part. We also requested that every worker select from 3 levels indicating how confident they were of their translation. In the background, the time required to complete the translation is measured from when the new phrase is shown until when the translation is submitted.

The methods selected for comparative evaluation are sentence selection based on 4-gram frequency (sent-by-4gram-freq) and phrase selection based on 4-gram frequency (4gram-freq) as baseline methods, and the phrase selection based on both parse trees and semi-maximality (reduced-struct-freq) as

[7] Specifically, we selected the shortest sentence including the phrase in the source corpus.

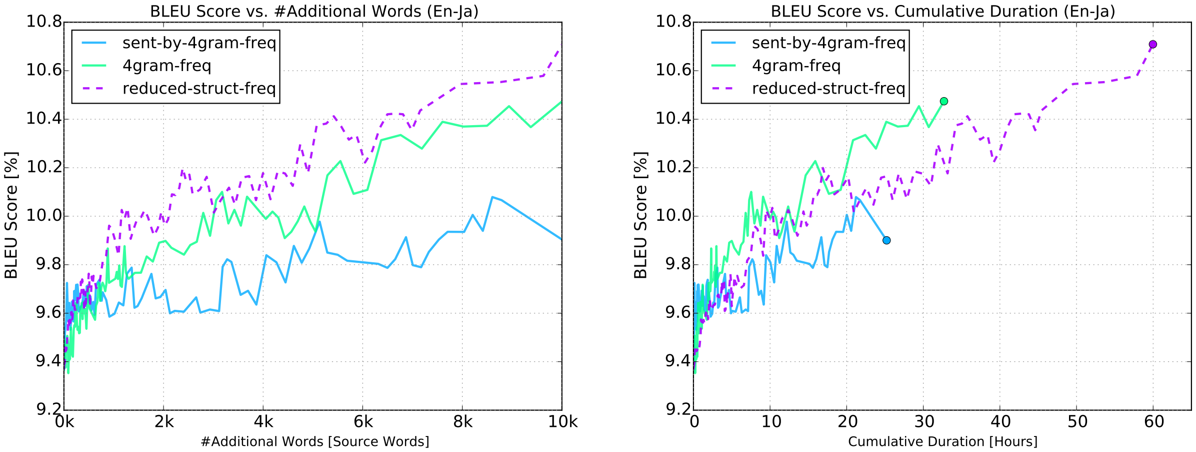

Figure 5: Transition of BLEU score vs. additional source words (left) and vs. cumulative working duration (right)

the proposed method. For each method we collected translations of 10k source words, alternating between segments selected by each method to prevent bias.

We used the same dataset as the English-Japanese translation task and the same tools in the simulation experiment (Section 5). However, for training target language models, we interpolated one trained with the base data and a second trained with collected data by using SRILM (Stolcke, 2002) because the hand-made data set was too small to train a full language model using only this data. We tuned the interpolation coefficient such that it maximizes the perplexity for the tuning dataset.

6.2 Results and Discussion

Efficiency results: Figure 5 shows the evaluation scores of SMT systems trained using varying amounts of collected phrases. In the left graph, we see the proposed method based on parse trees and phrase semi-maximality rapidly improves BLEU score, and requires fewer additional words than the conventional methods. Because the cost paid for translation often is decided by the number of words, this indicates that the proposed method has better cost performance in these situations. The right graph shows improvement by the amount of translation time. These results here are different, showing the 4-gram-freq baseline slightly superior. As discussed in Table 3, the methods based on parse trees select more uncovered 1-grams, namely unknown words, and specifically the proposed method selected more technical terms that took a longer time to translate.

Selection Methods	Total Working Time [Hours]	Average Confidence Level (3 Levels)
sent-by-4gram-freq	25.22	2.689
4gram-freq	32.70	2.601
reduced-struct-freq	59.97	**2.771**

Table 4: Total working time and average confidence level

Working time and confidence: We show the total time to collect the translations of 10k source words and average confidence level for each method in Table 4. The total working time for the proposed method is nearly double that of other methods, as seen in the right graph of Figure 5. On the other hand, the segments selected by the proposed method were given the highest confidence level, receiving the maximum value of 3 for about 79% of phrase pairs, indicating that the generated parallel data is of high quality. To some extent, this corroborates our hypothesis that the more syntactic phrases selected by the proposed method are easier to translate.

We can also examine the tendency of working time for segments of different lengths in Table 5. Interestingly, single words consistently have a longer average translation time than phrases of length 2-4, likely because they tend to be technical terms that require looking up in a dictionary. We show the average confidence levels corresponding to phrase length in Table 6. The confidence level of single words in the proposed method is lower than in the baseline method, likely because the baseline selected a smaller amount of single words, and those se-

Selection Method	Average Working Time [Seconds]				
	1 Word	2 Word Phrase	3 Word Phrase	4 Word Phrase	5+ Word Phrase
sent-by-4gram-freq	-	-	-	-	160.64

Selection Method	Average Confidence Level (3 Levels)				
	1 Word	2 Word Phrase	3 Word Phrase	4 Word Phrase	5+ Word Phrase
sent-by-4gram-freq	-	-	-	-	2.689
4gram-freq	2.885	2.585	2.422	2.300	-
reduced-struct-freq	2.802	2.796	2.778	2.708	2.737

Table 6: Average confidence level of manual translation corresponding to phrase length

lected were less likely to be technical terms. On the other hand, we can confirm that the confidence level for longer phrases in the baseline method decreases drastically, while it is stably high in our method, confirming the effectiveness of selecting syntactically coherent phrases.

Translation accuracy by confidence level: Finally, we show the accuracy of the SMT system trained by all the collected data in each method in Table 7. To utilize the confidence level annotation, we tested SMT systems trained by phrase pairs with confidence levels higher than 2 or 3. From the results, the accuracy of every method is improved when phrases pairs with confidence level 1 were filtered out. In contrast, the accuracy is conversely degraded if we use only phrase pairs with confidence level 3. The translation accuracy of 9.37% BLEU with the base SMT system without additional data became 10.72% after adding phrase pairs having confidence level 2 or higher, allowing for a relatively large gain of 1.35 BLEU points.

7 Conclusion and Future Work

In this paper, we proposed a new method for active learning in machine translation that selects syntactic, non-redundant phrases using parse trees and semimaximal phrases. We first performed simulation experiments and obtained improvements in translation accuracy with fewer additional words. Further manual translation experiments also demonstrated that our method allows for greater improvements in accuracy and translator confidence.

Selection Methods	BLEU Score [%]		
	Confidence 1+ (All)	Confidence 2+	Confidence 3
sent-by-4gram-freq	9.88	9.92	9.85
4gram-freq	10.48	10.54	10.36
reduced-struct-freq	10.70	**10.72**	10.67

Table 7: BLEU score when training on phrases with a certain confidence level

However, there are still a number of avenues for improvement. Particularly, as the proposed method selected segments that took more time to translate due to technical terms, the combination with methods to harvest unknown words (Daumé III and Jagarlamudi, 2011) or optimize the selected segments based on the time required (Sperber et al., 2014) is potentially useful. In addition, softer syntactic constraints that allow annotation of phrases with variables (Chiang, 2007) such as “one of the preceding X” are another interesting avenue of future work.

Abstract

We build a multi-source machine translation model and train it to maximize the probability of a target English string given French and German sources. Using the neural encoder-decoder framework, we explore several combination methods and report up to +4.8 Bleu increases on top of a very strong attention-based neural translation model.

1 Introduction

Kay (2000) points out that if a document is translated once, it is likely to be translated again and again into other languages. This gives rise to an interesting idea: a human does the first translation by hand, then turns the rest over to machine translation (MT). The translation system now has two strings as input, which can reduce ambiguity via "triangulation" (Kay's term). For example, the normally ambiguous English word "bank" may be more easily translated into French in the presence of a second, German input string containing the word "Flussufer" (river bank).

Och and Ney (2001) describe such a *multi-source* MT system. They first train separate bilingual MT systems $F{\rightarrow}E$, $G{\rightarrow}E$, etc. At runtime, they separately translate input strings f and g into candidate target strings e_1 and e_2, then select the best one of the two. A typical selection factor is the product of the system scores. Schwartz (2008) revisits such factors in the context of log-linear models and Bleu score, while Max et al. (2010) re-rank $F{\rightarrow}E$ n-best lists using n-gram precision with respect to $G{\rightarrow}E$ translations. Callison-Burch (2002) exploits hypothesis selection in multi-source MT to expand available corpora, via co-training.

Others use system combination techniques to merge hypotheses at the word level, creating the ability to synthesize new translations outside those proposed by the single-source translators. These methods include confusion networks (Matusov et al., 2006; Schroeder et al., 2009), source-side string combination (Schroeder et al., 2009), and median strings (González-Rubio and Casacuberta, 2010).

The above work all relies on base MT systems trained on *bilingual data*, using traditional methods. This follows early work in sentence alignment (Gale and Church, 1993) and word alignment (Simard, 1999), which exploited trilingual text, but did not build trilingual models. Previous authors possibly considered a three-dimensional translation table t$(e|f,g)$ to be prohibitive.

In this paper, by contrast, we train a P$(e|f,g)$ model directly on *trilingual data*, and we use that model to decode an (f,g) pair simultaneously. We view this as a kind of multi-tape transduction (Elgot and Mezei, 1965; Kaplan and Kay, 1994; Deri and Knight, 2015) with two input tapes and one output tape. Our contributions are as follows:

- We train a P$(e|f,g)$ model directly on trilingual data, and we use it to decode a new source string pair (f,g) into target string e.
- We show positive Bleu improvements over strong single-source baselines.
- We show that improvements are best when the two source languages are more distant from each other.

We are able to achieve these results using

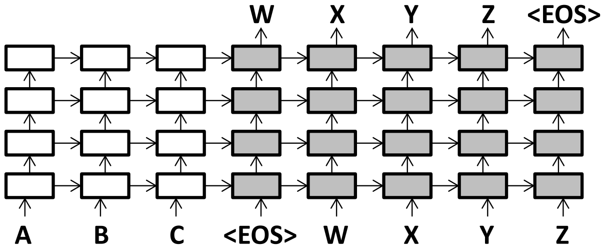

Figure 1: The encoder-decoder framework for neural machine translation (NMT) (Sutskever et al., 2014). Here, a source sentence C B A (presented in reverse order as A B C) is translated into a target sentence W X Y Z. At each step, an evolving real-valued vector summarizes the state of the encoder (white) and decoder (gray).

the framework of neural encoder-decoder models, where multi-target MT (Dong et al., 2015) and multi-source, cross-modal mappings have been explored (Luong et al., 2015a).

2 Multi-Source Neural MT

In the neural encoder-decoder framework for MT (Neco and Forcada, 1997; Castaño and Casacuberta, 1997; Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015b), we use a recurrent neural network (*encoder*) to convert a source sentence into a dense, fixed-length vector. We then use another recurrent network (*decoder*) to convert that vector in a target sentence.[1]

In this paper, we use a four-layer encoder-decoder system (Figure 1) with long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997) trained for maximum likelihood (via a softmax layer) with back-propagation through time (Werbos, 1990). For our baseline single-source MT system we use two different models, one of which implements the local attention plus feed-input model from Luong et al. (2015b).

Figure 2 shows our approach to multi-source MT. Each source language has its own encoder. The question is how to combine the hidden states and cell states from each encoder, to pass on to the decoder. Black *combiner* blocks implement a function whose input is two hidden states (h_1 and h_2) and two cell states (c_1 and c_2), and whose output is a single hidden state h and cell state c. We propose two combination methods.

2.1 Basic Combination Method

The Basic method works by concatenating the two hidden states from the source encoders, applying a linear transformation W_c (size 2000 x 1000), then sending its output through a tanh non-linearity. This operation is represented by the equation:

$$h = \tanh\Big(W_c[h_1; h_2]\Big) \tag{1}$$

W_c and all other weights in the network are learned from example string triples drawn from a trilingual training corpus.

The new cell state is simply the sum of the two cell states from the encoders.

$$c = c_1 + c_2 \tag{2}$$

We also attempted to concatenate cell states and apply a linear transformation, but training diverges due to large cell values.

2.2 Child-Sum Method

Our second combination method is inspired by the Child-Sum Tree-LSTMs of Tai et al. (2015). Here, we use an LSTM variant to combine the two hidden states and cells. The standard LSTM input, output, and new cell value are all calculated. Then cell states from each encoder get their own forget gates. The final cell state and hidden state are calculated as in a normal LSTM. More precisely:

$$i = \text{sigmoid}\Big(W_1^i h_1 + W_2^i h_2\Big) \tag{3}$$

$$f = \text{sigmoid}\Big(W_i^f h_i\Big) \tag{4}$$

$$o = \text{sigmoid}\Big(W_1^o h_1 + W_2^o h_2\Big) \tag{5}$$

$$u = \tanh\Big(W_1^u h_1 + W_2^u h_2\Big) \tag{6}$$

$$c = i_f \odot u_f + f_1 \odot c_1 + f_2 \odot c_2 \tag{7}$$

$$h = o_f \odot \tanh(c_f) \tag{8}$$

This method employs eight new matrices (the W's in the above equations), each of size 1000 x 1000. The $\odot$ symbol represents an elementwise multiplication. In equation 3, i represents the input gate of a typical LSTM cell. In equation 4,

[1] We follow previous authors in presenting the source sentence to the encoder in reverse order.

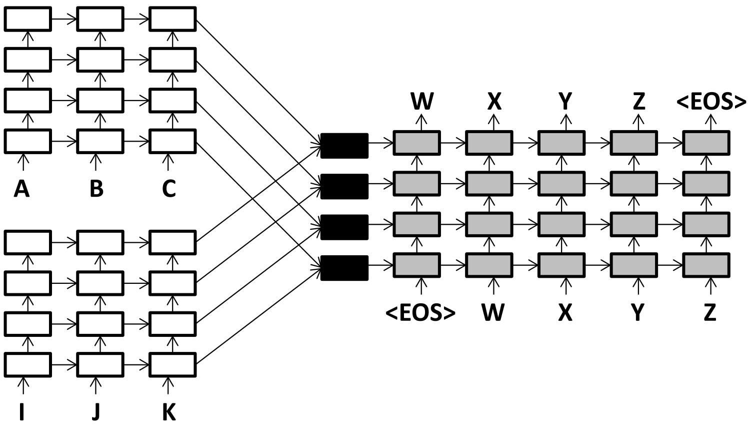

Figure 2: Multi-source encoder-decoder model for MT. We have two source sentences (C B A and K J I) in different languages. Each language has its own encoder; it passes its final hidden and cell state to a set of *combiners* (in black). The output of a combiner is a hidden state and cell state of the same dimension.

there are two forget gates indexed by the subscript i that serve as the forget gates for each of the incoming cells for each of the encoders. In equation 5, o represents the output gate of a normal LSTM. i, f, o, and u are all size-1000 vectors.

2.3 Multi-Source Attention

Our single-source attention model is modeled off the local-p attention model with feed input from Luong et al. (2015b), where hidden states from the top decoder layer can look back at the top hidden states from the encoder. The top decoder hidden state is combined with a weighted sum of the encoder hidden states, to make a better hidden state vector ($\tilde{h_t}$), which is passed to the softmax output layer. With input-feeding, the hidden state from the attention model is sent down to the bottom decoder layer at the next time step.

The local-p attention model from Luong et al. (2015b) works as follows. First, a position to look at in the source encoder is predicted by equation 9:

$$p_t = S \cdot \text{sigmoid}(v_p^T \tanh(W_p h_t)) \tag{9}$$

S is the source sentence length, and v_p and W_p are learned parameters, with v_p being a vector of dimension 1000, and W_p being a matrix of dimension 1000 x 1000.

After p_t is computed, a window of size $2D + 1$ is looked at in the top layer of the source encoder centered around p_t ($D = 10$). For each hidden state in this window, we compute an alignment score $a_t(s)$, between 0 and 1. This alignment score is computed by equations 10, 11 and 12:

$$a_t(s) = \text{align}(h_t, h_s)\text{exp}\Big(\frac{-(s - p_t)^2}{2\sigma^2}\Big) \tag{10}$$

$$\text{align}(h_t, h_s) = \frac{\exp(\text{score}(h_t, h_s))}{\sum_{s'} \exp(\text{score}(h_t, h_{s'}))} \tag{11}$$

$$\text{score}(h_t, h_s) = h_t^T W_a h_s \tag{12}$$

In equation 10, σ is set to be $D/2$ and s is the source index for that hidden state. W_a is a learnable parameter of dimension 1000 x 1000.

Once all of the alignments are calculated, c_t is created by taking a weighted sum of all source hidden states multiplied by their alignment weight.

The final hidden state sent to the softmax layer is given by:

$$\tilde{h_t} = tanh\Big(W_c[h_t; c_t]\Big) \tag{13}$$

We modify this attention model to look at both source encoders simultaneously. We create a context vector from each source encoder named c_t^1 and c_t^2 instead of the just c_t in the single-source attention model:

$$\tilde{h_t} = tanh\Big(W_c[h_t; c_t^1; c_t^2]\Big) \tag{14}$$

In our multi-source attention model we now have two p_t variables, one for each source encoder. We

	French	English	German
Word tokens	66.2m	59.4m	57.0m
Word types	424,832	381,062	865,806
Segment pairs	2,378,112		
Ave. segment length (tokens)	27.8	25.0	24.0

Figure 3: Trilingual corpus statistics.

also have two separate sets of alignments and therefore now have two c_t values denoted by c_t^1 and c_t^2 as mentioned above. We also have distinct W_a, v_p, and W_p parameters for each encoder.

3 Experiments

We use English, French, and German data from a subset of the WMT 2014 dataset (Bojar et al., 2014). Figure 3 shows statistics for our training set. For development, we use the 3000 sentences supplied by WMT. For testing, we use a 1503-line trilingual subset of the WMT test set.

For the single-source models, we follow the training procedure used in Luong et al. (2015b), but with 15 epochs and halving the learning rate every full epoch after the 10th epoch. We also re-scale the normalized gradient when norm > 5. For training, we use a minibatch size of 128, a hidden state size of 1000, and dropout as in Zaremba et al. (2014). The dropout rate is 0.2, the initial parameter range is [-0.1, +0.1], and the learning rate is 1.0. For the normal and multi-source attention models, we adjust these parameters to 0.3, [-0.08, +0.08], and 0.7, respectively, to adjust for overfitting.

Figure 4 shows our results for target English, with source languages French and German. We see that the Basic combination method yields a +4.8 Bleu improvement over the strongest single-source, attention-based system. It also improves Bleu by +2.2 over the non-attention baseline. The Child-Sum method gives improvements of +4.4 and +1.4. We confirm that two copies of the same French input yields no BLEU improvement. Figure 5 shows the action of the multi-attention model during decoding.

When our source languages are English and French (Figure 6), we observe smaller BLEU gains (up to +1.1). This is evidence that the more distinct the source languages, the better they disambiguate each other.

Target = English

4 Conclusion

We describe a multi-source neural MT system that gets up to +4.8 Bleu gains over a very strong attention-based, single-source baseline. We obtain this result through a novel encoder-vector combination method and a novel multi-attention system. We release the code for these experiments at www.github.com/isi-nlp/Zoph_RNN.

Controlling Politeness in Neural Machine Translation via Side Constraints

Rico Sennrich and **Barry Haddow** and **Alexandra Birch**
School of Informatics, University of Edinburgh

Abstract

Many languages use honorifics to express politeness, social distance, or the relative social status between the speaker and their addressee(s). In machine translation from a language without honorifics such as English, it is difficult to predict the appropriate honorific, but users may want to control the level of politeness in the output. In this paper, we perform a pilot study to control honorifics in neural machine translation (NMT) via *side constraints*, focusing on English→German. We show that by marking up the (English) source side of the training data with a feature that encodes the use of honorifics on the (German) target side, we can control the honorifics produced at test time. Experiments show that the choice of honorifics has a big impact on translation quality as measured by BLEU, and oracle experiments show that substantial improvements are possible by constraining the translation to the desired level of politeness.

1 Introduction

Many languages use honorifics to express politeness, social distance, or the relative social status between the speaker and their addressee(s). A widespread instance is the grammatical T-V distinction (Brown and Gilman, 1960), distinguishing between the familiar (Latin ***Tu***) and the polite (Latin ***Vos***) second person pronoun. In machine translation from a language without honorifics such as English, it is difficult to predict the appropriate honorific, but users may want to control the level of politeness in the output.

We propose a simple and effective method for including target-side T-V annotation in the training of a neural machine translation (NMT) system, which allows us to control the level of politeness at test time through what we call *side constraints*. It can be applied for translation between languages where the T-V distinction is missing from the source, or where the distribution differs. For instance, both Swedish and French make the T-V distinction, but reciprocal use of T pronouns is more widespread in Swedish than in French (Schüpbach et al., 2006). Hence, the Swedish form is not a reliable signal for the appropriate form in the French translation (or vice-versa).

Our basic approach of using side constraints to control target-side features that may be missing from the source, or are unreliable because of a category mismatch, is not limited to the T-V distinction, but could be applied to various linguistic features. This includes grammatical features such as tense and the number/gender of discourse participants, and more generally, features such as dialect and register choice.

This paper has the following contributions:

- we describe rules to automatically annotate the T-V distinction in German text.
- we describe how to use target-side T-V annotation in NMT training to control the level of politeness at test time via side constraints.
- we perform oracle experiments to demonstrate the impact of controlling politeness in NMT.

2 Background: Neural Machine Translation

Attentional neural machine translation (Bahdanau et al., 2015) is the current state of the art for

The research presented in this publication was conducted in cooperation with Samsung Electronics Polska sp. z o.o. - Samsung R&D Institute Poland.

Proceedings of NAACL-HLT 2016, pages 35–40,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

English→German (Jean et al., 2015b; Luong and Manning, 2015). We follow the neural machine translation architecture by Bahdanau et al. (2015), which we will briefly summarize here. However, our approach is not specific to this architecture.

The neural machine translation system is implemented as an attentional encoder-decoder network. The encoder is a bidirectional neural network with gated recurrent units (Cho et al., 2014) that reads an input sequence $x = (x_1, ..., x_m)$ and calculates a forward sequence of hidden states $(\overrightarrow{h_1}, ..., \overrightarrow{h_m})$, and a backward sequence $(\overleftarrow{h_1}, ..., \overleftarrow{h_m})$. The hidden states $\overrightarrow{h_j}$ and $\overleftarrow{h_j}$ are concatenated to obtain the annotation vector h_j.

The decoder is a recurrent neural network that predicts a target sequence $y = (y_1, ..., y_n)$. Each word y_i is predicted based on a recurrent hidden state s_i, the previously predicted word y_{i-1}, and a context vector c_i. c_i is computed as a weighted sum of the annotations h_j. The weight of each annotation h_j is computed through an *alignment model* α_{ij}, which models the probability that y_i is aligned to x_j. The alignment model is a single-layer feedforward neural network that is learned jointly with the rest of the network through backpropagation.

A detailed description can be found in (Bahdanau et al., 2015). Training is performed on a parallel corpus with stochastic gradient descent. For translation, a beam search with small beam size is employed.

3 NMT with Side Constraints

We are interested in machine translation for language pairs where politeness is not grammatically marked in the source text, but should be predicted in the target text. The basic idea is to provide the neural network with additional input features that mark *side constraints* such as politeness.

At training time, the correct feature is extracted from the sentence pair as described in the following section. At test time, we assume that the side constraint is provided by a user who selects the desired level of politeness of the translation.

We add side constraints as special tokens at the end of the source text, for instance <*T*> or <*V*>. The attentional encoder-decoder framework is then able to learn to pay attention to the side constraints. One could envision alternative architectures to incorporate side constraints, e.g. directly connecting them to all decoder hidden states, bypassing the attention model, or connecting them to the output layer (Mikolov and Zweig, 2012). Our approach is simple and applicable to a wide range of NMT architectures and our experiments suggest that the incorporation of the side constraint as an extra source token is very effective.

4 Automatic Training Set Annotation

Our approach relies on annotating politeness in the training set to obtain the politeness feature which we discussed previously. We choose a sentence-level annotation because a target-side honorific may have no word-level correspondence in the source. We will discuss the annotation of German as an example, but our method could be applied to other languages, such as Japanese (Nariyama et al., 2005).

German has distinct pronoun forms for informal and polite address, as shown in Table 1. A further difference between informal and polite speech are imperative verbs, and the original imperative forms are considered informal. The polite alternative is to use 3rd person plural forms with subject in position 2:

- *Ruf mich zurück.* (informal)
  (Call me back.)

- *Rufen Sie mich zurück.* (polite)
  (Call you me back.)

We automatically annotate politeness on a sentence level with rules based on a morphosyntactic annotation by ParZu (Sennrich et al., 2013). Sentences containing imperative verbs are labelled informal. Sentences containing an informal or polite pronoun from Table 1 are labelled with the corresponding class.

Some pronouns are ambiguous. Polite pronouns are distinguished from (neutral) 3rd person plural forms by their capitalization, and are ambiguous in sentence-initial position. In sentence-initial position, we consider them polite pronouns if the English source side contains the pronoun *you(r)*. For *Ihr* and *ihr*, we use the morphological annotation by ParZu to distinguish between the informal 2nd person plural nominative, the (neutral) 3rd person singular dative, and the possessive; for possessive pronouns, we

category	informal		polite
	sg.	pl.	sg./pl.
nominative	du	ihr	Sie
genitive	deiner	euer	Ihrer
dative	dir	euch	Ihnen
accusative	dich	euch	Sie
possessive (base form)	dein	euer	Ihr

Table 1: German address pronouns.

distinguish between polite forms and (neutral) 3rd person forms by their capitalization.

If a sentence matches rules for both classes, we label it as informal – we found that our lowest-precision rule is the annotation of sentence-initial *Sie*. All sentences without a match are considered neutral.

5 Evaluation

Our empirical research questions are as follows:

- can we control the production of honorifics in neural machine translation via side constraints?
- how important is the T-V distinction for translation quality (as measured by BLEU)?

5.1 Data and Methods

We perform English→German experiments on OpenSubtitles (Tiedemann, 2012)[1], a parallel corpus of movie subtitles. Machine translation is commonly used in the professional translation of movie subtitles in a post-editing workflow, and politeness is considered an open problem for subtitle translation (Etchegoyhen et al., 2014). We use OpenSubtitles2012 as training corpus, and random samples from OpenSubtitles2013 for testing. The training corpus consists of of 5.58 million sentence pairs, out of which we label 0.48 million sentence pairs as polite, and 1.09 million as informal.

We train an attentional encoder-decoder NMT system using Groundhog[2] (Bahdanau et al., 2015; Jean et al., 2015a). We follow the settings and training procedure described by Sennrich et al. (2015), using BPE to represent the texts with a fixed vocabulary of subword units (vocabulary size 90000).

The training set is annotated as described in section 4, and the source side is marked with the politeness feature as described in section 3. Note that there are only two values for the politeness feature, and neutral sentences are left unmarked. This is to allow users to select a politeness level for the whole document, without having to predict which translations should contain an address pronoun. Instead, we want the NMT model to ignore side constraints when they are irrelevant.

To ensure that the NMT model does not overly rely on the side constraints, and that performance does not degrade when no side constraint is provided at test time, only a subset of the labelled training instances are marked with a politeness feature at training time. We set the probability that a labelled training instance is marked, α, to 0.5 in our experiments. To ensure that the NMT model learns to ignore side constraints when they are irrelevant, and does not overproduce address pronouns when side constraints are active, we also mark neutral sentences with a random politeness feature with probability α. Keeping the mark-up probability α constant for all sentences in the training set prevents the introduction of unwanted biases. We re-mark the training set for each epoch of training. In preliminary experiments, we found no degradation in baseline performance when politeness features were included in this way during training.

The model is trained for approximately 9 epochs (7 days). At test time, all results are obtained with the same model, and the only variable is the side constraint used to control the production of honorifics. We test translation without side constraint, and translations that are constrained to be polite or informal. In an oracle experiment, we use the politeness label of the reference to determine the side constraint. This simulates a setting in which a user controls the desired politeness.

5.2 Results

Our first test set is a random sample of 2000 sentences from OpenSubtitles2013 where the English source contains a 2nd person pronoun. Results are shown in Table 2. Side constraints very effectively control whether the NMT system produces polite or informal output. Translations constrained to be polite are overwhelmingly labelled polite or neutral

side constraint	output label			BLEU
	neutral	polite	informal	
(reference)	429	524	1047	-
none	178	351	1471	20.7
polite	208	1728	64	17.9
informal	141	28	1831	20.2
oracle	161	567	1272	23.9

Table 2: Politeness and translation quality on test set of 2000 sentences from OpenSubtitles2013 that contain second person pronoun *you(r(s(elf)))* in English source text.

source	Give me the telephone!
reference	Gib mir das Telefon! [T]
none	Gib mir das Telefon! [T]
polite	Geben Sie mir das Telefon! [V]
informal	Gib mir das Telefon! [T]
source	Are you kidding?
reference	Das ist doch ein Witz! [N] (this is a joke!)
none	Machst du Witze? [T]
polite	Machen Sie Witze? [V]
informal	Machst du Witze? [T]
source	You foolish boy.
reference	Du dummer Junge. [T]
none	Du dummer Junge. [T]
polite	Du dummer Junge. [T]
informal	Du dummer Junge. [T]

Table 3: Translation examples with different side constraints. Translations marked as neutral [N], informal [T] or polite [V].

by our automatic target-side annotation (96%), and analogously, translations constrained to be informal are almost exclusively informal or neutral (98%).

We also see that BLEU is strongly affected by the choice. An oracle experiment in which the side constraint of every sentence is informed by the reference obtains an improvement of 3.2 BLEU over the baseline (20.7→23.9).

We note that the reference has a higher proportion of German sentences labelled neutral than the NMT systems. A close inspection shows that this is due to sentence alignment errors in OpenSubtitles, free translations as shown in Table 3, and sentences where *you* is generic and translated by the impersonal pronoun *man* in the reference.

The side constraints are only soft constraints, and are occasionally overridden by the NMT system. These cases tend to be sentences where the source text provides strong politeness clues, like the sentence *You foolish boy*. Neither the address *boy* nor the attribute *foolish* are likely in polite speech, and the sentence is translated with a T pronoun, regardless of the side constraint.

side constraint	output label			BLEU
	neutral	polite	informal	
(reference)	1406	189	405	-
none	1385	125	490	22.6
polite	1386	576	38	21.7
informal	1365	11	624	22.5
oracle	1374	185	441	24.0

Table 4: Politeness and translation quality on test set of 2000 random sentences from OpenSubtitles2013.

While Table 2 only contains sentences with an address pronoun in the source text, Table 4 represents a random sample. There are fewer address pronouns in the random sample, and thus more neutral sentences, but side constraints remain effective. This experiment also shows that we do not overproduce address pronouns when side constraints are provided, which validates our strategy of including side constraints with a constant probability α at training time.

The automatic evaluation with BLEU indicates that the T-V distinction is relevant for translation. We expect that the actual relevance for humans depends on the task. For gisting, we expect the T-V distinction to have little effect on comprehensibility. For professional translation that uses MT with post-editing, producing the desired honorifics is likely to improve post-editing speed and satisfaction. In an evaluation of MT for subtitle translation, Etchegoyhen et al. (2014) highlight the production of the appropriate T-V form as “a limitation of MT technology” that was “often frustrat[ing]” to post-editors.

6 Related Work

Faruqui and Pado (2012) have used a bilingual English–German corpus to automatically annotate the T-V distinction, and train a classifier to predict the address from monolingual English text. Applying a source-side classifier is potential future work, although we note that the baseline encoder–decoder NMT system already has some disambiguating power. Our T-V classification is more comprehensive, including more pronoun forms and imperative verbs.

Previous research on neural language models has proposed including various types of extra information, such as topic, genre or document context (Mikolov and Zweig, 2012; Aransa et al., 2015; Ji et al., 2015; Wang and Cho, 2015). Our method is somewhat similar, with the main novel idea being that we can target specific phenomena, such as honorifics, via an automatic annotation of the target side of a parallel corpus. On the modelling side, our method is slightly different in that we pass the extra information to the encoder of an encoder–decoder network, rather than the (decoder) hidden layer or output layer. We found this to be very effective, but trying different architectures is potential future work.

In rule-based machine translation, user options to control the level of politeness have been proposed in the 90s (Mima et al., 1997), and were adopted by commercial systems (SYSTRAN, 2004, 26). To our knowledge, controlling the level of politeness has not been explicitly addressed in statistical machine translation. While one could use data selection or weighting to control the honorifics produced by SMT, NMT allows us to very elegantly support multiple levels of politeness with a single model.

7 Conclusion

Machine translation should not only produce semantically accurate translations, but should also consider pragmatic aspects, such as producing socially appropriate forms of address. We show that by annotating the T-V distinction in the target text, and integrating the annotation as an additional input during training of a neural translation model, we can apply side constraints at test time to control the production of honorifics in NMT.

We currently assume that the desired level of politeness is specified by the user. Future work could aim to automatically predict it from the English source text based on textual features such as titles and names, or meta-textual information about the discourse participants.

While this paper focuses on controlling politeness, side constraints could be applied to a wide range of phenomena. It is a general problem in translation that, depending on the language pair, the translator needs to specify features in the target text that cannot be predicted from the source text. Apart from from the T-V distinction, this includes grammatical features such as clusivity, tense, and gender and number of the discourse participants, and more generally, features such as the desired dialect (e.g. when translating into Arabic) and text register. Side constraints can be applied to control these features. All that is required is that the feature can be annotated reliably, either using target-side information or metatextual information, at training time.

An Empirical Evaluation of Noise Contrastive Estimation for the Neural Network Joint Model of Translation

Colin Cherry
National Research Council Canada
Colin.Cherry@nrc-cnrc.gc.ca

Abstract

The neural network joint model of translation or NNJM (Devlin et al., 2014) combines source and target context to produce a powerful translation feature. However, its softmax layer necessitates a sum over the entire output vocabulary, which results in very slow maximum likelihood (MLE) training. This has led some groups to train using Noise Contrastive Estimation (NCE), which side-steps this sum. We carry out the first direct comparison of MLE and NCE training objectives for the NNJM, showing that NCE is significantly outperformed by MLE on large-scale Arabic-English and Chinese-English translation tasks. We also show that this drop can be avoided by using a recently proposed translation noise distribution.

1 Introduction

The Neural Network Joint Model of Translation, or NNJM (Devlin et al., 2014), is a strong feature for statistical machine translation. The NNJM uses both target and source tokens as context for a feed-forward neural network language model (LM). Unfortunately, its softmax layer requires a sum over the entire output vocabulary, which slows the calculation of LM probabilities and the maximum likelihood estimation (MLE) of model parameters.

Devlin et al. (2014) address this problem at run-time only with a self-normalized MLE objective. Others advocate the use of Noise Contrastive Estimation (NCE) to train NNJMs and similar monolingual LMs (Mnih and Teh, 2012; Vaswani et al., 2013; Baltescu and Blunsom, 2015; Zhang et al., 2015). NCE avoids the sum over the output vocabulary at both train- and run-time by wrapping the NNJM inside a classifier that attempts to separate real data from sampled noise, greatly improving training speed. The training efficiency of NCE is well-documented, and will not be evaluated here. However, the experimental evidence that NCE matches MLE in terms of resulting model quality is all on monolingual language modeling tasks (Mnih and Teh, 2012). Since cross-lingual contexts provide substantially stronger signals than monolingual ones, there is reason to suspect these results may not carry over to NNJMs.

To our knowledge there is no published work that directly compares MLE and NCE in the context of an NNJM; this paper fills that gap as its primary contribution. We measure model likelihood and translation quality in large-scale Arabic-to-English and Chinese-to-English translation tasks. We also test a recently-proposed translation noise distribution for NCE (Zhang et al., 2015), along with a mixture of noise distributions. Finally, we test a widely known, but apparently undocumented, technique for domain adaptation of NNJMs, demonstrating its utility, as well as its impact on the MLE-NCE comparison.

2 Methods

The NNJM adds a bilingual context window to the machinery of feed-forward neural network language models, or NNLMs (Bengio et al., 2003). An NNLM calculates the probability $p(e_i|e_{i-n+1}^{i-1})$ of a word e_i given its $n-1$ preceding words, while an NNJM assumes access to a source sentence F and an aligned source index a_i that points to the most influ-

Proceedings of NAACL-HLT 2016, pages 41–46,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

ential source word for the next translation choice. It calculates $p(e_i|e_{i-n+1}^{i-1}, f_{a_i-m}^{a_i+m})$, which accounts for $2m+1$ words of source context, centered around f_{a_i}. The two models differ only in their definition of the conditioning context, which we will generalize with the variable $c_i = e_{i-n+1}^{i-1}, f_{a_i-m}^{a_i+m}$. When unambiguous, we drop the subscript i from e and c.

The feed-forward neural network that powers both models takes a context sequence c as input to its network, which includes an embedding layer, one or more hidden layers, and a top-level softmax layer that assigns probabilities to each word in the vocabulary V. Let $s_c(e)$ represent the unnormalized neural network score for the word e. The softmax layer first calculates $Z_c = \sum_{e' \in V} \exp s_c(e')$, which allows it to then normalize the score into a log probability $\log p(e|c) = s_c(e) - \log Z_c$. Given a training set of word-context pairs, MLE training of NNJMs minimizes the negative log likelihood $\sum_{e,c} - \log p(e|c)$.

The problem with this objective is that calculating Z_c requires a sum over the entire vocabulary, which is very expensive. This problem has received much recent study, but Devlin et al. (2014) proposed a novel solution for their NNJM, which we refer to as *self-normalization*. Assume we are willing to incur the cost of calculating Z_c during training, which might be mitigated by special-purpose hardware such as graphical processing units (GPUs). One can modify the MLE objective to encourage $\log Z_c$ to be small, so that the term can be safely dropped at run-time:

$$\sum_{e,c} \left[- \log p(e|c) + \alpha \left(\log Z_c \right)^2 \right]$$

where α trades self-normalization against model likelihood. Devlin et al. (2014) have shown that self-normalization has minimal impact on model quality and a tremendous impact on run-time efficiency.

2.1 Noise Contrastive Estimation

Introduced by Gutmann and Hyvärinen (2010) and first applied to language modeling by Mnih and Teh (2012), NCE allows one to train self-normalized models without calculating Z. It does so by defining a noise distribution q over words in V, which is typically a **unigram noise** distribution q_u. It samples k noise words $\hat{e}_1^k$ for each training word e, and wraps the NNJM inside a binary classifier that attempts to separate true data from noise. Let D be a binary variable that is 1 for true data and 0 for noise. We know the joint noise probability $p(D=0, e|c) = \frac{k}{k+1} q(e)$, and we can approximate the joint data probability using our neural network $p(D=1, e|c) \approx \frac{1}{k+1} p(e|c) \approx \frac{1}{k+1} \exp s_c(e)$. Note that the final approximation drops Z_c from the calculation, improving efficiency and forcing the model to self-normalize. With these two terms in place, and a few manipulations of conditional probability, the NCE training objective can be given as:

$$- \sum_{e,c} \left[\log p(D=1|e,c) + \sum_{j=1}^{k} \log p(D=0|\hat{e}_j, c) \right]$$

which measures the probability that data is recognized as data, and noise is recognized as noise.

Note that q ignores the context c. Previous work on monolingual language modeling indicates that a unigram proposal distribution is sufficient for NCE training (Mnih and Teh, 2012). But for bilingual NNJMs, Zhang et al. (2015) have shown that it is beneficial to have q condition on *source* context. Recall that $c_i = e_{i-n+1}^{i-1}, f_{a_i-m}^{a_i+m}$. We experiment with a **translation noise** distribution $q_t(\hat{e}|f_{a_i})$. We estimate q_t by relative frequency from our training corpus, which implicitly provides us with one e_i, f_{a_i} pair for each training point e_i, c_i. Conditioning on f_{a_i} drastically reduces the entropy of the noise distribution, focusing training on the task of differentiating between likely translation candidates.

As our experiments will show, under NCE with translation noise, the NNJM no longer provides meaningful scores for the entire vocabulary. Therefore, we also experiment with a novel **mixture noise** distribution: $q_m(\hat{e}|f_{a_i}) = 0.5 q_u(\hat{e}) + 0.5 q_t(\hat{e}|f_{a_i})$.

3 Implementation details

We implement our NNJM and all candidate training objectives described above in a shared codebase in Theano (Bergstra et al., 2010). To ensure a fair comparison between MLE and NCE, the various systems share code for model structures and algorithms, differing only in their training objectives. A GeForce GTX TITAN GPU enables efficient MLE training. Following Devlin et al. (2014), all NNJMs use 3 tokens for target context, a source context window with $m = 5$, and a 192-node embedding layer.

We deviate from their configuration by using a single 512-node hidden layer, motivated by our internal development experiments. All NCE variants use $k = 100$ noise samples.

NNJM training data is pre-processed to limit vocabularies to 16K types for source or target inputs, and 32K types for target outputs. We build 400 deterministic word clusters for each corpus using `mkcls` (Och, 1999). Any word not among the 16K / 32K most frequent words is replaced with its cluster.

We train our models with mini-batch stochastic gradient descent, with a batch size of 128 words, and an initial learning rate of 0.3. We check our training objective on the development set every 20K batches, and if it fails to improve for two consecutive checks, the learning rate is halved. Training stops after 5 consecutive failed checks or after 60 checks. As NCE may take longer to converge than MLE, we occasionally let NCE models train to 90 checks, but this never resulted in improved performance. Finally, after training finishes on the complete training data, we use that model to initialize a second training run, on a smaller in-domain training set known to better match the test conditions.[1] This in-domain pass uses a lower initial learning rate of 0.03.

Our translation system is a multi-stack phrase-based decoder that is quite similar to Moses (Koehn et al., 2007). Its features include standard phrase table probabilities, KN-smoothed language models including a 6-gram model trained on the English Gigaword and a 4-gram model trained on the target side of the parallel training data, domain-adapted phrase tables and language models (Foster and Kuhn, 2007), a hierarchical lexicalized reordering model (Galley and Manning, 2008), and sparse features drawn from Hopkins and May (2011) and Cherry (2013). It is tuned with a batch-lattice variant of hope-fear MIRA (Chiang et al., 2008; Cherry and Foster, 2012).

4 Experiments

We test two translation scenarios drawn from the recent BOLT evaluations: Arabic-to-English and Chinese-to-English. The vital statistics for our corpora are given in Table 1. The training set mixes NIST data with BOLT-specific informal genres. The development and test sets are focused specifically on the web-forum genre, as is the in-domain subset of the training data (*In-dom*). The Arabic was segmented with MADA-ARZ (Habash et al., 2013), while the Chinese was segmented with a lexicon-based approach. All data was word-aligned with IBM-4 in GIZA++ (Och and Ney, 2003), with grow-diag-final-and symmetrization (Koehn et al., 2003).

Lang.	Train	In-dom	Dev	Test1	Test2
Arabic	38.6M	1.8M	72K	38K	40K
Chinese	29.2M	1.9M	77K	38K	36K

Table 1: Corpus sizes in terms of number of target tokens. Dev and Test sets have 3 references for Arabic and 5 for Chinese.

4.1 Comparing Training Objectives

Our main experiment is designed to answer two questions: (1) does training NNJMs with NCE impact translation quality? and (2) can any reduction be mitigated through alternate noise distributions? To this end, we train four NNJMs.

- **MLE**: Maximum likelihood training with self-normalization $\alpha = 0.1$
- **NCE-U**: NCE with unigram noise
- **NCE-T**: NCE with translation noise
- **NCE-M**: NCE with mixture noise

and compare their performance to that of a system with no NNJM. Each NNJM was trained as described in Section 3, varying only the learning objective.[2] To measure intrinsic NNJM quality, we report average negative log likelihoods (NLL) and average $|\log Z|$, both calculated on Dev. Lower NLL scores indicate better prediction accuracy, while lower $|\log Z|$ values indicate more effective self-normalization. We also provide average BLEU scores and standard deviations for Test1 and Test2, each calculated over 5 random tuning replications. Statistical significance is calculated with MultEval (Clark et al., 2011).

Our results are shown in Table 2. By comparing MLE to no NNJM, we can confirm that the NNJM is a very effective translation feature, showing large

[1] Recommended by Jacob Devlin, personal communication.

[2] The only exception was the Arabic NCE-M system, which showed some instability during optimization, leading us to reduce its initial learning rate to 0.2.

MLE	1.76	0.50	41.7	0.1	42.0	0.1	2.35	0.49	32.9	0.0	29.1	0.0
NCE-U	1.85	0.42	40.9	0.2	41.5	0.1	2.54	0.42	32.2	0.1	28.3	0.1
NCE-T	3.87	2.36	**41.6**	0.1	**42.4**	0.2	3.93	1.70	**32.7**	0.1	28.7	0.2
NCE-M	1.85	0.30	41.4	0.1	**42.1**	0.1	2.40	0.30	32.6	0.1	28.8	0.1

Table 2: Comparing various NNJM training objectives on two translation scenarios. BLEU results that are statistically better than NCE-U are underlined ($p \leq 0.05$). Those statistically equivalent to or better than MLE are in **bold** ($p \leq 0.05$).

BLEU improvements on all tests. By comparing MLE to NCE-U, we can see that NCE training does reduce translation quality. NCE-U outperforms having no NNJM, but lags behind MLE considerably, resulting in significantly worse performance on all tests. This is mitigated with translation noise: NCE-T and NCE-M both perform significantly better than NCE-U. Furthermore, in 3 out of 4 tests, NCE-T matches or exceeds the performance of MLE. The one Arabic-to-English case where NCE-T exceeds the performance of MLE is particularly intriguing, and warrants further study.

Though NCE-T performs very well as a translation feature, it is relatively lousy as a language model, with abnormally large values for both NLL and $|\log Z|$. This indicates that NCE-T is only good at predicting the next word from a pool of reasonable translation candidates. Scores for words drawn from the larger vocabulary are less accurate. However, the BLEU results for NCE-T show that this does not matter for translation performance. If model likelihoods over the complete vocabulary are needed, one can repair these estimates by mixing in unigram noise, as shown by NCE-M, which achieves the same or better likelihoods than NCE-U, with comparable BLEU scores to those of NCE-T.

Devlin et al. (2014) suggest that one drawback of NCE with respect to self-normalized MLE is NCE's lack of an α hyper-parameter to control the objective's emphasis on self-normalization. However, the $|\log Z|$ values for NCE-U are only slightly lower than those of MLE, and are larger than those of the superior NCE-M. This suggests that we could not have improved NCE-U's performance by adjusting its emphasis on self-normalization.

	General		Adapted	
Method	BLEU	Δ	BLEU	Δ
No NNJM	39.6	-1.4	39.6	-2.2
MLE	41.0	—	41.8	—
NCE-U	40.7	-0.3	41.2	-0.6
NCE-T	41.0	0.0	42.0	+0.2
NCE-M	40.9	-0.1	41.7	-0.1

Table 3: Comparing NNJM training objectives with and without a domain adaptation step for Arabic-to-English task.

4.2 Impact of the Domain Adaptation Pass

We began this project with the hypothesis that NCE may harm NNJM performance. But NCE-U performed worse than we expected. In particular, the differences between NCE-U and NCE-T are larger than those reported by Zhang et al. (2015). This led us to investigate the domain adaptation pass, which was used in our experiments but not those of Zhang et al. This step refines the model with a second training pass on an in-domain subset of the training data. We repeated our comparison for Arabic without domain adaptation, reporting BLEU averaged over two test sets and across 5 tuning replications. We also report each system's BLEU differential Δ with respect to MLE. The results are shown under *General* in Table 3, while *Adapted* summarizes our results from Table 2 in the same format.

The domain adaptation step magnifies the differences between training objectives, perhaps because it increases performance over-all. The spread between the worst and best NNJM is only 0.3 BLEU under *General*, while it is 0.8 BLEU under *Adapted*. Therefore, groups training unadapted models may not see as large drops from NCE-U as we have reported above. Note that we experimented with several configurations that account specifically for this domain-adaptation pass (noise distributions based on general versus in-domain corpora, alternate stopping criteria), so that NCE-U would be presented in the most positive possible light. Perhaps most importantly, Table 3 shows that the domain adaptation pass is quite effective, producing large improvements for all NNJMs.

4.3 Impact on Speed

MLE and NCE both produce self-normalized models, so they both have the same impact on decoding speed. With the optimizations described by Devlin et al. (2014), the impact of any single-hidden-layer NNJM is negligible.

For training, the main benefit of NCE is that it reduces the cost of the network's output layer, replacing a term that was linear in the vocabulary size with one that is linear in the sample size. In our experiments, this is a reduction from 32K to 100. The actual benefit from this reduction is highly implementation- and architecture-dependent. It is difficult to get a substantial speedup from NCE using Theano on GPU hardware, as both reward dense matrix operations, and NCE demands sparse vector operations (Jean et al., 2015). Therefore, our decision to implement all methods in a shared codebase, which ensured a fair comparison of model quality, also prevented us from providing a meaningful evaluation of training speed, as the code and architecture were implicitly optimized to favour the most demanding method (MLE). Fortunately, there is ample evidence that NCE can provide large improvements to per-batch training speeds for NNLMs, ranging from a 2× speed-up for 20K-word vocabularies on a GPU (Chen et al., 2015) to more than 10× for 70K-word vocabularies on a CPU (Vaswani et al., 2013). Meanwhile, our experiments show that 1.2M batches are sufficient for MLE, NCE-T and NCE-M to achieve very high quality; that is, none of these methods made use of early stopping during their main training pass. This indicates that per-batch speed is the most important factor when comparing the training times of these NNJMs.

5 Conclusions

We have shown that NCE training with a unigram noise distribution does reduce NNJM performance with respect to MLE training, both in terms of model likelihoods and downstream translation quality. This performance drop can be avoided if NCE uses a translation-aware noise distribution. We have emphasized the importance of a domain-specific training pass, and we have shown that this pass magnifies the differences between the various NNJM training objectives. In a few cases, NCE with translation noise actually outperformed MLE. This suggests that there is value in only considering plausible translation candidates during training. It would be interesting to explore methods to improve MLE with this intuition.

Abstract

We study the problem of generating abstractive summaries for opinionated text. We propose an attention-based neural network model that is able to absorb information from multiple text units to construct informative, concise, and fluent summaries. An importance-based sampling method is designed to allow the encoder to integrate information from an important subset of input. Automatic evaluation indicates that our system outperforms state-of-the-art abstractive and extractive summarization systems on two newly collected datasets of movie reviews and arguments. Our system summaries are also rated as more informative and grammatical in human evaluation.

1 Introduction

Collecting opinions from others is an integral part of our daily activities. Discovering what other people think can help us navigate through different aspects of life, ranging from making decisions on regular tasks to judging fundamental societal issues and forming personal ideology. To efficiently absorb the massive amount of opinionated information, there is a pressing need for automated systems that can generate concise and fluent opinion summary about an entity or a topic. In spite of substantial researches in opinion summarization, the most prominent approaches mainly rely on *extractive summarization* methods, where phrases or sentences from the original documents are selected for inclusion in the summary (Hu and Liu, 2004; Lerman et al., 2009). One of the problems that extractive methods suffer from is that they unavoidably include secondary or redundant information. On the contrary, *abstractive summarization* methods, which are able to generate text beyond the original input, can produce more coherent and concise summaries.

Movie: *The Martian*
Reviews:
- One the **smartest**, sweetest, and most satisfyingly suspenseful sci-fi films in years.
- ...an intimate sci-fi epic that is **smart**, spectacular and stirring.
- The Martian is a **thrilling**, human and moving sci-fi picture that is easily the most emotionally engaging film Ridley Scott has made...
- It's pretty sunny and often **funny**, a space oddity for a director not known for pictures with **a sense of humor**.
- The Martian **highlights the book's best qualities**, tones down its worst, and adds its own style...

Opinion Consensus (Summary): **Smart**, **thrilling**, and surprisingly **funny**, The Martian offers **a faithful adaptation of the bestselling book** that brings out the best in leading man Matt Damon and director Ridley Scott.

Topic: *This House supports the death penalty.*
Arguments:
- The state has a responsibility to protect the lives of innocent citizens, and enacting the death penalty may save lives by **reducing the rate of violent crime**.
- While the prospect of life in prison may be frightening, surely death is a more daunting prospect.
- A 1985 study by Stephen K. Layson at the University of North Carolina showed that a single execution **deters 18 murders**.
- Reducing the wait time on death row prior to execution can dramatically increase its **deterrent effect** in the United States.

Claim (Summary): The death penalty **deters crime**.

Figure 1: Examples for an opinion consensus of professional reviews (critics) about movie "*The Martian*" from www.rottentomatoes.com, and a claim about "death penalty" supported by arguments from idebate.org. Content with similar meaning is highlighted in the same color.

In this paper, we present *an attention-based neural network model for generating abstractive summaries of opinionated text*. Our system takes as input a set of text units containing opinions about the same topic (e.g. reviews for a movie, or arguments

Proceedings of NAACL-HLT 2016, pages 47–57,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

for a controversial social issue), and then outputs a one-sentence abstractive summary that describes the opinion consensus of the input.

Specifically, we investigate our abstract generation model on two types of opinionated text: *movie reviews* and *arguments on controversial topics*. Examples are displayed in Figure 1. The first example contains a set of professional reviews (or critics) about movie "The Martian" and an opinion consensus written by an editor. It would be more useful to automatically generate fluent opinion consensus rather than simply extracting features (e.g. plot, music, etc) and opinion phrases as done in previous summarization work (Zhuang et al., 2006; Li et al., 2010). The second example lists a set of arguments on "death penalty", where each argument supports the central claim "death penalty deters crime". Arguments, as a special type of opinionated text, contain reasons to persuade or inform people on certain issues. Given a set of arguments on the same topic, we aim at investigating the capability of our abstract generation system for the novel task of *claim generation*.

Existing abstract generation systems for opinionated text mostly take an approach that first identifies salient phrases, and then merges them into sentences (Bing et al., 2015; Ganesan et al., 2010). Those systems are not capable of generating new words, and the output summary may suffer from ungrammatical structure. Another line of work requires a large amount of human input to enforce summary quality. For example, Gerani et al. (2014) utilize a set of templates constructed by human, which are filled by extracted phrases to generate grammatical sentences that serve different discourse functions.

To address the challenges above, we propose to use an attention-based abstract generation model — a data-driven approach trained to generate informative, concise, and fluent opinion summaries. Our method is based on the recently proposed framework of neural encoder-decoder models (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014a), which translates a sentence in a source language into a target language. Different from previous work, our summarization system is designed to support multiple input text units. An attention-based model (Bahdanau et al., 2014) is deployed to allow the encoder to automatically search for salient information within context. Furthermore, we propose an importance-based sampling method so that the encoder can integrate information from an important subset of input text. The importance score of a text unit is estimated from a novel regression model with pairwise preference-based regularizer. With importance-based sampling, our model can be trained within manageable time, and is still able to learn from diversified input.

We demonstrate the effectiveness of our model on two newly collected datasets for movie reviews and arguments. Automatic evaluation by BLEU (Papineni et al., 2002) indicates that our system outperforms the state-of-the-art extract-based and abstract-based methods on both tasks. For example, we achieved a BLEU score of 24.88 on Rotten Tomatoes movie reviews, compared to 19.72 by an abstractive opinion summarization system from Ganesan et al. (2010). ROUGE evaluation (Lin and Hovy, 2003) also indicates that our system summaries have reasonable information coverage. Human judges further rated our summaries to be more informative and grammatical than compared systems.

2 Data Collection

We collected two datasets for movie reviews and arguments on controversial topics with gold-standard abstracts.[1] Rotten Tomatoes (`www.rottentomatoes.com`) is a movie review website that aggregates both professional critics and user-generated reviews (henceforth *RottenTomatoes*). For each movie, a one-sentence critic consensus is constructed by an editor to summarize the opinions in professional critics. We crawled 246,164 critics and their opinion consensus for 3,731 movies (i.e. around 66 reviews per movie on average). We select 2,458 movies for training, 536 movies for validation and 737 movies for testing. The opinion consensus is treated as the gold-standard summary.

We also collect an argumentation dataset from `idebate.org` (henceforth *Idebate*), which is a Wikipedia-style website for gathering pro and con arguments on controversial issues. The arguments under each debate (or topic) are organized into dif-

[1] The datasets can be downloaded from `http://www.ccs.neu.edu/home/luwang/`.

ferent "for" and "against" points. Each point contains a one-sentence central claim constructed by the editors to summarize the corresponding arguments, and is treated as the gold-standard. For instance, on a debate about "death penalty", one claim is "the death penalty deters crime" with an argument "enacting the death penalty may save lives by reducing the rate of violent crime" (Figure 1). We crawled 676 debates with 2,259 claims. We treat each sentence as an argument, which results in 17,359 arguments in total. 450 debates are used for training, 67 debates for validation, and 150 debates for testing.

3 The Neural Network-Based Abstract Generation Model

In this section, we first define our problem in Section 3.1, followed by model description. In general, we utilize a Long Short-Term Memory network for generating abstracts (Section 3.2) from a latent representation computed by an attention-based encoder (Section 3.3). The encoder is designed to search for relevant information from input to better inform the abstract generation process. We also discuss an importance-based sampling method to allow encoder to integrate information from an important subset of input (Sections 3.4 and 3.5). Post-processing (Section 3.6) is conducted to re-rank the generations and pick the best one as the final summary.

3.1 Problem Formulation

In summarization, the goal is to generate a summary y, composed by the sequence of words $y_1, ..., |y|$. Unlike previous neural encoder-decoder approaches which decode from only one input, our input consists of an arbitrary number of reviews or arguments (henceforth *text units* wherever there is no ambiguity), denoted as $x = \{x^1, ..., x^M\}$. Each text unit x^k is composed by a sequence of words $x^k_1, ..., x^k_{|x^k|}$. Each word takes the form of a representation vector, which is initialized randomly or by pre-trained embeddings (Mikolov et al., 2013), and updated during training. The summarization task is defined as finding $\hat{y}$, which is the most likely sequence of words $\hat{y}_1, ..., \hat{y}_N$ such that:

$$\hat{y} = argmax_y \log P(y|x) \tag{1}$$

where $\log P(y|x)$ denotes the conditional log-likelihood of the output sequence y, given the input text units x. In the next sections, we describe the attention model used to model $\log P(y|x)$.

3.2 Decoder

Similar as previous work (Sutskever et al., 2014b; Bahdanau et al., 2014), we decompose $\log P(y|x)$ into a sequence of word-level predictions:

$$\log P(y|x) = \sum_{j=1,...,|y|} \log P(y_j|y_1, ..., y_{j-1}, x) \tag{2}$$

where each word y_j is predicted conditional on the previously generated $y_1, ..., y_{j-1}$ and input x. The probability is estimated by standard word softmax:

$$p(y_j|y_1, ..., y_{j-1}, x) = softmax(\mathbf{h}_j) \tag{3}$$

$\mathbf{h}_j$ is the Recurrent Neural Networks (RNNs) state variable at timestamp j, which is modeled as:

$$\mathbf{h}_j = g(\mathbf{y}_{j-1}, \mathbf{h}_{j-1}, \mathbf{s}) \tag{4}$$

Here g is a recurrent update function for generating the new state $\mathbf{h}_j$ from the representation of previously generated word $\mathbf{y}_{j-1}$ (obtained from a word lookup table), the previous state $\mathbf{h}_{j-1}$, and the input text representation $\mathbf{s}$ (see Section 3.3).

In this work, we implement g using a Long Short-Term Memory (LSTM) network (Hochreiter and Schmidhuber, 1997), which has been shown to be effective at capturing long range dependencies. Here we summarize the update rules for LSTM cells, and refer readers to the original work (Hochreiter and Schmidhuber, 1997) for more details. Given an arbitrary input vector $\mathbf{u}_j$ at timestamp $j-1$ and the previous state $\mathbf{h}_{j-1}$, a typical LSTM defines the following update rules:

$$\begin{aligned}
\mathbf{i}_j &= \sigma(\mathbf{W}_{iu}\mathbf{u}_j + \mathbf{W}_{ih}\mathbf{h}_{j-1} + \mathbf{W}_{ic}\mathbf{c}_{j-1} + \mathbf{b}_i) \\
\mathbf{f}_j &= \sigma(\mathbf{W}_{fu}\mathbf{u}_j + \mathbf{W}_{fh}\mathbf{h}_{j-1} + \mathbf{W}_{fc}\mathbf{c}_{j-1} + \mathbf{b}_f) \\
\mathbf{c}_j &= \mathbf{f}_j \odot \mathbf{c}_{j-1} + \mathbf{i}_j \odot \tanh(\mathbf{W}_{cu}\mathbf{u}_j + \mathbf{W}_{ch}\mathbf{h}_{j-1} + \mathbf{b}_c) \\
\mathbf{o}_j &= \sigma(\mathbf{W}_{ou}\mathbf{u}_j + \mathbf{W}_{oh}\mathbf{h}_{j-1} + \mathbf{W}_{oc}\mathbf{c}_j + \mathbf{b}_o) \\
\mathbf{h}_j &= \mathbf{o}_j \odot \tanh(\mathbf{c}_j)
\end{aligned} \tag{5}$$

σ is component-wise logistic sigmoid function, and $\odot$ denotes Hadamard product. Projection matrices

$\mathbf{W}_{**}$ and biases $\mathbf{b}_*$ are parameters to be learned during training.

Long range dependencies are captured by the cell memory $\mathbf{c}_j$, which is updated linearly to avoid the vanishing gradient problem. It is accomplished by predicting two vectors $\mathbf{i}_j$ and $\mathbf{f}_j$, which determine what to keep and what to forget from the current timestamp. Vector $\mathbf{o}_j$ then decides on what information from the new cell memory $\mathbf{c}_j$ can be passed to the new state $\mathbf{h}_j$. Finally, the model concatenates the representation of previous output word $\mathbf{y}_{j-1}$ and the input representation $\mathbf{s}$ (see Section 3.3) as $\mathbf{u}_j$, which serves as the input at each timestamp.

3.3 Encoder

The representation of input text units $\mathbf{s}$ is computed using an attention model (Bahdanau et al., 2014). Given a single text unit $x_1, ..., x_{|x|}$ and the previous state $\mathbf{h_j}$, the model generates $\mathbf{s}$ as a weighted sum:

$$\sum_{i=1,...,|x|} a_i \mathbf{b}_i \tag{6}$$

where a_i is the attention coefficient obtained for word x_i, and $\mathbf{b}_i$ is the context dependent representation of x_i. In our work, we construct $\mathbf{b}_i$ by building a bidirectional LSTM over the whole input sequence $x_1, ..., x_{|x|}$ and then combining the forward and backward states. Formally, we use the LSTM formulation from Eq. 5 to generate the forward states $\mathbf{h}_1^f, ..., \mathbf{h}_{|x|}^f$ by setting $\mathbf{u}_j = \mathbf{x}_j$ (the projection word x_j using a word lookup table). Likewise, the backward states $\mathbf{h}_{|x|}^b, ..., \mathbf{h}_1^b$ are generated using a backward LSTM by feeding the input in the reverse order, that is, $\mathbf{u}_j = \mathbf{x}_{|x|-j+1}$. The coefficients a_i are computed with a softmax over all input:

$$a_i = softmax(v(\mathbf{b}_i, \mathbf{h}_{j-1})) \tag{7}$$

where function v computes the affinity of each word x_i and the current output context $\mathbf{h}_{j-1}$ — how likely the input word is to be used to generate the next word in summary. We set $v(\mathbf{b}_i, \mathbf{h}_{j-1}) = \mathbf{W}_s \cdot \tanh(\mathbf{W}_{cg}\mathbf{b}_i + \mathbf{W}_{hg}\mathbf{h}_{j-1})$, where $\mathbf{W}_*$ and $\mathbf{W}_{**}$ are parameters to be learned.

3.4 Attention Over Multiple Inputs

A key distinction between our model and existing sequence-to-sequence models (Sutskever et al., 2014b; Bahdanau et al., 2014) is that our input consists of multiple separate text units. Given an input of N text units, i.e. $\{x_1^k, ..., x_{|x^k|}^k\}_{k=1}^N$, a simple extension would be to concatenate them into one sequence as $z = x_1^1, ..., x_{|x^1|}^1, \text{SEG}, x_1^2, ..., x_{|x^2|}^2, \text{SEG}, x_1^N, ..., x_{|x^N|}^N$, where SEG is a special token that delimits inputs.

However, there are two problems with this approach. Firstly, the model is sensitive to the order of text units. Moreover, z may contain thousands of words. This will become a bottleneck for our model with a training time of $O(N|z|)$, since attention coefficients must be computed for all input words to generate each output word.

We address these two problems by sub-sampling from the input. The intuition is that even though the number of input text units is large, many of them are redundant or contain secondary information. As our task is to emphasize the main points made in the input, some of them can be removed without losing too much information. Therefore, we define an importance score $f(x^k) \in [0, 1]$ for each document x^k (see Section 3.5). During training, K candidates are sampled from a multinomial distribution which is constructed by normalizing $f(x^k)$ for input text units. Notice that the training process goes over the training set multiple times, and our model is still able to learn from more than K text units. For testing, top-K candidates with the highest importance scores are collapsed in descending order into z.

3.5 Importance Estimation

We now describe the importance estimation model, which outputs importance scores for text units. In general, we start with a ridge regression model, and add a regularizer to enforce the separation of summary-worthy text units from others.

Given a cluster of text units $\{x^1, ..., x^M\}$ and their summary y, we compute the number of overlapping content words between each text unit and summary y as its gold-standard importance score. The scores are uniformly normalized to $[0, 1]$. Each text unit x^k is represented as an $d-$dimensional feature vector $\mathbf{r_k} \in \mathbb{R}^d$, with label l_k. Text units in the training data are thus denoted with a feature matrix $\tilde{\mathbf{R}}$ and a label vector $\tilde{\mathbf{L}}$. We aim at learning $f(x^k) = \mathbf{r_k} \cdot \mathbf{w}$ by minimizing $||\tilde{\mathbf{R}}\mathbf{w} - \tilde{\mathbf{L}}||_2^2 + \beta \cdot ||\mathbf{w}||_2^2$. This is a standard formulation for ridge regression, and we use features in Table 1. Furthermore, pairwise preference constraints have been utilized for learning ranking models (Joachims, 2002). We then consider adding a *pairwise preference-based regularizing constraint* to incorporate a bias towards summary-worthy text units: $\lambda \cdot \sum_{\mathcal{T}} \sum_{x^p, x^q \in \mathcal{T}, l_p > 0, l_q = 0} ||(\mathbf{r_p} - \mathbf{r_q}) \cdot \mathbf{w} - 1||_2^2$, where $\mathcal{T}$ is a cluster of text units to be summarized. Term $(\mathbf{r_p} - \mathbf{r_q}) \cdot \mathbf{w}$ enforces the separation of summary-worthy text from the others. We further construct $\tilde{\mathbf{R}}'$ to contain all the pairwise differences $(\mathbf{r_p} - \mathbf{r_q})$. $\tilde{\mathbf{L}}'$ is a vector of the same size as $\tilde{\mathbf{R}}'$ with each element as 1. The objective function becomes:

$$J(\mathbf{w}) = ||\tilde{\mathbf{R}}\mathbf{w} - \tilde{\mathbf{L}}||_2^2 + \lambda \cdot ||\tilde{\mathbf{R}}'\mathbf{w} - \tilde{\mathbf{L}}'||_2^2 + \beta \cdot ||\mathbf{w}||_2^2 \quad (8)$$

λ, β are tuned on development set. With $\tilde{\boldsymbol{\beta}} = \beta \cdot \mathbf{I_d}$ and $\tilde{\boldsymbol{\lambda}} = \lambda \cdot \mathbf{I}_{|\mathbf{R}'|}$, **closed-form** solution for $\hat{\mathbf{w}}$ is:

$$\hat{\mathbf{w}} = (\tilde{\mathbf{R}}^{\mathbf{T}}\tilde{\mathbf{R}} + \tilde{\mathbf{R}}'^{\mathbf{T}}\tilde{\boldsymbol{\lambda}}\tilde{\mathbf{R}}' + \tilde{\boldsymbol{\beta}})^{-1}(\tilde{\mathbf{R}}^{\mathbf{T}}\tilde{\mathbf{L}} + \tilde{\mathbf{R}}'^{\mathbf{T}}\tilde{\boldsymbol{\lambda}}\tilde{\mathbf{L}}') \quad (9)$$

- num of words	- category in General Inquirer
- unigram	(Stone et al., 1966)
- num of POS tags	- num of positive/negative/neutral
- num of named entities	words (General Inquirer,
- centroidness (Radev, 2001)	MPQA (Wilson et al., 2005))
- avg/max TF-IDF scores	

Table 1: Features used for text unit importance estimation.

3.6 Post-processing

For testing phase, we re-rank the n-best summaries according to their cosine similarity with the input text units. The one with the highest similarity is included in the final summary. Uses of more sophisticated re-ranking methods (Charniak and Johnson, 2005; Konstas and Lapata, 2012) will be investigated in future work.

4 Experimental Setup

Data Pre-processing. We pre-process the datasets with Stanford CoreNLP (Manning et al., 2014) for tokenization and extracting POS tags and dependency relations. For RottenTomatoes dataset, we replace movie titles with a generic label in training, and substitute it with the movie name if there is any generic label generated in testing.

Pre-trained Embeddings and Features. The size of word representation is set to 300, both for input and output words. These can be initialized randomly or using pre-trained embeddings learned from Google news (Mikolov et al., 2013). We also extend our model with additional features described in Table 2. Discrete features, such as POS tags, are mapped into word representation via lookup tables. For continuous features (e.g TF-IDF scores), they are attached to word vectors as additional values.

- part of a named entity?	- category in General Inquirer
- capitalized?	- sentiment polarity
- POS tag	(General Inquirer, MPQA)
- dependency relation	- TF-IDF score

Table 2: Token-level features used for abstract generation.

Hyper-parameters and Stop Criterion. The LSTMs (Equation 5) for the decoder and encoders are defined with states and cells of 150 dimensions. The attention of each input word and state pair is computed by being projected into a vector of 100 dimensions (Equation 6).

Training is performed via Adagrad (Duchi et al., 2011). It terminates when performance does not improve on the development set. We use BLEU (up to 4-grams) (Papineni et al., 2002) as evaluation metric, which computes the precision of n-grams in generated summaries with gold-standard abstracts as the reference. Finally, the importance-based sampling rate (K) is set to 5 for experiments in Sections 5.2 and 5.3.

Decoding is performed by beam search with a beam size of 20, i.e. we keep 20 most probable output sequences in stack at each step. Outputs with `end of sentence` token are also considered for re-ranking. Decoding stops when every beam in stack generates the `end of sentence` token.

5 Results

5.1 Importance Estimation Evaluation

We first evaluate the importance estimation component described in Section 3.5. We compare with Support Vector Regression (SVR) (Smola and Vapnik, 1997) and two baselines: (1) a *length baseline* that ranks text units based on their length, and (2) a *centroid baseline* that ranks text units according to their centroidness, which is computed as the cosine similarity between a text unit and centroid of the cluster to be summarized (Erkan and Radev, 2004).

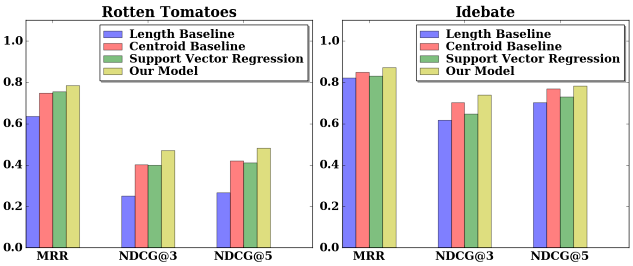

Figure 2: Evaluation of importance estimation by mean reciprocal rank (MRR), and normalized discounted cumulative gain at top 3 and 5 returned results (NDCG@3 and NDCG@5). Our regression model with pairwise preference-based regularizer uniformly outperforms baseline systems on both datasets.

We evaluate using mean reciprocal rank (MRR), and normalized discounted cumulative gain at top 3 and 5 returned results (NDCG@3). Text units are considered relevant if they have at least one overlapping content word with the gold-standard summary. From Figure 2, we can see that our importance estimation model produces uniformly better ranking performance on both datasets.

5.2 Automatic Summary Evaluation

For automatic summary evaluation, we consider three popular metrics. ROUGE (Lin and Hovy, 2003) is employed to evaluate n-grams recall of the summaries with gold-standard abstracts as reference. ROUGE-SU4 (measures unigram and skip-bigrams separated by up to four words) is reported. We also utilize BLEU, a precision-based metric, which has been used to evaluate various language generation systems (Chiang, 2005; Angeli et al., 2010; Karpathy and Fei-Fei, 2014). We further consider METEOR (Denkowski and Lavie, 2014). As a recall-oriented metric, it calculates similarity between generations and references by considering synonyms and paraphrases.

For comparisons, we first compare with an abstractive summarization method presented in Ganesan et al. (2010) on the RottenTomatoes dataset. Ganesan et al. (2010) utilize a graph-based algorithm to remove repetitive information, and merge opinionated expressions based on syntactic structures of product reviews.[2] For both datasets, we consider two extractive summarization approaches: (1) LexRank (Erkan and Radev, 2004) is an unsupervised method that computes text centrality based on PageRank algorithm; (2) Sipos et al. (2012) propose a supervised SUBMODULAR summarization model which is trained with Support Vector Machines. In addition, LONGEST sentence is picked up as a baseline.

Four variations of our system are tested. One uses randomly initialized word embeddings. The rest of them use pre-trained word embeddings, additional features in Table 2, and their combination. For all systems, we generate a one-sentence summary.

Results are displayed in Table 3. Our system with pre-trained word embeddings and additional features achieves the best BLEU scores on both datasets (in **boldface**) with statistical significance (two-tailed Wilcoxon signed rank test, $p < 0.05$). Notice that our system summaries are conciser (i.e. shorter on average), which lead to higher scores on precision based-metrics, e.g. BLEU, and lower scores on recall-based metrics, e.g. METEOR and ROUGE. On RottenTomatoes dataset, where summaries generated by different systems are similar in length, our system still outperforms other methods in METEOR and ROUGE in addition to their significantly better BLEU scores. This is not true on Idebate, since the length of summaries by extract-based systems is significantly longer. But the BLEU scores of our system are considerably higher. Among our four systems, models with pre-trained word embeddings in general achieve better scores. Though additional features do not always improve the performance, we find that they help our systems converge faster.

5.3 Human Evaluation on Summary Quality

For human evaluation, we consider three aspects: *informativeness* that indicates how much salient information is contained in the summary, *grammaticality* that measures whether a summary is grammatical, and *compactness* that denotes whether a summary contains unnecessary information. Each aspect is rated on a 1 to 5 scale (5 is the best). The judges are

[2] We do not run this model on Idebate because it relies on high redundancy to detect repetitive expressions, which is not observed on Idebate.

	RottenTomatoes				*Idebate*			
	Length	**BLEU**	**METEOR**	**ROUGE**	**Length**	**BLEU**	**METEOR**	**ROUGE**
Extract-Based Systems								
Longest	47.9	8.25	**8.43**	**6.43**	44.0	6.36	10.22	12.65

Table 3: Automatic evaluation results by BLEU, METEOR, and ROUGE SU-4 scores (multiplied by 100) for abstract generation systems. The average lengths for human written summaries are 11.5 and 24.6 for RottenTomatoes and Idebate. The best performing system for each column is highlighted in **boldface**, where our system with pre-trained word embeddings and additional features achieves the best BLEU scores on both datasets. Our systems that are statistically significantly better than the comparisons are highlighted with $*$ (two-tailed Wilcoxon signed rank test, $p < 0.05$). Our system also has the best METEOR and ROUGE scores (in *italics*) on RottenTomatoes dataset among learning-based systems.

	Info	**Gram**	**Comp**	**Avg Rank**	**Best%**
LexRank	3.4	4.5	4.3	2.7	11.5%
Opinosis	2.8	3.1	3.3	3.5	5.0%
Our System	**3.6**	**4.8**	4.2	**2.3**	**18.0%**
Human Abstract	4.2	4.8	4.5	1.5	65.5%

Table 4: Human evaluation results for abstract generation systems. Inter-rater agreement for overall ranking is 0.71 by Krippendorff's α. Informativeness (**Info**), grammaticality (**Gram**), and Compactness (**Comp**) are rated on a 1 to 5 scale, with 5 as the best. Our system achieves the best informativeness and grammaticality scores among the three learning-based systems. Our summaries are ranked as the best in 18% of the evaluations, and are also ranked higher than compared systems on average.

also asked to give a ranking on all summary variations according to their overall quality.

We randomly sampled 40 movies from RottenTomatoes test set, each of which was evaluated by 5 distinct human judges. We hired 10 proficient English speakers for evaluation. Three system summaries (LexRank, Opinosis, and our system) and human-written abstract along with 20 representative reviews were displayed for each movie. Reviews with the highest gold-standard importance scores were selected.

Results are reported in Table 4. As it can be seen, our system outperforms the abstract-based system Opinosis in all aspects, and also achieves better informativeness and grammaticality scores than LexRank, which extracts sentences in their original form. Our system summaries are ranked as the best in 18% of the evaluations, and has an average ranking of 2.3, which is higher than both Opinosis and LexRank on average. An inter-rater agreement of Krippendorff's α of 0.71 is achieved for overall ranking. This implies that our attention-based abstract generation model can produce summaries of better quality than existing summarization systems. We also find that our system summaries are constructed in a style closer to human abstracts than others. Sample summaries are displayed in Figure 3.

5.4 Sampling Effect

We further investigate whether taking inputs sampled from distributions estimated by importance scores trains models with better performance than the ones learned from fixed input or uniformly-sampled input. Recall that we sample K text units based on their importance scores (*Importance-Based Sampling*). Here we consider two other setups: one is sampling K text units uniformly from the input (*Uniform Sampling*), another is picking K text units with the highest scores (*Top K*). We try various K values. Results in Figure 4 demonstrates that Importance-Based Sampling can produce comparable BLEU scores to Top K methods, while both of them outperform Uniform Sampling. For METEOR score, Importance-Based Sampling uniformly outperforms the other two methods[3].

5.5 Further Discussion

Finally, we discuss some other observations and potential improvements. First, applying the re-ranking component after the model generates n-best abstracts leads to better performance. Preliminary experiments show that simply picking the top-1 gener-

[3] We observe similar results on the Idebate dataset

Movie: *The Neverending Story*
Reviews: (1) Here is a little adventure that fed on our uncultivated need to think, and wonder... (2) Magical storytelling targeted at children still fascinates. (3)...the art direction involved a lot of imagination.
Human: A magical journey about the power of a young boy's imagination to save a dying fantasy land, The Neverending Story remains a much-loved kids adventure.
LexRank: It pokes along at times and lapses occasionally into dark moments of preachy philosophy, but this is still a charming, amusing and harmless film for kids.
Opinosis: The Neverending Story is a silly fantasy movie that often shows its age .
Our System: The Neverending Story is an entertaining children's adventure, with heart and imagination to spare.

Movie: *Joe Strummer: The Future is Unwritten*
Reviews: (1) The late punk rock legend Joe Strummer is rendered fully human in Julian Temple's engrossing and all-encompassing portrait. (2) The movie fascinates not so much because of Strummer... but because of the way Temple organized and edited the film. (3) One of the most compelling documentary portraits of a musician yet made.
Human: Displaying Joe Strummer warts and all, The Future is Unwritten succeeds as both an engrossing documentary and a comprehensive examination of one of music's most legendary figures.
LexRank: Joe Strummer: The Future Is Unwritten is a film for fans – really big fans .
Opinosis: Joe Strummer: The Future Is Unwritten is for fans – really big fans .
Our System: Fascinating and insightful, Joe Strummer: The Future Is Unwritten is a thoroughly engrossing documentary.

Topic: *This House would detain terror suspects without trial.*
Arguments: (1) Governments must have powers to protect their citizens against threats to the life of the nation.(2) Everyone would recognise that rules that are applied in peacetime may not be appropriate during wartime.
Human: Governments must have powers to protect citizens from harm.
LexRank: This is not merely to directly protect citizens from political violence, but also because political violence handicaps the process of reconstruction in nation-building efforts.
Our System: Governments have the obligation to protect citizens from harmful substances.

Topic: *This House would replace Christmas with a festival for everyone.*
Arguments: (1) Christmas celebrations in the Western world... do not respect the rights of those who are not religious. (2) States should instead be sponsoring and celebrating events that everyone can join in equally, regardless of religion, race or class.
Human: States should respect the freedom from religion, as well as the freedom of religion.
LexRank: For school children who do not share the majority-Christian faith, Christmas celebrations require either their participation when they do not want to, through coercion, or their non-participation and therefore isolation whilst everyone else celebrations their inclusiveness.
Our System: People have a right to freedom of religion.

Figure 3: Sample summaries generated by different systems on movie reviews and arguments. We only show a subset of reviews and arguments due to limited space.

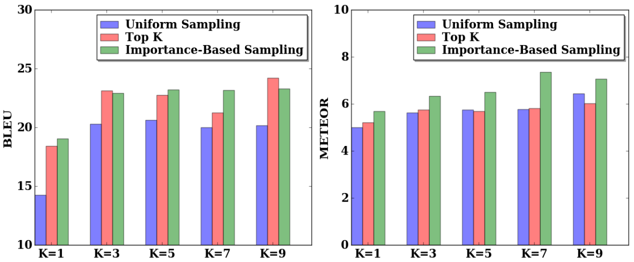

Figure 4: Sampling effect on RottenTomatoes.

ations produces inferior results than re-ranking them with simple heuristics. This suggests that the current models are oblivious to some task specific issues, such as informativeness. Post-processing is needed to make better use of the summary candidates. For example, future work can study other sophisticated re-ranking algorithms (Charniak and Johnson, 2005; Konstas and Lapata, 2012).

Furthermore, we also look at the difficult cases where our summaries are evaluated to have lower informativeness. They are often much shorter than the gold-standard human abstracts, thus the information coverage is limited. In other cases, some generations contain incorrect information on domain-dependent facts, e.g. named entities, numbers, etc. For instance, a summary "a poignant coming-of-age tale marked by a breakout lead performance from Cate Shortland" is generated for movie "Lore". This summary contains "Cate Shortland" which is the director of the movie instead of actor. It would require semantic features to handle this issue, which has yet to be attempted.

6 Related Work

Our work belongs to the area of opinion summarization. Constructing fluent natural language opinion summaries has mainly considered product reviews (Hu and Liu, 2004; Lerman et al., 2009), community question answering (Wang et al., 2014), and editorials (Paul et al., 2010). Extractive summarization approaches are employed to identify summary-worthy sentences. For example, Hu and Liu (2004) first identify the frequent product features and then attach extracted opinion sentences to the corresponding feature. Our model instead utilizes abstract generation techniques to construct natural language summaries. As far as we know, we are also the first to study claim generation for arguments.

Recently, there has been a growing interest in generating abstractive summaries for news articles (Bing et al., 2015), spoken meetings (Wang and Cardie, 2013), and product reviews (Ganesan et al., 2010; Di Fabbrizio et al., 2014; Gerani et al., 2014). Most approaches are based on phrase extraction, from which an algorithm concatenates them into sentences (Bing et al., 2015; Ganesan et al., 2010). Nevertheless, the output summaries are not guaranteed to be grammatical. Gerani et al. (2014) then design a set of manually-constructed realization templates for producing grammatical sentences that serve different discourse functions. Our approach does not require any human-annotated rules, and can be applied in various domains.

Our task is closely related to recent advances in neural machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014a). Based on the sequence-to-sequence paradigm, RNNs-based models have been investigated for compression (Filippova et al., 2015) and summarization (Filippova et al., 2015; Rush et al., 2015; Hermann et al., 2015) at sentence-level. Built on the attention-based translation model in Bahdanau et al. (2014), Rush et al. (2015) study the problem of constructing abstract for a single sentence. Our task differs from the models presented above in that our model carries out abstractive decoding from multiple sentences instead of a single sentence.

7 Conclusion

In this work, we presented a neural approach to generate abstractive summaries for opinionated text. We employed an attention-based method that finds salient information from different input text units to generate an informative and concise summary. To cope with the large number of input text, we deploy an importance-based sampling mechanism for model training. Experiments showed that our system obtained state-of-the-art results using both automatic evaluation and human evaluation.

Abstract

A key challenge for timeline summarization is to generate a concise, yet complete storyline from large collections of news stories. Previous studies in extractive timeline generation are limited in two ways: first, most prior work focuses on fully-observable ranking models or clustering models with hand-designed features that may not generalize well. Second, most summarization corpora are text-only, which means that text is the sole source of information considered in timeline summarization, and thus, the rich visual content from news images is ignored. To solve these issues, we leverage the success of matrix factorization techniques from recommender systems, and cast the problem as a sentence recommendation task, using a representation learning approach. To augment text-only corpora, for each candidate sentence in a news article, we take advantage of top-ranked relevant images from the Web and model the image using a convolutional neural network architecture. Finally, we propose a scalable low-rank approximation approach for learning joint embeddings of news stories and images. In experiments, we compare our model to various competitive baselines, and demonstrate the state-of-the-art performance of the proposed text-based and multimodal approaches.

1 Introduction

Timeline summarization is the task of organizing crucial milestones of a news story in a temporal order, e.g. (Kedzie et al., 2014; Lin et al., 2012). A timeline example for the *2010 British Oil spill* generated by our system is shown in Figure 1. The task is challenging, because the input often includes a large number of news articles as the story is developing each day, but only a small portion of the key information is needed for timeline generation. In addition to the conciseness requirement, timeline summarization also has to be complete—all key information, in whatever form, must be presented in the final summary.

To distill key insights from news reports, prior work in summarization often relies on feature engineering, and uses clustering techniques (Radev et al., 2004b) to select important events to be included in the final summary. While this approach is unsupervised, the process of feature engineering is always expensive, and the number of clusters is not easy to estimate. To present a complete summary, researchers from the natural language processing (NLP) community often solely rely on the textual information, while studies in the computer vision (CV) community rely solely on the image and video information. However, even though news images are abundantly available together with news stories, approaches that jointly learn textual and visual representations for summarization are not common.

In this paper, we take a more radical approach to timeline summarization. We formulate the problem as a sentence recommendation task—instead of recommending items to users as in a recommender system, we recommend important sentences to a timeline. Our approach does not require feature engineering: by using a matrix factorization framework, we are essentially performing representation learn-

ing to model the continuous representation of sentences and words. Since most previous timeline summarization work (and therefore, corpora) only focuses on textual information, we also provide a novel web-based approach for harvesting news images: we query Yahoo! image search with sentences from news articles, and extract visual cues using a 15-layer convolutional neural network architecture. By unifying text and images in the low-rank approximation framework, our approach learns a joint embedding of news story texts and images in a principled manner. In empirical evaluations, we conduct experiments on two publicly available datasets, and demonstrate the efficiency and effectiveness of our approach. By comparing to various baselines, we show that our approach is highly scalable and achieves state-of-the-art performance. Our main contributions are three-fold:

- We propose a novel matrix factorization approach for extractive summarization, leveraging the success of collaborative filtering;

- We are among the first to consider representation learning of a joint embedding for text and images in timeline summarization;

- Our model significantly outperforms various competitive baselines on two publicly available datasets.

2 Related Work

Supervised learning is widely used in summarization. For example, the seminal study by Kupiec et al. (1995) used a Naive Bayes classifier for selecting sentences. Recently, Wang et al. (2015) proposed a regression method that uses a joint loss function, combining news articles and comments. Additionally, unsupervised techniques such as language modeling (Allan et al., 2001) have been used for temporal summarization. In recent years, ranking and graph-based methods (Radev et al., 2004b; Erkan and Radev, 2004; Mihalcea and Tarau, 2004; Fader et al., 2007; Hassan et al., 2008; Mei et al., 2010; Yan et al., 2011b; Yan et al., 2011a; Zhao et al., 2013; Ng et al., 2014; Zhou et al., 2014; Glavaš and Šnajder, 2014; Tran et al., 2015; Dehghani and Asadpour, 2015) have also proved popular for extractive timeline summarization, often in an unsupervised setting. Dynamic programming (Kiernan and Terzi, 2009) and greedy algorithms (Althoff et al., 2015) have also been considered for constructing summaries over time.

Our work aligns with recent studies on latent variable models for multi-document summarization and storyline clustering. Conroy et al. (2001) were among the first to consider latent variable models, even though it is difficult to incorporate features and high-dimensional latent states in a HMM-based model. Ahmed et al. (2011) proposed a hierarchical nonparametric model that integrates a Recurrent Chinese Restaurant Process with Latent Dirichlet Allocation to cluster words over time. The main issues with this approach are that it does not generate human-readable sentences, and that scaling nonparametric Bayesian models is often challenging. Similarly, Huang and Huang (2013) introduced a joint mixture-event-aspect model using a generative method. Navarro-Colorado and Saquete (2015) combined temporal information with topic modeling, and obtained the best performance in the cross-document event ordering task of SemEval 2015.

There has been prior work (Wang et al., 2008; Lee et al., 2009) using matrix factorization to perform sentence clustering. A key distinction between our work and this previous work is that our method requires no additional sentence selection steps after sentence clustering, so we avoid error cascades.

Zhu and Chen (2007) were among the first to consider multimodal timeline summarization, but they focus on visualization, and do not make use of images. Wang et al. (2012) investigated multimodal timeline summarization by considering cosine similarity among various feature vectors, and then using a graph based algorithm to select salient topics. In the computer vision community, Kim and Xing (2014) made use of community web photos, and generate storyline graphs for image recommendation. Interestingly, Kim et al. (2014) combined images and videos for storyline reconstruction. However, none of the above studies combine textual and visual information for timeline summarization.

3 Our Approach

We now describe the technical details of our low-rank approximation approach. First, we motivate our approach. Next, we explain how we formulate the timeline summarization task as a matrix factorization problem. Then, we introduce a scalable approach for learning low-dimensional embeddings of news stories and images.

3.1 Motivation

We formulate timeline summarization as a low-rank matrix completion task because of the following considerations:

- **Simplicity** In the past decade, a significant amount of work on summarization has focused on designing various lexical, syntactic and semantic features. In contrast to prior work, we make use of low-rank approximation techniques to learn representations directly from data. This way, our model does not require strong domain knowledge or lots of feature engineering, and it is easy for developers to deploy the system in real-world applications.

- **Scalability** A major reason that recommender systems and collaborative filtering techniques have been very successful in industrial applications is that matrix completion techniques are relatively sophisticated, and are known to scale up to large recommendation datasets with more than 100 million ratings (Bennett and Lanning,

2007). Therefore, we believe that our approach is practical for processing large datasets in this summarization task.

- **Joint Multimodal Modeling** A key challenge of supervised learning approaches for summarization is to select informative sentences. In this work, we make use of multimodality to select important sentences.

3.2 Problem Formulation

Since the Netflix competition (Bell and Koren, 2007), collaborative filtering techniques with latent factor models have had huge success in recommender systems. These latent factors, often in the form of low-rank embeddings, capture not only explicit information but also implicit context from the input data. In this work, we propose a novel matrix factorization framework to "recommend" key sentences to a timeline. Figure 2 shows an overview of the framework.

More specifically, we formulate this task as a matrix completion problem. Given a news corpus, we assume that there are m total sentences, which are the rows in the matrix. The first column is the *metric* section, where we use ROUGE (Lin, 2004) as the metric to pre-compute a *sentence importance* score between a candidate sentence and a human-generated summary. During training, we use these scores to tune model parameters, and during testing, we predict the sentence importance scores given the features in other columns. That is, we learn the embedding of important sentences.

The second set of columns is the *text feature* section. In our experiments, this includes word observations, subject-verb-object (SVO) events, and the publication date of the document from which the candidate sentence is extracted. In our preprocessing step, we run the Stanford part-of-speech tagger (Toutanova et al., 2003) and MaltParser (Nivre et al., 2006) to generate SVO events based on dependency parses. Additional features can easily be incorporated into this framework; we leave the consideration of additional features for future work.

Finally, for each sentence, we use an image search engine to retrieve a top-ranked relevant image, and then we use a convolutional neural network (CNN) architecture to extract visual features in an unsupervised fashion. We use a CNN model from Simonyan and Zisserman (2015), which is trained on the ImageNet Challenge 2014 dataset (Russakovsky et al., 2014). In our work, we keep the 16 convolutional layers and max-pool operations. To extract neural network features, we remove the final fully-connected-1000 layer and the softmax function, resulting in 4096 features for each image.

The total number of columns in the input matrix is n. Our matrix M now encodes preferences for a sentence, together with its lexical, event, and temporal attributes, and visual features for an image highly relevant to the sentence. Here we use i to index the i-th sentence and j to index the j-th column. We scale the columns by the standard deviation.

3.3 Low-Rank Approximation

Following prior work (Koren et al., 2009), we are interested in learning two low-rank matrices $P \in \mathbf{R}^{k\times m}$ and $Q \in \mathbf{R}^{k\times n}$. The intuitition is that P is the embedding of all candidate sentences, and Q is the embedding of textual and visual features, as well as the sentence importance score, event, and temporal features. Here k is the number of latent dimensions, and we would like to approximate $M_{(i,j)} \simeq \vec{p_i}^T\vec{q_j}$, where $\vec{p_i}$ is the latent embedding vector for the i-th sentence and $\vec{q_j}$ is the latent embedding vector for the j-th column. We seek to approximate the matrix M by these two low-rank matrices P and Q. We can then formulate the optimization problem for this task:

$$\min_{P,Q} \sum_{(i,j)\in M} (M_{(i,j)} - \vec{p_i}^T\vec{q_j})^2 + \lambda_P||\vec{p_i}||^2 + \lambda_Q||\vec{q_j}||^2$$

here, λ_P and λ_Q are regularization coefficients to prevent the model from overfitting. To solve this optimization problem efficiently, a popular approach is stochastic gradient descent (SGD) (Koren et al., 2009). In contrast to traditional methods that require time-consuming gradient computation, SGD takes only a small number of random samples to compute the gradient. SGD is also natural to online algorithms in real-time streaming applications, where instead of retraining the model with all the data, parameters might be updated incrementally when new data comes in. Once we have selected a random sample $M_{(i,j)}$, we can simplify the objective function:

$$(M_{(i,j)} - \vec{p_i}^T\vec{q_j})^2 + \lambda_P(\vec{p_i}^T\vec{p_i}) + \lambda_Q(\vec{q_j}^T\vec{q_j})$$

Now, we can calculate the sub-gradients of the two latent vectors $\vec{p_i}$ and $\vec{q_j}$ to derive the following variable update rules:

$$\vec{p_i} \leftarrow \vec{p_i} + \delta(\ell_{(i,j)}q_j - \lambda_P\vec{p_i}) \tag{1}$$

$$\vec{q_j} \leftarrow \vec{q_j} + \delta(\ell_{(i,j)}p_i - \lambda_Q\vec{q_j}) \tag{2}$$

Here, δ is the learning rate, whereas $\ell_{(i,j)}$ is the loss function that estimates how well the model approximates the ground truth:

$$\ell(i,j) = M_{(i,j)} - \vec{p_i}^T\vec{q_j}$$

The low-rank approximation here is accomplished by reconstructing the M matrix with the two low-rank matrices P and Q, and we use the row and column regularizers to prevent the model from overfitting to the training data.

SGD-based optimization for matrix factorization can also be easily parallelized. For example, HOGWILD! (Recht et al., 2011) is a lock-free parallelization approach for SGD. In contrast to synchronous approaches where idle threads have to wait for busy threads to sync up parameters, HOGWILD! is an asynchronous method: it assumes that because text features are sparse, there is no need to perform synchronization of the threads. In reality, although this approach might not work for speech or image related tasks, it performs well in various text based tasks. In this work, we follow a recently proposed approach called fast parallel stochastic gradient descent (FPSG) (Chin et al., 2015), which is partly inspired by HOGWILD!.

3.4 Joint Modeling of Mixed Effects

Matrix factorization is a relatively complex method for modeling latent factors. So, an important question to ask is: in the context of timeline summarization, what is this matrix factorization framework modeling?

From equation (1), we can see that the latent sentence vector $\vec{p_i}$ will be updated whenever we encounter a $M_{(i,\cdot)}$ sample (e.g., all the word, event, time, and visual features for this particular sentence) in a full pass over the training data. An interesting aspect about matrix factorization is that, in addition to using the previous row embedding $\vec{p_i}$ to update the variables in equation (1), the column embedding $\vec{q_j}$ will also be used. Similarly, when updating the latent column embedding $\vec{q_j}$ in equation (2), the pass will visit all samples that have non-zero items in that column, while making use of the $\vec{p_i}$ vector. Essentially, in timeline summarization, this approach is modeling the mixed effects of sentence importance, lexical features, events, temporal information, and visual factors. For example, if we are predicting the ROUGE score of a new sentence at testing, the model will take the explicit sentence-level features into account, together with the learned latent embedding of ROUGE, which is recursively influenced by other metrics and features during training.

Our approach shares similarities with some recent advances in word embedding techniques. For example, word2vec uses the continuous bag-of-words (CBOW) and SkipGram algorithms (Mikolov et al., 2013) to learn continuous representations of words from large collections of text and relational data. A recent study (Levy and Goldberg, 2014) shows that the technique behind word2vec is very similar to implicit matrix factorization. In our work, we consider multiple sources of information to learn the joint embedding in a unified matrix factorization framework. In addition to word information, we also consider event and temporal cues.

3.5 The Matrix Factorization Based Timeline Summarization

We outline our matrix factorization based timeline summarization method in Algorithm 1. Since this is a supervised learning approach, we assume the corpus includes a collection of news documents S, as well as human-written summaries H for each day of the story. We also assume the publication date of each news document is known (or computable).

During training, we traverse each sentence in this corpus, and compute a *sentence importance score* (I_i) by comparing the sentence to the human generated summary for that day using ROUGE (Lin, 2004). If a human summary is not given for that day, I_i will be zero. We also extract subject-verb-object event representations, using the Stanford part-of-speech tagger (Toutanova et al., 2003) and MaltParser (Nivre et al., 2006). We use the publication date of the news document as the publication date of the sentence. Visual features are extracted using a very deep CNN (Simonyan and Zisserman, 2015). Finally, we merge these vectors into a joint vector to represent a row in our matrix factorization framework. Then, we perform stochastic gradient descent training to learn the hidden low-rank embeddings of sentences and features P and Q using the update rules outlined earlier.

Algorithm 1 A Matrix Factorization Based Timeline Summarization Algorithm

```
Input: news documents $S$, human summaries $H$ for each day $t$.
procedure TRAINING($S^{tr}$, $H$)
    for each training sentence $S_i^{tr}$ in $S^{tr}$ do
        $I_i \leftarrow$ ComputeImportanceScores($S_i^{tr}$,$H_t$)
        $\vec{E_i} \leftarrow$ ExtractSVOEvents($S_i^{tr}$)
        $\vec{D_i} \leftarrow$ ExtractPublicationDate($S_i^{tr}$)
        $\vec{V_i} \leftarrow$ ExtractVisualFeatures($V_i^{tr}$)
        $\vec{M_i} \leftarrow$ MergeVectors($I_i, \vec{E_i}, \vec{D_i}, \vec{V_i}$)
    end for
    for each epoch $e$ do
        for each cell $i, j$ in $M$ do
            $\vec{p_i}^{(e)} \leftarrow \vec{p_i}^{(e)} + \delta(\ell_{(i,j)} q_j^{(e)} - \lambda_P \vec{p_i}^{(e)})$
            $\vec{q_j}^{(e)} \leftarrow \vec{q_j}^{(e)} + \delta(\ell_{(i,j)} p_i^{(e)} - \lambda_Q \vec{q_j}^{(e)})$
        end for
    end for
end procedure
procedure TESTING($S^{te}$)
    for each test sentence $S_i^{te}$ in $S^{te}$ do
        $\vec{E_i} \leftarrow$ ExtractSVOEvents($S_i^{te}$)
        $\vec{D_i} \leftarrow$ ExtractPublicationDate($S_i^{te}$)
        $\vec{V_i} \leftarrow$ ExtractVisualFeatures($S_i^{te}$)
        $\vec{M_i} \leftarrow$ MergeVectors($\vec{E_i}, \vec{D_i}, \vec{V_i}$)
        $I_i \leftarrow$ PredictROUGE($\vec{M_i}, P, Q$)
    end for
    for each day $t$ in $S^{te}$ do
        $H^{te} \leftarrow$ SelectTopSentences($S_t^{te}$,$\vec{I_t}$)
    end for
end procedure
```

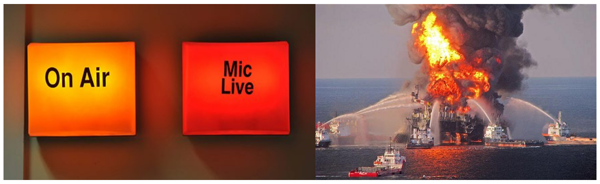
During testing, we still extract events and publication dates, and the PredictROUGE function estimates the sentence importance score I_i, using the trained latent low-rank matrices P and Q. To be more specific, we extract the text, vision, event, and publication date features for a candidate sentence i. Then, given these features, we update the embeddings for this sentence, and make the prediction by taking the dot product of this i-th column of P (i.e., $\vec{p_i}$) and the ROUGE column of Q (i.e., $\vec{q_1}$). This predicted scalar value I_i indicates the likelihood of the sentence being included in the final timeline summary. Finally, we go through the predicted results of each sentence in the timeline in temporal order, and include the top-ranked sentences with the highest sentence importance scores. It is natural to scale this method from daily summaries to weekly or monthly summaries.

4 Experiments

In this section, we investigate the empirical performance of the proposed method, comparing to various baselines. We first discuss our experimental settings, including our primary dataset and baselines. Then, we discuss our evaluation results. We demonstrate the robustness of our approach by varying the latent dimensions of the low-rank matrices. Next, we show additional experiments on a headline-based timeline summarization dataset. Finally, we provide a qualitative analysis of the output of our system.

4.1 Comparative Evaluation on the 17 Timelines Dataset

We use the 17 timelines dataset which has been used in several prior studies (Tran et al., 2013b; Tran et al., 2013a). It includes 17 timelines from 9 topics[1] from major news agencies such as CNN, BBC, and NBC News. Only English documents are included. The dataset contains 4,650 news documents. We use Yahoo! Image Search to retrieve the top-ranked image for each sentence.[2] We follow exactly the same topic-based cross-validation setup that was used in prior work (Tran et al., 2013b): we train on eight topics, test on the remaining topic, and repeat the process eight times. The number of training iterations was set to 20; the k was set to 200 for the text only model, and 300 for the joint text/image model; and the vocabulary is 10K words for all systems. The common summarization metrics ROUGE-1, ROUGE-2, and ROUGE-S are used to evaluate the quality of the machine-generated timelines. We consider the following baselines:



(a) ROUGE:0 (b) ROUGE:.009.

Figure 3: Examples of retrieved Web images. The left image was retrieved by using a non-informative sentence: "*The latest five minute news bulletin from BBC World Service*". The right image was retrieved using a crucial sentence with a non-zero ROUGE score vs. a human summary, "*Case study : Gulf of Mexico oil spill and BP On 20 April 2010 a deepwater oil well exploded in the Gulf of Mexico*".

- **Random**: summary sentences are randomly selected from the corpus.
- **MEAD**: a feature-rich, classic multi-document summarization system (Radev et al., 2004a) that uses centroid-based summarization techniques.
- **Chieu et al.** (Chieu and Lee, 2004): a multi-document summarization system that uses TFIDF scores to indicate the "popularity" of a sentence compared to other sentences.
- **ETS** (Yan et al., 2011b): a state-of-the-art unsupervised timeline summarization system.
- **Tran et al.** (Tran et al., 2013b): another state-of-the-art timeline summarization system based on learning to rank techniques, and for which results on the 17 Timelines dataset have been previously reported.
- **Regression**: a part of a state-of-the-art extractive summarization method (Wang et al., 2015) that formulates the sentence extraction task as a supervised regression problem. We use a state-of-the-art regression implementation in Vowpal Wabbit[3].

We report results for our system and the baselines on the 17 timelines dataset in Table 1. We see that the random baseline clearly performs worse than the other methods. Even though Chieu et al. (2004)

[1] The nine topics are the BP oil spill, Egyptian protests, Financial crisis, H1N1, Haiti earthquake, Iraq War, Libya War, Michael Jackson death, and Syrian crisis.

[2] We are not aware of any publicly available dataset for timeline summarization that includes both text and images. Most of these datasets are text-only, not including the original article file or links to accompanying images. We adopted this Web-based corpus enhancement technique as a proximity for news images. Our low-rank approximation technique can be applied to the original news images in the same way.

and MEAD (Radev et al., 2004a) are not specifically designed for the timeline summarization task, they perform relatively well against the ETS system for timeline summarization (Yan et al., 2011b). Tran et al. (2013b) was previously the state-of-the-art method on the 17 timelines dataset. The ROUGE regression method is shown as a strong supervised baseline. Our matrix factorization approach outperforms all of these methods, achieving the best results in all three ROUGE metrics. We also see that there is an extra boost in the performance when considering visual features for timeline summarization. Figure 3 shows an example of the retrieved images we used. In general, images retrieved by using more important sentences (measured by ROUGE) include objects, as well a more vivid and detailed scene.

4.2 Comparative Evaluation Results for Headline Based Timeline Summarization

To evaluate the robustness of our approach, we show the performance of our method on the recently released *crisis* dataset (Tran et al., 2015). The main difference between the crisis dataset and the 17 timelines dataset is that here we focus on a headline based timeline summarization task, rather than using sentences from the news documents. The crisis dataset includes four topics: Egypt revolution, Libya war, Syria war, and Yemen crisis. There are a total of 15,534 news documents in the dataset, and each topic has around 4K documents. There are 25 manually created timelines for these topics, collected from major news agencies such as BBC, CNN, and Reuters. We perform standard cross-validation on this dataset: we train on three topics, and test on the other. Here k is set to 300, and the vocabulary is 10K words for all systems. Table 3 shows the performance of our system. Our system is significantly better than the strong supervised regression baseline. When considering joint learning of text and vision, we see that there is a further improvement.

4.3 Headline Based Timeline Summarization: A Qualitative Analysis

In this section, we perform a qualitative analysis of the output of our system for the headline based timeline summarization task. We train the system on three topics, and show a sample of the output on the Syria war. Table 2 shows a subset of the timeline for the Syria war generated by our system. We see that most of the daily summaries are relevant to the topic, except the one generated on 2011-11-24. When evaluating the quality, we notice that most of them are of high quality: after the initial hypothesis of the Syria war on 2011-11-18, the following daily summaries concern the world's response to the crisis. We show that most of the relevant summaries are also providing specific information, with an exception on 2011-12-02. We suspect that this is because this headline contains three keywords "syria", "civil", "war", and also the key date information: the model was trained partly on the Libya war timeline, and therefore many features and parameters were activated in the matrix factorization framework to give a high recommendation in this testing scenario. In contrast, when evaluating the output of the joint text and vision system, we see that this error is eliminated: the selected sentence on 2011-12-02 is "*Eleven killed after weekly prayers in Syria on eve of Arab League deadline*".

5 Conclusions

In this paper, we introduce a low-rank approximation based approach for learning joint embeddings of news stories and images for timeline summarization. We leverage the success of matrix factorization techniques in recommender systems, and cast the multi-document extractive summarization task as a sentence recommendation problem. For each sentence in the corpus, we compute its similarity to a human-generated abstract, and extract lexical, event, and temporal features. We use a convolutional neural architecture to extract vision features. We demonstrate the effectiveness of this joint learning method by comparison with several strong baselines on the 17 timelines dataset and a headline based timeline summarization dataset. We show that image features improve the performance of our model significantly. This further motivates investment in joint multimodal learning for NLP tasks.

Abstract

Community created content (e.g., product descriptions, reviews) typically discusses one entity at a time and it can be hard as well as time consuming for a user to compare two or more entities. In response, we define a novel task of automatically generating *entity comparisons* from text. Our output is a table that semantically clusters descriptive phrases about entities. Our clustering algorithm is a Gaussian extension of probabilistic latent semantic analysis (pLSA), in which each phrase is represented in word vector embedding space. In addition, our algorithm attempts to balance information about entities in each cluster to generate meaningful comparison tables, where possible. We test our system's effectiveness on two domains, travel articles and movie reviews, and find that entity-balanced clusters are strongly preferred by users.

1 Introduction

The proliferation of Web 2.0 has enabled ready access to large amounts of community created content, such as status messages, blogs, wikis, and reviews. These form an important source of knowledge in our day to day decision making, such as deciding which restaurant to try, or which movie to watch, or which city to visit etc. Unfortunately, such content typically focuses on one real world entity at a time, whereas, a user deciding between alternatives is most interested in a *comparative* analysis of strengths and weaknesses of each.

There have been some recent attempts to create comparisons using expert knowledge, but generating such comparisons manually does not scale – even pairwise comparisons are quadratic in the number of entities. Few automated comparisons for specific products with pre-defined attributes (e.g., laptops, cameras) exist; they are typically powered by existing structured knowledge bases. To the best of our knowledge, prior work on automatically generating comparisons for arbitrary domains from unstructured text, does not exist.

We define a novel task of generating *entity comparisons* from textual corpora in which each document describes one entity at a time. For broad applicability, we do not restrict ourselves to a pre-defined ontology; instead, we use textual phrases that describe entities as our unit of information. We call these *descriptive phrases* – they encompass general attribute-value phrases, opinion phrases, and other descriptions of the facets of an entity. We generate entity comparisons in a tabular form where the phrases are organized semantically, thus, allowing for direct comparisons. Figure 1 shows a sample city comparison generated by our system for tourism.

Our comparison generation algorithm extracts descriptive phrases per entity and clusters them into semantic groups. We perform clustering via a topic model, where phrases from an entity are combined into one document. The topics identify prominent facets of the entities. Unfortunately, since the number of entities being compared is usually small, just statistical co-occurrence of words and phrases is not sufficient to identify good topics. In response, we use vector embeddings of descriptive phrases and

Proceedings of NAACL-HLT 2016, pages 69–79,
San Diego, California, June 12-17, 2016.

employ a *Gaussian extension* of probabilistic latent semantic analysis (pLSA) over these vectors.

We also modify Gaussian pLSA to additionally incorporate an *entity-balance* term, preferring topics in which phrases from the entities are represented in a proportionate measure. The balance term trades off the discovery of unique facets for each entity with that of common facets. This enables direct comparison between entities leading to an overall improved comparison table. Since the balance term is only a preference (not a constraint), it still allows the algorithm to exhibit clusters which may be sparsely represented (or not represented at all) in one of the entities.

We demonstrate the usefulness of our ideas on two domains – tourism and movies. Based on user experiments, we find that the entity-balanced model outputs much better comparisons as compared to an entity-oblivious model such as GMM. In summary, our paper makes the following contributions:

- We define a novel task of generating entity comparisons from a corpus that describes entities individually.
- We present the first system to output such a comparison. Our system runs Gaussian pLSA over the vector embeddings of extracted phrases, and preferentially tries to balance the entities in each topic.
- Human subject evaluations using Amazon Mechanical Turk (AMT) demonstrate that AMT workers overwhelmingly prefer comparisons generated using entity-balanced Gaussian pLSA compared to entity-oblivious clustering.

Cluster Labels	**Granada (Spain)**	**New York City (U.S.)**
art, arch.	moorish architecture religious art fine art beautiful architecture	contemporary art modern american art medieval art egyptian art
palace, courtyard	brick-walled courtyard lovely courtyard area nasrid royal palace alhambra palace	
museum, finest	alhambra museum archaeological museum world heritage site splendid arabic shops	fine art museums guggenheim museum islamic art collection metropolitan museum
gardens, park	partal gardens palace gardens pleasant gardens moorish style gardens	flushing meadows park central park renowned gardens natl. recreational area

Figure 1: Sample comparison (abridged) between Granada and New York generated by our system. A quick look reveals that that both cities have a nice set of museums and gardens to visit, while palaces and courtyards are only in Granada. Granada's art and architecture are more ornamental, whereas New York's might be more contemporary.

2 Related Work

Recently, the internet has seen a growth in websites offering comparisons for different entities. Product websites such as eBay maintain comparisons for products. Google also outputs pre-built comparisons between common entities when queried with the word "vs." between them. Both of these output purely structured attribute-value information and are unable to compare along more qualitative and descriptive dimensions such as ease of living or quality of nightlife when comparing cities, for example. Other websites such as WikiVS[1] contain user-contributed comparisons that have been categorized based on the nature of the entities being compared. These are manually curated and therefore do not scale to the quadratic number of entity pairs.

Perhaps the most closely related work to ours is the field of contrastive opinion mining and summarization (Kim et al., 2011; Liu and Zhang, 2012). Examples include extraction of contrastive sentiments on a product (Lerman and McDonald, 2009) and summarization of opinionated political articles (Paul et al., 2010). Contrastive opinion mining extracts contrasting view points about a *single* entity or event instead of comparing multiple ones. A recent preliminary study extends this for comparing reviews of two products (Sipos and Joachims, 2013). It uses a supervised method for learning sentence alignments per product-type, and does not organize various opinions for an entity via clustering.

Other related work includes comparative text mining tasks where document collections are analyzed to extract shared topics or themes (Zhai et al., 2004). Since such methods only identify latent topics for the full document collection, they can't be directly used for a specific comparison task.

Since our system is a combination of IE and clustering, we briefly describe related approaches for these subtasks.

Information Extraction: Our work is related to

[1] http://www.wikivs.com/wiki/Main_Page

the vast literature in information extraction, in particular Open IE (Banko et al., 2007). Our use of POS patterns for extracting domain-specific descriptive phrases is similar in spirit to ReVerb's patterns for relation extraction (Etzioni et al., 2011) and adjective-noun bigrams for fine grained attribute extraction (Huang et al., 2012; Yatani et al., 2011). Adapting the literature on entity set expansion (Pantel et al., 2009; Voorhees, 1994; Natsev et al., 2007), our system expands seed nouns for broader coverage. We use Wordnet and distributional similarity-based approaches for this (Curran, 2003; Voorhees, 1994).

Clustering: Our entity-balanced clustering algorithm is related but different from previous work on *balanced* clustering. Prior work (Banerjee and Ghosh, 2006; Yuepeng et al., 2011) has focused on generating different clusters to be equi-sized. Other work (Zhu et al., 2010; Ganganath et al., 2014) enforces size constraints on clusters. Our idea of balance, on the other hand, is targeted towards a better comparison and prefers that entities are well represented (balanced) in each cluster.

3 Task & System Description

Our motivation is to concisely compare two or more entities to aid a user's decision making. We make several choices in our task definition to help with this goal. First, we decide to output comparisons using a succinct tabular representation (see Figure 1). It has higher information density compared to, say, writing a natural language comparison summary.

Second, our unit of information is a *descriptive phrase*. We define it as any short phrase that describes an entity – these include attribute-value pairs (e.g., "Greek art"), opinion phrases (e.g., "spectacular views"), as well as other descriptions (e.g., "oldest church of Europe").

Third, for better readability, our table must organize the information coherently along various aspects relevant for a comparison. We achieve this by grouping related descriptive phrases. The choice of aspects should be dependent on the specific entities being compared, e.g., the facet of "beaches" may split into "water activities" and "beach types" for Jamaica v.s. Hawaii, but not for San Francisco v.s. Bombay.

Moreover, comparisons are meant to highlight both the similarities and the differences between entities. We therefore need to trade-off the discovery of unique facets of an entity with those which are common to the entities being compared. Thus, while clusters that balance the entities are preferable, it is also acceptable to have clusters where one of the entities is sparsely represented (or not represented at all). This would happen in situations where that entity does not express a particular aspect and other entities do. Comparisons must trade off semantic coherence of facets with entity-balance in each facet.

Last, but not the least, since the comparisons are targeted to aiding user's decision making, understanding her intent is important. As an example, the user may be interested in city-comparison for the purpose of tourism, or for choosing a city to live in. Descriptive phrases for the former could be related to sightseeing, shopping, etc., but for the latter they may cover aspects such as living expenses, transportation, and pollution. We accommodate this necessity by allowing minimal human supervision for specifying user intent. This supervision can come in forms such as an intent-relevant seed noun list, or topic-level annotation following unsupervised topic modeling, etc. This supervision further guides descriptive phrase extraction.

System Architecture: Our system consists of a pipeline of information extraction, clustering, cluster labeling and phrase ordering. IE extracts descriptive phrases relevant to user-intent and we develop a new clustering algorithm that produces better comparisons by balancing the entities in each cluster. We identify cluster labels based on the most frequent words in a cluster. We order phrases within a cluster based on the distance from the centroid. We now describe our IE and clustering techniques in detail.

3.1 Information Extraction

Our IE pipeline works in two steps. We first extract descriptive phrases via POS patterns and then filter out the non-topical phrases. For filtering, first we create a seed list of relevant nouns via minimal human supervision, which are then expanded by itemset expansion. Descriptive phrases with a noun in the expanded list are retained, and rest are filtered.

Preliminary analysis on a devset revealed that a large fraction of descriptive phrases are noun phrases (NPs). We first extract all NP chunks from the collection and, additionally, using POS tags, extract any adjective-noun bigrams that are part of a bigger NP chunk, or missed due to chunking errors. This forms the initial set of descriptive phrases.

Filtering for User Intent:

These descriptive phrases include those that are not relevant for user intent such as "excellent schools" for tourism. We filter these phrases by matching them to a list of intent-specific nouns. This list is created by first curating a seed list and then expanding it using item-set expansion. We employ two methods to obtain a seed list for specifying user intent: (1) a list of user-specified seed nouns, and (2) a labeling of LDA topics based on top words in each topic.

In the first approach we get the seed nouns directly from the domain expert. Our system supports the process by identifying frequent nouns and showing those to the annotator to annotate. For our tourism system, an author spent about three hours to produce a list of 100 seed nouns.

Since this process requires significant effort per user intent, we also investigate a semi-automatic approach in which we run Latent Dirichlet Allocation (LDA) (Blei et al., 2003) on the whole phrase list. We then show the top 20 words in each topic and ask the annotator to provide only topic-level annotations. We treat the top 15 words from each positively labeled topic to be in the seed set. Since the number of topics is usually not that large, this significantly reduces the time required for annotation. E.g., we ran LDA with 20 topics and it took about 10 mins. for an author to annotate them. However, the seed nouns are noisier due to noise in LDA.

Seed List Expansion: Finally, we use ideas from item-set expansion to expand the seed list for improved coverage. We implement two approaches for this step. In the first method (WN) we use Wordnet (Miller, 1995) to include words that are a direct hop away from the seed nouns. In the second approach (WV), we use word-vector embeddings (Collobert et al., 2011) and include top 10 neighbors of each seed in our expanded list. The expansions capture near-synonyms and topically related words.

IE Experiments: We now present comparisons of various IE methods on a small development set. We selected seven WikiTravel[2] articles (each article is on one city) and manually annotated an exhaustive set of descriptive phrases. This forms our devset for IE comparisons.

Method	**Prec.**	**Recall**	**F1**
All nouns	0.53	**0.67**	**0.59**
Seed Nouns only (Manual)	**0.77**	0.32	0.44
Seed (Manual) + WN	0.71	0.35	0.46
Seed (Manual) + WV	0.70	0.40	0.49
Seed Nouns only (LDA)	0.74	0.19	0.30
Seed (LDA) + WN	0.74	0.20	0.31
Seed (LDA) + WV	0.74	0.26	0.38

Table 1: Quality of extracted descriptive phrases on a devset

We chose various parameters in our IE systems so that our precision never drops below 0.70. For example, we used K=15 for choosing the top words from LDA into seed list. We use this target precision, because we believe that for any human-facing system the precision needs to be high for it to be considered acceptable by people.

Table 1 compares the performance of the various IE methods. Not surprisingly, we find that manual seed lists obtain a much higher recall as compared to LDA seeds, at approximately the same level of precision. Both Wordnet and word-vector improve the recall substantially, though vectors are more effective. The recall of all nouns is only 0.67 because a large number of descriptive phrases were larger n-grams (not just adjective-noun bigrams) and were missed due to chunking errors.

3.2 Building Clusters for Comparison

Our next task is to construct meaningful comparisons using these phrases. A useful comparison of entities should organize the available information in a way that is easy to comprehend by the user. Towards this goal, we group the related descriptive phrases across a number of clusters. But simply having a good clustering of descriptive phrases may not be enough. We would like to have a clustering that explicitly captures the individual characteristics of each of the entities as well as makes the relative strengths and weaknesses of each entity apparent. For example, Figure 2 (Right) shows three different clusterings of phrases from two cities; phrases from each city are in a different color. Here, the third clus-

[2] www.wikitravel.com

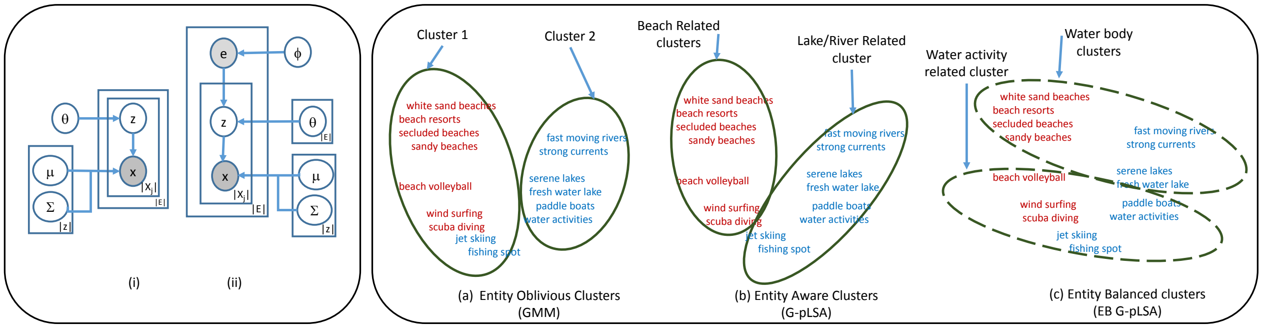

Figure 2: Left: Plate Notation of (i) Standard Gaussian Mixture Model (ii) Gaussian pLSA (and entity balanced Gaussian pLSA) **Right**: Three alternative clusterings (a), (b), (c) for descriptive phrases from two cities – each color is a different city. We prefer clusters shown in (c) as they balance information from both entities

tering is most appropriate for comparison, because not only is it a good clustering of descriptive phrases from each city considered separately, but the clusters produced also have *entity-balance*, i.e., the clusters produced have a good *balance* of both cities; both of these are key elements of comparison.

We first observe that a topic model such as Probabilistic Latent Semantic Analysis (pLSA) is a good fit to our clustering problem. In pLSA documents are characterized as mixtures of topics and topics as distributions over words. For our problem, we could combine all phrases for an entity into one document, and run pLSA to identify a coherent set of topics, which can then be used as clusters. Such a model will allow different entities to express topics in different proportions.

We note that LDA, which is a strict generalization of pLSA[3], is, in general, not a good fit for our task. LDA typically uses a *sparse* Dirichlet prior on document-topic distribution, which would not be appropriate since for comparison we would like to represent each entity in as many topics as possible.

Unfortunately, a direct application of pLSA may not yield good results. This is because typically the number of entities being compared (i.e., the number of documents in pLSA) is very small (often 2), therefore, there isn't enough statistical regularity to find good coherent topics. The alternative proposition of learning topics on the whole corpus isn't very appealing either, since that will learn global topics and not the topics particularly meaningful for the current comparison at hand.

In response, we exploit the availability of pre-trained word vectors as a source of background semantic knowledge for every phrase, and generalize the pLSA model to *Gaussian pLSA* (G-pLSA). We construct a vector representation for each descriptive phrase by averaging the word-vectors of individual words in a phrase (Mikolov et al., 2013)[4]. Thus, this model is pLSA with each topic-word distribution represented as a Gaussian distribution over descriptive phrases in the embedding space. This model is also similar to the recently introduced Gaussian LDA model (Das et al., 2015), but without LDA's Dirichlet priors as discussed above.

Gaussian pLSA has several advantages for our task. First, it can meaningfully learn topics only for the entities being compared, instead of needing to learn a global topic model over the whole corpus. Second, due to additional context from word vectors, the topics are expected to be much more coherent compared to traditional topic models for cases when the underlying corpus is small, as in our case. Finally, in our model the vectors are generated from a Gaussian distribution and that helps capture the *theme* of the cluster directly by enabling a centroid computation in the embedding space. This is especially useful for identifying and ranking important descriptive phrases per cluster while generating the comparison table.

Let $x_j^{(i)}, z_j^{(i)}$ denote the values of the i^{th} phrase and the corresponding cluster (topic) id, respectively, for the j^{th} entity e_j. Then, the log-likelihood

[3] LDA with uniform Dirichlet prior is equivalent to pLSA

[4] We use the pre-trained 300 dimension vectors available at http://code.google.com/p/word2vec/

$L(\Theta)$ of the observed data can be written as:

$$\sum_{j=1}^{|E|}\sum_{i=1}^{|X_j|}\log\Big[\sum_{z_j^{(i)}=1}^{|Z|} P(x_j^{(i)}|z_j^{(i)};\Theta)\cdot P(z_j^{(i)}|e_j;\Theta)\cdot P(e_j;\Theta)\Big] \tag{1}$$

Here, $|X_j|$ and $|Z|$ are the total number of phrases and clusters[5] respectively, for a given entity e_j and, $|E|$ is the total number of entities being considered for comparison. Θ denotes the vector of all the parameters. We optimize the expression $L(\Theta)$ using EM and estimate the parameters of the model. As can be seen, the clusters are shared across entities, and the phrases generated are independent of the entity given, a cluster and the entities themselves are free to exhibit clusters in different proportions.

We also note just as pLSA can be seen as a natural extension of mixture of unigrams (Blei et al., 2003), Gaussian pLSA is an extension from the Gaussian Mixture Model (GMM) which is entity-oblivious. GMM generates each phrase independent of the entity it came from and hence, distributes entity phrases arbitrarily across clusters. We use GMM as a baseline for our experiments. Figure 2 (left) illustrates the two models in plate notation.

Entity-Balanced Gaussian pLSA: Vanilla Gaussian pLSA may not always lead to a good clustering for comparison since the expression above does not involve any term to balance the entity-information in clusters, as motivated earlier. Thus, we incorporate a regularizer term to have a good balance (proportion) of entities in each cluster (see Figure 2 (right) (c)) resulting in our final model for comparison called *Entity-Balanced Gaussian pLSA (EB G-pLSA)*. The plate notation for EB G-pLSA is identical to G-pLSA.

Our regularizer is a function of the KL-divergence between multinomial distributions for every pair of entities. KL-divergence $KL(P||Q)$ between two discrete distributions $P(x)$ and $Q(x)$ is defined as $\sum_l P(x_l)log\left(\frac{P(x_l)}{Q(x_l)}\right)$. Its an asymmetric measure of similarity and is equal to 0 when the two distributions are identical (and greater than 0 otherwise). Symmetric KL-divergence is defined as $Sym\text{-}KL(P,Q) = KL(P||Q) + KL(Q||P)$.

Let $P_{\theta_j}(z|e_j)$ and $P_{\theta_k}(z|e_k)$ denote the multinomial distributions for generating the cluster id z given the entities e_j and e_k, respectively. Here, θ_j and θ_k denote the respective multinomial parameters. We add a regularizer term to the log-likelihood minimizing the sum of symmetric KL-divergence between the distributions $P_{\theta_j}(z|e_j)$ and $P_{\theta_k}(z|e_k)$ for every pair of entities e_j and e_k. Adding this regularizer requires the multinomial distributions to be similar to each other, thereby preferring balanced clusters over unbalanced ones. Our regularized average log-likelihood can be written as:

$$L_{reg}^{avg}(\Theta) = \frac{1}{|M|}L(\Theta) - \alpha\cdot\left[\sum_{j,k=1|j<k}^{|E|} Sym\text{-}KL(P_{\theta_j}, P_{\theta_k})\right] \tag{2}$$

$L(\Theta)$ is the total log-likelihood as defined in the previous equation. $M = \sum_{j=1}^{|E|}|X_j|$ and $|E|$ is the total number of entities being compared. α is a constant controlling the weight of the regularizer. Note that we add the regularizer term to the *average* log-likelihood (instead of the total log-likelihood) in order to have the same regularizer value for comparisons having varying number of data points (descriptive phrases). This is important to obtain a single value of α which would work well across different entity comparisons. In our experiments, α was tuned using held-out data and was found to be robust to small perturbations.

We use standard EM to optimize the regularized log-likelihood. Since the regularizer does not have any hidden variables, E-step is identical to the one for the unregularized case. During M-step, the values maximizing the mean parameters μ_z and the ϕ parameter can be obtained analytically. There is no closed form solution for the parameters θ_j, θ_k. We perform gradient descent to optimize these parameters during the M-step. In our experiments, we did not estimate the co-variance matrices Σ_z and kept them fixed as a diagonal matrix with the diagonal entry (variance) being 0.1. We did not learn the covariance matrices as that would have increased the number of parameters substantially, and thus, had the danger of over fitting. The small value of the variance chosen was to ensure less overlap between different clusters.

Clustering Experiments We conducted preliminary experiments to compare the performance of GMM (vanilla Gaussian mixture modeling using word vec-

[5] Note that number of clusters for all entities will be the same i.e $|Z_j| = Z$ for all j

	GMM	G-pLSA	EB G-pLSA
f-measure	0.42	0.43	0.44
pairwise accuracy	0.66	0.65	0.76

Table 2: Comparing clustering methods on development set

tors) with G-pLSA and EB G-pLSA on a development set consisting of 5 random city pairs. The descriptive phrases were constructed using the automated seed list as described in IE Section. We manually created the gold standard clusterings. The number of clusters was set to the number in the gold set for each of the city pairs.

We used f-measure and pairwise accuracy to evaluate the deviation from the gold standard for the clusterings produced by each of the algorithms. Table 2 shows the results. EB G-pLSA performs better than the other two algorithms on both the metrics, and especially on pairwise accuracy. Performance of G-pLSA is very similar to GMM.

4 Human Subject Evaluations

In order to evaluate the usefulness of our system we conducted extensive experiments on Amazon Mechanical Turk (AMT). Our experiments answer the following questions. (1) Are comparisons generated using our clustering methods G-pLSA and EB G-pLSA preferred by users against the entity oblivious baseline of GMM? (2) Are our system-generated comparison tables helpful to people for the task of entity comparison?

Datasets & System Settings: We experiment[6] on two datasets – tourism and movies. For tourism, we downloaded a collection of 16,785 travel articles from WikiTravel. The website contains articles that have been collaboratively written by Web users. Each article describes a city or a larger geographic area that is of interest to tourists. In addition, all articles contain sections[7] describing different aspects of a city from a tourism point of view (e.g., places to see, transportation, shopping and eating). For our proof of concept, we performed IE only on the 'places to see' sections.

For Movies dataset, we used the Amazon review data set (Leskovec and Krevl, 2014). It has over 7.9 million reviews for 250,000 movies. We combined all the reviews for a movie, thus, generating a large review document per movie. This dataset is much noisier compared to WikiTravel due to presence of slang, incorrect grammar, sarcasm, etc. In addition, users also tend to compare and contrast while reviewing movies so there are even references to other movies. As a result, the descriptive phrases extracted were much more noisy.

For the time consuming manual seed list setting of our IE system, we only use the tourism dataset. For movies, we generate seeds using annotation over LDA topics only. For all systems we use word-vectors to expand the seed list.

For each table, we generated k clusters where k was determined using a heuristic[8] (Mardia et al., 1980), and we displayed at most 30 phrases per cluster. We did not display any cluster that had less than 4 phrases.

4.1 Evaluation of Clustering Algorithms

In order to examine whether clustering using EB G-pLSA indeed produces best comparison tables, we conducted a human evaluation task on Amazon Mechanical Turk (AMT) where users of our system were asked to indicate their preference between two comparison tables. Since we have three systems we performed this pairwise study thrice. In each study, two comparison tables were generated from different systems. For each entity-pair we asked four workers each to select which comparison table they preferred. The order of the tables was randomized to remove any biasing effect. We paid \$0.3 for each table comparison. Table 3 reports the results for both domains where descriptive phrases were generated using LDA+WV.

On 30 city-pairs in the Tourism domain, workers preferred the comparison tables generated using EB G-pLSA 53% of the time and GMM was preferred only 13% (the rest were ties). It is worthwhile to note that whereas in 20% of the comparisons, EB G-pLSA had a clear 4-0 margin, there was no such comparison where all the workers preferred the GMM model. We also requested users to provide the reasons for their preferences. While most users specified a non-informative reason such as "like it better", some users gave specific reasons such as "subdivides the parts I find useful into more specific

[6] Code and data available on request

[7] http://wikitravel.org/en/Wikitravel:Article_templates/Sections

[8] No. of clusters = square root of half the number of phrases

Domain	Total pairs	EB G-pLSA Win		GMM Win		EB G-pLSA Win		G-pLSA Win		G-pLSA Win		GMM Win	
		4-0	3-1	1-3	0-4	4-0	3-1	1-3	0-4	4-0	3-1	1-3	0-4
Tourism	30	20%	33%	13%	0%	13%	30%	30%	0%	17%	27%	13%	3%
Movies	20	20%	35%	10%	0%	5%	35%	15%	5%	5%	45%	15%	5%

Table 3: User preference win-loss statistics for different clustering methods on both city and movie comparison task using the same IE system. Both EB G-pLSA and G-pLSA significantly outperform the baseline GMM model. EB G-pLSA has some edge over the G-pLSA model. Note: Ties have not been shown in the table.

categories" and "easy to understand and more specific points of comparison". Our results also show that G-pLSA is a distinct improvement over GMM (44% vs. 16%). EB G-pLSA had a marginal edge over G-pLSA (43% vs. 30%).

On movies domain, we report results on 20 movie-pairs and we again found an overwhelming preference for the system using EB G-pLSA for clustering. 55% of the time, the output of EB G-pLSA was preferred over GMM's 10%. Other comparisons between G-pLSA and GMM, and between our G-pLSA and EB G-pLSA systems also follow trends similar to tourism domain. The performance of EB G-pLSA is statistically significantly better than GMM for both the tourism and the movie datasets, with p values being less than 0.00004 and 0.002, respectively, using a one-sided students t-test. This strong preference suggests that the clustering induced by incorporating entity balance in the clusters produces much better comparison tables.

4.2 Value of Comparison Tables

The goal of our experiments in this section was to assess whether our comparison tables add value to some realistic task and to understand the overall usefulness of our system. To our knowledge there are no other automated systems comparing cities for tourism (or movies), hence we could not evaluate our system against existing approaches. Therefore, we decided to evaluate the benefit of the output generated by our system (i.e., comparison tables) against reading the original WikiTravel articles. For fairness we only use the 'places to see' sections from WikiTravel, since that was the raw text used in generating comparison tables in the first place.

Since the comparisons are generated automatically, people may not find them understandable, or there may be missing valuable information. We test this in a human subject evaluation. We adapt the evaluation methodology developed recently for contrasting multiple ways of presenting information and testing the overall learning of the subjects (Shahaf et al., 2012; Christensen et al., 2014). The evaluation is divided into two parts. In the first part the workers are given a limited time to read the information provided (articles or comparison tables) for an entity-pair. They are then asked to write a short 150-300 word summary contrasting different aspects of the two entities. Each user writes two summaries, one based on articles and the other based on our table. Our study pairs two users such that if user1 read the articles for city pair 1 and the table for city pair 2, their partner user will see the reverse. The workers were additionally asked which knowledge source they preferred and why.

Making a worker create summaries using both information sources helps reduce the effect of worker comprehension and skill in the evaluation of our task, as each worker contributes to summaries created using our system as well as the baseline. In order to reduce the effects of any sequence bias, half the mechanical turk workers were first shown the output of our system followed by the articles and the other half (partners) were shown content the other way around.

In the second part of this experiment we directly compare the knowledge acquisition of these workers. In particular, we ask a different set of workers to evaluate the summaries created by the partnered workers. In each task, a worker has to compare two summaries for the same entity-pair, one created using tables by one worker and other created using articles by their partner. Each summary pair was shown to four different users and each of them was asked to select the summary they preferred for comparing and contrasting the entities. Since we perform this experiment on Tourism data, the MTurk task descriptions explained that the intent of the comparison is tourism and their summaries or preferences must be from that perspective.

4.2.1 Results

We performed this evaluation on twenty city pairs using both our information extraction methods i.e. Manual+WV expansion (referred as TABLE-M) and LDA+WV expansion (referred as TABLE-LDA) along with the EB G-pLSA method for clustering. The city pairs were chosen such that the cities are related but not too similar, and the workers would likely not have thought of the specific comparisons before.

We found that in the first part where workers were given 10 minutes to create the summaries, they on average asked for 30% more time to create the summaries when information was presented as article. This supports our belief that our system-generated tables successfully reduce information overload. It also suggests that the structure added by the system (clusters) was useful for the comparison task and reduced workers' cognitive load.

We now present the results for the second part of the study in which workers evaluated the comparison summaries written by the workers in the first part. Within 20 city-pairs, summaries for 5 city pairs (25%) generated based on TABLE-M were preferred and 5 (25%) generated based on original articles were chosen. The workers were indifferent in 10 of the city pairs (both summaries got two votes each). This shows that despite having a very high compression ratio, workers still managed to create summaries that were comparable in quality to those created by reading original documents. We repeated the same study using TABLE-LDA and found that summaries for 8 city pairs (40%) generated based on TABLE-LDA were preferred and 5 (25%) generated based on original articles were chosen. The workers were indifferent in 6 of the city pairs (both summaries got two votes each).

We did not repeat this experiment using the Movies data set as the source articles were concatenated reviews with no structure and it would not be surprising that users prefer our system. In summary, we find that both our systems convey adequate and useful information in the comparisons and the summaries generated by users using our systems were found to be as good as the ones created by users reading the full articles.

5 Conclusions

We define a novel task of automatically generating tabular entity comparisons from unstructured text. We also implement the first system for this task that first extracts descriptive phrases from text and then clusters them to generate comparison tables. Our clustering algorithm is a Gaussian extension of p-LSA, where the descriptive phrases are represented using embeddings in the word vector space. In order to have a better comparison between entities, we incorporate a balance term which prefers clusters where entities are proportionately represented.

We perform extensive human-subject evaluations for our systems over Amazon Mechanical Turk (AMT) on two datasets – tourism and movies. We find that AMT workers overwhelmingly prefer EB G-pLSA based comparisons over GMM-based. We also assess the value of our generated comparisons over reading the original articles. We find that while both sets of workers learned as much, the workers viewing tables asked for less additional time to narrate a comparison in words. Overall, we believe that comparison tables add value for users deciding between multiple entities. In the future we wish to perform joint extraction and clustering instead of our current pipelined approach.

Acknowledgments

We would like to thank the users of our system: Bhadra Mani, Dinesh Khandelwal, Eshita Sharma, Kuntal Dey, Leela Muthana, Noira Khan, Samuel Kumar, Seher Contractor and Prachi Jain, and the anonymous Amazon mechnical turk workers for their evaluation and insights. We would also like to thank Ankit Anand, Happy Mittal and anonymous reviewers for their suggestions on improving the paper. The work was supported by IBM Research, Google language understanding and knowledge discovery focused research grants to Mausam, a KISTI grant and a Bloomberg grant also to Mausam. We would also like to acknowledge the IBM Research India PhD program that enables the first author to pursue the PhD at IIT Delhi.

Abstract

Student course feedback is generated daily in both classrooms and online course discussion forums. Traditionally, instructors manually analyze these responses in a costly manner. In this work, we propose a new approach to summarizing student course feedback based on the integer linear programming (ILP) framework. Our approach allows different student responses to share co-occurrence statistics and alleviates sparsity issues. Experimental results on a student feedback corpus show that our approach outperforms a range of baselines in terms of both ROUGE scores and human evaluation.

1 Introduction

Instructors love to solicit feedback from students. Rich information from student responses can reveal complex teaching problems, help teachers adjust their teaching strategies, and create more effective teaching and learning experiences. Text-based student feedback is often manually analyzed by teaching evaluation centers in a costly manner. Albeit useful, the approach does not scale well. It is therefore desirable to automatically summarize the student feedback produced in online and offline environments. In this work, student responses are collected from an introductory materials science and engineering course, taught in a classroom setting. Students are presented with prompts after each lecture and asked to provide feedback. These prompts solicit "*reflective feedback*" (Boud et al., 2013) from the students. An example is presented in Table 1.

Prompt
Describe what you found most interesting in today's class
Student Responses
S1: The main topics of this course seem interesting and correspond with my major (Chemical engineering)
S2: I found the group activity most interesting
S3: Process that make materials
S4: I found the properties of bike elements to be most interesting
S5: How materials are manufactured
S6: Finding out what we will learn in this class was interesting to me
S7: The activity with the bicycle parts
S8: "part of a bike" activity
... (*rest omitted, 53 responses in total.*)
Reference Summary
- group activity of analyzing bicycle's parts
- materials processing
- the main topic of this course

Table 1: Example student responses and a reference summary created by the teaching assistant. 'S1'–'S8' are student IDs.

In this work, we aim to summarize the student responses. This is formulated as an extractive summarization task, where a set of representative sentences are extracted from student responses to form a textual summary. One of the challenges of summarizing student feedback is its lexical variety. For example, in Table 1, "bike elements" (S4) and "bicycle parts" (S7), "the main topics of this course" (S1) and "what we will learn in this class" (S6) are different expressions that communicate the same or similar meanings. In fact, we observe 97% of the bigrams appear only once or twice in the student feedback corpus (§4), whereas in a typical news dataset (DUC 2004), it is about 80%. To tackle this challenge, we propose a new approach to summarizing

Proceedings of NAACL-HLT 2016, pages 80–85,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

student feedback, which extends the standard ILP framework by approximating the co-occurrence matrix using a low-rank alternative. The resulting system allows sentences authored by different students to share co-occurrence statistics. For example, “The activity with the bicycle parts” (S7) will be allowed to partially contain “bike elements” (S4) although the latter did not appear in the sentence. Experiments show that our approach produces better results on the student feedback summarization task in terms of both ROUGE scores and human evaluation.

2 ILP Formulation

Let $\mathcal{D}$ be a set of student responses that consist of M sentences in total. Let $y_j \in \{0,1\}, j = \{1, \cdots, M\}$ indicate if a sentence j is selected ($y_j = 1$) or not ($y_j = 0$) in the summary. Similarly, let N be the number of unique concepts in $\mathcal{D}$. $z_i \in \{0,1\}$, $i = \{1, \cdots, N\}$ indicate the appearance of concepts in the summary. Each concept i is assigned a weight of w_i, often measured by the number of sentences or documents that contain the concept. The ILP-based summarization approach (Gillick and Favre, 2009) searches for an optimal assignment to the sentence and concept variables so that the selected summary sentences maximize coverage of important concepts. The relationship between concepts and sentences is captured by a co-occurrence matrix $A \in \mathbb{R}^{N \times M}$, where $A_{ij} = 1$ indicates the i-th concept appears in the j-th sentence, and $A_{ij} = 0$ otherwise. In the literature, bigrams are frequently used as a surrogate for concepts (Gillick et al., 2008; Berg-Kirkpatrick et al., 2011). We follow the convention and use ‘concept’ and ‘bigram’ interchangeably in the paper.

$$\max_{\boldsymbol{y},\boldsymbol{z}} \quad \textstyle\sum_{i=1}^{N} w_i z_i \tag{1}$$

$$s.t. \quad \textstyle\sum_{j=1}^{M} A_{ij}\, y_j \geq z_i \tag{2}$$

$$A_{ij}\, y_j \leq z_i \tag{3}$$

$$\textstyle\sum_{j=1}^{M} l_j y_j \leq L \tag{4}$$

$$y_j \in \{0,1\}, z_i \in \{0,1\} \tag{5}$$

Two sets of linear constraints are specified to ensure the ILP validity: (1) a concept is selected if and only if at least one sentence carrying it has been selected (Eq. 2), and (2) all concepts in a sentence will be selected if that sentence is selected (Eq. 3). Finally, the selected summary sentences are allowed to contain a total of L words or less (Eq. 4).

3 Our Approach

Because of the lexical diversity in student responses, we suspect the co-occurrence matrix A may not establish a faithful correspondence between sentences and concepts. A concept may be conveyed using multiple bigram expressions; however, the current co-occurrence matrix only captures a binary relationship between sentences and bigrams. For example, we ought to give partial credit to “bicycle parts” (S7) given that a similar expression “bike elements” (S4) appears in the sentence. Domain-specific synonyms may be captured as well. For example, the sentence “I tried to follow along but I couldn’t *grasp the* concepts” is expected to partially contain the concept “understand the”, although the latter did not appear in the sentence.

The existing matrix A is highly sparse. Only 2.7% of the entries are non-zero in our dataset (§4). We therefore propose to *impute* the co-occurrence matrix by filling in missing values. This is accomplished by approximating the original co-occurrence matrix using a low-rank matrix. The low-rankness encourages similar concepts to be shared across sentences. The data imputation process makes two notable changes to the existing ILP framework. First, it extends the domain of A_{ij} from binary to a continuous scale $[0,1]$ (Eq. 2), which offers a better sentence-level semantic representation. The binary concept variables (z_i) are also relaxed to continuous domain $[0,1]$ (Eq. 5), which allows the concepts to be “partially” included in the summary.

Concretely, given the co-occurrence matrix $A \in \mathbb{R}^{N \times M}$, we aim to find a low-rank matrix $B \in \mathbb{R}^{N \times M}$ whose values are close to A at the observed positions. Our objective function is

$$\min_{B \in \mathbb{R}^{N \times M}} \frac{1}{2} \sum_{(i,j) \in \Omega} (A_{ij} - B_{ij})^2 + \lambda \left\| B \right\|_* , \tag{6}$$

where Ω represents the set of observed value positions. $\|B\|_*$ denotes the trace norm of B, i.e., $\|B\|_* = \sum_{i=1}^{r} \sigma_i$, where r is the rank of B and σ_i are the singular values. By defining the following projection operator P_Ω,

$$[P_\Omega(B)]_{ij} = \begin{cases} B_{ij} & (i,j) \in \Omega \\ 0 & (i,j) \notin \Omega \end{cases} \tag{7}$$

our objective function (Eq. 6) can be succinctly represented as

$$\min_{B \in \mathbb{R}^{N \times M}} \frac{1}{2} \|P_\Omega(A) - P_\Omega(B)\|_F^2 + \lambda \|B\|_*, \tag{8}$$

where $\|\cdot\|_F$ denotes the Frobenius norm.

Following (Mazumder et al., 2010), we optimize Eq. 8 using the proximal gradient descent algorithm. The update rule is

$$B^{(k+1)} = \text{prox}_{\lambda\rho_k}\Big(B^{(k)} + \rho_k\big(P_\Omega(A) - P_\Omega(B)\big)\Big), \tag{9}$$

where ρ_k is the step size at iteration k and the proximal function $\text{prox}_t(B)$ is defined as the singular value soft-thresholding operator, $\text{prox}_t(B) = U \cdot \text{diag}((\sigma_i - t)_+) \cdot V^\top$, where $B = U\text{diag}(\sigma_1, \cdots, \sigma_r)V^\top$ is the singular value decomposition (SVD) of B and $(x)_+ = \max(x, 0)$.

Since the gradient of $\frac{1}{2}\|P_\Omega(A) - P_\Omega(B)\|_F^2$ is Lipschitz continuous with $L = 1$ (L is the Lipschitz continuous constant), we follow (Mazumder et al., 2010) to choose fixed step size $\rho_k = 1$, which has a provable convergence rate of $O(1/k)$, where k is the number of iterations.

4 Dataset

Our dataset is collected from an introductory materials science and engineering class taught in a major U.S. university. The class has 25 lectures and enrolled 53 undergrad students. The students are asked to provide feedback after each lecture based on three prompts: 1) "describe what you found most interesting in today's class," 2) "describe what was confusing or needed more detail," and 3) "describe what you learned about how you learn." These open-ended prompts are carefully designed to encourage students to self-reflect, allowing them to "recapture experience, think about it and evaluate it" (Boud et al., 2013). The average response length is 10±8.3 words. If we concatenate all the responses to each lecture and prompt into a "pseudo-document", the document contains 378 words on average.

The reference summaries are created by a teaching assistant. She is allowed to create abstract summaries using her own words in addition to selecting phrases directly from the responses. Because summary annotation is costly and recruiting annotators with proper background is nontrivial, 12 out of the 25 lectures are annotated with reference summaries. There is one gold-standard summary per lecture and question prompt, yielding 36 document-summary pairs[1]. On average, a reference summary contains 30 words, corresponding to 7.9% of the total words in student responses. 43.5% of the bigrams in human summaries appear in the responses.

5 Experiments

Our proposed approach is compared against a range of baselines. They are 1) MEAD (Radev et al., 2004), a centroid-based summarization system that scores sentences based on length, centroid, and position; 2) LEXRANK (Erkan and Radev, 2004), a graph-based summarization approach based on eigenvector centrality; 3) SUMBASIC (Vanderwende et al., 2007), an approach that assumes words occurring frequently in a document cluster have a higher chance of being included in the summary; 4) BASELINE-ILP (Berg-Kirkpatrick et al., 2011), a baseline ILP framework without data imputation.

For the ILP based approaches, we use bigrams as concepts (bigrams consisting of only stopwords are removed[2]) and sentence frequency as concept weights. We use all the sentences in 25 lectures to construct the concept-sentence co-occurrence matrix and perform data imputation. It allows us to leverage the co-occurrence statistics both within and across lectures. For the soft-impute algorithm, we perform grid search (on a scale of [0, 5] with stepsize 0.5) to tune the hyper-parameter λ. To make the most use of annotated lectures, we split them into three folds. In each one, we tune λ on two folds and test it on the other fold. Finally, we report the averaged results. In all experiments, summary length is set to be 30 words or less, corresponding to the

[1] This data set is publicly available at `http://www.coursemirror.com/download/dataset`.

[2] Bigrams with one stopword are not removed because 1) they are informative ("a bike", "the activity", "how materials'); 2) such bigrams appear in multiple sentences and are thus helpful for matrix imputation.

average number of words in human summaries.

In Table 2, we present summarization results evaluated by ROUGE (Lin, 2004) and human judges. ROUGE is a standard evaluation metric that compares system and reference summaries based on n-gram overlaps. Our proposed approach outperforms all the baselines based on three standard ROUGE metrics.[3] When examining the imputed sentence-concept co-occurrence matrix, we notice some interesting examples that indicate the effectiveness of the proposed approach, shown in Table 3.

Sentence	Assoc. Bigrams
the printing needs to better so it can be easier to read	*the graph*
graphs make it *easier to* understand concepts	*hard to*
the naming system for the 2 *phase regions*	*phase diagram*
I tried to follow along but I couldn't *grasp the* concepts	*understand the*
no problems except for the specific equations used to determine properties from the stress - *strain graph*	*strain curves*

Table 3: Associated bigrams do not appear in the sentence, but after Matrix Imputation, they yield a decent correlation (cell value greater than 0.9) with the corresponding sentence.

Because ROUGE cannot thoroughly capture the semantic similarity between system and reference summaries, we further perform human evaluation. For each lecture and prompt, we present the prompt, a pair of system outputs in a random order, and the human summary to five Amazon turkers. The turkers are asked to indicate their preference for system A or B based on the semantic resemblance to the human summary on a 5-Likert scale ('Strongly preferred A', 'Slightly preferred A', 'No preference', 'Slightly preferred B', 'Strongly preferred B'). They are rewarded $0.08 per task. We use two strategies to control the quality of the human evaluation. First, we require the turkers to have a Human Intelligence Task (HIT) approval rate of 90% or above. Second, we insert some quality checkpoints by asking the turkers to compare two summaries of same text content but different sentence orders. Turkers who did not pass these tests are filtered out. Due to budget constraints, we conduct pairwise comparisons for three systems. The total number of comparisons is 3 system-system pairs × 12 lectures × 3 prompts × 5 turkers = 540 total pairs. We calculate the percentage of "wins" (strong or slight preference) for each system among all comparisons with its counterparts. Results are reported in the last column of Table 2. OUR APPROACH is preferred significantly more often than the other two systems[4]. Regarding the inter-annotator agreement, we find 74.3% of the individual judgements agree with the majority votes when using a 3-point Likert scale ('preferred A', 'no preference', 'preferred B').

Table 4 presents example system outputs. This offers intuitive understanding to our proposed approach.

[3] F-scores are slightly lower than P/R because of the averaging effect and can be illustrated in one example. Suppose we have P1=0.1, R1=0.4, F1=0.16 and P2=0.4, R2=0.1, F2=0.16. Then the macro-averaged P/R/F-scores are: P=0.25, R=0.25, F=0.16. In this case, the F-score is lower than both P and R.

[4] For the significance test, we convert a preference to a score ranging from -2 to 2 ('2' means 'Strongly preferred' to a system and '-2' means 'Strongly preferred' to the counterpart system), and use a two-tailed paired t-test with $p < 0.05$ to compare the scores.

Prompt
Describe what you found most interesting in today's class

Reference Summary
- unit cell direction drawing and indexing
- real world examples
- importance of cell direction on materials properties

System Summary (ILP BASELINE)
- drawing and indexing unit cell direction
- it was interesting to understand how to find apf and fd from last weeks class
- south pole explorers died due to properties of tin

System Summary (OUR APPROACH)
- crystal structure directions
- surprisingly i found nothing interesting today .
- unit cell indexing
- vectors in unit cells
- unit cell drawing and indexing
- the importance of cell direction on material properties

6 Related Work

Our previous work (Luo and Litman, 2015) proposes to summarize student responses by extracting phrases rather than sentences in order to meet the need of aggregating and displaying student responses in a mobile application (Luo et al., 2015; Fan et al., 2015). It adopts a clustering paradigm to address the lexical variety issue. In this work, we leverage matrix imputation to solve this problem and summarize student response at a sentence level.

The integer linear programming framework has demonstrated substantial success on summarizing news documents (Gillick et al., 2008; Gillick et al., 2009; Woodsend and Lapata, 2012; Li et al., 2013). Previous studies try to improve this line of work by generating better estimates of concept weights. Galanis et al. (2012) proposed a support vector regression model to estimate bigram frequency in the summary. Berg-Kirkpatrick et al. (2011) explored a supervised approach to learn parameters using a cost-augmentative SVM. Different from the above approaches, we focus on the co-occurrence matrix instead of concept weights, which is another important component of the ILP framework.

Most summarization work focuses on summarizing news documents, as driven by the DUC/TAC conferences. Notable systems include maximal marginal relevance (Carbonell and Goldstein, 1998), submodular functions (Lin and Bilmes, 2010), jointly extract and compress sentences (Zajic et al., 2007), optimize content selection and surface realization (Woodsend and Lapata, 2012), minimize reconstruction error (He et al., 2012), and dual decomposition (Almeida and Martins, 2013). Albeit the encouraging performance of our proposed approach on summarizing student responses, when applied to the DUC 2004 dataset (Hong et al., 2014) and evaluated using ROUGE we observe only comparable or marginal improvement over the ILP baseline. However, this is not surprising since the lexical variety is low (20% of bigrams appear more than twice compared to 3% of bigrams appear more than twice in student responses) and thus less data sparsity, so the DUC data cannot benefit much from imputation.

7 Conclusion

We make the first effort to summarize student feedback using an integer linear programming framework with data imputation. Our approach allows sentences to share co-occurrence statistics and alleviates sparsity issue. Our experiments show that the proposed approach performs competitively against a range of baselines and shows promise for future automation of student feedback analysis.

In the future, we may take advantage of the high quality student responses (Luo and Litman, 2016) and explore helpfulness-guided summarization (Xiong and Litman, 2014) to improve the summarization performance. We will also investigate whether the proposed approach benefits other informal text such as product reviews, social media discussions or spontaneous speech conversations, in which we expect the same sparsity issue occurs and the language expression is diverse.

Acknowledgments

Knowledge-Guided Linguistic Rewrites for Inference Rule Verification

Prachi Jain and **Mausam**
Indian Institute of Technology, Delhi
New Delhi, India
{csz148211,mausam}@cse.iitd.ac.in

Abstract

A corpus of inference rules between a pair of relation phrases is typically generated using the statistical overlap of argument-pairs associated with the relations (e.g., PATTY, CLEAN). We investigate *knowledge-guided linguistic rewrites* as a secondary source of evidence and find that they can vastly improve the quality of inference rule corpora, obtaining 27 to 33 point precision improvement while retaining substantial recall. The facts inferred using cleaned inference rules are 29-32 points more accurate.

1 Introduction

The visions of machine reading (Etzioni, 2007) and deep language understanding (Dorr, 2012) emphasize the ability to draw inferences from text to discover implicit information that may not be explicitly stated (Schubert, 2002). This has natural applications to textual entailment (Dagan et al., 2013), KB completion (Socher et al., 2013), and effective querying over Knowledge Bases (KBs).

One popular approach for fact inference is to use a set of *inference rules* along with probabilistic models such as Markov Logic Networks (Schoenmackers et al., 2008) or Bayesian Logic Programs (Raghavan et al., 2012) to produce human-interpretable proof chains. While scalable (Niu et al., 2011; Domingos and Webb, 2012), this is bound by the coverage and quality of the background knowledge – the set of inference rules that enable the inference (Clark et al., 2014).

Antecedent	**Consequent**	**Y/N?**
(X, make a note of, Y)	(X, write down, Y)	Y
(X, offer wide range of, Y)	(X, offer variety of, Y)	Y
(X, make full use of, Y)	(Y, be used by, X)	Y
(X, be wounded in, Y)	(X, be killed in, Y)	N
(X, be director of, Y)	(X, be vice president of, Y)	N
(X, be a student at, Y)	(X, be enrolled at, Y)	N

Figure 1: Sample rules verified (Y) and filtered (N) by our method. Rules #4, #5 were correctly and #6 wrongly filtered.

The paper focuses on generating a *high precision* subset of inference rules over Open Information Extraction (OpenIE) (Etzioni et al., 2011) relation phrases (see Fig 1). OpenIE systems generate a schema-free KB where entities and relations are represented via normalized but not disambiguated textual strings. Such OpenIE KBs scale to the Web.

Most existing large-scale corpora of inference rules are generated using distributional similarity, like argument-pair overlap (Schoenmackers et al., 2010; Berant et al., 2012), but often eschew any linguistic or compositional insights. Our early analysis revealed that such inference rules have very low precision, not enough to be useful for many real tasks. For human-facing applications (such as IE-based demos), high precision is critical. Inference rules have a multiplicative impact, since one poor rule could potentially generate many bad KB facts.

Contributions: We investigate the hypothesis that *"knowledge-guided linguistic rewrites can provide independent verification for statistically-generated Open IE inference rules."* Our system KGLR's rewrites exploit the compositional structure of Open IE relation phrases alongside knowledge in resources like Wordnet and thesaurus. KGLR independently verifies rules from existing inference rule

Proceedings of NAACL-HLT 2016, pages 86–92,
San Diego, California, June 12-17, 2016.

corpora (Berant et al., 2012; Pavlick et al., 2015) and can be seen as additional annotation on existing inference rules. The verified rules are 27 to 33 points more accurate than the original corpora and still retain a substantial recall. The precision of inferred knowledge also has a precision boost of over 29 points. We release our KGLR implementation, its annotations on two popular rule corpora along with gold set used for evaluation and the annotation guidelines for further use (available at *https://github.com/dair-iitd/kglr.git*).

2 Related work

Methods for inference over text include random walks over knowledge graphs (Lao et al., 2011), matrix completion (Riedel et al., 2013), deep neural networks (Socher et al., 2013; Rocktäschel et al., 2015a), natural logic inference (MacCartney and Manning, 2007) and graphical models (Schoenmackers et al., 2008; Raghavan et al., 2012). Most of these need (or benefit from) a background knowledge of inference rules, including matrix completion (Rocktäschel et al., 2015b).

Inference rules are predominantly generated via extended distributional similarity – two phrases having a high degree of argument overlap are similar, and thus candidates for a unidirectional or a bidirectional inference rule. Methods vary on the base representation, e.g., KB relations (Galárraga et al., 2013; Grycner et al., 2015), Open IE relation phrases (Schoenmackers et al., 2010), syntactic-ontological-lexical (SOL) patterns (Nakashole et al., 2012), and dependency paths (Lin and Pantel, 2001). An enhancement is global transitivity (TNCF algorithm) for improving recall (Berant et al., 2012). The highest precision setting of TNCF ($\lambda = 0.1$) was released as a corpus (informally called CLEAN) of Open IE inference rules.[1]

Distributional similarity approaches have two fundamental limitations. First, they miss obvious commonsense facts, e.g., ⟨(X, married, Y) → (X, knows, Y)⟩ – text will rarely say that a couple know each other. Second, they are consistently affected by statistical noise and end up generating a wide variety of inaccurate rules (see rules #4, and #5 in Figure 1). Our early experiments with CLEAN revealed its precision to be about 0.49, not enough to be useful in practice, especially for human-facing applications.

Similar to our paper, some past works have used alternative sources of knowledge. Weisman *et al.* (2012) study inference between verbs (e.g., ⟨startle → surprise⟩), but they get low (0.4) precision. Wordnet corpus to generate inference rules for natural logic (Angeli and Manning, 2014) improved noun-based inference. But, they recognize relation entailments as a key missing piece. Recently, natural logic semantics is added to a paraphrase corpus (PPDB2.0). Many of their features, e.g., lexical/orthographic, multilingual translation based, are complimentary to our method.

We test our KGLR algorithm on CLEAN and entailment/paraphrase subset of PPDB2.0 (which we call PPDB$_e$).

3 Knowledge-Guided Linguistic Rewrites (KGLR)

Given a rule ⟨(X, r_1, Y) → (X, r_2, Y)⟩ or ⟨(X, r_1, Y) → (Y, r_2, X)⟩ we present KGLR, a series of rewrites of relation phrase r_1 to prove r_2 (examples in Fig 1). The last two rewrites deal with reversal of argument order in r_2; others are for the first case.

Thesaurus Synonyms: Thesauri typically provide an expansive set of potential synonyms, encompassing near-synonyms and contextually synonymous words. Thesaurus synonyms are not that helpful for *generating* inference rules (or else we will generate rules like ⟨produce → percolate⟩). However, they are excellent in rule verification as they provide evidence independent from statistical overlap metrics.

We allow any word/phrase w_1 in r_1 to be replaced by any word/phrase w_2 from its thesaurus synsets as long as (1) w_2 has same part-of-speech as w_1 and (2) w_2 is seen in r_2 at the same distance from left of the phrase as w_1 in phrase r_1, but ignoring words dropped due to other rules whose details follows next. To define a thesaurus synset, we tag w_1 with its POS and look for all thesaurus synsets of that POS containing w_1. We allow this rewrite if PMI(w_1, w_2) $> \lambda$ (=-2.5 based on a devset). We calculate PMI as $log\frac{(\#w_1 \text{ occurs in synsets of } w_2 + \#w_2 \text{ occurs in synsets of } w_1)}{(\# \text{ of synsets of } w_1 \times \# \text{ of synsets of } w_2)}$. Some words can be both synonyms and antonyms in different situations. For example, thesaurus lists

[1] *http://u.cs.biu.ac.il/~nlp/resources/downloads/predicative-entailment-rules-learned-using-local-and-global-algorithms*

'bad' as both a synonym and antonym of 'good'. We don't allow such antonyms in these rewrites.

Thesarus synonyms can verify ⟨offer a vast range of → provide a wide range of⟩, since offer-provide, and vast-wide are thesaurus synonyms. We use Roget's 21^{st} Century Thesaurus in KGLR implementation.

Negating rules: We reject rules where r_2 explicitly negates r_1 or vice versa. We reject a rule if r_2 is same as r_1 if we drop 'not' from one of them. For example, the rule ⟨be the president of → be not the president of⟩, will be rejected.

Wordnet Hypernyms: We replace word/phrase w in r_1 by its Wordnet hypernym if it is in r_2. We prove ⟨be highlight of → be component of⟩, as Wordnet lists 'component' as a hypernym of 'highlight'.

Dropping Modifiers: We drop any adjective, adverb, superlatives or comparatives (e.g., 'more', 'most') from r_1. This lets us verify ⟨be most important part of → be part of⟩.

Gerund-Infinitive Equivalence: We convert infinitive constructions into gerunds and vice versa. For example, ⟨starts to drink ↔ starts drinking⟩.

Deverbal Nouns: We use Wordnet's derivationally related forms to compute a verb-noun pair list. We allow back and forth conversions from "be noun of" to related verb. So, we verify ⟨be cause of → cause⟩.

Light Verbs and Serial Verbs: If a light verb precede a word with derivationally related noun sense, we delete it. Similarly, if a serial verb precede a word with derivationally related verb sense, we delete it. We identify light verbs via the verbs that frequently precede a ⟨(a|an) (verb|deverbal noun)⟩ pair in Wikipedia. Serial verbs are identified as the verbs that frequently precede another verb in Wikipedia. Thus we can convert ⟨take a look at → look at⟩.

Preposition Synonyms: We manually create a list of preposition near-synonyms such as into-to, in-at, at-near. We replace a preposition by its near-synonym. This proves ⟨translated into → translated to⟩.

Be-Words & Determiners: We drop be-words ('is', 'was', 'be', etc.) and determiners from r_1 and r_2.

Active-Passive: We allow (X, $verb$, Y) to be rewritten as (Y, $be\ verb\ by$, X).

Redundant Prepositions: We find that often prepositions other than 'by' can be alternatively used with passive forms of some verbs. Moreover, some prepositions can be redundantly used in active forms too. For example, ⟨(X, absorb, Y) ↔ (Y, be absorbed *in*, X)⟩, or similarly, ⟨(X, attack, Y) ↔ (X, attack *on*, Y)⟩. To create such a list of verb-preposition pairs, we simply trust the argument-overlap statistics. Statistics here does not make that many errors since the base verb in both relations is the same.

3.1 Implementation

KGLR allows repeated application of these rewrites to modify r_1 and r_2. If it achieves $r_1 = r_2$ it verifies the inference rule. For tractable implementation KGLR uses a depth first search approach where a search node maintains both r_1 and r_2. Search does not allow rewrites that introduce any new lexical (lemmatized) entries not in original words(r_1) ∪ words(r_2). If it can't apply any rewrite to get a new node, it returns failure.

Many rules are proved by a sequence of rewrites. E.g., to prove ⟨(X, be a major cause of, Y) → (Y, be caused by, X)⟩, the proof proceeds as: (X, be a major cause of, Y) → (X, be major cause of, Y) → (X, be cause of, Y) → (X, cause, Y) → (Y, be caused by, X) by dropping determiner, dropping adjective, deverbal noun, and active-passive transformation respectively. Similarly, ⟨(X, helps to protect, Y) → (X, look after, Y)⟩ follows from gerund-infinitive conversion (helps protect), dropping support from serial verbs (protect), and thesaurus synonym (look after).

4 Experiments

KGLR verifies a subset of rules from CLEAN and PPDB$_e$ to produce, VCLEAN and VPPDB$_e$. Our experiments answer these research questions: (1) What is the precision and size of the verified subsets compared to original corpora?, (2) How does additional knowledge generated after performing inference using these rules compare with each other? and (3) Which rewrites are critical to KGLR performance?

Comparison of CLEAN and VCLEAN: The original CLEAN corpus has about 102K rules. KGLR verifies about 36K rules and filter 66K rules out. To estimate the precisions of CLEAN and VCLEAN we independently sampled a random subset of 200 inference rules from each and asked two annotators (graduate level NLP students) to label the rules as correct or incorrect. Rules were mixed together and the annotators were blind to the system that generated a rule. Our initial annotation guideline was similar to that of textual entailment – label a rule as correct if the consequent can usually be inferred given the antecedent, for most naturally occurring argument-pairs for the antecedent.

Our annotators faced one issue with the guideline – some inference rules were valid if (X,Y) were bound to specific types, but not for others. For example, $\langle$(X, be born in, Y) → (Y, be birthplace of, X)$\rangle$ is valid if Y is a location, not if Y is a year. Even seemingly correct inference rules, e.g., $\langle$(X, is the father of, Y) → (Y, is the child of, X)$\rangle$, can make unusual incorrect inferences: (Gandhi, is the father of, India) does not imply (India, is the child of, Gandhi). Unfortunately, these corpora don't associate argument-type information with their inference rules.

To mitigate this we refined the annotation guidelines to accept inference rules as correct as long as they are valid for *some* type-pair. The inter-annotator agreement with this modification was 94% (κ = 0.88). On the subset of the tags where the two annotators agreed we find the precision of Clean to be 48.9%, whereas VClean was evaluated to be 82.5% precise – much more useful for real-world applications. Multiplying the precision with their sizes, we find the effective yield[2] of Clean to be 50K compared to 30K for VClean. Overall, we find that VClean obtains a 33 point precision improvement with an effective yield of about 60%.

Error Analysis: Most of VClean errors are due to erroneous (or unusual) thesaurus synonyms. For missed recall, we analyzed Clean's sample missed by VClean. We find that only about 13% of those are world knowledge rules (e.g., rule #6 in Figure 1). Other missed recall is because of some missing rewrites, missing thesaurus synonyms, spelling mistakes. These can potentially be captured by using other resources and adding rewrite rules.

Comparison of PPDB$_e$ and VPPDB$_e$: Unlike Clean, PPDB2.0 associates a confidence value for each rule, which can be varied to obtain different levels of precision and yield. We control for yield so that we can compare precisions directly.

We operate on PPDB$_e$ subset that has an Open IE-like relation phrase on both sides; this was identified by matching to ReVerb syntactic patterns (Etzioni et al., 2011). This subset is of size 402K. KGLR on this produces 85K verified rules (VPPDB$_e$). We find the threshold for confidence values in PPDB$_e$ that achieves the same yield (confidence $>$ 0.342).

We perform annotation on PPDB$_e$(0.342) and VPPDB$_e$ using same annotation guidelines as before. The inter-annotator agreement was 91% (κ = 0.82). On the subset of the tags where the two annotators agreed we find the precision of PPDB$_e$ to be low – 44.2%, whereas VPPDB$_e$ was evaluated to be 71.4% precise. We notice that about 4 in 5 PPDB relation phrases are of length 1 or 2 (whereas 50% of CLEAN relation phrases are of length $\geq$ 3). This contributes to a slightly lower precision of VPPDB$_e$, as most rules are proved by *thesaurus synonymy* and the power of KGLR to handle compositionality of longer relation phrases does not get exploited.

Comparison of Inferred Facts: A typical use case of inference rules is in generating new facts by applying inference rules to a KB. We independently apply VClean's, Clean's, PPDB$_e$'s and VPPDB$_e$'s inference rules on a public corpus of 4.2 million ReVerb triples.[3] Since ReVerb itself has significant extraction errors (our estimate is 20% errors) and our goal is to evaluate the quality of inference, we restrict this evaluation to only the subset of accurate ReVerb extractions.

VClean *and* Clean *facts:* We sampled about 200 facts inferred by VClean rules and Clean rules each (applied over accurate ReVerb extractions) and gave the original sentence as well as inferred facts to two annotators. We obtained a high inter-annotator agreement of 96.3%(κ = 0.92) and we discarded disagreements from final analysis. Overall, facts inferred by Clean achieved a precision of about 49.1% and those inferred by VClean obtained a 81.6% precision. The estimated yields of fact corpora (precision×size) are 7 and 4.5 million for Clean and VClean respectively. This yield estimate does not include the initial 4.2 million facts.

PPDB$_e$ *and* VPPDB$_e$ *facts:* As done previously, we sampled 200 facts inferred by PPDB$_e$ and VPPDB$_e$ rules, which were annotated by two annotators. We obtained a good inter annotator agree-

[2] Yield is proportional to recall

Rule Yield	50,154	29,889
Fact Precision	49.1%	81.6%
Fact Yield	7 million	4.5 million
System	**PPDB$_e$(0.342)**	**VPPDB$_e$**
Size	85,272	85,261
Rule Precision	44.2%	71.4%
Fact Precision	22.16%	51.30%
Fact Yield	41 million	35 million

Figure 2: The precision and yield of inference rules after KGLR validation, and that of KB generated by inference using these rule-sets. Comparison with PPDB$_e$ is yield-controlled.

ment of 90.0%(κ = 0.8) and we discarded disagreements from final analysis. Overall, facts inferred by PPDB$_e$ achieved a really poor precision - 22.2% and those inferred by VPPDB$_e$ obtained an improvement of about 29 points (51.3% precision). Short relation phrases (mostly of length 1 or 2, which forms 80% of PPDB$_e$) contribute to low precision of VPPDB$_e$. Example low precision VPPDB$_e$ rules include ⟨ (X, be, Y) → (X, obtain, Y)⟩, ⟨ (X, include, Y) → (X, come, Y)⟩, which were inaccurately verified due to thesaurus errors. The estimated yields of fact corpora are 41 million and 35 million for PPDB$_e$ and VPPDB$_e$ respectively.

Ablation Study of KGLR rewrites: We evaluate the efficacy of different rewrites in KGLR by performing an ablation study (see Table 3). We ran KGLR by turning off one rewrite on a sample of 600 CLEAN rules (our development set) and calculating its precision and recall. The ablation study highlights that most rewrites add some value to the performance of KGLR, however *Antonyms* and *Dropping modifiers* are particularly important for precision and *Active-Passive* and *Redundant Preposition* add substantial recall.

5 Discussion

KGLR's value is in precision-sensitive tasks such as a human-facing demo, or downstream NLP application (like question answering) where error multiplication is highly undesirable. Along with high precision, it still obtains acceptably good yield.

Our annotators observe the importance of type-restriction of arguments for inference rules (similar to rules in (Schoenmackers et al., 2010)). Type annotation of existing inference rule corpora is an important step for obtaining high precision and clarity.

System	Precision	Recall
KGLR (all rules)	85.4%	62.0%
w/o Negating Rules	85.4%	62.0%
w/o Antonyms	84.2%	62.0%
w/o Wordnet Hypernyms	86.1%	59.3%
w/o Dropping Modifiers	84.9%	59.6%
w/o Gerund-Infinitive Equivalence	85.2%	61.0%
w/o Light and Serial Verbs	85.0%	59.9%
w/o Deverbal Nouns	85.4%	62.0%
w/o Preposition Synonyms	86.9%	56.9%
w/o Active-Passive	85.0%	54.5%
w/o Redundant Prepositions	86.1%	61.6%

Figure 3: Ablation study of rule verification using KGLR rewrites on our devset of 600 CLEAN rules

Inference rules are typically of two types – linguistic/synonym rewrites, which are captured by our work, and world knowledge rules (see rule #6 in Fig 1), which are not. We were surprised to estimate that about 87% of CLEAN, which is a statistically-generated corpus, is just linguistic rewrites! Obtaining world knowledge or common-sense rules at high precision and scale continues to be the key NLP challenge in this area.

6 Conclusions

We present Knowledge-guided Linguistic Rewrites (KGLR) which exploits the compositionality of relation phrases, guided by existing knowledge sources, such as Wordnet and thesaurus to identify a high precision subset of an inference rule corpus. Validated CLEAN has a high precision of 83% (vs 49%) at a yield of 60%. Validated PPDB$_e$ has a precision of 71% (vs 44%) at same yield. The precision of inferred facts has about 29-32 pt precision gain. We expect KGLR to be effective for precision-sensitive applications of inference. The complete code and data has been released for the research community.

Abstract

Abstractive Sentence Summarization generates a shorter version of a given sentence while attempting to preserve its meaning. We introduce a conditional recurrent neural network (RNN) which generates a summary of an input sentence. The conditioning is provided by a novel convolutional attention-based encoder which ensures that the decoder focuses on the appropriate input words at each step of generation. Our model relies only on learned features and is easy to train in an end-to-end fashion on large data sets. Our experiments show that the model significantly outperforms the recently proposed state-of-the-art method on the Gigaword corpus while performing competitively on the DUC-2004 shared task.

1 Introduction

Generating a condensed version of a passage while preserving its meaning is known as text summarization. Tackling this task is an important step towards natural language understanding. Summarization systems can be broadly classified into two categories. *Extractive models* generate summaries by cropping important segments from the original text and putting them together to form a coherent summary. *Abstractive models* generate summaries from scratch without being constrained to reuse phrases from the original text.

In this paper we propose a novel recurrent neural network for the problem of *abstractive sentence summarization*. Inspired by the recently proposed architectures for machine translation (Bahdanau et al., 2014), our model consists of a conditional recurrent neural network, which acts as a decoder to generate the summary of an input sentence, much like a standard recurrent language model. In addition, at every time step the decoder also takes a conditioning input which is the output of an encoder module. Depending on the current state of the RNN, the encoder computes scores over the words in the input sentence. These scores can be interpreted as a soft alignment over the input text, informing the decoder which part of the input sentence it should focus on to generate the next word. Both the decoder and encoder are jointly trained on a data set consisting of sentence-summary pairs. Our model can be seen as an extension of the recently proposed model for the same problem by Rush et al. (2015). While they use a feed-forward neural language model for generation, we use a recurrent neural network. Furthermore, our encoder is more sophisticated, in that it explicitly encodes the position information of the input words. Lastly, our encoder uses a convolutional network to encode input words. These extensions result in improved performance.

The main contribution of this paper is a novel convolutional attention-based conditional recurrent neural network model for the problem of abstractive sentence summarization. Empirically we show that our model beats the state-of-the-art systems of Rush et al. (2015) on multiple data sets. Particularly notable is the fact that even with a simple generation module, which does not use any extractive feature tuning, our model manages to significantly outperform their ABS+ system on the Gigaword data set and is comparable on the DUC-2004 task.

Proceedings of NAACL-HLT 2016, pages 93–98,
San Diego, California, June 12-17, 2016.

2 Previous Work

While there is a large body of work for generating extractive summaries of sentences (Jing, 2000; Knight and Marcu, 2002; McDonald, 2006; Clarke and Lapata, 2008; Filippova and Altun, 2013; Filippova et al., 2015), there has been much less research on abstractive summarization. A count-based noisy-channel machine translation model was proposed for the problem in Banko et al. (2000). The task of abstractive sentence summarization was later formalized around the DUC-2003 and DUC-2004 competitions (Over et al., 2007), where the TOPIARY system (Zajic et al., 2004) was the state-of-the-art. More recently Cohn and Lapata (2008) and later Woodsend et al. (2010) proposed systems which made heavy use of the syntactic features of the sentence-summary pairs. Later, along the lines of Banko et al. (2000), MOSES was used directly as a method for text simplification by Wubben et al. (2012). Other works which have recently been proposed for the problem of sentence summarization include (Galanis and Androutsopoulos, 2010; Napoles et al., 2011; Cohn and Lapata, 2013). Very recently Rush et al. (2015) proposed a neural attention model for this problem using a new data set for training and showing state-of-the-art performance on the DUC tasks. Our model can be seen as an extension of their model.

3 Attentive Recurrent Architecture

Let $\mathbf{x}$ denote the input sentence consisting of a sequence of M words $\mathbf{x} = [x_1, \ldots, x_M]$, where each word x_i is part of vocabulary $\mathcal{V}$, of size $|\mathcal{V}| = V$. Our task is to generate a target sequence $\mathbf{y} = [y_1, \ldots, y_N]$, of N words, where $N < M$, such that the meaning of $\mathbf{x}$ is preserved: $\mathbf{y} = \mathrm{argmax}_y P(y|\mathbf{x})$, where y is a random variable denoting a sequence of N words.

Typically the conditional probability is modeled by a parametric function with parameters θ: $P(y|\mathbf{x}) = P(y|\mathbf{x}; \theta)$. Training involves finding the θ which maximizes the conditional probability of sentence-summary pairs in the training corpus. If the model is trained to generate the next word of the summary, given the previous words, then the above conditional can be factorized into a product of individual conditional probabilities:

$$P(\mathbf{y}|\mathbf{x}; \theta) = \prod_{t=1}^{N} p(y_t|\{y_1, \ldots, y_{t-1}\}, \mathbf{x}; \theta). \quad (1)$$

In this work we model this conditional probability using an RNN Encoder-Decoder architecture, inspired by Cho et al. (2014) and subsequently extended in Bahdanau et al. (2014). We call our model RAS (Recurrent Attentive Summarizer).

3.1 Recurrent Decoder

The above conditional is modeled using an RNN:

$$P(y_t|\{y_1, \ldots, y_{t-1}\}, \mathbf{x}; \theta) = P_t = g_{\theta_1}(h_t, c_t),$$

where h_t is the hidden state of the RNN:

$$h_t = g_{\theta_1}(y_{t-1}, h_{t-1}, c_t).$$

Here c_t is the output of the encoder module (detailed in §3.2). It can be seen as a context vector which is computed as a function of the current state h_{t-1} and the input sequence $\mathbf{x}$.

Our Elman RNN takes the following form (Elman, 1990):

$$\begin{aligned} h_t &= \sigma(W_1 y_{t-1} + W_2 h_{t-1} + W_3 c_t) \\ P_t &= \rho(W_4 h_t + W_5 c_t), \end{aligned}$$

where σ is the sigmoid function and ρ is the softmax, defined as: $\rho(o_t) = e^{o_t} / \sum_j e^{o_j}$ and W_i ($i = 1, \ldots, 5$) are matrices of learnable parameters of sizes $W_{\{1,2,3\}} \in \mathcal{R}^{d \times d}$ and $W_{\{4,5\}} \in \mathcal{R}^{d \times V}$.

The LSTM decoder is defined as (Hochreiter and Schmidhuber, 1997):

$$\begin{aligned} i_t &= \sigma(W_1 y_{t-1} + W_2 h_{t-1} + W_3 c_t) \\ i'_t &= \tanh(W_4 y_{t-1} + W_5 h_{t-1} + W_6 c_t) \\ f_t &= \sigma(W_7 y_{t-1} + W_8 h_{t-1} + W_9 c_t) \\ o_t &= \sigma(W_{10} y_{t-1} + W_{11} h_{t-1} + W_{12} c_t) \\ m_t &= m_{t-1} \odot f_t + i_t \odot i'_t \\ h_t &= m_t \odot o_t \\ P_t &= \rho(W_{13} h_t + W_{14} c_t). \end{aligned}$$

Operator $\odot$ refers to component-wise multiplication, and W_i ($i = 1, \ldots, 14$) are matrices of learnable parameters of sizes $W_{\{1,\ldots,12\}} \in \mathcal{R}^{d \times d}$, and $W_{\{13,14\}} \in \mathcal{R}^{d \times V}$.

3.2 Attentive Encoder

We now give the details of the encoder which computes the context vector c_t for every time step t of the decoder above. With a slight overload of notation, for an input sentence $\mathbf{x}$ we denote by x_i the d dimensional learnable embedding of the i-th word ($x_i \in \mathcal{R}^d$). In addition the position i of the word x_i is also associated with a learnable embedding l_i of size d ($l_i \in \mathcal{R}^d$). Then the full embedding for i-th word in $\mathbf{x}$ is given by $a_i = x_i + l_i$. Let us denote by $B^k \in \mathcal{R}^{q \times d}$ a learnable weight matrix which is used to convolve over the full embeddings of consecutive words. Let there be d such matrices ($k \in \{1, \dots, d\}$). The output of convolution is given by:

$$z_{ik} = \sum_{h=-q/2}^{q/2} a_{i+h} \cdot b^k_{q/2+h}, \tag{2}$$

where b^k_j is the j-th column of the matrix B^k. Thus the d dimensional aggregate embedding vector z_i is defined as $z_i = [z_{i1}, \dots, z_{id}]$. Note that each word x_i in the input sequence is associated with one aggregate embedding vector z_i. The vectors z_i can be seen as a representation of the word which captures the position in which it occurs in the sentence and also the context in which it appears in the sentence. In our experiments the width q of the convolution matrix B^k was set to 5. To account for words at the boundaries of $\mathbf{x}$ we first pad the sequence on both sides with dummy words before computing the aggregate vectors z_i's.

Given these aggregate vectors of words, we compute the context vector c_t (the encoder output) as:

$$c_t = \sum_{j=1}^{M} \alpha_{j,t-1} x_j, \tag{3}$$

where the weights $\alpha_{j,t-1}$ are computed as

$$\alpha_{j,t-1} = \frac{\exp(z_j \cdot h_{t-1})}{\sum_{i=1}^{M} \exp(z_i \cdot h_{t-1})}. \tag{4}$$

3.3 Training and Generation

Given a training corpus $\mathcal{S} = \{(\mathbf{x}^i, \mathbf{y}^i)\}_{i=1}^{S}$ of S sentence-summary pairs, the above model can be trained end-to-end using stochastic gradient descent by minimizing the negative conditional log likelihood of the training data with respect to θ:

$$\mathcal{L} = -\sum_{i=1}^{S} \sum_{t=1}^{N} \log P(y^i_t | \{y^i_1, \dots, y^i_{t-1}\}, \mathbf{x}^i; \theta), \tag{5}$$

where the parameters θ constitute the parameters of the decoder and the encoder.

Once the parametric model is trained we generate a summary for a new sentence $\mathbf{x}$ through a word-based beam search such that $P(y|\mathbf{x})$ is maximized, $\operatorname{argmax} P(y_t | \{y_1, \dots, y_{t-1}\}, \mathbf{x})$. The search is parameterized by the number of paths k that are pursued at each time step.

4 Experimental Setup

4.1 Datasets and Evaluation

Our models are trained on the annotated version of the Gigaword corpus (Graff et al., 2003; Napoles et al., 2012) and we use only the annotations for tokenization and sentence separation while discarding other annotations such as tags and parses. We pair the first sentence of each article with its headline to form sentence-summary pairs. The data is pre-processed in the same way as Rush et al. (2015) and we use the same splits for training, validation, and testing. For Gigaword we report results on the same randomly held-out test set of 2000 sentence-summary pairs as (Rush et al., 2015).[1] We also evaluate our models on the DUC-2004 evaluation data set comprising 500 pairs (Over et al., 2007). Our evaluation is based on three variants of ROUGE (Lin, 2004), namely, ROUGE-1 (unigrams), ROUGE-2 (bigrams), and ROUGE-L (longest-common substring).

4.2 Architectural Choices

We implemented our models in the Torch library (http://torch.ch/)[2]. To optimize our loss (Equation 5) we used stochastic gradient descent with mini-batches of size 32. During training we measure the perplexity of the summaries in the validation set and adjust our hyper-parameters, such as the learning rate, based on this number.

[1] We remove pairs with empty titles resulting in slightly different accuracy compared to Rush et al. (2015) for their systems.

[2] Our code can found at www://github.com/facebook/namas

Model	Perplexity
Bag-of-Words	43.6
Convolutional (TDNN)	35.9
Attention-based (ABS)	27.1
RAS-Elman	**18.9**
RAS-LSTM	20.3

Table 1: Perplexity on the Gigaword validation set. Bag-of-words, Convolutional (TDNN) and ABS are the different encoders of Rush et. al., 2015.

For the decoder we experimented with both the Elman RNN and the Long-Short Term Memory (LSTM) architecture (as discussed in § 3.1). We chose hyper-parameters based on a grid search and picked the one which gave the best perplexity on the validation set. In particular we searched over the number of hidden units H of the recurrent layer, the learning rate η, the learning rate annealing schedule γ (the factor by which to decrease η if the validation perplexity increases), and the gradient clipping threshold κ. Our final Elman architecture (RAS-Elman) uses a single layer with $H = 512$, $\eta = 0.5$, $\gamma = 2$, and $\kappa = 10$. The LSTM model (RAS-LSTM) also has a single layer with $H = 512$, $\eta = 0.1$, $\gamma = 2$, and $\kappa = 10$.

5 Results

On the Gigaword corpus we evaluate our models in terms of perplexity on a held-out set. We then pick the model with best perplexity on the held-out set and use it to compute the F1-score of ROUGE-1, ROUGE-2, and ROUGE-L on the test sets, all of which we report. For the DUC corpus however, inline with the standard, we report the recall-only ROUGE. As baseline we use the state-of-the-art attention-based system (ABS) of Rush et al. (2015) which relies on a feed-forward network decoder. Additionally, we compare to an enhanced version of their system (ABS+), which relies on a range of separate extractive summarization features that are added as log-linear features in a secondary learning step with minimum error rate training (Och, 2003).

Table 1 shows that both our RAS-Elman and RAS-LSTM models achieve lower perplexity than ABS as well as other models reported in Rush et al. (2015). The RAS-LSTM performs slightly worse than RAS-Elman, most likely due to over-fitting. We attribute this to the relatively simple nature of this task which can be framed as English-to-English translation with few long-term dependencies. The ROUGE results (Table 2) show that our models comfortably outperform both ABS and ABS+ by a wide margin on all metrics. This is even the case when we rely only on very fast greedy search ($k = 1$), while as ABS uses a much wider beam of size $k = 50$; the stronger ABS+ system also uses additional extractive features which our model does not. These features cause ABS+ to copy 92% of words from the input into the summary, whereas our model copies only 74% of the words leading to more abstractive summaries. On DUC-2004 we report recall ROUGE as is customary on this dataset. The results (Table 3) show that our models are better than ABS+. However the improvements are smaller than for Gi-

	RG-1	RG-2	RG-L
ABS	29.55	11.32	26.42
ABS+	29.76	11.88	26.96
RAS-Elman ($k = 1$)	33.10	14.45	30.25
RAS-Elman ($k = 10$)	**33.78**	**15.97**	**31.15**
RAS-LSTM ($k = 1$)	31.71	13.63	29.31
RAS-LSTM ($k = 10$)	32.55	14.70	30.03
Luong-NMT	33.10	14.45	30.71

Table 2: F1 ROUGE scores on the Gigaword test set. ABS and ABS+ are the systems of Rush et al. 2015. k refers to the size of the beam for generation; $k = 1$ implies greedy generation. RG refers to ROUGE. Rush et al. (2015) previously reported ROUGE recall, while as we use the more balanced F-measure.

	RG-1	RG-2	RG-L
ABS	26.55	7.06	22.05
ABS+	28.18	8.49	23.81
RAS-Elman ($k = 1$)	29.13	7.62	23.92
RAS-Elman ($k = 10$)	**28.97**	**8.26**	**24.06**
RAS-LSTM ($k = 1$)	26.90	6.57	22.12
RAS-LSTM ($k = 10$)	27.41	7.69	23.06
Luong-NMT	28.55	8.79	24.43

Table 3: ROUGE results (recall-only) on the DUC-2004 test sets. ABS and ABS+ are the systems of Rush et al. 2015. k refers to the size of the beam for generation; $k = 1$ implies greedy generation. RG refers to ROUGE.

gaword which is likely due to two reasons: First, tokenization of DUC-2004 differs slightly from our training corpus. Second, headlines in Gigaword are much shorter than in DUC-2004.

For the sake of completeness we also compare our models to the recently proposed standard Neural Machine Translation (NMT) systems. In particular, we compare to a smaller re-implementation of the attentive stacked LSTM encoder-decoder of Luong et al. (2015). Our implementation uses two-layer LSTMs for the encoder-decoder with 500 hidden units in each layer. Tables 2 and 3 report ROUGE scores on the two data sets. From the tables we observe that the proposed RAS-Elman model is able to match the performance of the NMT model of Luong at al. (2015). This is noteworthy because RAS-Elman is significantly simpler than the NMT model at multiple levels. First, the encoder used by RAS-Elman is extremely light-weight (attention over the convolutional representation of the input words), compared to Luong's (a 2 hidden layer LSTM). Second, the decoder used by RAS-Elman is a single layer standard (Elman) RNN as opposed to a multi-layer LSTM. In an independent work, Nallapati et. al (2016) also trained a collection of standard NMT models and report numbers in the same ballpark as RAS-Elman on both datasets.

In order to better understand which component of the proposed architecture is responsible for the improvements, we trained the recurrent model with Rush et. al., (2015)'s ABS encoder on a subset of the Gigaword dataset. The ABS encoder, which does not have the position features, achieves a final validation perplexity of 38 compared to 29 for the proposed encoder, which uses position features as well as context information. This clearly shows the benefits of using the position feature in the proposed encoder.

Finally in Figure 1 we highlight anecdotal examples of summaries produced by the RAS-Elman system on the Gigaword dataset. The first two examples highlight typical improvements in the RAS model over ABS+. Generally the model produces more fluent summaries and is better able to capture the main actors of the input. For instance in Sentence 1, RAS-Elman correctly distinguishes the actions of "pepe" from "ferreira", and in Sentence 2 it identifies the correct role of the "think tank". The final two examples highlight typical mistakes of the models. In Sentence 3 both models take literally the figurative use of the idiom "a silence that spoke volumes," and produce fluent but nonsensical summaries. In Sentence 4 the RAS model mistakes the content of a relative clause for the main verb, leading to a summary with the opposite meaning of the input. These difficult cases are somewhat rare in the Gigaword, but they highlight future challenges for obtaining human-level sentence summary.

I(1): brazilian defender pepe is out for the rest of the season with a knee injury , his porto coach jesualdo ferreira said saturday .
G: football : pepe out for season
A+: ferreira out for rest of season with knee injury
R: brazilian defender pepe out for rest of season with knee injury

I(2): economic growth in toronto will suffer this year because of sars , a think tank said friday as health authorities insisted the illness was under control in canada 's largest city .
G: sars toll on toronto economy estimated at c$ # billion
A+: think tank under control in canada 's largest city
R: think tank says economic growth in toronto will suffer this year

I(3): colin l. powell said nothing – a silence that spoke volumes to many in the white house on thursday morning .
G: in meeting with former officials bush defends iraq policy
A+: colin powell speaks volumes about silence in white house
R: powell speaks volumes on the white house

I(4): an international terror suspect who had been under a controversial loose form of house arrest is on the run , british home secretary john reid said tuesday .
G: international terror suspect slips net in britain
A+: reid under house arrest terror suspect on the run
R: international terror suspect under house arrest

Figure 1: Example sentence summaries produced on Gigaword. **I** is the input, **G** is the true headline, **A** is ABS+, and **R** is RAS-ELMAN.

6 Conclusion

We extend the state-of-the-art model for abstractive sentence summarization (Rush et al., 2015) to a recurrent neural network architecture. Our model is a simplified version of the encoder-decoder framework for machine translation (Bahdanau et al., 2014). The model is trained on the Gigaword corpus to generate headlines based on the first line of each news article. We comfortably outperform the previous state-of-the-art on both Gigaword data and the DUC-2004 challenge even though our model does not rely on additional extractive features.

Integer Linear Programming for Discourse Parsing

Abstract

In this paper we present the first, to the best of our knowledge, discourse parser that is able to predict non-tree DAG structures. We use Integer Linear Programming (ILP) to encode both the objective function and the constraints as global decoding over local scores. Our underlying data come from multi-party chat dialogues, which require the prediction of DAGs. We use the dependency parsing paradigm, as has been done in the past (Muller et al., 2012; Li et al., 2014; Afantenos et al., 2015), but we use the underlying formal framework of SDRT and exploit SDRT's notions of *left* and *right distributive* relations. We achieve an F-measure of 0.531 for fully labeled structures which beats the previous state of the art.

1 Introduction

Multi-party dialogue parsing, in which complete discourse structures for multi-party dialogue or its close cousin, multi-party chat, are automatically constructed, is still in its infancy. Nevertheless, these are now very common forms of communication on the Web. Dialogue appears also importantly different from monologue. Afantenos et al. (2015) point out that forcing discourse structures to be trees will perforce miss 9% of the links in their corpus, because a significant number of discourse structures in the corpus are not trees. Although Afantenos et al. (2015) is the only prior paper we know of that studies dialogue parsing on multi-party dialogue, and that work relied on methods adapted to treelike structures, we think the area of multi-party dialogue and non-treelike discourse structures is ripe for investigation and potentially important for other genres like the discourse analysis of fora (Wang et al., 2011, for example). This paper proposes a method based on constraints using Integer Linear Programming decoding over local probability distributions to investigate both treelike and non-treelike, full discourse structures for multi-party dialogue. We show that our method outperforms that of Afantenos et al. (2015) on the corpus they developed.

Discourse parsing involves at least three main steps: the segmentation of a text into *elementary discourse units* (EDUs), the basic building blocks for discourse structures, the attachment of EDUs together into connected structures for texts, and finally the labelling of the links between discourse units with discourse relations. Much current work in discourse parsing focuses on the labelling of discourse relations, using data from the Penn Discourse Treebank (PDTB) (Prasad et al., 2008). This work has availed itself of increasingly sophisticated features of the semantics of the units to be related (Braud and Denis, 2015); but as the PDTB does not provide full discourse structures for texts, it is not relevant to our concerns here. *Rhetorical Structure Theory* (RST) (Mann and Thompson, 1987; Mann and Thompson, 1988; Taboada and Mann, 2006) does take into account the global structure of the document, and the RST Discourse Tree Bank Carlson et al. (2003) has texts annotated according to RST with full discourse structures. This has guided most work in recent discourse parsing of multi-sentence text (Subba and Di Eugenio, 2009; Hernault et al., 2010; duVerle and Prendinger, 2009; Joty et al., 2013; Joty et al., 2015).

Proceedings of NAACL-HLT 2016, pages 99–109,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

But RST requires that discourse structures be projective trees.

While projective trees are arguably a contender for representing the discourse structure of monologue text, multi-party chat dialogues exhibit crossing dependencies. This rules out using a theory like RST as a basis either for an annotation model or as a guide to learning discourse structure (Afantenos et al., 2015). Several subgroups of interlocutors can momentarily form and carry on a discussion amongst themselves, forming thus multiple concurrent discussion threads. Furthermore, participants of one thread may reply or comment to something said to another thread. One might conclude from the presence of multiple threads in dialogue that we should use non-projective trees to guide discourse parsing. But non-projective trees cannot always reflect the structure of a discourse either, as Asher and Lascarides (2003) argue on theoretical grounds. Afantenos et al. (2015) provide examples in which a question or a comment by speaker S that is addressed to all the engaged parties in the conversation receives an answer from all the other participants, all of which are then acknowledged by S with a simple *OK* or *No worries*, thus creating an intuitive, "lozenge" like structure, in which the acknowledgment has several incoming links representing discourse dependencies.

A final, important organizing element of the discourse structure for text and dialogue is the presence of clusters of EDUs that can act together as an argument to other discourse relations. This means that subgraphs of the entire discourse graph act as elements or nodes in the full discourse structure. These subgraphs are *complex discourse units* or CDUs.[1] Here is an example from the *Settlers* corpus:

(1) gotwoodforsheep: [Do you have a sheep?]$_a$
Thomas: [I do,]$_b$ [if you give me clay]$_c$
Thomas: [or wood.]$_d$

Thomas's response to gotwoodforsheep spans two turns in the corpus. More interestingly, the response is a conditional "yes" in which EDUs (c) and (d) jointly specify the antecedent of the discourse relation that links both to the EDU *I do*.

CDUs have been claimed to be an important organizing principle of discourse structure and important for the analysis of anaphora and ellipsis for over 20 years (Asher, 1993). Yet the computational community has ignored them; when they are present in annotated corpora, they have been eliminated. This attitude is understandable, because CDUs, as they stand, are not representable as trees in any straightforward way. But given that our method can produce non-treelike graphs, we take a first step towards the prediction of CDUs as part of discourse structure by encoding them in a hypergraph-like framework. In particular, we will transform our corpus by distributing relations on CDUs over all their constituents as we describe in section 3.

Our paper is organized as follows. The data that we have used are described in more detail in the following section, while the underlying linguistic theory that we are using is described in section 3. In section 4 we present in detail the model that we have used, in particular the ILP decoder and the constraints and objective function it exploits. We report our results in section 5. Section 6 provides the related work while section 7 concludes this paper.

2 Input data

For our experiments we used a corpus collected from chats involving an online version of the game *The Settlers of Catan* described in (Afantenos et al., 2012; Afantenos et al., 2015). *Settlers* is a multiparty, win-lose game in which players use resources such as wood and sheep to build roads and settlements. Players take turns directing the bargaining. This is the only discourse annotated corpus of multiagent dialogue of which we are aware, and it was one in which apparently non-treelike structures were already noted and also contains CDUs. Such a chat corpus is also useful to study because it approximates spoken dialogue in several ways—sentence fragments, non-standard orthography and occasional lack of syntax—without the inconvenience of transcribing speech. The corpus consists of 39 games annotated for discourse structure in the style of SDRT. Each game consists of several dialogues, and each dialogue represents a single bargaining session directed by a particular player or perhaps several connected sessions. Each dialogue is treated as hav-

[1] CDUs are a feature of SDRT as we explain below. They are also a feature of RST on some interpretations of the Satellite-Nucleus feature.

	Total	Training	Testing
Dialogues	1091	968	123
Turns	9160	8166	994
EDUs	10677	9545	1132
CDUs	1284	1132	152
Relation instances			
No distribution	10191	9127	1064
Partial dist.	11734	10507	1227
Full dist.	13675	12210	1465

Table 1: Dataset overview

ing its own discourse structure. About 10% of the corpus was held out for evaluation purposes while the rest was used for training. The dialogues in the corpus are mostly short with each speaker's turn containing typically only one, two or three EDUs, though the longest has 156 EDUs and 119 turns. Most of the discourse connections or relation instances in the corpus thus occur between speaker turns. Statistics on the number of dialogues, EDUs and relations contained in each sub-corpus can be found in table 1. Note that the number of relation instances in the corpus depends on how CDUs are translated, which we'll explain in the next section. The corpus has approximately the same number of EDUs and relations as the RST corpus (Carlson et al., 2003).

3 Linguistic Foundations

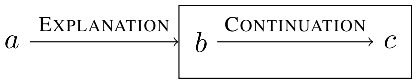
Segmented Discourse Representation Theory. We give a few details here on one discourse theory in which non-treelike discourse structures are countenanced and that underlies the annotations of the corpus we used. That theory is SDRT. In SDRT, a discourse structure, or *SDRS*, consists of a set of Discourse Units (DUs) and as Discourse Relations linking those units. DUs are distinguished into EDUs and CDUs. We identify EDUs here with phrases or sentences describing a state or an event; CDUs are SDRSs. Formally an SDRS for a given text segmented in EDUs $D = \{e_1, \ldots, e_n\}$, where e_i are the EDUs of D, is a tuple (V, E_1, E_2, ℓ) where V is a set of nodes or discourse units including $\{e_1, \ldots, e_n\}$, $E_1 \subseteq V \times V$ a set of edges representing discourse relations, $E_2 \subseteq V \times V$ a set of edges that represents parthood in the sense that if $(x, y) \in E_2$, then the unit x is an element of the CDU y; finally $\ell\colon E_1 \rightarrow$ *Relations* is a labelling function that assigns an edge in E_1 its discourse relation type.

From SDRT Structures to Dependency Structures. Predicting full SDRSs (V, E_1, E_2, ℓ) with $E_2 \neq \varnothing$ has been to date impossible, because no reliable method has been identified in the literature for calculating edges in E_2. Instead, most approaches (Muller et al., 2012; Afantenos et al., 2015, for example) simplify the underlying structures by a *head replacement strategy (HR)* that removes nodes representing CDUs from the original hypergraphs and replacing any incoming or outgoing edges on these nodes on the *heads* of those CDUs, forming thus dependency structures and not hypergraphs. A similar approach has also been followed by Hirao et al. (2013) and Li et al. (2014) in the context of RST to deal with multi-nuclear relations.

Transforming SDRSs using HR does not come without its problems. The decision to attach all incoming and outgoing links to a CDU to its head is one with little theoretical or semantic justification. The semantic effects of attaching an EDU to a CDU are not at all the same as attaching an EDU to the head of the CDU. For example, suppose we have a simple discourse with the following EDUs marked by brackets and discourse connectors in bold :

(2) [The French economy continues to suffer]$_a$ **because** [high labor costs remain high]$_b$ **and** [investor confidence remains low]$_c$.

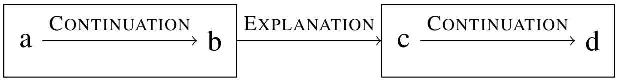
The correct SDRS for (2) is one in which both b and c *together* explain why the French economy continues to suffer. That is, b and c form a CDU and give rise to the following graph:



HR on (2) produces a graph whose strictly compositional interpretation would be false—b alone explains why the French economy continues to suffer. Alternatively an interpretation of the proposed translation an SDRS with CDUs would introduce spurious ambiguities: either b alone or b and c together provide the explanation. To make matters worse, given the semantics of discourse relations in SDRT (Asher and Lascarides, 2003), some relations have a semantics that implies that a relation between a CDU and some other discourse unit can be distributed over the discourse units that make up the CDU. But not all relations are distributive in this sense. For example, we could complicate (2) slightly:

(3) [The French economy continues to suffer]$_a$ **and** [the Italian economy remains in the doldrums]$_b$ **because of** [persistent high labor costs]$_c$ **and** [lack of investor confidence in both countries]$_d$.

In (3), the SDRS graph would be:



However, this SDRS entails that a is explained by $[c, d]$ *and* that b is explained by $[c, d]$. That is, Explanation "distributes" to the left but not to the right. Once again, the HR translation from SDRSs into dependency structures described above would get the intuitive meaning of this example wrong or introduce spurious ambiguities.

Given the above observations, we decided to take into account the formal semantics of the discourse relations before replacing CDUs. More precisely, we distinguish between *left distributive* and *right distributive* relations. In a nutshell, we examined the temporal and modal semantics of relations and classified them as to whether they were distributive with respect to their left or to their right argument; left distributive relations are those for which the source CDU node should be distributed while right distributive relations are those for which the target CDU node should be distributed. A relation can be both left and right distributive. Left distributive relations include Acknowledgement, Explanation, Comment, Continuation, Narration, Contrast, Parallel, Background, while right distributive relations include Result, Continuation, Narration, Comment, Contrast, Parallel, Background, Elaboration. In Figure 1 we show an example of how relations distribute between EDU/CDU, CDU/EDU and CDU/CDU.

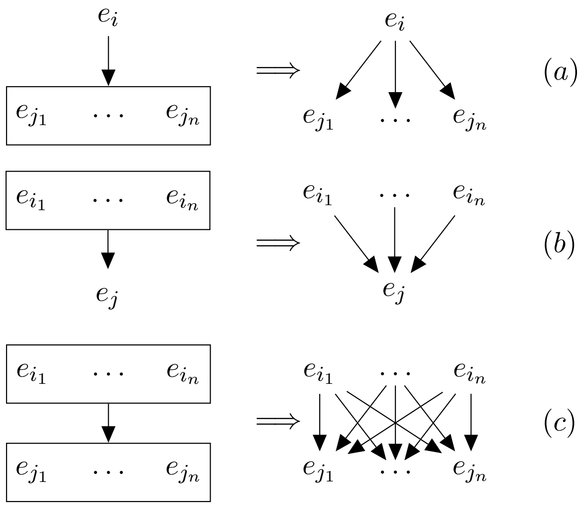


Figure 1: Distributing relations: (a) *right* distribution from an EDU to a CDU, (b) *left* distribution from a CDU to an EDU, (c) from a CDU to a CDU. We assume that all relations are both *right* and *left* distributive.

4 Underlying Model

Decoding over local scores. When we apply either a full or partial distributional (partial distribution takes into account which relations distribute in which direction) translation to the SDRSs in our corpus, we get dependency graphs that are not trees as input to our algorithms. We now approximate full SDRS graphs (V, E_1, E_2, ℓ) with graphs that distribute out E_2—that is, graphs of the form (V, E_1, ℓ) or more simply (V, E, ℓ). It is important to note that those graphs are not in general trees but rather Directed Acyclic Graphs (DAGs). We now proceed to detail how we learn such structures.

Ideally, what one wants is to learn a function $h : \mathcal{X}_{E^n} \mapsto \mathcal{Y}_G$ where $\mathcal{X}_{E^n}$ is the domain of instances representing a collection of EDUs for each dialogue and $\mathcal{Y}_G$ is the set of all possible SDRT graphs. However, given the complexity of this task and the fact that it would require an amount of training data that we currently lack in the community, we aim at the more modest goal of learning a function $h : \mathcal{X}_{E^2} \mapsto \mathcal{Y}_R$ where the domain of instances $\mathcal{X}_{E^2}$ represents parameters for a pair of EDUs and $\mathcal{Y}_R$ represents the set of SDRT relations.

An important drawback of this approach is that there are no formal guarantees that the predicted structures will be well-formed. They could for example contain cycles although they should be DAGs. Most approaches have circumvented this problem by using global decoding over local scores and by imposing specific constraints upon decoding. But, those constraints were mostly limited to the production of maximum spanning trees, and not full DAGs. We perform global decoding as well but use Integer Linear Programming (ILP) with an objective function and constraints that allow non-tree DAGs. We use a regularized maximum entropy (shortened MaxEnt) model (Berger et al., 1996) to get the local scores, both for attachment and labelling.

ILP for Global Decoding. ILP essentially involves an objective function that needs to be maximized under specific constraints. Our goal is to build the directed graph $G = \langle V, E, R \rangle$ with R being a function that provides labels for the edges in E. Vertices (EDUs) are referred by their position in textual order, indexed from 1. The m labels are referred by their index in alphabetical order, starting from 1. Let $n = |V|$.

The local model provides us with two real-valued functions:

$$s_a : \{1, \ldots, n\}^2 \mapsto [0, 1]$$

$$s_r : \{1, \ldots, n\}^2 \times \{1, \ldots, m\} \mapsto [0, 1]$$

$s_a(i, j)$ gives the score of attachment for a pair of EDUs (i, j); $s_r(i, j, k)$ gives the score for the attached pair of EDUs (i, j) linked with the relation type k. We define the n^2 binary variables a_{ij} and mn^2 binary variables r_{ijk}:

$$a_{ij} = 1 \equiv (i, j) \in V$$

$$r_{ijk} = 1 \equiv R(i, j) = k$$

The objective function that we want to maximize is

$$\sum_{i=1}^{n} \sum_{j=1}^{n} \left(a_{ij} s_a(i, j) + \sum_{k=1}^{m} r_{ijk} s_r(i, j, k) \right)$$

which gives us a score and a ranking for all candidate structures.

Our objective function is subject to several constraints. Because we have left the domain of trees well-explored by syntactic analysis and their computational implementations, we must design new constraints on discourse graphs, which we have developed from looking at our corpus while also being guided by theoretical principles. Some of these constraints come from SDRT, the underlying theory of the annotations. In SDRT discourse graphs should be DAGs with a unique root or source vertex, i.e. one that has no incoming edges. They should also be weakly connected; i.e. every discourse unit in it is connected to some other discourse unit. We implemented connectedness and the unique root property as constraints in ILP by using the following equations.

$$\sum_{i=1}^{n} h_i = 1$$

$$\forall j \quad 1 \leq n h_j + \sum_{i=1}^{n} a_{ij} \leq n$$

where h_i is a set of auxiliary variables indexed on $\{1, \ldots, n\}$. The above constraint presupposes that our graphs are acyclic.

Implementing acyclicity is facilitated by another constraint that we call the *turn constraint*. This constraint is also theoretically motivated. The graphs in our training corpus are *reactive* in the sense that speakers' contributions are reactions and attach anaphorically to prior contributions of other speakers. This means that edges between the contributions of different speakers are always oriented in one direction. A turn by one speaker can't be anaphorically and rhetorically dependent on a turn by another speaker that comes after it. Once made explicit, this constraint has an obvious rationale: people do not know what another speaker will subsequently say and thus they cannot create an anaphoric or rhetorical dependency on this unknown future act. This is not the case within a single speaker turn though; people can know what they will say several EDUs ahead so they can make such kinds of future directed dependencies. ILP allows us to encode this constraint as follows. We indexed turns from different speakers in textual order from 1 to n_t, while consecutive turns from the same speaker were assigned the same index. Let $t(i)$ be the turn index of EDU i, and $T(k)$ the set of all EDUs belonging to turn k. The following constraint forbids backward links between EDUs from distinct turns:

$$\forall i, j \quad (i > j) \wedge (t(i) \neq t(j)) \implies a_{ij} = 0$$

The observation concerning the turn constraint is also useful for the model that provides local scores. We used it for attachment and relation labelling during training and testing.

Given the turn constraint we only need to ensure acyclicity of the same speaker turn subgraphs. We introduce an auxiliary set of integer variables, (c_{ki}), indexed on $\{1, \ldots, n_t\} \times \{1, \ldots, n\}$ in order to express this constraint:

$$\forall k, i \quad 1 \leq c_{ki} \leq |T(k)|$$
$$\forall k, i, j \text{ such that } t(i) = t(j) = k$$
$$c_{kj} \leq c_{ki} - 1 + n(1 - a_{ij})$$

Another interesting observation concerns the density of the graph. The objective function being additive on positive terms, every extra edge improves the global score of the graph, which leads to an almost-complete graph unless the edge count is constrained. So we imposed an upper limit $\delta \in [1, n]$ representing the density of the graphs:

$$\sum_{i=1}^{n} \sum_{j=1}^{n} a_{ij} \leq \delta(n-1)$$

$\delta \in [1, n]$ since we need to have at least $n - 1$ edges for the graph to be connected and at maximum we can have $n(n-1)$ edges if the graph is complete without loops. δ being a hyper-parameter, we estimated it on a development corpus representing 20% of our total corpus.[2]

The development corpus also shows that graph density decreases as the number of vertices grow. A high δ entails a too large number of edges in longer dialogues. We compensate for this effect by using an additive cap $\eta \geq 0$ on the edge count, also estimated on the development corpus:[3]

$$\sum_{i=1}^{n} \sum_{j=1}^{n} a_{ij} \leq n - 1 + \eta$$

Another empirical observation concerning the corpus was that the number of outgoing edges from any EDU had an upper bound $e_o \ll n$. We set that as an ILP constraint:[4]

$$\forall i \quad \sum_{j=1}^{n} a_{ij} \leq e_o$$

These observations don't have a semantic explanation, but they suggest a pragmatic one linked at least to the type of conversation present in our corpus. Short dialogues typically involve a opening question broadcast to all the players in search of a bargain, and typically all the other players reply. The replies are then taken up and either a bargain is reached or it isn't. The players then move on. Thus, the density of the graph in such short dialogues will be determined by the number of players (in our case, four). In a longer dialogue, we have more directed discourse moves and threads involving subgroups of the participants appear, but once again in these dialogues it never happens that our participants return again and again to the same contribution; if the thread of commenting on a contribution ϕ continues, future comments attach to prior comments, not to ϕ. Our ILP constraints on density and edge counts thus suggest a novel way of capturing different dialogue types and linguistic constraints.

Finally, we included various minor constraints, such as the fact that EDUs cannot be attached to themselves,[5] if EDUs i and j are not attached the pair is not assigned any discourse relation label,[6] EDUs within a sequence of contributions by the same speaker in our corpus are linked at least to the previous EDU (Afantenos et al., 2015)[7] and edges with zero score are not included in the graph.[8]

For purposes of comparison with the ILP decoder, we tested the Chu-Liu-Edmonds version of the classic Maximum Spanning Tree (MST) algorithm McDonald et al. (2005) used for discourse parsing by Muller et al. (2012) and Li et al. (2014) and by Afantenos et al. (2015) on the *Settlers* corpus. This algorithm requires a specific node to be the root, i.e. a node without any incoming edges, of the initial complete graph. For each dialogue, we made an artificial node as the root with special dummy features. At the end of the procedure, this node points to the real root of the discourse graph. As baseline measures, we included what we call a LOCAL decoder which creates a simple classifier out of the raw local probability distribution. Since we use MaxEnt, this

[2] δ takes the values 1.0, 1.2 and 1.4 for the head, partial and full distribution of the relations, respectively.

[3] η takes the value of 4 for the full distribution while it has no upper bound for the head and partial distributions.

[4] e_o is estimated on the development corpus to the value of 6 for the head, partial and full distributions.

[5] $\forall i \; a_{ii} = 0$

[6] $\forall i, j \; \sum_{k=1}^{m} r_{ijk} = a_{ij}$

[7] $\forall i \quad t(i) = t(i+1) \implies a_{i,i+1} = 1$

[8] $\forall i, j \quad s_a(i,j) = 0 \implies a_{ij} = 0$ and $\forall i, j, k \quad s_r(i,j,k) = 0 \implies x_{ijk} = 0$

decoder selects

$$\hat{r} = \underset{r}{\text{argmax}} \left(\frac{1}{Z(c)} \exp \left(\sum_{i=1}^{m} w_i f_i(p, r) \right) \right)$$

with r representing a relation type or a binary attachment value. A final baseline was LAST, where each EDU is attached to the immediately preceding EDU in the linear, textual order.

5 Experiments and Results

Features for training the local model and getting scores for the decoders were extracted for every pair of EDUs. Features concerned each EDU individually as well as the pair itself. We used obvious, surface features such as: the position of EDUs in the dialogue, who their speakers are, whether two EDUs have the same speaker, the distance between EDUs, the presence of mood indicators ('?', '!') in the EDU, lexical features of the EDU (e.g., does a verb signifying an exchange occur in the EDU), and first and last words of the EDU. We also used the structures and Subject lemmas given by syntactic dependency parsing, provided by the Stanford CoreNLP pipeline (Manning et al., 2014). Finally we used Cadilhac et al. (2013)'s method for classifying EDUs with respect to whether they involved an offer, a counteroffer, or were other.

As mentioned earlier, in addition to the ILP and MST decoders we used two baseline decoders, LAST and LOCAL. The LAST decoder simply selects the previous EDU for attachment no matter what the underlying probability distribution is. This has proved a very hard baseline to beat in discourse. The LOCAL decoder is a naive decoder which in the case of attachment returns "attached" if the probability of attachment between EDUs i and j is higher than .5 and "non-attached" in the opposite case.

Each of the three distribution methods described in Section 3 (Head, Partial and Full Distribution) yielded different dependency graphs for our input documents, which formed three distinct corpora on which we trained and tested separately. For each of them, our training set represented 90% of the dependency graphs from the initial corpus, chosen at random; the test set representing the remaining 10%. Table 2 shows our evaluation results, comparing decoders and baselines for each of the distribution strategies. As can be seen, our ILP decoder consistently performs significantly better than the baselines as well as the MST decoder, which was the previous state of the art (Afantenos et al., 2015) even when restricted to tree structures and HR (setting the hyper-parameter $\delta = 1$). This prompted us to investigate how our objective function compared to MST's. We eliminated all constraints in ILP except acyclicity, connectedness, turn constraint and eliminating any constraint on outgoing edges (setting $\delta = \infty$); in this case, ILP's objective function performed better on the full structure prediction (.531 F1) than MST with attachment and labelling jointly maximized (.516 F1). This means that our objective function, although it maximizes scores and not probabilities, produces an ordering over outputs that outperforms classic MST. Our analysis showed further that the constraints on outgoing edges (the tuning of the hyperparameter $e_o = 6$) were very important for our corpus and our (admittedly flawed) local model; in other words, an ILP constrained tree for this corpus was a better predictor of the data with our local model than an unrestrained MST tree decoding.

We also note that our scores dropped in distributive settings but that ILP performed considerably better than the alternatives and better than the previous state of the art on dependency trees using HR on the gold and MST decoding. We need to investigate further constraints, and to refine and improve our features to get a better local model. Our local model will eventually need to be replaced by one that takes into account more of the surrounding structure when it assigns scores to attachments and labels. We also plan to investigate the use of recurrent neural networks in order to improve our local model.

6 Related Work

ILP has been used for various computational linguistics tasks: syntactic parsing (Martins et al., 2010; Fernández-González and Martins, 2015), semantic parsing (Das et al., 2014), coreference resolution (Denis and Baldridge, 2007) and temporal analysis (Denis and Muller, 2011). As far as we know, we are the first to use ILP to predict discourse structures.

Our use of dependency structures for discourse also has antecedents in the literature. The first we know of is Muller et al. (2012). Their prediction

Decoder	Model	Unlabelled Attachment			Labelled Attachment		
		Precision	Recall	F1	Precision	Recall	F1
				Head (no distribution)			
LAST	–	0.602	0.566	0.584	0.403	0.379	0.391

Table 2: Evaluation results.

model uses local probability distributions and global decoding, and they transform their data using HR, and so ignore the semantics of discourse relations. Hirao et al. (2013) and Li et al. (2014) also exploit dependency structures by transforming RST trees. Li et al. (2014) used both the Eisner algorithm (Eisner, 1996) as well as the MST algorithm as decoders. We plan to apply ILP techniques to the RST Tree Bank to compare our method with theirs.

Most work on discourse parsing focuses on the task of discourse relation labeling between pairs of discourse units—e.g., Marcu and Echihabi (2002) Sporleder and Lascarides (2005) and Lin et al. (2009)—without worrying about global structure. In essence the problem that they treat corresponds only to our local model. As we have argued above, this setting makes an unwarranted assumption, as it assumes independence of local attachment decisions. There is also work on discourse structure within a single sentence; e.g., Soricut and Marcu (2003), Sagae (2009). Such approaches do not apply to our data, as most of the structure in our dialogues lies beyond the sentence level.

As for other document-level discourse parsers, Subba and Di Eugenio (2009) use a transition-based approach, following the paradigm of Sagae (2009). duVerle and Prendinger (2009) and Hernault et al. (2010) both rely on locally greedy methods. They treat attachment prediction and relation label prediction as independent problems. Feng and Hirst (2012) extend this approach by additional feature engineering but is restricted to sentence-level parsing. Joty et al. (2013) and Joty et al. (2015) present a text-level discourse parser that uses Conditional Random Fields to capture label inter-dependencies and chart parsing for decoding and have the best results on non-dependency based discourse parsing, with an F1 of 0.689 on unlabelled structures and 0.5587 on labelled structures.

The afore-cited work concerns only monologue. Baldridge and Lascarides (2005) predicted tree discourse structures for 2 party "directed" dialogues from the Verbmobil corpus by training a PCFG that exploited the structure of the underlying task. Elsner and Charniak (2010), Elsner and Charniak (2011) present a combination of local coherence models initially provided for monologues showing that those models can satisfactorily model local coherence in chat dialogues. However, they do not present a full discourse parsing model. Our data required a more open domain approach and a more sophisticated approach to structure. Afantenos et al. (2015) worked on multi-party chat dialogues with the same corpus, but they too did not consider the semantics of discourse relations and replaced CDUs with their heads using HR. While this allowed them to use MST decoding over local probability distributions, this meant that their implementation had inherent limitations because it is limited to producing tree structures. They also used the turn constraint, but imposed exogenously to decoding; ILP allows us to integrate it into the structural decoding. We achieve better results than they on treelike graphs and we can explore the full range of non-treelike discourse graphs within the ILP framework. Our parser has thus much more room to improve than those restricted to MST decoding.

7 Conclusions and future work

We have presented a novel method for discourse parsing of multiparty dialogue using ILP with linguistically and empirically motivated constraints and an objective function that integrates both attachment and labelling tasks. We have shown also that our method performs better than the competition on multiparty dialogue data and that it can capture nontreelike structures found in the data.

We also have a better treatment of the hierarchical structure of discourse than the competition. Our treatment of CDUs in discourse annotations proposes a new distributional translation of those annotations into dependency graphs, which we think is promising for future work. After distribution, our training corpus has a very different qualitative look. There are treelike subgraphs and then densely connected clusters of EDUs, indicating the presence of CDUs. This gives us good reason to believe that in subsequent work, we will be able to predict CDUs and attack the problem of hierarchical discourse structure seriously.

Abstract

Sequence-to-sequence neural network models for generation of conversational responses tend to generate safe, commonplace responses (e.g., *I don't know*) regardless of the input. We suggest that the traditional objective function, i.e., the likelihood of output (response) given input (message) is unsuited to response generation tasks. Instead we propose using Maximum Mutual Information (MMI) as the objective function in neural models. Experimental results demonstrate that the proposed MMI models produce more diverse, interesting, and appropriate responses, yielding substantive gains in BLEU scores on two conversational datasets and in human evaluations.

1 Introduction

Conversational agents are of growing importance in facilitating smooth interaction between humans and their electronic devices, yet conventional dialog systems continue to face major challenges in the form of robustness, scalability and domain adaptation. Attention has thus turned to learning conversational patterns from data: researchers have begun to explore data-driven generation of conversational responses within the framework of statistical machine translation (SMT), either phrase-based (Ritter et al., 2011), or using neural networks to rerank, or directly in the form of sequence-to-sequence (SEQ2SEQ) models (Sordoni et al., 2015; Vinyals and Le, 2015; Shang et al., 2015; Serban et al., 2015; Wen et al., 2015). SEQ2SEQ models offer the promise of scalability and language-independence, together with the capacity to implicitly learn semantic and syntactic relations between pairs, and to capture contextual dependencies (Sordoni et al., 2015) in a way not possible with conventional SMT approaches (Ritter et al., 2011).

An engaging response generation system should be able to output grammatical, coherent responses that are diverse and interesting. In practice, however, neural conversation models tend to generate trivial or non-committal responses, often involving high-frequency phrases along the lines of *I don't know* or *I'm OK* (Sordoni et al., 2015; Serban et al., 2015; Vinyals and Le, 2015). Table 1 illustrates this phenomenon, showing top outputs from SEQ2SEQ models. All the top-ranked responses are generic. Responses that seem more meaningful or specific can also be found in the N-best lists, but rank much lower. In part at least, this behavior can be ascribed to the relative frequency of generic responses like *I don't know* in conversational datasets, in contrast with the relative sparsity of more contentful alternative responses.[1] It appears that by optimizing for the likelihood of outputs given inputs, neural models assign high probability to "safe" responses. This objective function, common in related tasks such as machine translation, may be unsuited to generation tasks involving intrinsically diverse outputs. Intuitively, it seems desirable to take into account not only the dependency of responses on messages, but also the inverse, the likelihood that a message will be provided to a given response.

We propose to capture this intuition by using Maximum Mutual Information (MMI), first introduced in

* The entirety of this work was conducted at Microsoft.

[1] In our training dataset from the OpenSubtitles database (OSDb), 0.45% sentences contain the sequence *I don't know*, a high rate considering huge diversity of this dataset.

Input: What are you doing?			
−0.86	I don't know.	−1.09	Get out of here.
−1.03	I don't know!	−1.09	I'm going home.
−1.06	Nothing.	−1.09	Oh my god!
−1.09	Get out of the way.	−1.10	I'm talking to you.
Input: what is your name?			
−0.91	I don't know.	...	
−0.92	I don't know!	−1.55	My name is Robert.
−0.92	I don't know, sir.	−1.58	My name is John.
−0.97	Oh, my god!	−1.59	My name's John.
Input: How old are you?			
−0.79	I don't know.	...	
−1.06	I'm fine.	−1.64	Twenty-five.
−1.17	I'm all right.	−1.66	Five.
−1.17	I'm not sure.	−1.71	Eight.

Table 1: Responses generated by a 4-layer SEQ2SEQ neural model trained on 20 million conversation pairs take from the OpenSubtitles dataset. Decoding is implemented with beam size set to 200. The top examples are the responses with the highest average probability log-likelihoods in the N-best list. Lower-ranked, less-generic responses were manually chosen.

speech recognition (Bahl et al., 1986; Brown, 1987), as an optimization objective that measures the mutual dependence between inputs and outputs. Below, we present practical strategies for neural generation models that use MMI as an objective function. We show that use of MMI results in a clear decrease in the proportion of generic response sequences, generating correspondingly more varied and interesting outputs.

2 Related work

The approach we take here is data-driven and end-to-end. This stands in contrast to conventional dialog systems, which typically are template- or heuristic-driven even where there is a statistical component (Levin et al., 2000; Oh and Rudnicky, 2000; Ratnaparkhi, 2002; Walker et al., 2003; Pieraccini et al., 2009; Young et al., 2010; Wang et al., 2011; Banchs and Li, 2012; Chen et al., 2013; Ameixa et al., 2014; Nio et al., 2014).

We follow a newer line of investigation, originally introduced by Ritter et al. (2011), which frames response generation as a statistical machine translation (SMT) problem. Recent progress in SMT stemming from the use of neural language models (Sutskever et al., 2014; Gao et al., 2014; Bahdanau et al., 2015; Luong et al., 2015) has inspired attempts to extend these neural techniques to response generation. Sordoni et al. (2015) improved upon Ritter et al. (2011) by rescoring the output of a phrasal SMT-based conversation system with a SEQ2SEQ model that incorporates prior context. (Serban et al., 2015; Shang et al., 2015; Vinyals and Le, 2015; Wen et al., 2015) apply direct end-to-end SEQ2SEQ models These SEQ2SEQ models are Long Short-Term Memory (LSTM) neural networks (Hochreiter and Schmidhuber, 1997) that can implicitly capture compositionality and long-span dependencies. (Wen et al., 2015) attempt to learn response templates from crowd-sourced data, whereas we seek to develop methods that can learn conversational patterns from naturally-occurring data.

Prior work in generation has sought to increase diversity, but with different goals and techniques. Carbonell and Goldstein (1998) and Gimpel (2013) produce *multiple* outputs that are mutually diverse, either non-redundant summary sentences or N-best lists. Our goal, however, is to produce a *single* non-trivial output, and our method does not require identifying lexical overlap to foster diversity.[2]

On a somewhat different task, Mao et al. (2015, Section 6) utilize a mutual information objective in the retrieval component of image caption retrieval. Below, we focus on the challenge of using MMI in response generation, comparing the performance of MMI models against maximum likelihood.

3 Sequence-to-Sequence Models

Given a sequence of inputs $X = \{x_1, x_2, ..., x_{N_x}\}$, an LSTM associates each time step with an input gate, a memory gate and an output gate, respectively denoted as i_k, f_k and o_k. We distinguish e and h where e_k denotes the vector for an individual text unit (for example, a word or sentence) at time step k while h_k denotes the vector computed by LSTM model at time k by combining e_k and h_{k-1}. c_k is the cell state vector at time k, and σ denotes the sigmoid function. Then, the vector representation h_k for each time step

[2] Augmenting our technique with MMR-based (Carbonell and Goldstein, 1998) diversity helped increase lexical but not semantic diversity (e.g., *I don't know* vs. *I haven't a clue*), and with no gain in performance.

k is given by:

$$i_k = \sigma(W_i \cdot [h_{k-1}, e_k]) \tag{1}$$
$$f_k = \sigma(W_f \cdot [h_{k-1}, e_k]) \tag{2}$$
$$o_k = \sigma(W_o \cdot [h_{k-1}, e_k]) \tag{3}$$
$$l_k = \tanh(W_l \cdot [h_{k-1}, e_k]) \tag{4}$$
$$c_k = f_k \cdot c_{k-1} + i_k \cdot l_k \tag{5}$$
$$h_k^s = o_k \cdot \tanh(c_k) \tag{6}$$

where W_i, W_f, W_o, $W_l \in \mathbb{R}^{D \times 2D}$. In SEQ2SEQ generation tasks, each input X is paired with a sequence of outputs to predict: $Y = \{y_1, y_2, ..., y_{N_y}\}$. The LSTM defines a distribution over outputs and sequentially predicts tokens using a softmax function:

$$\begin{aligned} p(Y|X) &= \prod_{k=1}^{N_y} p(y_k|x_1, x_2, ..., x_t, y_1, y_2, ..., y_{k-1}) \\ &= \prod_{k=1}^{N_y} \frac{\exp(f(h_{k-1}, e_{y_k}))}{\sum_{y'} \exp(f(h_{k-1}, e_{y'}))} \end{aligned}$$

where $f(h_{k-1}, e_{y_k})$ denotes the activation function between h_{k-1} and e_{y_k}, where h_{k-1} is the representation output from the LSTM at time $k-1$. Each sentence concludes with a special end-of-sentence symbol *EOS*. Commonly, input and output use different LSTMs with separate compositional parameters to capture different compositional patterns.

During decoding, the algorithm terminates when an *EOS* token is predicted. At each time step, either a greedy approach or beam search can be adopted for word prediction. Greedy search selects the token with the largest conditional probability, the embedding of which is then combined with preceding output to predict the token at the next step.

4 MMI Models

4.1 Notation

In the response generation task, let S denote an input message sequence (source) $S = \{s_1, s_2, ..., s_{N_s}\}$ where N_s denotes the number of words in S. Let T (target) denote a sequence in response to source sequence S, where $T = \{t_1, t_2, ..., t_{N_t}, \textit{EOS}\}$, N_t is the length of the response (terminated by an *EOS* token) and t denotes a word token that is associated with a D dimensional distinct word embedding e_t. V denotes vocabulary size.

4.2 MMI Criterion

The standard objective function for sequence-to-sequence models is the log-likelihood of target T given source S, which at test time yields the statistical decision problem:

$$\hat{T} = \arg\max_T \big\{ \log p(T|S) \big\} \tag{7}$$

As discussed in the introduction, we surmise that this formulation leads to generic responses being generated, since it only selects for targets given sources, not the converse. To remedy this, we replace it with Maximum Mutual Information (MMI) as the objective function. In MMI, parameters are chosen to maximize (pairwise) mutual information between the source S and the target T:

$$\log \frac{p(S,T)}{p(S)p(T)} \tag{8}$$

This avoids favoring responses that unconditionally enjoy high probability, and instead biases towards those responses that are specific to the given input. The MMI objective can written as follows:[3]

$$\hat{T} = \arg\max_T \big\{ \log p(T|S) - \log p(T) \big\}$$

We use a generalization of the MMI objective which introduces a hyperparameter λ that controls how much to penalize generic responses:

$$\hat{T} = \arg\max_T \big\{ \log p(T|S) - \lambda \log p(T) \big\} \tag{9}$$

An alternate formulation of the MMI objective uses Bayes' theorem:

$$\log p(T) = \log p(T|S) + \log p(S) - \log p(S|T)$$

which lets us rewrite Equation 9 as follows:

$$\begin{aligned} \hat{T} &= \arg\max_T \big\{ (1-\lambda) \log p(T|S) \\ &\qquad + \lambda \log p(S|T) - \lambda \log p(S) \big\} \\ &= \arg\max_T \big\{ (1-\lambda) \log p(T|S) + \lambda \log p(S|T) \big\} \end{aligned} \tag{10}$$

This weighted MMI objective function can thus be viewed as representing a tradeoff between sources

[3] Note: $\log \frac{p(S,T)}{p(S)p(T)} = \log \frac{p(T|S)}{p(T)} = \log p(T|S) - \log p(T)$

given targets (i.e., $p(S|T)$) and targets given sources (i.e., $p(T|S)$).

Although the MMI optimization criterion has been comprehensively studied for other tasks, such as acoustic modeling in speech recognition (Huang et al., 2001), adapting MMI to SEQ2SEQ training is empirically nontrivial. Moreover, we would like to be able to adjust the value λ in Equation 9 without repeatedly training neural network models from scratch, which would otherwise be extremely time-consuming. Accordingly, we did not train a joint model ($\log p(T|S) - \lambda \log p(T)$), but instead trained maximum likelihood models, and used the MMI criterion only during testing.

4.3 Practical Considerations

Responses can be generated either from Equation 9, i.e., $\log p(T|S) - \lambda \log p(T)$ or Equation 10, i.e., $(1-\lambda)\log p(T|S) + \lambda \log p(S|T)$. We will refer to these formulations as MMI-antiLM and MMI-bidi, respectively. However, these strategies are difficult to apply directly to decoding since they can lead to ungrammatical responses (with MMI-antiLM) or make decoding intractable (with MMI-bidi). In the rest of this section, we will discuss these issues and explain how we resolve them in practice.

4.3.1 MMI-antiLM

The second term of $\log p(T|S) - \lambda \log p(T)$ functions as an anti-language model. It penalizes not only high-frequency, generic responses, but also fluent ones and thus can lead to ungrammatical outputs. In theory, this issue should not arise when λ is less than 1, since ungrammatical sentences should always be more severely penalized by the first term of the equation, i.e., $\log p(T|S)$. In practice, however, we found that the model tends to select ungrammatical outputs that escaped being penalized by $p(T|S)$.

Solution Again, let N_t be the length of target T. $p(T)$ in Equation 9 can be written as:

$$p(T) = \prod_{k=1}^{N_t} p(t_k|t_1, t_2, ..., t_{k-1}) \tag{11}$$

We replace the language model $p(T)$ with $U(T)$, which adapts the standard language model by multiplying by a weight $g(k)$ that is decremented monotonically as the index of the current token k increases:

$$U(T) = \prod_{i=1}^{N_t} p(t_k|t_1, t_2, ..., t_{k-1}) \cdot g(k) \tag{12}$$

The underlying intuition here is as follows. First, neural decoding combines the previously built representation with the word predicted at the current step. As decoding proceeds, the influence of the initial input on decoding (i.e., the source sentence representation) diminishes as additional previously-predicted words are encoded in the vector representations.[4] In other words, the first words to be predicted significantly determine the remainder of the sentence. Penalizing words predicted early on by the language model contributes more to the diversity of the sentence than it does to words predicted later. Second, as the influence of the input on decoding declines, the influence of the language model comes to dominate. We have observed that ungrammatical segments tend to appear in the later parts of the sentences, especially in long sentences.

We adopt the most straightforward form of $g(k)$ by setting up a threshold (γ) by penalizing the first γ words where[5]

$$g(k) = \begin{cases} 1 & \text{if } k \le \gamma \\ 0 & \text{if } k > \gamma \end{cases} \tag{13}$$

The objective in Equation 9 can thus be rewritten as:

$$\log p(T|S) - \lambda \log U(T) \tag{14}$$

where direct decoding is tractable.

4.3.2 MMI-bidi

Direct decoding from $(1-\lambda)\log p(T|S) + \lambda \log p(S|T)$ is intractable, as the second part (i.e., $p(S|T)$) requires completion of target generation *before* $p(S|T)$ can be effectively computed. Due to the enormous search space for target T, exploring all possibilities is infeasible.

For practical reasons, then, we turn to an approximation approach that involves first generating N-best lists given the first part of objective function, i.e.,

[4] Attention models (Xu et al., 2015) may offer some promise of addressing this issue.

[5] We experimented with a smooth decay in $g(k)$ rather than a stepwise function, but this did not yield better performance.

standard SEQ2SEQ model $p(T|S)$. Then we rerank the N-best lists using the second term of the objective function. Since N-best lists produced by SEQ2SEQ models are generally grammatical, the final selected options are likely to be well-formed. Model reranking has obvious drawbacks. It results in non-globally-optimal solutions by first emphasizing standard SEQ2SEQ objectives. Moreover, it relies heavily on the system's success in generating a sufficiently diverse N-best set, requiring that a long list of N-best lists be generated for each message.

Nonetheless, these two variants of the MMI criterion work well in practice, significantly improving both interestingness and diversity.

4.4 Training

Recent research has shown that deep LSTMs work better than single-layer LSTMs for SEQ2SEQ tasks (Vinyals et al., 2015; Sutskever et al., 2014). We adopt a deep structure with four LSTM layers for encoding and four LSTM layers for decoding, each of which consists of a different set of parameters. Each LSTM layer consists of 1,000 hidden neurons, and the dimensionality of word embeddings is set to 1,000. Other training details are given below, broadly aligned with Sutskever et al. (2014).

- LSTM parameters and embeddings are initialized from a uniform distribution in $[-0.08, 0.08]$.
- Stochastic gradient decent is implemented using a fixed learning rate of 0.1.
- Batch size is set to 256.
- Gradient clipping is adopted by scaling gradients when the norm exceeded a threshold of 1.

Our implementation on a single GPU processes at a speed of approximately 600-1200 tokens per second on a Tesla K40.

The $p(S|T)$ model described in Section 4.3.1 was trained using the same model as that of $p(T|S)$, with messages (S) and responses (T) interchanged.

4.5 Decoding

4.5.1 MMI-antiLM

As described in Section 4.3.1, decoding using $\log p(T|S) - \lambda U(T)$ can be readily implemented by predicting tokens at each time-step. In addition, we found in our experiments that it is also important to take into account the length of responses in decoding. We thus linearly combine the loss function with length penalization, leading to an ultimate score for a given target T as follows:

$$Score(T) = p(T|S) - \lambda U(T) + \gamma N_t \tag{15}$$

where N_t denotes the length of the target and γ denotes associated weight. We optimize γ and λ using MERT (Och, 2003) on N-best lists of response candidates. The N-best lists are generated using the decoder with beam size $B = 200$. We set a maximum length of 20 for generated candidates. At each time step of decoding, we are presented with $B \times B$ candidates. We first add all hypotheses with an *EOS* token being generated at current time step to the N-best list. Next we preserve the top B unfinished hypotheses and move to next time step. We therefore maintain beam size of 200 constant when some hypotheses are completed and taken down by adding in more unfinished hypotheses. This will lead the size of final N-best list for each input much larger than the beam size.

4.5.2 MMI-bidi

We generate N-best lists based on $P(T|S)$ and then rerank the list by linearly combining $p(T|S)$, $\lambda p(S|T)$, and γN_t. We use MERT to tune the weights λ and γ on the development set.[6]

5 Experiments

5.1 Datasets

Twitter Conversation Triple Dataset We used an extension of the dataset described in Sordoni et al. (2015), which consists of 23 million conversational snippets randomly selected from a collection of 129M context-message-response triples extracted from the Twitter Firehose over the 3-month period from June through August 2012. For the purposes of our experiments, we limited context to the turn in the conversation immediately preceding the message. In our LSTM models, we used a simple input model in which contexts and messages are concatenated to form the source input.

[6] As with MMI-antiLM, we could have used grid search instead of MERT, since there are only 3 features and 2 free parameters. In either case, the search attempts to find the best tradeoff between $p(T|S)$ and $p(S|T)$ according to BLEU (which tends to weight the two models relatively equally) and ensures that generated responses are of reasonable length.

Model	# of training instances	BLEU	*distinct-1*	*distinct-2*
SEQ2SEQ (baseline)	23M	4.31	.023	.107
SEQ2SEQ (greedy)	23M	4.51	.032	.148
MMI-antiLM: $\log p(T\|S) - \lambda U(T)$	23M	4.86	.033	.175
MMI-bidi: $(1-\lambda)\log p(T\|S) + \lambda \log p(S\|T)$	23M	**5.22**	.051	.270
SMT (Ritter et al., 2011)	50M	3.60	.098	.351
SMT+neural reranking (Sordoni et al., 2015)	50M	4.44	**.101**	**.358**

Table 2: Performance on the Twitter dataset of 4-layer SEQ2SEQ models and MMI models. *distinct-1* and *distinct-2* are respectively the number of distinct unigrams and bigrams divided by total number of generated words.

For tuning and evaluation, we used the development dataset (2118 conversations) and the test dataset (2114 examples), augmented using information retrieval methods to create a multi-reference set, as described by Sordoni et al. (2015). The selection criteria for these two datasets included a component of relevance/interestingness, with the result that dull responses will tend to be penalized in evaluation.

OpenSubtitles dataset In addition to unscripted Twitter conversations, we also used the OpenSubtitles (OSDb) dataset (Tiedemann, 2009), a large, noisy, open-domain dataset containing roughly 60M-70M scripted lines spoken by movie characters. This dataset does not specify which character speaks each subtitle line, which prevents us from inferring speaker turns. Following Vinyals et al. (2015), we make the simplifying assumption that each line of subtitle constitutes a full speaker turn. Our models are trained to predict the current turn given the preceding ones based on the assumption that consecutive turns belong to the same conversation. This introduces a degree of noise, since consecutive lines may not appear in the same conversation or scene, and may not even be spoken by the same character.

This limitation potentially renders the OSDb dataset unreliable for evaluation purposes. For evaluation purposes, we therefore used data from the Internet Movie Script Database (IMSDB),[7] which explicitly identifies which character speaks each line of the script. This allowed us to identify consecutive message-response pairs spoken by different characters. We randomly selected two subsets as development and test datasets, each containing 2k pairs, with source and target length restricted to the range of [6,18].

Model	BLEU	*distinct-1*	*distinct-2*
SEQ2SEQ	1.28	0.0056	0.0136
MMI-antiLM	1.74 (+35.9%)	0.0184 (+228%)	0.066 (407%)
MMI-bidi	1.44 (+28.2%)	0.0103 (+83.9%)	0.0303 (+122%)

Table 3: Performance of the SEQ2SEQ baseline and two MMI models on the OpenSubtitles dataset.

5.2 Evaluation

For parameter tuning and final evaluation, we used BLEU (Papineni et al., 2002), which was shown to correlate reasonably well with human judgment on the response generation task (Galley et al., 2015). In the case of the Twitter models, we used multi-reference BLEU. As the IMSDB data is too limited to support extraction of multiple references, only single reference BLEU was used in training and evaluating the OSDb models.

We did not follow Vinyals et al. (2015) in using perplexity as evaluation metric. Perplexity is unlikely to be a useful metric in our scenario, since our proposed model is designed to steer away from the standard SEQ2SEQ model in order to diversify the outputs. We report degree of diversity by calculating the number of distinct unigrams and bigrams in generated responses. The value is scaled by total number of generated tokens to avoid favoring long sentences (shown as *distinct-1* and *distinct-2* in Tables 2 and 3).

5.3 Results

Twitter Dataset We first report performance on Twitter datasets in Table 2, along with results for different models (i.e., *Machine Translation* and *MT+neural reranking*) reprinted from Sordoni et al. (2015) on the same dataset. The baseline is the SEQ2SEQ model with its standard likelihood objective and a beam size of 200. We compare this base-

[7] IMSDB (`http://www.imsdb.com/`) is a relatively small database of around 0.4 million sentences and thus not suitable for open domain dialogue training.

line against greedy-search SEQ2SEQ (Vinyals and Le, 2015), which can help achieve higher diversity by increasing search errors.[8]

Machine Translation is the phrase-based MT system described in (Ritter et al., 2011). MT features include commonly used ones in Moses (Koehn et al., 2007), e.g., forward and backward maximum likelihood "translation" probabilities, word and phrase penalties, linear distortion, etc. For more details, refer to Sordoni et al. (2015).

MT+neural reranking is the phrase-based MT system, reranked using neural models. N-best lists are first generated from the MT system. Recurrent neural models generate scores for N-best list candidates given the input messages. These generated scores are re-incorporated to rerank all the candidates. Additional features to score [1-4]-gram matches between context and response and between message and context (context and message match CMM features) are also employed, as in Sordoni et al. (2015).

MT+neural reranking achieves a BLEU score of 4.44, which to the best of our knowledge represents the previous state-of-the-art performance on this Twitter dataset. Note that *Machine Translation* and *MT+neural reranking* are trained on a much larger dataset of roughly 50 million examples. A significant performance boost is observed from MMI-bidi over baseline SEQ2SEQ, both in terms of BLEU score and diversity.

The beam size of 200 used in our main experiments is quite conservative, and BLEU scores only slightly degrade when reducing beam size to 20. For MMI-bidi, BLEU scores for beam sizes of 200, 50, 20 are respectively 5.90, 5.86, 5.76. A beam size of 20 still produces relatively large N-best lists (173 elements on average) with responses of varying lengths, which offer enough diversity for the $p(S|T)$ model to have a significant effect.

OpenSubtitles Dataset All models achieve significantly lower BLEU scores on this dataset than on the Twitter dataset, primarily because the IMSDB data provides only single references for evaluation. We note, however, that baseline SEQ2SEQ models yield lower levels of unigram diversity (*distinct-1*) on the OpenSubtitles dataset than on the Twitter data (0.0056 vs 0.017), which suggests that other factors may be in play. It is likely that movie dialogs are much more concise and information-rich than typical conversations on Twitter, making it harder to match gold-standard responses and causing the learned models to strongly favor safe, conservative responses.

Comparator	Gain	95% CI
SMT (Ritter et al., 2011)	0.29	[0.25, 0.32]
SMT+neural reranking	0.28	[0.25, 0.32]
SEQ2SEQ (baseline)	0.11	[0.07, 0.14]
SEQ2SEQ (greedy)	0.08	[0.04, 0.11]

Table 6: MMI-bidi gains over comparator systems, based on pairwise human judgments.

Table 3 shows that the MMI-antiLM model yields a significant performance boost, with a BLEU score increase of up to 36% and a more than 200% jump in unigram diversity. Our interpretation of this huge performance improvement is that the diversity and complexity of input messages lead standard SEQ2SEQ models to generate very conservative responses,[9] which fail to match the more interesting reference strings typical of this dataset. This interpretation is also supported by the fact that the MMI-bidi model does not produce as significant a performance boost as MMI-antiLM. In the case of MMI-bidi, N-best lists generated using standard SEQ2SEQ models remain conservative and uninteresting, attenuating the impact of later reranking. An important potential limitation of MMI-bidi model is thus that its performance hinges on the initial generation of a highly diverse, informative N-best list.

Qualitative Evaluation We employed crowd-sourced judges to provide evaluations for a random sample of 1000 items in the Twitter test dataset. Table 6 shows the results of human evaluations between paired systems. Each output pair was ranked by 5 judges, who were asked to decide which of the two outputs was better. They were instructed to prefer outputs that were more specific (relevant) to the message and preceding context, as opposed to those that

[8] Another method would have been to sample from the $p(T|S)$ distribution to increase diversity. While these methods have merits, we think we ought to find a proper objective and optimize it exactly, rather than cope with an inadequate one and add noise to it.

[9] The strings *I don't know*, *I don't know what you are talking about*, *I don't think that is a good idea*, and *Oh my god* constitute 32% percent of all generated responses.

message	SEQ2SEQ	MMI $P(T\|S) - \lambda P(T)$
I did not get the report from an mi-6 agent.	I don't think that's a good idea.	You did the right thing, did you?
You haven't been given an assignment in this case.	I don't know what you are talking about.	I've been looking all over for you.
I'm losing my grip.	I don't know what you are talking about.	I'm the only one in the world.
I am ready to help.	Come on, come on	I have something we need to talk about.
You programmed me to gather intelligence. That's all I've ever done.	You know that, don't you?	You do have fun, don't you?
I mean, we'd have to talk to him.	I mean, I don't know.	I mean, he's a good guy.
This has nothing to do with him.	You don't know anything about him, do you?	I know him as much.
How come you never say it?	I don't know	Because I don't want to hurt you
He is the one behind this scheme to crash x-net.	I don't know what you are talking about	Yes, he is, isn't he?
How much time do you have here?	I don't know.	Not long enough. Sorry, sir.

Table 4: Responses from the SEQ2SEQ baseline and MMI-antiLM models on the OpenSubtitles dataset.

message	SEQ2SEQ	MMI-bidi
Ohh I've never seen that! How long does it take you guys to learn the drill?	I don't even know.	Like 2 weeks ago!!
You'll know when we sign Heskey in 2 weeks	I'll see what I can do	I sure hope so..
I'm waiting!! I have even got biscuits waiting for you??	I have no idea what you're talking about	I'll send you a pic when I get home xx
My parents actually had touch too much played at their wedding.	I have no idea what you're talking about	How old are they??
Say anything you want... I know you love me and I love you.	I love you so much.	I love you too, baby.
I am off all week next week	What time you going?	What time you going?
How are you doing?	I'm good, thanks.	I'm good, you?

Table 5: Responses from the SEQ2SEQ baseline and MMI-bidi models on the Twitter dataset.

Input: What are you doing?	
1. I've been looking for you.	4. I told you to shut up.
2. I want to talk to you.	5. Get out of here.
3. Just making sure you're OK.	6. I'm looking for a doctor.
Input: What is your name?	
1. Blue!	4. Daniel.
2. Peter.	5. My name is John.
3. Tyler.	6. My name is Robert.
Input: How old are you?	
1. Twenty-eight.	4. Five.
2. Twenty-four.	5. 15.
3. Long.	6. Eight.

Table 7: Examples generated by the MMI-antiLM model on the OpenSubtitles dataset.

were more generic. Ties were permitted. Identical strings were algorithmically assigned the same score. The mean of differences between outputs is shown as the gain for MMI-bidi over the competing system. At a significance level of $\alpha = 0.05$, we find that MMI-bidi outperforms both baseline and greedy SEQ2SEQ systems, as well as the weaker SMT and SMT+RNN baselines. MMI-bidi outperforms SMT in human evaluations *despite* the greater lexical diversity of MT output.

Separately, judges were also asked to rate overall quality of MMI-bidi output over the same 1000-item sample in isolation, each output being evaluated by 7 judges in context using a 5-point scale. The mean rating was 3.84 (median: 3.85, 1st Qu: 3.57, 3rd Qu: 4.14), suggesting that overall MMI-bidi output does appear reasonably acceptable to human judges.[10]

Table 7 presents the N-best candidates generated using the MMI-bidi model for the inputs of Table 1.

[10] In the human evaluations, we asked the annotators to prefer responses that were more specific to the context only when doing the pairwise evaluations of systems. The absolute evaluation was conducted separately (on different days) on the best system, and annotators were asked to evaluate the overall quality of the response, specifically *Provide your impression of overall quality of the response in this particular conversation.*

We see that MMI generates significantly more interesting outputs than SEQ2SEQ.

In Tables 4 and 5, we present responses generated by different models. All examples were randomly sampled (without cherry picking). We see that the baseline SEQ2SEQ model tends to generate reasonable responses to simple messages such as *How are you doing?* or *I love you*. As the complexity of the message increases, however, the outputs switch to more conservative, duller forms, such as *I don't know* or *I don't know what you are talking about*. An occasional answer of this kind might go unnoticed in a natural conversation, but a dialog agent that *always* produces such responses risks being perceived as uncooperative. MMI-bidi models, on the other hand, produce far more diverse and interesting responses.

6 Conclusions

We investigated an issue encountered when applying SEQ2SEQ models to conversational response generation. These models tend to generate safe, commonplace responses (e.g., *I don't know*) regardless of the input. Our analysis suggests that the issue is at least in part attributable to the use of unidirectional likelihood of output (responses) given input (messages). To remedy this, we have proposed using Maximum Mutual Information (MMI) as the objective function. Our results demonstrate that the proposed MMI models produce more diverse and interesting responses, while improving quality as measured by BLEU and human evaluation.

To the best of our knowledge, this paper represents the first work to address the issue of output diversity in the neural generation framework. We have focused on the algorithmic dimensions of the problem. Unquestionably numerous other factors such as grounding, persona (of both user and agent), and intent also play a role in generating diverse, conversationally interesting outputs. These must be left for future investigation. Since the challenge of producing interesting outputs also arises in other neural generation tasks, including image-description generation, question answering, and potentially any task where mutual correspondences must be modeled, the implications of this work extend well beyond conversational response generation.

Abstract

Moving from limited-domain natural language generation (NLG) to open domain is difficult because the number of semantic input combinations grows exponentially with the number of domains. Therefore, it is important to leverage existing resources and exploit similarities between domains to facilitate domain adaptation. In this paper, we propose a procedure to train multi-domain, Recurrent Neural Network-based (RNN) language generators via multiple adaptation steps. In this procedure, a model is first trained on counterfeited data synthesised from an out-of-domain dataset, and then fine tuned on a small set of in-domain utterances with a discriminative objective function. Corpus-based evaluation results show that the proposed procedure can achieve competitive performance in terms of BLEU score and slot error rate while significantly reducing the data needed to train generators in new, unseen domains. In subjective testing, human judges confirm that the procedure greatly improves generator performance when only a small amount of data is available in the domain.

1 Introduction

Modern Spoken Dialogue Systems (SDS) are typically developed according to a well-defined *ontology*, which provides a structured representation of the *domain* data that the dialogue system can talk about, such as searching for a restaurant or shopping for a laptop. Unlike conventional approaches employing a substantial amount of handcrafting for each individual processing component (Ward and Issar, 1994; Bohus and Rudnicky, 2009), statistical approaches to SDS promise a domain-scalable framework which requires a minimal amount of human intervention (Young et al., 2013). Mrkšić et al. (2015) showed improved performance in belief tracking by training a general model and adapting it to specific domains. Similar benefit can be observed in Gašić et al. (2015), in which a Bayesian committee machine (Tresp, 2000) was used to model policy learning in a multi-domain SDS regime.

In past decades, adaptive NLG has been studied from linguistic perspectives, such as systems that learn to tailor user preferences (Walker et al., 2007), convey a specific personality trait (Mairesse and Walker, 2008; Mairesse and Walker, 2011), or align with their conversational partner (Isard et al., 2006). Domain adaptation was first addressed by Hogan et al. (2008) using a generator based on the Lexical Functional Grammar (LFG) f-structures (Kaplan and Bresnan, 1982). Although these approaches can model rich linguistic phenomenon, they are not readily adaptable to data since they still require many handcrafted rules to define the search space. Recently, RNN-based language generation has been introduced (Wen et al., 2015a; Wen et al., 2015b). This class of statistical generators can learn generation decisions directly from dialogue act (DA)-utterance pairs without any semantic annotations (Mairesse and Young, 2014) or hand-coded grammars (Langkilde and Knight, 1998; Walker et al., 2002). Many existing adaptation approaches (Wen et al., 2013; Shi et al., 2015; Chen et al., 2015) can be directly applied due to the

San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

flexibility of the underlying RNN language model (RNNLM) architecture (Mikolov et al., 2010).

Discriminative training (DT) has been successfully used to train RNNs for various tasks. By optimising directly against the desired objective function such as BLEU score (Auli and Gao, 2014) or Word Error Rate (Kuo et al., 2002), the model can explore its output space and learn to discriminate between good and bad hypotheses. In this paper we show that DT can enable a generator to learn more efficiently when in-domain data is scarce.

The paper presents an incremental recipe for training multi-domain language generators based on a purely data-driven, RNN-based generation model. Following a review of related work in section 2, section 3 describes the detailed RNN generator architecture. The data counterfeiting approach for synthesising an in-domain dataset is introduced in section 4, where it is compared to the simple model fine-tuning approach. In section 5, we describe our proposed DT procedure for training natural language generators. Following a brief review of the data sets used in section 6, corpus-based evaluation results are presented in section 7. In order to assess the subjective performance of our system, a quality test and a pairwise preference test are presented in section 8. The results show that the proposed adaptation recipe improves not only the objective scores but also the user's perceived quality of the system. We conclude with a brief summary in section 9.

2 Related Work

Domain adaptation problems arise when we have a sufficient amount of labeled data in one domain (the *source* domain), but have little or no labeled data in another related domain (the *target* domain). Domain adaptability for real world speech and language applications is especially important because both language usage and the topics of interest are constantly evolving. Historically, domain adaptation has been less well studied in the NLG community. The most relevant work was done by Hogan et al. (2008). They showed that an LFG f-structure based generator could yield better performance when trained on in-domain sentences paired with pseudo parse tree inputs generated from a state-of-the-art, but out-of-domain parser. The SPoT-based generator proposed by Walker et al. (2002) has the potential to address domain adaptation problems. However, their published work has focused on tailoring user preferences (Walker et al., 2007) and mimicking personality traits (Mairesse and Walker, 2011). Lemon (2008) proposed a Reinforcement Learning (RL) framework in which policy and NLG components can be jointly optimised and adapted based on online user feedback. In contrast, Mairesse et al. (2010) has proposed using active learning to mitigate the data sparsity problem when training data-driven NLG systems. Furthermore, Cuayhuitl et al. (2014) trained statistical surface realisers from unlabelled data by an automatic slot labelling technique.

In general, feature-based adaptation is perhaps the most widely used technique (Blitzer et al., 2007; Pan and Yang, 2010; Duan et al., 2012). By exploiting correlations and similarities between data points, it has been successfully applied to problems like speaker adaptation (Gauvain and Lee, 1994; Leggetter and Woodland, 1995) and various tasks in natural language processing (Daumé III, 2009). In contrast, model-based adaptation is particularly useful for language modeling (LM) (Bellegarda, 2004). Mixture-based topic LMs (Gildea and Hofmann, 1999) are widely used in N-gram LMs for domain adaptation. Similar ideas have been applied to applications that require adapting LMs, such as machine translation (MT) (Koehn and Schroeder, 2007) and personalised speech recognition (Wen et al., 2012).

Domain adaptation for Neural Network (NN)-based LMs has also been studied in the past. A feature augmented RNNLM was first proposed by Mikolov and Zweig (2012), but later applied to multi-genre broadcast speech recognition (Chen et al., 2015) and personalised language modeling (Wen et al., 2013). These methods are based on fine-tuning existing network parameters on adaptation data. However, careful regularisation is often necessary (Yu et al., 2013). In a slightly different area, Shi et al. (2015) applied curriculum learning to RNNLM adaptation.

Discriminative training (DT) (Collins, 2002) is an alternative to the maximum likelihood (ML) criterion. For classification, DT can be split into two phases: (1) decoding training examples using the current model and scoring them, and (2) adjusting the model parameters to maximise the separation between the correct target annotation and the competing incorrect annotations. It has been successfully applied to many research problems, such as speech recognition (Kuo et al., 2002; Voigtlaender et al., 2015) and MT (He and Deng, 2012; Auli et al., 2014). Recently, Auli and Gao (2014) trained an RNNLM with a DT objective and showed improved performance on an MT task. However, their RNN probabilities only served as input features to a phrase-based MT system.

3 The Neural Language Generator

The neural language generation model (Wen et al., 2015a; Wen et al., 2015b) is a RNNLM (Mikolov et al., 2010) augmented with semantic input features such as a dialogue act[1] (DA) denoting the required semantics of the generated output. At every time step t, the model consumes the 1-hot representation of both the DA $\mathbf{d}_t$ and a token $\mathbf{w}_t$[2] to update its internal state $\mathbf{h}_t$. Based on this new state, the output distribution over the next output token is calculated. The model can thus generate a sequence of tokens by repeatedly sampling the current output distribution to obtain the next input token until an end-of-sentence sign is generated. Finally, the generated sequence is lexicalised[3] to form the target utterance.

The Semantically Conditioned Long Short-term Memory Network (SC-LSTM) (Wen et al., 2015b) is a specialised extension of the LSTM network (Hochreiter and Schmidhuber, 1997) for language generation which has previously been shown capable of learning generation decisions from paired DA-utterances end-to-end without a modular pipeline (Walker et al., 2002; Stent et al., 2004). Like LSTM, SC-LSTM relies on a vector of memory cells $\mathbf{c}_t \in \mathbb{R}^n$ and a set of elementwise multiplication gates to control how information is stored, forgotten, and exploited inside the network. The SC-LSTM architecture used in this paper is defined by the following equations,

$$\begin{pmatrix} \mathbf{i}_t \\ \mathbf{f}_t \\ \mathbf{o}_t \\ \mathbf{r}_t \\ \hat{\mathbf{c}}_t \end{pmatrix} = \begin{pmatrix} \text{sigmoid} \\ \text{sigmoid} \\ \text{sigmoid} \\ \text{sigmoid} \\ \tanh \end{pmatrix} \mathbf{W}_{5n,2n} \begin{pmatrix} \mathbf{w}_t \\ \mathbf{h}_{t-1} \end{pmatrix}$$

$$\mathbf{d}_t = \mathbf{r}_t \odot \mathbf{d}_{t-1}$$

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \hat{\mathbf{c}}_t + tanh(\mathbf{W}_{dc}\mathbf{d}_t)$$

$$\mathbf{h}_t = \mathbf{o}_t \odot \tanh(\mathbf{c}_t)$$

where n is the hidden layer size, $\mathbf{i}_t, \mathbf{f}_t, \mathbf{o}_t, \mathbf{r}_t \in [0,1]^n$ are input, forget, output, and reading gates respectively, $\hat{\mathbf{c}}_t$ and $\mathbf{c}_t$ are proposed cell value and true cell value at time t, $\mathbf{W}_{5n,2n}$ and $\mathbf{W}_{dc}$ are the model parameters to be learned. The major difference of the SC-LSTM compared to the vanilla LSTM is the introduction of the reading gates for controlling the semantic input features presented to the network. It was shown in Wen et al. (2015b) that these reading gates act like keyword and key phrase detectors that learn the alignments between individual semantic input features and their corresponding realisations without additional supervision.

After the hidden layer state is obtained, the computation of the next word distribution and sampling from it is straightforward,

$$p(w_{t+1}|w_t, w_{t-1}, ...w_0, \mathbf{d}_t) = softmax(\mathbf{W}_{ho}\mathbf{h}_t)$$

$$w_{t+1} \sim p(w_{t+1}|w_t, w_{t-1}, ...w_0, \mathbf{d}_t).$$

where $\mathbf{W}_{ho}$ is another weight matrix to learn. The entire network is trained end-to-end using a cross entropy cost function, between the predicted word distribution $\mathbf{p}_t$ and the actual word distribution $\mathbf{y}_t$, with regularisations on DA transition dynamics,

$$F(\theta) = \textstyle\sum_t \mathbf{p}_t^{\intercal} log(\mathbf{y}_t) + \|\mathbf{d}_{\mathrm{T}}\| + \sum_{t=0}^{\mathrm{T}-1} \eta \xi^{\|\mathbf{d}_{t+1} - \mathbf{d}_t\|} \quad (1)$$

where $\theta = \{\mathbf{W}_{5n,2n}, \mathbf{W}_{dc}, \mathbf{W}_{ho}\}$, $\mathbf{d}_{\mathrm{T}}$ is the DA vector at the last index T, and η and ξ are constants set to 10^{-4} and 100, respectively.

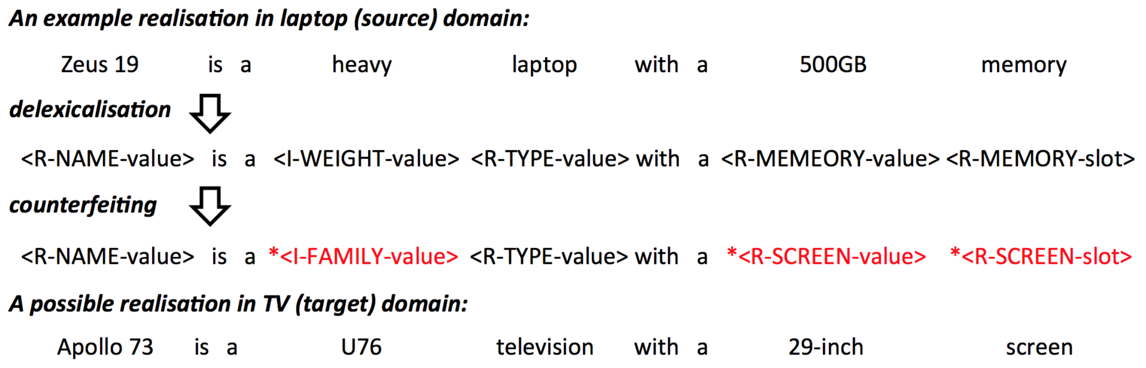
4 Training Multi-domain Models

Given training instances (represented by DA and sentence tuples $\{d_i, \Omega_i\}$) from the source domain $\mathbb{S}$ (rich) and the target domain $\mathbb{T}$ (limited), the goal is to find a set of SC-LSTM parameters $\theta_{\mathbb{T}}$ that can perform acceptably well in the target domain.

[1] A combination of an action type and a set of slot-value pairs. e.g. *inform(name="Seven days",food="chinese")*

[2] We use *token* instead of *word* because our model operates on text for which slot values are replaced by their corresponding slot tokens. We call this procedure delexicalisation.

[3] The process of replacing slot token by its value.



An example realisation in laptop (source) domain:
Zeus 19 is a heavy laptop with a 500GB memory
delexicalisation
<R-NAME-value> is a <I-WEIGHT-value> <R-TYPE-value> with a <R-MEMEORY-value> <R-MEMORY-slot>
counterfeiting
<R-NAME-value> is a *<I-FAMILY-value> <R-TYPE-value> with a *<R-SCREEN-value> *<R-SCREEN-slot>
A possible realisation in TV (target) domain:
Apollo 73 is a U76 television with a 29-inch screen

Figure 1: An example of data counterfeiting algorithm. Both slots and values are delexicalised. Slots and values that are not in the target domain are replaced during data counterfeiting (shown in *red* with * sign). The prefix inside bracket <> indicates the slot's functional class (I for *informable* and R for *requestable*).

4.1 Model Fine-Tuning

A straightforward way to adapt NN-based models to a target domain is to continue training or fine-tuning a well-trained generator on whatever new target domain data is available. This training procedure is as follows:

1. Train a source domain generator $\theta_{\mathbb{S}}$ on source domain data $\{d_i, \Omega_i\} \in \mathbb{S}$ with all values delexicalised[4].

2. Divide the adaptation data into training and validation sets. Refine parameters by training on adaptation data $\{d_i, \Omega_i\} \in \mathbb{T}$ with early stopping and a smaller starting learning rate. This yields the target domain generator $\theta_{\mathbb{T}}$.

Although this method can benefit from parameter sharing of the LM part of the network, the parameters of similar input slot-value pairs are not shared[4]. In other words, realisation of any unseen slot-value pair in the target domain can only be learned from scratch. Adaptation offers no benefit in this case.

4.2 Data Counterfeiting

In order to maximise the effect of domain adaptation, the model should be able to (1) generate acceptable realisations for unseen slot-value pairs based on similar slot-value pairs seen in the training data, and (2) continue to distinguish slot-value pairs that are similar but nevertheless distinct. Instead of exploring weight tying strategies in different training stages (which is complex to implement and typically relies on ad hoc tying rules), we propose instead a data counterfeiting approach to *synthesise* target domain data from source domain data. The procedure is shown in Figure 1 and described as following:

1. Categorise slots in both source and target domain into classes, according to some similarity measure. In our case, we categorise them based on their functional type to yield three classes: *informable*, *requestable*, and *binary*[5].

2. Delexicalise all slots and values.

3. For each slot s in a source instance $(d_i, \Omega_i) \in \mathbb{S}$, randomly select a new slot s' that belongs to both the target ontology and the class of s to replace s. Repeat this process for every slot in the instance and yield a new pseudo instance $(\hat{d}_i, \hat{\Omega}_i) \in \mathbb{T}$ in the target domain.

4. Train a generator $\hat{\theta}_{\mathbb{T}}$ on the counterfeited dataset $\{\hat{d}_i, \hat{\Omega}_i\} \in \mathbb{T}$.

5. Refine parameters on real in-domain data. This yields final model parameters $\theta_{\mathbb{T}}$.

This approach allows the generator to share realisations among slot-value pairs that have similar functionalities, therefore facilitates the transfer learning

[4] We have tried training with both slots and values delexicalised and then using the weights to initialise unseen slot-value pairs in the target domain. However, this yielded even worse results since the learned semantic alignment stuck at local minima. Pre-training only the LM parameters did not produce better results either.

[5] *Informable* class include all non-binary informable slots while *binary* class includes all binary informable slots.

	Laptop	Television
informable slots	family, *pricerange, batteryrating, driverange, weightrange, **isforbusinesscomputing**	family, *pricerange, screensizerange, ecorating, hdmiport, **hasusbport**
requestable slots	*name, *type, *price, warranty, battery, design, dimension, utility, weight, platform, memory, drive, processor	*name, *type, *price, resolution, powerconsumption, accessories, color, screensize, audio

bold=binary slots, *=overlap with SF Restaurant and Hotel domains, all *informable slots* can take ”dontcare” value

Table 1: Ontologies for Laptop and TV domains

of rare slot-value pairs in the target domain. Furthermore, the approach also preserves the co-occurrence statistics of slot-value pairs and their realisations. This allows the model to learn the gating mechanism even before adaptation data is introduced.

5 Discriminative Training

In contrast to the traditional ML criteria (Equation 1) whose goal is to maximise the log-likelihood of correct examples, DT aims at separating correct examples from competing incorrect examples. Given a training instance (d_i, Ω_i), the training process starts by generating a set of candidate sentences $Gen(d_i)$ using the current model parameter θ and DA d_i. The discriminative cost function can therefore be written as

$$\begin{aligned} F(\theta) &= -\mathbb{E}[L(\theta)] \\ &= -\sum_{\Omega \in Gen(d_i)} p_\theta(\Omega|d_i) L(\Omega, \Omega_i) \end{aligned} \quad (2)$$

where $L(\Omega, \Omega_i)$ is the scoring function evaluating candidate Ω by taking ground truth Ω_i as reference. $p_\theta(\Omega|d_i)$ is the normalised probability of the candidate and is calculated by

$$p_\theta(\Omega|d_i) = \frac{\exp[\gamma \log p(\Omega|d_i,\theta)]}{\sum_{\Omega' \in Gen(d_i)} \exp[\gamma \log p(\Omega'|d_i,\theta)]} \quad (3)$$

$\gamma \in [0, \infty]$ is a tuned scaling factor that flattens the distribution for $\gamma < 1$ and sharpens it for $\gamma > 1$. The unnormalised candidate likelihood $\log p(\Omega|d_i, \theta)$ is produced by summing token likelihoods from the RNN generator output,

$$\log p(\Omega|d_i, \theta) = \sum_{w_t \in \Omega} \log p(w_t|d_i, \theta) \quad (4)$$

The scoring function $L(\Omega, \Omega_i)$ can be further generalised to take several scoring functions into account

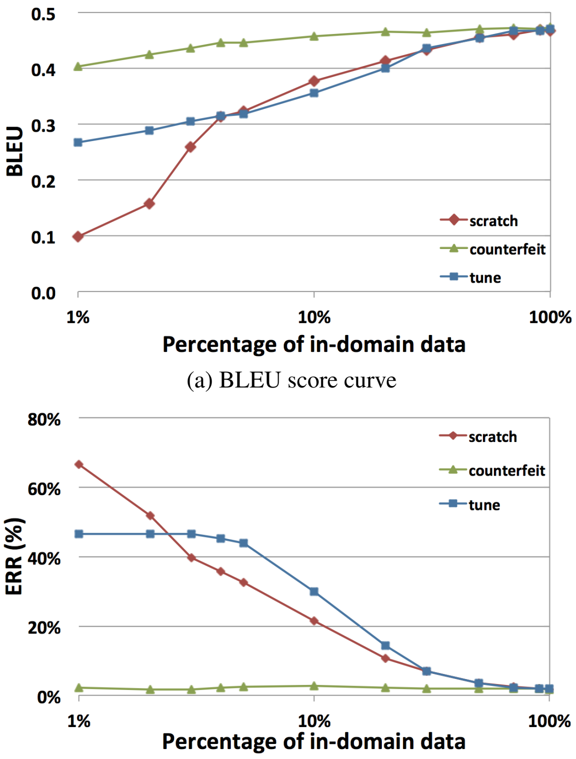
$$L(\Omega, \Omega_i) = \sum_j L_j(\Omega, \Omega_i)\beta_j \quad (5)$$

where β_j is the weight for j-th scoring function. Since the cost function presented here (Equation 2) is differentiable everywhere, back propagation can be applied to calculate the gradients and update parameters directly.

6 Datasets

In order to test our proposed recipe for training multi-domain language generators, we conducted experiments using four different domains: finding a restaurant, finding a hotel, buying a laptop, and buying a television. Datasets for the restaurant and hotel domains have been previously released by Wen et al. (2015b). These were created by workers recruited by Amazon Mechanical Turk (AMT) by asking them to propose an appropriate natural language realisation corresponding to each system dialogue act actually generated by a dialogue system. However, the number of actually occurring DA combinations in the restaurant and hotel domains were rather limited (∼200) and since multiple references were collected for each DA, the resulting datasets are not sufficiently diverse to enable the assessment of the generalisation capability of the different training methods over unseen semantic inputs.

In order to create more diverse datasets for the laptop and TV domains, we enumerated all possible combinations of dialogue act types and slots based on the ontology shown in Table 1. This yielded



(a) BLEU score curve

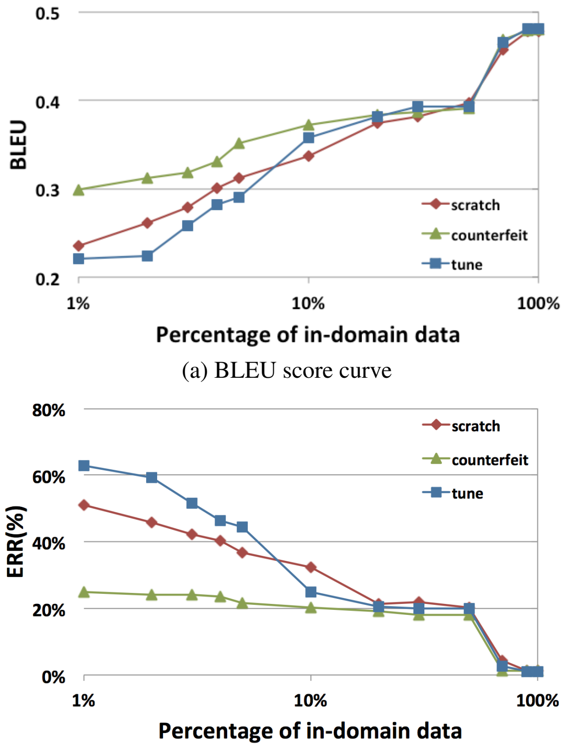
(b) Slot error rate curve

Figure 2: Results evaluated on TV domain by adapting models from laptop domain. Comparing train-from-scratch model (*scratch*) with model fine-tuning approach (*tune*) and data counterfeiting method (*counterfeit*). $10\% \approx 700$ examples.

about 13K distinct DAs in the laptop domain and 7K distinct DAs in the TV domain. We then used AMT workers to collect just one realisation for each DA. Since the resulting datasets have a much larger input space but only one training example for each DA, the system must learn partial realisations of concepts and be able to recombine and apply them to unseen DAs. Also note that the number of act types and slots of the new ontology is larger, which makes NLG in both laptop and TV domains much harder.

7 Corpus-based Evaluation

We first assess generator performance using two objective evaluation metrics, the BLEU-4 score (Papineni et al., 2002) and slot error rate ERR (Wen et al., 2015b). Slot error rates were calculated by averaging slot errors over each of the top 5 realisations in the entire corpus. We used multiple references to compute the BLEU scores when available (i.e. for the restaurant and hotel domains). In order to better compare results across different methods, we plotted the BLEU and slot error rate curves against different amounts of adaptation data. Note that in the graphs the *x*-axis is presented on a log-scale.



(a) BLEU score curve

(b) Slot error rate curve

Figure 3: The same set of comparison as in Figure 2, but the results were evaluated by adapting from SF restaurant and hotel joint dataset to laptop and TV joint dataset. $10\% \approx 2K$ examples.

7.1 Experimental Setup

The generators were implemented using the Theano library (Bergstra et al., 2010; Bastien et al., 2012), and trained by partitioning each of the collected corpora into a training, validation, and testing set in the ratio 3:1:1. All the generators were trained by treating each sentence as a mini-batch. An l_2 regularisation term was added to the objective function for every 10 training examples. The hidden layer size was set to be 100 for all cases. Stochastic gradient descent and back propagation through time (Werbos, 1990) were used to optimise the parameters. In order to prevent overfitting, early stopping was implemented using the validation set.

During decoding, we over-generated 20 utterances and selected the top 5 realisations for each DA according to the following reranking criteria,

$$R = -(F(\theta) + \lambda \mathrm{ERR}) \tag{6}$$

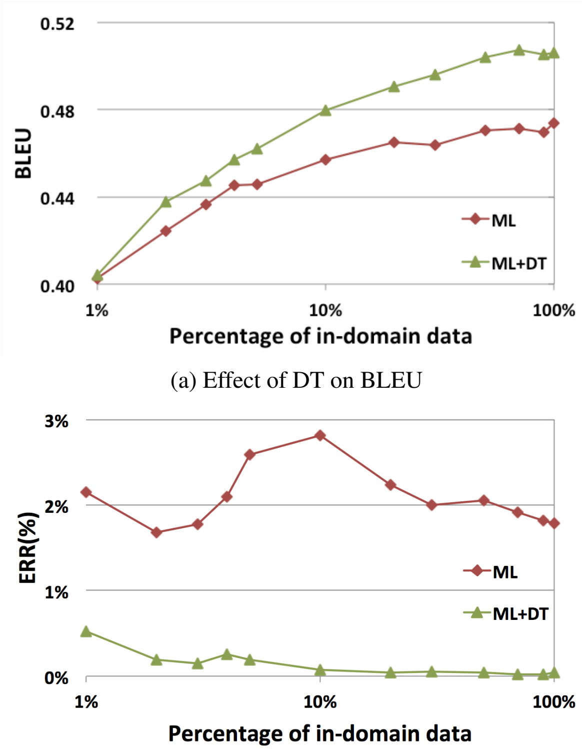
where λ is a tradeoff constant, $F(\theta)$ is the cost generated by network parameters θ, and the slot error rate ERR is computed by exact matching of the slot tokens in the candidate utterances. λ is set to a large value (10) in order to severely penalise nonsensical outputs. Since our generator works stochastically and the trained networks can differ depending on the initialisation, all the results shown below were averaged over 5 randomly initialised networks.

7.2 Data Counterfeiting

We first compared the data counterfeiting (*counterfeit*) approach with the model fine-tuning (*tune*) method and models trained from scratch (*scratch*). Figure 2 shows the result of adapting models between similar domains, from laptop to TV. Because of the parameter sharing in the LM part of the network, model fine-tuning (*tune*) achieves a better BLEU score than training from scratch (*scratch*) when target domain data is limited. However, if we apply the data counterfeiting (*counterfeit*) method, we obtain an even greater BLEU score gain. This is mainly due to the better realisation of unseen slot-value pairs. On the other hand, data counterfeiting (*counterfeit*) also brings a substantial reduction in slot error rate. This is because it preserves the co-occurrence statistics between slot-value pairs and realisations, which allows the model to learn good semantic alignments even before adaptation data is introduced. Similar results can be seen in Figure 3, in which adaptation was performed on more disjoint domains: restaurant and hotel joint domain to laptop and TV joint domain. The data counterfeiting (*counterfeit*) method is still superior to the other methods.

7.3 Discriminative Training

The generator parameters obtained from data counterfeiting and ML adaptation were further tuned by applying DT. In each case, the models were optimised using two objective functions: BLEU-4 score and slot error rate. However, we used a soft version of BLEU called sentence BLEU as described in Auli and Gao (2014), to mitigate the sparse n-gram match problem of BLEU at the sentence level. In our experiments, we set γ to 5.0 and β_j to 1.0 and -1.0 for BLEU and ERR, respectively. For each DA, we applied our generator 50 times to generate candidate sentences. Repeated candidates were removed. We treated the remaining candidates as a single batch and updated the model parameters by the procedure described in section 5. We evaluated performance of the algorithm on the laptop to TV adaptation scenario, and compared models with and without discriminative training (*ML+DT* & *ML*). The results are shown in Figure 4 where it can be seen that DT consistently improves generator performance on both metrics. Another interesting point to note is that slot error rate is easier to optimise compared to BLEU (ERR→ 0 after DT). This is probably because the sentence BLEU optimisation criterion is only an approximation of the corpus BLEU score used for evaluation.



(a) Effect of DT on BLEU

(b) Effect of DT on slot error rate

Figure 4: Effect of applying DT training after ML adaptation. The results were evaluated on laptop to TV adaptation. $10\% \approx 700$ examples.

8 Human Evaluation

Since automatic metrics may not consistently agree with human perception (Stent et al., 2005), human testing is needed to assess subjective quality. To do

Method	TV to Laptop		laptop to TV	
	Info.	Nat.	Info.	Nat.
scrALL	2.64	2.37	2.54	2.36
DT-10%	**2.52****	**2.25****	**2.51**	2.19**
ML-10%	2.51**	2.22**	2.45**	**2.22****
scr-10%	2.24**	2.03**	2.00**	1.92**

* p <0.05, ** p <0.005

Table 2: Human evaluation for utterance quality in two domains. Results are shown in two metrics (rating out of 3). Statistical significance was computed using a two-tailed Student's t-test, between the model trained with full data (*scrALL*) and all others.

this, a set of judges were recruited using AMT. We tested our models on two adaptation scenarios: laptop to TV and TV to laptop. For each task, two systems among the four were compared: training from scratch using full dataset (*scrALL*), adapting with DT training but only 10% of target domain data (*DT-10%*), adapting with ML training but only 10% of target domain data (*ML-10%*), and training from scratch using only 10% of target domain data (*scr-10%*). In order to evaluate system performance in the presence of language variation, each system generated 5 different surface realisations for each input DA and the human judges were asked to score each of them in terms of informativeness and naturalness (rating out of 3), and also asked to state a preference between the two. Here *informativeness* is defined as whether the utterance contains all the information specified in the DA, and *naturalness* is defined as whether the utterance could plausibly have been produced by a human. In order to decrease the amount of information presented to the judges, utterances that appeared identically in both systems were filtered out. We tested about 2000 DAs for each scenario distributed uniformly between contrasts except that allowed 50% more comparisons between *ML-10%* and *DT-10%* because they were close.

Table 2 shows the subjective quality assessments which exhibit the same general trend as the objective results. If a large amount of target domain data is available, training everything from scratch (*scrALL*) achieves a very good performance and adaptation is not necessary. However, if only a limited amount of in-domain data is available, efficient adaptation is critical (*DT-10% & ML-10% > scr-10%*). Moreover, judges also preferred the DT trained generator (*DT-10%*) compared to the ML trained generator (*ML-10%*), especially for *informativeness*. In the laptop to TV scenario, the *informativeness* score of DT method (*DT-10%*) was considered indistinguishable when comparing to the method trained with full training set (*scrALL*). The preference test results are shown in Table 3. Again, adaptation methods (*DT-10% & ML-10%*) are crucial to bridge the gap between domains when the target domain data is scarce (*DT-10% & ML-10% > scr-10%*). The results also suggest that the DT training approach (*DT-10%*) was preferred compared to ML training (*ML-10%*), even though the preference in this case was not statistically significant.

9 Conclusion and Future Work

In this paper we have proposed a procedure for training multi-domain, RNN-based language generators, by data counterfeiting and discriminative training. The procedure is general and applicable to any data-driven language generator. Both corpus-based evaluation and human assessment were performed. Objective measures on corpus data have demonstrated that by applying this procedure to adapt models between four different dialogue domains, good performance can be achieved with much less training data. Subjective assessment by human judges confirm the effectiveness of the approach.

The proposed domain adaptation method requires a small amount of annotated data to be collected offline. In our future work, we intend to focus on training the generator on the fly with real user feedback during conversation.

A Long Short-Term Memory Framework for Predicting Humor in Dialogues

Abstract

We propose a first-ever attempt to employ a Long Short-Term memory based framework to predict humor in dialogues. We analyze data from a popular TV-sitcom, whose canned laughters give an indication of when the audience would react. We model the setup-punchline relation of conversational humor with a Long Short-Term Memory, with utterance encodings obtained from a Convolutional Neural Network. Out neural network framework is able to improve the F-score of 8% over a Conditional Random Field baseline. We show how the LSTM effectively models the setup-punchline relation reducing the number of false positives and increasing the recall. We aim to employ our humor prediction model to build effective empathetic machine able to understand jokes.

1 Introduction

There has been many recent attempts to detect and understand humor, irony and sarcasm from sentences, usually taken from Twitter (Reyes et al., 2013; Barbieri and Saggion, 2014; Riloff et al., 2013; Joshi et al., 2015), customer reviews (Reyes and Rosso, 2012) or generic canned jokes (Yang et al., 2015). Bamman and Smith (2015) and Karoui et al. (2015) included the surrounding context.

Our work has a different focus from the above. We analyze transcripts of funny dialogues, a genre somehow neglected but important for human-robot interaction. Laughter is the natural reaction of people to a verbal or textual humorous stimulus. We want to predict when the audience would laugh. Compared to a typical canned joke or a sarcastic Tweet, a dialog utterance is perceived as funny only in relation to the dialog context and the past history. In a spontaneous setting a funny dialog is usually built through a setup which prepares the audience to receive the humorous discourse stimuli, followed by a punchline which releases the tension and triggers the laughter reaction (Attardo, 1997; Taylor and Mazlack, 2005). Automatic understanding of a humorous dialog is a first step to build an effective empathetic machine fully able to react to the user's humor and to other discourse stimuli. We are ultimately interested in developing robots that can bond with humans better (Devillers et al., 2015).

As a source of situational humor we study a popular TV sitcom: "The Big Bang Theory". The domain of sitcoms is of interest as it provides a full dialog setting, together with an indication of when the audience is expected to laugh, given by the background canned laughters. An example of dialog from this sitcom, as well as of the setup-punchline schema, is shown below (punchlines in bold):

> PENNY: *Okay, Sheldon, what can I get you?*
> SHELDON: *Alcohol.*
> PENNY: *Could you be a little more specific?*
> SHELDON: ***Ethyl alcohol.*** **LAUGH** ***Forty milliliters.*** **LAUGH**
> PENNY: *I'm sorry, honey, I don't know milliliters.*
> SHELDON: ***Ah. Blame President James Jimmy Carter.*** **LAUGH** ***He started America on a path to the metric system***

Proceedings of NAACL-HLT 2016, pages 130–135,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

but then just gave up. **LAUGH**

The utterances before the punchline are the setup. Without them, the punchlines may not be perceived as humorous (the last utterance, out of context, may be a political complaint), only with proper setup a laughter would be triggered. The humorous intent is also strengthen by the fact the dialog takes place in a bar (evident from the previous and following utterances), where a request of 40 ml of "Ethyl Alcohol" is unusual and weird.

Our previous attempts on the same corpus (Bertero and Fung, 2016b; Bertero and Fung, 2016a) showed that using a bag-of-ngram representation over a sliding window or a simple RNN to capture the contextual information of the setup was not ideal. For this reason we propose a method based on a Long Short-Term Memory network (Hochreiter and Schmidhuber, 1997), where we encode each sentence through a Convolutional Neural Network (Collobert et al., 2011). LSTM is successfully used in context-dependent sequential classification tasks such as speech recognition (Graves et al., 2013), dependency parsing (Dyer et al., 2015) and conversation modelling (Shang et al., 2015). This is also to our knowledge the first-ever attempt that a LSTM is applied to humor response prediction or general humor detection tasks.

2 Methodology

We employ a supervised classification method to detect when punchlines occur. The bulk of our classifier is made of a concatenation of a Convolutional Neural Network (Collobert et al., 2011) to encode each utterance, followed by a Long Short-Term Memory (Hochreiter and Schmidhuber, 1997) to model the sequential context of the dialog. Before the output softmax layer we add a vector of higher level syntactic, structural and sentiment features. A framework diagram is shown in Figure 1.

2.1 Convolutional Neural Network for each utterance

The first stage of our classifier is represented by a Convolutional Neural Network (Collobert et al., 2011). Low-level, high-dimensional input feature vectors are fed into a first embedding layer to obtain a low dimensional dense vector. A sliding window is then moved on these vectors and another layer is applied to each group of token vectors, in order to capture the local context of each token. A max-pooling operation is then applied to extract the most salient features of all the tokens into a single vector for the whole utterance. An additional layer is used to generalize and distribute each feature to its full range before obtaining the final utterance vector.

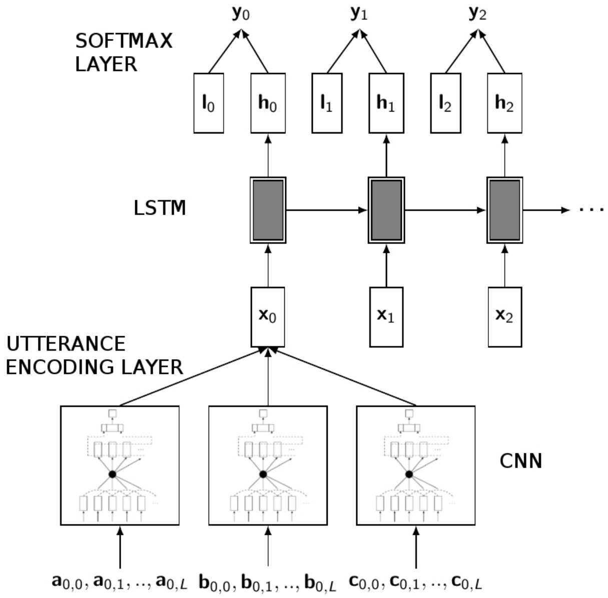

Figure 1: Framework diagram. $\mathbf{a}_t$, $\mathbf{b}_t$ and $\mathbf{c}_t$ are the CNN three input features (words, word2vec and character trigrams). $\mathbf{l}_t$ are the high level feature vectors, and $\mathbf{y}_t$ the outputs for each utterance.

In our task we use three input features:

1. Word tokens: each utterance token is represented as a one-hot vector. This feature models how much each word is likely to trigger humor in the specific corpus.

2. Character trigrams: each token is represented as a bag-of-character-trigrams vector. The feature models the role of the word signifier and removes the influence of the word stems.

3. Word2Vec: we extract for each token a word vector from word2vec (Mikolov et al., 2013), trained on the text9 Wikipedia corpus[1]. This representation models the general semantic

[1] Extension of the text8 corpus, obtained from http://mattmahoney.net/dc/textdata

meanings, and matches words that do not appear to others similar in meaning.

The convolution and max-pooling operation is applied individually to each feature, and the three vectors obtained are then concatenated together and fed to the final sentence encoding layer, which combines all the contributions.

2.2 Long/Short Term Memory for the utterance sequence

The LSTM is an improvement over the Recurrent Neural Network aimed to improve its memory capabilities. In a standard RNN the hidden memory layer is updated through a function of the input and the hidden layer at the previous time instant:

$$\mathbf{h}_t = \tanh(\mathbf{W}_x \mathbf{x}_t + \mathbf{W}_h \mathbf{h}_{t-1} + \mathbf{b}) \qquad (1)$$

where $\mathbf{x}$ is the network input and $\mathbf{b}$ the bias term. This kind of connection is not very effective to maintain the information stored for long time instants, as well as it does not allow to forget unneeded information between two time steps. The LSTM enhances the RNN with a series of three multiplicative gates. The structure is the following:

$$\mathbf{i}_t = \sigma(\mathbf{W}_{i_x} \mathbf{x}_t + \mathbf{W}_{i_h} \mathbf{h}_{t-1} + \mathbf{b}_i) \qquad (2)$$

$$\mathbf{f}_t = \sigma(\mathbf{W}_{f_x} \mathbf{x}_t + \mathbf{W}_{f_h} \mathbf{h}_{t-1} + \mathbf{b}_f) \qquad (3)$$

$$\mathbf{o}_t = \sigma(\mathbf{W}_{o_x} \mathbf{x}_t + \mathbf{W}_{o_h} \mathbf{h}_{t-1} + \mathbf{b}_o) \qquad (4)$$

$$\mathbf{s}_t = \tanh(\mathbf{W}_{s_x} \mathbf{x}_t + \mathbf{W}_{s_h} \mathbf{h}_{t-1} + \mathbf{b}_h) \qquad (5)$$

$$\mathbf{c}_t = \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \mathbf{s}_t \qquad (6)$$

$$\mathbf{h}_t = \tanh(\mathbf{c}_t) \odot \mathbf{o}_t \qquad (7)$$

where $\odot$ is the element-wise product. Each gate factor is able to let through or suppress a specific update contribution, thus allowing a selective information retaining. The input gate $\mathbf{i}$ is applied to the cell input $\mathbf{s}$, the forget gate $\mathbf{f}$ to the cell value at the previous time step $\mathbf{c}_{t-1}$, and the output gate $\mathbf{o}$ to the cell output for the current time instant $\mathbf{h}_t$. In this way a cell value can be retained for multiple time steps when $\mathbf{i} = 0$, ignored in the output when $\mathbf{o} = 0$, and forgotten when $\mathbf{f} = 0$.

As dialog utterances are sequential, we feed all utterance vectors of a sitcom scene in sequence into a Long Short-Term Memory block to incorporate contextual information. The memory unit of the LSTM keeps track of the context in each scene, and mimics human memory to accumulate the setup that may trigger a punchline.

Before the output we incorporate a set of high level features from our previous work (Bertero and Fung, 2016b) and past literature (Reyes et al., 2013; Barbieri and Saggion, 2014). They include:

- Structural features: average word length, sentence length, difference in sentence length with the five previous utterances.
- Part of speech proportion: noun, verbs, adjectives and adverbs.
- Antonyms: proportion of antonym words with the previous utterance (from WordNet (Miller, 1995)).
- Sentiment: positive, negative and average sentiment score among all words (from SentiWordNet (Esuli and Sebastiani, 2006)).
- Speaker and turn: speaker character identity and utterance position in the turn (beginning, middle, end, isolated).
- Speaking rate: time duration of the utterance from the subtitle files, divided by the sentence length.

All these features are concatenated to the LSTM output, and a softmax layer is applied to get the final output probabilities.

3 Experiments

3.1 Corpus

We built a corpus from the popular TV-sitcom “The Big Bang Theory”, seasons 1 to 6. We downloaded the subtitle files (annotated with the timestamps of each utterance) and the scripts[2], used to segment all the episodes into scenes and get the speaker identity of each utterance. We extracted the audio track of each episode in order to retrieve the canned laughters timestamps, with a vocal removal tool followed by a silence/sound detector. We then annotated each utterance as a punchline in case it was followed by a laughter within $1s$, assuming that utterances not

CNN	70.0	66.7	59.4	**62.9**
LSTM	68.4	66.2	53.4	59.1

Table 2: Comparison between a CNN and a LSTM sentence encoding input.

followed by a laughter would be the setup for the punchline.

We obtained a total of 135 episodes, 1589 overall scenes, 42.8% of punchlines, and an average interval between two punchlines of 2.2 utterances. We built a training set of 80% of the overall episodes, and a development and test set of 10% each. The episodes were drawn from all the seasons with the same proportion. The total number of utterances is 35865 for the training set, 3904 for the development set and 3903 for the test set.

3.2 Experimental setup and baseline

In the neural network we set the size to 100 for all the hidden layers of the CNN and the LSTM, and 5 to the convolutional window. We applied a dropout regularization layer (Srivastava et al., 2014) after the output of the LSTM, and L2 regularization on the softmax output layer. The network was trained with standard backpropagation, using each scene as a training unit. The development set was used to tune the hyperparameters, and to determine the early stopping condition. When the error on the development set began to increase for the first time we kept training only the final softmax layer, this improved the overall results. The neural network was implemented with THEANO toolkit (Bergstra et al., 2010). We ran experiments with and without the extra high-level feature vector.

As a baseline for comparison we used an implementation of the Conditional Random Field (Lafferty et al., 2001) from CRFSuite (Okazaki, 2007), with L2 regularization. We ran experiments using the same high level feature vector added at the end of the neural network, 1-2-3gram features of a window made by the utterance and the four previous, and the two feature sets combined. We also compared the overall system where we replace the CNN with an LSTM sentence encoder (Li et al., 2015), where we kept the same input features.

3.3 Results and discussion

Results of our system and our baselines are shown in table 1. The LSTM with the aid of the high level feature vector generally outperformed all the CRF baselines with the highest accuracy of 70.0% and the highest F-score of 62.9%. The biggest improvement of the LSTM is the improvement of the recall without affecting too much the precision. Lexical features given by n-gram from a context window are very useful to recognize more punchlines in our baseline experiment, but they also yield many false positives, when the same n-gram is used in different contexts. A CNN-LSTM network seems to overcome this issue as the CNN stage is better in modeling the lexical and semantic content of the utterance, as the LSTM allows to put each utterance in relation with the past context, filtering out many false positives from wrong contexts.

The choice of the CNN is further justified by the results obtained from the comparison between the CNN and the LSTM sentence encoding input, shown in table 2. The CNN is more effective, obtaining a recall of 10% higher and 6% more in F-score. The CNN is a simpler model that might benefit more of a small-size corpus. It also required a much shorter training time compared to the LSTM. We may consider in the future to use more data, and try other sentence input encoders, including deeper or bi-directional LSTMs, to find the most effective one.

Predicting humor response from the canned laughters is a particularly challenging task. In some cases canned laughters are inserted by the show producers with the purpose of solicit response to weak jokes, where otherwise people would not laugh. The audience must also be kept constantly amused, extra canned laughters may help in scenes where fewer jokes are used.

4 Conclusion and future work

We proposed a Long Short-Term Memory based framework to predict punchlines in a humorous dialog. We showed that our neural network is particularly effective in increasing the F-score to 62.9% over a Conditional Random Field baseline of 58.1%. We furthermore showed that the LSTM is more effective in obtaining an higher recall with fewer false positives compared to simple n-gram shifting context window features.

As future work we plan to use a virtual agent system to collect a set of human-robot humorous interactions, and adapt our model to predict humor from them.

Conversational Flow in Oxford-style Debates

Abstract

Public debates are a common platform for presenting and juxtaposing diverging views on important issues. In this work we propose a methodology for tracking how ideas flow between participants throughout a debate. We use this approach in a case study of Oxford-style debates—a competitive format where the winner is determined by audience votes—and show how the outcome of a debate depends on aspects of conversational flow. In particular, we find that winners tend to make better use of a debate's interactive component than losers, by actively pursuing their opponents' points rather than promoting their own ideas over the course of the conversation.

1 Introduction

Public debates are a common platform for presenting and juxtaposing diverging viewpoints. As opposed to monologues where speakers are limited to expressing their own beliefs, debates allow for participants to interactively attack their opponents' points while defending their own. The resulting flow of ideas is a key feature of this conversation genre.

In this work we introduce a computational framework for characterizing debates in terms of conversational flow. This framework captures two main debating strategies—promoting one's own points and attacking the opponents' points—and tracks their relative usage throughout the debate. By applying this methodology to a setting where debate winners are known, we show that conversational flow patterns are predictive of which debater is more likely to persuade an audience.

Case study: Oxford-style debates. Oxford-style debates provide a setting that is particularly convenient for studying the effects of conversational flow. In this competitive debate format, two teams argue for or against a preset motion in order to persuade a live audience to take their position. The audience votes before and after the debate, and the winning team is the one that sways more of the audience towards its view. This setup allows us to focus on the effects of conversational flow since it disentangles them from the audience's prior leaning.[1]

The debate format involves an opening statement from the two sides, which presents an overview of their arguments before the discussion begins. This allows us to easily identify talking points held by the participants prior to the interaction, and consider them separately from points introduced spontaneously to serve the discussion.

This work is taking steps towards better modeling of conversational dynamics, by: (i) introducing a debate dataset with rich metadata (Section 2), (ii) proposing a framework for tracking the flow of ideas (Section 3), and (iii) showing its effectiveness in a predictive setting (Section 4).

2 Debate Dataset: Intelligence Squared

In this study we use transcripts and results of Oxford-style debates from the public debate series "Intelligence Squared Debates" (IQ2 for short).[2] These debates are recorded live, and contain motions covering a diversity of topics ranging from for-

[1] Other potential confounding factors are mitigated by the tight format and topic enforced by the debate's moderator.

San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

eign policy issues to the benefits of organic food. Each debate consists of two opposing teams—one for the motion and one against— of two or three experts in the topic of the particular motion, along with a moderator. Each debate follows the Oxford-style format and consists of three rounds. In the *introduction*, each debater is given 7 minutes to lay out their main points. During the *discussion*, debaters take questions from the moderator and audience, and respond to attacks from the other team. This round lasts around 30 minutes and is highly interactive; teams frequently engage in direct conversation with each other. Finally, in the *conclusion*, each debater is given 2 minutes to make final remarks.

Our dataset consists of the transcripts of all debates held by IQ2 in the US from September 2006 up to September 2015; in total, there are 108 debates.[3] Each debate is quite extensive: on average, 12801 words are uttered in 117 turns by members of either side per debate.[4]

Winning side labels. We follow IQ2's criteria for deciding who wins a debate, as follows. Before the debate, the live audience votes on whether they are for, against, or undecided on the motion. A second round of voting occurs after the debate. A side wins the debate if the difference between the percentage of votes they receive post- and pre-debate (the "delta") is greater than that of the other side's. Often the debates are quite tight: for 30% of the debates, the difference between the winning and losing sides' deltas is less than 10%.

Audience feedback. We check that the voting results are meaningful by verifying that audience reactions to the debaters are related to debate outcome. Using laughter and applause received by each side in each round[5] as markers of positive reactions, we note that differences in audience reception of the two sides emerge over the course of the debate. While both sides get similar levels of reaction during the introduction, winning teams tend to receive more laughter during the discussion ($p < 0.001$)[6] and more applause during the conclusion ($p = 0.05$).

Example debate. We will use a debate over the motion "Millennials don't stand a chance" (henceforth *Millennials*) as a running example.[7] The For side won the debate with a delta of 20% of the votes, compared to the Against side which only gained 5%.

3 Modeling Idea Flow

Promoting one's own points and addressing the opponent's points are two primary debating strategies. Here we introduce a methodology to identify these strategies, and use it to investigate their usage and effect on a debate's outcome.[8]

Identifying talking points. We first focus on ideas which form the basis of a side's stance on the motion. We identify such *talking points* by considering words whose frequency of usage differs significantly between the two teams during the introduction, before any interaction takes place. To find these words, we use the method introduced by Monroe et al. (2008) in the context of U.S. Senate speeches. In particular, we estimate the divergence between the two sides' word-usage in the introduction, where word-usage is modeled as multinomial distributions smoothed with a uniform Dirichlet prior, and divergence is given by log-odds ratio. The most discriminating words are those with the highest and lowest z-scores of divergence estimates. For a side X, we define the set of talking points $\mathcal{W}_X$ to be the k words with the highest or lowest z-scores.[9] We distinguish between X's *own* talking points $\mathcal{W}_X$, and the *opposing* talking points $\mathcal{W}_Y$ belonging to its opponent Y. These are examples of talking points for the "Millennials" debate:

Side	Talking points
For	debt, boomer, college, reality
Against	economy, volunteer, home, engage

The flow of talking points. A side can either promote its own talking points, address its opponent's points, or steer away from these initially salient

[3] We omitted one debate due to pdf parsing errors.

[4] The processed data is available at `http://www.cs.cornell.edu/~cristian/debates/`.

[5] Laughter and applause are indicated in the transcripts.

[6] Unless otherwise indicated, all reported p-values are calculated using the Wilcoxon signed-rank test.

[7] `http://www.intelligencesquaredus.org/debates/past-debates/item/1019-millennials-dont-stand-a-chance`

[8] In the subsequent discussion, we treat all utterances of a particular side as coming from a single speaker and defer modeling interactions within teams to future work.

[9] In order to focus on concepts central to the sides' arguments, we discard stopwords, perform stemming on the text, and take $k = 20$. We set these parameters by examining one subsequently discarded debate.

Talking point	volunteer	boomer
Introduction	AGAINST: [millennials] **volunteer** more than any generation. 73 percent of millennials **volunteered** for a nonprofit in 2012. And the percentage of [students] believing that it's [...] important to help people in need is [at the highest level] in 40 years.	FOR: [*referring to college completion rate*] the **boomer** generation is now [at] 32 percent. [Millennials] are currently at [...] 33 percent. So this notion that [millennials] have more education at this point in time than anybody else is not actually true.
Discussion	FOR: I'd make the argument [that] **volunteering** [is done] for exntrinsic [sic] reasons. So, it's done for college applications, or it's done because it's a requirement in high school.	FOR: It stinks to be young, having gone through what your generation [*referring to millennials*] has gone through. But keep in mind that [...] the **boomers** [...] have gone through the same.

Table 1: Example talking points used throughout the "Millennials" debate. Each talking point belongs to the side uttering the first excerpt, taken from the introduction; the second excerpt is from the discussion section. In the first example, the For side addresses the opposing talking point **volunteer** during the discussion; in the second example the For side refers to their own talking point **boomer** and recalls it later in the discussion.

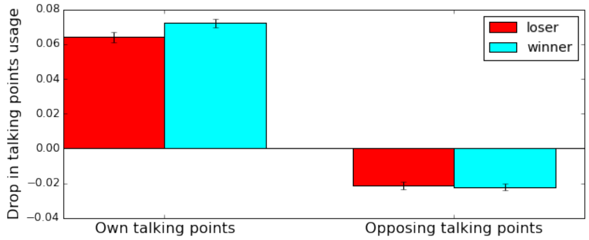

Figure 1: The start of the debate's interactive stage triggers a drop in self-coverage (> 0, indicated by leftmost two bars) and a rise in opponent-coverage (< 0, indicated by rightmost bars), with eventual winners showing a more pronounced drop in self-coverage (comparing the two bars on the left).

ideas altogether. We quantify the use of these strategies by comparing the airtime debaters devote to talking points. For a side X, let the *self-coverage* $f_r(X, X)$ be the fraction of content words uttered by X in round r that are among their own talking points $\mathcal{W}_X$; and the *opponent-coverage* $f_r(X, Y)$ be the fraction of its content words covering opposing talking points $\mathcal{W}_Y$.

Not surprisingly, we find that self-coverage dominates during the discussion ($f_{\text{Disc}}(X, X) > f_{\text{Disc}}(X, Y)$, $p < 0.001$). However, this does not mean debaters are simply giving monologues and ignoring each other: the effect of the interaction is reflected in a sharp drop in self-coverage and a rise in opponent-coverage once the discussion round begins. Respectively, $f_{\text{Disc}}(X, X) < f_{\text{Intro}}(X, X)$ and $f_{\text{Disc}}(X, Y) > f_{\text{Intro}}(X, Y)$, both $p < 0.001$. Examples of self- and opponent-coverage of two talking points in the "Millennials" debate from the introduction and discussion are given in Table 1.

Does the change in focus translate to any strategic advantages? Figure 1 suggests this is the case: the drop in self-coverage is slightly larger for the side that eventually wins the debate ($p = 0.08$). The drop in the sum of self- and opponent-coverage is also larger for winning teams, suggesting that they are more likely to steer away from discussing *any* talking points from either side ($p = 0.05$).

Identifying discussion points. Having seen that debaters can benefit by shifting away from talking points that were salient during the introduction, we now examine the ideas that spontaneously arise to serve the discussion. We model such *discussion points* as words introduced to the debate during the discussion by a debater and adopted by his opponents at least twice.[10] This allows us to focus on words that become relevant to the conversation; only 3% of all newly introduced words qualify, amounting to about 10 discussion points per debate.

The flow of discussion points. The adoption of discussion points plays an important role in persuading the audience: during the discussion, eventual winners adopt more discussion points introduced by their opponents than eventual losers ($p < 0.01$). Two possible strategic interpretations emerge. From a topic control angle (Nguyen et al., 2014), perhaps losers are more successful at imposing their discussion points to gain control of the discussion. This view appears counterintuitive given work linking topic control to influence in other settings (Planalp and Tracy, 1980; Rienks et al., 2006).

[10] Ignoring single repetitions discards simple echoing of words used by the previous speaker.

AGAINST: I would say [millennials] are effectively moving towards goals [...] it might seem like immaturity if you don't actually talk to millennials and look at the **statistics**. FOR: –actually, the numbers are showing [...] that it's worsening [...] Same **statistics**, dreadful **statistics**.
AGAINST: [...] there's a incredible [sic] advantage that millennials have when it comes to social media [...] because we have an understanding of that landscape as **digital** natives [...] FOR: Generation X [...] is also known as the **digital** generation. The companies [...] that make you **digital** natives were all founded by [...] people in generation X. It's simply inaccurate every time somebody says that the millennial generation is the only generation [...]

Table 2: Example discussion points introduced by the Against side in the "Millennials" debate. For each point, the first excerpt is the context in which the point was first mentioned by the Against side in the discussion, and the second excerpt shows the For side challenging the point later on.

An alternative interpretation could be that winners are more active than losers in contesting their opponents' points, a strategy that might play out favorably to the audience. A post-hoc manual examination supports this interpretation: 78% of the valid discussion points are picked up by the opposing side in order to be challenged;[11] this strategy is exemplified in Table 2. Overall, these observations tying the flow of discussion points to the debate's outcome suggest that winners are more successful at using the interaction to engage with their opponents' ideas.

4 Predictive Power

We evaluate the predictive power of our flow features in a binary classification setting: predict whether the For or Against side wins the debate.[12] This is a challenging task even for humans, thus the dramatic reveal at the end of each IQ2 debate that partly explains the popularity of the show. Our goal here is limited to understanding which of the flow features that we developed carry predictive power.

Conversation flow features. We use all conversational features discussed above. For each side X we include $f_{\text{Disc}}(X, X)$, $f_{\text{Disc}}(X, Y)$, and their sum. We also use the drop in self-coverage given by subtracting corresponding values for $f_{\text{Intro}}(\cdot, \cdot)$, and the number of discussion points adopted by each side. We call these the *Flow* features.

Baseline features. To discard the possibility that our results are simply explained by debater verbosity, we use the number of words uttered and number of turns taken by each side (*length*) as baselines. We also compare to a unigram baseline (*BOW*).

Audience features. We use the counts of applause and laughter received by each side (described in Section 2) as rough indicators of how well the audience can foresee a debate's outcome.

Prediction accuracy is evaluated using a leave-one-out (LOO) approach. We use logistic regression; model parameters for each LOO train-test split are selected via 3-fold cross-validation on the training set. To find particularly predictive flow features, we also try using univariate feature selection on the flow features before the model is fitted in each split; we refer to this setting as *Flow**.[13]

We find that conversation flow features obtain the best accuracy among all listed feature types (Flow: 63%; Flow*: 65%), performing significantly higher than a 50% random baseline (binomial test $p < 0.05$), and comparable to audience features (60%). In contrast, the length and BOW baselines do not perform better than chance. We note that *Flow* features perform competitively despite being the only ones that do not factor in the concluding round.

The features selected most often in the Flow* task are: the number of discussion points adopted (with positive regression coefficients), the recall of talking points during the discussion round (negative coefficients), and the drop in usage of own talking points from introduction to discussion (positive coefficients). The relative importance of these features, which focus on the interaction between teams, suggests that audiences tend to favor debating strategies which emphasize the discussion.

[11] Three annotators (including one author) informally annotated a random sample of 50 discussion points in the context of all dialogue excerpts where the point was used. According to a majority vote, in 26 cases the opponents challenged the point, in 7 cases the point was supported, 4 cases were unclear, and in 13 cases the annotators deemed the discussion point invalid. We discuss the last category in Section 6.

[12] The task is balanced: after removing three debates ending in a tie, we have 52 debates won by For and 53 by Against.

[13] We optimize the regularizer (ℓ_1 or ℓ_2), and the value of the regularization parameter C (between 10^{-5} and 10^5). For Flow* we also optimize the number of features selected.

5 Further Related Work

Previous work on conversational structure has proposed approaches to model dialogue acts (Samuel et al., 1998; Ritter et al., 2010; Ferschke et al., 2012) or disentangle interleaved conversations (Elsner and Charniak, 2010; Elsner and Charniak, 2011). Other research has considered the problem of detecting conversation-level traits such as the presence of disagreements (Allen et al., 2014; Wang and Cardie, 2014) or the likelihood of relation dissolution (Niculae et al., 2015). At the participant level, several studies present approaches to identify ideological stances (Somasundaran and Wiebe, 2010; Rosenthal and McKeown, 2015), using features based on participant interactions (Thomas et al., 2006; Sridhar et al., 2015), or extracting words and reasons characterizing a stance (Monroe et al., 2008; Nguyen et al., 2010; Hasan and Ng, 2014). In our setting, both the stances and the turn structure of a debate are known, allowing us to instead focus on the debate's outcome.

Existing research on argumentation strategies has largely focused on exploiting the structure of monologic arguments (Mochales and Moens, 2011), like those of persuasive essays (Feng and Hirst, 2011; Stab and Gurevych, 2014). In addition, Tan et al. (2016) has examined the effectiveness of arguments in the context of a forum where people invite others to challenge their opinions. We complement this line of work by looking at the relative persuasiveness of participants in extended conversations as they exchange arguments over multiple turns.

Previous studies of influence in extended conversations have largely dealt with the political domain, examining moderated but relatively unstructured settings such as talk shows or presidential debates, and suggesting features like topic control (Nguyen et al., 2014), linguistic style matching (Romero et al., 2015) and turn-taking (Prabhakaran et al., 2013). With persuasion in mind, our work extends these studies to explore a new dynamic, the flow of ideas between speakers, in a highly structured setting that controls for confounding factors.

6 Limitations and Future Work

This study opens several avenues for future research. One could explore more complex representations of talking points and discussion points, for instance using topic models or word embeddings. Furthermore, augmenting the flow of content in a conversation with the speakers' linguistic choices could better capture their intentions. In addition, it would be interesting to study the interplay between our conversational flow features and relatively monologic features that consider the argumentative and rhetorical traits of each side separately. More explicitly comparing and contrasting monologic and interactive dynamics could lead to better models of conversations. Such approaches could also help clarify some of the intuitions about conversations explored in this work, particularly that engaging in dialogue carries different strategic implications from self-promotion.

Our focus in this paper is on capturing and understanding conversational flow. We hence make some simplifying assumptions that could be refined in future work. For instance, by using a basic unigram-based definition of discussion points, we do not account for the context or semantic sense in which these points occur. In particular, our annotators found that a significant proportion of the discussion points under our definition actually referred to differing ideas in the various contexts in which they appeared. We expect that improving our retrieval model will also improve the robustness of our idea flow analysis. A better model of discussion points could also provide more insight into the role of these points in persuading the audience.

While Oxford-style debates are a particularly convenient setting for studying the effects of conversational flow, our dataset is limited in terms of size. It would be worthwhile to examine the flow features we developed in the context of settings with richer incentives beyond persuading an audience, such as in the semi-cooperative environment of Wikipedia talk pages. Finally, our methodology could point to applications in areas such as education and cooperative work, where it is key to establish the link between conversation features and an interlocutor's ability to convey their point (Niculae and Danescu-Niculescu-Mizil, 2016).

Abstract

In this work, we present a novel *counter-fitting* method which injects antonymy and synonymy constraints into vector space representations in order to improve the vectors' capability for judging semantic similarity. Applying this method to publicly available pre-trained word vectors leads to a new state of the art performance on the SimLex-999 dataset. We also show how the method can be used to tailor the word vector space for the downstream task of dialogue state tracking, resulting in robust improvements across different dialogue domains.

1 Introduction

Many popular methods that induce representations for words rely on the *distributional hypothesis* – the assumption that semantically similar or related words appear in similar contexts. This hypothesis supports unsupervised learning of meaningful word representations from large corpora (Curran, 2003; Ó Séaghdha and Korhonen, 2014; Mikolov et al., 2013; Pennington et al., 2014). Word vectors trained using these methods have proven useful for many downstream tasks including machine translation (Zou et al., 2013) and dependency parsing (Bansal et al., 2014).

One drawback of learning word embeddings from co-occurrence information in corpora is that it tends to coalesce the notions of *semantic similarity* and *conceptual association* (Hill et al., 2014b). Furthermore, even methods that can distinguish similarity from association (e.g., based on syntactic co-occurrences) will generally fail to tell synonyms from antonyms (Mohammad et al., 2008). For example, words such as *east* and *west* or *expensive* and *inexpensive* appear in near-identical contexts, which means that distributional models produce very similar word vectors for such words. Examples of such anomalies in GloVe vectors can be seen in Table 1, where words such as *cheaper* and *inexpensive* are deemed similar to (their antonym) *expensive*.

A second drawback is that similarity and antonymy can be application- or domain-specific. In our case, we are interested in exploiting distributional knowledge for the *dialogue state tracking* task (DST). The DST component of a dialogue system is responsible for interpreting users' utterances and updating the system's *belief state* – a probability distribution over all possible states of the dialogue. For example, a DST for the restaurant domain needs to detect whether the user wants a *cheap* or *expensive* restaurant. Being able to generalise using distributional information while still distinguishing between semantically different yet conceptually related words

Proceedings of NAACL-HLT 2016, pages 142–148,
San Diego, California, June 12-17, 2016.

(e.g. *cheaper* and *pricey*) is critical for the performance of dialogue systems. In particular, a dialogue system can be led seriously astray by false synonyms.

We propose a method that addresses these two drawbacks by using synonymy and antonymy relations drawn from either a general lexical resource or an application-specific ontology to fine-tune distributional word vectors. Our method, which we term *counter-fitting*, is a lightweight post-processing procedure in the spirit of *retrofitting* (Faruqui et al., 2015). The second row of Table 1 illustrates the results of counter-fitting: the nearest neighbours capture true similarity much more intuitively than the original GloVe vectors. The procedure improves word vector quality regardless of the initial word vectors provided as input.[1] By applying counter-fitting to the Paragram-SL999 word vectors provided by Wieting et al. (2015), we achieve new state-of-the-art performance on SimLex-999, a dataset designed to measure how well different models judge semantic similarity between words (Hill et al., 2014b). We also show that the counter-fitting method can inject knowledge of dialogue domain ontologies into word vector space representations to facilitate the construction of semantic dictionaries which improve DST performance across two different dialogue domains. Our tool and word vectors are available at `github.com/nmrksic/counter-fitting`.

2 Related Work

Most work on improving word vector representations using lexical resources has focused on bringing words which are known to be semantically related closer together in the vector space. Some methods modify the prior or the regularization of the original training procedure (Yu and Dredze, 2014; Bian et al., 2014; Kiela et al., 2015). Wieting et al. (2015) use the Paraphrase Database (Ganitkevitch et al., 2013) to train word vectors which emphasise word similarity over word relatedness. These word vectors achieve the current state-of-the-art performance on the SimLex-999 dataset and are used as input for counter-fitting in our experiments.

Recently, there has been interest in lightweight post-processing procedures that use lexical knowledge to refine off-the-shelf word vectors without requiring large corpora for (re-)training as the aforementioned "heavyweight" procedures do. Faruqui et al.'s (2015) *retrofitting* approach uses similarity constraints from WordNet and other resources to pull similar words closer together.

The complications caused by antonymy for distributional methods are well-known in the semantics community. Most prior work focuses on extracting antonym pairs from text rather than exploiting them (Lin et al., 2003; Mohammad et al., 2008; Turney, 2008; Hashimoto et al., 2012; Mohammad et al., 2013). The most common use of antonymy information is to provide features for systems that detect contradictions or logical entailment (Marcu and Echihabi, 2002; de Marneffe et al., 2008; Zanzotto et al., 2009). As far as we are aware, there is no previous work on exploiting antonymy in dialogue systems. The modelling work closest to ours are Liu et al. (2015), who use antonymy and WordNet hierarchy information to modify the heavyweight Word2Vec training objective; Yih et al. (2012), who use a Siamese neural network to improve the quality of Latent Semantic Analysis vectors; Schwartz et al. (2015), who build a standard distributional model from co-occurrences based on *symmetric patterns*, with specified antonymy patterns counted as negative co-occurrences; and Ono et al. (2015), who use thesauri and distributional data to train word embeddings specialised for capturing antonymy.

3 Counter-fitting Word Vectors to Linguistic Constraints

Our starting point is an indexed set of word vectors $V = \{\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_N\}$ with one vector for each word in the vocabulary. We will inject semantic relations into this vector space to produce new word vectors $V' = \{\mathbf{v'}_1, \mathbf{v'}_2, \ldots, \mathbf{v'}_N\}$. For antonymy and synonymy we have a set of constraints A and S, respectively. The elements of each set are pairs of word indices; for example, each pair (i, j) in S is such that the i-th and j-th words in the vocabulary are synonyms. The objective function used to counter-fit the pre-trained word vectors V to the sets of linguistic constraints A and S contains three different terms:

[1] When we write "improve", we refer to improving the vector space for a specific purpose. We do not expect that a vector space fine-tuned for semantic similarity will give better results on semantic relatedness. As Mohammad et al. (2008) observe, antonymous concepts are related but not similar.

1. Antonym Repel (AR): This term serves to *push* antonymous words' vectors away from each other in the transformed vector space V':

$$\text{AR}(V') = \sum_{(u,w)\in A} \tau\left(\delta - d(\mathbf{v}'_u, \mathbf{v}'_w)\right)$$

where $d(v_i, v_j) = 1 - \cos(v_i, v_j)$ is a distance derived from cosine similarity and $\tau(x) \triangleq max(0, x)$ imposes a margin on the cost. Intuitively, δ is the "ideal" minimum distance between antonymous words; in our experiments we set $\delta = 1.0$ as it corresponds to vector orthogonality.

2. Synonym Attract (SA): The counter-fitting procedure should seek to bring the word vectors of known synonymous word pairs closer together:

$$\text{SA}(V') = \sum_{(u,w)\in S} \tau\left(d(\mathbf{v}'_u, \mathbf{v}'_w) - \gamma\right)$$

where γ is the "ideal" maximum distance between synonymous words; we use $\gamma = 0$.

3. Vector Space Preservation (VSP): the topology of the original vector space describes relationships between words in the vocabulary captured using distributional information from very large textual corpora. The VSP term bends the transformed vector space towards the original one as much as possible in order to preserve the semantic information contained in the original vectors:

$$\text{VSP}(V, V') = \sum_{i=1}^{N} \sum_{j\in N(i)} \tau\left(d(\mathbf{v}'_i, \mathbf{v}'_j) - d(\mathbf{v}_i, \mathbf{v}_j)\right)$$

For computational efficiency, we do not calculate distances for every pair of words in the vocabulary. Instead, we focus on the (pre-computed) neighbourhood $N(i)$, which denotes the set of words within a certain radius ρ around the i-th word's vector in the original vector space V. Our experiments indicate that counter-fitting is relatively insensitive to the choice of ρ, with values between 0.2 and 0.4 showing little difference in quality; here we use $\rho = 0.2$.

The objective function for the training procedure is given by a weighted sum of the three terms:

$$C(V, V') = k_1\text{AR}(V') + k_2\text{SA}(V') + k_3\text{VSP}(V, V')$$

where $k_1, k_2, k_3 \geq 0$ are hyperparameters that control the relative importance of each term. In our experiments we set them to be equal: $k_1 = k_2 = k_3$. To minimise the cost function for a set of starting vectors V and produce counter-fitted vectors V', we run stochastic gradient descent (SGD) for 20 epochs. An end-to-end run of counter-fitting takes less than two minutes on a laptop with four CPUs.

3.1 Injecting Dialogue Domain Ontologies into Vector Space Representations

Dialogue state tracking (DST) models capture users' goals given their utterances. Goals are represented as sets of constraints expressed by *slot-value* pairs such as [food: *Indian*] or [parking: *allowed*]. The set of slots S and the set of values V_s for each slot make up the *ontology* of a dialogue domain.

In this paper we adopt the recurrent neural network (RNN) framework for tracking suggested in (Henderson et al., 2014d; Henderson et al., 2014c; Mrkšić et al., 2015). Rather than using a spoken language understanding (SLU) decoder to convert user utterances into meaning representations, this model operates directly on the n-gram features extracted from the automated speech recognition (ASR) hypotheses. A drawback of this approach is that the RNN model can only perform exact string matching to detect the slot names and values mentioned by the user. It cannot recognise synonymous words such as *pricey* and *expensive*, or even subtle morphological variations such as *moderate* and *moderately*. A simple way to mitigate this problem is to use *semantic dictionaries*: lists of rephrasings for the values in the ontology. Manual construction of dictionaries is highly labour-intensive; however, if one could automatically detect high-quality rephrasings, then this capability would come at no extra cost to the system designer.

To obtain a set of word vectors which can be used for creating a semantic dictionary, we need to *inject* the domain ontology into the vector space. This can be achieved by introducing antonymy constraints between all the possible values of each slot (i.e. *Chinese* and *Indian*, *expensive* and *cheap*, etc.). The remaining linguistic constraints can come from semantic lexicons: the richer the sets of injected synonyms and antonyms are, the better the resulting word representations will become.

Model / Word Vectors	ρ
Neural MT Model (Hill et al., 2014a)	0.52
Symmetric Patterns (Schwartz et al., 2015)	0.56
Non-distributional Vectors (Faruqui and Dyer, 2015)	0.58

GloVe vectors + Retrofitting	0.53
GloVe + Counter-fitting	0.58
Paragram-SL999 (Wieting et al., 2015)	0.69
Paragram-SL999 + Retrofitting	0.68
Paragram-SL999 + Counter-fitting	**0.74**
Inter-annotator agreement	0.67
Annotator/gold standard agreement	0.78

Table 2: Performance on SimLex-999. Retrofitting uses the code and (PPDB) data provided by the authors

4 Experiments

4.1 Word Vectors and Semantic Lexicons

Two different collections of pre-trained word vectors were used as input to the counter-fitting procedure:

1. **Glove Common Crawl** 300-dimensional vectors made available by Pennington et al. (2014).

2. **Paragram-SL999** 300-dimensional vectors made available by Wieting et al. (2015).

The synonymy and antonymy constraints were obtained from two semantic lexicons:

1. **PPDB 2.0 (Pavlick et al., 2015):** the latest release of the Paraphrase Database. A new feature of this version is that it assigns relation types to its word pairs. We identify the *Equivalence* relation with synonymy and *Exclusion* with antonymy. We used the largest available (XXXL) version of the database and only considered single-token terms.

2. **WordNet (Miller, 1995)**: a well known semantic lexicon which contains vast amounts of high quality human-annotated synonym and antonym pairs. Any two words in our vocabulary which had antonymous word senses were considered antonyms; WordNet synonyms were not used.

In total, the lexicons yielded 12,802 antonymy and 31,828 synonymy pairs for our vocabulary, which consisted of 76,427 most frequent words in OpenSubtitles, obtained from `invokeit.wordpress.com/frequency-word-lists/`.

Semantic Resource	Glove	Paragram
Baseline (no linguistic constraints)	0.41	0.69
PPDB− (PPDB antonyms)	0.43	0.69
PPDB+ (PPDB synonyms)	0.46	0.68
WordNet− (WordNet antonyms)	0.52	0.74
PPDB− and PPDB+	0.50	0.69
WordNet− and PPDB−	0.53	0.74
WordNet− and PPDB+	0.58	0.74
WordNet− and PPDB− and PPDB+	0.58	0.74

Table 3: SimLex-999 performance when different sets of linguistic constraints are used for counter-fitting

4.2 Improving Lexical Similarity Predictions

In this section, we show that counter-fitting pre-trained word vectors with linguistic constraints improves their usefulness for judging semantic similarity. We use Spearman's rank correlation coefficient with the SimLex-999 dataset, which contains word pairs ranked by a large number of annotators instructed to consider only semantic similarity.

Table 2 contains a summary of recently reported competitive scores for SimLex-999, as well as the performance of the unaltered, retrofitted and counter-fitted GloVe and Paragram-SL999 word vectors. To the best of our knowledge, the 0.685 figure reported for the latter represents the current high score. This figure is above the average inter-annotator agreement of 0.67, which has been referred to as the ceiling performance in most work up to now.

In our opinion, the average inter-annotator agreement is not the only meaningful measure of ceiling performance. We believe it also makes sense to compare: **a)** the model ranking's correlation with the gold standard ranking to: **b)** the average rank correlation that individual human annotators' rankings achieved with the gold standard ranking. The SimLex-999 authors have informed us that the average annotator agreement with the gold standard is 0.78.[2] As shown in Table 2, the reported performance of all the models and word vectors falls well below this figure.

Retrofitting pre-trained word vectors improves GloVe vectors, but not the already semantically specialised Paragram-SL999 vectors. Counter-fitting substantially improves both sets of vectors, showing that injecting antonymy relations goes a long way

[2] This figure is now reported as a potentially fairer ceiling performance on the SimLex-999 website: `http://www.cl.cam.ac.uk/~fh295/simlex.html`.

False Synonyms	Fixed	False Antonyms	Fixed
sunset, sunrise	✓	dumb, dense	
forget, ignore		adult, guardian	
girl, maid		polite, proper	✓✓
happiness, luck	✓✓	strength, might	
south, north	✓	water, ice	
go, come	✓	violent, angry	✓✓
groom, bride		cat, lion	✓✓
dinner, breakfast		laden, heavy	✓✓
-	-	engage, marry	

Table 4: Highest-error SimLex-999 word pairs using Paragram vectors (before counter-fitting)

towards improving word vectors for the purpose of making semantic similarity judgements.

Table 3 shows the effect of injecting different categories of linguistic constraints. GloVe vectors benefit from all three sets of constraints, whereas the quality of Paragram vectors, already exposed to PPDB, only improves with the injection of WordNet antonyms. Table 4 illustrates how incorrect similarity predictions based on the original (Paragram) vectors can be fixed through counter-fitting. The table presents eight false synonyms and nine false antonyms: word pairs with predicted rank in the top (bottom) 200 word pairs and gold standard rank 500 or more positions lower (higher). Eight of these errors are fixed by counter-fitting: the difference between predicted and gold-standard ranks is now 100 or less. Interestingly, five of the eight corrected word pairs do not appear in the sets of linguistic constraints; these are indicated by double ticks in the table. This shows that secondary (i.e. *indirect*) interactions through the three terms of the cost function do contribute to the semantic content of the transformed vector space.

4.3 Improving Dialogue State Tracking

Table 5 shows the dialogue state tracking datasets used for evaluation. These datasets come from the Dialogue State Tracking Challenges 2 and 3 (Henderson et al., 2014a; Henderson et al., 2014b).

We used four different sets of word vectors to construct semantic dictionaries: the original GloVe and Paragram-SL999 vectors, as well as versions counter-fitted to each domain ontology. The constraints used for counter-fitting were all those from the previous section as well as antonymy constraints among the set of values for each slot. We treated all vocabulary words within some radius t of a slot value as rephrasings of that value. The optimal value of t was determined using a grid search: we generated a dictionary and trained a model for each potential t, then evaluated on the development set. Table 6 shows the performance of RNN models which used the constructed dictionaries. The dictionaries induced from the pre-trained vectors substantially improved tracking performance over the baselines (which used no semantic dictionaries). The dictionaries created using the counter-fitted vectors improved performance even further. Contrary to the SimLex-999 experiments, starting from the Paragram vectors did not lead to superior performance, which shows that injecting the application-specific ontology is at least as important as the quality of the initial word vectors.

Dataset	Train	Dev	Test	#Slots
Restaurants	1612	506	1117	4
Tourist Information	1600	439	225	9

Table 5: Number of dialogues in the dataset splits used for the Dialogue State Tracking experiments

Word Vector Space	Restaurants	Tourist Info
Baseline (no dictionary)	68.6	60.5
GloVe	72.5	60.9
GloVe + Counter-fitting	73.4	**62.8**
Paragram-SL999	73.2	61.5
Paragram-SL999 + Counter-fitting	**73.5**	61.9

Table 6: Performance of RNN belief trackers (ensembles of four models) with different semantic dictionaries

5 Conclusion

We have presented a novel *counter-fitting* method for injecting linguistic constraints into word vector space representations. The method efficiently post-processes word vectors to improve their usefulness for tasks which involve making semantic similarity judgements. Its focus on separating vector representations of antonymous word pairs lead to substantial improvements on genuine similarity estimation tasks. We have also shown that counter-fitting can tailor word vectors for downstream tasks by using it to inject domain ontologies into word vectors used to construct semantic dictionaries for dialogue systems.

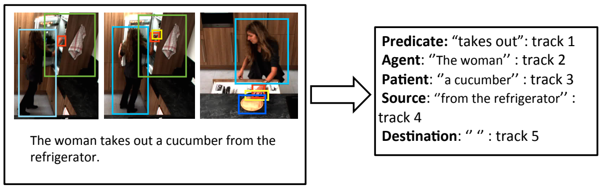
Abstract

Semantic Role Labeling (SRL) captures semantic roles (or participants) such as `agent`, `patient`, and `theme` associated with verbs from the text. While it provides important intermediate semantic representations for many traditional NLP tasks (such as information extraction and question answering), it does not capture grounded semantics so that an artificial agent can reason, learn, and perform the actions with respect to the physical environment. To address this problem, this paper extends traditional SRL to grounded SRL where arguments of verbs are grounded to participants of actions in the physical world. By integrating language and vision processing through joint inference, our approach not only grounds explicit roles, but also grounds implicit roles that are not explicitly mentioned in language descriptions. This paper describes our empirical results and discusses challenges and future directions.

1 Introduction

Linguistic studies capture semantics of verbs by their frames of thematic roles (also referred to as semantic roles or verb arguments) (Levin, 1993). For example, a verb can be characterized by `agent` (i.e., the animator of the action) and `patient` (i.e., the object on which the action is acted upon), and other roles such as `instrument`, `source`, `destination`, etc. Given a verb frame, the goal of Semantic Role Labeling (SRL) is to identify linguistic entities from the text that serve different thematic roles (Palmer et al., 2005; Gildea and Jurafsky, 2002; Collobert et al., 2011; Zhou and Xu, 2015). For example, given the sentence *the woman takes out a cucumber from the refrigerator.*, *takes out* is the main verb (also called `predicate`); the noun phrase *the woman* is the `agent` of this action; *a cucumber* is the `patient`; and *the refrigerator* is the `source`.



The woman takes out a cucumber from the refrigerator.

Predicate: "takes out": track 1
Agent: "The woman" : track 2
Patient: "a cucumber" : track 3
Source: "from the refrigerator" : track 4
Destination: " " : track 5

Figure 1: An example of grounded semantic role labeling for the sentence *the woman takes out a cucumber from the refrigerator*. The left hand side shows three frames of a video clip with the corresponding language description. The objects in the bounding boxes are tracked and each track has a unique identifier. The right hand side shows the grounding results where each role including the implicit role (`destination`) is grounded to a track id.

SRL captures important semantic representations for actions associated with verbs, which have shown beneficial for a variety of applications such as information extraction (Emanuele et al., 2013) and question answering (Shen and Lapata, 2007). However, the traditional SRL is not targeted to represent verb semantics that are grounded to the physical world so that artificial agents can truly understand the ongoing activities and (learn to) perform the specified actions. To address this issue, we propose a new task on grounded semantic role labeling.

Figure 1 shows an example of grounded SRL.

Proceedings of NAACL-HLT 2016, pages 149–159,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

The sentence *the woman takes out a cucumber from the refrigerator* describes an activity in a visual scene. The semantic role representation from linguistic processing (including implicit roles such as `destination`) is first extracted and then grounded to tracks of visual entities as shown in the video. For example, the verb phrase *take out* is grounded to a trajectory of the right hand. The role `agent` is grounded to the person who actually does the *take-out* action in the visual scene (*track 1*) ; the `patient` is grounded to the cucumber taken out (*track 3*); and the `source` is grounded to the refrigerator (*track 4*). The implicit role of `destination` (which is not explicitly mentioned in the language description) is grounded to the cutting board (*track 5*).

To tackle this problem, we have developed an approach to jointly process language and vision by incorporating semantic role information. In particular, we use a benchmark dataset (TACoS) which consists of parallel video and language descriptions in a complex cooking domain (Regneri et al., 2013) in our investigation. We have further annotated several layers of information for developing and evaluating grounded semantic role labeling algorithms. Compared to previous works on language grounding (Tellex et al., 2011; Yu and Siskind, 2013; Krishnamurthy and Kollar, 2013), our work presents several contributions. First, beyond arguments explicitly mentioned in language descriptions, our work simultaneously grounds explicit and implicit roles with an attempt to better connect verb semantics with actions from the underlying physical world. By incorporating semantic role information, our approach has led to better grounding performance. Second, most previous works only focused on a small number of verbs with limited activities. We base our investigation on a wider range of verbs and in a much more complex domain where object recognition and tracking are notably more difficult. Third, our work results in additional layers of annotation to part of the TACoS dataset. This annotation captures the structure of actions informed by semantic roles from the video. The annotated data is available for download [1]. It will provide a benchmark for future work on grounded SRL.

2 Related Work

Recent years have witnessed an increasing amount of work in integrating language and vision, from earlier image annotation (Ramanathan et al., 2013; Kazemzadeh et al., 2014) to recent image/video caption generation (Kuznetsova et al., 2013; Venugopalan et al., 2015; Ortiz et al., ; Elliott and de Vries, 2015; Devlin et al., 2015), video sentence alignment (Naim et al., 2015; Malmaud et al., 2015), scene generation (Chang et al., 2015), and multimodel embedding incorporating language and vision (Bruni et al., 2014; Lazaridou et al., 2015).

What is more relevant to our work here is recent progress on grounded language understanding, which involves learning meanings of words through connections to machine perception (Roy, 2005) and grounding language expressions to the shared visual world, for example, to visual objects (Liu et al., 2012; Liu and Chai, 2015), to physical landmarks (Tellex et al., 2011; Tellex et al., 2014), and to perceived actions or activities (Tellex et al., 2014; Artzi and Zettlemoyer, 2013).

Different approaches and emphases have been explored. For example, linear programming has been applied to mediate perceptual differences between humans and robots for referential grounding (Liu and Chai, 2015). Approaches to semantic parsing have been applied to ground language to internal world representations (Chen and Mooney, 2008; Artzi and Zettlemoyer, 2013). Logical Semantics with Perception (LSP) (Krishnamurthy and Kollar, 2013) was applied to ground natural language queries to visual referents through jointly parsing natural language (combinatory categorical grammar (CCG)) and visual attribute classification. Graphical models have been applied to word grounding. For example, a generative model was applied to integrate And-Or-Graph representations of language and vision for joint parsing (Tu et al., 2014). A Factorial Hidden Markov Model (FHMM) was applied to learn the meaning of nouns, verbs, prepositions, adjectives and adverbs from short video clips paired with sentences (Yu and Siskind, 2013). Discriminative models have also been applied to ground human commands or instructions to perceived visual entities, mostly for robotic applications (Tellex et al., 2011; Tellex et al., 2014). More recently, deep learn-

[1] `http://lair.cse.msu.edu/gsrl.html`

ing has been applied to ground phrases to image regions (Karpathy and Fei-Fei, 2015).

3 Method

We first describe our problem formulation and then provide details on the learning and inference algorithms.

3.1 Problem Formulation

Given a sentence S and its corresponding video clip V, our goal is to ground explicit/implicit roles associated with a verb in S to video tracks in V. In this paper, we focus on the following set of semantic roles: {`predicate, patient, location, source, destination, tool`}. In the cooking domain, as actions always involve hands, the `predicate` is grounded to the hand pose represented by a trajectory of relevant hand(s). Normally `agent` would be grounded to the person who does the action. As there is only one person in the scene, we thus ignore the grounding of the `agent` in this work.

Video tracks capture tracks of objects (including hands) and locations. For example, in Figure 1, there are 5 tracks: human, hand, cucumber, refrigerator and cutting board. Regarding the representation of locations, instead of discretization of a whole image to many small regions(large search space), we create locations corresponding to five spatial relations (center, up, down, left, right) with respect to each object track, which means we have 5 times number of locations compared with number of objects. For instance, in Figure 1, the `source` is grounded to the center of the bounding boxes of the refrigerator track; and the `destination` is grounded to the center of the cutting board track.

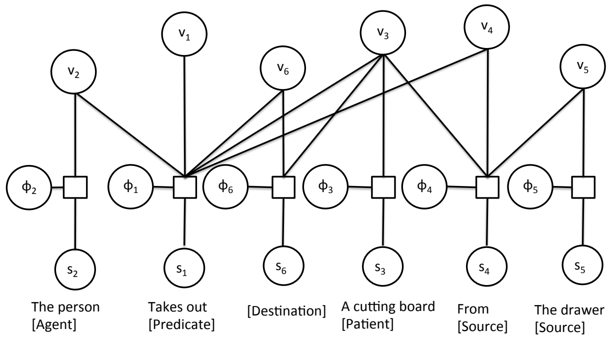


Figure 2: The CRF structure of sentence "*the person takes out a cutting board from the drawer*". The text in the square bracket indicates the corresponding semantic role.

We use Conditional Random Field(CRF) to model this problem. An example CRF factor graph is shown in Figure 2. The CRF structure is created based on information extracted from language. More Specifically, $s_1, ..., s_6$ refers to the observed text and its semantic role. Notice that s_6 is an implicit role as there is no text from the sentence describing `destination`. Also note that the whole prepositional phrase "from the drawer" is identified as the `source` rather than "the drawer" alone. This is because the prepositions play an important role in specifying location information. For example, "near the cutting boarding" is describing a location that is near to, but not exactly at the location of the cutting board. Here $v_1, ..., v_6$ are grounding random variables which take values from object tracks and locations in the video clip, and $\phi_1, ..., \phi_6$ are binary random variables which take values $\{0,1\}$. When ϕ_i equals to 1, it means v_i is the correct grounding of corresponding linguistic semantic role, otherwise it is not. The introduction of random variables ϕ_i follows previous work from Tellex and colleagues (Tellex et al., 2011), which makes CRF learning more tractable.

3.2 Learning and Inference

In the CRF model, we do not directly model the objective function as:

$$p(v_1, ..., v_k | S, V)$$

where S refers to the sentence, V refers to the corresponding video clip and v_i refers to the grounding variable. Because the gradient based learning method needs the expectation of $v_1, ..., v_k$, which is infeasible, we instead use the following objective function:

$$P(\phi | s_1, s_2, \ldots, s_k, v_1, v_2, \ldots, v_k, V)$$

where ϕ is a binary random vector $[\phi_1, ..., \phi_k]$, indicating whether the grounding is correct. In this way, the objective function factorizes according to the structure of language with local normalization at each factor.

Gradient ascent with L2 regularization was used for parameter learning to maximize the objective function:

$$\frac{\partial L}{\partial w} = \sum_i F(\phi_i, s_i, v_i, V) - \sum_i \mathbb{E}_{P(\phi_i|s_i,v_i,V)} F(\phi_i, s_i, v_i, V)$$

where F refers to the feature function. During the training, we also use random grounding as negative samples for discriminative training.

During inference, the search space can be very large when the number of objects in the world increases. To address this problem we apply beam search to first ground roles including `patient`, `tool`, and then other roles including `location`, `source`, `destination` and `predicate`.

4 Evaluation

4.1 Dataset

We conducted our investigation based on a subset of the TACoS corpus (Regneri et al., 2013). This dataset contains a set of video clips paired with natural language descriptions related to several cooking tasks. The natural language descriptions were collected through crowd-sourcing on top of the "MPII Cooking Composite Activities" video corpus (Rohrbach et al., 2012). In this paper, we selected two tasks "cutting cucumber" and "cutting bread" as our experimental data. Each task has 5 videos showing how different people perform the same task. Each video is segmented to a sequence of video clips where each video clip comes with one or more language descriptions. The original TACoS dataset does not contain annotation for grounded semantic roles.

Table 1: Statistics for a set of verbs and their semantic roles in our annotated dataset. The entry indicates the number of explicit/implicit roles for each category. "–" denotes no such role is observed in the data.[1]

Verb	Patient	Source	Destn	Location	Tool
take	251 / 0	102 / 149	2 / 248	–	–
put	94 / 0	–	75 / 19	–	–
get	247 / 0	62 / 190	0 / 239	–	–
cut	134 / 1	64 / 64	–	3 / 131	5 / 130
open	23 / 0	–	–	0 / 23	2 / 21
wash	93 / 0	–	–	26 / 58	2 / 82
slice	69 / 1	–	–	2 / 68	2 / 66
rinse	76 / 0	0 / 74	–	8 / 64	–
place	104 / 1	–	105 / 7	–	–
peel	29 / 0	–	–	1 / 27	2 / 27
remove	40 / 0	34 / 6	–	–	–

To support our investigation and evaluation, we had made a significant effort adding the following annotations. For each video clip, we annotated the objects' bounding boxes, their tracks, and their labels (cucumber, cutting_board, etc.) using VATIC (Vondrick et al., 2013). On average, each video clip is annotated with 15 tracks of objects. For each sentence, we annotated the ground truth parsing structure and the semantic frame for each verb. The ground truth parsing structure is the representation of dependency parsing results. The semantic frame of a verb includes slots, fillers, and their groundings. For each semantic role (including both explicit roles and implicit roles) of a given verb, we also annotated the ground truth grounding in terms of the object tracks and locations. In total, our annotated dataset includes 976 pairs of video clips and corresponding sentences, 1094 verbs occurrences, and 3593 groundings of semantic roles. To check annotation agreement, 10% of the data was annotated by two annotators. The kappa statistics is 0.83 (Cohen and others, 1960).

From this dataset, we selected 11 most frequent verbs (i.e., *get, take, wash, cut, rinse, slice, place, peel, put, remove, open*) in our current investigation for the following reasons. First, they are used more frequently so that we can have sufficient samples of each verb to learn the model. Second, they cover different types of actions: some are more related to the change of the state such as *take*, and some are more related to the process such as *wash*. As it turns out, these verbs also have different semantic role patterns as shown in Table 1. The `patient` roles of all these verbs are explicitly specified. This is not surprising as all these verbs are transitive verbs. There is a large variation for other roles. For example, for the verb *take*, the `destination` is rarely specified by lin-

[1] For some verbs (e.g., *get*), there is a slight discrepancy between the sum of implicit/explicit roles across different categories. This is partly due to the fact that some verb occurrences take more than one objects as grounding to a role. It is also possibly due to missed/duplicated annotation for some categories.

guistic expressions (i.e., only 2 instances), however it can be inferred from the video. For the verb *cut*, the `location` and the `tool` are also rarely specified by linguistic expressions. Nevertheless, these implicit roles contribute to the overall understanding of actions and should also be grounded too.

4.2 Automated Processing

To build the structure of the CRF as shown in Figure 2 and extract features for learning and inference, we have applied the following approaches to process language and vision.

Language Processing. Language processing consists of three steps to build a structure containing syntactic and semantic information. First, the Stanford Parser (Manning et al., 2014) is applied to create a dependency parsing tree for each sentence. Second, Senna (Collobert et al., 2011) is applied to identify semantic role labels for the key verb in the sentence. The linguistic entities with semantic roles are matched against the dependency nodes in the tree and the corresponding semantic role labels are added to the tree. Third, for each verb, the Propbank (Palmer et al., 2005) entries are searched to extract all relevant semantic roles. The implicit roles (i.e., not specified linguistically) are added as direct children of verb nodes in the tree. Through these three steps, the resulting tree from language processing has both explicit and implicit semantic roles. These trees are further transformed to the CRF structures based on a set of rules.

Vision Processing. A set of visual detectors are first trained for each type of objects. Here a random forest classifier is adopted. More specifically, we use 100 trees with HoG features (Dalal and Triggs, 2005) and color descriptors (Van De Weijer and Schmid, 2006). Both HoG and Color descriptors are used, because some objects are more structural, such as knives, human; some are more textured such as towels. With the learned object detectors, given a candidate video clip, we run the detectors at each 10th frame (less than 0.5 second), and find the candidate windows for which the detector score corresponding to the object is larger than a threshold (set as 0.5). Then using the detected window as a starting point, we adopt tracking-by-detection (Danelljan et al., 2014) to go forward and backward to track this object and obtain the candidate track with this object label.

Feature Extraction. Features in the CRF model can be divided into the following three categories:

1. *Linguistic features* include word occurrence and semantic role information. They are extracted by language processing.

2. *Track label features* are the label information for tracks in the video. The labels come from human annotation or automated visual processing depending on different experimental settings (described in Section 4.3).

3. *Visual features* are a set of features involving geometric relations between tracks in the video. One important feature is the histogram comparison score. It measures the similarity between distance histograms. Specifically, histograms of distance values between the tracks of the `predicate` and other roles for each verb are first extracted from the training video clips. For an incoming distance histogram, we calculate its Chi-Square distances (Zhang et al., 2007) from the pre-extracted training histograms with the same verb and the same role. its histogram comparison score is set to be the average of top 5 smallest Chi-Square distances. Other visual features include geometric information for single tracks and geometric relations between two tracks. For example, size, average speed, and moving direction are extracted for a single track. Average distance, size-ratio, and relative direction are extracted between two tracks. For features that are continuous, we discretized them into uniform bins.

To ground language into tracks from the video, instead of using track label features or visual features alone, we use a Cartesian product of these features with linguistic features. To learn the behavior of different semantic roles of different verbs, visual features are combined with the presence of both verbs and semantic roles through Cartesian product. To learn the correspondence between track labels and words, track label features are combined with the presence of words also through Cartesian product.

To train the model, we randomly selected 75% of annotated 976 pairs of video clips and corresponding sentences as training set. The remaining 25% were used as the testing set.

4.3 Experimental Setup

Comparison. To evaluate the performance of our approach, we compare it with two approaches.

- **Baseline**: To identify the grounding for each semantic role, the first baseline chooses the most possible track based on the object type conditional distribution given the verb and semantic role. If an object type corresponds to multiple tracks in the video, e.g., multiple drawers or knives, we then randomly select one of the tracks as grounding. We ran this baseline method five times and reported the average performance.

- **Tellex (2011)**: The second approach we compared with is based on an implementation (Tellex et al., 2011). The difference is that they don't explicitly model fine-grained semantic role information. For a better comparison, we map the grounding results from this approach to different explicit semantic roles according to the SRL annotation of the sentence. Note that this approach is not able to ground implicit roles.

More specifically, we compare these two approaches with two variations of our system:

- **GSRL$_{\textbf{wo\_V}}$**: The CRF model using linguistic features and track label features (described in Section 4.2).

- **GSRL**: The full CRF model using linguistic features, track label features, and visual features(described in Section 4.2).

Configurations. Both automated language processing and vision processing are error-prone. To further understand the limitations of grounded SRL, we compare performance under different configurations along the two dimensions: (1) the CRF structure is built upon annotated ground-truth language parsing versus automated language parsing; (2) object tracking and labeling is based on annotation versus automated processing. These lead to four different experimental configurations.

Evaluation Metrics. For experiments that are based on annotated object tracks, we can simply use the traditional *accuracy* that directly measures the percentage of grounded tracks that are correct. However, for experiments using automated tracking, evaluation can be difficult as tracking itself poses significant challenges. The grounding results (to tracks) cannot be directly compared with the annotated ground-truth tracks. To address this problem, we have defined a new metric called *approximate accuracy*. This metric is motivated by previous computer vision work that evaluates tracking performance (Bashir and Porikli, 2006). Suppose the ground truth grounding for a role is track gt and the predicted grounding is track pt. The two tracks gt and pt are often not the same (although may have some overlaps). Suppose the number of frames in the video clip is k. For each frame, we calculate the distance between the centroids of these two tracks. If their distance is below a predefined threshold, we consider the two tracks overlap in this frame. We consider the grounding is correct if the ratio of the overlapping frames between gt and pt exceeds 50%. As can be seen, this is a lenient and an approximate measure of accuracy.

4.4 Results

The results based on the ground-truth language parsing are shown in Table 2, and the results based on automated language parsing are shown in Table 3. For results based on annotated object tracking, the performance is reported in *accuracy* and for results based on automated object tracking, the performance is reported in *approximate accuracy*. When the number of testing samples is less than 15, we do not show the result as it tends to be unreliable (shown as *NA*). Tellex (2011) does not address implicit roles (shown as "–"). The best performance score is shown in bold. We also conducted a two-tailed bootstrap significance testing (Efron and Tibshirani, 1994). The score with a "*" indicates it is statistically significant ($p < 0.05$) compared to the baseline approach. The score with a "+" indicates

it is statistically significant ($p < 0.05$) compared to the approach (Tellex et al., 2011).

For experiments based on automated object tracking, we also calculated an *upper_bound* to assess the best possible performance which can be achieved by a perfect grounding algorithm given the current vision processing results. This *upper_bound* is calculated based on grounding each role to the track which is closest to the ground-truth annotated track. For the experiments based on annotated tracking, the *upper_bound* would be 100%. This measure provides some understandings about how good the grounding approach is given the limitation of vision processing. Notice that the grounding results in the gold/automatic language processing setting are not directly comparable as the automatic SRL can misidentify frame elements.

4.5 Discussion

As shown in Table 2 and Table 3, our approach consistently outperforms the baseline (for both explicit and implicit roles) and the Tellex (2011) approach. Under the configuration of gold recognition/tracking, the incorporation of visual features further improves the performance. However, this performance gain is not observed when automated object tracking and labeling is used. One possible explanation is that as we only had limited data, we did not use separate data to train models for

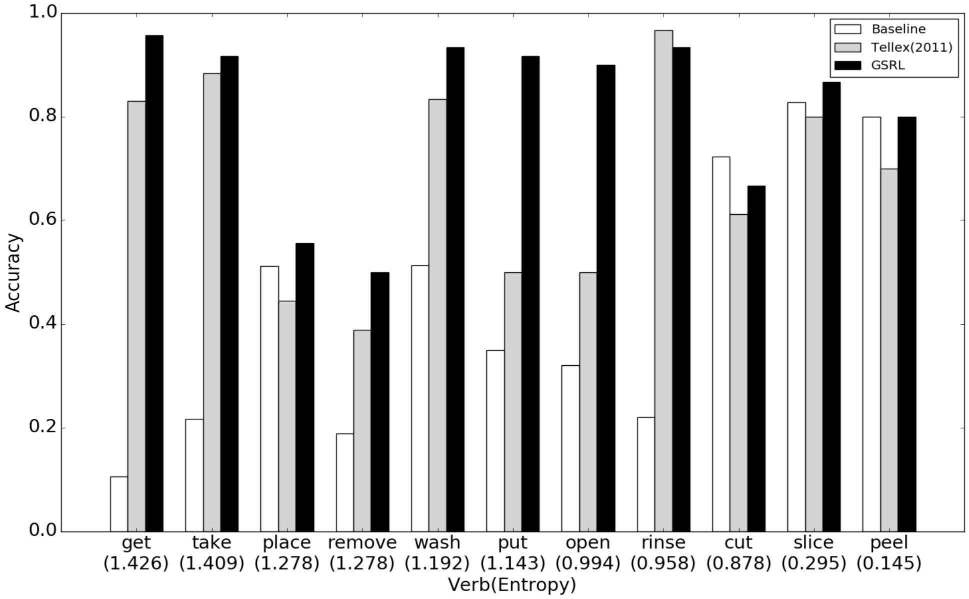

Figure 3: The relation between the accuracy and the entropy of each verb's patient from the gold language, gold visual recognition/tracking setting. The entropy for the patient role of each verb is shown below the verb.

object recognition/tracking. So the GSRL model was trained with gold recognition/tracking data and tested with automated recognition/tracking data.

By comparing our method with Tellex (2011), we can see that by incorporating fine grained semantic role information, our approach achieves better performance on almost all the explicit role (except for the `patient` role under the automated tracking condition).

The results have also shown that some roles are easier to ground than others in this domain. For example, the `predicate` role is grounded to the hand tracks (either left hand or right hand), there are not many variations such that the simple baseline can achieve pretty high performance, especially when annotated tracking is used. The same situation happens to the `location` role as most of the locations happen near the *sink* when the verb is *wash*, and near the *cutting board* for verbs like *cut*, etc. However, for the `patient` role, there is a large difference between our approach and baseline approaches as there is a larger variation of different types of objects that can participate in the role for a given verb.

For experiments with automated tracking, the *upper_bound* for each role also varies. Some roles (e.g., `patient`) have a pretty low upper bound. The accuracy from our full GSRL model is already quite close to the upper bound. For other roles such as `predicate` and `destination`, there is a larger gap between the current performance and the upper bound. This difference reflects the model's capability in grounding different roles.

Figure 3 shows a close-up look at the grounding performance to the `patient` role for each verb under the gold parsing and gold tracking configuration. The reason we only show the results of `patient` role here is every verb has this role to be grounded. For each verb, we also calculated its entropy based on the distribution of different types of objects that can serve as the `patient` role in the training data. The entropy is shown at the bottom of the figure. For verbs such as *take* and *put*, our full GSRL model leads to much better performance compared to the baseline. As the baseline approach relies on the entropy of the potential grounding for a role, we further measured the improvement of the performance and calculated the correlation between the improvement and the entropy of each verb. The result shows that Pearson coefficient between the entropy and the improvement of GSRL over the baseline is 0.614. This indicates the improvement from GSRL is positively correlated with the entropy value associated with a role, implying the GSRL model can deal with more uncertain situations. For the verb *cut*, The GSRL model performs slightly worse than the baseline. One explanation is that the possible objects that can participate as a patient for *cut* are relatively constrained where simple features might be sufficient. A large number of features may introduce noise, and thus jeopardizing the performance.

We further compare the performance of our full GRSL model with Tellex (2011) (also shown in Figure 3) on the `patient` role of different verbs. Our approach outperforms Tellex (2011) on most of the verbs, especially *put* and *open*. A close look at the results have shown that in those cases, the `patient` roles are often specified by pronouns. Therefore, the track label features and linguistic features are not very helpful, and the correct grounding mainly depends on visual features. Our full GSRL model can better capture the geometry relations between different semantic roles by incorporating fine-grained role information.

5 Conclusion and Future Work

This paper investigates a new problem on grounded semantic role labeling. Besides semantic roles explicitly mentioned in language descriptions, our approach also grounds implicit roles which are not explicitly specified. As implicit roles also capture important participants related to an action (e.g., tools used in the action), our approach provides a more complete representation of action semantics which can be used by artificial agents for further reasoning and planning towards the physical world. Our empirical results on a complex cooking domain have shown that, by incorporating semantic role information with visual features, our approach can achieve better performance compared to baseline approaches. Our results have also shown that grounded semantic role labeling is a challenging problem which often depends on the quality of automated visual processing (e.g., object tracking and recognition).

There are several directions for future improvement. First, the current alignment between a video clip and a sentence is generated by some heuristics which are error-prone. One way to address this is to treat alignment and grounding as a joint problem. Second, our current visual features have not shown effective especially when they are extracted based on automatic visual processing. This is partly due to the complexity of the scene from the TACoS dataset and the lack of depth information. Recent advances in object tracking algorithms (Yang et al., 2013; Milan et al., 2014) together with 3D sensing can be explored in the future to improve visual processing. Moreover, linguistic studies have shown that action verbs such as *cut* and *slice* often denote some change of state as a result of the action (Hovav and Levin, 2010; Hovav and Levin, 2008). The change of state can be perceived from the physical world. Thus another direction is to systematically study causality of verbs. Causality models for verbs can potentially provide top-down information to guide intermediate representations for visual processing and improve grounded language understanding.

The capability of grounding semantic roles to the physical world has many important implications. It will support the development of intelligent agents which can reason and act upon the shared physical world. For example, unlike traditional action recognition in computer vision (Wang et al., 2011), grounded SRL will provide deeper understanding of the activities which involve participants in the actions guided by linguistic knowledge. For agents that can act upon the physical world such as robots, grounded SRL will allow the agents to acquire the grounded structure of human commands and thus perform the requested actions through planning (e.g., to follow the command "put the cup on the table"). Grounded SRL will also contribute to robot action learning where humans can teach the robot new actions (e.g., simple cooking tasks) through both task demonstration and language instruction.

Abstract

Metaphor is pervasive in our communication, which makes it an important problem for natural language processing (NLP). Numerous approaches to metaphor processing have thus been proposed, all of which relied on linguistic features and textual data to construct their models. Human metaphor comprehension is, however, known to rely on both our linguistic and perceptual experience, and vision can play a particularly important role when metaphorically projecting imagery across domains. In this paper, we present the first metaphor identification method that simultaneously draws knowledge from linguistic and visual data. Our results demonstrate that it outperforms linguistic and visual models in isolation, as well as being competitive with the best-performing metaphor identification methods, that rely on hand-crafted knowledge about domains and perception.

1 Introduction

Metaphor lends vividness, sophistication and clarity to our thought and communication. At the same time, it plays a fundamental structural role in our cognition, helping us to organise and project knowledge (Lakoff and Johnson, 1980; Feldman, 2006). Metaphors arise due to systematic associations between distinct, and seemingly unrelated, concepts. For instance, when we talk about "the *turning wheels* of a political regime", "*rebuilding* the campaign *machinery*" or "*mending* foreign policy", we view *politics* and *political systems* in terms of *mechanisms*, they can *function, break, be mended* etc. The existence of this association allows us to transfer knowledge and imagery from the domain of *mechanisms* (the source domain) to that of *political systems* (the target domain). According to Lakoff and Johnson (1980), such metaphorical mappings, or *conceptual metaphors*, form the basis of metaphorical language.

Metaphor is pervasive in our communication, which makes it important for NLP applications dealing with real-world text. A number of approaches to metaphor processing have thus been proposed, using supervised classification (Gedigian et al., 2006; Mohler et al., 2013; Tsvetkov et al., 2013; Hovy et al., 2013; Dunn, 2013a), clustering (Shutova et al., 2010; Shutova and Sun, 2013), vector space models (Shutova et al., 2012; Mohler et al., 2014), lexical resources (Krishnakumaran and Zhu, 2007; Wilks et al., 2013) and web search with lexico-syntactic patterns (Veale and Hao, 2008; Li et al., 2013; Bollegala and Shutova, 2013). So far, these and other metaphor processing works relied on textual data to construct their models. Yet, several experiments indicated that perceptual properties of concepts, such as concreteness and imageability, are important features for metaphor identification (Turney et al., 2011; Neuman et al., 2013; Gandy et al., 2013; Strzalkowski et al., 2013; Tsvetkov et al., 2014). However, all of these methods used manually-annotated linguistic resources to determine these properties (such as the MRC concreteness database (Wilson, 1988)). To the best of our knowledge, there has not yet been a metaphor processing method that employed information learned from both linguistic and visual data. Ample re-

search in cognitive science suggests that human meaning representations are not merely a product of our linguistic exposure, but are also grounded in our perceptual system and sensori-motor experience (Barsalou, 2008; Louwerse, 2011). Semantic models integrating information from multiple modalities have been shown successful in tasks such as modeling semantic similarity and relatedness (Silberer and Lapata, 2012; Bruni et al., 2014), lexical entailment (Kiela et al., 2015a), compositionality (Roller and Schulte im Walde, 2013) and bilingual lexicon induction (Kiela et al., 2015b). Using visual information is particularly relevant to modelling metaphor, where imagery is ported across domains.

In this paper, we present the first metaphor identification method integrating meaning representations learned from linguistic and visual data. We construct our representations using a skip-gram model of Mikolov et al. (2013a) trained on textual data to obtain linguistic embeddings and a deep convolutional neural network (Kiela and Bottou, 2014) trained on image data to obtain visual embeddings. Linguistic word embeddings have been previously successfully used to answer analogy questions (Mikolov et al., 2013b; Levy and Goldberg, 2014). These works have shown that such representations capture the nuances of word meaning needed to recognise relational similarity (e.g. between pairs "*king : queen*" and "*man : woman*"), quantified by the respective vector offsets (*king* – *queen* ≈ *man* – *woman*). In our experiments, we investigate how well these representations can capture information about source and target domains and their interaction in a metaphor. We then enrich these representations with visual information. We first acquire linguistic and visual embeddings for individual words and then extend the methods to learn embeddings for longer phrases. The focus of our experiments is on metaphorical expressions in verb–subject, verb–direct object and adjectival modifier–noun constructions. We thus learn embeddings for verbs, adjectives, nouns, as well as verb–noun and adjective–noun phrases. We then use a set of arithmetic operations on word and phrase embedding vectors to classify phrases as literal or metaphorical. To the best of our knowledge, our approach is also the first one to apply word or phrase embeddings to the task of metaphor identification.

Our results demonstrate that the joint model incorporating linguistic and visual representations outperforms the linguistic model in isolation, as well as being competitive with the best-performing metaphor identification methods that rely on hand-crafted information about domains, concreteness and imageability.

2 Related work

A strand of metaphor processing research cast the problem as a classification of linguistic expressions as metaphorical or literal. They experimented with a number of features, including lexical and syntactic information and higher-level features such as semantic roles and domain types. Gedigian et al. (2006) classified verbs related to MOTION and CURE within the domain of financial discourse. They used the maximum entropy classifier and the verbs' nominal arguments and their semantic roles as features, reporting encouraging results. Dunn (2013a) used a logistic regression classifier and high-level properties of concepts extracted from SUMO ontology, including domain types (ABSTRACT, PHYSICAL, SOCIAL, MENTAL) and event status (PROCESS, STATE, OBJECT). Tsvetkov et al. (2013) also used logistic regression and coarse semantic features, such as concreteness, animateness, named entity types and WordNet supersenses. They have shown that the model learned with such coarse semantic features is portable across languages. The work of Hovy et al. (2013) is notable as they focused on compositional rather than categorical features. They trained an SVM with dependency-tree kernels to capture compositional information, using lexical, part-of-speech tag and WordNet supersense representations of sentence trees. Mohler et al. (2013) aimed at modelling conceptual information. They derived semantic signatures of texts as sets of highly-related and interlinked WordNet synsets. The semantic signatures served as features to train a set of classifiers (maximum entropy, decision trees, SVM, random forest) that map new metaphors to the semantic signatures of the known ones.

Turney et al. (2011) hypothesized that metaphor is commonly used to describe abstract concepts in terms of more concrete or physical experiences. Thus, Turney and colleagues expected that there would be some discrepancy in the level of concreteness of source and target terms in the metaphor. They developed a method to automatically measure concreteness of words and applied it to identify verbal and adjectival metaphors. Neuman et al. (2013) and Gandy et al. (2013) followed in Turney's steps, extending the models by incorporating information about selectional preferences.

Heintz et al. (2013) and Strzalkowski et al. (2013) focused on modeling topical structure of text to identify metaphor. Their main hypothesis was that metaphorical language (coming from a different domain) would represent atypical vocabulary within the topical structure of the text. Strzalkowski et al. (2013) acquired a set of topic chains by linking semantically related words in a given text. They then looked for vocabulary outside the topic chain and yet connected to topic chain words via syntactic dependencies and exhibiting high imageability. Heintz et al. (2013) used LDA topic modelling to identify sets of source and target domain vocabulary. In their system, the acquired topics represented source and target domains, and sentences containing vocabulary from both were tagged as metaphorical.

Other approaches addressed automatic identification of conceptual metaphor. Mason (2004) automatically acquired domain-specific selectional preferences of verbs, and then, by mapping their common nominal arguments in different domains, arrived at the corresponding metaphorical mappings. For example, the verb *pour* has a strong preference for *liquids* in the LAB domain and for *money* in the FINANCE domain, suggesting the mapping MONEY is LIQUID. Shutova et al. (2010) pointed out that the metaphorical uses of words constitute a large portion of the dependency features extracted for abstract concepts from corpora. For example, the feature vector for *politics* would contain GAME or MECHANISM terms among the frequent features. As a result, distributional clustering of abstract nouns with such features identifies groups of diverse concepts metaphorically associated with the same source domain (or sets of source domains). Shutova et al. (2010) exploit this property of co-occurrence vectors to identify new metaphorical mappings starting from a set of examples. Shutova and Sun (2013) used hierarchical clustering to derive a network of concepts in which metaphorical associations are learned in an unsupervised way.

3 Method

3.1 Learning linguistic representations

We obtained our linguistic representations using the log-linear skip-gram model of Mikolov et al. (2013a). Given a corpus of words w and their contexts c, the model learns a set of parameters θ that maximize the overall corpus probability

$$\arg\max_{\theta} \prod_{w} [\prod_{c \in C(w)} p(c|w;\theta)], \qquad (1)$$

where $C(w)$ is a set of contexts of word w and $p(c|w;\theta)$ is a softmax function:

$$p(c|w;\theta) = \frac{e^{v_c \cdot v_w}}{\sum_{c' \in C} e^{v_{c'} \cdot v_w}}, \qquad (2)$$

where v_c and v_w are vector representations of c and w. The parameters we need to set are thus v_{c_i} and v_{w_i} for all words in our word vocabulary V and context vocabulary C, and the set of dimensions $i \in 1, \ldots, d$. Given a set D of word-context pairs, embeddings are learned by optimizing the following objective:

$$\begin{aligned} &\arg\max_{\theta} \sum_{(w,c) \in D} \log p(c|w) = \\ &\sum_{(w,c) \in D} (\log e^{v_c \cdot v_w} - \log \sum_{c' \in C} e^{v_{c'} \cdot v_w}) \end{aligned} \qquad (3)$$

We used a recent dump of Wikipedia[1] as our corpus. The text was lemmatized, tagged, and parsed with Stanford CoreNLP (Manning et al., 2014). Words that appeared less than 100 times in their lemmatized form were ignored. The 100-dimensional word and phrase embeddings were learned in two stages: in a first pass, we obtained word-level embeddings (e.g. for *white* and *rabbit*) using the standard skip-gram with negative sampling of Eq. (3); we then obtained phrase embeddings (e.g. for *white rabbit*) through a second pass over the same corpus. In the second pass, the vectors v_c and $v_{c'}$ of Eq. (3) were set to their values from the first pass, and kept fixed. Verb-noun phrases were extracted by finding `nsubj` and `dobj` arcs with VB head and NN dependent; analogously, adjective-noun phrases were extracted by finding `amod` arcs with NN head and JJ dependent. No frequency cutoff was applied for

[1] https://dumps.wikimedia.org/enwiki/20150805/

phrases. All embeddings were trained on the corpus for 3 epochs, using a symmetric window of 5, and 10 negative samples per word-context pair.

3.2 Learning visual representations

Visual embeddings were obtained in a manner similar to Kiela and Bottou (2014). Using the deep learning framework Caffe (Jia et al., 2014), we extracted image embeddings from a deep convolutional neural network that was trained on the ImageNet classification task (Russakovsky et al., 2015). The network (Krizhevsky et al., 2012) consists of 5 convolutional layers, followed by two fully connected rectified linear unit (ReLU) layers that feed into a softmax for classification. The network learns through a multinomial logistic regression objective:

$$\begin{aligned} J(\theta) = -\sum_{i=1}^{D}\sum_{k=1}^{K} \mathbf{1}\{y^{(i)} = k\} \\ \log \frac{\exp(\theta^{(k)\top} x^{(i)})}{\sum_{j=1}^{K} \exp(\theta^{(j)\top} x^{(i)})} \end{aligned} \quad (4)$$

where $\mathbf{1}\{\cdot\}$ is the indicator function and we train on D examples with K classes. We obtain image embeddings by doing a forward pass with a given image and taking the 4096-dimensional fully connected layer that precedes the softmax (typically called FC7) as the representation of that image.

To construct our embeddings, we used up to 10 images for a given word or phrase, which were obtained through Google Images. It has been shown that images from Google yield higher quality representations than comparable resources such as Flickr and are competitive with hand-crafted datasets (Fergus et al., 2005; Bergsma and Goebel, 2011). We created our final visual representations for words and phrases by taking the average of the extracted image embeddings for a given word or phrase.

3.3 Multimodal fusion strategies

While it is desirable to jointly learn representations from different modalities at the same time, this is often not feasible (or may lead to poor performance) due to data sparsity. Instead, we learn uni-modal representations independently, as described above, and then combine them into multi-modal ones. Previous work in multi-modal semantics (Bruni et al., 2014) investigated different ways of combining, or *fusing*, linguistic and perceptual cues. When calculating similarity, for instance, one can either combine the representations first and subsequently compute similarity scores; or compute similarity scores independently per modality and afterwards combine the scores. In contrast with joint learning (which has also been called *early fusion*), these two possibilities represent *middle* and *late* fusion, respectively (Kiela and Clark, 2015).

We experiment with middle and late fusion strategies. In middle fusion, we L-2 normalise and concatenate the vectors for linguistic and visual representations and then compute a metaphoricity score for a phrase based on this joint representation. In late fusion, we first compute the metaphoricity scores based on linguistic and visual representations independently, and then combine the metaphoricity scores by taking their average.

3.4 Measuring metaphoricity

We investigate a set of arithmetic operations on the linguistic, visual and multimodal embedding vectors to determine whether the two words in the phrase belong to the same domain or rather a word from one domain is metaphorically used to describe another.

3.4.1 Word-level embeddings

In our first set of experiments, we compare embeddings learned for individual words in order to determine whether they come from the same domain. This is done by determining similarity between the representations of the two words in a phrase:

$$\text{sim}(word_1, word_2), \quad (5)$$

where $word_1$ is either a verb or an adjective, $word_2$ is a noun, and similarity is defined as cosine similarity:

$$\cos(x, y) = \frac{x \cdot y}{||x||||y||} \quad (6)$$

We expect the similarity of word representations to be lower for metaphorical expressions (where one word comes from the source domain and one from the target), than for the literal ones (where both words come from the target domain). We will further refer to this method as WORDCOS.

3.4.2 Phrase-level embeddings

In our second set of experiments, we investigate compositional properties of metaphorical phrases by comparing the embeddings learned for the whole phrase with those of the individual words in the phrase. This allows us to determine which properties the phrase shares with each of the words, providing another criterion for metaphor identification. We expect that the embeddings of literal phrases will be more similar to the embeddings of individual words in the phrase (or a combination thereof) than those of metaphorical phrases. We use the following measures to test this hypothesis:

$$\text{PhrasCos1: } \cos(phrase - word_1, word_2) \tag{7}$$

$$\text{PhrasCos2: } \cos(phrase - word_2, word_1) \tag{8}$$

$$\text{PhrasCos3: } \cos(phrase, word_1 + word_2), \tag{9}$$

where $phrase$ is the phrase embedding vector, and $word_1$ and $word_2$ are defined as above.

3.4.3 Classification

We use a small development set (a collection of phrases annotated as metaphorical or literal) to determine an optimal classification threshold for each of the above scoring methods. We have optimized the threshold by maximizing classification accuracy on the development set.[2] All instances with values above the threshold were considered literal and those with values below the threshold metaphorical. The thresholds were then applied to classify the test instances as literal or metaphorical.

4 Experiments

4.1 Annotated datasets

We evaluate our method using two datasets manually annotated for metaphoricity:

Mohammad et al. dataset (MOH) Mohammad et al. (2016) annotated different senses of WordNet (Fellbaum, 1998) verbs for metaphoricity. They extracted verbs that had between three and ten senses in WordNet and the sentences exemplifying them in the corresponding glosses. The verb uses in the sentences (1639 in total) were then annotated for metaphoricity by 10 annotators each via the crowdsourcing platform CrowdFlower[3]. Mohammad et al. selected the verbs that were tagged by at least 70% of the annotators as metaphorical or literal to create their dataset. We extracted verb–direct object and verb–subject relations of the annotated verbs from this dataset, discarding the instances with pronominal or clausal subject or object. This resulted in a dataset of 647 verb–noun pairs, 316 of which were metaphorical and 331 literal. Figure 1 shows some examples of annotated verbs from Mohammad et al.'s dataset.

Verb noun	Class	Relation
blister foot	literal	SV
blister administration	metaphorical	VO
blur haze	literal	SV
blur vision	literal	VO
blur distinction	metaphorical	SV
boost economy	metaphorical	VO
boost voltage	literal	VO
bounce ball	literal	SV
bounce people	metaphorical	VO
bow person	literal	SV
bow government	metaphorical	SV
breathe person	literal	SV
breathe life	metaphorical	VO
breathe fabric	metaphorical	SV
breathe wine	metaphorical	SV

Figure 1: Annotated verb–direct object and verb–subject pairs from MOH

Tsvetkov et al. dataset (TSV) Tsvetkov et al. (2014) created a large dataset of adjective–noun pairs that they annotated for metaphoricity. Starting with a 1000 frequent adjectives, they extracted nouns they co-occur with in TenTen Web Corpus[4] using SketchEngine and in collections of metaphor on the Web. Tsvetkov et al. divided the data into a training set (containing 884 literal and 884 metaphorical pairs) and test set (111 literal and 111 metaphorical pairs). We will refer to their training set as TSV-TRAIN and to the test set as TSV-TEST. The test set was annotated for metaphoricity by 5 annotators with an inter-annotator agreement of $\kappa = 0.76$. Figure 2 shows a portion of the anno-

[2] We have also experimented with optimizing F-score on the development set and the results exhibited similar trends across methods.

[4] https://www.sketchengine.co.uk/xdocumentation/wiki/Corpora/enTenTen

Metaphorical:	**Literal:**
bald assertion	cold beer
blind alley	cold weather
breezy disregard	huge number
dry wit	dead animal
dumb luck	deep sea
foggy brain	gold coin
healthy balance	dry skin
hollow mockery	honest opinion
honest meal	empty can
juicy scandal	good idea
spicy language	foggy night
stale cliché	frosty morning
steep discount	firm mattress

Figure 2: Annotated adjective–noun pairs from TSV-TEST

tated test set. Metaphorical phrases that depend on wider context for their interpretation (e.g. *drowning students*) were removed. The training set was annotated by one annotator only, and it is thus likely that the annotations are less reliable than those in the test set. We thus evaluate our methods on Tsvetkov et al.'s test set (TSV-TEST). However, we will also report results on TSV-TRAIN to confirm whether the observed trends hold in a larger, though likely noisier, dataset.

We selected the above two datasets since they include examples for different senses (both metaphorical and literal) of the same verbs or adjectives. This allows us to test the extent to which our model is able to discriminate between different word senses, as opposed to merely selecting the most frequent class for a given word.

4.2 Experimental setup

We divided the verb- and adjective-noun datasets into development and test sets. The verb–noun development set contained 80 instances from MOH (40 literal and 40 metaphorical), leaving us with the test set of 567 verb-noun pairs from MOH. We created the adjective–noun development set using 80 adjective-noun pairs (40 literal and 40 metaphorical) from TSV-TRAIN, leaving all of the 222 adjective–noun pairs in TSV-TEST for evaluation. In a separate experiment, we also applied our methods to the remainder of TSV-TRAIN (1688 adjective–noun pairs) to evaluate our system on a larger adjective dataset.

We used the development sets to determine an optimal threshold value for each of our scoring methods. The thresholds for verb-noun and adjective-noun phrases were optimized independently using the corresponding development sets. We experimented with the three phrase-level scoring methods on the development sets, and found that PHRASCOS1 consistently outperformed PHRASCOS2 and PHRASCOS3 for both verb–noun and adjective–noun phrases. We thus report results for PHRASCOS1 on our test sets.

Features	Method	P	R	$F1$
Linguistic	WORDCOS	0.67	0.76	**0.71**
	PHRASCOS1	0.38	0.94	0.54
Visual	WORDCOS	0.49	0.97	0.65
	PHRASCOS1	0.56	0.79	0.66
Multimodal	WORDMID	0.56	0.86	0.68
	PHRASMID	0.44	0.93	0.59
	WORDLATE	0.49	0.96	0.65
	PHRASLATE	0.41	0.92	0.57
	MIXLATE	0.65	0.87	**0.75**

Table 1: System performance on Mohammad et al. dataset (MOH) in terms of precision (P), recall (R) and F-score ($F1$)

We first evaluated the performance of WORDCOS and PHRASCOS1 using linguistic and visual representations in isolation, and then evaluated the multimodal models using middle and late fusion strategies. In middle fusion, we concatenated the linguistic and visual vectors, and then applied WORDCOS and PHRASCOS1 methods to the resulting multimodal vectors. We will refer to these methods as WORDMID and PHRASMID respectively. In late fusion, we used an average of linguistic and visual scores to determine metaphoricity. We experimented with three different scoring methods: (1) WORDLATE, where linguistic and visual WORDCOS scores were combined; (2) PHRASLATE, where linguistic and visual PHRASCOS1 scores were combined; and (3) MIXLATE, where linguistic and WORDCOS and visual PHRASCOS1 scores were combined.

4.3 Results and discussion

We evaluated the performance of our methods on the MOH and TSV-TEST test sets in terms of precision, recall and F-score and the results are presented in Tables 1 and 2 respectively. When using linguistic embeddings alone, WORDCOS outperforms

Features	Method	P	R	$F1$
Linguistic	WORDCOS	0.73	0.80	**0.76**
	PHRASCOS1	0.43	0.96	0.57
Visual	WORDCOS	0.50	0.95	0.66
	PHRASCOS1	0.60	0.91	**0.73**
Multimodal	WORDMID	0.59	0.85	0.70
	PHRASMID	0.54	0.93	0.68
	WORDLATE	0.69	0.72	0.70
	PHRASLATE	0.50	1.00	0.67
	MIXLATE	0.67	0.96	**0.79**

Table 2: System performance on Tsvetkov et al. test set (TSV-TEST) in terms of precision (P), recall (R) and F-score ($F1$)

PHRASECOS1 for both verbs and adjectives by 17-19%. This suggests that linguistic word embeddings already successfully capture domain and compositional information necessary for metaphor identification. In contrast, the visual PHRASECOS1 model, when applied in isolation, tends to outperform the visual WORDCOS model. PHRASCOS1 measures to what extent the meaning of the phrase can be composed by simple combination of the representations of individual words. In metaphorical language, however, a meaning transfer takes place and this is no longer the case. Particularly in visual data, where no linguistic conventionality and stylistic effects take place, PHRASCOS1 captures this property. For adjectives this trend was more evident than for verbs. The visual PHRASECOS1 model, even when applied on its own, attains a high F-score of 0.73 on TSV-TEST, suggesting that concreteness and other visual features are highly informative in identification of adjectival metaphors. This effect was present, though not as pronounced, for verbal metaphors, where the vision-only PHRASECOS1 attains an F-score of 0.66.

The multimodal model, integrating linguistic and visual embeddings, outperforms the linguistic models for both verbs and adjectives, clearly demonstrating the utility of visual features across word classes. The late fusion method MIXLATE, which combines the linguistic WORDCOS score and the visual PHRASECOS1, attains an F-score of 0.75 for verbs and 0.79 for adjectives, which makes it best-performing among our fusion strategies. When the same type of scoring (i.e. either WORDCOS or PHRASCOS1) is used with both linguistic and visual embeddings, middle and late fusion techniques attain comparable levels of performance, with WORDCOS being the leading measure. The reason behind the higher performance of MIXLATE is likely to be the combination of different scoring methods, one of which is more suitable for the linguistic model and the other for the visual one.

The differences between verbs and adjectives with respect to the utility of visual information can be explained by the following two factors. Firstly, previous psycholinguistic research on abstractness and concreteness (Hill et al., 2014) suggests that humans find it easier to judge the level of concreteness of adjectives and nouns than that of verbs. It is thus possible that visual representations capture the concreteness of adjectives and nouns more accurately than that of verbs. Besides concreteness, it is also likely that perceptual properties in general are more important for the semantics of nouns (e.g. objects) and adjectives (their attributes), than for the semantics of verbs (actions), since the latter are grounded in our motor activity and not merely perception. Secondly, following the majority of multimodal semantic models, we used images as our visual data rather than videos. However, some verbs, e.g. stative verbs and verbs for continuous actions, may be better captured in video than images. We thus expect that using video data along with the images as input to the acquisition of visual embeddings is likely to improve metaphor identification performance for verbal metaphors. However, we leave the investigation of this issue for future work.

In an additional experiment, we evaluated our methods on the larger TSV-TRAIN dataset (specifically using its portion that was not employed for development purposes) and the trends observed were the same. MIXLATE attained an F-score of 0.71, outperforming language-only and vision-only models. The performance of all scoring methods on TSV-TRAIN was lower than that on the TSV-TEST. This may be the result of the fact that the labelling of TSV-TRAIN was less consistent than that of TSV-TEST. As TSV-TEST is a set of metaphors annotated by 5 annotators with a high agreement, the evaluation on TSV-TEST is likely to be more reliable (Tsvetkov et al., 2014).

It is important to note that, unlike other supervised approaches to metaphor, our methods do not require large training sets to learn the respective thresholds. The results reported here were obtained using only 80 annotated examples for training. This is sufficient since the necessary lexical knowledge and the knowledge about domain, concreteness and visual properties of concepts is already captured in the linguistic and visual embeddings. However, we additionally investigated how stable the thresholds learned by the model are using the TSV-TRAIN dataset. For this purpose, we divided the dataset into 10 portions of approximately 170 examples (balanced for metaphoricity). We then trained the thresholds first on a small set of 170 examples and then increasing the dataset by 170 examples at each round. The thesholds appear to be relatively stable, with a standard deviation of 0.03 for MIXLATE; 0.02 for WORDCOS (linguistic); and 0.05 for PHRASECOS1 (visual). This suggests that our methods do not require a large annotated dataset and training on a small number of examples is sufficient.

Despite the limited need in training data and no reliance on hand-coded lexical resources, the performance of our method favourably compares to that of existing metaphor identification systems (Turney et al., 2011; Neuman et al., 2013; Gandy et al., 2013; Dunn, 2013b; Tsvetkov et al., 2013; Hovy et al., 2013; Hovy et al., 2013; Shutova and Sun, 2013; Strzalkowski et al., 2013; Beigman Klebanov et al., 2015), that typically use such resources. For instance, Turney et al. (2011) used hand-annotated abstractness scores for words to develop their system, and reported an F-score of 0.68 for verb–noun metaphors and an accuracy of 0.79 for adjective–noun metaphors (though the latter was only evaluated on a small dataset of 10 adjectives and Turney and colleagues did not report results in terms of F-score, which is likely to be lower). Our use of visual features is in line with Turney's hypothesis concerning the relevance of concreteness features to metaphor processing. However, our results indicate that extracting this information from image data directly is a more suitable way to capture the concreteness itself, as well as capturing other relevant perceptual properties of concepts. The method of Tsvetkov et al. (2014) used both concreteness features (which they extracted from the MRC concreteness database) and hand-coded domain information for words (which they extracted from WordNet). They report a high F-score of 0.85 for adjective–noun classification on TSV-TEST. The performance of our method on the same dataset is a little lower than that of Tsvetkov et al. However, we do not use any hand-annotated resources and acquire linguistic, domain and perceptual information in the data-driven way. It is thus encouraging that, even though resource-lean, our methods approach the performance level of the methods using hand-annotated features (as in case of Tsvetkov et al. (2014)) or outperform them (as in case of Turney et al. (2011), Neuman et al. (2013), Dunn (2013b), Mohler et al. (2013), Gandy et al. (2013), Strzalkowski et al. (2013), Beigman Klebanov et al. (2015) and many others). For further comparison with these approaches and their results see a recent review by Shutova (2015).

5 Conclusion

We presented the first method that uses visual features for metaphor identification. Our results demonstrate that the multi-modal model combining both linguistic and visual knowledge outperforms language-only models, suggesting the importance of visual information for metaphor processing. Unlike previous metaphor processing approaches, that employed hand-crafted resources to model perceptual properties of concepts, our method learns visual knowledge from images directly, thus reducing the risk of human annotation noise and having a wider coverage and applicability. Since the method relies on automatically acquired lexical knowledge, in the form of linguistic and visual embeddings, and is otherwise resource-independent, it can be applied to unrestricted text in any domain and easily tailored to other metaphor processing tasks.

In the future, it would be interesting to apply multimodal word and phrase embeddings to automatically interpret metaphorical language, e.g. by deriving literal or conventional paraphrases for metaphorical expressions (similarly to the task of Shutova (2010)). Multimodal embeddings are also likely to provide useful information for the models of metaphor translation, as they have already proved successful in bilingual lexicon induction more generally (Kiela et al., 2015b). Finally, it would be interesting to further investigate compositional properties of metaphorical language using multimodal phrase embeddings and to apply the embeddings to automatically generalise metaphorical associations between distinct concepts or domains.

Abstract

Recently there has been a lot of interest in learning common representations for multiple views of data. Typically, such common representations are learned using a parallel corpus between the two views (say, 1M images and their English captions). In this work, we address a real-world scenario where no direct parallel data is available between two views of interest (say, V_1 and V_2) but parallel data is available between each of these views and a pivot view (V_3). We propose a model for learning a common representation for V_1, V_2 and V_3 using only the parallel data available between V_1V_3 and V_2V_3. The proposed model is generic and even works when there are n views of interest and only one pivot view which acts as a bridge between them. There are two specific downstream applications that we focus on (i) transfer learning between languages L_1,L_2,...,L_n using a pivot language L and (ii) cross modal access between images and a language L_1 using a pivot language L_2. Our model achieves state-of-the-art performance in multilingual document classification on the publicly available multilingual TED corpus and promising results in multilingual multimodal retrieval on a new dataset created and released as a part of this work.

1 Introduction

The proliferation of multilingual and multimodal content online has ensured that multiple views of the same data exist. For example, it is common to find the same article published in multiple languages online in multilingual news articles, multilingual wikipedia articles, *etc*. Such multiple views can even belong to different modalities. For example, images and their textual descriptions are two views of the same entity. Similarly, audio, video and subtitles of a movie are multiple views of the same entity.

Learning common representations for such multiple views of data will help in several downstream applications. For example, learning a common representation for images and their textual descriptions could help in finding images which match a given textual description. Further, such common representations can also facilitate transfer learning between views. For example, a document classifier trained on one language (view) can be used to classify documents in another language by representing documents of both languages in a common subspace.

Existing approaches to common representation learning (Ngiam et al., 2011; Klementiev et al., 2012; Chandar et al., 2013; Chandar et al., 2014; Andrew et al., 2013; Wang et al., 2015) except (Hermann and Blunsom, 2014b) typically require parallel data between all views. However, in many real-world scenarios such parallel data may not be available. For example, while there are many publicly available datasets containing images and their corresponding English captions, it is very hard to find datasets containing images and their corresponding captions in Russian, Dutch, Hindi, Urdu, *etc.* In this work, we are interested in addressing such scenarios. More specifically, we consider scenarios where we have n different views but parallel data is only available between each of these views, and a pivot view. In particular, there is no parallel data available between the non-pivot views.

To this end, we propose Bridge Correlational

Proceedings of NAACL-HLT 2016, pages 171–181,
San Diego, California, June 12-17, 2016.

Neural Networks (Bridge CorrNets) which learn aligned representations across multiple views using a pivot view. We build on the work of (Chandar et al., 2016) but unlike their model, which only addresses scenarios where direct parallel data is available between two views, our model can work for $n(\geq 2)$ views even when no parallel data is available between all of them. Our model only requires parallel data between each of these n views and a pivot view. During training, our model maximizes the correlation between the representations of the pivot view and each of the n views. Intuitively, the pivot view ensures that similar entities across different views get mapped close to each other since the model would learn to map each of them close to the corresponding entity in the pivot view.

We evaluate our approach using two downstream applications. First, we employ our model to facilitate transfer learning between multiple languages using English as the pivot language. For this, we do an extensive evaluation using 110 source-target language pairs and clearly show that we outperform the current state-of-the art approach (Hermann and Blunsom, 2014b). Second, we employ our model to enable cross modal access between images and French/German captions using English as the pivot view. For this, we created a test dataset consisting of images and their captions in French and German in addition to the English captions which were publicly available. To the best of our knowledge, this task of retrieving images given French/German captions (and vice versa) without direct parallel training data between them has not been addressed in the past. Even on this task we report promising results. Code and data used in this paper can be downloaded from `http://sarathchandar.in/bridge-corrnet`.

2 Related Work

Canonical Correlation Analysis (CCA) and its variants (Hotelling, 1936; Vinod, 1976; Nielsen et al., 1998; Cruz-Cano and Lee, 2014; Akaho, 2001) are the most commonly used methods for learning a common representation for two views. However, most of these models generally work with two views only. Even though there are multi-view generalizations of CCA (Tenenhaus and Tenenhaus, 2011; Luo et al., 2015), their computational complexity makes them unsuitable for larger data sizes.

Another class of algorithms for multiview learning is based on Neural Networks. One of the earliest neural network based model for learning common representations was proposed in (Hsieh, 2000). Recently, there has been a renewed interest in this field and several neural network based models have been proposed. For example, Multimodal Autoencoder (Ngiam et al., 2011), Deep Canonically Correlated Autoencoder (Wang et al., 2015), Deep CCA (Andrew et al., 2013) and Correlational Neural Networks (CorrNet) (Chandar et al., 2016). CorrNet performs better than most of the above mentioned methods and we build on their work as discussed in the next section.

One of the tasks that we address in this work is multilingual representation learning where the aim is to learn aligned representations for words across languages. Some notable neural network based approaches here include the works of (Klementiev et al., 2012; Zou et al., 2013; Mikolov et al., 2013; Hermann and Blunsom, 2014b; Hermann and Blunsom, 2014a; Chandar et al., 2014; Soyer et al., 2015; Gouws et al., 2015). However, except for (Hermann and Blunsom, 2014a; Hermann and Blunsom, 2014b), none of these other works handle the case when parallel data is not available between all languages. Our model addresses this issue and outperforms the model of Hermann and Blunsom (2014b).

The task of cross modal access between images and text addressed in this work comes under MultiModal Representation Learning where each view belongs to a different modality. Ngiam et al. (2011) proposed an autoencoder based solution to learning common representation for audio and video. Srivastava and Salakhutdinov (2014) extended this idea to RBMs and learned common representations for image and text. Other solutions for image/text representation learning include (Zheng et al., 2014a; Zheng et al., 2014b; Socher et al., 2014). All these approaches require parallel data between the two views and do not address multimodal, multilingual learning in situations where parallel data is available only between different views and a pivot view.

In the past, pivot/bridge languages have been used to facilitate MT (for example, (Wu and Wang, 2007; Cohn and Lapata, 2007; Utiyama and Isahara, 2007;

Nakov and Ng, 2009)), transitive CLIR (Ballesteros, 2000; Lehtokangas et al., 2008), transliteration and transliteration mining (Khapra et al., 2010a; Kumaran et al., 2010; Khapra et al., 2010b; Zhang et al., 2011). None of these works use neural networks but it is important to mention them here because they use the concept of a pivot language (view) which is central to our work.

3 Bridge Correlational Neural Network

In this section, we describe Bridge CorrNet which is an extension of the CorrNet model proposed by (Chandar et al., 2016). They address the problem of learning common representations between two views when parallel data is available between them. We propose an extension to their model which simultaneously learns a common representation for M views when parallel data is available only between one pivot view and the remaining $M-1$ views.

Let these views be denoted by $V_1, V_2, ..., V_M$ and let $d_1, d_2, ..., d_M$ be their respective dimensionalities. Let the training data be $\mathcal{Z} = \{z^i\}_{i=1}^N$ where each training instance contains only two views, *i.e.*, $z^i = (v_j^i, v_M^i)$ where $j \in \{1, 2, .., M-1\}$ and M is a pivot view. To be more clear, the training data contains N_1 instances for which (v_1^i, v_M^i) are available, N_2 instances for which (v_2^i, v_M^i) are available and so on till N_{M-1} instances for which (v_{M-1}^i, v_M^i) are available (such that $N_1 + N_2 + ... + N_{M-1} = N$). We denote each of these disjoint pairwise training sets by $\mathcal{Z}_1$, $\mathcal{Z}_2$ to $\mathcal{Z}_{M-1}$ such that $\mathcal{Z}$ is the union of all these sets.

As an illustration consider the case when English, French and German texts are the three views of interest with English as the pivot view. As training data, we have N_1 instances containing English and their corresponding French texts and N_2 instances containing English and their corresponding German texts. We are then interested in learning a common representation for English, French and German even though we do not have any training instance containing French and their corresponding German texts.

Bridge CorrNet uses an encoder-decoder architecture with a correlation based regularizer to achieve this. It contains one encoder-decoder pair for each of the M views. For each view V_j, we have,

$$h_{V_j}(v_j) = f(W_j v_j + b) \tag{1}$$

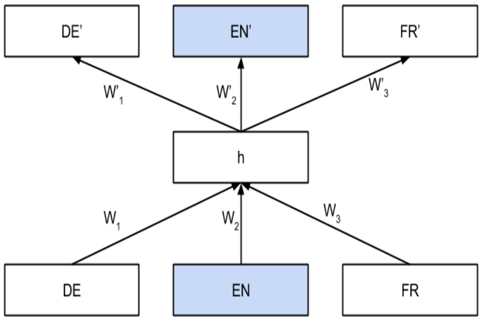

Figure 1: Bridge Correlational Neural Network. The views are English, French and German with English being the pivot view.

where f is any non-linear function such as sigmoid or tanh, $W_j \in \mathbb{R}^{k \times d_j}$ is the encoder matrix for view V_j, $b \in \mathbb{R}^k$ is the common bias shared by all the encoders. We also compute a hidden representation for the concatenated training instance $z = (v_j, v_M)$ using the following encoder function:

$$h_Z(z) = f(W_j v_j + W_M v_M + b) \tag{2}$$

In the remainder of this paper, whenever we drop the subscript for the encoder, then the encoder is determined by its argument. For example $h(v_j)$ means $h_{V_j}(v_j)$, $h(z)$ means $h_Z(z)$ and so on.

Our model also has a decoder corresponding to each view as follows:

$$g_{V_j}(h) = p(W'_j h + c_j) \tag{3}$$

where p can be any activation function, $W'_j \in \mathbb{R}^{d_j \times k}$ is the decoder matrix for view V_j, $c_j \in \mathbb{R}^{d_j}$ is the decoder bias for view V_j. We also define $g(h)$ as simply the concatenation of $[g_{V_j}(h), g_{V_M}(h)]$.

In effect, $h_{V_j}(.)$ encodes the input v_j into a hidden representation h and then $g_{V_j}(.)$ tries to decode/reconstruct v_j from this hidden representation h. Note that h can be computed using $h(v_j)$ or $h(v_M)$. The decoder can then be trained to decode/reconstruct both v_j and v_M given a hidden representation computed using any one of them. More formally, we train Bridge CorrNet by minimizing the following objective function:

$$\begin{aligned}\mathcal{J}_{\mathcal{Z}}(\theta) = &\sum_{i=1}^{N} L(z^i, g(h(z^i))) + \sum_{i=1}^{N} L(z^i, g(h(v^i_{l(i)}))) \\ &+ \sum_{i=1}^{N} L(z^i, g(h(v^i_{M}))) - \lambda \operatorname{corr}(h(V_{l(i)}), h(V_M))\end{aligned} \tag{4}$$

where $l(i) = j$ if $z^i \in \mathcal{Z}_j$ and the correlation term corr is defined as follows:

$$\text{corr} = \frac{\sum_{i=1}^{N}(h(x^i) - \overline{h(X)})(h(y^i) - \overline{h(Y)})}{\sqrt{\sum_{i=1}^{N}(h(x^i) - \overline{h(X)})^2 \sum_{i=1}^{N}(h(y^i) - \overline{h(Y)})^2}} \tag{5}$$

Note that $g(h(z^i))$ is the reconstruction of the input z^i after passing through the encoder and decoder. L is a loss function which captures the error in this reconstruction, λ is the scaling parameter to scale the last term with respect to the remaining terms, $\overline{h(X)}$ is the mean vector for the hidden representations of the first view and $\overline{h(Y)}$ is the mean vector for the hidden representations of the second view.

We now explain the intuition behind each term in the objective function. The first term captures the error in reconstructing the concatenated input z^i from itself. The second term captures the error in reconstructing both views given the non-pivot view, $v^i_{l(i)}$. The third term captures the error in reconstructing both views given the pivot view, v^i_M. Minimizing the second and third terms ensures that both the views can be predicted from any one view. Finally, the correlation term ensures that the network learns correlated common representations for all views.

Our model can be viewed as a generalization of the two-view CorrNet model proposed in (Chandar et al., 2016). By learning joint representations for multiple views using disjoint training sets $\mathcal{Z}_1$, $\mathcal{Z}_2$ to $\mathcal{Z}_{M-1}$ it eliminates the need for ${}^nC_2$ pair-wise parallel datasets between all views of interest. The pivot view acts as a bridge and ensures that similar entities across different views get mapped close to each other since all of them would be close to the corresponding entity in the pivot view.

Note that unlike the objective function of CorrNet (Chandar et al., 2016), the objective function of Equation 4, is a dynamic objective function which changes with each training instance. In other words, $l(i) \in \{1, 2, .., M-1\}$ varies for each $i \in \{1, 2, .., N\}$. For efficient implementation, we construct mini-batches where each mini-batch will come from only one of the sets $\mathcal{Z}_1$ to $\mathcal{Z}_{M-1}$. We randomly shuffle these mini-batches and use corresponding objective function for each mini-batch.

As a side note, we would like to mention that in addition to $\mathcal{Z}_1$, $\mathcal{Z}_2$ to $\mathcal{Z}_{M-1}$ as defined earlier, if additional parallel data is available between some of the non-pivot views then the objective function can be suitably modified to use this parallel data to further improve the learning. However, this is not the focus of this work and we leave this as a possible future work.

4 Datasets

In this section, we describe the two datasets that we used for our experiments.

4.1 Multlingual TED corpus

Hermann and Blunsom (2014b) provide a multilingual corpus based on the TED corpus for IWSLT 2013 (Cettolo et al., 2012). It contains English transcriptions of several talks from the TED conference and their translations in multiple languages. We use the parallel data between English and other languages for training Bridge Corrnet (English, thus, acts as the pivot langauge). Hermann and Blunsom (2014b) also propose a multlingual document classification task using this corpus. The idea is to use the keywords associated with each talk (document) as class labels and then train a classifier to predict these classes. There are one or more such keywords associated with each talk but only the 15 most frequent keywords across all documents are considered as class labels. We used the same pre-processed splits[1] as provided by (Hermann and Blunsom, 2014b). The training corpus consists of a total of 12,078 parallel documents distributed across 12 language pairs.

4.2 Multilingual Image Caption dataset

The MSCOCO dataset[2] contains images and their English captions. On an average there are 5 captions per image. The standard train/valid/test splits for this dataset are also available online. However, the reference captions for the images in the test split are not provided. Since we need such reference captions for evaluations, we create a new train/valid/test of this dataset. Specifically, we take 80K images from the standard train split and 40K images from the standard valid split. We then randomly split the merged 120K images into train(118K), validation (1K) and test set (1K).

[1] http://www.clg.ox.ac.uk/tedcorpus

[2] http://mscoco.org/dataset/

We then create a multilingual version of the test data by collecting French and German translations for all the 5 captions for each image in the test set. We use crowdsourcing to do this. We used the CrowdFlower platform and solicited one French and one German translation for each of the 5000 captions using native speakers. We got each translation verified by 3 annotators. We restricted the geographical location of annotators based on the target language. We found that roughly 70% of the French translations and 60% of the German translations were marked as correct by a majority of the verifiers. On further inspection with the help of in-house annotators, we found that the errors were mainly syntactic and the content words are translated correctly in most of the cases. Since none of the approaches described in this work rely on syntax, we decided to use all the 5000 translations as test data. This multilingual image caption test data (MIC test data) will be made publicly available[3] and will hopefully assist further research in this area.

5 Experiment 1: Transfer learning using a pivot language

From the TED corpus described earlier, we consider English transcriptions and their translations in 11 languages, *viz.*, Arabic, German, Spanish, French, Italian, Dutch, Polish, Portuguese (Brazilian), Roman, Russian and Turkish. Following the setup of Hermann and Blunsom (2014b), we consider the task of cross language learning between each of the ${}^{11}C_2$ non-English language pairs. The task is to classify documents in a language when no labeled training data is available in this language but training data is available in another language. This involves the following steps:

1. Train classifier: Consider one language as the source language and the remaining 10 languages as target languages. Train a document classifier using the labeled data of the source language, where each training document is represented using the hidden representation computed using a trained Bridge Cornet model. As in (Hermann and Blunsom, 2014b) we used an averaged perceptron trained for 10 epochs as the classifier for all our experiments. The train split provided by (Hermann and Blunsom, 2014b) is used for training.

2. Cross language classification: For every target language, compute a hidden representation for every document in its test set using Bridge CorrNet. Now use the classifier trained in the previous step to classify this document. The test split provided by (Hermann and Blunsom, 2014b) is used for testing.

5.1 Training and tuning Bridge Cornet

For the above process to work, we first need to train Bridge Cornet so that it can then be used for computing a common hidden representation for documents in different languages. For training Bridge CorrNet, we treat English as the pivot language (view) and construct parallel training sets $\mathcal{Z}_1$ to $\mathcal{Z}_{11}$. Every instance in $\mathcal{Z}_1$ contains the English and Arabic view of the same talk (document). Similarly, every instance in $\mathcal{Z}_2$ contains the English and German view of the same talk (document) and so on. For every language, we first construct a vocabulary containing all words appearing more than 5 times in the corpus (all talks) of that language. We then use this vocabulary to construct a bag-of-words representation for each document. The size of the vocabulary ($|V|$) for different languages varied from 31213 to 60326 words. To be more clear, $v_1 = v_{arabic} \in \mathbb{R}^{|V|_{arabic}}$, $v_2 = v_{german} \in \mathbb{R}^{|V|_{german}}$ and so on.

We train our model for 10 epochs using the above training data $\mathcal{Z} = \{\mathcal{Z}_1, \mathcal{Z}_2, ..., \mathcal{Z}_{11}\}$. We use hidden representations of size $D = 128$, as in (Hermann and Blunsom, 2014b). Further, we used stochastic gradient descent with mini-batches of size 20. Each mini-batch contains data from only one of the $\mathcal{Z}_i s$. We get a stochastic estimate for the correlation term in the objective function using this mini-batch. The hyperparameter λ was tuned to each task using a training/validation split for the source language and using the performance on the validation set of an averaged perceptron trained on the training set (notice that this corresponds to a monolingual classification experiment, since the general assumption is that no labeled data is available in the target language).

5.2 Results

We now present the results of our cross language classification task in Table 1. Each row corresponds to a source language and each column corresponds to a target language. We report the average F1-

Table 3: : F1-scores on the TED corpus document classification task when training and evaluating on the same language. Results other than Bridge CorrNet are taken from (Hermann and Blunsom, 2014b).

scores over all the 15 classes. We compare our results with the best results reported in (Hermann and Blunsom, 2014b) (see Table 2). Out of the 110 experiments, our model outperforms the model of (Hermann and Blunsom, 2014b) in 107 experiments. This suggests that our model efficiently exploits the pivot language to facilitate cross language learning between other languages.

Finally, we present the results for a monolingual classification task in Table 3. The idea here is to see if learning common representations for multiple views can also help in improving the performance of a task involving only one view. Hermann and Blunsom (2014b) argue that a Naive Bayes (NB) classifier trained using a bag-of-words representation of the documents is a very strong baseline. In fact, a classifier trained on document representations learned using their model does not beat a NB classifier for the task of monolingual classification. Rows 2 to 5 in Table 3 show the different settings tried by them (we refer the reader to (Hermann and Blunsom, 2014b) for a detailed description of these settings). On the other hand our model is able to beat NB for 5/11 languages. Further, for 4 other languages (German, French, Romanian, Russian) its performance is only marginally poor than that of NB.

6 Experiment 2: Cross modal access using a pivot language

In this experiment, we are interested in retrieving images given their captions in French (or German) and vice versa. However, for training we do not have any parallel data containing images and their French (or German) captions. Instead, we have the following datasets: (i) a dataset $\mathcal{Z}_1$ containing images and their English captions and (ii) a dataset $\mathcal{Z}_2$ containing English and their parallel French (or German) documents. For $\mathcal{Z}_1$, we use the training split of MSCOCO dataset which contains 118K images and their English captions (see Section 4.2). For $\mathcal{Z}_2$, we use the English-French (or German) parallel documents from the train split of the TED corpus (see Section 4.1). We use English as the pivot language and train Bridge Cornet using $\mathcal{Z} = \{\mathcal{Z}_1, \mathcal{Z}_2\}$ to learn common representations for images, English text and French (or German) text. For text, we use bag-of-words representation and for image, we use the 4096 (fc6) representation got from a pretrained ConvNet (BVLC Reference CaffeNet (Jia et al., 2014)). We learn hidden representations of size $D = 200$ by training Bridge Cornet for 20 epochs using stochastic gradient descent with mini-batches of size 20. Each mini-batch contains data from only one of the $\mathcal{Z}_i s$.

For the task of retrieving captions given an image, we consider the 1000 images in our test set (see section 4.2) as queries. The 5000 French (or German) captions corresponding to these images (5 per image) are considered as documents. The task is then to retrieve the relevant captions for each image. We represent all the captions and images in the common space as computed using Bridge Cornet. For a given query, we rank all the captions based on the Euclidean distance between the representation of the image and the caption. For the task of retrieving images given a caption, we simply reverse the role of the captions and images. In other words, each of the 5000 captions is treated as a query and the 1000 images are treated as documents. λ was tuned to each task using a training/validation split. For the task of retrieving French/German captions given an image, λ was tuned using the performance on the validation set for retrieving French (or German) sentences for a given English sentence. For the other task, λ was tuned using the performance on the validation set for retrieving images, given English captions. We do not use any image-French/German parallel data for tuning the hyperparameters.

We use recall@k as the performance metric and compare the following methods in Table 4:

1. En-Image CorrNet: This is the CorrNet model trained using only $\mathcal{Z}_1$ as defined earlier in this section. The task is to retrieve English captions for a given image (or vice versa). This gives us an idea about the performance we could expect if direct parallel data is available between images and their captions in some language. We used the publicly available implementation of CorrNet provided by (Chandar et al., 2016).

2. Bridge CorrNet: This is the Bridge CorrNet model trained using $\mathcal{Z}_1$ and $\mathcal{Z}_2$ as defined earlier in this section. The task is to retrieve French (or German) captions for a given image (or vice versa).

3. Bridge MAE: The Multimodal Autoencoder (MAE) proposed by (Ngiam et al., 2011) was the only competing model which was easily extendable to the bridge case. We train their model using $\mathcal{Z}_1$ and $\mathcal{Z}_2$ to minimize a suitably modified objective function. We then use the representations learned to retrieve French (or German) captions for a given image (or vice versa).

4. 2-CorrNet: Here, we train two individual CorrNets using $\mathcal{Z}_1$ and $\mathcal{Z}_2$ respectively. For the task of retrieving images given a French (or German) caption we first find its nearest English caption using the Fr-En (or De-En) CorrNet. We then use this English caption to retrieve images using the En-Image CorrNet. Similarly, for retrieving captions given an image we use the En-Image CorrNet followed by the En-Fr (or En-De) CorrNet.

5. CorrNet + MT: Here, we train an En-Image CorrNet using $\mathcal{Z}_1$ and an Fr/De-En MT system[4] using $\mathcal{Z}_2$. For the task of retrieving images given a French (or German) caption we translate the caption to English using the MT system. We then use this English caption to retrieve images using the En-Image CorrNet. For retrieving captions given images, we first translate all the 5000 French (or Germam) captions to English. We then embed these English translations (documents) and images (queries) in the com-

Table 4: Performance of different models for image to caption (I to C) and caption to image (C to I) retrieval

mon space computed using Image-En CorrNet and do a retrieval as explained earlier.

6. Random: A random image is returned for the given caption (and vice versa).

From Table 4, we observe that `CorrNet + MT` is a very strong competitor and gives the best results. The main reason for this is that over the years MT has matured enough for language pairs such as Fr-En and De-En and it can generate almost perfect translations for short sentences (such as captions). In fact, the results for this method are almost comparable to what we could have hoped for if we had direct parallel data between Fr-Images and De-Images (as approximated by the first row in the table which reports cross-modal retrieval results between En-Images using direct parallel data between them for training). However, we would like to argue that learning a joint embedding for multiple views instead of having multiple pairwise systems is a more elegant solution and definitely merits further attention. Further, a "translation system" may not be available when we are dealing with modalities other than text (for example, there are no audio-to-video translation systems). In such cases, BridgeCorrNet could still be employed. In this context, the performance of BridgeCorrNet is definitely promising and shows that a model which jointly learns representations for multiple views can perform better than methods which learn pair-wise common representations (2-CorrNet).

6.1 Qualitative Analysis

To get a qualitative feel for our model's performance, we refer the reader to Table 5 and 6. The first row in Table 5 shows an image and its top-5 nearest German captions (based on Euclidean distance between their common representations). As per our parallel image caption test set, only the second and fourth caption actually correspond to this image. However, we observe that the first and fifth caption are also semantically very related to the image. Both these captions talk about horses, grass or water body (ocean), *etc*. Similarly the last row in Table 5 shows an image and its top-5 nearest French captions. None of these captions actually correspond to the image as per our parallel image caption test set. However, clearly the first, third and fourth caption are semantically very relevant to this image as all of them talk about baseball. Even the remaining two captions capture the concept of a *sport* and *raquet*. We can make a similar observation from Table 6 where most of the top-5 retrieved images do not correspond to the French/German caption but they are semantically very similar. It is indeed impressive that the model is able to capture such cross modal semantics between images and French/German even without any direct parallel data between them.

7 Conclusion

In this paper, we propose Bridge Correlational Neural Networks which can learn common representations for multiple views even when parallel data is available only between these views and a pivot view. Our method performs better than the existing state of the art approaches on the cross language classification task and gives very promising results on the cross modal access task. We also release a new multilingual image caption benchmark (MIC benchmark) which will help in further research in this field[5].

[5] Details about the MIC benchmark and performance of various state-of-the-art models will be maintained at `http://sarathchandar.in/bridge-cornet`

Abstract

We introduce a new task, visual sense disambiguation for verbs: given an image and a verb, assign the correct sense of the verb, i.e., the one that describes the action depicted in the image. Just as textual word sense disambiguation is useful for a wide range of NLP tasks, visual sense disambiguation can be useful for multimodal tasks such as image retrieval, image description, and text illustration. We introduce VerSe, a new dataset that augments existing multimodal datasets (COCO and TUHOI) with sense labels. We propose an unsupervised algorithm based on Lesk which performs visual sense disambiguation using textual, visual, or multimodal embeddings. We find that textual embeddings perform well when gold-standard textual annotations (object labels and image descriptions) are available, while multimodal embeddings perform well on unannotated images. We also verify our findings by using the textual and multimodal embeddings as features in a supervised setting and analyse the performance of visual sense disambiguation task. VerSe is made publicly available and can be downloaded at: `https://github.com/spandanagella/verse`.

1 Introduction

Word sense disambiguation (WSD) is a widely studied task in natural language processing: given a word and its context, assign the correct sense of the word based on a pre-defined sense inventory (Kilgarrif, 1998). WSD is useful for a range of NLP tasks, including information retrieval, information extraction, machine translation, content analysis, and lexicography (see Navigli (2009) for an overview). Standard WSD disambiguates words based on their *textual context*; however, in a multimodal setting (e.g., newspaper articles with photographs), *visual context* is also available and can be used for disambiguation. Based on this observation, we introduce a new task, *visual sense disambiguation* (VSD) for verbs: given an image and a verb, assign the correct sense of the verb, i.e., the one depicted in the image. While VSD approaches for nouns exist, VSD for verbs is a novel, more challenging task, and related in interesting ways to *action recognition* in computer vision. As an example consider the verb *play*, which can have the senses *participate in sport*, *play on an instrument*, and *be engaged in playful activity*, depending on its visual context, see Figure 1.

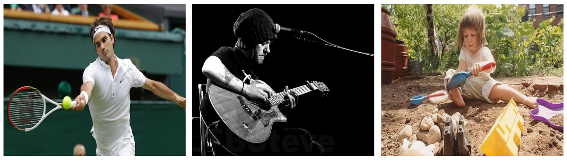

Figure 1: Visual sense ambiguity: three of the senses of the verb *play*.

We expect visual sense disambiguation to be useful for multimodal tasks such as image retrieval. As an example consider the output of Google Image Search for the query *sit*: it recognizes that the verb has multiple senses and tries to cluster relevant images. However, the result does not capture the polysemy of the verb well, and would clearly benefit from VSD (see Figure 2).

Visual sense disambiguation has previously been attempted for nouns (e.g., *apple* can mean *fruit* or *computer*), which is a substantially easier task that can be solved with the help of an object detector

Proceedings of NAACL-HLT 2016, pages 182–192,

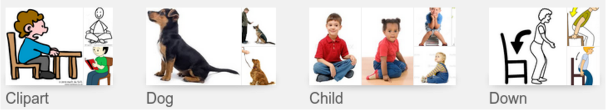

Figure 2: Google Image Search trying to disambiguate *sit*. All clusters pertain to the *sit down* sense, other senses (*baby sit*, *convene*) are not included.

(Barnard et al., 2003; Loeff et al., 2006; Saenko and Darrell, 2008; Chen et al., 2015). VSD for nouns is helped by resources such as ImageNet (Deng et al., 2009), a large image database containing 1.4 million images for 21,841 noun synsets and organized according to the WordNet hierarchy. However, we are not aware of any previous work on VSD for verbs, and no ImageNet for verbs exists. Not only image retrieval would benefit from VSD for verbs, but also other multimodal tasks that have recently received a lot of interest, such as automatic image description and visual question answering (Karpathy and Li, 2015; Fang et al., 2015; Antol et al., 2015).

In this work, we explore the new task of visual sense disambiguation for verbs: given an image and a verb, assign the correct sense of the verb, i.e., the one that describes the action depicted in the image. We present VerSe, a new dataset that augments existing multimodal datasets (COCO and TUHOI) with sense labels. VerSe contains 3518 images, each annotated with one of 90 verbs, and the OntoNotes sense realized in the image. We propose an algorithm based on the Lesk WSD algorithm in order to perform unsupervised visual sense disambiguation on our dataset. We focus in particular on how to best represent word senses for visual disambiguation, and explore the use of textual, visual, and multimodal embeddings. Textual embeddings for a given image can be constructed over object labels or image descriptions, which are available as gold-standard in the COCO and TUHOI datasets, or can be computed automatically using object detectors and image description models.

Our results show that textual embeddings perform best when gold-standard textual annotations are available, while multimodal embeddings perform best when automatically generated object labels are used. Interestingly, we find that automatically generated image descriptions result in inferior performance.

Dataset	Verbs	Acts	Images	Sen	Des

2 Related Work

There is an extensive literature on word sense disambiguation for nouns, verbs, adjectives and adverbs. Most of these approaches rely on lexical databases or sense inventories such as WordNet (Miller et al., 1990) or OntoNotes (Hovy et al., 2006). Unsupervised WSD approaches often rely on distributional representations, computed over the target word and its context (Lin, 1997; McCarthy et al., 2004; Brody and Lapata, 2008). Most supervised approaches use sense annotated corpora to extract linguistic features of the target word (context words, POS tags, collocation features), which are then fed into a classifier to disambiguate test data (Zhong and Ng, 2010). Recently, features based on sense-specific semantic vectors learned using large corpora and a sense inventory such as WordNet have been shown to achieve state-of-the-art results for supervised WSD (Rothe and Schutze, 2015; Jauhar et al., 2015).

As mentioned in the introduction, all existing work on visual sense disambiguation has used nouns, starting with Barnard et al. (2003). Sense discrimination for web images was introduced by Loeff et al. (2006), who used spectral clustering over multimodal features from the images and web text. Saenko and Darrell (2008) used sense definitions in a dictionary to learn a latent LDA space overs senses, which they then used to construct sense-specific classifiers by exploiting the text surrounding an image.

2.1 Related Datasets

Most of the datasets relevant for verb sense disambiguation were created by the computer vision community for the task of human action recognition (see

Table 1 for an overview). These datasets are annotated with a limited number of actions, where an action is conceptualized as verb-object pair: *ride horse*, *ride bicycle*, *play tennis*, *play guitar*, etc. Verb sense ambiguity is ignored in almost all action recognition datasets, which misses important generalizations: for instance, the actions *ride horse* and *ride bicycle* represent the same sense of *ride* and thus share visual, textual, and conceptual features, while this is not the case for *play tennis* and *play guitar*. This is the issue we address by creating a dataset with explicit sense labels.

VerSe is built on top of two existing datasets, TUHOI and COCO. The Trento Universal Human-Object Interaction (TUHOI) dataset contains 10,805 images covering 2974 actions. Action (human-object interaction) categories were annotated using crowdsourcing: each image was labeled by multiple annotators with a description in the form of a verb or a verb-object pair. The main drawback of TUHOI is that 1576 out of 2974 action categories occur only once, limiting its usefulness for VSD. The Microsoft Common Objects in Context (COCO) dataset is very popular in the language/vision community, as it consists of over 120k images with extensive annotation, including labels for 91 object categories and five descriptions per image. COCO contains no explicit action annotation, but verbs and verb phrases can be extracted from the descriptions. (But note that not all the COCO images depict actions.)

The recently created Humans Interacting with Common Objects (HICO) dataset is conceptually similar to VerSe. It consists of 47774 images annotated with 111 verbs and 600 human-object interaction categories. Unlike other existing datasets, HICO uses sense-based distinctions: actions are denoted by sense-object pairs, rather than by verb-object pairs. HICO doesn't aim for complete coverage, but restricts itself to the top three WordNet senses of a verb. The dataset would be suitable for performing visual sense disambiguation, but has so far not been used in this way.

3 VerSe Dataset and Annotation

We want to build an unsupervised visual sense disambiguation system, i.e., a system that takes an image and a verb and returns the correct sense of the verb. As discussed in Section 2.1, most existing datasets are not suitable for this task, as they do not include word sense annotation. We therefore develop our own dataset with gold-standard sense annotation. The Verb Sense (VerSe) dataset is based on COCO and TUHOI and covers 90 verbs and around 3500 images. VerSe serves two main purposes: (1) to show the feasibility of annotating images with verb senses (rather than verbs or actions); (2) to function as test bed for evaluating automatic visual sense disambiguation methods.

Verb: touch

- □ make physical contact with, possibly with the effect of physically manipulating. They touched their fingertips together and smiled
- □ affect someone emotionally The president's speech touched a chord with voters.
- □ be or come in contact without control They sat so close that their arms touched.
- □ make reference to, involve oneself with They had wide-ranging discussions that touched on the situation in the Balkans.
- □ Achieve a value or quality Nothing can touch cotton for durability.
- □ Tinge; repair or improve the appearance of He touched on the paintings, trying to get the colors right.

Figure 3: Example item for depictability and sense annotation: synset definitions and examples (in blue) for the verb *touch*.

Verb Selection Action recognition datasets often use a limited number of verbs (see Table 1). We addressed this issue by using images that come with descriptions, which in the case of action images typically contain verbs. The COCO dataset includes images in the form of sentences, the TUHOI dataset is annotated with verbs or prepositional verb phrases for a given object (e.g., *sit on* chair), which we use in lieu of descriptions. We extracted all verbs from all the descriptions in the two datasets and then selected those verbs that have more than one sense in the OntoNotes dictionary, which resulted in 148 verbs in total (94 from COCO and 133 from TUHOI).

Depictability Annotation A verb can have multiple senses, but not all of them may be depictable, e.g., senses describing cognitive and perception processes. Consider two senses of *touch*: *make physical contact* is depictable, whereas *affect emotionally* describes a cognitive process and is not depictable. We therefore need to annotate the synsets of a verb as depictable or non-depictable. Amazon Mechanical Turk (AMT) workers were presented with the definitions of all the synsets of a verb, along with ex-

Verb type	Examples	Verbs	Images	Senses	Depct	ITA
Motion	run, walk, jump, etc.	39	1812	10.76	5.79	0.680
Non-motion	sit, stand, lay, etc.	51	1698	8.27	4.86	0.636

Table 2: Overview of VerSe dataset divided into motion and non-motion verbs; Depct: depictable senses; ITA: inter-annotator agreement.

amples, as given by OntoNotes. An example for this annotation is shown in Figure 3. We used OntoNotes instead of WordNet, as WordNet senses are very fine-grained and potentially make depictability and sense annotation (see below) harder. Granularity issues with WordNet for text-based WSD are well documented (Navigli, 2009).

OntoNotes lists a total of 921 senses for our 148 target verbs. For each synset, three AMT workers selected all depictable senses. The majority label was used as the gold standard for subsequent experiments. This resulted in a 504 depictable senses. Inter-annotator agreement (ITA) as measured by Fleiss' Kappa was 0.645.

Sense Annotation We then annotated a subset of the images in COCO and TUHOI with verb senses. For every image we assigned the verb that occurs most frequently in the descriptions for that image (for TUHOI, the descriptions are verb-object pairs, see above). However, many verbs are represented by only a few images, while a few verbs are represented by a large number of images. The datasets therefore show a Zipfian distribution of linguistic units, which is expected and has been observed previously for COCO (Ronchi and Perona, 2015). For sense annotation, we selected only verbs for which either COCO or TUHOI contained five or more images, resulting in a set of 90 verbs (out of the total 148). All images for these verbs were included, giving us a dataset of 3518 images: 2340 images for 82 verbs from COCO and 1188 images for 61 verbs from TUHOI (some verbs occur in both datasets).

These image-verb pairs formed the basis for sense annotation. AMT workers were presented with the image and all the depictable OntoNotes senses of the associated verb. The workers had to chose the sense of the verb that was instantiated in the image (or "none of the above", in the case of irrelevant images). Annotators were given sense definitions and examples, as for the depictability annotation (see Figure 3). For every image-verb pair, five annotators performed the sense annotation task. A total of 157 annotators participated, reaching an inter-annotator agreement of 0.659 (Fleiss' Kappa). Out of 3528 images, we discarded 18 images annotated with "none of the above", resulting in a set of 3510 images covering 90 verbs and 163 senses. We present statistics of our dataset in Table 2; we group the verbs into motion verbs and non-motion verb using Levin (1993) classes.

4 Visual Sense Disambiguation

For our disambiguation task, we assume we have a set of images I, and a set of polysemous verbs V and each image $i \in I$ is paired with a verb $v \in V$. For example, Figure 1 shows different images paired with the verb *play*. Every verb $v \in V$, has a set of senses $\mathcal{S}(v)$, described in a dictionary $\mathcal{D}$. Now given an image i paired with a verb v, our task is to predict the correct sense $\hat{s} \in \mathcal{S}(v)$, i.e., the sense that is depicted by the associated image. Formulated as a scoring task, disambiguation consists of finding the maximum over a suitable scoring function Φ:

$$\hat{s} = \operatorname*{arg\,max}_{s \in \mathcal{S}(v)} \Phi(s, i, v, \mathcal{D}) \tag{1}$$

For example, in Figure 1, the correct sense for the first image is *participate in sport*, for the second one it is *play on an instrument*, etc.

The Lesk (1986) algorithm is a well known knowledge-based approach to WSD which relies on the calculation of the word overlap between the sense definition and the context in which a word occurs. It is therefore an unsupervised approach, i.e., it does not require sense-annotated training data, but instead exploits resources such as dictionaries or ontologies to infer the sense of a word in context. Lesk uses the following scoring function to disambiguate the sense of a verb v:

$$\Phi(s, v, \mathcal{D}) = |\mathit{context}(v) \cap \mathit{definition}(s, \mathcal{D})| \tag{2}$$

Here, $\mathit{context}(v)$ the set of words that occur close the target word v and $\mathit{definition}(s, \mathcal{D})$ is the set of words in the definition of sense s in the dictionary $\mathcal{D}$. Lesk's approach is very sensitive to the exact wording of definitions and results are known to change dramatically for different sets of definitions (Navigli, 2009). Also, sense definitions are often very

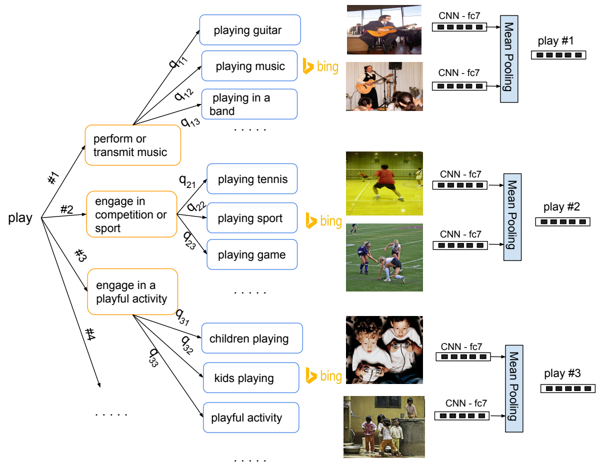

Figure 5: Extracting visual sense representation for the verb *play*.

short and do not provide sufficient vocabulary or context.

We propose a new variant of the Lesk algorithm to disambiguate the verb sense that is depicted in an image. In particular, we explore the effectiveness of textual, visual and multimodal representations in conjunction with Lesk. An overview of our methodology is given in Figure 4. For a given image i labeled with verb v (here *play*), we create a representation (the vector $\mathbf{i}$), which can be text-based (using the object labels and descriptions for i), visual, or multimodal. Similarly, we create text-based, visual, and multimodal representations (the vector $\mathbf{s}$) for every sense s of a verb. Based on the representations $\mathbf{i}$ and $\mathbf{s}$ (detailed below), we can then score senses as:[1]

$$\Phi(s, v, i, \mathcal{D}) = \mathbf{i} \cdot \mathbf{s} \tag{3}$$

Note that this approach is unsupervised: it requires no sense annotated training data; we will use the sense annotations in our VerSe dataset only for evaluation.

4.1 Sense Representations

For each candidate verb sense, we create a text-based sense representation $\mathbf{s^t}$ and a visual sense representation $\mathbf{s^c}$.

Text-based Sense Representation We create a vector $\mathbf{s^t}$ for every sense $s \in \mathcal{S}(v)$ of a verb v from its definition and the example usages provided in the OntoNotes dictionary $\mathcal{D}$. We apply word2vec (Mikolov et al., 2013), a widely used model of word embeddings, to obtain a vector for every content word in the definition and examples of the sense. We then take the average of these vectors to compute an overall representation of the verb sense. For our experiments we used the pre-trained 300 dimensional vectors available with the word2vec package (trained on part of Google News dataset, about 100 billion words).

Visual Sense Representation Sense dictionaries typically provide sense definitions and example sentences, but no visual examples or images. For nouns, this is remedied by ImageNet (Deng et al., 2009), which provides a large number of example images for a subset of the senses in the WordNet noun hierarchy. However, no comparable resource is available for verbs (see Section 2.1).

In order to obtain visual sense representation $\mathbf{s^c}$, we therefore collected sense-specific images for the verbs in our dataset. For each verb sense s, three trained annotators were presented with the definition and examples from OntoNotes, and had to formulate a query $Q(s)$ that would retrieve images depicting the verb sense when submitted to a search engine. For every query q we retrieved images $I(q)$ using Bing image search (for examples, see Figure 5). We used the top 50 images returned by Bing for every query.

Once we have images for every sense, we can turn these images into feature representations us-

[1] Taking the dot product of two normalized vectors is equivalent to using cosine as similarity measure. We experimented with other similarity measures, but cosine performed best.

ing a convolutional neural network (CNN). Specifically, we used the VGG 16-layer architecture (VGGNet) trained on 1.2M images of the 1000 class ILSVRC 2012 object classification dataset, a subset of ImageNet (Simonyan and Zisserman, 2014). This CNN model has a top-5 classification error of 7.4% on ILSVRC 2012. We use the publicly available reference model implemented using CAFFE (Jia et al., 2014) to extract the output of the fc7 layer, i.e., a 4096 dimensional vector $\mathbf{c_i}$, for every image i. We perform mean pooling over all the images extracted using all the queries of a sense to generate a single visual sense representation $\mathbf{s^c}$ (shown in Equation 4):

$$\mathbf{s^c} = \frac{1}{n} \sum_{q_j \in Q(s)} \sum_{i \in I(q_j)} \mathbf{c_i} \tag{4}$$

where n is the total number of images retrieved per sense s.

4.2 Image Representations

We first explore the possibility of representing the image indirectly, viz., through text associated with it in the form of object labels or image descriptions (as shown in Figure 4). We experiment with two different forms of textual annotation: GOLD annotation, where object labels and descriptions are provided by human annotators, and predicted (PRED) annotation, where state-of-the-art object recognition and image description generation systems are applied to the image.

Object Labels (O) GOLD object annotations are provided with the two datasets we use. Each image sampled from COCO is annotated with one or more of 91 object categories. Each image from TUHOI is annotated with one more of 189 object categories. PRED object annotations were generated using the same VGG-16-layer CNN object recognition model that was used to compute visual sense representations. Only object labels with object detection threshold of $t > 0.2$ were used.

Descriptions (C) To obtain GOLD image descriptions, we used the used human-generated descriptions that come with COCO. For TUHOI images, we generated descriptions of the form subject-verb-object, where the subject is always *person*, and the verb-object pairs are the action labels that come with TUHOI. To obtain PRED descriptions, we generated three descriptions for every image using the state-of-the-art image description system of Vinyals et al. (2015).[2]

We can now create a textual representation $\mathbf{i^t}$ of the image i. Again, we used word2vec to obtain word embeddings, but applied these to the object labels and to the words in the image descriptions. An overall representation of the image is then computed by averaging these vectors over all labels, all content words in the description, or both.

Creating a visual representation $\mathbf{i^c}$ of an image i is straightforward: we extract the fc7 layer of the VGG-16 network when applied to the image and use the resulting vector as our image representation (same setup as in Section 4.1).

Apart from experimenting with separate textual and visual representations of images, it also makes sense to combine the two modalities into a multimodal representation. The simplest approach is a concatenation model which appends textual and visual features. More complex multimodal vectors can be created using methods such as Canonical Correlation Analysis (CCA) and Deep Canonical Correlation Analysis (DCCA) (Hardoon et al., 2004; Andrew et al., 2013; Wang et al., 2015). CCA allows us to find a latent space in which the linear projections of text and image vectors are maximally correlated (Gong et al., 2014; Hodosh et al., 2015). DCCA can be seen as non-linear version of CCA and has been successfully applied to image description task (Yan and Mikolajczyk, 2015), outperforming previous approaches, including kernel-based CCA.

We use both CCA and DCCA to map the vectors $\mathbf{i^t}$ and $\mathbf{i^c}$ (which have different dimensions) into a joint latent space of n dimensions. We represent the projected vectors of textual and visual features for image i as $\mathbf{i^{t'}}$ and $\mathbf{i^{c'}}$ and combine them to obtain multimodal representation $\mathbf{i^m}$ as follows:

$$\mathbf{i^m} = \lambda_t \mathbf{i^{t'}} + \lambda_c \mathbf{i^{c'}} \tag{5}$$

We experimented with a number of parameter settings for λ_t and λ_c for textual and visual models respectively. We use the same model to combine the multimodal representation for sense s as follows:

$$\mathbf{s^m} = \lambda_t \mathbf{s^{t'}} + \lambda_c \mathbf{s^{c'}} \tag{6}$$

[2] We used Karpathy's implementation, publicly available at `https://github.com/karpathy/neuraltalk`.

We use these vectors ($\mathbf{i^t}$, $\mathbf{s^t}$), ($\mathbf{i^c}$, $\mathbf{s^c}$) and ($\mathbf{i^m}$, $\mathbf{s^m}$) as described in Equation 3 to perform sense disambiguation.

5 Experiments

5.1 Unsupervised Setup

To train the CCA and DCCA models, we use the text representations learned from image descriptions of COCO and Flickr30k dataset as one view and the VGG-16 features from the respective images as the second view. We divide the data into train, test and development samples (using a 80/10/10 split). We observed that the correlation scores for DCCA model were better than for the CCA model. We use the trained models to generate the projected representations of text and visual features for the images in VerSe. Once the textual and visual features are projected, we then merge them to get the multimodal representation. We experimented with different ways of combining visual and textual features projected using CCA or DCCA: (1) weighted interpolation of textual and visual features (see Equations 5 and 6), and (2) concatenating the vectors of textual and visual features.

To evaluate our proposed method, we compare against the first sense heuristic, which defaults to the sense listed first in the dictionary (where senses are typically ordered by frequency). This is a strong baseline which is known to outperform more complex models in traditional text-based WSD. In VerSe we observe skewness in the distribution of the senses and the first sense heuristic is as strong as over text. Also the most frequent sense heuristic, which assigns the most frequently annotated sense for a given verb in VerSe, shows very strong performance. It is supervised (as it requires sense annotated data to obtain the frequencies), so it should be regarded as an upper limit on the performance of the unsupervised methods we propose (also, in text-based WSD, the most frequent sense heuristic is considered an upper limit, Navigli (2009)).

5.1.1 Results

In Table 3, we summarize the results of the gold-standard (GOLD) and predicted (PRED) settings for motion and non-motion verbs across representations. In the GOLD setting we find that for both types of verbs, textual representations based on image descriptions (C) outperform visual representations (CNN features). The text-based results compare favorably to the original Lesk (as described in Equation 2), which performs at 30.7 for motion verbs and 36.2 for non-motion verbs in the GOLD setting. This improvement is clearly due to the use of word2vec embeddings.[3] Note that CNN-based visual features alone performed better than gold-standard object labels alone in the case of motion verbs.

We also observed that adding visual features to textual features improves performance in some cases: multimodal features perform better than textual features alone both for object labels (CNN+O) and for image descriptions (CNN+C). However, adding CNN features to textual features based on object labels and descriptions together (CNN+O+C) resulted in a small decrease in performance. Furthermore, we note that CCA models outperform simple vector concatenation in case of GOLD setting for motion verbs, and overall DCCA performed considerably worse than concatenation. Note that for CCA and DCCA we report the best performing scores achieved using weighted interpolation of textual and visual features with weights $\lambda_t = 0.5$ and $\lambda_c = 0.5$.

When comparing to our baseline and upper limit, we find that the all the GOLD models which use descriptions-based representations (except DCCA) outperform to the first sense heuristic for motion-verbs (accuracy 70.8), whereas they performed below the first sense heuristic in case of non-motion verbs (accuracy 80.6). As expected, both motion and non-motion verbs performed significantly below the most frequent sense heuristic (accuracy 86.2 and 90.7 respectively), which we argued provides an upper limit for unsupervised approaches.

We now turn the PRED configuration, i.e., to results obtained using object labels and image descriptions predicted by state-of-the-art automatic systems. This is arguably the more realistic scenario, as it only requires images as input, rather than assuming human-generated object labels and image descriptions (though object detection and image description systems are required instead). In the PRED setting, we find that textual features based on ob-

[3] We also experimented with Glove vectors (Pennington et al., 2014) but observed that word2vec representations consistently achieved better results that Glove vectors.

CNN	80.0	55.6	80.0	55.6
CNN+O	80.0	56.5	80.0	52.1
CNN+C	80.0	56.5	80.3	60.0
CNN+O+C	80.0	59.1	80.0	55.6

Table 5: Accuracy scores for non-motion verbs for both supervised and unsupervised approaches using different types of sense and image representation features.

ject labels (O) outperform both first sense heuristic and textual features based on image descriptions (C) in the case of motion verbs. Combining textual and visual features via concatenation improves performance for both motion and non-motion verbs. The overall best performance of 72.6 for predicted features is obtained by combining CNN features and embeddings based on object labels and outperforms first sense heuristic in case of motion verbs (accuracy 70.8). In the PRED setting for both classes of verbs the simpler concatenation model performed better than the more complex CCA and DCCA models. Note that for CCA and DCCA we report the best performing scores achieved using weighted interpolation of textual and visual features with weights $\lambda_t = 0.3$ and $\lambda_c = 0.7$. Overall, our findings are consistent with the intuition that motion verbs are easier to disambiguate than non-motion verbs, as they are more depictable and more likely to involve objects. Note that this is also reflected in the higher interannotator agreement for motion verbs (see Table 2).

5.2 Supervised Experiments and Results

Along with the unsupervised experiments we investigated the performance of textual and visual representations of images in a simplest supervised setting. We trained logistic regression classifiers for sense prediction by dividing the images in VerSe dataset into train and test splits. To train the classifiers we selected all the verbs which has atleast 20 images annotated and has at least two senses in VerSe. This resulted in 19 motion verbs and 19 non-motion verbs. Similar to our unsupervised experiments we explore multimodal features by using both textual and visual features for classification (similar to concatenation in unsupervised experiments).

Verb	Image	Predicted Descriptions	Pred. Obj.
play		A man holding a nintendo wii game controller. A man and a woman playing a video game. A man and a woman are playing a video game.	person, bassoon, violin fiddle, oboe, hautboy
swing		A woman standing next to a fire hydrant. A woman walking down a street holding an umbrella. A woman standing on a sidewalk holding an umbrella.	person, horizontal bar, high bar, pole
feed		A couple of cows standing next to each other. A cow that is standing in the dirt. A close up of a horse in a stable	arabian camel, dromedary, person

Table 6: Images that were assigned an incorrect sense in the PRED setting.

In Table 4 we report accuracy scores for 19 motion verbs using a supervised logistic regression classifier and for comparison we also report the scores of our proposed unsupervised algorithm for both GOLD and PRED setting. Similarly in Table 5 we report the accuracy scores for 19 non-motion verbs. We observe that all supervised classifiers for both motion and non-motion verbs performing better than first sense baseline. Similar to our findings using an unsupervised approach we find that in most cases multimodal features obtained using concatenating textual and visual features has outperformed textual or visual features alone especially in the PRED setting which is arguably the more realistic scenario. We observe that the features from PRED image descriptions showed better results for non-motion verbs for both supervised and unsupervised approaches whereas PRED object features showed better results for motion verbs. We also observe that supervised classifiers outperform most frequent sense for motion verbs and for non-motion verbs our scores match with most frequent sense heuristic.

5.3 Error Analysis

In order to understand the cases where the proposed unsupervised algorithm failed, we analyzed the images that were disambiguated incorrectly. For the PRED setting, we observed that using predicted image descriptions yielded lower scores compared to predicted object labels. The main reason for this is that the image description system often generates irrelevant descriptions or descriptions not related to the action depicted, whereas the object labels predicted by the CNN model tend to be relevant. This highlights that current image description systems still have clear limitations, despite the high evaluation scores reported in the literature (Vinyals et al., 2015; Fang et al., 2015). Examples are shown in Table 6: in all cases human generated descriptions and object labels that are relevant for disambiguation, which explains the higher scores in the GOLD setting.

6 Conclusion

We have introduced the new task of visual verb sense disambiguation: given an image and a verb, identify the verb sense depicted in the image. We developed the new VerSe dataset for this task, based on the existing COCO and TUHOI datasets. We proposed an unsupervised visual sense disambiguation model based on the Lesk algorithm and demonstrated that both textual and visual information associated with an image can contribute to sense disambiguation. In an in-depth analysis of various image representations we showed that object labels and visual features extracted using state-of-the-art convolutional neural networks result in good disambiguation performance, while automatically generated image descriptions are less useful.

Stating the Obvious: Extracting Visual Common Sense Knowledge

Abstract

Obtaining common sense knowledge using current information extraction techniques is extremely challenging. In this work, we instead propose to derive simple common sense statements from fully annotated object detection corpora such as the Microsoft Common Objects in Context dataset. We show that many thousands of common sense facts can be extracted from such corpora at high quality. Furthermore, using WordNet and a novel submodular k-coverage formulation, we are able to generalize our initial set of common sense assertions to unseen objects and uncover over 400k potentially useful facts.

1 Introduction

How can we discover that bowls can hold broccoli, that if a knife touches a cake then a person is probably cutting cake, or that cutlery can be on dining tables? We propose to leverage the effort of computer vision researchers in creating large scale datasets for object detection and use these resources instead to extract symbolic representations of visual common sense. The knowledge we compile is physical, not commonly covered in text and more exhaustive than what people can usually produce.

Our focus is particularly on visual common sense, defined as the information about spatial and functional properties of entities in the world. We propose to extract three types of knowledge from the Microsoft Common Objects in Context dataset (Lin et al., 2014) (MS-COCO), consisting of 300,000 images, covering 80 objects, with object segments and natural language captions. First, we find spatial relations, e.g. *holds*(bed, dog), from outlines of co-occurring objects. Next, we construct entailment rules like *holds*(bed, dog) $\Rightarrow$ *laying-on*(dog, bed) by associating spatial relations with text in captions. Finally, we uncover general facts such as *holds*(furniture, domestic animal), applicable to object types not present in MS-COCO by using WordNet (Miller, 1995) and a novel submodular k-coverage formulation.

Evaluations using crowdsourcing show our methods can discover many thousands of high quality explicit statements of visual common sense. While some of this knowledge can be potentially extracted from text (Vanderwende, 2005), we found that from our top 100 extracted spatial relations, e.g. *holds*(bed, dog), only 4 are present in some form in the *AtLocation* relations in the popular ConceptNet (Speer and Havasi, 2013) knowledge base. This shows that the knowledge we derive provides complimentary information for other more general knowledge bases. Such common sense facts have proved useful for query expansion (Kotov and Zhai, 2012; Bouchoucha et al., 2013) and could benefit entailment (Dagan et al., 2010), grounded entailment (Bowman et al., 2015), or visual recognition tasks (Zhu et al., 2014).

2 Related Work

Common sense knowledge has been predominately created directly from human input or extracted from text (Lenat et al., 1990; Liu and Singh, 2004; Carlson et al., 2010). In contrast, our work is focused on visual common sense extracted from images anno-

tated with regions and descriptions.

There has also been recent interest in the vision community to build databases of visual common sense knowledge. Efforts have focused on a small set of relations, such as *similar to* or *part of* (Chen et al., 2013). Webly supervised techniques (Divvala et al., 2014; Chen et al., 2013) have also been used to test whether a particular object-relation-object triplet occurs in images (Sadeghi et al., 2015). In contrast, we use seven spatial relations and allow natural language relations that represent a larger array of higher level semantics. We also leverage existing efforts on annotating large scale image datasets instead of relying on the noisy outputs of a computer vision system.

On a technical level, our methods for extracting common sense facts from images rely on Pointwise-Mutual Information (PMI), analogous to other rule extraction systems based on text (Lin and Pantel, 2001; Schoenmackers et al., 2010). We view objects as an analogy for words, images as documents, and object-object configurations as typed bigrams. Our methods for generalizing relations are inspired by work that tries to predict a class label for an image given a hierarchy of concepts (Deng et al., 2012; Ordonez et al., 2013; Ordonez et al., 2015). Yet our work is the first to deal with visual relations between pairs of concepts in the hierarchy by using a sub-modular formulation that maximizes the amount of coverage of subordinate categories while avoiding contradictions with an initial set of discovered common-sense assertions.

3 Methods

We assume the availability of an object-level annotated image dataset D containing a set of images with textual descriptions. Each object in an image must be annotated with: (1) a mask or polygon outlining the extents of the object, and (2) the category of the object from a set of categories V and (3) an overall description of the image.

We produce three types of common sense facts, each with an associated scoring function: (1) Object-object relationships implicitly encoded in the relative configurations between objects in the annotated image data, i.e. *on*(bed, dog) (sec 3.1) , (2) Entailment relations encoded in the relationships between object-object configurations and textual descriptions i.e. *on*(bed, dog) ⇒ *laying-on*(bed, dog) (sec 3.2), and (3) Generalized relations induced by using the semantic hierarchy of concepts in WordNet, i.e. *on*(furniture , domestic-animal) (sec 3.3).

3.1 Mining Object-Object Relations

Our objective in this section is to score and rank a set of relations $S_1 = \{r(o_1, o_2)\}$, where r is a object-object relation and $o_1, o_2 \in V$, using a function $\gamma_1 : S_1 \rightarrow \mathbb{R}$. First, we define a vocabulary R of object-object relations between pairs of annotated objects. Our relations are inspired by Region Connection Calculus (Randell et al., 1992), and the Visual Dependency Grammar of (Elliott et al., 2014; Elliott and de Vries, 2015), details in Figure 1.

For every image, we record the instances of each of these object-object relations $r(o_1, o_2)$ between all co-occurring objects in D[1]. We use Point-wise Mutual Information (PMI) to estimate the evidence for

[1] For symmetric relations like *above*(o_1, o_2), and *under*(o_1, o_2) we only record one of the relations.

Quality

r(o₁, o₂)	holds(person, o₂)	holds(o₁, person)	r(o₁, frisbee)
holds(pizza, broccoli)	holds(person, tie)	holds(bus, person)	touches(dog, frisbee)
holds(person, tie)	holds(person, toothbrush)	holds(train, person)	touches(person, frisbee)
holds(dining table, sandwich)	holds(person, cellphone)	holds(airplane, person)	holds(dog, frisbee)
holds(dining table, broccoli)	holds(person, baseball glove)	holds(boat, person)	holds(person, frisbee)
holds(dining table, pizza)	holds(person, remote)	holds(tv, person)	besides(umbrella, frisbee)
…	…	…	…
holds(cell_phone, person)	holds(person, bench)	holds(dining table, person)	besides(person, frisbee)
above(person, bus)	holds(person, dining table)	holds(cell phone, person)	above(car, frisbee)
above(bicycle, car)	holds(person, car)	holds(chair, person)	above(person, frisbee)

Figure 2: Example of our extracted object-object relations. The first column contains the overall 3 best and worst relations ranked by PMI, the following columns show similar results for the queries: what does a person hold? what holds a person?, and what interacts with a frisbee?

each relationship triplet:

$$\gamma_1(r(o_1, o_2)) = log\frac{p[r(o_1, o_2)]}{p[r]p[(o_1, o_2)]}, \qquad (1)$$

We estimate these probabilities by counting object-object-relation co-ocurrences using existential quantifiers for every image. This means every image can at most contribute one to the count of $r(o_1, o_2)$ so that we do not exacerbate the results by images with many identical object types taken from unusual viewpoints. In Figure 2, we provide examples of our extracted object-object relations.

3.2 Mining Entailment Relations

In this section we combine our relation-based tuples mined from visual annotations (section 2) with more than 400k textual descriptions included in MS-COCO. We generate a set of entailments $S_2 = \{r(o_1, o_2) \Rightarrow z\}$, where $r(o_1, o_2)$ is an element from S_1 and z is a consequent obtained from textual descriptions. Similarly as in the previous section, we rank the relations in S_2 using a function $\gamma_2 : S_2 \rightarrow \mathbb{R}$.

We start by generating an exhaustive list of candidate consequents z. We first pre-process the image captions with the part-of-speech tagger and lemmatizer from the Stanford Core NLP toolkit (Manning et al., 2014), and remove stop words. Then we generate a list of n-length skipgrams in each caption. The set of n-skipgrams are filtered based on predefined lexical patterns[2], and redundancies are removed[3]. Skipgrams, z, are then paired with co-occurring relations, $r(o_1, o_2)$, removing pairs with the disconnected-from spatial relation (see Figure 1). Pairs are scored with the conditional probability:

$$\gamma_2(r(o_1, o_2) \Rightarrow z) = \frac{P[z, r(o_1, o_2)]}{P[r(o_1, o_2)]} \qquad (2)$$

The consequent z can take the form q, $q(o_1)$, $q(o_2)$, or $q(o_1, o_2)$, by performing a simple alignment with the arguments in the antecedent. We perform this alignment by mapping the object categories in the antecedent $r(o_1, o_2)$ to WordNet synsets, and matching any word in z to any word in the gloss set of the predicate arguments o_1 and o_2. The unmatched words in z form the relation, whereas matched words form arguments. We produce the form q if there are no matches, $q(o_1)$, or $q(o_2)$ when one argument word matches, and $q(o_1, o_2)$ when both match. Examples of discovered entailments are in Figure 3.

3.3 Generalizing Relations using WordNet

In this section we present an approach to generalize an initial set of relations, S, to objects not found in the original vocabulary V. Using WordNet we construct a superset G containing all possible parent relations for the relations in S by replacing their arguments o_1, o_2 by all their possible hypernyms. Our objective is to select a subset T from G that contains high quality and diverse generalized relations.

Figure 3: Left: correctly identified entailment relations and right: failure cases.

Note that elements in G can be too general and contradict statements in S while others could be correct but add little new knowledge. To balance these concerns, we formulate the selection as an optimization problem by maximizing a fitness function $\mathcal{L}$:

$$\max_{T} \mathcal{L}(T), \text{ such that } |T| = k, \text{ and } T \subseteq G, \quad (3)$$

$$\mathcal{L}(T) = \lambda \log(1+\psi(T)) + \sum_{t \in T} \log(1+\phi(t, S)), \quad (4)$$

where ψ is a *coverage* term that computes the total number of facts implied through hyponym relationships by the elements in T. The second term ϕ is a *consistency* term that measures the compatibility of a generalized relation t with the relations in S. We assume that if a relation is missing from S, then it is false (this corresponds to a closed world assumption over the domain of S). Thus, ϕ is the ratio of the scores of relations in S consistent with relation t (i.e. evidence for t based on S), and a value that is proportional to the number of missing relations from S (i.e. the amount of counter-evidence). More concretely:

$$\phi(t, S) = \frac{\sum_{s:t \Rightarrow s \wedge s \in S} \gamma(s)}{\mu \cdot (1 + \sum_{s:t \Rightarrow s \wedge s \notin S} 1) \cdot d(t, S)}, \quad (5)$$

where μ is a constant and d is the product of the WordNet distances of the synsets involved in t to their nearest synset in S. This penalizes relations that are far away from categories in S. The optimization defined in Equation 3 is an instance of the submodular k-coverage problem. We use a greedy algorithm that adds elements to T that maximize $\mathcal{L}$, which due to the submodular nature of the problem approximates the solution up to a constant factor.

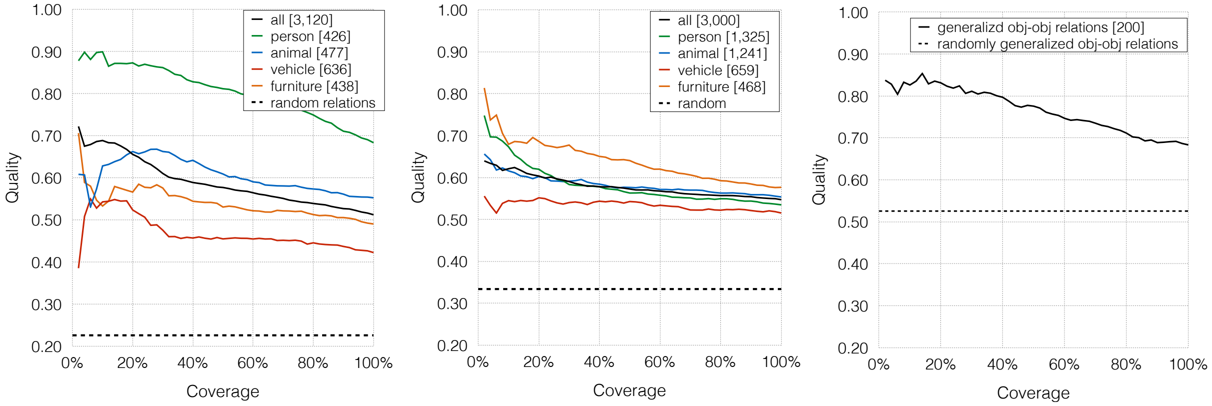
4 Experimental Setup

Object-Object Relations: We filter out from the initial set of candidate relations the ones that occur less than 20 times. We extract more than 3.1k unique statements (6k including symmetric spatial relations). *Entailment Relations*: We use skipgrams of length 2-6 allowing at most 6 skips, filter candidates such that they occur at least 5 times, and return the top 10 most likely entailments per spatial relation. Overall, 6.3k unique statements are extracted (10k including symmetric relations). *Generalized Relations*: We optimize Equation 4 only for object-object relations because the closed world assumption makes counts for implications sparse. The parameter μ is set to the average of the scores, $\lambda = 0.05$ and $k = 200$.

5 Evaluation

We evaluated the quality of the common sense we derive on Amazon Mechanical Turk. Annotators are presented with possible facts and asked to grade statements on a five point scale. Each fact was evaluated by 10 workers and we normalize their average responses to a scale from 0 to 1. Figure 4 shows plots of quality vs. coverage, where coverage means the top percent of relations sorted by our predicted quality scores.

Object-Object Relations As a baseline, 1000 randomly sampled relations have a quality of 0.225. Figure 4a shows our PMI measure ranks many high quality facts at the top, with the top quintile of the ranking being rated above 0.63 in quality. Facts about persons are higher quality, likely because this category is in over 50% of the images in MS-COCO.



(a) Object-object relations

(b) Entailment relations

(c) Generalizations

Figure 4: Quality of extracted common sense, as judged by people. Legends show total relations covered at 100% for a few high level types in MS-COCO.

Entailment Relations Turkers were instructed to assign the lowest score when they could not understand the consequent of the entailment relation. As a baseline, 1000 randomly sampled implications that meet our patterns have a quality of 0.33. Figure 4b shows that extracting high quality entailment is harder than object-object relations likely because supposition and consequent need to coordinate. Relations involving furniture are rated higher and manual inspection revealed that many relations about furniture imply stative verbs or spatial terms.

Generalized Relations To evaluate generalizations, Figure 4c, we also present users with definitions[4]. As a baseline, 200 randomly sampled generalizations from our 3k object-object relations have a quality of 0.53. Generalizations we find are high quality and cover over 400k objects facts not present in MS-COCO. Examples from the 200 we derive include: *holds*(dining-table, cutlery), *holds*(bowl, edible fruit) or *on*(domestic animal, bed).

6 Conclusion

In this work, we use an existing object detection dataset to extract 16k common sense statements about annotated categories. We also show how to generalize using WordNet and induced hundreds of thousands of facts about *unseen* objects. The information we extracted is visual, large scale and good quality. It has the potential to be useful for both visual recognition and entailment applications.

7 Acknowledgments

The authors would like to thank Hannaneh Hajishirzi, Yejin Choi, and Luke Zettlemoyer for helpful comments on the draft and the reviewers for useful feedback. We also thank Ani Kembhavi, and Roozbeh Mottaghi for helping to formalize visual common sense and Mechanical Turkers who helped evaluate output.

Abstract

We introduce recurrent neural network grammars, probabilistic models of sentences with explicit phrase structure. We explain efficient inference procedures that allow application to both parsing and language modeling. Experiments show that they provide better parsing in English than any single previously published supervised generative model and better language modeling than state-of-the-art sequential RNNs in English and Chinese.

1 Introduction

Sequential recurrent neural networks (RNNs) are remarkably effective models of natural language. In the last few years, language model results that substantially improve over long-established state-of-the-art baselines have been obtained using RNNs (Zaremba et al., 2015; Mikolov et al., 2010) as well as in various conditional language modeling tasks such as machine translation (Bahdanau et al., 2015), image caption generation (Xu et al., 2015), and dialogue generation (Wen et al., 2015). Despite these impressive results, sequential models are *a priori* inappropriate models of natural language, since relationships among words are largely organized in terms of latent nested structures rather than sequential surface order (Chomsky, 1957).

In this paper, we introduce **recurrent neural network grammars** (RNNGs; §2), a new generative probabilistic model of sentences that explicitly models nested, hierarchical relationships among words and phrases. RNNGs operate via a recursive syntactic process reminiscent of probabilistic context-free grammar generation, but decisions are parameterized using RNNs that condition on the entire syntactic derivation history, greatly relaxing context-free independence assumptions.

The foundation of this work is a top-down variant of transition-based parsing (§3). We give two variants of the algorithm, one for parsing (given an observed sentence, transform it into a tree), and one for generation. While several transition-based neural models of syntactic generation exist (Henderson, 2003, 2004; Emami and Jelinek, 2005; Titov and Henderson, 2007; Buys and Blunsom, 2015b), these have relied on structure building operations based on parsing actions in shift-reduce and left-corner parsers which operate in a largely bottom-up fashion. While this construction is appealing because inference is relatively straightforward, it limits the use of top-down grammar information, which is helpful for generation (Roark, 2001).[1] RNNGs maintain the algorithmic convenience of transition-based parsing but incorporate top-down (i.e., root-to-terminal) syntactic information (§4).

The top-down transition set that RNNGs are based on lends itself to discriminative modeling as well, where sequences of transitions are modeled conditional on the full input sentence along with the incrementally constructed syntactic structures. Similar to previously published discriminative bottom-up transition-based parsers (Henderson, 2004; Sagae and Lavie, 2005; Zhang and Clark, 2011, *inter alia*), greedy prediction with our model yields a linear-time deterministic parser (provided an upper bound on the number of actions taken between processing subsequent terminal symbols is imposed); however, our algorithm generates arbitrary tree structures directly, without the binarization required by shift-reduce parsers. The discriminative model also lets us use ancestor sampling to obtain samples of parse trees for sentences, and this is used to solve

[1] The left-corner parsers used by Henderson (2003, 2004) incorporate limited top-down information, but a complete path from the root of the tree to a terminal is not generally present when a terminal is generated. Refer to Henderson (2003, Fig. 1) for an example.

Proceedings of NAACL-HLT 2016, pages 199–209,
San Diego, California, June 12-17, 2016.

a second practical challenge with RNNGs: approximating the marginal likelihood and MAP tree of a sentence under the generative model. We present a simple importance sampling algorithm which uses samples from the discriminative parser to solve inference problems in the generative model (§5).

Experiments show that RNNGs are effective for both language modeling and parsing (§6). Our generative model obtains (i) the best-known parsing results using a single supervised generative model and (ii) better perplexities in language modeling than state-of-the-art sequential LSTM language models. Surprisingly—although in line with previous parsing results showing the effectiveness of generative models (Henderson, 2004; Johnson, 2001)—parsing with the generative model obtains significantly better results than parsing with the discriminative model.

2 RNN Grammars

Formally, an RNNG is a triple (N, Σ, Θ) consisting of a finite set of nonterminal symbols (N), a finite set of terminal symbols (Σ) such that $N \cap \Sigma = \emptyset$, and a collection of neural network parameters Θ. It does not explicitly define rules since these are implicitly characterized by Θ. The algorithm that the grammar uses to generate trees and strings in the language is characterized in terms of a transition-based algorithm, which is outlined in the next section. In the section after that, the semantics of the parameters that are used to turn this into a stochastic algorithm that generates pairs of trees and strings are discussed.

3 Top-down Parsing and Generation

RNNGs are based on a top-down generation algorithm that relies on a stack data structure of partially completed syntactic constituents. To emphasize the similarity of our algorithm to more familiar bottom-up shift-reduce recognition algorithms, we first present the parsing (rather than generation) version of our algorithm (§3.1) and then present modifications to turn it into a generator (§3.2).

3.1 Parser Transitions

The parsing algorithm transforms a sequence of words $\boldsymbol{x}$ into a parse tree $\boldsymbol{y}$ using two data structures (a stack and an input buffer). As with the bottom-up algorithm of Sagae and Lavie (2005), our algorithm begins with the stack (S) empty and the complete sequence of words in the input buffer (B). The buffer contains unprocessed terminal symbols, and the stack contains terminal symbols, "open" nonterminal symbols, and completed constituents. At each timestep, one of the following three classes of operations (Fig. 1) is selected by a classifier, based on the current contents on the stack and buffer:

- NT(X) introduces an "open nonterminal" X onto the top of the stack. Open nonterminals are written as a nonterminal symbol preceded by an open parenthesis, e.g., "(VP", and they represent a nonterminal whose child nodes have not yet been fully constructed. Open nonterminals are "closed" to form complete constituents by subsequent REDUCE operations.
- SHIFT removes the terminal symbol x from the front of the input buffer, and pushes it onto the top of the stack.
- REDUCE repeatedly pops completed subtrees or terminal symbols from the stack until an open nonterminal is encountered, and then this open NT is popped and used as the label of a new constituent that has the popped subtrees as its children. This new completed constituent is pushed onto the stack as a single composite item. A single REDUCE operation can thus create constituents with an unbounded number of children.

The parsing algorithm terminates when there is a single completed constituent on the stack and the buffer is empty. Fig. 2 shows an example parse using our transition set. Note that in this paper we do not model preterminal symbols (i.e., part-of-speech tags) and our examples therefore do not include them.[2]

Our transition set is closely related to the operations used in Earley's algorithm which likewise introduces nonterminals symbols with its PREDICT

[2] Preterminal symbols are, from the parsing algorithm's point of view, just another kind of nonterminal symbol that requires no special handling. However, leaving them out reduces the number of transitions by $O(n)$ and also reduces the number of action types, both of which reduce the runtime. Furthermore, standard parsing evaluation scores do not depend on preterminal prediction accuracy.

operation and later COMPLETEs them after consuming terminal symbols one at a time using SCAN (Earley, 1970). It is likewise closely related to the "linearized" parse trees proposed by Vinyals et al. (2015) and to the top-down, left-to-right decompositions of trees used in previous generative parsing and language modeling work (Roark, 2001, 2004; Charniak, 2010).

A further connection is to $LL(^*)$ parsing which uses an unbounded lookahead (compactly represented by a DFA) to distinguish between parse alternatives in a top-down parser (Parr and Fisher, 2011); however, our parser uses an RNN encoding of the lookahead rather than a DFA.

Constraints on parser transitions. To guarantee that only well-formed phrase-structure trees are produced by the parser, we impose the following constraints on the transitions that can be applied at each step which are a function of the parser state (B, S, n) where n is the number of open nonterminals on the stack:

- The NT(X) operation can only be applied if B is not empty and $n < 100$.[3]
- The SHIFT operation can only be applied if B is not empty and $n \geq 1$.
- The REDUCE operation can only be applied if the top of the stack is not an open nonterminal symbol.
- The REDUCE operation can only be applied if $n \geq 2$ or if the buffer is empty.

To designate the set of valid parser transitions, we write $\mathcal{A}_D(B, S, n)$.

3.2 Generator Transitions

The parsing algorithm that maps from sequences of words to parse trees can be adapted with minor changes to produce an algorithm that stochastically generates trees and terminal symbols. Two changes are required: (i) there is no input buffer of unprocessed words, rather there is an output buffer (T), and (ii) instead of a SHIFT operation there are GEN(x) operations which generate terminal symbol $x \in \Sigma$ and add it to the top of the stack and the output buffer. At each timestep an action is stochastically selected according to a conditional distribution that depends on the current contents of B and T. The algorithm terminates when a single completed constituent remains on the stack. Fig. 4 shows an example generation sequence.

Constraints on generator transitions. The generation algorithm also requires slightly modified constraints. These are:

- The GEN(x) operation can only be applied if $n \geq 1$.
- The REDUCE operation can only be applied if the top of the stack is not an open nonterminal symbol and $n \geq 1$.

To designate the set of valid generator transitions, we write $\mathcal{A}_G(T, S, n)$.

This transition set generates trees using nearly the same structure building actions and stack configurations as the "top-down PDA" construction proposed by Abney et al. (1999), albeit without the restriction that the trees be in Chomsky normal form.

3.3 Transition Sequences from Trees

Any parse tree can be converted to a sequence of transitions via a depth-first, left-to-right traversal of a parse tree. Since there is a unique depth-first, leftro-right traversal of a tree, there is exactly one transition sequence of each tree. For a tree $\boldsymbol{y}$ and a sequence of symbols $\boldsymbol{x}$, we write $\boldsymbol{a}(\boldsymbol{x}, \boldsymbol{y})$ to indicate the corresponding sequence of generation transitions, and $\boldsymbol{b}(\boldsymbol{x}, \boldsymbol{y})$ to indicate the parser transitions.

3.4 Runtime Analysis

A detailed analysis of the algorithmic properties of our top-down parser is beyond the scope of this paper; however, we briefly state several facts. Assuming the availability of constant time push and pop operations, the runtime is linear in the number of the nodes in the parse tree that is generated by the parser/generator (intuitively, this is true since although an individual REDUCE operation may require

[3] Since our parser allows unary nonterminal productions, there are an infinite number of valid trees for finite-length sentences. The $n < 100$ constraint prevents the classifier from misbehaving and generating excessively large numbers of nonterminals. Similar constraints have been proposed to deal with the analogous problem in bottom-up shift-reduce parsers (Sagae and Lavie, 2005).

Stack$_t$	**Buffer**$_t$	**Open NTs**$_t$	**Action**	**Stack**$_{t+1}$	**Buffer**$_{t+1}$	**Open NTs**$_{t+1}$

Figure 4: Joint generation of a parse tree and sentence.

applying a number of pops that is linear in the number of input symbols, the total number of pop operations across an entire parse/generation run will also be linear). Since there is no way to bound the number of output nodes in a parse tree as a function of the number of input words, stating the runtime complexity of the parsing algorithm as a function of the input size requires further assumptions. Assuming our fixed constraint on maximum depth, it is linear.

3.5 Comparison to Other Models

Our generation algorithm algorithm differs from previous stack-based parsing/generation algorithms in two ways. First, it constructs rooted tree structures top down (rather than bottom up), and second, the transition operators are capable of directly generating arbitrary tree structures rather than, e.g., assuming binarized trees, as is the case in much prior work that has used transition-based algorithms to produce phrase-structure trees (Sagae and Lavie, 2005; Zhang and Clark, 2011; Zhu et al., 2013).

4 Generative Model

RNNGs use the generator transition set just presented to define a joint distribution on syntax trees ($\boldsymbol{y}$) and words ($\boldsymbol{x}$). This distribution is defined as a sequence model over generator transitions that is parameterized using a continuous space embedding of the algorithm state at each time step ($\mathbf{u}_t$); i.e.,

$$\begin{aligned} p(\boldsymbol{x}, \boldsymbol{y}) &= \prod_{t=1}^{|\boldsymbol{a}(\boldsymbol{x},\boldsymbol{y})|} p(a_t \mid \boldsymbol{a}_{<t}) \\ &= \prod_{t=1}^{|\boldsymbol{a}(\boldsymbol{x},\boldsymbol{y})|} \frac{\exp \mathbf{r}_{a_t}^{\top} \mathbf{u}_t + b_{a_t}}{\sum_{a' \in \mathcal{A}_G(T_t, S_t, n_t)} \exp \mathbf{r}_{a'}^{\top} \mathbf{u}_t + b_{a'}}, \end{aligned}$$

and where action-specific embeddings $\mathbf{r}_a$ and bias vector $\mathbf{b}$ are parameters in Θ.

The representation of the algorithm state at time t, $\mathbf{u}_t$, is computed by combining the representation of the generator's three data structures: the output buffer (T_t), represented by an embedding $\mathbf{o}_t$, the stack (S_t), represented by an embedding $\mathbf{s}_t$, and the history of actions ($\boldsymbol{a}_{<t}$) taken by the generator, represented by an embedding $\mathbf{h}_t$,

$$\mathbf{u}_t = \tanh\left(\mathbf{W}[\mathbf{o}_t; \mathbf{s}_t; \mathbf{h}_t] + \mathbf{c}\right),$$

where $\mathbf{W}$ and $\mathbf{c}$ are parameters. Refer to Figure 5 for an illustration of the architecture.

The output buffer, stack, and history are sequences that grow unboundedly, and to obtain representations of them we use recurrent neural networks to "encode" their contents (Cho et al., 2014). Since the output buffer and history of actions are only appended to and only contain symbols from a finite alphabet, it is straightforward to apply a standard RNN encoding architecture. The stack (S) is more complicated for two reasons. First, the elements of the stack are more complicated objects than symbols from a discrete alphabet: open nonterminals, terminals, and full trees, are all present on the stack. Second, it is manipulated using both push and pop operations. To efficiently obtain representations of S under push and pop operations, we use stack LSTMs (Dyer et al., 2015).

4.1 Syntactic Composition Function

When a REDUCE operation is executed, the parser pops a sequence of completed subtrees and/or tokens (together with their vector embeddings) from the stack and makes them children of the most recent open nonterminal on the stack, "completing" the constituent. To compute an embedding of this new subtree, we use a composition function based on bidirectional LSTMs, which is illustrated in Fig. 6.

The first vector read by the LSTM in both the forward and reverse directions is an embedding of the label on the constituent being constructed (in the figure, NP). This is followed by the embeddings of the child subtrees (or tokens) in forward or reverse order. Intuitively, this order serves to "notify" each LSTM what sort of head it should be looking for as it processes the child node embeddings. The final state of the forward and reverse LSTMs are concatenated, passed through an affine transformation and a tanh nonlinearity to become the subtree embedding.[4] Because each of the child node embeddings ($\mathbf{u}$, $\mathbf{v}$, $\mathbf{w}$ in Fig. 6) is computed similarly (if it corresponds to an

[4] We found the many previously proposed syntactic composition functions inadequate for our purposes. First, we must contend with an unbounded number of children, and many previously proposed functions are limited to binary branching nodes (Socher et al., 2013b; Dyer et al., 2015). Second, those that could deal with n-ary nodes made poor use of nonterminal information (Tai et al., 2015), which is crucial for our task.

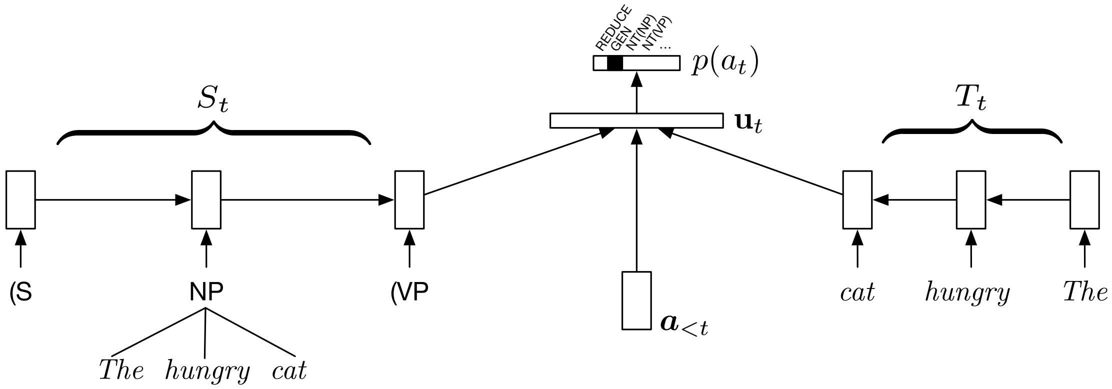

Figure 5: Neural architecture for defining a distribution over a_t given representations of the stack (S_t), output buffer (T_t) and history of actions ($\boldsymbol{a}_{<t}$). Details of the composition architecture of the NP, the action history LSTM, and the other elements of the stack are not shown. This architecture corresponds to the generator state at line 7 of Figure 4.

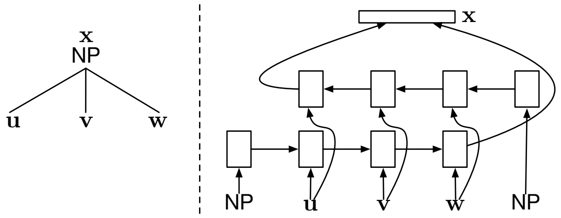

Figure 6: Syntactic composition function based on bidirectional LSTMs that is executed during a REDUCE operation; the network on the right models the structure on the left.

internal node), this composition function is a kind of recursive neural network.

4.2 Word Generation

To reduce the size of $\mathcal{A}_G(S, T, n)$, word generation is broken into two parts. First, the decision to generate is made (by predicting GEN as an action), and then choosing the word, conditional on the current parser state. To further reduce the computational complexity of modeling the generation of a word, we use a class-factored softmax (Baltescu and Blunsom, 2015; Goodman, 2001). By using $\sqrt{|\Sigma|}$ classes for a vocabulary of size $|\Sigma|$, this prediction step runs in time $O(\sqrt{|\Sigma|})$ rather than the $O(|\Sigma|)$ of the full-vocabulary softmax. To obtain clusters, we use the greedy agglomerative clustering algorithm of Brown et al. (1992).

4.3 Training

The parameters in the model are learned to maximize the likelihood of a corpus of trees.

4.4 Discriminative Parsing Model

A discriminative parsing model can be obtained by replacing the embedding of T_t at each time step with an embedding of the input buffer B_t. To train this model, the conditional likelihood of each sequence of actions given the input string is maximized.[5]

5 Inference via Importance Sampling

Our generative model $p(\boldsymbol{x}, \boldsymbol{y})$ defines a joint distribution on trees ($\boldsymbol{y}$) and sequences of words ($\boldsymbol{x}$). To evaluate this as a language model, it is necessary to compute the marginal probability $p(\boldsymbol{x}) = \sum_{\boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{x})} p(\boldsymbol{x}, \boldsymbol{y}')$. And, to evaluate the model as a parser, we need to be able to find the MAP parse tree, i.e., the tree $\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x})$ that maximizes $p(\boldsymbol{x}, \boldsymbol{y})$. However, because of the unbounded dependencies across the sequence of parsing actions in our model, exactly solving either of these inference problems is intractable. To obtain estimates of these, we use a variant of importance sampling (Doucet and Johansen, 2011).

Our importance sampling algorithm uses a conditional proposal distribution $q(\boldsymbol{y} \mid \boldsymbol{x})$ with the following properties: (i) $p(\boldsymbol{x}, \boldsymbol{y}) > 0 \implies q(\boldsymbol{y} \mid \boldsymbol{x}) > 0$; (ii) samples $\boldsymbol{y} \sim q(\boldsymbol{y} \mid \boldsymbol{x})$ can be obtained efficiently; and (iii) the conditional probabilities $q(\boldsymbol{y} \mid \boldsymbol{x})$ of these samples are known. While many such distributions are available, the discrim-

[5] For the discriminative parser, the POS tags are processed similarly as in (Dyer et al., 2015); they are predicted for English with the Stanford Tagger (Toutanova et al., 2003) and Chinese with Marmot (Mueller et al., 2013).

inatively trained variant of our parser (§4.4) fulfills these requirements: sequences of actions can be sampled using a simple ancestral sampling approach, and, since parse trees and action sequences exist in a one-to-one relationship, the product of the action probabilities is the conditional probability of the parse tree under q. We therefore use our discriminative parser as our proposal distribution.

Importance sampling uses **importance weights**, which we define as $w(\boldsymbol{x}, \boldsymbol{y}) = p(\boldsymbol{x}, \boldsymbol{y})/q(\boldsymbol{y} \mid \boldsymbol{x})$, to compute this estimate. Under this definition, we can derive the estimator as follows:

$$\begin{aligned} p(\boldsymbol{x}) &= \sum_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x})} p(\boldsymbol{x}, \boldsymbol{y}) = \sum_{\boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x})} q(\boldsymbol{y} \mid \boldsymbol{x}) w(\boldsymbol{x}, \boldsymbol{y}) \\ &= \mathbb{E}_{q(\boldsymbol{y} \mid \boldsymbol{x})} w(\boldsymbol{x}, \boldsymbol{y}). \end{aligned}$$

We now replace this expectation with its Monte Carlo estimate as follows, using N samples from q:

$$\begin{gathered} \boldsymbol{y}^{(i)} \sim q(\boldsymbol{y} \mid \boldsymbol{x}) \quad \text{for } i \in \{1, 2, \ldots, N\} \\ \mathbb{E}_{q(\boldsymbol{y} \mid \boldsymbol{x})} w(\boldsymbol{x}, \boldsymbol{y}) \overset{\text{MC}}{\approx} \frac{1}{N} \sum_{i=1}^{N} w(\boldsymbol{x}, \boldsymbol{y}^{(i)}) \end{gathered}$$

To obtain an estimate of the MAP tree $\hat{\boldsymbol{y}}$, we choose the sampled tree with the highest probability under the joint model $p(\boldsymbol{x}, \boldsymbol{y})$.

6 Experiments

We present results of our two models both on parsing (discriminative and generative) and as a language model (generative only) in English and Chinese.

Data. For English, §2–21 of the Penn Treebank are used as training corpus for both, with §24 held out as validation, and §23 used for evaluation. Singleton words in the training corpus with unknown word classes using the the Berkeley parser's mapping rules.[6] Orthographic case distinctions are preserved, and numbers (beyond singletons) are not normalized. For Chinese, we use the Penn Chinese Treebank Version 5.1 (CTB) (Xue et al., 2005).[7] For the Chinese experiments, we use a single unknown word class. Corpus statistics are given in Table 1.[8]

Table 1: Corpus statistics.

	PTB-train	PTB-test	CTB-train	CTB-test
Sequences	39,831	2,416	50,734	348
Tokens	950,012	56,684	1,184,532	8,008
Types	23,815	6,823	31,358	1,637
UNK-Types	49	42	1	1

Model and training parameters. For the discriminative model, we used hidden dimensions of 128 and 2-layer LSTMs (larger numbers of dimensions reduced validation set performance). For the generative model, we used 256 dimensions and 2-layer LSTMs. For both models, we tuned the dropout rate to maximize validation set likelihood, obtaining optimal rates of 0.2 (discriminative) and 0.3 (generative). For the sequential LSTM baseline for the language model, we also found an optimal dropout rate of 0.3. For training we used stochastic gradient descent with a learning rate of 0.1. All parameters were initialized according to recommendations given by Glorot and Bengio (2010).

English parsing results. Table 2 (last two rows) gives the performance of our parser on Section 23, as well as the performance of several representative models. For the discriminative model, we used a greedy decoding rule as opposed to beam search in some shift-reduce baselines. For the generative model, we obtained 100 independent samples from a flattened distribution of the discriminative parser (by exponentiating each probability by $\alpha = 0.8$ and renormalizing) and reranked them according to the generative model.[9]

Chinese parsing results. Chinese parsing results were obtained with the same methodology as in English and show the same pattern (Table 6).

Language model results. We report held-out per-word perplexities of three language models, both sequential and syntactic. Log probabilities are normalized by the number of words (excluding the stop

symbol), inverted, and exponentiated to yield the perplexity. Results are summarized in Table 4.

7 Discussion

It is clear from our experiments that the proposed generative model is quite effective both as a parser and as a language model. This is the result of (i) relaxing conventional independence assumptions (e.g., context-freeness) and (ii) inferring continuous representations of symbols alongside non-linear models of their syntactic relationships. The most significant question that remains is why the discriminative model—which has more information available to it than the generative model—performs worse than the generative model. This pattern has been observed before in neural parsing by Henderson (2004), who hypothesized that larger, unstructured conditioning contexts are harder to learn from, and provide opportunities to overfit. Our discriminative model conditions on the entire history, stack, and buffer, while our generative model only accesses the history and stack. The fully discriminative model of Vinyals et al. (2015) was able to obtain results similar to those of our generative model (albeit using much larger training sets obtained through semisupervision) but similar results to those of our discriminative parser using the same data. In light of their results, we believe Henderson's hypothesis is correct, and that generative models should be considered as a more statistically efficient method for learning neural networks from small data.

8 Related Work

Our language model combines work from two modeling traditions: (i) recurrent neural network language models and (ii) syntactic language modeling. Recurrent neural network language models use RNNs to compute representations of an unbounded history of words in a left-to-right language model (Zaremba et al., 2015; Mikolov et al., 2010; Elman, 1990). Syntactic language models jointly generate a syntactic structure and a sequence of words (Baker, 1979; Jelinek and Lafferty, 1991). There is an extensive literature here, but one strand of work has emphasized a bottom-up generation of the tree, using variants of shift-reduce parser actions to define the probability space (Chelba and Jelinek, 2000; Emami and Jelinek, 2005). The neural-network–based model of Henderson (2004) is particularly similar to ours in using an unbounded history in a neural network architecture to parameterize generative parsing based on a left-corner model. Dependency-only language models have also been explored (Titov and Henderson, 2007;

Buys and Blunsom, 2015a,b). Modeling generation top-down as a rooted branching process that recursively rewrites nonterminals has been explored by Charniak (2000) and Roark (2001). Of particular note is the work of Charniak (2010), which uses random forests and hand-engineered features over the entire syntactic derivation history to make decisions over the next action to take.

The neural networks we use to model sentences are structured according to the syntax of the sentence being generated. Syntactically structured neural architectures have been explored in a number of applications, including discriminative parsing (Socher et al., 2013a; Kiperwasser and Goldberg, 2016), sentiment analysis (Tai et al., 2015; Socher et al., 2013b), and sentence representation (Socher et al., 2011; Bowman et al., 2006). However, these models have been, without exception, discriminative; this is the first work to use syntactically structured neural models to generate language. Earlier work has demonstrated that sequential RNNs have the capacity to recognize context-free (and beyond) languages (Sun et al., 1998; Siegelmann and Sontag, 1995). In contrast, our work may be understood as a way of incorporating a context-free inductive bias into the model structure.

9 Outlook

RNNGs can be combined with a particle filter inference scheme (rather than the importance sampling method based on a discriminative parser, §5) to produce a left-to-right marginalization algorithm that runs in expected linear time. Thus, they could be used in applications that require language models.

A second possibility is to replace the sequential generation architectures found in many neural network transduction problems that produce sentences conditioned on some input. Previous work in machine translation has showed that conditional syntactic models can function quite well without the computationally expensive marginalization process at decoding time (Galley et al., 2006; Gimpel and Smith, 2014).

A third consideration regarding how RNNGs, human sentence processing takes place in a left-to-right, incremental order. While an RNNG is not a processing model (it is a grammar), the fact that it is left-to-right opens up several possibilities for developing new sentence processing models based on an explicit grammars, similar to the processing model of Charniak (2010).

Finally, although we considered only the supervised learning scenario, RNNGs are joint models that could be trained without trees, for example, using expectation maximization.

10 Conclusion

We introduced recurrent neural network grammars, a probabilistic model of phrase-structure trees that can be trained generatively and used as a language model or a parser, and a corresponding discriminative model that can be used as a parser. Apart from out-of-vocabulary preprocessing, the approach requires no feature design or transformations to treebank data. The generative model outperforms every previously published parser built on a single supervised generative model in English, and a bit behind the best-reported generative model in Chinese. As language models, RNNGs outperform the best single-sentence language models.

Abstract

We present expected F-measure training for shift-reduce parsing with RNNs, which enables the learning of a global parsing model optimized for sentence-level F1. We apply the model to CCG parsing, where it improves over a strong greedy RNN baseline, by 1.47% F1, yielding state-of-the-art results for shift-reduce CCG parsing.

1 Introduction

Shift-reduce parsing is a popular parsing paradigm, one reason being the potential for fast parsers based on the linear number of parsing actions needed to analyze a sentence (Nivre and Scholz, 2004; Sagae and Lavie, 2006; Zhang and Clark, 2011; Goldberg et al., 2013; Zhu et al., 2013; Xu et al., 2014). Recent work has shown that by combining distributed representations and neural network models (Chen and Manning, 2014), accurate and efficient shift-reduce parsing models can be obtained with little feature engineering, largely alleviating the feature sparsity problem of linear models.

In practice, the most common objective for optimizing neural network shift-reduce parsing models is maximum likelihood. In the greedy search setting, the log-likelihood of each target action is maximized during training, and the most likely action is committed to at each step of the parsing process during inference (Chen and Manning, 2014; Dyer et al., 2015). In the beam search setting, Zhou et al. (2015) show that sentence-level likelihood, together with contrastive learning (Hinton, 2002), can be used to derive a global model which incorporates beam search at both training and inference time (Zhang and Clark, 2008), giving significant accuracy gains over a fully greedy model. However, despite the effectiveness of optimizing likelihood, it is often desirable to directly optimize for task-specific metrics, which often leads to higher accuracies for a variety of models and applications (Goodman, 1996; Och, 2003; Smith and Eisner, 2006; Rosti et al., 2010; Auli and Lopez, 2011; He and Deng, 2012; Auli et al., 2014; Auli and Gao, 2014; Gao et al., 2014).

In this paper, we present a global neural network parsing model, optimized for a task-specific loss based on expected F-measure. The model naturally incorporates beam search during training, and is globally optimized, to learn shift-reduce action *sequences* that lead to parses with high expected F-scores. In contrast to Auli and Lopez (2011), who optimize a CCG parser for F-measure via softmax-margin (Gimpel and Smith, 2010), we directly optimize an expected F-measure objective, derivable from only a set of shift-reduce action sequences and sentence-level F-scores. More generally, our method can be seen as an alternative approach for training a neural beam search parsing model (Watanabe and Sumita, 2015; Weiss et al., 2015; Zhou et al., 2015), combining the benefits of global learning and task-specific optimization.

We also introduce a simple recurrent neural network (RNN) model to shift-reduce parsing on which the greedy baseline and the global model is based. Compared with feed-forward networks, RNNs have the potential to capture and use an *unbounded* history, and they have been used to learn explicit representations for parser states as well as actions

Proceedings of NAACL-HLT 2016, pages 210–220,

performed on the stack and queue in shift-reduce parsers (Dyer et al., 2015; Watanabe and Sumita, 2015), following Miikkulainen (1996) and Mayberry and Miikkulainen (1999). In comparison, our model is a natural extension of the feed-forward architecture in Chen and Manning (2014) using Elman RNNs (Elman, 1990).

We apply our models to CCG, and evaluate the resulting parsers on standard CCGBank data (Hockenmaier and Steedman, 2007). More specifically, by combining the global RNN parsing model with a bidirectional RNN CCG supertagger that we have developed (§4) — building on the supertagger of Xu et al. (2015), we obtain accuracies higher than the shift-reduce CCG parsers of Zhang and Clark (2011) and Xu et al. (2014). Finally, although we choose to focus on shift-reduce parsing for CCG, we expect the methods to generalize to other shift-reduce parsers.

2 RNN Models

In this section, we start by describing the baseline model, which is also taken as the pretrained model to train the global model (§2.4). We abstract away from the details of CCG and present the models in a canonical shift-reduce parsing framework (Aho and Ullman, 1972), which is henceforth assumed: partially constructed derivations are maintained on a *stack*, and a *queue* stores remaining words from the input string; the initial parse item has an empty stack and no input has been consumed on the queue. Parsing proceeds by applying a sequence of shift-reduce actions to transform the input until the queue has been exhausted and no more actions can be applied.

2.1 Model

Our recurrent neural network model is a standard Elman network (Elman, 1990) which is factored into an input layer, a hidden layer with recurrent connections, and an output layer. Similar to Chen and Manning (2014), the input layer x_t encodes stack and queue contexts of a parse item through concatenation of feature embeddings. The output layer y_t represents a probability distribution over possible parser actions for the current item.

The current state of the hidden layer is determined by the current input and the previous hidden layer state. The weights between the layers are represented by a number of matrices: matrix $\mathbf{U}$ contains weights between the input and hidden layers, $\mathbf{V}$ contains weights between the hidden and output layers, and $\mathbf{W}$ contains weights between the previous hidden layer and the current hidden layer.

The hidden and output layers at time step t are computed via a series of vector-matrix products and non-linearities:

$$h_t = f(x_t\mathbf{U} + h_{t-1}\mathbf{W}),$$
$$y_t = g(h_t\mathbf{V}),$$

where

$$f(z) = \frac{1}{1+e^{-z}}, \quad g(z_m) = \frac{e^{z_m}}{\sum_k e^{z_k}}$$

are sigmoid[1] and softmax functions, respectively.

2.2 Feature Embeddings

Given a parse item, we first extract features using a set of predefined feature templates; each template belongs to a feature type f (such as word or POS tag), which has an associated look-up table, denoted as L_f, to project a feature to its distributed representation; and $L_f \in \mathbb{R}^{n_f \times d_f}$, where n_f is the vocabulary size of feature type f and d_f is its embedding dimension. The embedding for a concrete feature is obtained by retrieving the corresponding row from L_f. At time step t, the input layer x_t is:

$$x_t = [e_{f_{1,1}}; \ldots ; e_{f_{1,|f_1|}}; \ldots ; e_{f_{k,1}}; \ldots ; e_{f_{k,|f_k|}}],$$

where ";" denotes concatenation, $|f_k|$ is the number of feature templates for the k^{th} feature type and $x_t \in \mathbb{R}^{1\times(d_{f_1}|f_1|+\ldots+d_{f_k}|f_k|)}$. For each feature type, a special embedding is used for unknown features.

2.3 Greedy Training

To train a greedy model, we extract gold-standard actions from the training data and minimize cross-entropy loss with stochastic gradient descent (SGD) using backpropagation through time (BPTT; Rumelhart et al., 1988). Similar to Chen and Manning (2014), we compute the softmax over only feasible actions at each step.

Unfortunately, although we use an RNN, which keeps a representation of previous parse items in its

[1] We also experimented with $\tanh$, and found no difference in resulting performance.

hidden state and has the potential to capture long-term dependencies, the resulting model is still fully greedy: a locally optimal action is taken at each step given the current input x_t and the previous hidden state h_{t-1}. Therefore, once a sub-optimal action has been committed to by the parser at any step, it has no means to recover and has to continue from that mistake. Such mistakes accumulate until the goal is reached, and they are referred to as *search errors*.

In order to enlarge the search space of the greedy model thereby alleviating some search errors, we experiment with applying beam search decoding during inference; and we observe some accuracy improvements by taking the highest scored action sequence as the output (Table 3). However, since the greedy model itself is only optimized locally, as expected, the improvements diminish after a certain beam size. Instead, we show below that by using the greedy model weights as a starting point, we can train a global model optimized for an expected F-measure loss, which gives further significant accuracy improvements (§5).

2.4 Expected F1 Training

The RNN we use to train the global model has the same Elman architecture as the greedy model. Given the greedy model, we summarize its weights as $\theta = \{\mathbf{U}, \mathbf{V}, \mathbf{W}\}$ and initialize the weights of the global model to θ, and training proceeds as follows:

1. We use a beam-search decoder to parse a sentence x_n in the training data and let the decoder generate a *k*-best list[2] of output parses using the *current* θ, denoted as $\Lambda(x_n)$. Similar to other structured training approaches that use inexact beam search (Zhang and Clark, 2008; Weiss et al., 2015; Watanabe and Sumita, 2015; Zhou et al., 2015), $\Lambda(x_n)$ is as an approximation to the set of all possible parses of an input sentence.

2. Let y_i be the shift-reduce action sequence of a parse in the *k*-best list $\Lambda(x_n)$, and let $|y_i|$ be its total number of actions and y_{ij} be the j^{th} action in y_i, for $1 \leq j \leq |y_i|$. We compute the log-linear action sequence score of y_i, $\rho(y_i)$, as a sum of individual action scores in that sequence: $\rho(y_i) = \sum_{j=1}^{|y_i|} \log s_\theta(y_{ij})$, where $s_\theta(y_{ij})$ is the softmax action score of y_{ij} given by the RNN model. For each y_i, we also compute its sentence-level F1 using the set of labeled, directed dependencies, denoted as Δ, associated with its parse item. (We assume F1 over labeled, directed dependencies is also the parser evaluation metric.)

3. We compute the negative expected F1 objective (-xF1, defined below) for x_n using the scores obtained in the above step and minimize this objective using SGD (maximizing the expected F1 for x_n). These three steps repeat for other sentences in the training data, updating θ after processing each sentence, and training iterates in epochs until convergence.

We note that the above process is different from parse reranking (Collins, 2000; Charniak and Johnson, 2005), in which $\Lambda(x_n)$ would stay the same for each x_n in the training data across all epochs, and a reranker is trained on all fixed $\Lambda(x_n)$; whereas the xF1 training procedure is on-line learning with parameters updated after processing each sentence and each $\Lambda(x_n)$ is generated with a new θ.

More formally, we define the loss $J(\theta)$, which incorporates all action scores in each action sequence, and all action sequences in $\Lambda(x_n)$, for each x_n as

$$\begin{aligned} J(\theta) &= -\mathrm{xF1}(\theta) \\ &= -\sum_{y_i \in \Lambda(x_n)} p(y_i|\theta)\mathrm{F1}(\Delta_{y_i}, \Delta_{x_n}^G), \end{aligned} \quad (1)$$

where $\mathrm{F1}(\Delta_{y_i}, \Delta_{x_n}^G)$ is the sentence level F1 of the parse derived by y_i, with respect to the gold-standard dependency structure $\Delta_{x_n}^G$ of x_n; $p(y_i|\theta)$ is the normalized probability score of the action sequence y_i, computed as

$$p(y_i|\theta) = \frac{\exp\{\rho(y_i)\}}{\sum_{y \in \Lambda(x_n)} \exp\{\rho(y)\}}. \quad (2)$$

To apply SGD, we derive the error gradients used for backpropagation. First, by applying the chain

[2] We do not put a limit on k, and whenever an item is finished, it is appended to the *k*-best list. We found the size of the *k*-best lists were on average twice the size of a given beam size.

rule to $J(\theta)$, we have

$$\frac{\partial J(\theta)}{\partial \theta} = - \sum_{y_i \in \Lambda(x_n)} \sum_{y_{ij} \in y_i} \frac{\partial J(\theta)}{\partial s_\theta(y_{ij})} \frac{\partial s_\theta(y_{ij})}{\partial \theta}$$
$$= - \sum_{y_i \in \Lambda(x_n)} \sum_{y_{ij} \in y_i} \delta_{y_{ij}} \frac{\partial s_\theta(y_{ij})}{\partial \theta},$$

where $\frac{\partial s_\theta(y_{ij})}{\partial \theta}$ is the standard softmax gradients. Next, to compute $\delta_{y_{ij}}$, which are the error gradients propagated from the loss to the softmax layer, we rewrite the loss in (1) as

$$J(\theta) = -\text{xF1} = -\frac{G(\theta)}{Z(\theta)} \quad (3)$$
$$= -\frac{\sum_{y_i \in \Lambda(x_n)} \exp\{\rho(y_i)\} \text{F1}(\Delta_{y_i}, \Delta^G_{x_n})}{\sum_{y_i \in \Lambda(x_n)} \exp\{\rho(y_i)\}},$$

and by simplifying:

$$\frac{\partial G(\theta)}{\partial s_\theta(y_{ij})} = \frac{1}{s_\theta(y_{ij})} \exp\{\rho(y_i)\} \text{F1}(\Delta_{y_i}, \Delta^G_{x_n}),$$

$$\frac{\partial Z(\theta)}{\partial s_\theta(y_{ij})} = \frac{1}{s_\theta(y_{ij})} \exp\{\rho(y_i)\},$$

since

$$\frac{\partial \rho(y_i)}{\partial s_\theta(y_{ij})} = \frac{1}{s_\theta(y_{ij})}.$$

Finally, using (2) and (3) plus the above simplifications, the error term $\delta_{y_{ij}}$ can be derived using the quotient rule:

$$\begin{aligned}
\delta_{y_{ij}} &= -\frac{\partial \text{xF1}(\theta)}{\partial s_\theta(y_{ij})} \\
&= -\frac{\partial (G(\theta)/Z(\theta))}{\partial s_\theta(y_{ij})} \\
&= \frac{G(\theta)Z'(\theta) - G'(\theta)Z(\theta)}{Z^2(\theta)} \\
&= \frac{\exp\{\rho(y_i)\}}{Z(\theta)} (\text{xF1}(\theta) - \text{F1}(\Delta_{y_i}, \Delta^G_{x_n})) \frac{1}{s_\theta(y_{ij})} \\
&= p(y_i|\theta)(\text{xF1}(\theta) - \text{F1}(\Delta_{y_i}, \Delta^G_{x_n})) \frac{1}{s_\theta(y_{ij})},
\end{aligned} \quad (4)$$

which has a simple closed form.

A naive implementation of the xF1 training procedure would backpropagate the error gradients individually for each y_i in $\Lambda(x_n)$. To make it efficient, we observe that the unfolded network in the beam containing all y_i becomes a DAG (with one hidden state leading to one or more resulting hidden states) and apply backpropagation through structure (Goller and Kuchler, 1996) to obtain the gradients.

3 Shift-Reduce CCG Parsing

We explain the application of the RNN models to CCG by first describing the CCG mechanisms used in our parser, followed by details of the shift-reduce transition system.

3.1 Combinatory Categorial Grammar

A *lexicon*, together with a set of CCG *rules*, formally constitute a CCG. The former defines a mapping from words to sets of lexical categories representing syntactic types, and the latter gives schemas which dictate whether two categories can be combined. Given the lexicon and the rules, the syntactic types of complete constituents can be obtained by recursive combination of categories using the rules.

More generally, both lexical and non-lexical CCG categories can be either *atomic* or *complex*: atomic categories are categories without any slashes, and complex categories are constructed recursively from atomic ones using forward ($/$) and backward slashes ($\backslash$) as two binary operators. As such, all categories can be represented as follows (Vijay-Shanker and Weir, 1993; Kuhlmann and Satta, 2014):

$$x := \alpha|_1 z_1|_2 z_2 \ldots |_m z_m,$$

where $m \geq 0$, α is an atomic category, $|_1, \ldots, |_m \in \{\backslash, /\}$ and z_i are meta-variables for categories.

CCG *rules* have the following two schematic forms, each a generalized version of *functional composition* (Vijay-Shanker and Weir, 1993):

$$x/y \quad y|_1 z_1 \ldots |_m z_m \rightarrow x|_1 z_1 \ldots |_m z_m,$$
$$y|_1 z_1 \ldots |_m z_m \quad x\backslash y \rightarrow x|_1 z_1 \ldots |_m z_m.$$

The first schematic form above instantiates into a forward application rule ($>$) for $m = 0$, and forward composition rules ($>_\mathbf{B}$) for $m > 0$. Similarly, the second schematic form, which is symmetric to the first, instantiates into backward application ($<$) and composition ($<_\mathbf{B}$) rules.

Fig.1 shows an example CCG derivation. All the *rule instances* in this derivation are instantiated from

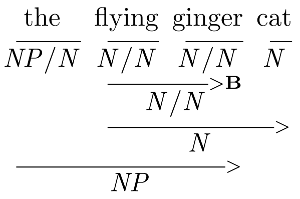

Figure 1: An example CCG derivation.

forward rules; for example, $N/N\ N/N \rightarrow N/N$ is an instance of forward composition and $N/N\ N \rightarrow N$ is an instance of forward application.

Given CCGBank (Hockenmaier and Steedman, 2007), there are two approaches to extract a grammar from this data. The first is to treat all CCG derivations as phrase-structure trees, and a binary, context-free "cover" grammar, consisting of all CCG rule instances in the treebank, is extracted from local trees in all the derivations (Fowler and Penn, 2010; Zhang and Clark, 2011). In contrast, one can extract the lexicon from the treebank and define only the rule schemas, without explicitly enumerating any rule instances (Hockenmaier, 2003). This is the approach taken in the C&C parser (Clark and Curran, 2007) and the one we use here. Moreover, following Zhang and Clark (2011), our CCG parsing model is also a normal-form model, which models action sequences of normal-form derivations in CCGBank.

3.2 The Transition System

The transition system we use in this work is based on the CCG transition system of Zhang and Clark (2011). We denote parse items as $(j, \delta, \beta, \Delta)$[3], where δ is the stack (with top element $\delta|s_0$), β is the queue (with top element $x_{w_j}|\beta$), j is the positional index of the word at the front of the queue, and Δ is the set of CCG dependencies realized for the input consumed so far (needed to calculate the expected F-score). We also assume a set of lexical categories has been assigned to each word using a supertagger (Bangalore and Joshi, 1999; Clark and Curran, 2004). The transition system is specified using three action types:

- SHIFT (sh) removes one of the lexical categories x_{w_j} of the front word w_j in the queue, and pushes it onto the stack; and removes w_j from the queue.

input: $w_0 \dots w_{n-1}$

axiom: $0 : (0, \epsilon, \beta, \phi)$

goal: $2n - 1 + \mu : (n, \delta, \epsilon, \Delta)$

$$\frac{\omega : (j, \delta, x_{w_j}|\beta, \Delta)}{\omega + 1 : (j+1, \delta|x_{w_j}, \beta, \Delta)} \quad (\mathsf{sh}; 0 \leq j < n)$$

$$\frac{\omega : (j, \delta|s_1|s_0, \beta, \Delta)}{\omega + 1 : (j, \delta|x, \beta, \Delta \cup \langle x \rangle))} \quad (\mathsf{re}; s_1 s_0 \rightarrow x)$$

$$\frac{\omega : (j, \delta|s_0, \beta, \Delta)}{\omega + 1 : (j, \delta|x, \beta, \Delta)} \quad (\mathsf{un}; s_0 \rightarrow x)$$

Figure 2: The shift-reduce deduction system.

- REDUCE (re) combines the top two subtrees s_0 and s_1 on the stack using a CCG rule ($s_1 s_0 \rightarrow x$) and replaces them with a subtree rooted in x. It also appends the set of newly created dependencies on x, denoted as $\langle x \rangle$, to Δ.

- UNARY (un) applies either a type-raising or type-changing rule ($s_0 \rightarrow x$) to the stack-top element and replaces it with a unary subtree rooted in x.

The deduction system (Fig. 2) of our shift-reduce parser follows from the transition system.[4] Each parse item is associated with a step indicator ω, which denotes the number of actions used to build it. Given a sentence of length n, a full derivation requires $2n - 1 + \mu$ steps to terminate, where μ is the total number of un actions applied. In Zhang and Clark (2011), a *finish* action is used to indicate termination, which we do not use in our parser: an item finishes when no further action can be taken. Another difference between the transition systems is that Zhang and Clark (2011) omit the Δ field in each parse item, due to their use of a context-free, phrase-structure cover, and dependencies are recovered at a post-processing step; in our system, we build dependencies as parsing proceeds.

[3] We partly adopt standard notations from dependency parsing (Nivre, 2008).

[4] We abuse notation slightly for the sh deduction, using $x_{w_j}|\beta$ to denote that the lexical category x_{w_j} is available for the front word on the queue.

s_0.w	s_1.w	s_2.w	s_3.w
s.w$_0$	$s_.$w$_1$	s.w$_2$	s.w$_3$
s_0.l.w	s_1.l.w	s_o.r.w	s_1.r.w
q_0.w	q_1.w	q_2.w	q_3.w
s_0.c	s_0.l.c	s_0.r.c	
s_1.c	s_1.l.c	s_1.r.c	
s_2.c	s_3.c		

Table 1: Atomic feature templates.

3.3 RNN CCG Parsing

We use the same set of CCG rules as in Clark and Curran (2007) and the total number of output units in our RNN model is equal to the number of lexical categories (i.e., all possible sh actions), plus 10 units for re[5] and 18 units for un actions.

All features in our model fall into three types: word, POS tag and CCG category. Table 1 shows the atomic feature templates and we have $|f_w| = 16$, $|f_p| = 16$ and $|f_c| = 8$ (all word-based features are generalized to POS features). Each template has two parts: the first part denotes parse item context and the second part denotes the feature type. s denotes stack contexts and q denotes queue contexts; e.g., s_0 is the top subtree on the stack, and s_o.l is its left child. w represents head words of constituents and w$_0$ is the right-most word of the input string that has been shifted onto the stack.

4 Bidirectional Supertagging

We extend the RNN supertagging model of Xu et al. (2015) by using a bidirectional RNN (BRNN). The BRNN processes an input in both directions with two separate hidden layers, which are then fed to one output layer to make predictions. At each time step t, we compute the *forward* hidden state h_t for $t = (0, 1, \ldots, n-1)$; the *backward* hidden state h'_t is computed similarly but from the reverse direction for $t = (n-1, n-2, \ldots, 0)$ as

$$h'_t = f(x_t\mathbf{U}' + h_{t+1}\mathbf{W}'), \tag{5}$$

and the output layer, for $t = (0, 1, \ldots, n-1)$, is computed as

$$y_t = f([h_t; h'_t]\mathbf{V}'). \tag{6}$$

The BRNN introduces two new parameter matrices $\mathbf{U}'$ and $\mathbf{W}'$ and replaces the old hidden-to-output matrix $\mathbf{V}$ with $\mathbf{V}'$ to take two hidden layers as input. We use the same three feature embedding types as Xu et al. (2015), namely word, suffix and capitalization, and all features are extracted from a context window size of 7 surrounding the current word.

5 Experiments

Setup. All experiments were performed on CCGBank (Hockenmaier and Steedman, 2007) with the standard split.[6] We used the C&C supertagger (Clark and Curran, 2007) and the RNN supertagger model of Xu et al. (2015) as two supertagger baselines. For the parsing experiments, the baselines were the shift-reduce CCG parsers of Zhang and Clark (2011) and Xu et al. (2014) and the C&C parser of (Clark and Curran, 2007).

To train the RNN parser, we used 10-fold cross validation for both POS tagging and supertagging. For both development and test parsing experiments, we used the C&C POS tagger and automatically assigned POS tags. The BRNN supertagging model was used as the supertagger by all RNN parsing models for both training and testing. F-score over directed, labeled CCG predicate-argument dependencies was used as the parser evaluation metric, obtained using the script from C&C.

Hyperparameters. For the BRNN supertagging model, we used identical hyperparameter settings as in Xu et al. (2015). For all RNN parsing models, the weights were uniformly initialized using the interval $[-2.0, 2.0]$, and scaled by their fan-in (Bengio, 2012); the hidden layer size was 220, and 50-dimensional embeddings were used for all feature types and scaled Turian embeddings were used (Turian et al., 2010) for word embeddings. We also pretrained CCG lexcial category and POS embeddings by using the GENSIM word2vec implementation.[7] The data used for this was obtained by parsing a Wikipedia dump using the C&C parser and concatenating the output with CCGBank Sections 02-21. Embeddings for unknown words and CCG categories outside of the lexical category set were uniformly initialized ($[-2.0, 2.0]$) without scaling.

[5] In principle, only 1 re unit is needed, but we use 9 additional units to handle non-standard CCG rules in the treebank.

[6] Training: Sections 02-21; development: Section 00; test Section 23.

Supertagger	Dev	Test
C&C (gold POS)	92.60	93.32
C&C (auto POS)	91.50	92.02
RNN	93.07	93.00
BRNN	**93.49**	**93.52**

Table 2: 1-best supertagging accuracy comparison.

To train all the models, we used a fixed learning rate of 0.0025 and did not truncate the gradients for BPTT, except for training the greedy RNN parsing model where we used a BPTT step size of 9. We applied dropout at the input layer (Legrand and Collobert, 2015), with a dropout rate of 0.25 for the supertagger and 0.30 for the parser.

5.1 Supertagging Results

Table 2 shows 1-best supertagging results. The MaxEnt C&C supertagger uses POS tag features and a tag dictionary, neither of which are used by the RNN supertaggers. For all supertaggers, the same set of 425 lexical categories is used (Clark and Curran, 2007). On the test set, our BRNN supertagger achieves a 1-best accuracy of 93.52%, an absolute improvement of 0.52% over the RNN model, demonstrating the usefulness of contextual information from both input directions.

Fig. 3a shows multi-tagging accuracy comparison for the three supertaggers by varying the variable-width beam probability cut-off value β for each supertagger. The β value determines the average number of supertags (ambiguity) assigned to each word by pruning supertags whose probabilities are not within β times the probability of the 1-best supertag; for this experiment we used β values ranging from 0.09 to 2×10^{-4} and it can be seen that the BRNN supertagger consistently achieves better accuracies at similar ambiguity levels.

Finally, all shift-reduce CCG parsers mentioned in this paper take multi-tagging output obtained with a *fixed* β for training and testing; and in general, a smaller β value can be used by a shift-reduce CCG parser than by the C&C parser. This is because a β value too small may explode the dynamic program of the C&C parser, and it thus relies on an adaptive supertagging strategy (Clark and Curran, 2007), by starting from a large β value and backing off to smaller values if no spanning analysis can found with the current β.

	Supertagger β			
	0.09	0.08	0.07	0.06
$b = 1$	84.61	84.58	84.55	84.50
$b = 2$	84.94	84.86	84.86	84.81
$b = 4$	85.01	84.95	84.92	84.92
$b = 6$	**85.02**	84.96	84.94	84.93
$b = 8$	**85.02**	84.99	84.96	84.95
$b = 16$	85.01	84.95	84.97	84.98

Table 3: The effect on dev F1 by varying the beam size and supertagger β value for the greedy RNN model.

5.2 Parsing Results

To pretrain the greedy model, we trained 10 cross-validated BRNN supertagging models to supply supertags for the parsing model, and used a supertagger β value of 0.00025 which gave on average 5.02 supertags per word. We ran SGD training for 60 epochs, observing no accuracy gains after that, and the best greedy model was obtained after the 52nd epoch (Fig. 3b).

Furthermore, we found that using a relatively smaller supertagger β value (higher ambiguity) for training, and a larger β value (lower ambiguity) for testing, resulted in more accurate models; and we chose the final β value used for the greedy model to be 0.09 using the dev set (Table 3). This observation was different from Zhang and Clark (2011) and Xu et al. (2014), which are two shift-reduce CCG parsers using the averaged perceptron and beam search (Collins, 2002; Collins and Roark, 2004; Zhang and Clark, 2008): they used the same β values for training and testing, which resulted in lower accuracy for our greedy model.

Table 3 also shows the effect on dev F1 by using different beam sizes at test time for the greedy model: with $b = 6$, we obtained an accuracy of 85.02%, an improvement of 0.41% over $b = 1$ (with a β value of 0.09); we saw accuracy gains up to $b = 8$ (with very minimal gains with $b = 16$ for β values 0.06 and 0.07), after which the accuracy started to drop. F1 on dev with $b = 6$ across all training epochs are shown in Fig. 3b as well, and the best model was obtained after the 43rd epoch.

For the xF1 model, we used $b = 8$ and a supertagger β value of 0.09 for both training and testing. Fig.3c shows dev F1 versus the number of training epochs. The best dev F1 was obtained after the 54th epoch with an accuracy of 85.73%, 1.12%

Table 4: Final parsing results on Section 00 and Section 23 (100% coverage). Zhang and Clark (2011)* is a reimplementation of the original. All speed results (sents/sec) are obtained using Section 23 and precomputation is used for all RNN parsers. LP (labeled precision); LR (labeled recall); LF (labeled F-score over CCG dependencies); CAT (lexical category assignment accuracy). All experiments using auto POS.

higher than that of the greedy model with $b = 1$ and 0.71% higher than the greedy model with $b \in \{6, 8\}$. This result improves over shift-reduce CCG models of Zhang and Clark (2011) and Xu et al. (2014) by 0.73% and 0.55%, respectively (Table 4).

Table 4 summarizes final results.[8] RNN-xF1, the xF1 trained beam-search model, is currently the most accurate shift-reduce CCG parser, achieving a final F-score of 86.42%, and gives an F-score improvement of 1.47% over the greedy RNN baseline. We show the results for the model of Xu et al. (2014) for reference only, since it uses a more sophisticated dependency, rather than normal-form derivation, model.

At test time, we also used the precomputation trick of Devlin et al. (2014) to speed up the RNN models by caching the top 20K word embeddings and all POS embeddings,[9] and this made the greedy RNN parser more than 3 times faster than the C&C parser (all speed experiments were measured on a workstation with an Intel Core i7 4.0GHz CPU).[10]

6 Related Work

Optimizing for Task-specific Metrics. Our training objective is largely inspired by task-specific optimization for parsing and MT. Goodman (1996) proposed algorithms for optimizing a parser for various constituent matching criteria, and it was one of the earliest work that we are aware of on optimizing a parser for evaluation metrics. Smith and Eisner (2006) proposed a framework for minimizing expected loss for log-linear models and applied it to dependency parsing by optimizing for labeled attachment scores, although they obtained little per-

[8] The C&C parser fails to produce spanning analyses for a very small number of sentences (Clark and Curran, 2007) on both dev and test sets, which is not the case for any of the shift-reduce parsers; and for brevity, we omit C&C coverage results.

[9] We used $b = 8$ to do the precomputation.

[10] The speed results for the C&C parser were obtained using the per-compiled C&C binary for Linux available from `http://svn.ask.it.usyd.edu.au/trac/candc/wiki/Download`.

formance improvements. Auli and Lopez (2011) optimized the C&C parser for F-measure. However, they used the softmax-margin (Gimpel and Smith, 2010) objective, which required decomposing precision and recall statistics over parse forests. Instead, we directly optimize for an F-measure loss. In MT, task-specific optimization has also received much attention (e.g., see Och (2003)). Closely related to our work, Gao and He (2013) proposed training a Markov random field translation model as an additional component in a log-linear phrase-based translation system using a *k*-best list based expected BLEU objective; using the same objective, Auli et al. (2014) and Auli and Gao (2014) trained a large scale phrase-based reordering model and a RNN language model respectively, all as additional components within a log-linear translation model. In contrast, our RNN parsing model is trained in an end-to-end fashion with an expected F-measure loss and all parameters of the model are optimized using backpropagation and SGD.

Parsing with RNNs. A line of work is devoted to parsing with RNN models, including using RNNs (Miikkulainen, 1996; Mayberry and Miikkulainen, 1999; Legrand and Collobert, 2015; Watanabe and Sumita, 2015) and LSTM (Hochreiter and Schmidhuber, 1997) RNNs (Vinyals et al., 2015; Ballesteros et al., 2015; Dyer et al., 2015; Kiperwasser and Goldberg, 2016). Legrand and Collobert (2015) used RNNs to learn conditional distributions over syntactic rules; Vinyals et al. (2015) explored sequence-to-sequence learning (Sutskever et al., 2014) for parsing; Ballesteros et al. (2015) utilized character-level representations and Kiperwasser and Goldberg (2016) built an easy-first dependency parser using tree-structured compositional LSTMs. However, all these parsers use greedy search and are trained using the maximum likelihood criterion (except Kiperwasser and Goldberg (2016), who used a margin-based objective). For learning global models, Watanabe and Sumita (2015) used a margin-based objective, which was not optimized for the evaluation metric; although not using RNNs, Weiss et al. (2015) proposed a method using the averaged perceptron with beam search (Collins, 2002; Collins and Roark, 2004; Zhang and Clark, 2008), which required fixing the neural network representations, and thus their model parameters were not learned using end-to-end backpropagation.

Finally, a number of recent work (Bengio et al., 2015; Vaswani and Sagae, 2016) explored training neural network models for parsing and other tasks such that the network learns from the oracle as well as its own predictions, and are hence more robust to search errors during inference. In principle, these techniques are largely orthogonal to both global learning and task-based optimization, and we would expect further accuracy gains are possible by combining these techniques in a single model.

7 Conclusion

Neural network shift-reduce parsers are often trained by maximizing likelihood, which does not optimize towards the final evaluation metric. In this paper, we addressed this problem by developing expected F-measure training for an RNN shift-reduce parsing model. We have demonstrated the effectiveness of our method on shift-reduce parsing for CCG, achieving higher accuracies than all shift-reduce CCG parsers to date and the de facto C&C parser.[11] We expect the general framework will be applicable to models using other types of neural networks such as feed-forward or LSTM nets, and to shift-reduce parsers for constituent and dependency parsing.

Abstract

We demonstrate that a state-of-the-art parser can be built using only a lexical tagging model and a deterministic grammar, with no explicit model of bi-lexical dependencies. Instead, all dependencies are implicitly encoded in an LSTM supertagger that assigns CCG lexical categories. The parser significantly outperforms all previously published CCG results, supports efficient and optimal A* decoding, and benefits substantially from semi-supervised tri-training. We give a detailed analysis, demonstrating that the parser can recover long-range dependencies with high accuracy and that the semi-supervised learning enables significant accuracy gains. By running the LSTM on a GPU, we are able to parse over 2600 sentences per second while improving state-of-the-art accuracy by 1.1 F1 in domain and up to 4.5 F1 out of domain.

1 Introduction

Combinatory Categorial Grammar (CCG) is a strongly lexicalized formalism—the vast majority of attachment decisions during parsing are specified by the selection of lexical entries for words (see Figure 1 for examples). State-of-the-art parsers typically include a supertagging model, to select possible lexical categories, and a bi-lexical dependency model, to resolve the remaining parse attachment ambiguities. In this paper, we introduce a long short-term memory (LSTM) CCG parsing model that has no explicit model of bi-lexical dependencies, but instead relies on a bi-directional recurrent neural network (RNN) supertagger to capture all long distance dependencies. This approach has a number of advantages: it is conceptually simple, allows for the reuse of existing optimal and efficient parsing algorithms, benefits significantly from semi-supervised learning, and is highly accurate both in and out of domain. The parser is publicly released.[1]

Neural networks have shown strong performance in a range of NLP tasks; however they can break the dynamic programs for structured prediction problems, such as parsing, when vector embeddings are recursively computed for subparts of the output. Existing neural net parsers either (1) use greedy inference techniques including shift-reduce parsing (Henderson et al., 2013; Chen and Manning, 2014; Weiss et al., 2015; Dyer et al., 2015), constituency parse re-ranking (Socher et al., 2013), and string-to-string transduction (Vinyals et al., 2015), or (2) avoid recursive computations entirely (Durrett and Klein, 2015). Our approach gives a simple alternative: we only train a model for tagging decisions, where we can easily use recurrent architectures such as LSTMs (Hochreiter and Schmidhuber, 1997), and rely on the highly lexicalized nature of the CCG grammar to allow this tagger to specify nearly every aspect of the complete parse.

Our LSTM supertagger is bi-directional and includes a softmax potential over tags for each word in the sentence. During training, we jointly optimize all LSTM parameters, including the word embeddings, to maximize the conditional likelihood of supertag sequences. For inference, we use a recently introduced A* CCG parsing algorithm (Lewis and Steedman, 2014a), which efficiently searches for the

Figure 1: Four examples of prepositional phrase attachment in CCG. In the upper two parses, the attachment decision is determined by the choice of supertags. In the lower parses, the attachment is ambiguous given the supertags. In such cases, our parser deterministically attaches low (i.e. preferring the lower-right parse).

highest probability sequence of tags that combine to produce a complete parse tree. Whenever there is parsing ambiguity not specified by the supertags, the model attaches low (see Figure 1).

This approach is not only conceptually simple but also highly effective, as we demonstrate with extensive experiments. Because the A* algorithm is extremely efficient and the LSTMs can be run in parallel on GPUs, the end-to-end parser can process over 2600 sentences per second. This is more than three times the speed of any publicly available parser for any formalism. Apart from Hall et al. (2014), we are not aware of efficient algorithms for running other state-of-art-parsers on GPUs. The LSTM parameters also benefit from semi-supervised training, which we demonstrate by employing a recently introduced tri-training scheme (Weiss et al., 2015). Finally, the recurrent nature of the LSTM allows for effective modelling of long distance dependencies, as we show empirically. Our approach significantly advances the state-of-the-art on benchmark datasets—improving accuracy by 1.1 F1 in domain and up to 4.5 F1 out of domain.

2 Background

Combinatory Categorial Grammar (CCG) Compared to a phrase-structure grammar, CCG contains a much smaller set of binary rules (we use 11), but a much larger set of lexical tags (we use 425). The binary rules are conjectured to be language-universal, and most language-specific information is lexicalized (Steedman, 2000). The large tag set means that most (but not all) attachment decisions are determined by tagging decisions. Figure 1 shows how a prepositional phrase attachment decision can be encoded in the choice of tags.

The process of assigning CCG categories to words is called *supertagging*. All supertaggers used in practice are probabilistic, providing a distribution over possible tags for each word. Parsing models either use these scores directly (Auli and Lopez, 2011b), or as a form of beam search (Clark and Curran, 2007), typically in conjunction with models of the dependencies or derivation.

Supertag-Factored A* CCG Parsing Lewis and Steedman (2014a) introduced supertag-factored CCG parsers, in which the score for a parse is simply the sum of the scores of its supertags. The parser takes in a distribution over supertags for each word, and outputs the highest scoring parse—subject to the hard constraint that the parse only uses standard CCG combinators (resolving any remaining ambiguity by attaching low). One advantage of the supertag-factored model is that it allows a simple A* parsing algorithm, which provably finds the highest scoring supertag sequence that can be combined to construct a complete parse.

In A* parsing, partial parses $y_{i,j}$ of span $i \dots j$ are maintained in a sorted agenda and added to the chart in order of their cost, which is the sum of their Viterbi inside score $g(y_{i,j})$ and an upper bound on their Viterbi outside score $h(y_{i,j})$. When $y_{i,j}$ is

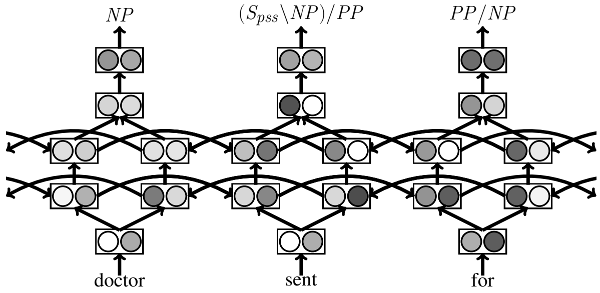

Figure 2: Visualization of our supertagging model, based on stacked bi-directional LSTMs. Each word is fed into stacked LSTMs reading the sentence in each direction, the outputs of the LSTMs are combined, and there is a final softmax over categories.

added to the chart, the agenda is updated with any new partial parses that can be created by combining $y_{i,j}$ with existing chart items (Algorithm 1). If h is a monotonic upper bound on the outside score, the first chart entry for a span with a given category is guaranteed to be optimal—all other possible completions of the competing partial parses provably have lower scores, due to the outside score bounds. There is no guarantee this certificate of optimality is achieved efficiently for parses of the whole sentence, and in the worst case the algorithm could fill the entire parse chart. However, as we will see later, A* parsing is very efficient in practice for the models we present in this paper.

In the supertag-factored model, g and h are computed as follows, where $g(y_k)$ is the score for word k having tag y_k.

$$g(y_{i,j}) = \sum_{k=i}^{j} g(y_k) \tag{1}$$

$$h(y_{i,j}) = \sum_{k=1}^{i-1} \max_{y_k} g(y_k) + \sum_{k=j+1}^{N} \max_{y_k} g(y_k) \tag{2}$$

where Eq. 1 follows from the definition of the supertag factored model and Eq. 2 combines this definition with the fact that the max score over all supertags for a word is an upperbound on the score for the actual supertag used in the best parse.

3 LSTM CCG Supertagging Model

Supertagging is *almost parsing* (Bangalore and Joshi, 1999)—consequently the task is very challenging, with hundreds of tags, and the correct assignment often depending on long-range dependencies. For example, in *The doctor sent for the patient arrived*, the category for *sent* depends on the final word. Recent work has made dramatic progress, using feed-forward neural networks (Lewis and Steedman, 2014b) and RNNs (Xu et al., 2015).

Algorithm 1 Agenda-based parsing algorithm

Definitions $x_{1...N}$ is the input words, and y variables denote scored partial parses. TAG($x_{1...N}$) returns a set of scored pre-terminals for every word. ADD(C, y) adds partial parse y to chart C. RULES(C, y) returns the set of scored partial parses that can be created by combining y with existing entries in C. The agenda A is ordered as described in Section 2.

```
function PARSE($x_{1...N}$)
    $A \leftarrow \emptyset$                          ▷ Empty agenda $A$
    for $y \in$ TAG($x_{1...N}$) do
        PUSH($A, y$)
    $C \leftarrow \emptyset$                          ▷ Empty chart $C$
    while $C_{1,N} = \emptyset \wedge A \neq \emptyset$ do
        y ← EXTRACT_MAX($A$)
        if $y \notin C$ then
            ADD($C, y$)
            for $y' \in$ RULES($C, y$) do
                INSERT($A, y'$)
    return $C_{1,N}$
```

We make several extensions to previous work on supertagging. Firstly, we use bi-directional models, to capture both previous and subsequent sentence context into supertagging decisions. Secondly, we use LSTMs, rather than RNNs. Many tagging decisions rely on long-range context, and RNNs typically struggle to account for sequences of longer than a few words (Hochreiter and Schmidhuber, 1997). Finally, we use a deep architecture, to allow the modelling of complex interactions in the context.

Our supertagging model is summarized in Figure 2. Each word is mapped to an embedding vector. This vector is a concatenation of an embedding for the word (lower-cased), and embeddings for features of the word (we use 1 to 4 character prefixes and suffixes). The embedding vector is used as input to two stacked LSTMs (with depth 2), one processing the sentence left-to-right, and the other right-to-left.

The outputs from the LSTMs are projected into a further hidden layer, a bias is added, and a ReLU non-linearity is applied. This layer gives a context-dependent representation of the word that is fed into a softmax over supertags.

We use a variant on the standard LSTM with coupled 'input' and 'forget' gates, and peephole connections. Each LSTM cell at position t takes three inputs: a cell state vector c_{t-1} and hidden state vector h_{t-1} from the cell at position $t-1$, and x_t from the layer below. It outputs h_t to the layer above, and c_t and h_t to the cell at $t+1$. c_t and h_t are computed as follows, where σ is the component-wise logistic sigmoid, and $\circ$ is the component-wise product:

$$i_t = \sigma(W_i[c_{t-1}, h_{t-1}, x_t] + b_i) \quad (3)$$

$$\tilde{c_t} = \tanh(W_c[h_{t-1}, x_t] + b_{\tilde{c}}) \quad (4)$$

$$o_t = \sigma(W_o[\tilde{c_t}, h_{t-1}, x_t] + b_o) \quad (5)$$

$$c_t = i_t \circ \tilde{c_t} + (\mathbf{1} - i_t)c_{t-1} \quad (6)$$

$$h_t = o_t \circ \tanh(c_t) \quad (7)$$

We train the model using stochastic gradient descent, with a minibatch size of 1, a learning rate of 0.01, and using momentum with $\mu = 0.7$. We then fine-tune models using a larger minibatch size of 32. Gradients whose L_2 norm exceeds 5 are clipped. Training was run for 30 epochs, shuffling the order of sentences after each epoch, and we used the model parameters with the highest development supertagging accuracy. The input layer uses dropout with a rate of 0.5. All trainable parameters have L_2 regularization of $\Lambda = 10^{-6}$. Word embedding are initialized using 50-dimensional pre-trained values from Turian et al. (2010). For prefix and suffix embeddings, we use randomly initialized 32-dimensional vectors—features occurring less than 3 times are replaced with an 'unknown' embedding. We add special start and end tokens to each sentence, with trainable parameters. The LSTM state size is 128 and the ReLU layer has a size of 64.

4 Parsing Models

Our experiments focus on two parsing models:

Supertag-Factored We use the supertagging model described in Section 3 to build a supertag-factored parser, closely following the approach described in Section 2. We also add a penalty of 0.1 (tuned on development data) for every time a unary rule is applied in a parse. The attach-low heuristic is implemented by adding a small penalty of $-\epsilon d$ at every binary rule instantiation, where d is the absolute distance between the heads of the left and right children, and ϵ is a small constant. We increase the penalty to 10ϵ for clitics, to encourage these to attach locally. Because these penalties are ≤ 0, they do not affect the A* upper bound calculations.

Dependencies We also train a model with dependency features, to investigate how much they improve accuracy beyond the supertag-factored model. We adapt a joint CCG and SRL model (Lewis et al., 2015) to CCGbank parsing, by assigning every CCGbank dependency a role based on its argument number (i.e., the first argument of every category has role *ARG0*). A global log-linear model is trained to maximize the marginal likelihood of the gold dependencies. We use the same features and hyper-parameters as Lewis et al. (2015), except that we do not use the supertagger score feature (to separate the effect of the dependencies features from the supertagger). We choose this model because it has an A* parsing algorithm, meaning that we do not need to use aggressive beam search.

5 Semi-supervised Learning

A number of papers have shown that strong parsers can be improved by exploiting text without gold-standard annotations. Recent work suggests *tri-training*, in which the output of two parsers is intersected to create training data for a third parser, is highly effective (Weiss et al., 2015).

We perform the first application of tri-training to a lexicalized formalism. Following Weiss et al., we parse the corpus of Chelba et al. (2013) with a shift-reduce parser and a chart-based model. We use the shift-reduce parser from Ambati et al. (2016) and our dependency model (without using a supertagger feature, to limit the correlation with our tagging model). On development sentences where the parsers produce the same supertags (40%), supertagging accuracy is 98.0%. This subset is considerably easier than general text—our CCGbank-trained supertagger is 97.4% accurate on this data—but tri-training still provides useful additional training data.

In total, we include 43 million words of text that the parsers annotate with the same supertags and 15 copies of the gold CCGbank training data. Our experiments show that tri-training improves both supertagging and parsing accuracy.

6 GPU Parsing

Our parser makes an unusual trade-off, by combining a complex tagging model with a deterministic parsing model. The A* parsing algorithm is extremely efficient, and the overall time required to process a sentence is dominated by the supertagger.

GPUs can improve performance over CPUs by computing many vector operations in parallel. There are two major obstacles to using GPUs for parsing. First, most models use sparse rather than dense features, which are difficult to compute efficiently on GPUs. The most successful implementation we are aware of exploits the fact that the Berkeley parser is unlexicalized to run parsing operations in parallel (Hall et al., 2014). Second, most neural models have features that depend on the current parse or stack state (e.g. Chen and Manning (2014)). This makes it difficult to exploit the parallelism of GPUs, because these data structures are typically built incrementally on CPU. It may be possible to write GPU-specific code that maintains the entire parse state on GPU, but we are not aware of any such implementations.

In contrast, our supertagger only uses matrix operations, and does not take any parse state as input—meaning it is straightforward to run on a GPU. To exploit the parallelism of GPUs, we process thousands of sentences simultaneously—improving parsing efficiency by an order-of-magnitude over CPU. A major advantage of our model is that it allows all of the computationally intensive decisions to occur on GPUs. Unlike existing GPU parsers, the LSTM can be run with generic library code.[2]

7 Experiments

7.1 Experimental setup

We trained our parser on Sections 02-21 of CCGbank (Hockenmaier and Steedman, 2007), using Section 00 for development, and Section 23 for test. Our experiments use a supertagger beam of 10^{-4}—which does not affect the final scores, but reduces overheads such as building the initial agenda.

Model	Dev	Test
C&C tagger	91.5	92.0
NN	91.3	91.6
RNN	93.1	93.0
LSTM	94.1	94.3
LSTM + Tri-training	**94.9**	**94.7**

Table 1: Supertagging accuracy on CCGbank.

Model	P	R	F1
C&C	86.2	84.2	85.2
C&C + RNN	87.7	86.4	87.0
EASYCCG	83.7	83.0	83.3
Dependencies	86.5	85.8	86.1
LSTM	87.7	86.7	87.2
LSTM + Dependencies	88.2	87.3	87.8
LSTM + Tri-training	**88.6**	**87.5**	**88.1**
LSTM + Tri-training + Dependencies	88.2	87.3	87.8

Table 2: Labelled F1 for CCGbank dependencies on the CCGbank test set (Section 23).

Where results are available, we compare our work with the following models: EASYCCG, which has the same parsing model as our parser, but uses a feed-forward neural-network supertagger (NN); the C&C parser (Clark and Curran, 2007), and C&C+RNN (Xu et al., 2015), which is the C&C parser with an RNN supertagger. All results are for 100% coverage of the test data.

We refer to the models described in Section 4 as LSTM and DEPENDENCIES respectively. We also report the performance of LSTM+DEPENDENCIES, which combines the model scores (weighting the LSTM score by 1.8, tuned on development data).

7.2 Supertagging Results

The most direct measure of the effectiveness of our LSTM and tri-training is on the supertagging task. Results are shown in Table 1. The improvement of our deep LSTM over the RNN model is greater than the improvement of the RNN over C&C model. Further gains follow from tri-training, improving the state-of-the-art by 1.7%.

7.3 English Parsing Results

Parsing results are shown in Figure 2. Surprisingly, our CCGBank-trained LSTM outperforms any previous approach.[3] The ensemble of the LSTM

[2] We use TensorFlow (Abadi et al., 2015).

[3] We cannot compare directly with Fowler and Penn (2010)'s adaptation of the Berkeley parser to CCG, or Auli and Lopez

Model	Questions			Bioinfer		
	P	R	F1	P	R	F1
C&C	-	-	86.6	77.8	71.4	74.5
EasyCCG	78.1	78.2	78.1	76.8	77.6	77.2
C&C + RNN	-	-	-	80.1	75.5	77.7
LSTM	87.6	87.4	87.5	80.1	80.9	80.5
LSTM + Dependencies	**88.2**	**87.9**	**88.0**	77.8	80.1	79.4
LSTM + Tri-training	-	-	-	**81.8**	**82.6**	**82.2**

Table 3: Out-of-domain experiments.

and the Dependency model outperforms the LSTM alone, showing that dependency features are capturing some generalizations that the LSTM does not. However, semi-supervised learning substantially improves the LSTM, matching the accuracy of the ensemble—showing that the LSTM is expressive enough to compensate given sufficient data.

7.4 Out-of-domain Experiments

We also evaluate on two out-of-domain datasets used by Rimell and Clark (2008), but did no development on this data. In both cases, we use Rimell and Clark's scripts for converting CCG parses to the target dependency representations. The datasets are:

QUESTIONS 500 questions from TREC (Rimell and Clark, 2008). Questions frequently contain very long range dependencies, providing an interesting test of the LSTM supertagger's ability to capture unbounded dependencies. We follow Rimell and Clark by re-training the supertagger on the concatenation of the CCGbank training data and 10 copies of the QUESTIONS training data.

BIOINFER 500 sentences from biomedical abstracts. This dataset tests the parser's robustness to a large amount of unseen vocabulary.

Results are shown in Table 3. Our LSTM parser outperforms existing work on question parsing, showing that it can successfully model the long-range dependencies found in questions. Adding dependency features yields only a small improvement.

On the BIOINFER corpus, our tri-trained LSTM parser is 4.5 F1 better than the previous state-of-the-art. Dependency features appear to be much less robust to unseen words than the LSTM tagging model, and are unhelpful. Because the parser was not trained or developed on this domain, it is likely to perform similarly well on other domains.

Parser	**Sentences per second**
SpaCy*[4]	778
Berkeley GPU* (Hall et al., 2014)	687
Chen and Manning (2014)*	391
C&C	66
EasyCCG	606
LSTM	214
LSTM + Dependencies	58
LSTM GPU	2670

Table 4: Sentences parsed per second on our hardware. Parsers marked * use non-CCG formalisms but are the fastest available CPU and GPU parsers.

7.5 Efficiency Experiments

In contrast to standard parsing algorithms, the efficiency of our model depends directly on the accuracy of the supertagger in guiding the search. We therefore measure the efficiency empirically.

Results are shown in Table 4.[5] Our parser runs more slowly than EasyCCG on CPU, due to the more complex tagging model (but is 4.8 F1 more accurate). Adding dependencies substantially reduces efficiency, due to calculating sparse features. Without dependencies, the run time is dominated by the LSTM supertagger. Running the supertagger on a GPU reduces parsing times dramatically—outperforming SpaCy, the fastest publicly available parser (Choi et al., 2015). Roughly half the parsing time is spent on GPU supertagging, and half on CPU parsing. To better exploit batching in the GPU, our implementation dynamically buckets sentences by length (bins of width 10), and tags batches when the bucket size reaches 3072 (the number of threads on our GPU). We are not aware of any GPU implementations of shift-reduce parsers or lexicalized chart parsers, so it is unclear if most other state-of-the-art parsers can be adapted to exploit GPUs.

(2011b)'s joint parsing and supertagging model, due to differences in the experimental setup. These models are 0.3 and 1.5 F1 more accurate than the C&C baseline respectively, which is well within the margin of improvement obtained by our model.

[5] All timing experiments use a single 3.5GHz core and (where applicable) a single NVIDIA TITAN X GPU.

Supertagger	Accuracy
Bidirectional RNNs	93.4
Forward LSTM only	83.5
Backward LSTM only	89.5
Bidirectional LSTMs	**94.1**

Table 5: Development supertagging accuracy.

Word Class	NN	LSTM	LSTM+ Tri-training
All	91.32	94.14	**94.90**
Unseen Words	90.39	94.21	**95.26**
Unseen Usages	45.80	59.37	**62.46**
Prepositions	78.11	84.40	**85.98**
Verbs	82.55	87.85	**89.24**
Wh-words	90.47	92.09	**94.16**
Long range	74.80	83.99	**86.31**

Table 6: Development supertagging accuracy on several classes of words. *Long range* refers to words taking an argument at least 5 words away.

8 Ablations

We also measure performance while removing different aspects of the full parsing model.

8.1 Supertagger Model Architecture

Numerous variations are possible on our supertagging architecture. Apart from tri-training, the major differences from the previous state-of-the-art (Xu et al., 2015) are that we use LSTMs rather than RNNs, and that we use bidirectional networks rather than only a forward-directional RNN. These modifications lead to a 1.3% improvement in accuracy. Table 5 shows performance while ablating these changes; they all contribute substantially to tagging accuracy.

Table 6 shows several classes of words where the LSTM model outperforms the baseline neural network that uses only local context (NN). The performance increase on unseen words is likely due to the fact that the LSTM can model more context to determine the category for a word. Unsurprisingly, this leads to a large improvement in accuracy for words taking non-local arguments. Finally, we see a large improvement in prepositional phrase attachment. This improvement is likely to be due to the deep architecture, which can better take into account the interaction between the preposition, its argument noun phrase, and its nominal or verbal attachment.

Relaxation	LSTM+ Tri-train F1	LSTM+ Dependencies F1
-	87.9	87.9
$\{NP, N\}$	87.8	87.7
$\{NP, PP\}$	87.7	87.6
$\{NP, PP, N, N_{num}\}$	87.4	87.2
*	78.3	79.3

Table 7: Effect of simulating weaker grammars, by allowing the specified atomic categories to unify. * allows all atomic categories to unify, except conjunctions and punctuation. Results are on development sentences of length $\leq$40.

8.2 Semi-supervised learning

Table 6 also shows cases where the semi-supervised models perform better. Accuracy improves on unseen words—showing that tri-training can be a more effective way of generalizing to unseen words than pre-trained word embeddings alone. We also see improvement in accuracy on wh-words, which we attribute to the training data containing more examples of rare categories used for wh-words in pied-piping and similar constructions. One case where performance remains weak for all models is on unseen usages—where words occur in the CCGbank training data, but not with the category required in the test data. The improvement from tri-training is limited, likely due to the weakness of the baseline parses, and new techniques will be required to correct such errors.

8.3 Effect of Grammar

A subtle but crucial point is that our method depends on the strictness of the CCGbank grammar to exclude ungrammatical derivations. Because there is no dependency model, we rely on the deterministic CCG grammar as a hard constraint. There is a trade-off between restrictive grammars which may be brittle on noisy text, and weaker grammars that may overgenerate ungrammatical sentences.

We measure this trade-off by testing weaker grammars, which merge categories that are normally distinct. For example, if we merge PP and NP, then an $S\backslash NP$ can take either a PP or NP argument.

Table 7 shows that relaxing the grammar significantly hurts performance; the deterministic constraints are crucial to training a high quality LSTM

CCG parser. With a very relaxed grammar in which all atoms can unify, dependencies features help compensate for the weakened grammar. Future work should explore further strengthening the grammar—-e.g. marking plurality on *NP*s to enforce plural agreement, or using slash-modalities to prevent over-generation arising from composition (Baldridge and Kruijff, 2003).

8.4 Effect of Dependency Features

Perhaps our most surprising result is that high accuracy can be achieved with a rule-based grammar and no dependency features. We performed several experiments to verify whether the model can capture long-range dependencies, and the extent to which dependency features are required to further improve parsing performance.

Supertagging accuracy is still the bottleneck A natural question is whether further improvements to our model will require a more powerful parsing model (such as adding dependency or derivation features), or if future work should focus on the supertagger. We found that on sentences where all the supertags are correct in the final parse (51%), the F1 is very high: 97.7. On parses containing supertag errors, the F1 drops to just 80.3. This result suggests that parsing accuracy can be significantly increased by improving the supertagger, and that very high performance could be attained only using a supertagging model.

'Attach low' heuristic is surprisingly effective Given a sequence of supertags, our grammar is still ambiguous. As explained in Section 2, we resolve these ambiguities by attaching low. To investigate the accuracy of this heuristic, we performed oracle decoding given the highest scoring supertags—and found that F1 improved by 1.3, showing that there are limits to what can be achieved with a rule-based grammar. In contrast, an 'attach high' heuristic scores 5.2 F1 less than attaching low, suggesting that these decisions are reasonably frequent, but that attaching low is much more common.

Would adding a dependency model help here? We consider several dependencies whose attachment is often ambiguous given the supertags. Results are shown in Table 8. Any improvements from the dependency model are small—it is difficult to improve on the 'attach low' heuristic with current models.

Dependency	Attach Low Heuristic	Dependencies Model
Relative clause	84.66	**85.44**
Adnominal PP	91.67	**93.67**
Adverbial PP	**97.78**	95.86
Adverb	**99.09**	98.09

Table 8: Per-relation accuracy for several dependencies whose attachments are often ambiguous given the supertags. Results are only on sentences where the parsers assign the correct supertags.

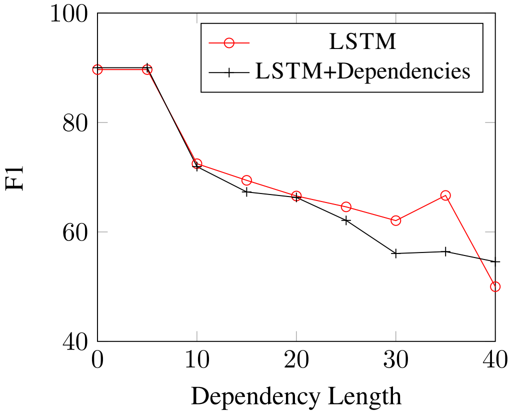

Figure 3: F1 on dependencies of various lengths.

Supertag-factored model is accurate on long-range dependencies One motivation for CCG parsing is to recover long-range dependencies. While we do not explicitly model these dependencies, they can still be extracted from the parse. Instead, we rely on the LSTM supertagger to implicitly model the dependencies—a task that becomes more challenging with longer dependencies. We investigate the accuracy of our parser for dependencies of different lengths. Figure 3 shows that adding dependencies features does not improve the recovery of long-range dependencies over the LSTM alone; the LSTM accurately models long-range dependencies.

9 Related Work

Recent work has applied neural networks to parsing, mostly using neural classifiers in shift-reduce parsers (Henderson et al., 2013; Chen and Manning, 2014; Dyer et al., 2015; Weiss et al., 2015). Unlike our approach, none of these report both state-of-the-art speed and accuracy. Vinyals et al. (2015) instead propose embedding entire sentences in a vector space, and then generating parse trees as strings. Our model achieves state-of-the-art accuracy with a non-ensemble model trained on the standard training data, whereas their model requires ensembles or extra supervision to match the state of the art.

Most work on CCG parsing has either used CKY chart parsing (Hockenmaier, 2003; Clark and Curran, 2007; Fowler and Penn, 2010; Auli and Lopez, 2011a) or shift-reduce algorithms (Zhang and Clark, 2011; Xu et al., 2014; Ambati et al., 2015). These methods rely on beam-search to cope with the huge space of possible CCG parses. Instead, we use Lewis and Steedman (2014a)'s A* algorithm. By using a semi-supervised LSTM supertagger, we improved over Lewis and Steedman's parser by 4.8 F1.

CCG supertagging was first attempted with maximum-entropy Markov models (Clark, 2002)—in practice, the combination of sparse features and a large tag set makes such models brittle. Lewis and Steedman (2014b) applied feed-forward neural networks to supertagging, motivated by using pre-trained work embeddings to reduce sparsity. Xu et al. (2015) showed further improvements by using RNNs to condition on non-local context. Concurrently with this work, Xu et al. (2016) explored bidirectional RNN models, and Vaswani et al. (2016) use bidirectional LSTMs with a different training procedure.

Our tagging model is closely related to the bi-directional LSTM POS tagging model of Ling et al. (2015). We see larger gains over the state-of-the-art—likely because supertagging involves more long-range dependencies than POS tagging.

Other work has successfully applied GPUs to parsing, but has required GPU-specific code and algorithms (Yi et al., 2011; Johnson, 2011; Canny et al., 2013; Hall et al., 2014). GPUs have also been used for machine translation (He et al., 2015).

10 Conclusions and Future Work

We have shown that a combination of deep learning, linguistics and classic AI search can be used to build a parser with both state-of-the-art speed and accuracy. Future work will explore using our parser to recover other representations from CCG, such as Universal Dependencies (McDonald et al., 2013) or semantic roles. The major obstacle is the mismatch between these representations and CCGbank—we will therefore investigate new techniques for obtaining other representations from CCG parses. We will also explore new A* parsing algorithms that explicitly model the global parse structure using neural networks, while maintaining optimality guarantees.

Abstract

In this paper we present new state-of-the-art performance on CCG supertagging and parsing. Our model outperforms existing approaches by an absolute gain of 1.5%. We analyze the performance of several neural models and demonstrate that while feed-forward architectures can compete with bidirectional LSTMs on POS tagging, models that encode the complete sentence are necessary for the long range syntactic information encoded in supertags.

1 Introduction

Morphosyntactic labels for words are commonly used in a variety of NLP applications. For this reason, part-of-speech (POS) tagging and supertagging have drawn significant attention from the community. Combinatory Categorial Grammar is a lexicalized grammar formalism that is widely used for syntactic and semantic parsing. Supertagging (Clark, 2002; Bangalore and Joshi, 2010) assigns complex syntactic labels to words to enable fast and accurate parsing. The disambiguation of correctly labeling a word with one of over 1,200 CCG labels is difficult compared to choosing on of the 45 POS labels in the Penn Treebank (Marcus et al., 1993). In addition to the large label space of CCG supertags, labeling a word correctly depends on knowledge of syntactic phenomena arbitrarily far in the sentence (Hockenmaier and Steedman, 2007). This is because supertags encode highly specific syntactic information (e.g. types and locations of arguments) about a word's usage in a sentence.

In this paper, we show that Bidirectional Long Short-Term Memory recurrent neural networks (bi–LSTMs) (Graves, 2013; Zaremba et al., 2014), which can use information from the entire sentence, are a natural and powerful architecture for CCG supertagging. In addition to the bi–LSTM, we create a simple yet novel model that outperforms the previous state-of-the-art RNN model that uses handcrafted features (Xu et al., 2015) by 1.5%. Concurrent to this work (Lewis et al., 2016) introduced a different training methodology for bi-LSTM for supertagging. We provide a detailed analysis of the quality of various LSTM architectures, forward, backward, and bi-directional, shedding light over the ability of the bi–LSTM to exploit rich sentential context necessary for performing supertagging. We also show that a baseline feed-forward neural network (NN) architecture significantly outperforms previous feed-forward NN baselines, with slightly fewer features, achieving better accuracy than the RNN model from (Xu et al., 2015).

Recently, bi–LSTMs have achieved high accuracies in a simpler sequence labeling task: part-of-speech tagging (Wang et al., 2015; Ling et al., 2015) on the Penn treebank, with small improvements over local models. However, we achieve strong accuracies compared to (Wang et al., 2015) using feed-forward neural network model trained on local context, showing that this task does not require bi–LSTMs. Our strong feed-forward NN baselines show the power of feed-forward NNs for some tasks.

Our main contributions are the introduction of a new bi–LSTM model for CCG supertagging that achieves state-of-the-art, on both CCG supertagging and parsing, and a detailed analysis of our results, including a comparison of bi–LSTMs and simpler feed forward NN models for supertagging and POS tagging, which suggests that the added complexity of bi–LSTMs may not be necessary for POS tagging, where local contexts suffice to a much greater extent than in supertagging.

2 Models And Training

We use feed-forward neural network models and bidirectional LSTM (bi–LSTM) based models in this work.

2.1 Feed-Forward

For both POS tagging and our baseline supertagging model, we use feed-forward neural networks with two hidden layers of rectified linear units (Nair and Hinton, 2010). For supertagging, we use a slightly smaller set than Lewis and Steedman (2014a), using a left and right 3-word window with suffix and capitalization features for the center word. However, unlike them, we train on the full set of supertag categories observed during training.

In POS tagging, when tagging word w_i, we consider only features from a window of five words, with w_i at the center. For each w_j with $i - 2 \leq j \leq i + 2$, we add w_j lowercased and a string that encodes the basic "word shape" of w_j. This is computed by replacing all sequences of uppercase letters with *A*, all sequences of lowercase letters with *a*, all sequences of digits with *9*, and all sequences of other characters with $*$. Finally, we add two and three letter suffixes and two letter prefix for w_i only.

2.2 LSTM models

We experiment with two kinds of bi–LSTM models. We train a basic bi–LSTM where the forward and backward LSTMs take input words w_i and produce hidden state $\overrightarrow{h}_i$ and $\overleftarrow{h}_i$. For each position, we produce $\tilde{h}_i$, where

$$\tilde{h}_i = \sigma(W_{\overleftarrow{h}} \overleftarrow{h}_i^T + W_{\overrightarrow{h}} \overrightarrow{h}_i^T), \tag{1}$$

where $\sigma(x) = \max(0, x)$ is a rectifier nonlinearity, and where $W_{\overleftarrow{h}}$ and $W_{\overrightarrow{h}}$ are parameters to be learned. The unnormalized likelihood of an output supertag is computed using supertag embeddings D_{t_i} and biases b_{t_i} as $p(t_i \mid \tilde{h}_i) = D_{t_i} \tilde{h}_i^T + b_{t_i}$. The final softmax layer computes normalized supertag probabilities.

Although bidirectional LSTMs can capture long distance interactions between words, each output label is predicted independently. To explicitly model supertag interactions, our next model combines two models, the bi–LSTM and a LSTM language model (LM) over the supertags (Figure 1). At position i, the LM accepts an input supertag t_{i-1} producing hidden state h_i^{LM}, and a second combiner layer, parametrized by matrices W_{LM} and $W_{\tilde{h}}$ transforms $\tilde{h}_i$ and h_i^{LM} to h_i similar to the combiner for $\tilde{h}_i$ (Equation 1). Output supertag probabilities are computed just as before, replacing replacing $\tilde{h}_i$ with h_i. We refer to this model as bi–LSTM–LM. For all our LSTM models, we only use words as input features.

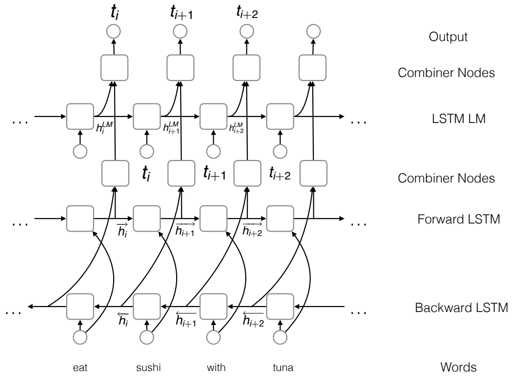

Figure 1: We add a language model between supertags.

2.3 Training

We train our models to maximize the log-likelihood of the data with minibatch gradient ascent. Gradients of the models are computed with backpropagation (Chauvin and Rumelhart, 1995). Since gold supertags are available during training time and not while decoding, a bi–LSTM–LM trained on gold supertags might not recover from errors caused by using incorrectly predicted supertags. This results in the bi–LSTM–LM slightly underperforming the bi–LSTM (we refer to training with gold supertags as g–train in Table 1). To bridge this gap between training and testing we also experiment with a sampling training regime in addition to training.

Scheduled sampling: Following (Bengio et al., 2015; Ranzato et al., 2015), for each output token, with some probability p, we use the most likely predicted supertag ($arg\ max_{t_i} P(t_i \mid h_i)$) from the model in position $i-1$ as input to the supertag LSTM LM in position i and use the gold supertag with probability $1 - p$. We denote this training as ss–train–1. We also experiment with using the 5-best previous predicted supertags from the output distribution at position $i - 1$ and feed them to the LM as input in position i as a bit vector. Additionally, we

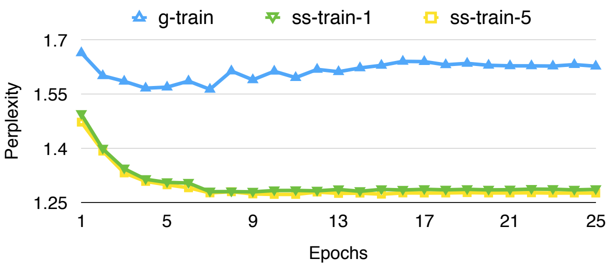

Figure 2: Scheduled sampling improves the perplexity of the gold sequence under predicted tags. We see that the perplexity of the gold supertag sequence when using predicted tags for the LM is lower for ss–train–1 and ss–train–5 than with g–train.

use their probabilities (re-normalized over the 5-best tags) and scale the input supertag embeddings with their re-normalized probability during look-up. We refer to this setting as ss–train–5. In this work, we use an inverse sigmoid schedule to compute p,

$$p = \frac{k}{k + e^{\frac{s}{k}}},$$

where s is the epoch number and k is a hyperparameter that is tuned.[1] In Figure 2, we see that for the development set training with scheduled sampling improves the perplexity of the gold supertag sequence when using predicted supertags, indicating better recovery from conditioning on erroneous supertags. For both ss-train and g-train, we use gold supertags for the output layer and train the model to maximize the log-likelihood of the data.[2]

2.4 Architectures

Our feed-forward models use 2048 rectifier units in the first hidden layer, 50 and 128 rectifier units in the second hidden layer for POS tagging and Supertagging respectively, and 64 dim. input embeddings.

Our LSTM based models use 512 hidden states. We pre-train our word embeddings with a 7-gram feed-forward neural language model using the NPLM toolkit[3] on a concatenation of the BLLIP corpus (Charniak et al., 2000) and WSJ sections 02–21 of the Penn Treebank.

Model	Supertag Accuracy All	Seen	Novel	% P
Lewis et al. (2014)	91.30			
Wenduan et al. (2015)	93.07			
Feed Forward + g–train	93.29	93.77	**91.53**	70.3
Forward LSTM + g–train	83.70	85.76	46.22	20.7
Backward LSTM + g–train	88.82	90.06	66.22	40.6
bi–LSTM	94.08	95.03	76.36	81.1
bi–LSTM–LM + g–train	93.89	94.93	76.83	96.5
bi–LSTM–LM + ss–train–1	**94.24**	**95.22**	76.70	87.8
bi–LSTM–LM + ss–train–5	94.23	95.20	76.62	94.5

Table 1: Accuracies on the development section. The language model provides a boost in performance, and large gains on the parseability of the sequence (%P). The numbers for bi–LSTM–LM + ss–train–1 and + g–train are with beam decoding. All others use greedy decoding. Interestingly, greedy decoding with ss–train–5 works as well as beam decoding with ss–train–1.

2.5 Decoding

We perform greedy decoding. For each position i, we select the most probable supertag from the output distribution. For the bi–LSTM–LM models trained with g–train and ss–train–1, we feed the most likely supertag from the output distribution as LM input in the next position. We decode with beam search (size 12) for bi–LSTM–LMs trained with g–train and ss–train–1. For the bi–LSTM–LMs trained with ss–train–5, we perform greedy decoding similar to training, feeding the k-best supertags from the output supertag distribution in position $i - 1$ as input to the LM in position i, along with the renormalized probabilities. We don't perform beam decoding for ss–train–5, as the previous k-best inputs already capture different paths through the network.[4]

3 Data

For supertagging, experiments were run with the standard splits of CCGbank. Unlike previous work no features were extracted for the LSTM models and rare categories were not thresholded. Words were lowercased and digits replaced with @.

CCGbank's training section contains 1,284 lexical categories (394 in Dev). The distribution of categories has a long tail, with only a third of those cate-

[1] The reader should refer to (Bengio et al., 2015) for details.

[2] We use dropout for all our feed-forward (Srivastava, 2013) and bi-LSTM based models (Zaremba et al., 2014). We carry out a grid search over dropout probabilities and sampling schedules. We train the LSTMs for 25 epochs and the feed-forward models for 30 epochs, tuning on the development data.

gories having a frequency count ≥ 10 (the threshold used by existing literature). Following (Lewis and Steedman, 2014b), we allow the model to predict all categories for a word, not just those with which the word was observed to co-occur in the training data. Accuracies on these unseen (word, cat) pairs are presented in the third column of Table 1.

4 Results

Table 3 presents our Feed-Forward POS tagging results. We achieve 97.28% on the development set and 97.4% on test. Although slightly below state-of-the-art, we approach existing work with bi–LSTMs, and our models are much simpler and faster to train.[5]

Table 1 shows a steady increase in performance as the model is provided additional context. The forward and backward models are presented with information that may be arbitrarily far away in the sentence, but only in a specific direction. This yields weaker results than the Feed Forward model which can see in both directions within a small window. The real gains are achieved by the Bidirectional LSTM which incorporates knowledge from the entire sentence. Our addition of a language model and changes to training, further improve the performance. Our final model (bi–LSTM–LM+ss–train–1 model with beam decoding) has a test accuracy of 94.5%, 1.5% above state-of-the-art.

4.1 Parsing

Our primary goal in this paper was to demonstrate how a bi–LSTM captures new and different information from uni-directional or feed-forward approaches. This advantage also translates to gains in parsing. Table 4 presents new state-of-the-art parsing results for both (Xu et al., 2015) and our bi–LSTM–LM +ss–train–1. These results were attained using our part-of-speech tags (Table 3) and the Java implementation (Clark et al., 2015) of the C&C parser (Clark and Curran, 2007)[6].

4.2 Error Analysis

Our analysis indicates that the information following a word is more informative than what preceded it. Table 2 compares how well our models recover common and syntactically interesting supertags. In particular, the Forward and Backward models, motivate the need for a Bi-directional approach.

[5] We use train, dev, and test splits of WSJ sections 00–18, 19–21, and 22–24, for POS tagging.

[6] Results are presented on the standard development and test splits (Section 00 and 23), and with a beam threshold of 10^{-6}. For a fair comparison to prior work we report results without the skimmer, so no partial credit is given to parse failures. The skimmer boosts performance to 87.91/88.39 for Dev and Test.

	(S[dcl]\NP)/(S[adj]\NP)	
Forward	**Backward**	**Bidirectional**
((S[dcl]\NP)/PP)/(S[adj]\NP)	((S[dcl]\NP)/PP)/(S[adj]\NP)	(S[dcl]\NP)/(S[pss]\NP)

(S[dcl]\NP)/(S[pss]\NP)	((S[dcl]\NP)/(S[adj]\NP))/(S[adj]\NP)	(S[dcl]\NP)/(S[adj]\NP))/(S[adj]\NP)

Table 5: "Neighbor" categories as determined by embedding-based vector similarity for each class of model. As expected for this category, the Backward model captures the argument preference while the Forward model correctly predicts the result.

The first two rows show prepositional phrase attachment decisions (noun and verb attaching categories are in rows one and two, respectively). Here the forward model outperforms the backward model, presumably because knowing the word to be modified and the preposition, is more important than observing the object of the prepositional phrase (the information available to the backward model).

Conversely, the backward model outperforms the forward model in most of the remaining categories. (Di-)transitive verbs (lines 4 & 5) require knowledge of future arguments in the sentence (e.g. separated by a relative clause). Because English has strict SVO word-order, the presence of a subject is more predictable than the presence of an (in-)direct object. It is therefore not surprising that the backward model is often comparable to the Feed Forward model.

If the information missing from either the forward or backward models were local, the bidirectional model should perform the same as the Feed-Forward model, instead it surpasses it, often by a large margin. This implies there is long range information necessary for choosing a supertag.

Embeddings In addition, we can visualize the information captured by our models by investigating a category's nearest neighbors based on the learned embeddings. Table 5 shows nearest neighbor categories for (S[dcl]\NP)/(S[adj]\NP) under the Forward, Backward, and Bidirectional models.

We see see that the forward model learns internal structure with the query category, but the list of arguments is nearly random. In contrast, the backward model clusters categories primarily based on the final argument, perhaps sharing similarities in the subject argument only because of the predictable SVO nature of English text. However, due to its lack of forward context the model incorrectly associates categories with less-common first arguments (e.g. S[qem]). Finally, the bidirectional embeddings appear to cleanly capture the strengths of both the forward and backward models.

Consistency and Internal Structure Because supertags are highly structured their co-occurence in a sentence must be permitted by the combinators of CCG. Without encoding this explicitly, the language model dramatically increases the percent of predicted sequences that result in a valid parse by up to 15% (last column of Table 2).

Sparsity One consideration of our approach is that we do not threshold rare categories or use any tag dictionaries; our models are presented with the full space of CCG categories, despite the long tail. This did not did not hurt performance and the models learned to successfully use several categories which were outside the set of traditionally-thresholded frequent categories. Additionally, the total number of categories used correctly at least once by the bidirectional models was substantially higher than the other models ($\sim$270 vs. $\sim$220 of 394), though the large number of unused categories ($\geq$120) indicates that there is still substantial room for improvement.

5 Conclusions and Future Work

Because bi–LSTMs with a language model encode an entire sentence at decision time, we demonstrated large gains in supertagging and parsing. Future work will investigate improving performance on rare categories.

Abstract

Word segmentation is usually recognized as the first step for many Chinese natural language processing tasks, yet its impact on these subsequent tasks is relatively under-studied. For example, how to solve the *mismatch* problem when applying an existing word segmenter to new data? Does a better word segmenter yield a better subsequent NLP task performance? In this work, we conduct an initial attempt to answer these questions on two related subsequent tasks: semantic slot filling in spoken language understanding and named entity recognition. We propose three techniques to solve the mismatch problem: using word segmentation outputs as additional features, adaptation with partial-learning and taking advantage of n-best word segmentation list. Experimental results demonstrate the effectiveness of these techniques for both tasks and we achieve an error reduction of about 11% for spoken language understanding and 24% for named entity recognition over the baseline systems.

1 Introduction

Unlike English text in which sentences are sequences of words separated by white spaces, in Chinese text (as are some other languages including Arabic, Japanese, etc.), sentences are represented as strings of characters without similar natural delimiters. Therefore, it is generally claimed that the first step in a Chinese language processing task is to identify the sequence of words in a sentence and mark boundaries in appropriate places, which is refereed to as the task of Chinese Word Segmentation (CWS).

(1) Input: 能穿多少穿多少
CWS 1: 能|穿|**多少**|穿|多少[1]
(Put on as **much** clothes as possible.)
CWS 2: 能|穿|多|**少**|穿|多|少
(Put on as **little** clothes as possible.)

Word segmentations in Chinese text do reduce ambiguities. In the example (1), the same span of text (the input) can convey entirely opposite meanings (the English sentences in parentheses) depending on how word boundaries (CWS 1 and CWS 2) are labeled. Therefore, it is generally believed that more accurate word segmentations should benefit more the subsequent Chinese language processing tasks, such as part-of-speech tagging, named entity recognition, etc. There has been quite a number of research in the field of CWS to improve segmentation accuracy, yet its impact on the subsequent processing is relatively under-studied. Chang et al. (2008) explore how word segmentation improves machine translation; and Ni and Leung (2014) explore how word segmentation impacts automatic speech recognition yet do not have conclusive findings. In this research, we aim to better understand how CWS benefits the subsequent NLP tasks, using semantic slot filling in spoken language understanding (SLU) and named entity recognition (NER) as two case studies.

In particular, we investigate the impact of Chinese word segmentation in three different situations.

First, assuming domain data (the data for a particular subsequent task, e.g. SLU or NER) having no word boundary annotation (§4), we can apply word segmenters trained with publicly-available data to the domain data to get the word boundary. However, existing word segmenters may have a domain mismatch problem due to the fact that they may have different genre from the subsequent task and are usually segmented with different standards (Huang and Zhao, 2007). Therefore, we propose three techniques to solve this problem. Note, these techniques can be used together.

1) We use word segmentation outputs as additional features in subsequent tasks (§3.2), which is more robust against error propagation than using segmented word units.

2) We adapt existing word segmenters with partially-labeled data derived from the subsequent task training data (§3.3), further improving the end-to-end performance.

3) We take advantage of the n-best list of word segmentation outputs (§3.4), making the subsequent task less sensitive to word segmentation errors.

Second, assuming domain training data (e.g., NER) is already segmented with word boundary (§5), we are able to train a domain word segmenter with the data itself and apply it to the testing data. This allows us to see the differences between a word segmenter trained with in-domain data and one trained with publicly-available data.

Last, assuming both domain training and testing data have word boundary information (§5), it allows to explore the upper bound performance of the subsequent task with a perfect word segmenter.

Experimental results show that the proposed techniques do improve the end-to-end performance and we achieve an error rate reduction of 11% for SLU and 24% for NER over their corresponding baseline systems. In addition, we found that even a word segmenter that is only moderately reliable is still able to improve the end-to-end performance, and a word segmenter trained with in-domain data is not necessarily better compared to a word segmenter trained with out-domain data in terms of the end-to-end performance.

2 Related Work

Word segmentation has received steady attention over the past two decades. People have shown that models trained with limited text can have a reasonable accuracy (Li and Sun, 2009; Zhang et al., 2013a; Li et al., 2013; Cheng et al., 2015). However, the fact is that none of existing algorithms is robust enough to reliably segment unfamiliar types of texts without fine-tuning (Huang et al., 2007). Several approaches have proposed to eliminate this issue, for example the use of unlabeled data (Sun and Xu, 2011; Wang et al., 2011; Zhang et al., 2013b) and partially-labeled data (Yang and Vozila, 2014; Takahasi and Mori, 2015). In our work, we encounter the same issue when applying word segmentation to the subsequent tasks and thus we propose three approaches to solve this problem.

Word segmentation has been applied in several subsequent tasks, e.g. NER (Zhai et al., 2004), information retrieval (Peng et al., 2002), automatic speech recognition (Ni and Leung, 2014), machine translation (Xu et al., 2008; Chang et al., 2008; Zhang et al., 2008; Zeng et al., 2014), etc. In general, there are two types of approaches to utilize word segmentation in subsequent tasks: *pipeline* and *joint-learning*. The pipeline approach creates word segmentation first and then feeds the segmented words into subsequent task(s). It is straightforward, but suffers from error propagation since an incorrect word segmentation would cause an error in the subsequent task. The joint-learning approach trains a model to learn both word segmentation and the subsequent task(s) at the same time. A number of subsequent tasks have been unified into joint models, including disambiguation (Wang et al., 2012), part-of-speech tagging (Jiang et al., 2008a; Jiang et al., 2008b; Zhang and Clark, 2010; Sun, 2011), NER (Gao et al., 2005; Xu et al., 2014; Peng and Dredze, 2015), and parsing (Hatori et al., 2012; Qian and Liu, 2012). However, the joint-learning process generally assumes the availability of manual word segmentations for the training data, which limits the use of this approach. Thus in this work, we focus on the pipeline approach, but instead of feeding the segmented words, we use word segmentation results as additional features in the subsequent tasks, which is more robust against error propagation.

3 Applying CWS to Subsequent Tasks

In this section, we describe how to integrate word segmentation information when domain data having no word boundary information, using SLU and NER as two case studies.

We first introduce the baseline system, and then describe the techniques that we propose to solve the domain mismatch problem when applying automatic CWS to the subsequent NLP tasks.

3.1 Baseline system

Both of the SLU and NER can be formulated as sequence labeling tasks, and can be solved using machine learning techniques such as Conditional Random Field (CRF), Recurrent Neural Network, or their combinations (Wan et al., 2011; Mesnil et al., 2015; Rondeau and Su, 2015). We adopt the tool wapiti (Lavergne et al., 2010), which is an implementation of CRF. In the baseline system, each Chinese character is treated as a labeling unit. Here is an example of our training sentences for SLU:'三|division 元|division 里|division 莫|street 干|street 山|street 路|street 周|locref 围|locref 的|unk 餐|query 厅|query' (Find the restaurants near Sanyuanli Mogan Mountain road). The input features for training the baseline CRF model are character ngrams in the K-window and label bigrams. For computational efficiency, we use trigram within 5-character window. Given the current character c_0, we extract the following character ngram features: c_{-2}, c_{-1}, c_0, c_1, c_2, $c_{-2}c_{-1}$, $c_{-1}c_0$, c_0c_1, c_1c_2, $c_{-2}c_{-1}c_0$, $c_{-1}c_0c_1$, and $c_0c_1c_2$.

3.2 Using CWS as features

When word segmentation information is not available within the domain data, we can use publicly-available corpora such as the Chinese Tree Bank (Levy and Manning, 2003), to train an automatic word segmenter.

A dominant approach for supervised CWS is to formulate it as a character sequence labeling problem, and label each character with its location in a word (Xue, 2003). A popular labeling scheme is 'BIES': 'B' for the beginning character of a word, 'I' for the internal characters, 'E' for the ending character, and 'S' for single-character word. Following (Yang and Vozila, 2014), we train our automatic word segmenter with CRF using the input features of character unigrams and bigrams, consecutive character equivalence, separated character equivalence, punctuation, character sequence pattern, anchor of word unigram and bigram. This word segmenter achieves state-of-the-art or comparable performance.

A straightforward way to integrate word segmentation is the traditional pipeline approach. It uses word segmentation first and feeds the segmented words to subsequent task(s), named as **Word Unit**. However, this method suffers from the error propagation problem since an incorrect word segmentation would cause an error in the subsequent task. Therefore, we proposed to use word segmentation outputs as additional features (**As Features**) in the subsequent tasks, as introduced below. We hypothesize the **As Features** is less sensitive to word segmentation errors since the CRF model can still rely on the character features when a word segmentation is not perfect.

Word Unit We can use segmented words instead of characters as labeling units for the CRF learning. During training we can run *forced-decoding* (Lavergne et al., 2010) on word segmentation so that word boundaries are consistent with semantic slot or named entity boundaries. During testing we simply apply the word segmenter to the sentences.

As Features We can still keep using characters as the labeling units, but add the word segmentation information as additional features. Given the current character c_0 and word segmentation output represented as 'BIES' tag t_0, we extract the character ngram features together with the following word segmentation tag ngram features: t_{-2}, t_{-1}, t_0, t_1, t_2, $t_{-2}t_{-1}$, $t_{-1}t_0$, t_0t_1, t_1t_2, $t_{-2}t_{-1}t_0$, $t_{-1}t_0t_1$, and $t_0t_1t_2$. The tag ngram features provide word segmentation information indirectly. For example, t_0t_1='BE' indicates c_0 initiates a two-character word, while $t_0t_1t_2$='BII' means that c_0 is probably a beginning of a long word.

3.3 Adaptation with Partial-learning

The publicly-available corpora for word segmentation, however, may create a domain-mismatch prob-

Figure 1: Partially-labeled word segmentations derived from named entity labels. The first character in a name (‘美’ in the organization name ‘美中贸易全国委员会’) can only be labeled as ‘S’ or ‘B’, while the last one (‘会’) can only be labeled as ‘S’ or ‘E’; similarly, a character after a name (‘主’) can only be labeled as ‘S’ or ‘B’, while a character before a slot (‘席’) can only be labeled as ‘S’ or ‘E’.

lem (especially for the SLU data). First, these corpora tend to be news articles and thus have different genre in content. Second, these corpora are usually segmented with different standards (Huang and Zhao, 2007) and it is unclear which one would serve the purpose of the subsequent task.

Even if the NER/SLU task training data is not word segmented, the semantic slot and named entity labels actually provide valuable information on word boundaries. As illustrated in Fig. 1, the first character in an organization/person/location name can only be labeled as ‘S’ or ‘B’, while the last one can only be labeled as ‘S’ or ‘E’; similarly, a character after a name can only be labeled as ‘S’ or ‘B’, while a character before a name can only be labeled as ‘S’ or ‘E’. We can thus create partially-labeled CWS data from SLU and NER labels. These partially-labeled data can then be used to adapt the out-of-domain word segmenter trained from publicly-available corpus.

Täckström et al. (2013) propose the approach *partial-label learning* to learn from partially-labeled data, and Yang and Vozila (2014) apply it to Chinese word segmentation. In partial-label training, each item in the sequence receives multiple labels, and each sequence has a lattice constraint, as shown in Fig. 1. The basic idea is to marginalize the probability mass of the constrained lattice in a cost function. The marginal probability of the lattice is defined as Equation 1, where C denotes the input character sequence, L denotes the label sequence, and $\hat{Y}(C,\tilde{L})$ denotes the constrained lattice (with regard to the input sequence C and the partial-labels $\tilde{L}$).

$$p_\theta(\hat{Y}(C,\tilde{L})|C) = \sum_{L \in \hat{Y}(C,\tilde{L})} p_\theta(L|C) \tag{1}$$

The optimization objective function is to maximize the log-likelihood of the training set, in which likelihood is calculated via the probability mass of the constrained lattice, as shown in Equation 2. Here n denotes the number of sentences in the training set.

$$L(\theta) = \sum_{i=1}^{n} \log p_\theta(\hat{Y}(C_i,\tilde{L}_i)|C_i) \tag{2}$$

With CRF[2], a gradient-based approach such as L-BFGS can be used to optimize Equation 2. We expect that this adaptation process should help to provide better word segmentation information that further improves the subsequent task performance.

3.4 N-best CWS

Only using the best word segmentation output as features for the subsequent tasks might not be sufficient (as we will show in our experiments). Indeed we can make use of the n-best word segmentation outputs. The task of SLU or NER is to find the best label sequence L, given the character sequence C, represented as $\arg\max_L P(L|C)$. By including the word segmentation information, we can rewrite it by marginalizing over all possible word segmentations.

$$\begin{aligned} \arg\max_L P(L|C) &= \arg\max_L \sum_j P(L,W_j|C) \\ &= \arg\max_L \sum_j P(L|W_j,C) \cdot P(W_j|C) \end{aligned} \tag{3}$$

[2] We modified wapiti to implement partial learning.

Where, W_j is each possible word segmentation. This formula can be understood as two components: $P(W_j|C)$ is the word segmentation model and $P(L|W_j, C)$ is the SLU/NER model. In practice, we can use the n-best outputs associated posterior probabilities from the wapiti, for both $P(W_j|C)$ and $P(L|W_j, C)$.[3]

4 CWS for SLU

In this section, we investigate the impact of CWS to the task of spoken language understanding (SLU) by making use of existing word segmenters trained with publicly-available data (1^{st} situation in §1). This is motivated by the fact that our SLU training and testing data are not pre-segmented by semantic word units.

We choose semantic slot filling in SLU because it is becoming popular as it is a critical component to support conversational virtual assistants, such as Apple Siri, Samsung S Voice, Microsoft Cortana, Nuance Nina, just to name a few. The task of SLU is to convert a user utterance into a machine-readable semantic representation, which typically includes two sub-tasks: intent recognition and semantic slot filling (Tur et al., 2013). Intent recognition is to determine the intention of the user utterance. For example, for the input utterance ‘book a ticket from Boston to Seattle’, SLU will determine that its intent is *ticket-booking* as opposed to *music-playing*. Semantic slot filling is to extract the designated slot values for the recognized intent from the input utterance. For example, SLU will extract ‘depart:Boston’ and ‘arrive:Seattle’ from the above user utterance. In this paper, we assume the availability and correctness of intent recognition, and focus only on semantic slot filling.

4.1 SLU experiments setting

As described above, intent recognition is the first step in SLU, and the availability of which is assumed in this research work. We organize our training and testing data for semantic slot filling according to their intents. A single model for semantic slot filling is trained for each individual intent because different intents have different designated slots. For example, for the intent *ticket-booking*, the designated slots are the arrival and departure city/airport, airline, date, etc.; While the *local-search* intent is more interested in the city, address, street name, type of point of interest, etc. For evaluation, each model is applied to the corresponding intent’s testing data. At the end, we gather the automatic semantic labels of all intents in a pool and calculate F-measure.

Our SLU data consists of about 2 million sentences for training and 260 thousand sentences for testing, distributing into 170 intents.

	CTB6	**PKU**
number of sentences	23,458	19,058
number of unique character	4,223	4,685
number of unique word	42,127	55,302
average sentence length	45.0	95.8
average word length	1.7	1.7

Table 1: Statistics of two publicly-available corpus for CWS training.

4.2 Results and discussion

We build two word segmenters from two public corpora, the Chinese Tree Bank 6 (CTB6) and the PKU corpus from the SIGHAN Bakeoff 2005, respectively. The data statistics of the two corpora are shown in Table 1.

The SLU performances are summarized in Table 2. **Baseline** using only character ngram features gives an F-measure of 93.92%. When switching to using automatic segmented words as the labeling units (**Word Unit**), the performance is a lot worse in both cases (87.10% for CTB6 and 88.68% for PKU). This indeed is not too surprising because errors in CWS propagate into SLU semantic slot filling. If an error results in a word crossing the boundary of semantic slots, it will definitely lead to an error in SLU semantic slot filling.

On the other hand, when supplying the automatic ‘BIES’ ngrams from CWS to SLU semantic slot filling (**As Features**), we observe a nice gain in both cases, 94.41% for CTB6 and 94.13% for PKU. Using the ngram ‘BIES’ as input features provides useful information of word segmentation to SLU semantic slot filling, while it is less sensitive to word segmentation errors.

[3] During training we build the SLU/NER model with 1-best word segmentation; during evaluation, we use n-best word segmentation and n-best SLU/NER.

	CTB6			PKU		
	R (%)	**P (%)**	**F (%)**	**R (%)**	**P (%)**	**F (%)**
Baseline	94.10	93.73	93.92	94.10	93.73	93.92
Word Unit	89.42	84.90	87.10	90.29	87.12	88.68
As Features	94.13	94.70	94.41*	94.10	94.16	94.13*
Partial Learning	94.18	94.76	94.47*	94.19	94.77	94.48*
N-best	**94.36**	**94.84**	**94.60***	**94.37**	**94.85**	**94.61***

Table 2: SLU Results in Recall (R), Precision (P), and F-measure (F). * means it is statistically significant better than **Baseline** using a Z-test with a confidence level of 99%.

(2) Input: 查找[**湖南财政**经济学院][附近]的[餐厅][4]
CWS: 查找|**湖南**|**财政**|经济|学院|附近|的|餐厅
(Find the restaurants near Hunan College of Finance and Economics)

Example (2) illustrates that how CWS helps SLU semantic slot filling. For the sentence, the baseline system extracts '湖南财' as a location name. However, the word segmentation separates the words '湖南' (Hunan) and '财政' (Finance), which reduces the probability score of '湖南财' being a slot value because it crosses word boundaries. With CWS information, the system is able to extract '湖南财政经济学院' (Hunan College of Finance and Economics) as a slot value.

(3) Input: 转发[**淘宝网**的链接]
CWS 1: 转发|**淘**|**宝网**|的|链接
(Forward the link of bao.com)
CWS 2: 转发|**淘宝网**|的|链接
(Forward the link of taobao.com)
(4) Input: 亲[**四季酒店**]在哪里
CWS 1: **亲四季酒店**|在|哪里
(Where is the Kiss Four Seasons Hotel)
CWS 2: 亲|**四季酒店**|在|哪里
(Dear, where is the Four Seasons Hotel)

Adapting the word segmentation with SLU partially-labeled data gives further gain to semantic slot filling. In the case of CTB6 it reaches an F-measure of 94.47%, and 94.48% in PKU, using the ngram of 'BIES' labels from the adapted segmenters. Here are two examples showing how the adaptation process further improves SLU. In the example (3), we have the incorrect word segmentation (CWS 1) before adaptation. It splits a word '淘宝网' (taobao.com) and thus labels '宝网的链接' as a semantic slot. From the adaptation the system learns that '淘宝网' is a word, and it generates the correct word segmentation (CWS 2) and thus is able to create the correct semantic slot value '淘宝网的链接' (the link of taobao.com). Similarly, in the example (4), the sentence is initially under-segmented (CWS 1) and it creates the incorrect semantic slot value '亲四季酒店'. From the adaptation the system learns to put a word boundary between '亲' and '四' and then the correct slot value '四季酒店' (Four Seasons Hotel) is extracted.

Finally, we take 10-best outputs from the adapted word segmenter, for each word segmentation generate 10-best SLU outputs, sum up the probabilities, and search for the best semantic label sequence following Equation 3. We further push the performance to an F-measure of 94.60% for CTB6 and 94.61% for PKU. Compared with the baseline system that uses character ngrams as input features, the information of CWS helps us achieve an error reduction of about 11%.

5 CWS for NER

In our experiments on SLU, we showed how CWS helps the subsequent task when no in-domain word segmentation data is available (1^{st} situation in §1). In this section, we investigate the impact of CWS to another important subsequent task: named entity recognition (NER). For the NER data we use, both the domain training and testing data have word boundary information, which allows us to explore the differences between word segmenters trained with in-domain data and publicly-available data (2^{nd} situation). It also allows us to see the performance of the subsequent task using manual word segmen-

[4] Semantic slots in the input sentence are marked by '[]'.

tation (3^{rd} situation). Moreover, it allows us to see the relationship between the performance of word segmentation and the end-to-end subsequent task.

5.1 NER experiments setting

For NER experiments, we use the benchmark NER data from the third SIGHAN Chinese language processing Bakeoff (SIGHAN-3) (Levow, 2006). It consists of 46,364 sentences in the training set and 4,365 sentences in the testing set. These data are annotated with both word boundaries and NER information.

5.2 Results and discussion

Baseline system which only uses character ngram features (same configuration as the SLU task) gives the performance of 85.81% in F-measure, as shown in Table 3.[5]

Oracle system uses character ngram features together with manual in-domain word boundary information during both training and testing, showing that *perfect* word segmentation information does help NER a lot. Again this suggests that *good* word segmentation does reduce ambiguities for the subsequent NLP tasks, as we argue in the introduction. Of course, since manual word segmentation is not generally available (esp. on testing), this raises the motivation of our research work: what is the impact of automatic CWS on NER and how to make the best out of it.

To understand the impact of automatic CWS on NER, we discard the manual word segmentations in the NER data, and build two word segmenters from two public corpora, CTB6 and PKU respectively, same as we did for the SLU experiments. We also adapt them to NER with partial-label learning, and finally apply n-best CWS to NER decoding. Here we only report the results for **As Features**, as summarized in Table 3. Similar to SLU, when supplying the automatic 'BIES' ngrams from CWS to NER (**As Features**), we observe a nice gain in both cases of **CTB6** and **PKU**. The NER F-measure improves to 86.40% and 87.05% respectively. In addition, adapting the word segmentation with NER partially-labeled data gives a further gain for both CTB6 and PKU, with an F-measure of 86.96% and 87.64% respectively. Note that, the adaptation process does improve the CWS performances for both CTB6 and PKU.

In-domain CWS

NER system uses the NER training data to build a word segmenter and then apply it to the NER training and testing data to extract the word segmentation features. A naive thought is that it will result in a better NER performance than **CTB6** and **PKU** since a word segmenter trained with the in-domain data should be better than one trained with publicly-available data due to the domain mismatch issue. As shown in Table 3, it is true that the word segmentation F-measures of **NER** are much better than **CTB6** and **PKU**. However, to our surprise, the NER F-measure is only 83.45%, which is even worse than **Baseline**.

We hypothesize that this is due to the mismatch of the training CWS and testing CWS (as shown in Table 3, CWS F (train) and F (test)). When CWS accuracy is high on the training data, the NER model trained with such data puts more weight on word segmentation features rather than character features. However, during testing, the performance of CWS drops, resulting in more word segmentation errors, with a high chance to propagate to NER errors; even worse, a lot of these CWS errors are around NERs since a lot of NERs are OOVs and thus are challenging to segment correctly. To test this hypothesis, we use 3-fold cross-validation to get the word boundary information during the CWS training, and thus the model is named as **NER 3-fold**. Note, although the performance of CWS decreases in the training, it has a more balanced CWS performance between training and testing, which gives a better NER performance (improving 83.45% from **NER** to 86.80%).

N-best CWS

The model **N-best** takes N-best outputs from the adapted word segmenter, for each word segmentation generate K-best NER outputs, sums up the probabilities and searches for the best named-entity

[5] We also train a model to learn both word segmentation and NER at the same time (**Joint-learning**) using char ngram features, and then during decoding we marginalize all possible CWS sequences to search for the best NER labels. The performance, however, is only 85.39% in F-measure, suggesting it is non-trivial to leverage the gain from joint-training and the comparison between joint-training and our approaches is out of the scope of this paper.

		CWS		NER

NER	As Features	99.64	95.70	80.88	86.19	83.45
	N-best	-	-	84.55	87.47	85.98
NER 3-fold	As Features	94.69	95.70	83.61	90.25	86.80*
	N-best	-	-	87.22	91.30	89.21*
SIGHAN-3 Best System		-	-	84.20	88.94	86.51

Table 3: CWS and NER Results in F-measure. **CWS F (Train)** and **CWS F (Test)** are the word segmentation F-measure in the training and testing data respectively. **NER F** is the named-entity testing F-measure. '-' means that the metric does not apply. For example, **Baseline** has no word segmentation model and F-measure cannot be calculated for N-best models. For **N-best**, we set N=10 and K=2. '*' means it is statistically significant better than **Baseline** using a Z-test with a confidence level of 99%.

label sequence following Equation 3. We can see a big jump in **N-best** performances for all the models in Table 3. This verifies our hypothesis that 1-best CWS is not sufficient.

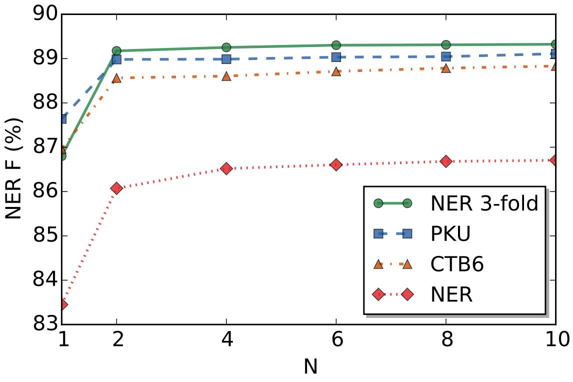

Figure 2: N-best results when varying N ($K = 1$)

To better understand how **N-best** helps NER, we vary the parameter N and the performance of NER (K=1) is shown in Fig. 2. The N-best performance improves dramatically when N jumps from 1 to 2. After that the performance seems to quickly saturate. We also found that the performance does not change much when changing K. These results show that in practice we can set N=2 and K=1, which is cost-efficient.

SIGHAN-3 evaluation

In the closed track evaluation of SIGHAN-3 (Levow, 2006), participants could only use the information found in the provided training data. Our best model (**NER 3-fold**) belongs to this track since it uses only the word segmentation annotation in the training data set. Our model outperforms all the submissions as shown in Table 3. Furthermore, even if manual word segmentation does not exist in the data, the model **CTB6 N-best** and **PKU N-best** which using existing word segmenters trained from publicly-available data can still outperform all the submissions in SIGHAN-3. Note that, these models use only character and word segmentation features without requiring additional name lists, part-of-speech taggers, etc.

6 Conclusion and future work

Chinese word segmentation is an important research topic and usually is the first step in Chinese natural language processing, yet its impact on the subsequent processing is relatively under-studied. To our knowledge, this research work is the first attempt to understand in depth how automatic CWS impacts the two related subsequent tasks: SLU semantic slot filling and named entity recognition.

In this work, we proposed three techniques to solve the domain mismatch problem when applying CWS to other tasks: using word segmentation outputs as additional features, adaptation with partial-learning and taking advantage of n-best list. All three techniques work for both tasks.

We also examined the impact of CWS in three different situations: First, when domain data has no word boundary information, we showed that a word segmenter built from public out-of-domain data is able to improve the end-to-end performance. In addition, adapting it with the partially-labeled data derived from human annotation can further improve the performance. Moreover, marginalizing n-best word segmentations leads to further improvement. Second, when domain word segmentation is available, the word segmenter trained with the domain data itself has a better CWS performance but it does not necessarily have a better end-to-end task performance. A word segmenter with more balanced performance on the training and testing data may obtain a better end-to-end performance. Third, when testing data is manually segmented, word segmentation does help the task a lot. This is not a typical use case in reality, but it does suggest that word segmentation does reduce ambiguities for the subsequent NLP tasks.

In the future, we can try to sequentially stack two CRFs (one for word segmentation and one of subsequent task). We also would like to explore more subsequent tasks beyond sequence labeling problems.

Abstract

In this paper we tackle a challenging name tagging problem in an emergent setting - the tagger needs to be complete within a few hours for a new incident language (IL) using very few resources. Inspired by observing how human annotators attack this challenge, we propose a new expectation-driven learning framework. In this framework we rapidly acquire, categorize, structure and zoom in on IL-specific expectations (rules, features, patterns, gazetteers, etc.) from various non-traditional sources: consulting and encoding linguistic knowledge from native speakers, mining and projecting patterns from both mono-lingual and cross-lingual corpora, and typing based on cross-lingual entity linking. We also propose a cost-aware combination approach to compose expectations. Experiments on seven low-resource languages demonstrate the effectiveness and generality of this framework: we are able to setup a name tagger for a new IL within two hours, and achieve 33.8%-65.1% F-score [1].

1 Introduction: "Tibetan Room"

In many emergent situations such as disease outbreaks and natural disasters, there is great demand to rapidly develop a Natural Language Processing (NLP) system, such as name tagger, for a "surprise" Incident Language (IL) with very few resources. Traditional supervised learning methods that rely on large-scale manual annotations would be too costly.

Let's start by investigating how a human would discover information in a foreign IL environment. When we are in a foreign country, even if we don't know the language, we would still be able to guess the word "*gate*" from the airport broadcast based on its frequency and position in a sentence; guess the word "*station*" by pattern mining of many subway station labels; and guess the word "*left*" or "*right*" from a taxi driver's GPS speaker by matching movement actions. We designed a "***Tibetan Room***" game, similar to "*Chinese Room*" (Searle, 1980), by asking a human user who doesn't know Tibetan to find persons, locations and organizations from some Tibetan documents. We designed an interface where test sentences are presented to the player one by one. When the player clicks token, the interface will display up to 100 manually labeled Tibetan sentences that include this token. The player can also see translations of some common words and a small gazetteer of common names (800 entries) in the interface.

14 players who don't know Tibetan joined the game. Their name tagging F-scores ranged from 0% to 94%. We found that good players usually bring in some kind of "***expectations***" derived from their own native languages, or general linguistic knowledge, or background knowledge about the scenario. Then they actively search, confirm, adjust and update these expectations during tagging. For example, they know from English that location names are often ended with suffix words such as "*city*" and "*country*", so they search for phrases starting or ending with the translations of these suffix words. After they successfully tag some seeds, they will continue to discover more names based on more expectations.

[1] The resources developed in this paper, including the survey, patterns and gazetteers, are available at http://nlp.cs.rpi.edu/data/elisaienaacl16.zip

Proceedings of NAACL-HLT 2016, pages 249–259,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

For example, if they already tagged an organization name A, and now observe a sequence matching a common English pattern "*[A (Organization)]' s [Title] [B (Person)]*", they will tag *B* as a person name. And if they know the scenario is about Ebola, they will be looking for a phrase with translation similar to "*West Africa*" and tag it as a location. Similarly, based on the knowledge that names appear in a conjunction structure often have the same type, they propagate high-confidence types across multiple names. They also keep gathering and synthesizing common contextual patterns and rules (such as position, frequency and length information) about names and non-names to expand their expectations. For example, after observing a token frequently appearing between a subsidiary and a parent organization, they will predict it as a preposition similar to "*of*" in English, and tag the entire string as a nested organization.

Based on these lessons learned from this game, we propose to automatically acquire and encode expectations about what will appear in IL data (names, patterns, rules), and encode those expectations to drive IL name tagging. We explored various ways of systematically discovering and unifying latent and expressed expectations from nontraditional resources:

- **Language Universals**: Language-independent rules and patterns;
- **Native Speaker**: Interaction with native speakers through a machine-readable survey and supervised active learning;
- **Prior Mining**: IL entity prior knowledge mining from both mono-lingual and cross-lingual corpora and knowledge bases;

Furthermore, in emergent situations these expectations might not be available at once, and they may have different costs, so we need to organize and prioritize them to yield optimal performance within given time bounds. Therefore we also experimented with various **cost-aware** composition methods with the input of acquired expectations, plus a time bound for development (1 hour, 2 hours), and the output as a wall-time schedule that determines the best sequence of applying modules and maximizes the use of all available resources. Experiments on seven low-resource languages demonstrate that our framework can create an effective name tagger for an IL within a couple of hours using very few resources.

2 Starting Time: Language Universals

First we use some language universal rules, gazetteers and patterns to generate a binary feature vector $F = \{f_1, f_2, ...\}$ for each token. Table 1 shows these features along with examples. An identification rule is $r_I = \langle T_I, f = \{f_a, f_b, ...\}\rangle$ where T_I is a "B/I/O" tag to indicate the beginning, inside or outside of a name, and $\{f_a, f_b, ...\}$ is a set of selected features. If the features are all matched, the token will be tagged as T_I. Similarly, a classification rule is $r_C = \langle T_C, f = \{f_a, f_b, ...\}\rangle$, where T_C is "Person/Organization/Location". These rules are triggered in order, and some examples are as follows: ⟨B, {AllUppercased}⟩, ⟨PER, {PersonGaz}⟩, ⟨ORG, {Capitalized, LongLength}⟩, etc.

3 Expectation Learning

3.1 Approach Overview

Figure 1 illustrates our overall approach of acquiring various expectations, by simulating the strategies human players adopted during the Tibetan Room game. Next we will present details about discovering expectations from each source.

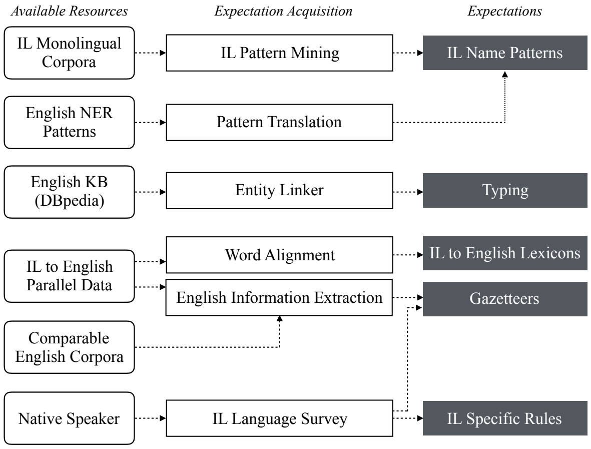

Figure 1: Expectation Driven Name Tagger Overview

3.2 Survey with Native Speaker

The best way to understand a language is to consult people who speak it. We introduce a human-in-

Features	Examples (Feature name is underlined)
in English Gazetteer	- **PerGaz**: person $(472, 765)$; **LocGaz**: location $(211, 872)$; **OrgGaz**: organization $(124, 403)$; **Title** (889); **NoneName** $(2, 380)$.
Case	- **Capitalized**; - **AllUppercased**; - **MixedCase**
Punctuation	- **IternalPeriod**: includes an internal period
Digit	- **Digits**: consisted of digits
Length	- **LongLength**: a name including more than 4 tokens is likely to be an ORG
TF-IDF	- **TF-IDF**: if a capitalized word appears at the beginning of a sentence, and has a low TF-IDF, then it's unlikely to be a name
Patterns	- **Pattern1**: "*Title* ⟨ PER Name ⟩"
	- **Pattern2**: "$\langle PERName \rangle, 00*$," where 00 are two digits
	- **Pattern3**: "$[\langle Name_i \rangle ...], \langle Name_n - 1 \rangle \langle singleterm \rangle \langle Name_n \rangle$" where all names have the same type.
Multi-occurrences	- **MultipleOccurrence**: If a word appears in both uppercased and lowercased forms in a single document, it's unlikely to be a name.

Table 1: Universal Name Tagger Features

the-loop process to acquire knowledge from native speakers. To meet the needs in the emergent setting, we design a comprehensive survey that aims to acquire a wide-range of IL-specific knowledge from native speakers in an efficient way. The survey categorizes questions and organizes them into a tree structure, so that the order of questions is chosen based on the answers of previous questions. The survey answers are then automatically translated into rules, patterns or gazetteers in the tagger. Some example questions are shown in Table 2.

3.3 Mono-lingual Expectation Mining

We use a bootstrapping method to acquire IL patterns from unlabeled mono-lingual IL documents. Following the same idea in (Agichtein and Gravano, 2000; Collins and Singer, 1999), we first use names identified by high-confident rules as seeds, and generalize patterns from the contexts of these seeds. Then we evaluate the patterns and apply high-quality ones to find more names as new seeds. This process is repeated iteratively [2].

We define a pattern as a triple $\langle left, name, right \rangle$, where $name$ is a name, left and right[3] are context vectors with weighted terms (the weight is computed based on each token's tf-idf score). For example, from a Hausa sentence "***gwamnatin kasar Sin ta*** *samar wa kasashen yammacin Afirka ... (the Government of China has given ... products to the West African countries)*", we can discover a pattern:

- $left$: ⟨**gwamnatin** (goevernment), 0.5⟩, ⟨**kasar** (country), 0.6⟩
- $name$: ⟨**Sin** (China), 0.5⟩
- $right$: ⟨**ta** (by), 0.2⟩

This pattern matches strings like "*gwamnatin kasar Fiji ta (by the government of Fiji)*".

For any two triples $t_i = \langle l_i, name_i, r_i \rangle$ and $t_j = \langle l_j, name_j, r_j \rangle$, we comput e their similarity by:

$$Sim(t_i, t_j) = l_i \cdot l_j + r_i \cdot r_j$$

We use this similarity measurement to cluster all triples and select the centroid triples in each cluster as candidate patterns.

Similar to (Agichtein and Gravano, 2000), we evaluate the quality of a candidate pattern P by:

$$Conf(P) = \frac{P_{positive}}{(P_{positive} + P_{negative})}$$

,where $P_{positive}$ is the number of positive matches for P and $P_{negative}$ is the number of negative matches. Due to the lack of syntactic and semantic resources to refine these lexical patterns, we set a conservative confidence threshold 0.9.

3.4 Cross-lingual Expectation Projection

Name tagging research has been done for high-resource languages such as English for over twenty years, so we have learned a lot about them. We collected 1,362 patterns from English name tagging literature. Some examples are listed below:

- $\langle \{\}, \{PER\}, \{< say >, < . >\} \rangle$
- $\langle \{< headquarter >, < in >\}, \{LOC\}, \{\} \rangle$
- $\langle \{< secretary >, < of >\}, \{ORG\}, \{\} \rangle$
- $\langle \{< in >, < the >\}, \{LOC\}, \{< area >\} \rangle$

[2] We empirically set the number of iterations as 2 in this paper.

[3] $left$ and $right$ are the context three tokens before and after the name

True/False Questions
1. The letters of this language have upper and lower cases
2. The names of people, organizations and locations start with a capitalized (uppercased) letter
3. The first word of a sentence starts with a capitalized (uppercased) letter
4. Some periods indicate name abbreviations, e.g., St. = Saint, I.B.M. = International Business Machines.
5. Locations usually include designators, e.g., in a format like "country United states", "city Washington"
6. Some prepositions are part of names
Text input
1. Morphology: please enter preposition suffixes as many as you can (e.g. "'da" in "Ankara'da yaşıyorum (I live in Ankara)" is a preposition suffix which means "in").
Translation
1. Please translate the following English words and phrases: - organization suffix: agency, group, council, party, school, hospital, company, office, ... - time expression: January, ..., December; Monday, ..., Sunday; ...

Table 2: Survey Question Examples

Besides the static knowledge like patterns, we can also dynamically acquire expected names from topically-related English documents for a given IL document. We apply the Stanford name tagger (Finkel et al., 2005) to the English documents to obtain a list of expected names. Then we translate the English patterns and expected names to IL. When there is no human constructed English-to-IL lexicon available, we derive a word-for-word translation table from a small parallel data set using the GIZA++ word alignment tool (Och and Ney, 2003). We also convert IL text to Latin characters based on Unicode mapping[4], and then apply Soundex code (Mortimer and Salathiel, 1995; Raghavan and Allan, 2004) to find the IL name equivalent that shares the most similar pronunciation as each English name. For example, the Bengali name "টনি ব্লেয়ার" and "*Tony Blair*" have the same Soundex code "*T500 B460*".

3.5 Mining Expectations from KB

In addition to unstructured documents, we also try to leverage structured English knowledge bases (KBs) such as DBpedia[5]. Each entry is associated with a set of types such as `Company`, `Actor` and `Agent`. We utilize the Abstract Meaning Representation corpus (Banarescu et al., 2013) which contains both entity type and linked KB title annotations, to automatically map $9,514$ entity types in DBPedia to three main entity types of interest: Person (PER), Location (LOC) and Organization (ORG).

Then we adopt a language-independent cross-lingual entity linking system (Wang et al., 2015) to link each IL name mention to English DBPedia. This linker is based on an unsupervised quantified collective inference approach. It constructs knowledge networks from the IL source documents based on entity mention co-occurrence, and knowledge networks from KB. Each IL name is matched with candidate entities in English KB using name translation pairs derived from inter-lingual KB links in Wikipedia and DBPedia. We also apply the word-for-word translation tables constructed from parallel data as described in Section 3.4 to translate some uncommon names. Then it performs semantic comparison between two knowledge networks based on three criteria: salience, similarity and coherence. Finally we map the DBPedia types associated with the linked entity candidates to obtain the entity type for each IL name.

4 Supervised Active Learning

We anticipated that not all expectations can be encoded as explicit rules and patterns, or covered by projected names, therefore for comparison we introduce a supervised method with pool-based active learning to learn implicit expectations (features, new names, etc.) directly from human data annotation. We exploited basic lexical features including ngrams, adjacent tokens, casing information, punctuations and frequency to train a Conditional Random Fields (CRFs) (Lafferty et al., 2001) based model through active learning (Settles, 2010).

We segment documents into sentences and use each sentence as a training unit. Let $\mathbf{x}_b^*$ be the most informative instance according to a query strategy

[4] http://www.ssec.wisc.edu/ tomw/java/unicode.html

[5] http://dbpedia.org

$\phi(\mathbf{x})$, which is a function used to evaluate each instance $\mathbf{x}$ in the unlabeled pool U. Algorithm 1 illustrates the procedure.

Algorithm 1 Pool-based Active Learning

```
$L \leftarrow$ labeled set, $U \leftarrow$ unlabeled pool
$\phi(\cdot) \leftarrow$ query strategy, $B \leftarrow$ query batch size
$M \leftarrow$ maximum number of tokens
while Length($L$)$< M$ do
    $\theta =$ train($L$);
    for $b \in \{1, 2, ..., B\}$ do
        $\mathbf{x}_b^* = \arg\max_{x \in U} \phi(\mathbf{x})$
        $L = L \cup \{\mathbf{x}_b^*, \text{label}(\mathbf{x}_b^*)\}$
        $U = U - \mathbf{x}_b^*$
    end for
end while
```

Jing et al. (2004) proposed an entropy measure for active learning for image retrieval task. We compared it with other measures proposed by (Settles and Craven, 2008) and found that **sequence entropy (SE)** is most effective for our name tagging task. We use ϕ^{SE} to represent how informative a sentence is:

$$\phi^{SE}(\mathbf{x}) = -\sum_{t=1}^{T}\sum_{m=1}^{M} P_\theta(y_t = m) log P_\theta(y_t = m)$$

, where T is the length of $\mathbf{x}$, m ranges over all possible token labels and $P_\theta(y_t = m)$ is the probability when y_t is tagged as m.

5 Cost-aware Combination

A new requirement for IL name tagging is a **Linguistic Workflow Generator**, which can generate an activity schedule to organize and maximize the use of acquired expectations to yield optimal F-scores within given time bounds. Therefore, the input to the IL name tagger is not only the test data, but also a time bound for development (1 hour, 2 hours, 24 hours, 1 week, 1 month, etc.).

Figure 2 illustrates our cost-aware expectation composition approach. Given some IL documents as input, as the clock ticks, the system delivers name tagging results at time 0 (immediately), time 1 (e.g., in one hour) and time 2 (e.g., in two hours). At time 0, name tagging results are provided by the universal tagger described in Section 2. During the first hour, we can either ask the native speaker to annotate a small amount of data for supervised active learning of a CRFs model, or fill in the survey to build a rule-based tagger. We estimate the confidence value of each expectation-driven rule based on its precision score on a small development set of ten documents. Then we apply these rules in the priority order of their confidence values. When the results of two taggers are conflicting on either mention boundary or type, if the applied rule has high confidence we will trust its output, otherwise adopt the CRFs model's output.

Language	IL Test Docs	Name	Unique Name	IL Dev. Docs	IL-English Docs
Bengali	100	4,713	2,820	12,495	169
Hausa	100	1,619	950	13,652	645
Tagalog	100	6,119	3,375	1,616	145
Tamil	100	4120	2,871	4,597	166
Thai	100	4,954	3,314	10,000	191
Turkish	100	2,694	1,323	10,000	484
Yoruba	100	3,745	2,337	427	252

Table 3: Data Statistics

6 Experiments

In this section we will present our experimental details, results and observations.

6.1 Data

We evaluate our framework on seven low-resource incident languages: Bengali, Hausa, Tagalog, Tamil, Thai, Turkish and Yoruba, using the ground-truth name tagging annotations from the DARPA LORELEI program [6]. Table 3 shows data statistics.

6.2 Cost-aware Overall Performance

We test with three checking points: starting time, within one hour, and within two hours. Based on the combination approach described in Section 5, we can have three possible combinations of the expectation-driven learning and supervised active learning methods during two hours: (1) expectation-driven learning + supervised active learning; (2) supervised active learning + expectation-driven learning; and (3) supervised active learning for two hours. Figure 3 compares the overall performance of these combinations for each language.

We can see that our approach is able to rapidly set up a name tagger for an IL and achieves promising performance. During the first hour, there is no clear winner between expectation-driven learning or

[6] http://www.darpa.mil/program/low-resource-languages-for-emergent-incidents

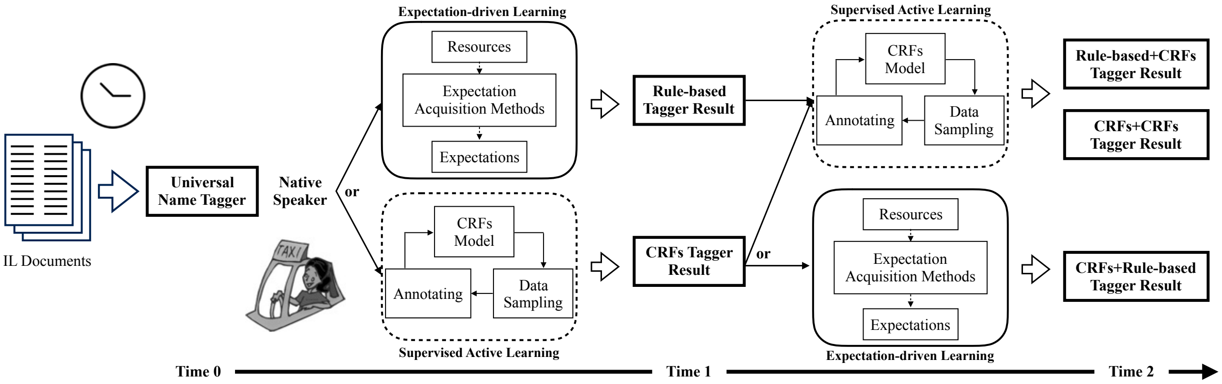

Figure 2: Cost-aware Expectation Composition

supervised active learning. But it's clear that supervised active learning for two hours is generally not the optimal solution. Using Hausa as a case study, we take a closer look at the supervised active learning curve as shown in Figure 4. We can see that supervised active learning based on simple lexical features tends to converge quickly. As time goes by it will reach its own upper-bound of learning and generalizing linguistic features. In these cases our proposed expectation-driven learning method can compensate by providing more explicit and deeper IL-specific linguistic knowledge.

6.3 Comparison of Expectation Discovery Methods

Table 4 shows the performance gain of each type of expectation acquisition method. IL gazetteers covered some common names, especially when the universal case-based rules failed at identifying names from non-Latin languages. IL name patterns were mainly effective for classification. For example, the Tamil name "கத்தோலிக்கன் சிரியன் வங்கியில (Catholic Syrian Bank)" was classified as an organization because it ends with an organization suffix word "வங்கியில(bank)". The patterns projected from English were proven very effective at identifying name boundaries. For example, some non-names such as titles are also capitalized in Turkish, so simple case-based patterns produced many spurious names. But projected patterns can fix many of them. In the following Turkish sentence, "*Ancak Avrupa Birliği Dış İlişkiler Sorumlusu Catherine Ashton,...(But European Union foreign policy chief Catherine Ashton,...)*", among all these capitalized tokens, after we confirmed "*Avrupa Birliği (European Union)*" as an organization and "*Dış İlişkiler Sorumlusu (foreign policy chief)*" as a title, we applied a pattern projected from English "*[Organization] [Title] [Person]*" and successfully identified "*Catherine Ashton*" as a person. Cross-lingual entity linking based typing successfully enhanced classification accuracy, especially for languages where names often appear the same as their English forms and so entity linking achieved high accuracy. For example, "*George Bush*" keeps the same in Hausa, Tagalog and Yoruba as English.

6.4 Impact of Supervised Active Learning

Figure 5 shows the comparison of supervised active learning and passive learning (random sampling in training data selection). We asked a native speaker to annotate Chinese news documents in one hour, and estimated the human annotation speed approximately as 7,000 tokens per hour. Therefore we set the number of tokens as 7,000 for one hour, and 14,000 for two hours. We can clearly see that supervised active learning significantly outperforms passive learning for all languages, especially for Tamil, Tagalog and Yoruba. Because of the rich morphology in Turkish, the gain of supervised active learning is relatively small because simple lexical features cannot capture name-specific characteristics regardless of the size of labeled data. For example, some prepositions (e.g., "*nin (in)*") can be part of the names, so it's difficult to determine name boundaries, such as "*<ORG Ludian bölgesi **hastanesi**>**nin** (in <ORG Ludian Hospital>)*"

Thai	48.5	21.8	72.8	48.6	72.0	35.0
Turkish	64.3	41.3	73.0	63.1	69.1	43.6
Yoruba	69.3	38.3	60.0	57.2	82.3	47.1

* typing accuracy is computed on correctly identified names

Table 5: Breakdown Scores

Table 5 presents the detailed break-down scores for all languages. We can see that name identification, especially organization identification is the main bottleneck for all languages. For example, many organization names in Hausa are often very long, nested or all low-cased, such as "*makarantar horas da Malaman makaranta ta Bawa Jan Gwarzo (Bawa Jan Gwarzo Memorial Teachers College)*" and "*kungiyar masana'antu da tattalin arziki ta kasar Sin (China's Association of Business and Industry)*". Our name tagger will further benefit from more robust universal word segmentation, rich morphology analysis and IL-specific knowledge. For example, in Tamil "ஃ" is a visarga used as a diacritic to write foreign sounds, so we can infer a phrase including it (e.g., "ஹெய்ஃபாவின் (Haifa)") is likely to be a foreign name. Therefore our survey should be enriched by exercising with many languages to capture more categories of linguistic phenomena.

7 Related Work

Name Tagging is a well-studied problem. Many types of frameworks have been used, including rules (Farmakiotou et al., 2000; Nadeau and Sekine, 2007), supervised models using monolingual labeled data (Zhou and Su, 2002; Chieu and Ng, 2002; Rizzo and Troncy, 2012; McCallum and Li, 2003; Li and McCallum, 2003), bilingual labeled data (Li et al., 2012; Kim et al., 2012; Che et al., 2013; Wang et al., 2013) or naturally partially annotated data such as Wikipedia (Nothman et al., 2013), bootstrapping (Agichtein and Gravano, 2000; Niu et al., 2003; Becker et al., 2005; Wu et al., 2009; Chiticariu et al., 2010), and unsupervised learning (Mikheev et al., 1999; McCallum and Li, 2003; Etzioni et al., 2005; Nadeau et al., 2006; Nadeau and Sekine, 2007; Ji and Lin, 2009).

Name tagging has been explored for many non-English languages such as in Chinese (Ji and Grishman, 2005; Li et al., 2014), Japanese (Asahara and Matsumoto, 2003; Li et al., 2014), Arabic (Maloney and Niv, 1998), Catalan (Carreras et al., 2003), Bulgarian (Osenova and Kolkovska, 2002), Dutch (De Meulder et al., 2002), French (Béchet et al., 2000), German (Thielen, 1995), Italian (Cucchiarelli et al., 1998), Greek (Karkaletsis et al., 1999), Spanish (Arévalo et al., 2002), Portuguese (Hana et al., 2006), Serbo-croatian (Nenadić and Spasić, 2000), Swedish (Dalianis and Åström, 2001) and Turkish (Tür et al., 2003). However, most of previous work relied on substantial amount of resources such as language-specific rules, basic tools such as part-of-speech taggers, a large amount of labeled data, or a huge amount of Web ngram data, which are usually unavailable for low-resource ILs. In contrast, in this paper we put the name tagging task in a new emergent setting where we need to process a surprise IL within very short time using very few resources.

The TIDES 2003 Surprise Language Hindi Named Entity Recognition task (Li and McCallum, 2003) had a similar setting. A name tagger was required to be finished within a time bound (five days). However, 628 labeled documents were provided in the TIDES task, while in our setting no labeled documents are available at the starting point. Therefore we applied active learning to efficiently annotate about 40 documents for each language and proposed new methods to learn expectations. The results of the tested ILs are still far from perfect, but we hope our detailed comparison and result analysis can introduce new ideas to balance the quality and cost of name tagging.

8 Conclusions and Future Work

Name tagging for a new IL is a very important but also challenging task. We conducted a thorough study on various ways of acquiring, encoding and composing expectations from multiple non-traditional sources. Experiments demonstrate that this framework can be used to build a promising name tagger for a new IL within a few hours. In the future we will exploit broader and deeper entity prior knowledge to improve name identification. We will aim to make the framework more transparent for native speakers so the survey can be done in an automatic interactive question-answering fashion. We will also develop methods to make the tagger capable of active self-assessment to produce the best workflow within time bounds.

Abstract

State-of-the-art named entity recognition systems rely heavily on hand-crafted features and domain-specific knowledge in order to learn effectively from the small, supervised training corpora that are available. In this paper, we introduce two new neural architectures—one based on bidirectional LSTMs and conditional random fields, and the other that constructs and labels segments using a transition-based approach inspired by shift-reduce parsers. Our models rely on two sources of information about words: character-based word representations learned from the supervised corpus and unsupervised word representations learned from unannotated corpora. Our models obtain state-of-the-art performance in NER in four languages without resorting to any language-specific knowledge or resources such as gazetteers. [1]

1 Introduction

Named entity recognition (NER) is a challenging learning problem. One the one hand, in most languages and domains, there is only a very small amount of supervised training data available. On the other, there are few constraints on the kinds of words that can be names, so generalizing from this small sample of data is difficult. As a result, carefully constructed orthographic features and language-specific knowledge resources, such as gazetteers, are widely used for solving this task. Unfortunately, language-specific resources and features are costly to develop in new languages and new domains, making NER a challenge to adapt. Unsupervised learning from unannotated corpora offers an alternative strategy for obtaining better generalization from small amounts of supervision. However, even systems that have relied extensively on unsupervised features (Collobert et al., 2011; Turian et al., 2010; Lin and Wu, 2009; Ando and Zhang, 2005b, *inter alia*) have used these to augment, rather than replace, hand-engineered features (e.g., knowledge about capitalization patterns and character classes in a particular language) and specialized knowledge resources (e.g., gazetteers).

In this paper, we present neural architectures for NER that use no language-specific resources or features beyond a small amount of supervised training data and unlabeled corpora. Our models are designed to capture two intuitions. First, since names often consist of multiple tokens, reasoning jointly over tagging decisions for each token is important. We compare two models here, (i) a bidirectional LSTM with a sequential conditional random layer above it (LSTM-CRF; §2), and (ii) a new model that constructs and labels chunks of input sentences using an algorithm inspired by transition-based parsing with states represented by stack LSTMs (S-LSTM; §3). Second, token-level evidence for "being a name" includes both orthographic evidence (what does the word being tagged as a name look like?) and distributional evidence (where does the word being tagged tend to occur in a corpus?). To capture orthographic sensitivity, we use character-based word representation model (Ling et al., 2015b) to capture distributional sensitivity, we combine these representations with distributional representations (Mikolov et al., 2013b). Our word representations combine both of these, and dropout training is used to encourage the model to learn to trust both sources of evidence (§4).

Experiments in English, Dutch, German, and Spanish show that we are able to obtain state-

[1] The code of the LSTM-CRF and Stack-LSTM NER systems are available at `https://github.com/glample/tagger` and `https://github.com/clab/stack-lstm-ner`

Proceedings of NAACL-HLT 2016, pages 260–270,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

of-the-art NER performance with the LSTM-CRF model in Dutch, German, and Spanish, and very near the state-of-the-art in English without any hand-engineered features or gazetteers (§5). The transition-based algorithm likewise surpasses the best previously published results in several languages, although it performs less well than the LSTM-CRF model.

2 LSTM-CRF Model

We provide a brief description of LSTMs and CRFs, and present a hybrid tagging architecture. This architecture is similar to the ones presented by Collobert et al. (2011) and Huang et al. (2015).

2.1 LSTM

Recurrent neural networks (RNNs) are a family of neural networks that operate on sequential data. They take as input a sequence of vectors $(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)$ and return another sequence $(\mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_n)$ that represents some information about the sequence at every step in the input. Although RNNs can, in theory, learn long dependencies, in practice they fail to do so and tend to be biased towards their most recent inputs in the sequence (Bengio et al., 1994). Long Short-term Memory Networks (LSTMs) have been designed to combat this issue by incorporating a memory-cell and have been shown to capture long-range dependencies. They do so using several gates that control the proportion of the input to give to the memory cell, and the proportion from the previous state to forget (Hochreiter and Schmidhuber, 1997). We use the following implementation:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}_{xi}\mathbf{x}_t + \mathbf{W}_{hi}\mathbf{h}_{t-1} + \mathbf{W}_{ci}\mathbf{c}_{t-1} + \mathbf{b}_i) \\
\mathbf{c}_t &= (1 - \mathbf{i}_t) \odot \mathbf{c}_{t-1} + \\
&\qquad \mathbf{i}_t \odot \tanh(\mathbf{W}_{xc}\mathbf{x}_t + \mathbf{W}_{hc}\mathbf{h}_{t-1} + \mathbf{b}_c) \\
\mathbf{o}_t &= \sigma(\mathbf{W}_{xo}\mathbf{x}_t + \mathbf{W}_{ho}\mathbf{h}_{t-1} + \mathbf{W}_{co}\mathbf{c}_t + \mathbf{b}_o) \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t),
\end{aligned}$$

where σ is the element-wise sigmoid function, and $\odot$ is the element-wise product.

For a given sentence $(\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n)$ containing n words, each represented as a d-dimensional vector, an LSTM computes a representation $\overrightarrow{\mathbf{h}_t}$ of the left context of the sentence at every word t. Naturally, generating a representation of the right context $\overleftarrow{\mathbf{h}_t}$ as well should add useful information. This can be achieved using a second LSTM that reads the same sequence in reverse. We will refer to the former as the forward LSTM and the latter as the backward LSTM. These are two distinct networks with different parameters. This forward and backward LSTM pair is referred to as a bidirectional LSTM (Graves and Schmidhuber, 2005).

The representation of a word using this model is obtained by concatenating its left and right context representations, $\mathbf{h}_t = [\overrightarrow{\mathbf{h}_t}; \overleftarrow{\mathbf{h}_t}]$. These representations effectively include a representation of a word in context, which is useful for numerous tagging applications.

2.2 CRF Tagging Models

A very simple—but surprisingly effective—tagging model is to use the $\mathbf{h}_t$'s as features to make independent tagging decisions for each output y_t (Ling et al., 2015b). Despite this model's success in simple problems like POS tagging, its independent classification decisions are limiting when there are strong dependencies across output labels. NER is one such task, since the "grammar" that characterizes interpretable sequences of tags imposes several hard constraints (e.g., I-PER cannot follow B-LOC; see §2.4 for details) that would be impossible to model with independence assumptions.

Therefore, instead of modeling tagging decisions independently, we model them jointly using a conditional random field (Lafferty et al., 2001). For an input sentence

$$\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_n),$$

we consider $\mathbf{P}$ to be the matrix of scores output by the bidirectional LSTM network. $\mathbf{P}$ is of size $n \times k$, where k is the number of distinct tags, and $P_{i,j}$ corresponds to the score of the j^{th} tag of the i^{th} word in a sentence. For a sequence of predictions

$$\mathbf{y} = (y_1, y_2, \ldots, y_n),$$

we define its score to be

$$s(\mathbf{X}, \mathbf{y}) = \sum_{i=0}^{n} A_{y_i, y_{i+1}} + \sum_{i=1}^{n} P_{i, y_i}$$

where $\mathbf{A}$ is a matrix of transition scores such that $A_{i,j}$ represents the score of a transition from the tag i to tag j. y_0 and y_n are the *start* and *end* tags of a sentence, that we add to the set of possible tags. $\mathbf{A}$ is therefore a square matrix of size $k+2$.

A softmax over all possible tag sequences yields a probability for the sequence $\mathbf{y}$:

$$p(\mathbf{y}|\mathbf{X}) = \frac{e^{s(\mathbf{X},\mathbf{y})}}{\sum_{\widetilde{\mathbf{y}} \in \mathbf{Y_X}} e^{s(\mathbf{X},\widetilde{\mathbf{y}})}}.$$

During training, we maximize the log-probability of the correct tag sequence:

$$\begin{aligned}\log(p(\mathbf{y}|\mathbf{X})) &= s(\mathbf{X},\mathbf{y}) - \log\left(\sum_{\widetilde{\mathbf{y}} \in \mathbf{Y_X}} e^{s(\mathbf{X},\widetilde{\mathbf{y}})}\right)\\ &= s(\mathbf{X},\mathbf{y}) - \underset{\widetilde{\mathbf{y}} \in \mathbf{Y_X}}{\text{logadd}}\, s(\mathbf{X},\widetilde{\mathbf{y}}), \qquad (1)\end{aligned}$$

where $\mathbf{Y_X}$ represents all possible tag sequences (even those that do not verify the IOB format) for a sentence $\mathbf{X}$. From the formulation above, it is evident that we encourage our network to produce a valid sequence of output labels. While decoding, we predict the output sequence that obtains the maximum score given by:

$$\mathbf{y}^* = \underset{\widetilde{\mathbf{y}} \in \mathbf{Y_X}}{\text{argmax}}\, s(\mathbf{X},\widetilde{\mathbf{y}}). \qquad (2)$$

Since we are only modeling bigram interactions between outputs, both the summation in Eq. 1 and the maximum a posteriori sequence $\mathbf{y}^*$ in Eq. 2 can be computed using dynamic programming.

2.3 Parameterization and Training

The scores associated with each tagging decision for each token (i.e., the $P_{i,y}$'s) are defined to be the dot product between the embedding of a word-in-context computed with a bidirectional LSTM—exactly the same as the POS tagging model of Ling et al. (2015b) and these are combined with bigram compatibility scores (i.e., the $A_{y,y'}$'s). This architecture is shown in figure 1. Circles represent observed variables, diamonds are deterministic functions of their parents, and double circles are random variables.

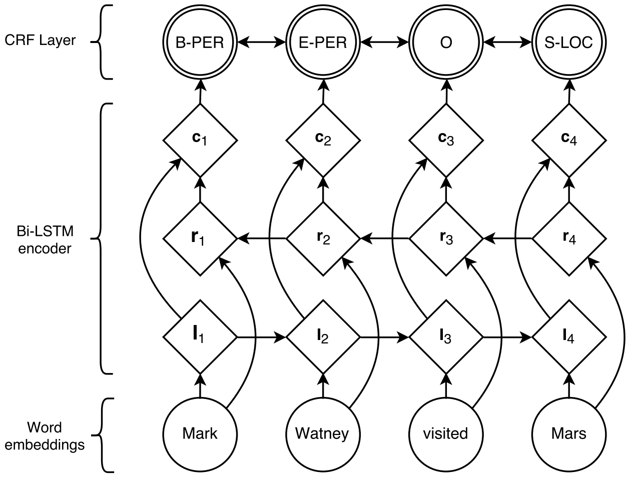

Figure 1: Main architecture of the network. Word embeddings are given to a bidirectional LSTM. $\mathbf{l}_i$ represents the word i and its left context, $\mathbf{r}_i$ represents the word i and its right context. Concatenating these two vectors yields a representation of the word i in its context, $\mathbf{c}_i$.

The parameters of this model are thus the matrix of bigram compatibility scores $\mathbf{A}$, and the parameters that give rise to the matrix $\mathbf{P}$, namely the parameters of the bidirectional LSTM, the linear feature weights, and the word embeddings. As in part 2.2, let $\mathbf{x}_i$ denote the sequence of word embeddings for every word in a sentence, and y_i be their associated tags. We return to a discussion of how the embeddings $\mathbf{x}_i$ are modeled in Section 4. The sequence of word embeddings is given as input to a bidirectional LSTM, which returns a representation of the left and right context for each word as explained in 2.1.

These representations are concatenated ($\mathbf{c}_i$) and linearly projected onto a layer whose size is equal to the number of distinct tags. Instead of using the softmax output from this layer, we use a CRF as previously described to take into account neighboring tags, yielding the final predictions for every word y_i. Additionally, we observed that adding a hidden layer between $\mathbf{c}_i$ and the CRF layer marginally improved our results. All results reported with this model incorporate this extra-layer. The parameters are trained to maximize Eq. 1 of observed sequences of NER tags in an annotated corpus, given the observed words.

2.4 Tagging Schemes

The task of named entity recognition is to assign a named entity label to every word in a sentence. A single named entity could span several tokens within a sentence. Sentences are usually represented in the IOB format (Inside, Outside, Beginning) where every token is labeled as B-*label* if the token is the beginning of a named entity, I-*label* if it is inside a named entity but not the first token within the named entity, or O otherwise. However, we decided to use the IOBES tagging scheme, a variant of IOB commonly used for named entity recognition, which encodes information about singleton entities (S) and explicitly marks the end of named entities (E). Using this scheme, tagging a word as I-*label* with high-confidence narrows down the choices for the subsequent word to I-*label* or E-*label*, however, the IOB scheme is only capable of determining that the subsequent word cannot be the interior of another label. Ratinov and Roth (2009) and Dai et al. (2015) showed that using a more expressive tagging scheme like IOBES improves model performance marginally. However, we did not observe a significant improvement over the IOB tagging scheme.

3 Transition-Based Chunking Model

As an alternative to the LSTM-CRF discussed in the previous section, we explore a new architecture that chunks and labels a sequence of inputs using an algorithm similar to transition-based dependency parsing. This model directly constructs representations of the multi-token names (e.g., the name *Mark Watney* is composed into a single representation).

This model relies on a stack data structure to incrementally construct chunks of the input. To obtain representations of this stack used for predicting subsequent actions, we use the Stack-LSTM presented by Dyer et al. (2015), in which the LSTM is augmented with a "stack pointer." While sequential LSTMs model sequences from left to right, stack LSTMs permit embedding of a stack of objects that are both added to (using a push operation) and removed from (using a pop operation). This allows the Stack-LSTM to work like a stack that maintains a "summary embedding" of its contents. We refer to this model as Stack-LSTM or S-LSTM model for simplicity.

Finally, we refer interested readers to the original paper (Dyer et al., 2015) for details about the Stack-LSTM model since in this paper we merely use the same architecture through a new transition-based algorithm presented in the following Section.

3.1 Chunking Algorithm

We designed a transition inventory which is given in Figure 2 that is inspired by transition-based parsers, in particular the arc-standard parser of Nivre (2004). In this algorithm, we make use of two stacks (designated *output* and *stack* representing, respectively, completed chunks and scratch space) and a *buffer* that contains the words that have yet to be processed. The transition inventory contains the following transitions: The SHIFT transition moves a word from the buffer to the stack, the OUT transition moves a word from the buffer directly into the output stack while the REDUCE(y) transition pops all items from the top of the stack creating a "chunk," labels this with label y, and pushes a representation of this chunk onto the output stack. The algorithm completes when the stack and buffer are both empty. The algorithm is depicted in Figure 2, which shows the sequence of operations required to process the sentence *Mark Watney visited Mars*.

The model is parameterized by defining a probability distribution over actions at each time step, given the current contents of the stack, buffer, and output, as well as the history of actions taken. Following Dyer et al. (2015), we use stack LSTMs to compute a fixed dimensional embedding of each of these, and take a concatenation of these to obtain the full algorithm state. This representation is used to define a distribution over the possible actions that can be taken at each time step. The model is trained to maximize the conditional probability of sequences of reference actions (extracted from a labeled training corpus) given the input sentences. To label a new input sequence at test time, the maximum probability action is chosen greedily until the algorithm reaches a termination state. Although this is not guaranteed to find a global optimum, it is effective in practice. Since each token is either moved directly to the output (1 action) or first to the stack and then the output (2 actions), the total number of actions for a sequence of length n is maximally $2n$.

It is worth noting that the nature of this algorithm

$\mathbf{Out}_t$	$\mathbf{Stack}_t$	$\mathbf{Buffer}_t$	**Action**	$\mathbf{Out}_{t+1}$	$\mathbf{Stack}_{t+1}$	$\mathbf{Buffer}_{t+1}$	**Segments**

REDUCE(PER)	[(Mark Watney)-PER]	[]	[visited, Mars]	(Mark Watney)-PER
OUT	[(Mark Watney)-PER, visited]	[]	[Mars]	
SHIFT	[(Mark Watney)-PER, visited]	[Mars]	[]	
REDUCE(LOC)	[(Mark Watney)-PER, visited, (Mars)-LOC]	[]	[]	(Mars)-LOC

Figure 3: Transition sequence for *Mark Watney visited Mars* with the Stack-LSTM model.

model makes it agnostic to the tagging scheme used since it directly predicts labeled chunks.

3.2 Representing Labeled Chunks

When the REDUCE(y) operation is executed, the algorithm shifts a sequence of tokens (together with their vector embeddings) from the stack to the output buffer as a single completed chunk. To compute an embedding of this sequence, we run a bidirectional LSTM over the embeddings of its constituent tokens together with a token representing the type of the chunk being identified (i.e., y). This function is given as $g(\mathbf{u}, \ldots, \mathbf{v}, \mathbf{r}_y)$, where $\mathbf{r}_y$ is a learned embedding of a label type. Thus, the output buffer contains a single vector representation for each labeled chunk that is generated, regardless of its length.

4 Input Word Embeddings

The input layers to both of our models are vector representations of individual words. Learning independent representations for word types from the limited NER training data is a difficult problem: there are simply too many parameters to reliably estimate. Since many languages have orthographic or morphological evidence that something is a name (or not a name), we want representations that are sensitive to the spelling of words. We therefore use a model that constructs representations of words from representations of the characters they are composed of (4.1). Our second intuition is that names, which may individually be quite varied, appear in regular contexts in large corpora. Therefore we use embeddings learned from a large corpus that are sensitive to word order (4.2). Finally, to prevent the models from depending on one representation or the other too strongly, we use dropout training and find this is crucial for good generalization performance (4.3).

4.1 Character-based models of words

An important distinction of our work from most previous approaches is that we learn character-level features while training instead of hand-engineering prefix and suffix information about words. Learning character-level embeddings has the advantage of learning representations specific to the task and domain at hand. They have been found useful for morphologically rich languages and to handle the out-of-vocabulary problem for tasks like part-of-speech tagging and language modeling (Ling et al., 2015b) or dependency parsing (Ballesteros et al., 2015).

Figure 4 describes our architecture to generate a word embedding for a word from its characters. A character lookup table initialized at random contains an embedding for every character. The character embeddings corresponding to every character in a word are given in direct and reverse order to a forward and a backward LSTM. The embedding for a word derived from its characters is the concatenation of its forward and backward representations from the bidirectional LSTM. This character-level representation is then concatenated with a word-level representation from a word lookup-table. During testing, words that do not have an embedding in the lookup table are mapped to a UNK embedding. To train the UNK embedding, we replace singletons with the UNK embedding with a probability 0.5. In all our experiments, the hidden dimension of the forward and backward character LSTMs are 25 each, which results in our character-based representation of words being of dimension 50.

Recurrent models like RNNs and LSTMs are capable of encoding very long sequences, however, they have a representation biased towards their most recent inputs. As a result, we expect the final representation of the forward LSTM to be an accurate representation of the suffix of the word, and the final state of the backward LSTM to be a better representation of its prefix. Alternative approaches—most notably like convolutional networks—have been proposed to learn representations of words from their characters (Zhang et al., 2015; Kim et al., 2015). However, convnets are designed to discover position-invariant features of their inputs. While this is appropriate for many problems, e.g., image recognition (a cat can appear anywhere in a picture), we argue that important information is position dependent (e.g., prefixes and suffixes encode different information than stems), making LSTMs an *a priori* better function class for modeling the relationship between words and their characters.

4.2 Pretrained embeddings

As in Collobert et al. (2011), we use pretrained word embeddings to initialize our lookup table. We observe significant improvements using pretrained word embeddings over randomly initialized ones. Embeddings are pretrained using skip-n-gram (Ling et al., 2015a), a variation of word2vec (Mikolov et al., 2013a) that accounts for word order. These embeddings are fine-tuned during training.

Word embeddings for Spanish, Dutch, German and English are trained using the Spanish Gigaword version 3, the Leipzig corpora collection, the German monolingual training data from the 2010 Machine Translation Workshop and the English Gigaword version 4 (with the LA Times and NY Times portions removed) respectively.[2] We use an embedding dimension of 100 for English, 64 for other languages, a minimum word frequency cutoff of 4, and a window size of 8.

4.3 Dropout training

Initial experiments showed that character-level embeddings did not improve our overall performance when used in conjunction with pretrained word representations. To encourage the model to depend on both representations, we use dropout training (Hinton et al., 2012), applying a dropout mask to the final embedding layer just before the input to the bidirectional LSTM in Figure 1. We observe a significant improvement in our model's performance after using dropout (see table 5).

5 Experiments

This section presents the methods we use to train our models, the results we obtained on various tasks and the impact of our networks' configuration on model performance.

5.1 Training

For both models presented, we train our networks using the back-propagation algorithm updating our parameters on every training example, one at a time, using stochastic gradient descent (SGD) with

[2] (Graff, 2011; Biemann et al., 2007; Callison-Burch et al., 2010; Parker et al., 2009)

a learning rate of 0.01 and a gradient clipping of 5.0. Several methods have been proposed to enhance the performance of SGD, such as Adadelta (Zeiler, 2012) or Adam (Kingma and Ba, 2014). Although we observe faster convergence using these methods, none of them perform as well as SGD with gradient clipping.

Our LSTM-CRF model uses a single layer for the forward and backward LSTMs whose dimensions are set to 100. Tuning this dimension did not significantly impact model performance. We set the dropout rate to 0.5. Using higher rates negatively impacted our results, while smaller rates led to longer training time.

The stack-LSTM model uses two layers each of dimension 100 for each stack. The embeddings of the actions used in the composition functions have 16 dimensions each, and the output embedding is of dimension 20. We experimented with different dropout rates and reported the scores using the best dropout rate for each language.[3] It is a greedy model that apply locally optimal actions until the entire sentence is processed, further improvements might be obtained with beam search (Zhang and Clark, 2011) or training with exploration (Ballesteros et al., 2016).

5.2 Data Sets

We test our model on different datasets for named entity recognition. To demonstrate our model's ability to generalize to different languages, we present results on the CoNLL-2002 and CoNLL-2003 datasets (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003) that contain independent named entity labels for English, Spanish, German and Dutch. All datasets contain four different types of named entities: locations, persons, organizations, and miscellaneous entities that do not belong in any of the three previous categories. Although POS tags were made available for all datasets, we did not include them in our models. We did not perform any dataset preprocessing, apart from replacing every digit with a zero in the English NER dataset.

5.3 Results

Table 1 presents our comparisons with other models for named entity recognition in English. To make the comparison between our model and others fair, we report the scores of other models with and without the use of external labeled data such as gazetteers and knowledge bases. Our models do not use gazetteers or any external labeled resources. The best score reported on this task is by Luo et al. (2015). They obtained a F_1 of 91.2 by jointly modeling the NER and entity linking tasks (Hoffart et al., 2011). Their model uses a lot of hand-engineered features including spelling features, WordNet clusters, Brown clusters, POS tags, chunks tags, as well as stemming and external knowledge bases like Freebase and Wikipedia. Our LSTM-CRF model outperforms all other systems, including the ones using external labeled data like gazetteers. Our Stack-LSTM model also outperforms all previous models that do not incorporate external features, apart from the one presented by Chiu and Nichols (2015).

Tables 2, 3 and 4 present our results on NER for German, Dutch and Spanish respectively in comparison to other models. On these three languages, the LSTM-CRF model significantly outperforms all previous methods, including the ones using external labeled data. The only exception is Dutch, where the model of Gillick et al. (2015) can perform better by leveraging the information from other NER datasets. The Stack-LSTM also consistently presents state-the-art (or close to) results compared to systems that do not use external data.

As we can see in the tables, the Stack-LSTM model is more dependent on character-based representations to achieve competitive performance; we hypothesize that the LSTM-CRF model requires less orthographic information since it gets more contextual information out of the bidirectional LSTMs; however, the Stack-LSTM model consumes the words one by one and it just relies on the word representations when it chunks words.

5.4 Network architectures

Our models had several components that we could tweak to understand their impact on the overall performance. We explored the impact that the CRF, the character-level representations, pretraining of our

word embeddings and dropout had on our LSTM-CRF model. We observed that pretraining our word embeddings gave us the biggest improvement in overall performance of $+7.31$ in F_1. The CRF layer gave us an increase of $+1.79$, while using dropout resulted in a difference of $+1.17$ and finally learning character-level word embeddings resulted in an increase of about $+0.74$. For the Stack-LSTM we performed a similar set of experiments. Results with different architectures are given in table 5.

6 Related Work

In the CoNLL-2002 shared task, Carreras et al. (2002) obtained among the best results on both Dutch and Spanish by combining several small fixed-depth decision trees. Next year, in the CoNLL-2003 Shared Task, Florian et al. (2003) obtained the best score on German by combining the output of four diverse classifiers. Qi et al. (2009) later improved on this with a neural network by doing unsupervised learning on a massive unlabeled corpus.

Several other neural architectures have previously been proposed for NER. For instance, Collobert et al. (2011) uses a CNN over a sequence of word embeddings with a CRF layer on top. This can be thought of as our first model without character-level embeddings and with the bidirectional LSTM being replaced by a CNN. More recently, Huang et al. (2015) presented a model similar to our LSTM-CRF, but using hand-crafted spelling features. Zhou and Xu (2015) also used a similar model and adapted it to the semantic role labeling task. Lin and Wu (2009) used a linear chain CRF with L_2 regularization, they added phrase cluster features extracted from the web data and spelling features. Passos et al. (2014) also used a linear chain CRF with spelling features and gazetteers.

Language independent NER models like ours have also been proposed in the past. Cucerzan and Yarowsky (1999; 2002) present semi-supervised bootstrapping algorithms for named entity recognition by co-training character-level (word-internal) and token-level (context) features. Eisenstein et al. (2011) use Bayesian nonparametrics to construct a database of named entities in an almost unsupervised setting. Ratinov and Roth (2009) quantitatively compare several approaches for NER and build their own supervised model using a regularized average perceptron and aggregating context information.

Finally, there is currently a lot of interest in models for NER that use letter-based representations. Gillick et al. (2015) model the task of sequence-labeling as a sequence to sequence learning problem and incorporate character-based representations into their encoder model. Chiu and Nichols (2015) employ an architecture similar to ours, but instead use CNNs to learn character-level features, in a way similar to the work by Santos and Guimarães (2015).

7 Conclusion

This paper presents two neural architectures for sequence labeling that provide the best NER results ever reported in standard evaluation settings, even compared with models that use external resources, such as gazetteers.

A key aspect of our models are that they model output label dependencies, either via a simple CRF architecture, or using a transition-based algorithm to explicitly construct and label chunks of the input. Word representations are also crucially important for success: we use both pre-trained word representations and "character-based" representations that capture morphological and orthographic information. To prevent the learner from depending too heavily on one representation class, dropout is used.

Dynamic Feature Induction:
The Last Gist to the State-of-the-Art

Jinho D. Choi

jinho.choi@emory.edu

Abstract

We introduce a novel technique called dynamic feature induction that keeps inducing high dimensional features automatically until the feature space becomes 'more' linearly separable. Dynamic feature induction searches for the feature combinations that give strong clues for distinguishing certain label pairs, and generates joint features from these combinations. These induced features are trained along with the primitive low dimensional features. Our approach was evaluated on two core NLP tasks, part-of-speech tagging and named entity recognition, and showed the state-of-the-art results for both tasks, achieving the accuracy of 97.64 and the F1-score of 91.00 respectively, with about a 25% increase in the feature space.

1 Introduction

Feature engineering typically involves two processes: the process of discovering novel features with domain knowledge, and the process of optimizing combinations between existing features. Discovering novel features may require linguistic background as well as good understanding in machine learning such that it is often difficult to do. Optimizing feature combinations can be also difficult but usually requires less domain knowledge and more importantly, it can be as effective as discovering new features. It has been shown for many tasks that approaches using simple machine learning with extensive feature engineering outperform ones using more advanced machine learning with less intensive feature engineering (Xue and Palmer, 2004; Bengtson and Roth, 2008; Ratinov and Roth, 2009; Zhang and Nivre, 2011).

Recently, people have tried to automate the second part of feature engineering, the optimization of feature combinations, through leading-edge models such as neural networks (Collobert et al., 2011). Coupled with embedding approaches (Mikolov et al., 2013; Le and Mikolov, 2014; Pennington et al., 2014), neural networks can find the optimal feature combinations using techniques such as random weight initialization and back-propagation, and have established the new state-of-the-art for several tasks (Socher et al., 2013; Devlin et al., 2014; Yu et al., 2014). However, neural networks are not as good at optimizing combinations between sparse features, which are still the most dominating factors in natural language processing.

This paper introduces a new technique called dynamic feature induction that automates the optimization of feature combinations (Section 3), and can be easily adapted to any NLP task using sparse features. Dynamic feature induction allows humans to focus on the first part of feature engineering, the discovery of novel features, while machines handle the second part. Our approach was experimented with two core NLP tasks, part-of-speech tagging (Section 4) and named entity recognition (Section 5) and showed the state-of-the-art results for both tasks.

2 Background

2.1 Nonlinearity in NLP

Linear classification algorithms such as Perceptron, Winnow, or Support Vector Machines with a linear kernel have performed exceptionally well for various NLP tasks (Collins, 2002; Zhang and Johnson, 2003; Pradhan et al., 2005). This is not because our feature space is linearly separable by nature, but sparse fea-

Proceedings of NAACL-HLT 2016, pages 271–281,
San Diego, California, June 12-17, 2016.

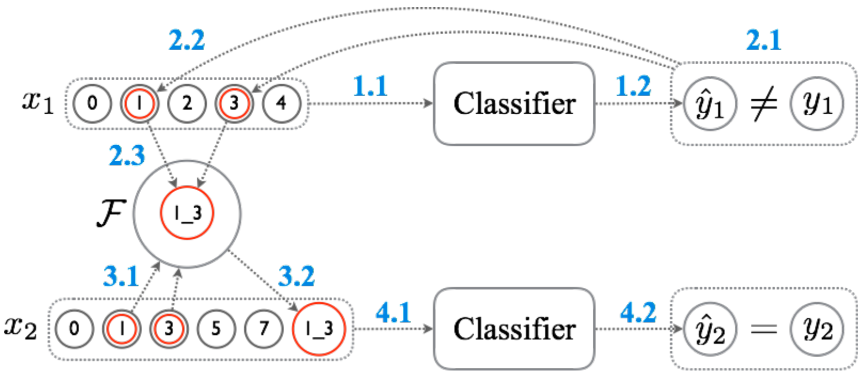

Figure 1: Overview of dynamic feature induction.

tures introduced to NLP yield very high dimensional vector space such that it is rather forced to be linearly separable. For example, NLP features for a word w_i typically involve the word forms of w_{i-1} and w_i (e.g., f_{i-1}, f_i). If the feature space is not linearly separable with these features, a common trick is to introduce 'higher' dimension features by joining 'lower' dimension features together (e.g., f_{i-1}-f_i). The more joint features we introduce, the higher chance we get for the feature space being linearly separable although these joint features can be very overfitted.

Let us define low dimensional features as the primitive features such as f_{i-1} or f_i, and high dimensional features as the joint features such as f_i-f_{i+1}. [1] Low dimensional features are well explored for most NLP tasks; it is the high dimensional features that are quite sensitive to specific tasks. Finding high dimensional features can be a manual intensive work and this is what dynamic feature induction intends to take over.

2.2 Related Work

Kudo and Matsumoto (2003) introduced the polynomial kernel expansion that explicitly enumerated the feature combinations. Our approach is distinguished because they used a frequency-based PrefixSpan algorithm (Pei et al., 2001) whereas we used the online learning weights for finding the feature combinations. Goldberg and Elhadad (2008) suggested an efficient algorithm for computing polynomial kernel SVMs by combining inverted indexing and kernel expansion. Their work is focused more on improving support vector machines whereas our work is generalized to any linear classification algorithm.

Okanohara and Tsujii (2009) introduced an approach for generating feature combinations using ℓ_1 regularization and grafting (Perkins et al., 2003). Although we share similar ideas, their grafting algorithm starts with an empty feature set whereas ours starts with low dimensional features, and their correlation parameters $\alpha_{i,y}$ are pre-computed whereas ours are dynamically determined. Strubell et al. (2015) suggested an algorithm that dynamically selected strong features during decoding. Our work is distinguished because we do not run multiple training phases as they do for figuring our strong features.

3 Dynamic Feature Induction

The intuition behind dynamic feature induction is to keep populating high dimensional features by joining low dimensional features together until the feature space becomes 'more' linearly separable.[2] Figure 1 shows how features are induced during training:

1. Given a training instance (x_1, y_1), where x_1 is a feature set consisting of 5 features and y_1 is the gold label, the classifier predicts the label $\hat{y}_1$.

2. Let us refer "strong features for y against $\hat{y}$" to features that give strong clues for distinguishing y from $\hat{y}$. If $\hat{y}_1$ is not equal to y_1 (2.1), strong features for y_1 against $\hat{y}_1$ in x_1 are selected (2.2), and combinations of these features are added to the induced feature set $\mathcal{F}$ (2.3).

3. Given a new training instance (x_2, y_2), combinations of features in x_2 are checked by $\mathcal{F}$ (3.1), and appended to x_2 if allowed (3.2).

[1] The joint features tend to yield a much higher dimensional feature space than the primitive features.

[2] The term 'more' is used because dynamic feature induction does not guarantee for the feature space to be linearly separable.

4. The extended feature set x_2 is fed into the classifier. If $\hat{y}_2$ is equal to y_2, no feature combination is induced from x_2.

Thus, high dimensional features in $\mathcal{F}$ are incrementally induced and learned along with low dimensional features during training. During decoding, each feature set is extended by the induced features in $\mathcal{F}$, and the prediction is made using the extended feature set. The size of $\mathcal{F}$ can grow up to $|\mathcal{X}|^2$, where $|\mathcal{X}|$ is the size of low dimensional features. However, we found that $|\mathcal{F}|$ is more like $1/4 \cdot |\mathcal{X}|$ in practice.

The following sections explain our approach in details. Sections 3.1, 3.2, and 3.3 describe how features are induced and learned during training. Sections 3.4 and 3.5 describe how the induced features are stored and expanded during decoding.

3.1 Feature Induction

Algorithm 1 shows an online learning algorithm that induces and learns high dimensional features during training. It takes the set of training instances D and the learning rate η, and returns the weight vector **w** and the set of induced features $\mathcal{F}$.

Algorithm 1 Feature Induction

```
 Input:  $D$: training set, $\eta$: learning rate.
Output:  $\mathbf{w}$: weight vector, $\mathcal{F}$: induced feature set.

 1:  $\mathbf{w} \leftarrow \mathbf{g} \leftarrow 0$
 2:  $\mathcal{F} \leftarrow \varnothing$
 3:  until max epoch is reached do
 4:    foreach $(x, y) \in D$ do
 5:      $\hat{y} \leftarrow \arg\max_{y' \in \mathcal{Y}} (\mathbf{w} \cdot \phi(x, y', \mathcal{F}) - I_y(y'))$
 6:      if $y \neq \hat{y}$ then
 7:        $\partial \leftarrow \phi(x, y, \mathcal{F}) - \phi(x, \hat{y}, \mathcal{F})$
 8:        $\mathbf{g} \leftarrow \mathbf{g} + \partial \circ \partial$
 9:        $\mathbf{w} \leftarrow \mathbf{w} + (\eta/(\rho+\sqrt{\mathbf{g}})) \cdot \partial$
10:        $\mathbf{v} \leftarrow [\mathbf{w} \circ \phi(x, y, \varnothing)]_y - [\mathbf{w} \circ \phi(x, \hat{y}, \varnothing)]_{\hat{y}}$
11:        $\mathcal{L} \leftarrow \arg k \max_{\forall i} \mathbf{v}_i$
12:        for $i = 2$ to $|\mathcal{L}|$ do
13:          $\mathcal{F} \leftarrow \mathcal{F} \cup \{(\mathcal{L}_1, \mathcal{L}_i)\}$
14:  return $\mathbf{w}, \mathcal{F}$
```

The algorithm begins by initializing the weight vector **w**, the diagonal vector **g**, and the induced feature set $\mathcal{F}$ (lines 1-2). For each instance $(x, y) \in D$ where y is the gold-label for the feature set x, it predicts $\hat{y}$ maximizing $\mathbf{w} \cdot \phi(x, y', \mathcal{F}) - I_y(y')$, where I is defined as follows (lines 4-5):

$$I_y(y') \leftarrow \begin{cases} 1, & \text{if } y = y'. \\ 0, & \text{otherwise.} \end{cases}$$

The feature map ϕ takes $(x, y, \mathcal{F})$, and returns a $d \times l$-dimensional vector, where d and l are the sizes of features and labels, respectively; each dimension contains the value for a particular feature and a label.[3] If certain combinations between features in x exist in $\mathcal{F}$, they are appended to the feature vector along with the low dimensional features (see Section 3.5 for more details). The indicator function I allows our algorithm to be optimized for the hinge loss for multiclass classification (Crammer and Singer, 2002):

$$\ell_h = \max[0, 1 + \mathbf{w} \cdot (\phi(x, \hat{y}, \mathcal{F}) - \phi(x, y, \mathcal{F}))]$$

If y is not equal to $\hat{y}$ (line 6), the partial vector ∂ is measured (line 7), and **g** and **w** are updated (lines 8-9) by AdaGrad (Duchi et al., 2011), where the learning rate η is adjusted by **g** (in our case, ρ =1E-5). Once **w** is updated, the d-dimensional vector **v** is generated by subtracting $[\mathbf{w} \circ \phi(x, \hat{y}, \varnothing)]_{\hat{y}}$ from $[\mathbf{w} \circ \phi(x, y, \varnothing)]_y$ (line 10), where $[\ldots]_y$ returns only the portion of the values relevant to y (Figure 2).

The i'th element in **v** represents the strength of the i'th feature for y against $\hat{y}$; the greater $\mathbf{v}_i$ is, the stronger the i'th feature is. Next, indices of the top-k entries in **v** are collected in the ordered list $\mathcal{L}$ (line 11), representing the strongest features for y against $\hat{y}$.[4] Finally, the pairs of the first index in $\mathcal{L}$, representing the strongest feature, and the other indices in $\mathcal{L}$ are added to the induced feature set $\mathcal{F}$ (lines 12-13). For example, if $\mathcal{L} = [i, j, k]$ such that $\mathbf{v}_i \geq \mathbf{v}_j \geq \mathbf{v}_k > 0$, two pairs, (i, j) and (i, k), are added to $\mathcal{F}$.

For all our experiments, $k = 3$ is used; increasing k beyond this cutoff did not show much improvement. Notice that all induced features in $\mathcal{F}$ are derived by joining only low dimensional features together. Our algorithm does not join a high dimensional feature with either a low dimensional feature or another high dimensional feature. This was done intentionally to prevent from the feature space being exploded; such features can be induced by replacing $\varnothing$ with $\mathcal{F}$ in the line 10 as follows:

$$\mathbf{v} \leftarrow [\mathbf{w} \circ \phi(x, y, \mathcal{F})]_y - [\mathbf{w} \circ \phi(x, \hat{y}, \mathcal{F})]_{\hat{y}}$$

[3] In most cases, these values are either 0 or 1.

[4] 'arg k max' returns the ordered list of indices whose values in **v** are $^{1)}$ k-largest and $^{2)}$ greater than 0.

$-$
$[\mathbf{w} \circ \phi(x, y_2, \varnothing)]_{y_2}$
$||$
$\mathbf{v}$

Figure 2: Given the weight vector $\mathbf{w}$ and the feature map ϕ, $[\mathbf{w} \circ \phi(x, y, \varnothing)]_y$ takes the Hadamard product between $\mathbf{w}$ and $\phi(x, y, \varnothing)$, then truncates the resulting vector with respect to the label y.

It is worth mentioning that we did not find it useful for joining intermediate features together (e.g., (j, k) in the above example). It is possible to utilize these combinations by weighting them differently, which we will explore in the future. Additionally, we experimented with the combinations between strong and weak features (joining i'th and j'th features, where $\mathbf{v}_i > 0$ and $\mathbf{v}_j < 0$), which again was not so useful. We are planning to evaluate our approach on more tasks and data, which will give us better understanding of what combinations are the most effective.

3.2 Regularized Dual Averaging

Each high dimensional feature in $\mathcal{F}$ is induced for making classification between two labels, y and $\hat{y}$, but it may or may not be helpful for distinguishing labels other than those two. Our algorithm can be modified to learn the weights of the induced features only for their relevant labels by adding the label information to $\mathcal{F}$, which would change the line 13 in Algorithm 1 as follows:

$$\mathcal{F} \leftarrow \mathcal{F} \cup \{(\mathcal{L}_1, \mathcal{L}_i, y, \hat{y})\}$$

However, introducing features targeting specific label pairs potentially confuses the classifier, especially when they are trained with the low dimensional features targeting all labels. Instead, it is better to apply a feature selection technique such as ℓ_1 regularization so the induced features can be selectively learned for labels that find those features useful. We adapt regularized dual averaging (Xiao, 2010), which efficiently finds the convergence rates for online convex optimization, and works most effectively with sparse feature vectors. To apply regularized dual averaging, the line 1 in Algorithm 1 is changed to:

$$\mathbf{w} \leftarrow \mathbf{g} \leftarrow \mathbf{c} \leftarrow 0; \;\; t \leftarrow 1$$

$\mathbf{c}$ is a $d \times l$-dimensional vector consisting of accumulative penalties. t is the number of weight vectors generated during training. Although $\mathbf{w}$ is technically not updated when $y = \hat{y}$, it is still considered a new vector. Thus, t is incremented for every training instance, so $t \leftarrow t + 1$ is inserted after the line 5. $\mathbf{c}$ is updated by adding the partial vector ∂ as follows (to be inserted after the line 7):

$$\mathbf{c} \leftarrow \mathbf{c} + \partial$$

Thus, each dimension in $\mathbf{c}$ represents the accumulative penalty (or reward) for a particular feature and a label. At last, the line 9 is changed to:

$$\mathbf{w} \leftarrow (\eta/(\rho+\sqrt{\mathbf{g}})) \cdot \ell_1(\mathbf{c}, t, \lambda)$$

$$\ell_1(\mathbf{c}, t, \lambda) \leftarrow \begin{cases} \mathbf{c}_i - \mathrm{sgn}(\mathbf{c}_i) \cdot \lambda \cdot t, & |\mathbf{c}_{\forall i}| > \lambda \cdot t. \\ 0, & \text{otherwise.} \end{cases}$$

The function ℓ_1 takes $\mathbf{c}$, t, and the regularizer parameter λ tuned during development. If the absolute value of the accumulative penalty $\mathbf{c}_i$ is greater than $\lambda \cdot t$, the weight $\mathbf{w}_i$ is updated by λ and t; otherwise, it is assigned to 0. For our experiments, RDA was able to throw out irrelevant features successfully, and showed improvement in accuracy; in fact, dynamic feature induction without RDA did not show as much improvement over low dimensional features.

3.3 Locally Optimal Learning to Search

Features in most NLP tasks are extracted from structures (e.g., sequence, tree). For structured learning, we adapt "locally optimal learning to search" (Chang et al., 2015b), that is a member of imitation learning similar to DAGGER (Ross et al., 2011). LOLS not only performs well relative to the reference policy, but also can improve upon the reference policy, showing very good results for tasks such as part-of-speech tagging and dependency parsing. We adapt LOLS by setting the reference policy as follows:

1. The reference policy π determines how often the gold label y is picked over the predicted label $\hat{y}$ to build a structure. For all our experiments, π is initialized to 0.95.

2. For the first epoch, since π is 0.95, y is randomly picked over $\hat{y}$ for 95% of the time.

3. After every epoch, π is multiplied by 0.95. This allows the next epoch to pick y less often than the previous epoch (e.g., π becomes $0.95^2 = 0.9025$ for the 2nd epoch so y is picked about 90% of the time instead of 95%).

For our experiments, LOLS gave only marginal improvement, probably because the tasks we evaluated, part-of-speech tagging and named entity recognition, did not yield complex structures. However, we still included this in our framework because we wanted to evaluate our approach on more tasks such as dependency parsing where learning to search algorithms show a clear advantage (Goldberg and Nivre, 2012; Choi and McCallum, 2013; Chang et al., 2015a).

3.4 Feature Hashing

Feature hashing is a technique of converting string features to vectors (Ganchev and Dredze, 2008; Weinberger et al., 2009). Given a string feature f and a hash function h, the index of f in the vector space is determined by taking the remainder of the hash code:

$$k \leftarrow h_{\text{string}\rightarrow\text{int}}(f) \textbf{ mod } \delta$$

The divisor δ is tuned during development. Feature hashing allows to convert string features into sparse vectors without reserving an extra space for a map whose keys and values are the string features and their indices. Given a feature index pair (i, j) representing strong features for y against $\hat{y}$ (Section 3.1), the index of the induced feature can be measured as follows:

$$k \leftarrow h_{\text{int}\rightarrow\text{int}}(i \cdot |\mathcal{X}| + j) \textbf{ mod } \delta$$

For efficiency, feature hashing is adapted to our system such that the induced feature set $\mathcal{F}$ is actually not a set but a δ-dimensional boolean array, where each dimension represents the validity of the corresponding induced feature. Thus, the line 13 in Algorithm 1 is changed to:

$$k \leftarrow h_{\text{int}\rightarrow\text{int}}(\mathcal{L}_1 \cdot |\mathcal{X}| + \mathcal{L}_i) \textbf{ mod } \delta$$
$$\mathcal{F}_k \leftarrow \texttt{True}$$

For the choice of h, `xxHash` is used, that is a fast non-cryptographic hash algorithm showing the perfect score on the Q.Score.[5]

3.5 Feature Expansion

Algorithm 2 describes how high dimensional features are expanded from low dimensional features during training and decoding. It takes the sparse vector $\mathbf{x}^l$ containing only low dimensional features and returns a new sparse vector $\mathbf{x}^{l+h}$ containing both low and high dimensional features.

Algorithm 2 Feature Expansion

```
Input:  $\mathbf{x}^l$: sparse feature vector containing only
        low dimensional features.
Output: $\mathbf{x}^{l+h}$: sparse feature vector containing both
        low and high dimensional features.

1: $\mathbf{x}^{l+h} \leftarrow \text{copy}(\mathbf{x}^l)$
2: for $i \leftarrow 1$ to $|\mathbf{x}^l|$ do
3:   for $j \leftarrow i+1$ to $|\mathbf{x}^l|$ do
4:     $k \leftarrow h_{\text{int}\rightarrow\text{int}}(i \cdot |\mathcal{X}| + j) \textbf{ mod } \delta$
5:     if $\mathcal{F}_k$ then $\mathbf{x}^{l+h}.\text{append}(k)$
6: return $\mathbf{x}^{l+h}$
```

The algorithm begins by copying $\mathbf{x}^l$ to $\mathbf{x}^{l+h}$ (line 1). For every combination $(i, j) \in \mathbf{x}^l \times \mathbf{x}^l$, where i and j represent the corresponding feature indices (lines 2-3), it first measures the index k of the feature combination (line 4), then checks if this combination is valid (Section 3.4). If the combination is valid, meaning that ($\mathcal{F}_k = \texttt{True}$), k is added to $\mathbf{x}^{l+h}$ (line 5). Finally, $\mathbf{x}^{l+h}$ is returned with the expanded high dimensional features.

4 Part-of-Speech Tagging

4.1 Corpus

The Wall Street Journal corpus from the Penn Treebank III is used (Marcus et al., 1993) with the standard split for part-of-speech tagging experiments.

Set	Sections	Sentences	ALL	OOV
TRN	0-18	38,219	912,344	0
DEV	19-21	5,527	131,768	4,467
TST	22-24	5,462	129,654	3,649

Table 1: Distributions of the Wall Street Journal corpus. TRN: training, DEV: development, TST: evaluation, ALL: all words, OOV: out-of-vocabulary words.

4.2 Tagging and Learning Algorithms

A one-pass, left-to-right tagging algorithm is used for our experiments. Such a simple algorithm is chosen because we want to see the performance gain purely from our approach, not by a more sophisticated tagging algorithm (Toutanova et al., 2003; Shen et al., 2007), which may improve the performance further.

For learning, the final algorithm from Section 3 is used. Additionally, mini-batch is applied, where each batch consists of training instances from k-number of sentences, causing the sizes of these batches different. We found that grouping instances with respect to the sentence boundary was more effective than batching them across arbitrary sentences. For all our experiments, the learning rate $\eta = 0.02$ and the mini-batch boundary $k = 5$ were used without tuning.

4.3 Ambiguity Classes

The ambiguity class of a word is the concatenation of all possible tags for that word. For example, if the word ‘study’ can be tagged by NN (common noun) or VB (base verb), its ambiguity class becomes NN_VB. Instead of building ambiguity classes only from the training dataset, we automatically tagged a mixture of large datasets, the English Wikipedia articles[6] and the New York Times corpus,[7] and pre-constructed ambiguity classes using the automatic tags before training. This was motivated by Moore (2015), who showed extraordinary results on the out-of-vocabulary words by limiting the classification to the ambiguity classes collected from such large corpora. We used the ClearNLP POS tagger (Choi and Palmer, 2012) for tagging the data (about 141M words), threw away tags appearing less than a certain threshold, and created the ambiguity classes. For each word, tags appearing less than 20% of the time for that word were discarded. As the result, about 2M ambiguity classes were collected from these datasets.

4.4 Feature Template

Table 2 shows the template for low dimensional features. Digits inside the curly brackets imply the context windows with respect to the word w_i to be tagged. For example, $f_{\{0,\pm1\}}$ represents the word-forms of w_i, w_{i-1}, and w_{i+1}. No joint features (e.g., f_0-f_1) are included in this template; they should be automatically induced by dynamic feature induction.

Orthographic (Giménez and Màrquez, 2004) and word shape (Finkel et al., 2005) features are adapted from the previous work. The positional features indicate whether w_i is the first or the last word in the sentence. Word clusters are trained on the same datasets in Section 4.3 using Brown et al. (1992).

$$f_{:\{0,\pm1,\pm2\}}, f_{u:\{0,\pm1,\pm2\}}, s_{:\{0,\pm1\}}, c_{:\{0,\pm1\}},$$
$$\pi_{2:\{0\}}, \pi_{3:\{0\}}, \sigma_{1:\{0\}}, \sigma_{2:\{0\}}, \sigma_{3:\{0\}}, \sigma_{4:\{0\}},$$
$$p_{:\{0,-1,-2,-3\}}, a_{:\{0,1,2,3\}}, \mathcal{O}_{:\{0\}}, \mathcal{P}_{:\{0\}}$$

Table 2: Feature template for part-of-speech tagging. f: word-form, f_u: uncapitalized word-form, s: word shape, c: word cluster, π_k: k’th prefix, σ_k: k’th suffix, p: part-of-speech tag, a: ambiguity class, $\mathcal{O}$: orthographic feature set, $\mathcal{P}$: positional feature set.

4.5 Development

The regularization parameter λ (Section 3.2) and the modulo divisor δ (Section 3.4) are tuned during development through grid search on $\lambda \in$ [1E-9, 1E-6] and $\delta \in$ [1.5M, 5M]. Table 3 shows the accuracies achieved by our models on the development set.

Model	ALL	OOV	FEAT
M$_0$: baseline	97.09	86.14	365,400
M$_1$: M$_0$ + ext. ambi.	97.37	91.92	365,409
M$_2$: M$_1$ + clusters	97.45	91.96	372,181
M$_3$: M$_1$ + dynamic	97.42	92.10	468,378
M$_4$: M$_2$ + dynamic	97.48	92.21	473,134

Table 3: Part-of-speech tagging accuracies on the development set. FEAT: the number of features generated by each model.

[6] dumps.wikimedia.org/enwiki

[7] catalog.ldc.upenn.edu/LDC2008T19

M_0 used the tagging and the learning algorithms in Section 4.2 and the feature template in Section 4.4, where the ambiguity classes were collected only from the training dataset; dynamic feature induction was not used for M_0. By applying the external ambiguity classes in Section 4.3, M_1 achieved about a 5.8% improvement on OOV. M_2 gained small improvements by adding word clusters. Coupled with dynamic feature induction, M_3 and M_4 gained about 0.04% and 0.2% improvements on average for ALL and OOV.

For both M_3 and M_4, about 100K more features were generated from M_1 and M_2, implying that about 25% of the features were automatically induced by dynamic feature induction. It is worth pointing out that improving upon M_1 was a difficult task because it was already reaching near the state-of-the-art. The external ambiguity classes by themselves were strong enough to make accurate predictions such that the induced features did not find a critical role in the classification.

4.6 Evaluation

Table 4 shows the accuracies achieved by the models from Section 4.5 and the previous state-of-the-art approaches on the evaluation set.

Approach	ALL	OOV	EXT
Manning (2011)	97.29	89.70	
Manning (2011)	97.32	90.79	✓
Shen et al. (2007)	97.33	89.61	
Sun (2014)	97.36	-	
Moore (2015)	97.36	91.09	✓
Spoustová et al. (2009)	97.44	-	✓
Søgaard (2011)	97.50	-	✓
Tsuboi (2014)	97.51	91.64	✓
This work: M_0	97.18	86.35	
This work: M_1	97.37	91.34	✓
This work: M_2	97.46	91.23	✓
This work: M_3	97.52	91.53	✓
This work: M_4	**97.64**	**92.03**	✓

Table 4: Part-of-speech tagging accuracies on the evaluation set. EXT: whether or not the approach used external data.

The results on the evaluation set appear much more promising. Still, the biggest gain was made by M_1, but our final model M_4 was able to achieve a 0.8% improvement on OOV over M_2, and showed the state-of-the-art results on both ALL and OOV. Interestingly, M_2 showed a slightly lower accuracy on OOV than M_1 even with the additional word cluster features. On the other hand, M_2 did show a slightly higher accuracy on ALL, indicating that the model was probably too overfitted to the in-vocabulary words.[8] However, M_4 was still able to achieve improvements over M_2 on both ALL and OOV, implying that dynamic feature induction facilitated the classifier to be trained more robustly.

5 Named Entity Recognition

5.1 Corpus

The English corpus from the CoNLL'03 shared task is used (Tjong Kim Sang and De Meulder, 2003) for named entity recognition experiments.

Set	Articles	Sentences	Words
`TRN`	946	14,987	203,621
`DEV`	216	3,466	51,362
`TST`	231	3,684	46,435

Table 5: Distributions of the English corpus from the CoNLL'03 shared task. `TRN`: training, `DEV`: development, `TST`: evaluation.

5.2 Feature Template

Table 6 shows the feature template for NER, adapting the specifications in Table 2. Following the state-of-the-art approaches (Table 8), word clusters are trained on the Reuters Corpus Volume I (Lewis et al., 2004) using Brown et al. (1992). Named entity gazetteers are collected from DBPedia.[9] Word embeddings are trained on the datasets in Section 4.3 using Mikolov et al. (2013) and appended to the sparse feature vectors as dense vectors. Note that the word embedding features did not participate in dynamic feature induction; it was not intuitive how to combine sparse and dense features together so we left it as a future work.

$$f_{:\{0,\pm1\}},\ f_{u:\{0,\pm1,\pm2\}},\ s_{:\{0,\pm1\}},\ l_{:\{0\}},\ c_{:\{0,1,2\}},$$
$$e_{:\{0,\pm1,\pm2,\pm3,\pm4\}},\ \pi_{1:\{0\}},\ \pi_{3:\{1\}},\ \sigma_{1:\{0\}},\ \sigma_{3:\{-1,0\}},$$
$$p_{:\{0,\pm1,\pm2\}},\ n_{:\{-1,-2,-3\}},\ z_{:\{\pm1,0,2,3\}},\ \mathcal{O}_{:\{0\}},\ \mathcal{O}_{:\{1\}}$$

Table 6: Feature template for named entity recognition. f: word-form, f_u: uncapitalized word-form, s: word shape, l: lemma, c: word cluster, e: word embedding, π_k: k'th prefix, σ_k: k'th suffix, p: part-of-speech tag, n: named entity tag, z: named entity gazetteer, $\mathcal{O}$: orthographic feature set.

[8] A similar trend is shown in Table 3 for M_1 and M_2.

[9] `wiki.dbpedia.org/downloads2015-04`

5.3 Development

The regularization parameter and the modulo divisor are tuned during development through the same grid search in Section 4.5. Table 7 shows the precisions and the recalls achieved by our models on the development set (the F1-scores are shown in Table 8).

Model	P	R	FEAT
M_0: baseline	90.87	89.15	164,440
M_1: M_0 + gazetteers	92.30	90.61	164,720
M_2: M_1 + clusters	93.66	91.79	169,232
M_3: M_2 + embeddings	94.14	92.43	169,682
M_4: M_3 + dynamic	94.50	93.10	208,860

Table 7: Precision and recall on the development set for named entity recognition. P: precision, R: recall.

M_0 used the tagging and the learning algorithms in Section 4.2 and the feature template in Section 5.2, excluding the gazetteer, cluster, and embedding features; dynamic feature induction was not applied to M_0. $M_{\{1,2,3\}}$ gained incremental improvements from the gazetteer, cluster, and embedding features, respectively. M_4 showed 0.36% and 0.67% improvements on precision and recall respectively, and generated about 40K more features compared to M_3. This is about 23% increase in features that is similar to the increase shown in Table 3.

5.4 Evaluation

Table 8 shows the F1-scores achieved by our models and the previous state-of-the-art approaches.[10]

Approach	DEV	TST
Turian et al. (2010)	93.25	89.41
Suzuki and Isozaki (2008)	**94.48**	89.92
Ratinov and Roth (2009)	93.50	90.57
Lin and Wu (2009)	-	90.90
Passos et al. (2014)	94.46	90.90
This work: M_0	90.00	84.44
This work: M_1	91.45	86.85
This work: M_2	92.72	89.64
This work: M_3	93.27	90.57
This work: M_4	93.79	**91.00**

Table 8: F1-scores on the development and the evaluation sets for named entity recognition.

All models showed improvements over their predecessors; the improvements made in TST were more dramatic than the ones made in DEV although they followed a very similar trend. Notice that M_3, not using dynamic feature induction, showed very similar scores to Ratinov and Roth (2009). This was not surprising because M_3 adapted many features suggested by them, except for the non-local features.[11]

M_4 achieved about 0.5% improvements over M_3, showing the state-of-the-art result on TST. Considering that M_3 was already near state-of-the-art, this improvement was meaningful. It was interesting that Suzuki and Isozaki (2008) achieved the state-of-the-art result on DEV although their score on TST was much lower than the other approaches. This might be because features extracted from the huge external data they used were overfitted to DEV, but more thorough analysis needs to be done. On the other hand, Passos et al. (2014) achieved the near state-of-the-art result on DEV while it also got a very high score on TST by utilizing phrase embeddings, which we will look into in the future.

6 Conclusion

In this paper, we introduced a novel technique called dynamic feature induction that automatically induces high dimensional features so the feature space can be more linearly separable. Our approach was evaluated on two NLP tasks, part-of-speech tagging and named entity recognition, and showed the state-of-the-art results on both tasks. The improvements achieved by dynamic feature induction might not be statistically significant, but important because they gave the last gist to the state-of-the-art; without this last gist, our system would have not reached the bar.

It is worth mentioning that we also experimented with several feature templates including many joint features without applying dynamic feature induction. The results we got from these manually induced features were not any better (often worse) than the ones achieved by dynamic feature induction, which was very encouraging. In the future, we will experiment our approach on more NLP tasks such as dependency parsing and conference resolution where induced features should play a more critical role.

[10] Ratinov and Roth (2009) reported the F1-score of 90.80 on the evaluation set, but that model was trained on both the training and the development sets so not compared in this table.

[11] We transformed the original data into the BILOU notation, which was also suggested by Ratinov and Roth (2009).

We concede that our approach is more empirically motivated than theoretically justified. For instance, the choice of k (line 11) or the combination configuration for $\mathcal{L}$ (line 13) in Algorithm 1 are rather empirically derived. All the parameters are automatically tuned by running grid searches on the development sets (Sections 4.5 and 5.3); it would be intellectually intriguing to find a more principled way of adjusting these hyper-parameters than just brute-force search.

The locally optimal learning to search is used to help structured learning although it gives a relatively smaller impact to the tasks involving sequence classification such as part-of-speech tagging and named entity recognition. This framework is used because we plan to apply our approach on more structurally oriented tasks such as dependency parsing and AMR parsing. Our work is also related to feature grouping, which has been shown to be beneficial in learning high-dimensional data (Zhong and Kwok, 2011; Suzuki and Nagata, 2013). It will be interesting to compare our work to the previous work and see the strengths and weaknesses of our approach.

Abstract

In named entity recognition task especially for massive data like Twitter, having a large amount of high quality gazetteers can alleviate the problem of training data scarcity. One could collect large gazetteers from knowledge graph and phrase embeddings to obtain high coverage of gazetteers. However, large gazetteers cause a side-effect called "feature under-training", where the gazetteer features overwhelm the context features. To resolve this problem, we propose the dropout conditional random fields, which decrease the influence of gazetteer features with a high weight. Our experiments on named entity recognition with Twitter data lead to higher F1 score of 69.38%, about 4% better than the strong baseline presented in Smith and Osborne (2006).

1 Introduction

Nowadays, people are generating tremendous amount of information on social websites. For example, more than 200 million tweets are generated everyday on Twitter (Ritter et al., 2011). Twitter has become a key news source, in addition to standard news channels. As such, social scientists are starting to pay attention to it in recent years (Bollen et al., 2011; Chung and Mustafaraj, 2011; Xu et al., 2014; Calvin et al., 2015; Baldwin et al., 2015; Bellmore et al., 2015). The traditional machine learned modeling approaches trained with small and clean general text, such as news articles, perform poorly when applied to tweets, because tweets are structurally very different from general text. Thus, it is necessary to build new models for Twitter. One could label a reasonable size of tweets to train a model for a natural language processing (NLP) application. The problem is that it is very expensive to refresh the annotated data to keep the model up-to-date, because users generate tweets in a unprecedented rate (Hachman, 2011).

An obvious solution to the problem is to develop methods of utilizing a large amount of unlabeled data. One way is to induce word embeddings in a real-valued vector space from a large number of tweets (Kim et al., 2015a; Mikolov et al., 2013; Pennington et al., 2014). It is shown that the task-specific embeddings induced on tweets provide more powerful than those created from out-of-domain texts (Owoputi et al., 2012; Anastasakos et al., 2014).

Another method is to build the task-specific gazetteers. Task-specific gazetteers make the models more general and increase their coverage for unseen events. They have been proven to be useful on a number of tasks (Smith and Osborne, 2006; Li et al., 2009; Liu and Sarikaya, 2014; Kim et al., 2015b; Kim et al., 2015c). Since gazetteers can improve modeling performance, here we more focus on how to use gazetteer more effectively. To build gazetteers with sufficient coverage for our task, we first expand gazetteers from knowledge graph and phrase embeddings.

However, since the expanded gazetteers cover significant proportions of the entities in the training data, the weight of gazetteers features are easily inflated and thus the model tends to rely too much on lexical features extracted from the gazetteers fea-

[§] Both authors contributed equally.

San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

tures to assign a tag rather than the contextual features such as n-gram, a phenomenon called "feature under-training". As a result, we often observe noticeable performance degradation at test time when the entity value does not exist in the training set or the entity dictionary.

To solve this problem, we introduce a model called dropout CRFs [1] and compare to the combination model proposed by Smith and Osborne (2006). In our experiments, we show that the proposed method significantly improves the F1 score from 65.54% to 69.38%, compared to the baseline.

2 Model

For the named entity recognition (NER) task, the input is a sentence consisting of a sequence of words, $x = (x_1 \ldots x_n)$ and the output is a sequence of corresponding named entity tags $y = (y_1 \ldots y_n)$. We model the conditional probability $p(y|x;\theta)$ using linear-chain CRFs (Lafferty et al., 2001):

$$p(y|x;\theta) = \frac{\exp(\theta \cdot \Phi(x,y))}{\sum_{y' \in \mathcal{Y}(x)} \exp(\theta \cdot \Phi(x,y'))}$$

where θ is a set of model parameters. $\mathcal{Y}$ contains all possible label sequences of x, and Φ maps (x,y) into a feature vector that is a linear combination of local feature vectors: $\Phi(x,y) = \sum_{j=1}^{n} \phi(x_j, y_{j-1}, y_j)$. Given fully observed training data, $\{(x^{(i)}, y^{(i)})\}_{i=1}^{N}$, the objective of the training is to find θ that maximizes the log likelihood of the training data under the model with l_2-regularization:

$$\theta^* = \underset{\theta}{\operatorname{argmax}} \sum_{i=1}^{N} \log p(y^{(i)}|x^{(i)};\theta) - \frac{\lambda}{2} ||\theta||^2 . \qquad (1)$$

CRFs have benefited from having a rich set of gazetteers as features in the model (Smith and Osborne, 2006; Liu and Sarikaya, 2014; Hillard et al., 2011; Kim et al., 2014; Kim et al., 2015c; Kim et al., 2015b; Kim et al., 2015d). Smith and Osborne (2006) point out that common gazetteer features fire often enough to overwhelm other features during inference. They address this problem by building a combination of two models: one without gazetteers and another with gazetteers. Instead of combining two models, we propose a simple model by having a new penalty term to the equation (1):

$$\theta^* = \underset{\theta}{\operatorname{argmax}} \sum_{i=1}^{N} \log p(y^{(i)}|x^{(i)};\theta) - \frac{\lambda_1}{2} ||\theta||^2 - \lambda_2 \sum_{g \in G} \theta_g \operatorname{freq}(g), \qquad (2)$$

where G is a set of gazetteers and freq(g) counts how many times words appear in gazetteer g from training data. In our experiments, we tuned both penalty weights for local features and for gazetteer features based on a small held-out validation set. The θ_g is a member of model parameter θ and each gazetteer has its own parameter θ_g. The introduced penalty decreases common gazetteers' influence on model's decisions. By this term, we call our model *dropout CRFs*. The original dropout technique removes features randomly - for each training instance, only a random subset of the features will be activated (Hinton et al., 2012; Xu and Sarikaya, 2014). While it can be perceived as a general treatment to the under-training problem, it is not specifically directed at the problem we are facing in named entity recognition (NER) task. In NER, the under-training problem is more specific - the contextual features may not get large enough weights due to the strong influence of the gazetteer features. The negative impact of such under-training is also more measurable - if a named entity is unseen, the chance of a detection error becomes much higher. Therefore, we focus on decreasing influence of specific features. For specific features, we reduce the coverage of dropout from all features to gazetteer feature through *feature dependent regularization*. Also, the objective function of dropout CRFs, given in equation (2), is still convex because the equation (1) is convex and the new penalty term is linear with respect to θ. Therefore, a standard optimization algorithm finds optimal θ without sacrificing any abilities, which original CRFs have.

[1] The original dropout technique is to inactivate features randomly. Here, we consider to decrease the weight of a specific feature.

3 Features

In this section, we detail the feature templates used for our experiments. Besides basic features, we also employ part-of-speech (POS) tags, chunks, word representations and gazetteers. We run task-specific POS-tagger and chunker, which are trained on tweets annotated with Twitter-specific tags (Ritter et al., 2011) as well as standard Penn Treebank tags, of Owoputi et al. (2012) to produce POS tags and chunks. We explain the word representations and gazetteer features in the following subsections.

3.1 Basic Features

The model of Ritter et al. (2011) employs the features described in this subsection. They are composed of the following features: (1) n-grams: unigrams and bigrams, (2) capitalization, (3) three character suffix and prefix presence, (4) binary features that indicate presence of hyphen, punctuation mark, single-digit and double-digit, (5) gazetteers (6) topics inferred by LabeledLDA (Ramage et al., 2009), and (7) brown cluster (Brown et al., 1992) produced by Ritter et al. (2011).

To alleviate the problem of word sparsity, we also use task-specific latent continuous word representations, induced on 65 million unlabeled tweets with 1.3 billion tokens. We create three sets of word representations: CCA (Dhillon et al., 2012; Kim et al., 2015a) based on matrix factorization, word2vec (Mikolov et al., 2013) and glove (Pennington et al., 2014), which are gradient based. All word representation algorithms produce 50-dimensional word vectors for all words occurring at least 40 times in the data. We use left and right word of the target word as context for learning the word representations.

We also use compounding embeddings as an additional feature. Combining multiple sets of features has been proven to be effective (Koo et al., 2008; Kim and Snyder, 2013; Yu et al., 2013). We explore four different ways of combining the word representations: element-wise averaging, element-wise multiplication, concatenation and hierarchical clustering. We empirically determined that the element-wise averaging achieves better performance than single embeddings and other combination methods. We do not describe the results for embedding combinations in detail here.

4 Gazetteers

NER models degrades when they encounter unseen words during training. To make the problem worse, tweets contain many rare words and it is prohibitively expensive to create a training set with sufficient lexical coverage. To alleviate the problem, we extend the original gazetteers with two methods: gathering data from knowledge graph and constructing task-specific gazetteer with phrase embeddings.

4.1 Expansion from Knowledge Graph

To expand gazetteers from knowledge graph, we apply the following processing steps. We first extract the seed words from training data. With seed words, we then collect the relevant lexicons from knowledge graph such as Freebase, Wikipedia and Yelp. For example, "Dior" is related to *company* and *product* from knowledge graph. We collect all lexicons associated with seed words. In addition, we post-process gazetteers for variance: i) organization: it is composed with full name with abbreviation, such as "Indigenous Land Corporation (ILC)". We also generate variants of full names ("Indigenous Land Corporation") and abbreviation ("ILC"), respectively, ii) facility: because the term *elementary* indicates a school, we add a lexicon removing the word *school* of "tedder elementary school". At the end of the processing, we end up with 2.7 millions lexicon items.

4.2 Constructing Gazetteers with Phrase Embeddings

We now describe how to construct task-specific gazetteer with phrase embeddings. We use canonical correlation analysis (CCA) (Hotelling, 1936) to induce vector representations for phrase embeddings. To extract candidate phrases from unlabeled Twitter data, we first count the frequency of the context words set for each token. The size of context words set ranges from 1 to 3. The context words set occurring more than 100 are used as a rule to extract candidate phrases.

Let n be the number of candidate phrases extracted by rules. Let $x_1 \dots x_n$ be the original representations of the candidate phrases itself and $y_1 \dots y_n$ be the original representations of two words to the left and right of the candidate phrases.

We use the following definition for the original representations. Let d be the number of distinct candidate phrases and d' be the number of distinct context words set.

- $x_l \in \mathbb{R}^d$ is a zero vector, in which the entry corresponding to the candidate phrases of the l-th instance is set to 1.
- $y_l \in \mathbb{R}^{d'}$ is a zero vector, in which the entries corresponding to context words set surrounding candidate phrases are set to 1.

Using CCA, we obtain phrase embeddings U with k-dimensional space. To train a classifier, we manually construct a training data with 5 positive and 5 negative samples, for each gazetteer. With this data, we learn a binary classifier with the phrase embeddings as a feature. Using this classifier, we predict whether the phrases fit to the gazetteers; we refer the readers to Neelakantan and Collins (2014) for details.

5 Experiments

To demonstrate the effectiveness of the dropout CRFs, we run experiments on named entity recognition task on the Twitter dataset of Baldwin et al. (2015). We refer the readers to Baldwin et al. (2015) for the details of the dataset. We split the data into 70% for training, 10% for tuning, and 20% for testing. For all the experiments presented in this section, both CRFs and dropout CRFs are trained using the L-BFGS (Liu and Nocedal, 1989).

5.1 Effectiveness of the Gazetteers

One of our contributions is to augment the size of gazetteers with knowledge graph and phrase embeddings. Table 1 represents the performance of a model with original gazetteers, which are collected by Ritter et al. (2011) from freebase (Base Gazet) and with gazetteers we extended (Our Gazet). The size of *Base Gazet* is 2.9 million and the size of *Our Gazet* is 6.6 million, which has an additional 3.7 million entries compared to the *Base Gazet*. The model trained *Our Gazet* improves the F1 score from 62.76% to 64.67%, compared to the baseline. As shown in Table 1, we believe that larger gazetteers can mitigate the "unseen words" problem by increasing the coverage of the gazetteers.

	F1
Base Gazet	62.76
Our Gazet	64.67

Table 1: Comparison of models with or without new gazetteers. **Base Gazet** is a model with gazetteers collected by Ritter et al. (2011) and **Our gazet** is a model with gazetteers we constructed by augmenting the *Base Gazet* with additional items, using knowledge graph and phrase embeddings.

5.2 Effectiveness of the Dropout CRFs

We conducted additional experiments with the CRF model that uses *Our Gazet*. Table 2 shows the overall results for models with and without dropout. We compare three models: the vanilla CRFs (CRFs$_{vanilla}$), the combination model as described in Smith and Osborne (2006) (CRFs$_{LOP}$) and our dropout model (CRFs$_{dropout}$). To avoid model parameters for gazetteer features getting over-regularized, Smith and Osborne (2006) propose to train separate models with and without gazetteers. They combine predictions from the two models by using logarithmic opinion pool (LOP). We refer the reader to Smith et al. (2005) for further details.

The CRFs$_{vanila}$ yields 64.03% F1 score and the CRFs$_{LOP}$ improves the performance to 65.54%. The CRFs$_{dropout}$, which reduces the influence of gazetteer features, improves the F1 score to 69.38%, which corresponds to a 13% decrease in error relative to vanilla CRFs.

	F1
CRFs$_{vanila}$	64.67
CRFs$_{LOP}$	65.54
CRFs$_{dropout}$	69.38

Table 2: Comparison of models with or without dropout. CRFs$_{vanilla}$ is the vanilla CRFs with all features. CRFs$_{LOP}$ is a combination of CRFs with all features except for gazetteers and CRFs with gazetteers only, using logarithmic opinion pool (LOP). CRFs$_{dropout}$ is the dropout CRFs with all features.

5.3 Analysis

While previous NER tasks mostly focus on reporting numbers on the original data set (Baldwin et al., 2015; Yang and Kim, 2015; Kim et al., 2015c), we further investigate how the tagging performance may change, if entities are unseen at test time. To enable such analysis, we create additional test set based on the original test set by replacing each word in `person` and `company` entities with a special token, *XXXXX*, indicating unseen words. This new test set represents an extreme case, where none of the words contained in the gazetteers are observed in the training data.

Table 3 represents the comparison of vanilla CRF model and dropout model for unseen test. Gazetteer is helpful to resolve "unseen words" problem. Unfortunately, frequent appearance of gazetteer makes a model learn weak context feature and strong gazetteer feature. By forcing a weight of gazetteer feature low, the dropout model allows the weak context features to become strong and the large weight of gazetteer feature to become smaller. Consequently, CRF$_{dropout}$ shows the significant improvement compared to CRF$_{vanilla}$.

Tags	**CRF**$_{dropout}$	**CRF**$_{vanilla}$
person	74.43	65.81
company	65.74	57.19

Table 3: Comparison of vanilla CRF model and dropout model for unseen test

To see a change of feature weight when we apply dropout technique, we show the feature weights for the word "cahill" of vanilla CRFs and dropout CRFs in Table 4. In vanilla CRFs, gazetteers have a strong weight compared to the context features. However, our dropout CRFs decrease the weight of gazetteer features, while making the context features larger, to steer the models' decision in the right direction.

6 Conclusion

In this paper, we showed how to improve the CRF based NER model for Twitter by exploiting a large number of gazetteers. Using gazetteers in modeling helps the coverage and generalization but simply incorporating gazetteers of all of large sizes into the model may lead to "under-training" of parameters corresponding to the context features. We addressed this problem by adding the dropout penalty term in the CRF training, which improves better parameter. The proposed technique results in significant improvements over the baseline.

cahill (answer: geo-loc prediction: person)

CRFs$_{vanila}$
people.person → I-person : 7.46
lastname.5000 → I-person: 9.63
lastname.5000 → I-geo-loc: 4.01
people.person.lastnames → I-person : 6.6
w[-1]|w[0]='s|Cahill → I-person : -1.24
w[-1]|w[0]='s|Cahill → I-geo-loc : 0.28
w[-1]='s → I-person : 0.97
w[-1]='s → I-geo-loc : -0.13

CRFs$_{dropout}$
people.person → I-person : 5.2
lastname.5000 → I-person: 4.67
lastname.5000 → I-geo-loc: 4.19
people.person.lastnames → I-person : 4.36
w[-1]|w[0]='s|Cahill → I-person : 1.98
w[-1]|w[0]='s|Cahill → I-geo-loc : 3.02
w[-1]='s → I-person : 1.41
w[-1]='s → I-geo-loc : 1.82

Table 4: Snapshot of feature weights for the word "cahill", given sentence *tonight 's cahill event*. The vanilla CRFs predict it to `person` and dropout CRFs predict it to `geo-loc` correctly.

One of the future directions of research is to extend the same idea to various sequence learning problems: part-of-speech tagging and slot tagging.

Abstract

Events and entities are closely related; entities are often actors or participants in events and events without entities are uncommon. The interpretation of events and entities is highly contextually dependent. Existing work in information extraction typically models events separately from entities, and performs inference at the sentence level, ignoring the rest of the document. In this paper, we propose a novel approach that models the dependencies among variables of events, entities, and their relations, and performs joint inference of these variables across a document. The goal is to enable access to document-level contextual information and facilitate context-aware predictions. We demonstrate that our approach substantially outperforms the state-of-the-art methods for event extraction as well as a strong baseline for entity extraction.

1 Introduction

Events are things that happen or occur; they involve entities (people, objects, etc.) who perform or are affected by the events and spatio-temporal aspects of the world. Understanding events and their descriptions in text is necessary for any generally-applicable machine reading systems. It is also essential in facilitating practical applications such as news summarization, information retrieval, and knowledge base construction.

The interpretation of event descriptions is highly contextually dependent. To make correct predictions, a model needs to account for mentions of events and entities together with the discourse context. Consider, for example, the following excerpt from a news report:

> "On *Thursday*, there was a massive *U.S.* **aerial bombardment** in which more than 300 *Tomahawk cruise missiles* rained down on *Baghdad*. *Earlier Saturday*, *Baghdad* was again **targeted**. ..."

The excerpt describes two U.S. attacks on Baghdad. The two event anchors (triggers) are boldfaced and the mentions of entities and spatio-temporal information are italicized. The first event anchor "aerial bombardment" along with its surrounding entity mentions — "U.S.", "Tomahawk cruise missiles", and "Baghdad", describe an attack from the U.S. on Baghdad with Tomahawk cruise missiles being the weapon. The second sentence on its own contains little event-related information, but together with the context of the previous sentence, it indicates another U.S. attack on Baghdad.

State-of-the-art event extraction systems have difficulties inferring such information due to two main reasons. First, they extract events and entities in separate stages: entities such as people, organization, and locations are first extracted by a named entity tagger, and then these extracted entities are used as inputs for extracting events and their arguments (Li et al., 2013). This often causes errors to propagate. In the above example, if the entity tagger mistakenly identifies "Baghdad" as a person, then the event extractor will fail to extract "Baghdad" as the place where the attack happened. In fact, previous work (Li et al., 2013) observes that using previously extracted entities in event extraction results in

Proceedings of NAACL-HLT 2016, pages 289–299,
San Diego, California, June 12-17, 2016.

a substantial decrease in performance compared to using gold-standard entity information.

Second, most existing work extracts events independently from each individual sentence, ignoring the rest of the document (Li et al., 2013; Judea and Strube, 2015; Nguyen and Grishman, 2015). Very few attempts have been made to incorporate document context for event extraction. Ji and Grishman (2008) model the information flow in two stages: the first stage trains classifiers for event triggers and arguments within each sentence; the second stage applies heuristic rules to adjust the classifiers' outputs to satisfy document-wide (or document-cluster-wide) consistency. Liao and Grishman (2010) further improved the rule-based inference by training additional classifiers for event triggers and arguments using document-level information. Both approaches only propagate the highly confident predictions from the first stage to the second stage. To the best of our knowledge, there is no unified model that jointly extracts events from sentences across the whole document.

In this paper, we propose a novel approach that simultaneously extracts events and entities within a document context.[1] We first decompose the learning problem into three tractable subproblems: (1) learning the dependencies between a single event and all of its potential arguments, (2) learning the co-occurrence relations between events across the document, and (3) learning for entity extraction. Then we combine the learned models for these subproblems into a joint optimization framework that simultaneously extracts events, semantic roles, and entities in a document. In summary, our main contributions are:

1. We propose a structured model for learning within-event structures that can effectively capture the dependencies between an event and its arguments, and between the semantic roles and entity types for the arguments.

2. We introduce a joint inference framework that combines probabilistic models of within-event structures, event-event relations, and entity extraction for joint extraction of the set of entities and events over the whole document.

3. We conduct extensive experiments on the Automatic Content Extraction (ACE) corpus, and show that our approach significantly outperforms the state-of-the-art methods for event extraction and a strong baseline for entity extraction.

2 Task Definition

We adopt the ACE definition for entities ((LDC), 2005a) and events ((LDC), 2005b):

- **Entity mention**: An entity is an object or set of objects in the world. An entity mention is a reference to an entity in the form of a noun phrase or a pronoun.

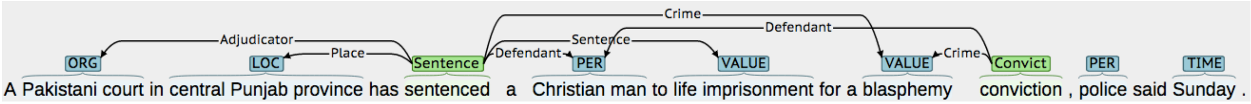
- **Event trigger**: the word or phrase that clearly expresses its occurrence. Event triggers can be verbs, nouns, and occasionally adjectives like "dead" or "bankrupt".

- **Event argument**: event arguments are entities that fill specific roles in the event. They mainly include participants (i.e., the entities that are involved in the event) and general event attributes such as place and time, and some event-type-specific attributes that have certain values (e.g., JOB-TITLE, CRIME).

We are interested in extracting entity mentions, event triggers, and event arguments. We consider ACE entity types PER, ORG, GPE, LOC, FAC, VEH, WEA and ACE VALUE and TIME expressions[2], and focus on 33 ACE event subtypes, each of which has its own set of semantic roles for the potential arguments. There are 35 such roles in total, but we collapse 8 of them that are time-related (e.g., TIME-HOLDS, TIME-AT-END) into one, because most of these roles have very few training examples. Figure 2 shows an example of ACE annotations for events and entities in a sentence. Note that not every entity mention in the sentence is involved in events and a single entity mention can be associated with multiple events.

[1] The code for our system is available at `https://github.com/bishanyang/EventEntityExtractor`.

[2] To simplify notation, we include values and times when referring to entities in the rest of the paper.



Crime
Defendant
Adjudicator

VALUE
Convict
PER
TIME
A Pakistani court in central Punjab province has sentenced a Christian man to life imprisonment for a blasphemy conviction , police said Sunday .

Figure 1: An example of ACE annotations of events and entities. The event triggers and the entity mentions are marked in different colors. Each event trigger has an event subtype marked above it and each entity mention has an entity type marked above it. Each event trigger evokes an event with semantic roles that are filled by entity mentions. The roles are marked on the links between event trigger and entity mentions. For example, "conviction" evokes a CONVICT event, and has the CRIME and DEFENDANT roles filled by "blasphemy" and "Christian man" respectively.

3 Approach

In this section, we describe our approach for joint extraction of events and entities within a document context. We first decompose the learning problem into three tractable subproblems: learning within-event structures, learning event-event relations, and learning for entity extraction. We will describe the probabilistic models for learning these subproblems. Then we present a joint inference framework that integrates these learned models into a single model to jointly extract events and entities across a document.

3.1 Learning Within-event Structures

As described in Section 2, a mention of an event consists of an event trigger and a set of event arguments. Each event argument is also an entity mention with an entity type. In the following, we develop a probabilistic model to learn such dependency structure for each individual event mention.

Given a document x, we first generate a set of event trigger candidates $\mathcal{T}$ and a set of entity candidates $\mathcal{N}$.[3] For each trigger candidate $i \in \mathcal{T}$, we associate it with a discrete variable t_i that takes values from the 33 ACE event types and a NONE class indicating other events or no events. Denote the set of entity candidates that are potential arguments for trigger candidate i as $\mathcal{N}_i$.[4] For each $j \in \mathcal{N}_i$, we associate it with a discrete variable r_{ij} which models the event-argument relation between trigger candidate i and entity candidate j. It takes values from 28 semantic roles and a NONE class indicating invalid roles. Each argument candidate j is also associated with an entity type variable a_j, which takes values from 9 entity types and a NONE class indicating invalid entity types.

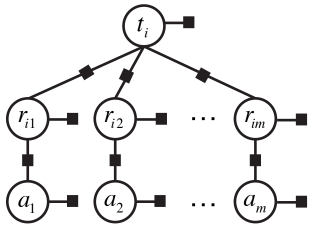

Figure 2: A factor graph representation of the within-event model, relating the event type t_i of trigger candidate i to the role type r_{ij} of each argument candidate j along with its entity type a_j.

We define the joint distribution of variables t_i, $\mathbf{r}_{i\cdot} = \{r_{ij}\}_{j\in\mathcal{N}_i}$, and $\mathbf{a}_{\cdot} = \{a_j\}_{j\in\mathcal{N}_i}$ conditioned on the observations, which can be factorized according to the factor graph shown in Figure 2:

$$p_{\boldsymbol{\theta}}(t_i, \mathbf{r}_{i\cdot}, \mathbf{a}_{\cdot}|i, \mathcal{N}_i, x) \propto \exp\Bigg(\boldsymbol{\theta}_1^T f_1(t_i, i, x) + \sum_{j\in\mathcal{N}_i} \boldsymbol{\theta}_2^T f_2(r_{ij}, i, j, x) + \sum_{j\in\mathcal{N}_i} \boldsymbol{\theta}_3^T f_3(t_i, r_{ij}, i, j, x) + \sum_{j\in\mathcal{N}_i} \boldsymbol{\theta}_4^T f_4(a_j, j, x) + \sum_{j\in\mathcal{N}_i} \boldsymbol{\theta}_5^T f_5(r_{ij}, a_j, j, x)\Bigg) \quad (1)$$

where $\boldsymbol{\theta}_1, ..., \boldsymbol{\theta}_5$ are vectors of parameters that need to be estimated, and $f_1, ..., f_5$ are different forms of feature functions which we will describe later.

Note that not all configurations of the variables are valid in our model. Based on the definitions in Section 2, each event type takes arguments with certain semantic roles. For example, the arguments of the event MARRY can only play the roles of

[3] We describe how to extract these candidates in Section 4.

[4] In this paper we only consider entity mentions that are in the same sentence as the trigger to be potential event arguments due to the ACE annotations. However, our model is general and can handle event-argument relations across sentences with appropriate features.

PERSON, TIME, and PLACE. In addition, a NONE event type should not take any arguments. Similarly, each semantic role should be filled with entities with compatible types. For example, the PERSON role type can only be filled with an entity of type PER. However, a NONE role type can be filled with an entity of any type. To account for these compatibility constraints, we enforce the probabilities of all invalid configurations to be zero.

Features. f_1, f_2, and f_4 are unary feature functions that depend on trigger variable t_i, argument variable r_{ij}, and entity variable a_j respectively. We construct a set of features for each feature function (see Table 1). Many of these features overlap with those used in previous work (Li et al., 2013; Li et al., 2014), except for the word embedding features for triggers and the features for entities which are derived from multiple entity resources. f_3 and f_5 are pairwise feature functions that depend on trigger-argument pair (t_i, r_{ij}) and argument-entity pair (r_{ij}, a_j) respectively. We consider simple indicator functions $\mathbb{1}_{t,r}$ and $\mathbb{1}_{r,a}$ as features ($\mathbb{1}_y(x)$ equals 1 when $x = y$ and 0 otherwise).

Training. For model training, we find the optimal parameters $\boldsymbol{\theta}$ using the maximum-likelihood estimates with an L2 regularization:

$$\boldsymbol{\theta}^* = \arg\max_{\boldsymbol{\theta}} \mathcal{L}(\boldsymbol{\theta}) - \lambda||\boldsymbol{\theta}||_2^2$$

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_i \log p(t_i, \mathbf{r}_{i\cdot}, \mathbf{a}_\cdot | i, \mathcal{N}_i, x)$$

We use L-BFGS to optimize the training objective. To calculate the gradient, we use the sum-product algorithm to compute the exact marginals for the unary cliques t_i, r_{ij}, a_j and the pairwise cliques $(t_i, r_{ij}), (r_{ij}, a_j)$. Typically the training complexity for graphical models with unary and pairwise cliques is quadratic in the size of the label set. However, the complexity of our model is much lower than that since we only need to compute the joint distributions over valid variable configurations. Denote the number of event subtypes as T, the number of event argument roles as N, the average number of argument roles for each event subtype as k_1, the average number of entity types for each event argument as k_2, and the average number of argument candidates for each trigger candidate as M. The complexity of computing the joint distribution is $O(M \times (k_1 T + k_2 N))$, and k_1 and k_2 are expected to be small in practice ($k_1 = 6, k_2 = 3$ in ACE).

3.2 Learning Event-Event Relations

So far we have described a model for learning structures for a single event. However, the inference of the event types for individual events may depend on other events that are mentioned in the document. For example, an ATTACK event is more likely to occur with INJURE and DIE events than with life events like MARRY and BORN. In order to capture this intuition, we develop a pairwise model of event-event relations in a document.

Our training data consists of all pairs of trigger candidates that co-occur in the same sentence or are connected by a coreferent subject/object if they are in different sentences.[5] We want to propagate information between these trigger pairs since they are more likely to be related.

Formally, given a trigger candidate pair (i, i'), we estimate the probabilities for their event types $(t_i, t_{i'})$ as

$$p_{\boldsymbol{\phi}}(t_i, t_{i'}|x, i, i') \propto \exp\left(\boldsymbol{\phi}^T g(t_i, t_{i'}, x, i, i')\right) \quad (2)$$

where $\boldsymbol{\phi}$ is a vector of parameters and g is a feature function that depends on the trigger candidate pair and their context. We consider both trigger-specific features and relational features. For trigger-specific features, we use the same trigger features listed in Table 1. For relational features, we consider for each pair of trigger candidates: (1) whether they are connected by a conjunction dependency relation (based on dependency parsing); (2) whether they share a subject or an object (based on dependency parsing and coreference resolution); (3) whether they have the same head word lemma; (4) whether they share a semantic frame based on FrameNet. During training, we use L-BFGS to compute the maximum-likelihood estimates of ϕ.

3.3 Entity Extraction

For entity extraction, we trained a standard linear-chain Conditional Random Field (CRF) (Lafferty et al., 2001) using the BIO scheme (i.e., identifying the **B**eginning, the **I**nside and the **O**utside of the

[5] We use the Stanford coreference system (Lee et al., 2013) for within-document entity coreference.

Category	Type	Features
Trigger	*Lexical resources:* WordNet Nomlex FrameNet Word2Vec	1. lemmas of the words in the trigger mention 2. nominalization of the words based on Nomlex (Macleod et al., 1998) 3. context words within a window of size 2 4. similarity features between the head word and a list of trigger seeds based on WordNet (Bronstein et al., 2015) 5. semantic frames that associate with the head word and its p-o-s tag based on FrameNet (Li et al., 2014) 6. pre-trained vector for the head word (Mikolov et al., 2013)
	Syntactic resources: Stanford parser	7. dependency edges involving the head word, both lexicalized and unlexicalized 8. whether the head word is a pronoun
Argument	*Lexical resources:* WordNet	1. lemmas of the words in the entity mention 2. lemmas of the words in the trigger mention 3. words between the entity mention and the trigger mention
	Syntactic resources: Stanford parser	4. the relative position of the entity mention to the trigger mention (before, after, or contain) 5. whether the entity mention and the trigger mention are in the same clause 6. the shortest dependency paths between the entity mention and the trigger mention
Entity	*Entity resources:* Stanford NER NELL KB	1. Gender and animacy attributes of the entity mention 2. Stanford NER type for the entity mention 3. Semantic type for the entity mention based on the NELL knowledge base (Mitchell et al., 2015) 4. Predicted entity type and confidence score for the entity mention output by the entity extractor described in Section 3.3

Table 1: Features for event triggers, event arguments, and entity mentions.

text segments). We use features that are similar to those from previous work (Ratinov and Roth, 2009): (1) current words and part-of-speech tags; (2) context words in a window of size 2; (3) word type such as all-capitalized, is-capitalized, and all-digits; (4) Gazetteer-based entity type if the current word matches an entry in the gazetteers collected from Wikipedia (Ratinov and Roth, 2009). In addition, we consider pre-trained word embeddings (Mikolov et al., 2013) as dense features for each word in order to improve the generalizability of the model.

3.4 Joint Inference

Our end goal is to extract coherent event mentions and entity mentions across a document. To achieve this, we propose a joint inference approach that allows information flow among the three local models and finds globally-optimal assignments of all variables, including the trigger variables $\mathbf{t}$, the argument role variables $\mathbf{r}$, and the entity variables $\mathbf{a}$. Specifically, we define the following objective:

$$\max_{\mathbf{t},\mathbf{r},\mathbf{a}} \sum_{i\in\mathcal{T}} E(t_i,\mathbf{r}_{i\cdot},\mathbf{a}_\cdot) + \sum_{i,i'\in\mathcal{T}} R(t_i,t_{i'}) + \sum_{j\in\mathcal{N}} D(a_j) \tag{3}$$

The first term is the sum of confidence scores for individual event mentions based on the parameter estimates from the within-event model. $E(t_i,\mathbf{r}_{i\cdot},\mathbf{a}_\cdot)$ can be further decomposed into three parts.

$$\begin{aligned} &E(t_i,\mathbf{r}_{i\cdot},\mathbf{a}_\cdot) = \\ &\log p_{\boldsymbol{\theta}}(t_i|i,\mathcal{N}_i,x) + \sum_{j\in\mathcal{N}_i} \log p_{\boldsymbol{\theta}}(t_i,r_{ij}|i,\mathcal{N}_i,x) \\ &+ \sum_{j\in\mathcal{N}_i} \log p_{\boldsymbol{\theta}}(r_{ij},a_j|i,\mathcal{N}_i,x) \end{aligned}$$

The second term is the sum of confidence scores for event relations based on the parameter estimates from the pairwise event model, where $R(t_i,t_{i'}) = \log p_{\boldsymbol{\phi}}(t_i,t_{i'}|i,i',x)$. The third term is the sum of confidence scores for entity mentions, where $D(a_j) = \log p_\psi(a_j|j,x)$ and $p_\psi(a_j|j,x)$ is the marginal probability derived from the linear-chain CRF described in Section 3.3. The optimization is subjected to agreement constraints that enforce the overlapping variables among the three components to agree on their values.

The joint inference problem can be formulated as an integer linear program (ILP). To solve it efficiently, we find solutions for the relaxation of the problem using a dual decomposition algorithm AD^3 (Martins et al., 2011). AD^3 has been shown to be orders of magnitude faster than a general purpose ILP solver in practice (Das et al., 2012). It is also particularly suitable for our problem since it involves decompositions that have many overlapping simple factors. We observed that AD^3 recovers the exact solutions for all the test documents in our experiments and the runtime for labeling each document is only three seconds in average in a 64-bit machine with two 2GHz CPUs and 8GB of RAM.

4 Experiments

We conduct experiments on the ACE2005 corpus.[6] It contains text documents from a variety of sources such as newswire reports, weblogs, and discussion forums. We use the same data split as in Li et al. (2013). Table 2 shows the data statistics.

We adopt the evaluation metrics for events as defined in Li et al. (2013). An event trigger is correctly identified if its offsets match those of a gold-standard trigger; and it is correctly classified if its event subtype (33 in total) also match the subtype of the gold-standard trigger. An event argument is correctly identified if its offsets and event subtype match those of any of the reference argument mentions in the document; and it is correctly classified if its semantic role (28 in total) is also correct. For entities, a predicted mention is correctly extracted if its head offsets and entity type (9 in total) match those of the reference entity mention.

Note that our approach requires entity mention candidates and event trigger candidates as input. Instead of enumerating all possible text spans, we generate high-quality entity mentions from the k-best predictions of our CRF entity extractor (in Section 3.3).[7] Similarly, we train a CRF for event trigger extraction using the same features except for the gazetteers, and generate trigger candidates based on the k-best predictions. We set $k = 50$ for entities and $k = 10$ for event triggers based on performance on the development set. They cover 92.3% of the gold-standard entity mentions and 96.3% of the gold-standard event triggers in the test set.

	Train	Dev	Test
Documents	529	40	30
Sentences	14,837	863	672
Triggers	4,337	497	438
Arguments	7,768	933	911
Entity Mentions	48,797	3,917	4,184

4.1 Results

Event Extraction. We compare the proposed models WITHINEVENT (in Section 3.1) and JOINTEVENTENTITY (in Section 3.4) with two strong baselines. One is JOINTBEAM (Li et al., 2013), a state-of-the-art event extractor that uses a structured perceptron with beam search for sentence-level joint extraction of event triggers and arguments. The other is STAGEDMAXENT, a typical two-stage approach that detects event triggers first and then event arguments. We use the same event trigger candidates and entity mention candidates as input to all the comparing models except for JOINTBEAM, because JOINTBEAM only extracts event mentions and assumes entity mentions are given. We consider a realistic experimental setting where no gold-standard annotations are available for entities during testing. To obtain results from JOINTBEAM, we ran the actual system[8] used in Li et al. (2013) using the entity mentions output by our CRF-based entity extractor.

Table 3 shows the average[9] precision, recall, and F1 score for event triggers and event arguments. We can see that our WITHINEVENT model, which explicitly models the trigger-argument dependencies and argument-role-entity-type dependencies, outperforms the MaxEnt pipeline, especially in event argument extraction. This shows that modeling the trigger-argument dependencies is effective in reducing error propagation.

Comparing to the state-of-the-art event extractor JOINTBEAM, the improvements introduced by WITHINEVENT are substantial in both event triggers and event arguments. We believe there are two main reasons: (1) WITHINEVENT considers all possible joint trigger/argument label assignments, whereas

[6] http://www.itl.nist.gov/iad/mig/tests/ace/2005/

[7] During training, we randomly split the training data into 10 parts and consider the k-best predictions for each part.

Model	PER	GPE	ORG	TIME
CRFEntity	85.1	87.0	65.4	78.4
JointEventEntity	**87.1**	87.0	**70.2**	**80.2**

Table 6: Entity extraction results (F1 score) per entity type.

JointBeam considers only a subset of the possible assignments based on a heuristic beam search. More specifically, when predicting labels for token i, JointBeam considers only the K-best ($K = 4$ in their paper) partial trigger/argument label configurations for the previous $i - 1$ tokens. As the length of the sentence increases, a large amount of information will be thrown away. (2) WithinEvent models argument-role-entity-type dependencies, whereas JointBeam assumes the entity types are given. This can cause error propagation.

JointEventEntity provides the best performance among all the models on all evaluation categories. It boosts both precision and recall compared to WithinEvent.[10] This demonstrates the advantages of JointEventEntity in allowing information propagation across event mentions and entity mentions and making more context-aware and semantically coherent predictions.

We also compare the results of JointEventEntity with the best known results on the ACE event extraction task in Table 4. Cross-doc (Ji and Grishman, 2008) performs cross-document inference of events using document clustering information, and CNN (Nguyen and Grishman, 2015) is a convolutional neural network for extracting event triggers at the sentence level. We see that JointEventEntity outperforms both models and achieves new state-of-the-art results for event trigger and argument extraction in an end-to-end evaluation setting.

Entity Extraction. In addition to extracting event mentions, JointEventEntity also extracts entity mentions. We compare its output with the output of a strong entity extraction baseline CRFEntity (described in Section 3.3). Table 5 shows the (micro-)average precision, recall, and F1 score. We see that JointEventEntity introduces a significant improvement in recall and F1. Table 6 further shows the F1 score for four major entity types PER, GPE, ORG, and TIME in ACE. The promising improvements indicate that joint modeling of events and entities allows for more accurate predictions about not only events but also entities.

4.2 Error Analysis

Table 7 divides the errors made by JointEventEntity based on different subtasks and the classification error types in each task. For event triggers, the majority of the errors relates to missing triggers and only 3.7% involves misclassified event types (e.g., a Demonstration event is mistaken for a Transport event). Among the missing triggers, we examine the cases where the event types are correctly identified in a sentence but with in-

[10] All significance tests reported in this paper were computed using the paired bootstrap procedure (Berg-Kirkpatrick et al., 2012) with 10,000 samples of the test documents.

Error Type	Missing	Spurious	Misclassified
TRIGGER	62.1%	34.2%	3.7%
ARGUMENT	71.2%	24.7%	4.1%
ENTITY	43.4%	30.5%	26.1%

Table 7: Classification of errors made by JOINTEVENTENTITY.

correct triggers and find that there are only 5% of such cases. For event arguments, the majority of the errors relates to missing arguments and only 4.1% is about misclassified argument roles. Among the missing event arguments, 10% of them has correctly identified entity types.

In general, the errors for event extraction are commonly due to three reasons: (1) Lexical sparsity. For example, in the sentence "At least three members of a family ... were **hacked** to death ...", our model fails to detect that "hacked" triggers an ATTACK event, because it has never seen "hacked" with this sense during training. Using WordNet and pretrained word vectors may alleviate the sparsity issue. It is also important to disambiguate word senses in context. (2) Shallow understanding of context, especially long-range context. For example, given the sentence "**She** is being held on 50,000 dollars bail on a charge of first-degree reckless **homicide** ...", the model detects that "homicide" triggers an event, but fails to detect that "She" refers to the AGENT who committed the homicide. This is mainly due to the complex long-distance dependency between the trigger and the argument. (3) Use of complex language such as metaphor, idioms, and sarcasm. Addressing these phenomena is in general difficult since it requires richer background knowledge and more sophisticated inference.

For entity extraction, we find that integrating event information into entity extraction successfully improves recall and F1. However, since the ACE dataset is restricted to a limited set of events, a large portion of the sentences does not contain any event triggers and event arguments that are of interest. For these sentences, there is little or no benefit of joint modeling. We also find that some entity misclassification errors can be avoided if entity coreference information is available. We plan to investigate coreference resolution as an additional component to our joint model in future work.

5 Related Work

Event extraction has been mainly studied using the ACE data (Doddington et al., 2004) and biomedical data for the BioNLP shared tasks (Kim et al., 2009). To reduce task complexity, early work employs a pipeline of classifiers that extracts event triggers first, and then determines their arguments (Ahn, 2006; Björne et al., 2009). Recently, Convolutional Neural Networks have been used to improve the pipeline classifiers (Nguyen and Grishman, 2015; Chen et al., 2015). As pipeline approaches suffer from error propagation, researchers have proposed methods for joint extraction of event triggers and arguments, using either structured perceptron (Li et al., 2013), Markov Logic (Poon and Vanderwende, 2010), or dependency parsing algorithms (McClosky et al., 2011). However, existing joint models largely rely on heuristic search to aggressively shrink the search space. One exception is work in Riedel and McCallum (2011), which uses dual decomposition to solve joint inference with runtime guarantees. Our work is similar to Riedel and McCallum (2011). However, there are two main differences: first, our model extracts both event mentions and entity mentions; second, it performs joint inference across sentence boundaries. Although our approach is evaluated on ACE, it can be easily adapted to BioNLP data by using appropriate features for events triggers, argument roles, and entities. We consider this as future work.

There has been work on improving event extraction by exploiting document-level context. Berant et al. (2014) exploits event-event relations, e.g., causality, inhibition, which frequently occur in biological texts. For general texts most work focuses on exploiting temporal event relations (Chambers and Jurafsky, 2008; Do et al., 2012; McClosky and Manning, 2012). For the ACE domain, there is work on utilizing event type co-occurrence patterns to propagation event classification decisions (Ji and Grishman, 2008; Liao and Grishman, 2010). Our model is similar to their work. It models the co-occurrence relations between event types (e.g., a DIE event tends to co-occur with ATTACK events and TRANSPORT events). It can be extended to handle other types of event relations (e.g., causal and temporal) by designing appropriate features. Chambers and

Jurafsky (2009; 2011) learn narrative schemas by linking event verbs that have coreferring syntactic arguments. Our model also adopts this intuition to relate event triggers across sentences. In addition, each event argument is grounded by its entity type (e.g., an entity mention of type PER can only fill roles that can be played by a person).

6 Conclusion

In this paper, we introduce a new approach for automatic extraction of events and entities across a document. We first decompose the learning problem into three tractable subproblems: learning within-event structures, learning event-event relations, and learning for entity extraction. We then integrate these learned models into a single model that performs joint inference of all event triggers, semantic roles for events, and entities across the whole document. Experimental results demonstrate that our approach outperforms the state-of-the-art event extractors by a large margin and substantially improves a strong entity extraction baseline. For future work, we plan to integrate entity and event coreference as additional components into the joint inference framework. We are also interested in investigating the integration of more sophisticated event-event relation models of causality and temporal ordering.

Abstract

Event extraction is a particularly challenging problem in information extraction. The state-of-the-art models for this problem have either applied convolutional neural networks in a pipelined framework (Chen et al., 2015) or followed the joint architecture via structured prediction with rich local and global features (Li et al., 2013). The former is able to learn hidden feature representations automatically from data based on the continuous and generalized representations of words. The latter, on the other hand, is capable of mitigating the error propagation problem of the pipelined approach and exploiting the inter-dependencies between event triggers and argument roles via discrete structures. In this work, we propose to do event extraction in a joint framework with bidirectional recurrent neural networks, thereby benefiting from the advantages of the two models as well as addressing issues inherent in the existing approaches. We systematically investigate different memory features for the joint model and demonstrate that the proposed model achieves the state-of-the-art performance on the ACE 2005 dataset.

1 Introduction

We address the problem of event extraction (EE): identifying event triggers of specified types and their arguments in text. Triggers are often single verbs or normalizations that evoke some events of interest while arguments are the entities participating into such events. This is an important and challenging task of information extraction in natural language processing (NLP), as the same event might be present in various expressions, and an expression might expresses different events in different contexts.

There are two main approaches to EE: (i) the joint approach that predicts event triggers and arguments for sentences *simultaneously* as a structured prediction problem, and (ii) the pipelined approach that first performs trigger prediction and then identifies arguments in *separate* stages.

The most successful joint system for EE (Li et al., 2013) is based on the structured perceptron algorithm with a large set of local and global features[1]. These features are designed to capture the *discrete* structures that are intuitively helpful for EE using the NLP toolkits (e.g., part of speech tags, dependency and constituent tags). The advantages of such a joint system are twofold: (i) mitigating the error propagation from the upstream component (trigger identification) to the downstream classifier (argument identification), and (ii) benefiting from the the inter-dependencies among event triggers and argument roles via global features. For example, consider the following sentence (taken from Li et al. (2013)) in the ACE 2005 dataset:

In Baghdad, a <u>*cameraman*</u> **died** *when an American tank* **fired** *on the Palestine hotel.*

In this sentence, **died** and **fired** are the event triggers for the events of types *Die* and *Attack*, respectively. In the pipelined approach, it is often simple for the argument classifiers to realize that *camera-*

[1] Local features encapsulate the characteristics for the individual tasks (i.e, trigger and argument role labeling) while global features target the dependencies between triggers and arguments and are only available in the joint approach.

Proceedings of NAACL-HLT 2016, pages 300–309,
San Diego, California, June 12-17, 2016.

man is the *Target* argument of the *Die* event due to the proximity between *cameraman* and *died* in the sentence. However, as *cameraman* is far away from *fired*, the argument classifiers in the pipelined approach might fail to recognize *cameraman* as the *Target* argument for the event *Attack* with their local features. The joint approach can overcome this issue by relying on the global features to encode the fact that a *Victim* argument for the *Die* event is often the *Target* argument for the *Attack* event in the same sentence.

Despite the advantages presented above, the joint system by Li et al. (2013) suffers from the lack of generalization over the unseen words/features and the inability to extract the underlying structures for EE (due to its *discrete* representation from the hand-crafted feature set) (Nguyen and Grishman, 2015b; Chen et al., 2015).

The most successful pipelined system for EE to date (Chen et al., 2015) addresses these drawbacks of the joint system by Li et al. (2013) via dynamic multi-pooling convolutional neural networks (DMCNN). In this system, words are represented by the *continuous* representations (Bengio et al., 2003; Turian et al., 2010; Mikolov et al., 2013a) and features are automatically learnt from data by the DMCNN, thereby alleviating the unseen word/feature problem and extracting more effective features for the given dataset. However, as the system by Chen et al. (2015) is pipelined, it still suffers from the inherent limitations of error propagation and failure to exploit the inter-dependencies between event triggers and argument roles (Li et al., 2013). Finally, we notice that the discrete features, shown to be helpful in the previous studies for EE (Li et al., 2013), are not considered in Chen et al. (2015).

Guided by these characteristics of the EE systems by Li et al. (2013) and Chen et al. (2015), in this work, we propose to solve the EE problem with the joint approach via recurrent neural networks (RNNs) (Hochreiter and Schmidhuber, 1997; Cho et al., 2014) augmented with the discrete features, thus inheriting all the benefits from both systems as well as overcoming their inherent issues. To the best of our knowledge, this is the first work to employ neural networks to do joint EE.

Our model involves two RNNs that run over the sentences in both forward and reverse directions to learn a richer representation for the sentences. This representation is then utilized to predict event triggers and argument roles jointly. In order to capture the inter-dependencies between triggers and argument roles, we introduce memory vectors/matrices to store the prediction information during the course of labeling the sentences.

We systematically explore various memory vector/matrices as well as different methods to learn word representations for the joint model. The experimental results show that our system achieves the state-of-the-art performance on the widely used ACE 2005 dataset.

2 Event Extraction Task

We focus on the EE task of the Automatic Context Extraction (ACE) evaluation[2]. ACE defines an event as something that happens or leads to some change of state. We employ the following terminology:

- **Event mention**: a phrase or sentence in which an event occurs, including one trigger and an arbitrary number of arguments.
- **Event trigger**: the main word that most clearly expresses an event occurrence.
- **Event argument**: an entity mention, temporal expression or value (e.g. *Job-Title*) that servers as a participant or attribute with a specific role in an event mention.

ACE annotates 8 types and 33 subtypes (e.g., *Attack*, *Die*, *Start-Position*) for event mentions that also correspond to the types and subtypes of the event triggers. Each event subtype has its own set of roles to be filled by the event arguments. For instance, the roles for the *Die* event include *Place*, *Victim* and *Time*. The total number of roles for all the event subtypes is 36.

Given an English text document, an event extraction system needs to recognize event triggers with specific subtypes and their corresponding arguments with the roles for each sentence. Following the previous work (Liao and Grishman, 2011; Li et al., 2013; Chen et al., 2015), we assume that the argument candidates (i.e, the entity mentions, temporal expressions and values) are provided (by the ACE annotation) to the event extraction systems.

[2] http://projects.ldc.upenn.edu/ace

3 Model

We formalize the EE task as follow. Let $W = w_1 w_2 \dots w_n$ be a sentence where n is the sentence length and w_i is the i-th token. Also, let $E = e_1, e_2, \dots, e_k$ be the entity mentions[3] in this sentence (k is the number of the entity mentions and can be zero). Each entity mention comes with the offsets of the head and the entity type. We further assume that $i_1, i_2, \dots, i_k$ be the indexes of the last words of the mention heads for $e_1, e_2, \dots, e_k$, respectively.

In EE, for every token w_i in the sentence, we need to predict the event subtype (if any) for it. If w_i is a trigger word for some event of interest, we then need to predict the roles (if any) that each entity mention e_j plays in such event.

The joint model for event extraction in this work consists of two phases: (i) the *encoding phase* that applies recurrent neural networks to induce a more abstract representation of the sentence, and (ii) the *prediction phase* that uses the new representation to perform event trigger and argument role identification simultaneously for W. Figure 1 shows an overview of the model.

3.1 Encoding

3.1.1 Sentence Encoding

In the encoding phase, we first transform each token w_i into a real-valued vector x_i using the concatenation of the following three vectors:

1. The word embedding vector of w_i: This is obtained by looking up a pre-trained word embedding table D (Collobert and Weston, 2008; Turian et al., 2010; Mikolov et al., 2013a).

2. The real-valued embedding vector for the entity type of w_i: This vector is motivated from the prior work (Nguyen and Grishman, 2015b) and generated by looking up the entity type embedding table (initialized randomly) for the entity type of w_i. Note that we also employ the BIO annotation schema to assign entity type labels to each token in the sentences using the heads of the entity mentions as do Nguyen and Grishman (2015b).

3. The binary vector whose dimensions correspond to the possible relations between words in the dependency trees. The value at each dimension of this vector is set to 1 only if there exists one edge of the corresponding relation connected to w_i in the dependency tree of W. This vector represents the dependency features that are shown to be helpful in the previous research (Li et al., 2013).

Note that we do not use the relative position features, unlike the prior work on neural networks for EE (Nguyen and Grishman, 2015b; Chen et al., 2015). The reason is we predict the whole sentences for triggers and argument roles jointly, thus having no fixed positions for anchoring in the sentences.

The transformation from the token w_i to the vector x_i essentially converts the input sentence W into a sequence of real-valued vectors $X = (x_1, x_2, \dots, x_n)$, to be used by recurrent neural networks to learn a more effective representation.

3.1.2 Recurrent Neural Networks

Consider the input sequence $X = (x_1, x_2, \dots, x_n)$. At each step i, we compute the hidden vector α_i based on the current input vector x_i and the previous hidden vector α_{i-1}, using the non-linear transformation function Φ: $\alpha_i = \Phi(x_i, \alpha_{i-1})$. This recurrent computation is done over X to generate the hidden vector sequence $(\alpha_1, \alpha_2, \dots, \alpha_n)$, denoted by $\overrightarrow{\text{RNN}}(x_1, x_2, \dots, x_n) = (\alpha_1, \alpha_2, \dots, \alpha_n)$.

An important characteristics of the recurrent mechanism is that it adaptively accumulates the context information from position 1 to i into the hidden vector α_i, making α_i a rich representation. However, α_i is not sufficient for the event trigger and argument predictions at position i as such predictions might need to rely on the context information in the future (i.e, from position i to n). In order to address this issue, we run a second RNN in the reverse direction from X_n to X_1 to generate the second hidden vector sequence: $\overleftarrow{\text{RNN}}(x_n, x_{n-1}, \dots, x_1) = (\alpha'_n, \alpha'_{n-1}, \dots, \alpha'_1)$ in which α'_i summarizes the context information from position n to i. Eventually, we obtain the new representation $(h_1, h_2, \dots, h_n)$ for X by concatenating the hidden vectors in $(\alpha_1, \alpha_2, \dots, \alpha_n)$ and $(\alpha'_n, \alpha'_{n-1}, \dots, \alpha'_1)$: $h_i = [\alpha_i, \alpha'_i]$. Note that h_i essentially encapsulates the context information over the whole sentence (from 1 to n) with a greater focus on position i.

Regarding the non-linear function, the simplest

[3] From now on, when mentioning entity mentions, we always refer to the ACE entity mentions, times and values.

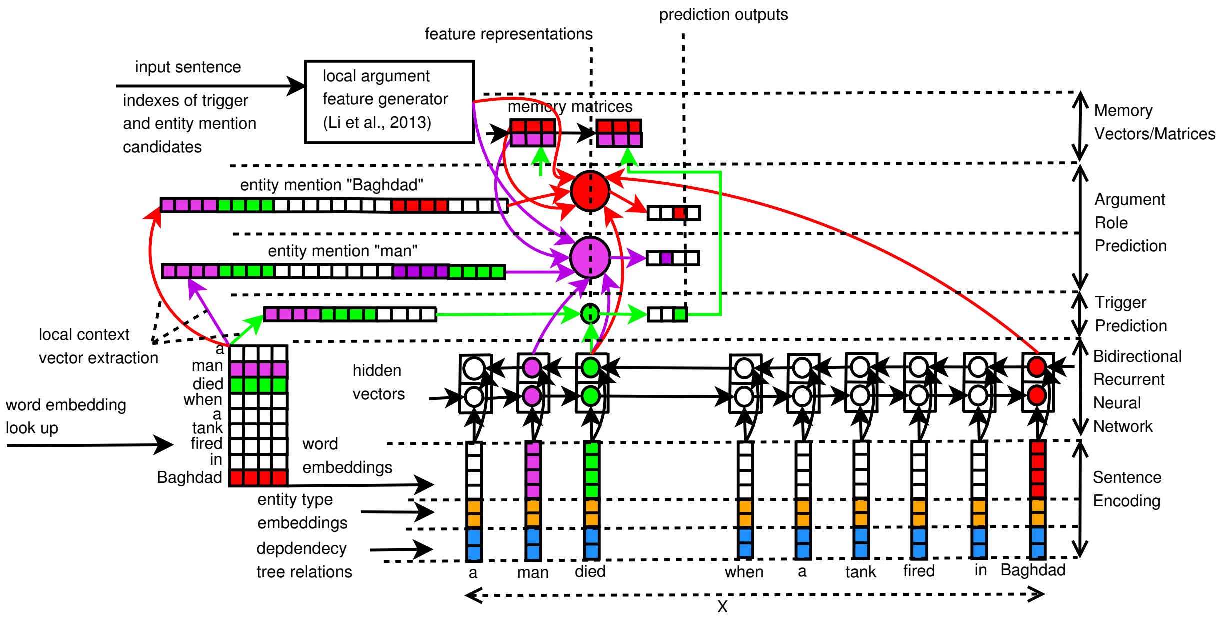

Figure 1: The joint EE model for the input sentence "*a man died when a tank fired in Baghdad*" with local context window $d = 1$. We only demonstrate the memory matrices $G_i^{\text{arg/trg}}$ in this figure. Green corresponds to the trigger candidate "*died*" at the current step while violet and red are for the entity mentions "*man*" and "*Baghdad*" respectively.

form of Φ in the literature considers it as a one-layer feed-forward neural network. Unfortunately, this function is prone to the "*vanishing gradient*" problem (Bengio et al., 1994), making it challenging to train RNNs properly. This problem can be alleviated by long-short term memory units (LSTM) (Hochreiter and Schmidhuber, 1997; Gers, 2001). In this work, we use a variant of LSTM; called the *Gated Recurrent Units* (GRU) from Cho et al. (2014). GRU has been shown to achieve comparable performance (Chung et al., 2014; Józefowicz et al., 2015).

3.2 Prediction

In order to jointly predict triggers and argument roles for W, we maintain a binary memory vector G_i^{trg} for triggers, and binary memory matrices G_i^{arg} and $G_i^{\text{arg/trg}}$ for arguments (at each time i). These vector/matrices are set to zeros initially ($i = 0$) and updated during the prediction process for W.

Given the bidirectional representation $h_1, h_2, \ldots, h_n$ in the encoding phase and the initialized memory vector/matrices, the joint prediction procedure loops over n tokens in the sentence (from 1 to n). At each time step i, we perform the following three stages in order:

(i) *trigger prediction* for w_i.

(ii) *argument role prediction* for all the entity mentions $e_1, e_2, \ldots, e_k$ with respect to the current token w_i.

(iii) *compute* G_i^{trg}, G_i^{arg} and $G_i^{\text{arg/trg}}$ for the current step using the previous memory vector/matrices G_{i-1}^{trg}, G_{i-1}^{arg} and $G_{i-1}^{\text{arg/trg}}$, and the prediction output in the earlier stages.

The output of this process would be the predicted trigger subtype t_i for w_i, the predicted argument roles $a_{i1}, a_{i2}, \ldots, a_{ik}$ and the memory vector/matrices G_i^{trg}, G_i^{arg} and $G_i^{\text{arg/trg}}$ for the current step. Note that t_i should be the event subtype if w_i is a trigger word for some event of interest, or "*Other*" in the other cases. a_{ij}, in constrast, should be the argument role of the entity mention e_j with respect to w_i if w_i is a trigger word and e_j is an argument of the corresponding event, otherwise a_{ij} is set to "*Other*" ($j = 1$ to k).

3.2.1 Trigger Prediction

In the trigger prediction stage for the current token w_i, we first compute the feature representation vector R_i^{trg} for w_i using the concatenation of the following three vectors:

- h_i: the hidden vector to encapsulate the global context of the input sentence.

- L_i^{trg}: the local context vector for w_i. L_i^{trg} is generated by concatenating the vectors of the words in a context window d of w_i: $L_i^{\text{trg}} = [D[w_{i-d}], \ldots, D[w_i], \ldots, D[w_{i+d}]]$.
- G_{i-1}^{trg}: the memory vector from the previous step.

The representation vector $R_i^{\text{trg}} = [h_i, L_i^{\text{trg}}, G_{i-1}^{\text{trg}}]$ is then fed into a feed-forward neural network F^{trg} with a softmax layer in the end to compute the probability distribution $P_{i;t}^{\text{trg}}$ over the possible trigger subtypes: $P_{i;t}^{\text{trg}} = P_i^{\text{trg}}(l = t) = F_t^{\text{trg}}(R_i^{\text{trg}})$ where t is a trigger subtype. Finally, we compute the predicted type t_i for w_i by: $t_i = \text{argmax}_t(P_{i;t}^{\text{trg}})$.

3.2.2 Argument Role Prediction

In the argument role prediction stage, we first check if the predicted trigger subtype t_i in the previous stage is "*Other*" or not. If yes, we can simply set a_{ij} to "*Other*" for all $j = 1$ to k and go to the next stage immediately. Otherwise, we loop over the entity mentions $e_1, e_2, \ldots, e_k$. For each entity mention e_j with the head index of i_j, we predict the argument role a_{ij} with respect to the trigger word w_i using the following procedure.

First, we generate the feature representation vector R_{ij}^{arg} for e_j and w_i by concatenating the following vectors:

- h_i and h_{i_j}: the hidden vectors to capture the global context of the input sentence for w_i and e_j, respectively.
- L_{ij}^{arg}: the local context vector for w_i and e_j. L_{ij}^{arg} is the concatenation of the vectors of the words in the context windows of size d for w_i and w_{i_j}: $L_{ij}^{\text{arg}} = [D[w_{i-d}], \ldots, D[w_i], \ldots, D[w_{i+d}], D[w_{i_j-d}], \ldots, D[w_{i_j}], \ldots, D[w_{i_j+d}]]$.
- B_{ij}: the hidden vector for the binary feature vector V_{ij}. V_{ij} is based on the local argument features between the tokens i and i_j from (Li et al., 2013). B_{ij} is then computed by feeding V_{ij} into a feed-forward neural network F^{binary} for further abstraction: $B_{ij} = F^{\text{binary}}(V_{ij})$.
- $G_{i-1}^{\text{arg}}[j]$ and $G_{i-1}^{\text{arg/trg}}[j]$: the memory vectors for e_j that are extracted out of the memory matrices G_{i-1}^{arg} and $G_{i-1}^{\text{arg/trg}}$ from the previous step.

In the next step, we again use a feed-forward neural network F^{arg} with a softmax layer in the end to transform $R_{ij}^{\text{arg}} = [h_i, h_{i_j}, L_{ij}^{\text{arg}}, B_{ij}, G_{i-1}^{\text{arg}}[j], G_{i-1}^{\text{arg/trg}}[j]]$ into the probability distribution $P_{ij;a}^{\text{trg}}$ over the possible argument roles: $P_{ij;a}^{\text{arg}} = P_{ij}^{\text{arg}}(l = a) = F_a^{\text{arg}}(R_{ij}^{\text{arg}})$ where a is an argument role. Eventually, the predicted argument role for w_i and e_j is $a_{ij} = \text{argmax}_a(P_{ij;a}^{\text{arg}})$.

Note that the binary vector V_{ij} enriches the feature representation R_{ij}^{arg} for argument labeling with the discrete structures discovered in the prior work on feature analysis for EE (Li et al., 2013). These features include the shortest dependency paths, the entity types, subtypes, etc.

3.2.3 The Memory Vector/Matrices

An important characteristics of EE is the existence of the dependencies between trigger labels and argument roles within the same sentences (Li et al., 2013). In this work, we encode these dependencies into the memory vectors/matrices G_i^{trg}, G_i^{arg} and $G_i^{\text{arg/trg}}$ ($i = 0$ to n) and use them as features in the trigger and argument prediction explicitly (as shown in the representation vectors R_i^{trg} and R_{ij}^{arg} above). We classify the dependencies into the following three categories:

1. The **dependencies among trigger subtypes**: are captured by the memory vectors G_i^{trg} ($G_i^{\text{trg}} \in \{0,1\}^{n_T}$ for $i = 0, \ldots, n$, and n_T is the number of the possible trigger subtypes). At time i, G_i^{trg} indicates which event subtypes have been recognized before i. We obtain G_i^{trg} from G_{i-1}^{trg} and the trigger prediction output t_i at time i: $G_i^{\text{trg}}[t] = 1$ if $t = t_i$ and $G_{i-1}^{\text{trg}}[t]$ otherwise.

A motivation for such dependencies is that if a *Die* event appears somewhere in the sentences, the possibility for the later occurrence of an *Attack* event would be likely.

2. The **dependencies among argument roles**: are encoded by the memory matrix G_i^{arg} ($G_i^{\text{arg}} \in \{0,1\}^{k \times n_A}$ for $i = 0, \ldots, n$, and n_A is the number of the possible argument roles). At time i, G_i^{arg} summarizes the argument roles that the entity mentions has played with some event in the past. In particular, $G_i^{\text{arg}}[j][a]$ = 1 if and only if e_j has the role of a with some event before time i. G_i^{arg} is computed from G_{i-1}^{arg}, and the prediction outputs t_i and $a_{i1}, \ldots, a_{ik}$ at time i: $G_i^{\text{arg}}[j][a] = 1$ if $t_i \neq$ "*Other*" and $a = a_{ij}$, and $G_{i-1}^{\text{arg}}[j][a]$ otherwise (for $j = 1$ to k).

3. The **dependencies between argument roles and trigger subtypes**: are encoded by the memory matrix $G_i^{\text{arg/trg}}$ ($G_i^{\text{arg/trg}} \in \{0,1\}^{k \times n_T}$ for $i = 0$ to n). At time i, $G_i^{\text{arg/trg}}$ specifies which entity mentions have been identified as arguments for which event subtypes before. In particular, $G_i^{\text{arg/trg}}[j][t] = 1$ if and only if e_j has been detected as an argument for some event of subtype t before i. $G_i^{\text{arg/trg}}$ is computed from $G_{i-1}^{\text{arg/trg}}$ and the trigger prediction output t_i at time i: $G_i^{\text{arg/trg}}[j][t] = 1$ if $t_i \neq$ "*Other*" and $t = t_i$, and $G_{i-1}^{\text{arg/trg}}[j][t]$ otherwise (for all $j = 1$ to k).

3.3 Training

Denote the given trigger subtypes and argument roles for W in the training time as $T = t_1^*, t_2^*, \ldots, t_n^*$ and $A = (a_{ij}^*)_{i=1,n}^{j=1,k}$. We train the network by minimizing the joint negative log-likelihood function C for triggers and argument roles:

$$\begin{aligned} C(T, A, X, E) &= -\log P(T, A|X, E) \\ &= -\log P(T|X, E) - \log P(A|T, X, E) \\ &= -\sum_{i=1}^{n} \log P_{i;t_i^*}^{\text{trg}} \\ &\quad - \sum_{i=1}^{n} I(t_i \neq \text{"}\textit{Other}\text{"}) \sum_{j=1}^{k} \log P_{ij;a_{ij}^*}^{\text{arg}} \end{aligned}$$

where I is the indicator function.

We apply the stochastic gradient descent algorithm with mini-batches and the AdaDelta update rule (Zeiler, 2012). The gradients are computed using back-propagation. During training, besides the weight matrices, we also optimize the word and entity type embedding tables to achieve the optimal states. Finally, we rescale the weights whose Frobenius norms exceed a hyperparameter (Kim, 2014; Nguyen and Grishman, 2015a).

4 Word Representation

Following the prior work (Nguyen and Grishman, 2015b; Chen et al., 2015), we pre-train word embeddings from a large corpus and employ them to initialize the word embedding table. One of the models to train word embeddings have been proposed in Mikolov et al. (2013a; 2013b) that introduce two log-linear models, i.e the continuous bag-of-words model (CBOW) and the continuous skip-gram model (SKIP-GRAM). The CBOW model attempts to predict the current word based on *the average of the context word vectors* while the SKIP-GRAM model aims to predict the surrounding words in a sentence given the current word. In this work, besides the CBOW and SKIP-GRAM models, we examine a concatenation-based variant of CBOW (C-CBOW) to train word embeddings and compare the three models to understand their effectiveness for EE. The objective of C-CBOW is to predict the target word using *the concatenation of the vectors of the words surrounding it.*

5 Experiments

5.1 Resources, Parameters and Dataset

For all the experiments below, in the encoding phase, we use 50 dimensions for the entity type embeddings, 300 dimensions for the word embeddings and 300 units in the hidden layers for the RNNs.

Regarding the prediction phase, we employ the context window of 2 for the local features, and the feed-forward neural networks with one hidden layer for F^{trg}, F^{arg} and F^{binary} (the size of the hidden layers are 600, 600 and 300 respectively).

Finally, for training, we use the mini-batch size = 50 and the parameter for the Frobenius norms = 3.

These parameter values are either inherited from the prior research (Nguyen and Grishman, 2015b; Chen et al., 2015) or selected according to the validation data.

We pre-train the word embeddings from the English Gigaword corpus utilizing the word2vec toolkit[4] (modified to add the C-CBOW model). Following Baroni et al. (2014), we employ the context window of 5, the subsampling of the frequent words set to $1e$-05 and 10 negative samples.

We evaluate the model with the ACE 2005 corpus. For the purpose of comparison, we use the same data split as the previous work (Ji and Grishman, 2008; Liao and Grishman, 2010; Li et al., 2013; Nguyen and Grishman, 2015b; Chen et al., 2015). This data split includes 40 newswire articles (672 sentences) for the test set, 30 other documents (836 sentences) for the development set and 529 remaining documents (14,849 sentences) for the training set. Also,

[4] `https://code.google.com/p/word2vec/`

we follow the criteria of the previous work (Ji and Grishman, 2008; Liao and Grishman, 2010; Li et al., 2013; Chen et al., 2015) to judge the correctness of the predicted event mentions.

5.2 Memory Vector/Matrices

This section evaluates the effectiveness of the memory vector and matrices presented in Section 3.2.3. In particular, we test the joint model on different cases where the memory vector for triggers G^{trg} and the memory matrices for arguments $G^{\text{arg/trg}}$ and G^{arg} are included or excluded from the model. As there are 4 different ways to combine $G^{\text{arg/trg}}$ and G^{arg} for argument labeling and two options to to employ G^{trg} or not for trigger labeling, we have 8 systems for comparison in total. Table 1 reports the identification and classification performance (F1 scores) for triggers and argument roles on the development set. Note that we are using the word embeddings trained with the C-CBOW technique in this section.

System		*No*	$G^{\text{arg/trg}}$	G^{arg}	$G^{\text{arg/trg}}$+G^{arg}
No	Trigger	67.9	**68.0**	64.6	64.2
	Argument	55.6	**58.1**	55.2	53.1
G^{trg}	Trigger	63.8	61.0	61.3	66.8
	Argument	55.2	56.6	54.7	53.6

Table 1: Performance of the Memory Vector/Matrices on the development set. *No* means not using the memory vector/matrices.

We observe that the memory vector G^{trg} is not helpful for the joint model as it worsens both trigger and argument role performance (considering the same choice of the memory matrices $G^{\text{arg/trg}}$ and G^{arg} (i.e, the same row in the table) and except in the row with $G^{\text{arg/trg}} + G^{\text{arg}}$).

The clearest trend is that $G^{\text{arg/trg}}$ is very effective in improving the performance of argument labeling. This is true in both the inclusion and exclusion of G^{trg}. G^{arg} and its combination with $G^{\text{arg/trg}}$, on the other hand, have negative effect on this task. Finally, $G^{\text{arg/trg}}$ and G^{arg} do not contribute much to the trigger labeling performance in general (except in the case where G^t, $G^{\text{arg/trg}}$ and G^{arg} are all applied).

These observations suggest that the dependencies *among trigger subtypes* and *among argument roles* are not strong enough to be helpful for the joint model in this dataset. This is in contrast to the dependencies *between argument roles and trigger subtypes* that improve the joint model significantly.

The best system corresponds to the application of the memory matrix $G^{\text{arg/trg}}$ and will be used in all the experiments below.

5.3 Word Embedding Evaluation

We investigate different techniques to obtain the pretrained word embeddings for initialization in the joint model of EE. Table 2 presents the performance (for both triggers and argument roles) on the development set when the CBOW, SKIP-GRAM and C-CBOW techniques are utilized to obtain word embeddings from the same corpus. We also report the performance of the joint model when it is initialized with the Word2Vec word embeddings from Mikolov et al. (2013a; 2013b) (trained with the Skip-gram model on Google News) (WORD2VEC). Finally, for comparison, the performance of the random word embeddings (RANDOM) is also included. All of these word embeddings are updated during the training of the model.

Word Embeddings	Trigger	Argument
RANDOM	59.9	50.1
SKIP-GRAM	66.7	57.1
CBOW	66.5	53.8
WORD2VEC	66.9	56.4
C-CBOW	**68.0**	**58.1**

Table 2: Performance of the Word Embedding Techniques.

The first observation from the table is that RANDOM is not good enough to initialize the word embeddings for joint EE and we need to borrow some pre-trained word embeddings for this purpose. Second, SKIP-GRAM, WORD2VEC and CBOW have comparable performance on trigger labeling while the argument labeling performance of SKIP-GRAM and WORD2VEC is much better than that of CBOW for the joint EE model. Third and most importantly, among the compared word embeddings, it is clear that C-CBOW significantly outperforms all the others. We believe that the better performance of C-CBOW stems from its concatenation of the multiple context word vectors, thus providing more information to learn better word embeddings than SKIP-GRAM and WORD2VEC. In addition, the concate-

Model	Trigger Identification (%)			Trigger Identification + Classification (%)			Argument Identification (%)			Argument Role (%)		
	P	R	F	P	R	F	P	R	F	P	R	F
Li's basline	76.2	60.5	67.4	74.5	59.1	65.9	74.1	37.4	49.7	65.4	33.1	43.9
Liao's cross-event†		N/A		68.7	68.9	68.8	50.9	49.7	50.3	45.1	44.1	44.6
Hong's cross-entity†		N/A		72.9	64.3	68.3	53.4	52.9	53.1	51.6	45.5	48.3
Li's structure	76.9	65.0	70.4	73.7	62.3	67.5	69.8	47.9	56.8	64.7	44.4	52.7
DMCNN	80.4	67.7	**73.5**	75.6	63.6	69.1	68.8	51.9	59.1	62.2	46.9	53.5
JRNN	68.5	75.7	71.9	66.0	73.0	**69.3**	61.4	64.2	**62.8**	54.2	56.7	**55.4**

Table 3: Overall Performance on the Blind Test Data. "†" designates the systems that employ the evidences beyond sentence level.

nation mechanism essentially helps to assign different weights to different context words, thereby being more flexible than CBOW that applies a single weight for all the context words.

From now on, for consistency, C-CBOW would be utilized in all the following experiments.

5.4 Comparison to the State of the art

The state-of-the-art systems for EE on the ACE 2005 dataset have been the pipelined system with dynamic multi-pooling convolutional neural networks by Chen et al. (2015) (**DMCNN**) and the joint system with structured prediction and various discrete local and global features by Li et al. (2013) (**Li's structure**).

Note that the pipelined system in Chen et al. (2015) is also the best-reported system based on neural networks for EE. Table 3 compares these state-of-the-art systems with the joint RNN-based model in this work (denoted by **JRNN**). For completeness, we also report the performance of the following representative systems:

1) **Li's baseline**: This is the pipelined system with local features by Li et al. (2013).

2) **Liao's cross event**: is the system by Liao and Grishman (2010) with the document-level information.

3) **Hong's cross-entity** (Hong et al., 2011): This system exploits the cross-entity inference, and is also the best-reported pipelined system with discrete features in the literature.

From the table, we see that JRNN achieves the best F1 scores (for both trigger and argument labeling) among all of the compared models. This is significant with the argument role labeling performance (an improvement of 1.9% over the best-reported model DMCNN in Chen et al. (2015)), and demonstrates the benefit of the joint model with RNNs and memory features in this work. In addition, as JRNN significantly outperforms the joint model with discrete features in Li et al. (2013) (an improvement of 1.8% and 2.7% for trigger and argument role labeling respectively), we can confirm the effectiveness of RNNs to learn effective feature representations for EE.

5.5 Sentences with Multiple Events

In order to further prove the effectiveness of JRNN, especially for those sentences with multiple events, we divide the test data into two parts according to the number of events in the sentences (i.e, single event and multiple events) and evaluate the performance separately, following Chen et al. (2015). Table 4 shows the performance (F1 scores) of JRNN, DMCNN and two other baseline systems, named **Embeddings+T** and **CNN** in Chen et al. (2015). Embeddings+T uses word embeddings and the traditional sentence-level features in (Li et al., 2013) while CNN is similar to DMCNN, except that it applies the standard pooling mechanism instead of the dynamic multi-pooling method (Chen et al., 2015).

The most important observation from the table is that JRNN significantly outperforms all the other methods with large margins when the input sentences contain more than one events (i.e, the row labeled with **1/N** in the table). In particular, JRNN is 13.9% better than DMCNN on trigger labeling while the corresponding improvement for argument role labeling is 6.5%, thereby further suggesting the benefit of JRNN with the memory features. Regard-

Stage	Model	1/1	1/N	all
Trigger	Embedding+T	68.1	25.5	59.8
	CNN	72.5	43.1	66.3
	DMCNN	74.3	50.9	69.1
	JRNN	**75.6**	**64.8**	**69.3**
Argument	Embedding+T	37.4	15.5	32.6
	CNN	51.6	36.6	48.9
	DMCNN	**54.6**	48.7	53.5
	JRNN	50.0	**55.2**	**55.4**

Table 4: System Performance on Single Event Sentences (**1/1**) and Multiple Event Sentences (**1/N**).

ing the performance on the single event sentences, JRNN is still the best system on trigger labeling although it is worse than DMCNN on argument role labeling. This can be partly explained by the fact that DMCNN includes the position embedding features for arguments and the memory matrix $G^{\text{arg/trg}}$ in JRNN is not functioning in this single event case.

6 Related Work

Early research on event extraction has primarily focused on local sentence-level representations in a pipelined architecture (Grishman et al., 2005; Ahn, 2006). After that, higher level features has been investigated to improve the performance (Ji and Grishman, 2008; Gupta and Ji, 2009; Patwardhan and Riloff, 2009; Liao and Grishman, 2010; Liao and Grishman, 2011; Hong et al., 2011; McClosky et al., 2011; Huang and Riloff, 2012; Li et al., 2013). Besides, some recent research has proposed joint models for EE, including the methods based on Markov Logic Networks (Riedel et al., 2009; Poon and Vanderwende, 2010; Venugopal et al., 2014), structured perceptron (Li et al., 2013; Li et al., 2014b), and dual decomposition (Riedel et al. (2009; 2011a; 2011b)).

The application of neural networks to EE is very recent. In particular, Nguyen and Grishman (2015b) study domain adaptation and event detection via CNNs while Chen et al. (2015) apply dynamic multi-pooling CNNs for EE in a pipelined framework. However, none of these work utilizes RNNs to perform joint EE as we do in this work.

7 Conclusion

We present a joint model to do EE based on bidirectional RNN to overcome the limitation of the previous models for this task. We introduce the memory matrix that can effectively capture the dependencies between argument roles and trigger subtypes. We demonstrate that the concatenation-based variant of the CBOW word embeddings is very helpful for the joint model. The proposed joint model is empirically shown to be effective on the sentences with multiple events as well as yields the state-of-the-art performance on the ACE 2005 dataset. In the future, we plan to apply this joint model on the event argument extraction task of the KBP evaluation as well as extend it to other joint tasks such as mention detection together with relation extraction etc.

Abstract

Long Short-Term Memory (LSTM) networks, a type of recurrent neural network with a more complex computational unit, have been successfully applied to a variety of sequence modeling tasks. In this paper we develop Tree Long Short-Term Memory (TREELSTM), a neural network model based on LSTM, which is designed to predict a tree rather than a linear sequence. TREELSTM defines the probability of a sentence by estimating the generation probability of its dependency tree. At each time step, a node is generated based on the representation of the generated subtree. We further enhance the modeling power of TREELSTM by explicitly representing the correlations between left and right dependents. Application of our model to the MSR sentence completion challenge achieves results beyond the current state of the art. We also report results on dependency parsing reranking achieving competitive performance.

1 Introduction

Neural language models have been gaining increasing attention as a competitive alternative to n-grams. The main idea is to represent each word using a real-valued feature vector capturing the contexts in which it occurs. The conditional probability of the next word is then modeled as a smooth function of the feature vectors of the preceding words and the next word. In essence, similar representations are learned for words found in similar contexts resulting in similar predictions for the next word. Previous approaches have mainly employed feed-forward (Bengio et al., 2003; Mnih and Hinton, 2007) and recurrent neural networks (Mikolov et al., 2010; Mikolov, 2012) in order to map the feature vectors of the context words to the distribution for the next word. Recently, RNNs with Long Short-Term Memory (LSTM) units (Hochreiter and Schmidhuber, 1997; Hochreiter, 1998) have emerged as a popular architecture due to their strong ability to capture long-term dependencies. LSTMs have been successfully applied to a variety of tasks ranging from machine translation (Sutskever et al., 2014), to speech recognition (Graves et al., 2013), and image description generation (Vinyals et al., 2015).

Despite superior performance in many applications, neural language models essentially predict sequences of words. Many NLP tasks, however, exploit syntactic information operating over tree structures (e.g., dependency or constituent trees). In this paper we develop a novel neural network model which combines the advantages of the LSTM architecture and syntactic structure. Our model estimates the probability of a sentence by estimating the generation probability of its dependency tree. Instead of explicitly encoding tree structure as a set of features, we use four LSTM networks to model four types of dependency edges which altogether specify how the tree is built. At each time step, one LSTM is activated which predicts the next word conditioned on the sub-tree generated so far. To learn the representations of the conditioned sub-tree, we force the four LSTMs to share their hidden layers. Our model is also capable of generating trees just by sampling from a trained model and can be seamlessly integrated with text generation applications.

Proceedings of NAACL-HLT 2016, pages 310–320,
San Diego, California, June 12-17, 2016.

Our approach is related to but ultimately different from recursive neural networks (Pollack, 1990) a class of models which operate on structured inputs. Given a (binary) parse tree, they recursively generate parent representations in a bottom-up fashion, by combining tokens to produce representations for phrases, and eventually the whole sentence. The learned representations can be then used in classification tasks such as sentiment analysis (Socher et al., 2011b) and paraphrase detection (Socher et al., 2011a). Tai et al. (2015) learn distributed representations over syntactic trees by generalizing the LSTM architecture to tree-structured network topologies. The key feature of our model is not so much that it can learn semantic representations of phrases or sentences, but its ability to predict tree structure and estimate its probability.

Syntactic language models have a long history in NLP dating back to Chelba and Jelinek (2000) (see also Roark (2001) and Charniak (2001)). These models differ in how grammar structures in a parsing tree are used when predicting the next word. Other work develops dependency-based language models for specific applications such as machine translation (Shen et al., 2008; Zhang, 2009; Sennrich, 2015), speech recognition (Chelba et al., 1997) or sentence completion (Gubbins and Vlachos, 2013). All instances of these models apply Markov assumptions on the dependency tree, and adopt standard n-gram smoothing methods for reliable parameter estimation. Emami et al. (2003) and Sennrich (2015) estimate the parameters of a structured language model using feed-forward neural networks (Bengio et al., 2003). Mirowski and Vlachos (2015) re-implement the model of Gubbins and Vlachos (2013) with RNNs. They view sentences as sequences of words over a tree. While they ignore the tree structures themselves, we model them explicitly.

Our model shares with other structured-based language models the ability to take dependency information into account. It differs in the following respects: (a) it does not artificially restrict the depth of the dependencies it considers and can thus be viewed as an infinite order dependency language model; (b) it not only estimates the probability of a string but is also capable of generating dependency trees; (c) finally, contrary to previous dependency-based language models which encode syntactic information as features, our model takes tree structure into account more directly via representing different types of dependency edges explicitly using LSTMs. Therefore, there is no need to manually determine which dependency tree features should be used or how large the feature embeddings should be.

We evaluate our model on the MSR sentence completion challenge, a benchmark language modeling dataset. Our results outperform the best published results on this dataset. Since our model is a general tree estimator, we also use it to rerank the top K dependency trees from the (second order) MSTPasrser and obtain performance on par with recently proposed dependency parsers.

2 Tree Long Short-Term Memory Networks

We seek to estimate the probability of a sentence by estimating the generation probability of its dependency tree. Syntactic information in our model is represented in the form of dependency paths. In the following, we first describe our definition of dependency path and based on it explain how the probability of a sentence is estimated.

2.1 Dependency Path

Generally speaking, a dependency path is the path between ROOT and w consisting of the nodes on the path and the edges connecting them. To represent dependency paths, we introduce four types of edges which essentially define the "shape" of a dependency tree. Let w_0 denote a node in a tree and $w_1, w_2, \dots, w_n$ its left dependents. As shown in Figure 1, LEFT edge is the edge between w_0 and its first left dependent denoted as (w_0, w_1). Let w_k (with $1 < k \leq n$) denote a non-first left dependent of w_0. The edge from w_{k-1} to w_k is a NX-LEFT edge (NX stands for NEXT), where w_{k-1} is the right adjacent sibling of w_k. Note that the NX-LEFT edge (w_{k-1}, w_k) replaces edge (w_0, w_k) (illustrated with a dashed line in Figure 1) in the original dependency tree. The modification allows information to flow from w_0 to w_k through $w_1, \dots, w_{k-1}$ rather than directly from w_0 to w_k. RIGHT and NX-RIGHT edges are defined analogously for right dependents.

Given these four types of edges, dependency paths (denoted as $\mathcal{D}(w)$) can be defined as follows

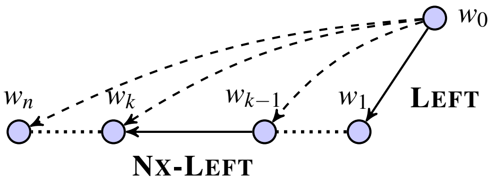

Figure 1: LEFT and NX-LEFT edges. Dotted line between w_1 and w_{k-1} (also between w_k and w_n) indicate that there may be ≥ 0 nodes inbetween.

bearing in mind that the first right dependent of ROOT is its only dependent and that w^p denotes the parent of w. We use $(\dots)$ to denote a sequence, where $()$ is an empty sequence and $\|$ is an operator for concatenating two sequences.

(1) if w is ROOT, then $\mathcal{D}(w) = ()$

(2) if w is a **left dependent** of w^p

(a) if w is the first left dependent, then $\mathcal{D}(w) = \mathcal{D}(w^p) \| (\langle w^p, \text{LEFT}\rangle)$

(b) if w is not the first left dependent and w^s is its right adjacent sibling, then $\mathcal{D}(w) = \mathcal{D}(w^s) \| (\langle w^s, \text{NX-LEFT}\rangle)$

(3) if w is a **right dependent** of w^p

(a) if w is the first right dependent, then $\mathcal{D}(w) = \mathcal{D}(w^p) \| (\langle w^p, \text{RIGHT}\rangle)$

(b) if w is not the first right dependent and w^s is its left adjacent sibling, then $\mathcal{D}(w) = \mathcal{D}(w^s) \| (\langle w^s, \text{NX-RIGHT}\rangle)$

A dependency tree can be represented by the set of its dependency paths which in turn can be used to reconstruct the original tree.[1]

Dependency paths for the first two levels of the tree in Figure 2 are as follows (ignoring for the moment the subscripts which we explain in the next section). $\mathcal{D}(\text{sold}) = (\langle \text{ROOT}, \text{RIGHT}\rangle)$ (see definitions (1) and (3a)), $\mathcal{D}(\text{year}) = \mathcal{D}(\text{sold}) \| (\langle \text{sold}, \text{LEFT}\rangle)$ (see (2a)), $\mathcal{D}(\text{manufacturer}) = \mathcal{D}(\text{year}) \| (\langle \text{year}, \text{NX-LEFT}\rangle)$ (see (2b)), $\mathcal{D}(\text{cars}) = \mathcal{D}(\text{sold}) \| (\langle \text{sold}, \text{RIGHT}\rangle)$ (see (3a)), $\mathcal{D}(\text{in}) = \mathcal{D}(\text{cars}) \| (\langle \text{cars}, \text{NX-RIGHT}\rangle)$ (according to (3b)).

2.2 Tree Probability

The core problem in syntax-based language modeling is to estimate the probability of sentence S given its corresponding tree T, $P(S|T)$. We view the probability computation of a dependency tree as a generation process. Specifically, we assume dependency trees are constructed top-down, in a breadth-first manner. Generation starts at the ROOT node. For each node at each level, first its left dependents are generated from closest to farthest and then the right dependents (again from closest to farthest). The same process is applied to the next node at the same level or a node at the next level. Figure 2 shows the breadth-first traversal of a dependency tree.

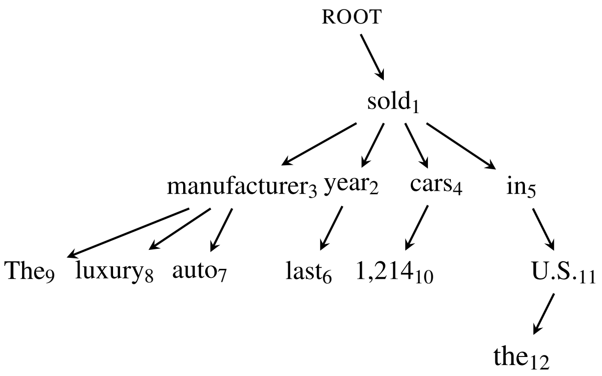

Figure 2: Dependency tree of the sentence *The luxury auto manufacturer last year sold 1,214 cars in the U.S.* Subscripts indicate breadth-first traversal. ROOT has only one dependent (i.e., *sold*) which we view as its first right dependent.

Under the assumption that each word w in a dependency tree is *only* conditioned on its *dependency path*, the probability of a sentence S given its dependency tree T is:

$$P(S|T) = \prod_{w \in \text{BFS}(T) \setminus \text{ROOT}} P(w|\mathcal{D}(w)) \qquad (1)$$

where $\mathcal{D}(w)$ is the dependency path of w. Note that each word w is visited according to its breadth-first search order (BFS(T)) and the probability of ROOT is ignored since every tree has one. The role of ROOT in a dependency tree is the same as the begin of sentence token (BOS) in a sentence. When computing $P(S|T)$ (or $P(S)$), the probability of ROOT (or BOS) is ignored (we assume it always exists), but is used to predict other words. We explain in the next section how TREELSTM estimates $P(w|\mathcal{D}(w))$.

2.3 Tree LSTMs

A dependency path $\mathcal{D}(w)$ is subtree which we denote as a sequence of $\langle$*word*, *edge-type*$\rangle$ tuples. Our

[1] Throughout this paper we assume all dependency trees are projective.

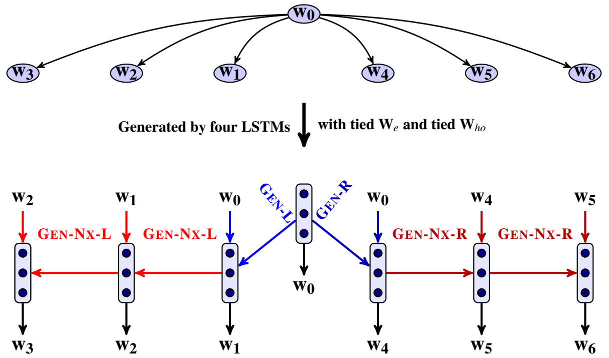

Figure 3: Generation process of left (w_1, w_2, w_3) and right (w_4, w_5, w_6) dependents of tree node w_o (top) using four LSTMs (Gen-L, Gen-R, Gen-Nx-L and Gen-Nx-R). The model can handle an arbitrary number of dependents due to Gen-Nx-L and Gen-Nx-R.

innovation is to learn the representation of $\mathcal{D}(w)$ using four LSTMs. The four LSTMs (Gen-L, Gen-R, Gen-Nx-L and Gen-Nx-R) are used to represent the four types of edges (Left, Right, Nx-Left and Nx-Right) introduced earlier. Gen, Nx, L and R are shorthands for Generate, Next, Left and Right. At each time step, an LSTM is chosen according to an edge-type; then the LSTM takes a word as input and predicts/generates its dependent or sibling. This process can be also viewed as adding an edge and a node to a tree. Specifically, LSTMs Gen-L and Gen-R are used to generate the first left and right dependent of a node (w_1 and w_4 in Figure 3). So, these two LSTMs are responsible for going deeper in a tree. While Gen-Nx-L and Gen-Nx-R generate the remaining left/right dependents and therefore go wider in a tree. As shown in Figure 3, w_2 and w_3 are generated by Gen-Nx-L, whereas w_5 and w_6 are generated by Gen-Nx-R. Note that the model can handle any number of left or right dependents by applying Gen-Nx-L or Gen-Nx-R multiple times.

We assume time steps correspond to the steps taken by the breadth-first traversal of the dependency tree and the sentence has length n. At time step t ($1 \leq t \leq n$), let $\langle w_{t'}, z_t \rangle$ denote the last tuple in $\mathcal{D}(w_t)$. Subscripts t and t' denote the breadth-first search order of w_t and $w_{t'}$, respectively. $z_t \in \{\text{Left}, \text{Right}, \text{Nx-Left}, \text{Nx-Right}\}$ is the edge type (see the definitions in Section 2.1). Let $\mathbf{W}_e \in \mathbb{R}^{s \times |V|}$ denote the word embedding matrix and $\mathbf{W}_{ho} \in \mathbb{R}^{|V| \times d}$ the output matrix of our model, where $|V|$ is the vocabulary size, s the word embedding size and d the hidden unit size. We use tied $\mathbf{W}_e$ and tied $\mathbf{W}_{ho}$ for the four LSTMs to reduce the number of parameters in our model. The four LSTMs also share their hidden states. Let $\mathbf{H} \in \mathbb{R}^{d \times (n+1)}$ denote the *shared* hidden states of all time steps and $e(w_t)$ the one-hot vector of w_t. Then, $\mathbf{H}[:,t]$ represents $\mathcal{D}(w_t)$ at time step t, and the computation[2] is:

$$\mathbf{x}_t = \mathbf{W}_e \cdot e(w_{t'}) \tag{2a}$$

$$\mathbf{h}_t = \text{LSTM}^{z_t}(\mathbf{x}_t, \mathbf{H}[:,t']) \tag{2b}$$

$$\mathbf{H}[:,t] = \mathbf{h}_t \tag{2c}$$

$$\mathbf{y}_t = \mathbf{W}_{ho} \cdot \mathbf{h}_t \tag{2d}$$

where the initial hidden state $\mathbf{H}[:,0]$ is initialized to a vector of small values such as 0.01. According to Equation (2b), the model selects an LSTM based on edge type z_t. We describe the details of LSTM^{z_t} in the next paragraph. The probability of w_t given its dependency path $\mathcal{D}(w_t)$ is estimated by a *softmax* function:

$$P(w_t|\mathcal{D}(w_t)) = \frac{\exp(\mathbf{y}_{t,w_t})}{\sum_{k'=1}^{|V|} \exp(\mathbf{y}_{t,k'})} \tag{3}$$

We must point out that although we use four jointly trained LSTMs to encode the hidden states, the training and inference complexity of our model is no different from a regular LSTM, since at each time step only one LSTM is working.

We implement LSTM^z in Equation (2b) using a deep LSTM (to simplify notation, from now on we write z instead of z_t). The inputs at time step t are $\mathbf{x}_t$ and $\mathbf{h}_{t'}$ (the hidden state of an earlier time step t') and the output is $\mathbf{h}_t$ (the hidden state of current time step). Let L denote the layer number of LSTM^z and $\hat{\mathbf{h}}_t^l$ the internal hidden state of the l-th layer of the LSTM^z at time step t, where $\mathbf{x}_t$ is $\hat{\mathbf{h}}_t^0$ and $\mathbf{h}_{t'}$ is $\hat{\mathbf{h}}_{t'}^L$. The LSTM architecture introduces multiplicative gates and memory cells $\hat{\mathbf{c}}_t^l$ (at l-th layer) in order to address the *vanishing gradient* problem which makes it difficult for the standard RNN model to learn long-distance correlations in a sequence. Here, $\hat{\mathbf{c}}_t^l$ is a linear combination of the current input signal $\mathbf{u}_t$ and an earlier memory cell $\hat{\mathbf{c}}_{t'}^l$. How much input information $\mathbf{u}_t$ will flow into $\hat{\mathbf{c}}_t^l$ is controlled

[2] We ignore all bias terms for notational simplicity.

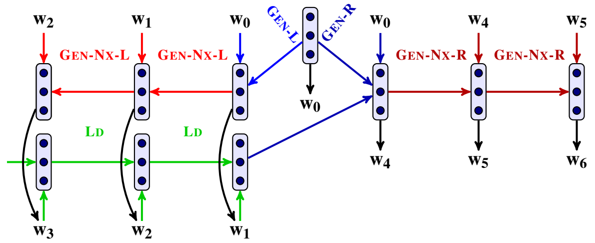

Figure 4: Generation of left and right dependents of node w_0 according to LDTREELSTM.

by input gate $\mathbf{i}_t$ and how much of the earlier memory cell $\hat{\mathbf{c}}^l_{t'}$ will be forgotten is controlled by forget gate $\mathbf{f}_t$. This process is computed as follows:

$$\mathbf{u}_t = \tanh(\mathbf{W}^{z,l}_{ux} \cdot \hat{\mathbf{h}}^{l-1}_t + \mathbf{W}^{z,l}_{uh} \cdot \hat{\mathbf{h}}^l_{t'}) \tag{4a}$$

$$\mathbf{i}_t = \sigma(\mathbf{W}^{z,l}_{ix} \cdot \hat{\mathbf{h}}^{l-1}_t + \mathbf{W}^{z,l}_{ih} \cdot \hat{\mathbf{h}}^l_{t'}) \tag{4b}$$

$$\mathbf{f}_t = \sigma(\mathbf{W}^{z,l}_{fx} \cdot \hat{\mathbf{h}}^{l-1}_t + \mathbf{W}^{z,l}_{fh} \cdot \hat{\mathbf{h}}^l_{t'}) \tag{4c}$$

$$\hat{\mathbf{c}}^l_t = \mathbf{f}_t \odot \hat{\mathbf{c}}^l_{t'} + \mathbf{i}_t \odot \mathbf{u}_t \tag{4d}$$

where $\mathbf{W}^{z,l}_{ux} \in \mathbb{R}^{d \times d}$ ($\mathbf{W}^{z,l}_{ux} \in \mathbb{R}^{d \times s}$ when $l = 1$) and $\mathbf{W}^{z,l}_{uh} \in \mathbb{R}^{d \times d}$ are weight matrices for $\mathbf{u}_t$, $\mathbf{W}^{z,l}_{ix}$ and $\mathbf{W}^{z,l}_{ih}$ are weight matrices for $\mathbf{i}_t$ and $\mathbf{W}^{z,l}_{fx}$, and $\mathbf{W}^{z,l}_{fh}$ are weight matrices for $\mathbf{f}_t$. σ is a sigmoid function and $\odot$ the element-wise product.

Output gate $\mathbf{o}_t$ controls how much information of the cell $\hat{\mathbf{c}}^l_t$ can be seen by other modules:

$$\mathbf{o}_t = \sigma(\mathbf{W}^{z,l}_{ox} \cdot \hat{\mathbf{h}}^{l-1}_t + \mathbf{W}^{z,l}_{oh} \cdot \hat{\mathbf{h}}^l_{t'}) \tag{5a}$$

$$\hat{\mathbf{h}}^l_t = \mathbf{o}_t \odot \tanh(\hat{\mathbf{c}}^l_t) \tag{5b}$$

Application of the above process to all layers L, will yield $\hat{\mathbf{h}}^L_t$, which is $\mathbf{h}_t$. Note that in implementation, all $\hat{\mathbf{c}}^l_t$ and $\hat{\mathbf{h}}^l_t$ ($1 \leq l \leq L$) at time step t are stored, although we only care about $\hat{\mathbf{h}}^L_t$ ($\mathbf{h}_t$).

2.4 Left Dependent Tree LSTMs

TREELSTM computes $P(w|\mathcal{D}(w))$ based on the dependency path $\mathcal{D}(w)$, which ignores the interaction between left and right dependents on the same level. In many cases, TREELSTM will use a verb to predict its object directly without knowing its subject. For example, in Figure 2, TREELSTM uses ⟨ROOT, RIGHT⟩ and ⟨ *sold*, RIGHT ⟩ to predict *cars*. This information is unfortunately not specific to *cars* (many things can be sold, e.g., *chocolates*, *candy*). Considering *manufacturer*, the left dependent of *sold* would help predict *cars* more accurately.

In order to jointly take left and right dependents into account, we employ yet another LSTM, which goes from the furthest left dependent to the closest left dependent (LD is a shorthand for left dependent). As shown in Figure 4, LD LSTM learns the representation of all left dependents of a node w_0; this representation is then used to predict the first right dependent of the same node. Non-first right dependents can also leverage the representation of left dependents, since this information is injected into the hidden state of the first right dependent and can percolate all the way. Note that in order to retain the generation capability of our model (Section 3.4), we only allow right dependents to leverage left dependents (they are generated before right dependents).

The computation of the LDTREELSTM is almost the same as in TREELSTM except when $z_t = \text{GEN-R}$. In this case, let $\mathbf{v}_t$ be the corresponding left dependent sequence with length K ($\mathbf{v}_t = (w_3, w_2, w_1)$ in Figure 4). Then, the hidden state ($\mathbf{q}_k$) of $\mathbf{v}_t$ at each time step k is:

$$\mathbf{m}_k = \mathbf{W}_e \cdot e(\mathbf{v}_{t,k}) \tag{6a}$$

$$\mathbf{q}_k = \text{LSTM}^{\text{LD}}(\mathbf{m}_k, \mathbf{q}_{k-1}) \tag{6b}$$

where $\mathbf{q}_K$ is the representation for all left dependents. Then, the computation of the current hidden state becomes (see Equation (2) for the original computation):

$$\mathbf{r}_t = \begin{bmatrix} \mathbf{W}_e \cdot e(w_{t'}) \\ \mathbf{q}_K \end{bmatrix} \tag{7a}$$

$$\mathbf{h}_t = \text{LSTM}^{\text{GEN-R}}(\mathbf{r}_t, \mathbf{H}[:, t']) \tag{7b}$$

where $\mathbf{q}_K$ serves as additional input for $\text{LSTM}^{\text{GEN-R}}$. All other computational details are the same as in TreeLSTM (see Section 2.3).

2.5 Model Training

On small scale datasets we employ Negative Log-likelihood (NLL) as our training objective for both TREELSTM and LDTREELSTM:

$$\mathcal{L}^{\text{NLL}}(\theta) = -\frac{1}{|\mathcal{S}|} \sum_{S \in \mathcal{S}} \log P(S|T) \tag{8}$$

where S is a sentence in the training set $\mathcal{S}$, T is the dependency tree of S and $P(S|T)$ is defined as in Equation (1).

On large scale datasets (e.g., with vocabulary size of 65K), computing the output layer activations and the *softmax* function with NLL would become prohibitively expensive. Instead, we employ Noise Contrastive Estimation (NCE; Gutmann and Hyvärinen (2012), Mnih and Teh (2012)) which treats the normalization term $\hat{Z}$ in $\hat{P}(w|\mathcal{D}(w_t)) = \frac{\exp(\mathbf{W}_{ho}[w,:]\cdot\mathbf{h}_t)}{\hat{Z}}$ as constant. The intuition behind NCE is to discriminate between samples from a data distribution $\hat{P}(w|\mathcal{D}(w_t))$ and a known noise distribution $P_n(w)$ via binary logistic regression. Assuming that noise words are k times more frequent than real words in the training set (Mnih and Teh, 2012), then the probability of a word w being from our model $P_d(w, \mathcal{D}(w_t))$ is $\frac{\hat{P}(w|\mathcal{D}(w_t))}{\hat{P}(w|\mathcal{D}(w_t))+kP_n(w)}$. We apply NCE to large vocabulary models with the following training objective:

$$\mathcal{L}^{\text{NCE}}(\theta) = -\frac{1}{|\mathcal{S}|}\sum_{T\in\mathcal{S}}\sum_{t=1}^{|T|}\Big(\log P_d(w_t, \mathcal{D}(w_t)) + \sum_{j=1}^{k}\log[1 - P_d(\tilde{w}_{t,j}, \mathcal{D}(w_t))]\Big)$$

where $\tilde{w}_{t,j}$ is a word sampled from the noise distribution $P_n(w)$. We use smoothed unigram frequencies (exponentiating by 0.75) as the noise distribution $P_n(w)$ (Mikolov et al., 2013b). We initialize $\ln\hat{Z} = 9$ as suggested in Chen et al. (2015), but instead of keeping it fixed we also learn $\hat{Z}$ during training (Vaswani et al., 2013). We set $k = 20$.

3 Experiments

We assess the performance of our model on two tasks: the Microsoft Research (MSR) sentence completion challenge (Zweig and Burges, 2012), and dependency parsing reranking. We also demonstrate the tree generation capability of our models. In the following, we first present details on model training and then present our results. We implemented our models using the Torch library (Collobert et al., 2011) and our code is available at `https://github.com/XingxingZhang/td-treelstm`.

3.1 Training Details

We trained our model with back propagation through time (Rumelhart et al., 1988) on an Nvidia GPU Card with a mini-batch size of 64. The objective (NLL or NCE) was minimized by stochastic gradient descent. Model parameters were uniformly initialized in $[-0.1, 0.1]$. We used the NCE objective on the MSR sentence completion task (due to the large size of this dataset) and the NLL objective on dependency parsing reranking. We used an initial learning rate of 1.0 for all experiments and when there was no significant improvement in log-likelihood on the validation set, the learning rate was divided by 2 per epoch until convergence (Mikolov et al., 2010). To alleviate the exploding gradients problem, we rescaled the gradient g when the gradient norm $||g|| > 5$ and set $g = \frac{5g}{||g||}$ (Pascanu et al., 2013; Sutskever et al., 2014). Dropout (Srivastava et al., 2014) was applied to the 2-layer TREELSTM and LDTREELSTM models. The word embedding size was set to $s = d/2$ where d is the hidden unit size.

3.2 Microsoft Sentence Completion Challenge

The task in the MSR Sentence Completion Challenge (Zweig and Burges, 2012) is to select the correct missing word for 1,040 SAT-style test sentences when presented with five candidate completions. The training set contains 522 novels from the Project Gutenberg which we preprocessed as follows. After removing headers and footers from the files, we tokenized and parsed the dataset into dependency trees with the Stanford Core NLP toolkit (Manning et al., 2014). The resulting training set contained 49M words. We converted all words to lower case and replaced those occurring five times or less with UNK. The resulting vocabulary size was 65,346 words. We randomly sampled 4,000 sentences from the training set as our validation set.

The literature describes two main approaches to the sentence completion task based on word vectors and language models. In vector-based approaches, all words in the sentence and the five candidate words are represented by a vector; the candidate which has the highest average similarity with the sentence words is selected as the answer. For language model-based methods, the LM computes the probability of a test sentence with each of the five candidate words, and picks the candidate completion which gives the highest probability. Our model belongs to this class of models.

Table 2: Performance of TreeLSTM and LdTreeLSTM on reranking the top dependency trees produced by the 2nd order MSTParser (McDonald and Pereira, 2006). Results for the NN and S-LSTM parsers are reported in Chen and Manning (2014) and Dyer et al. (2015), respectively. * indicates that the model is initialized with pre-trained word vectors.

Table 1 presents a summary of our results together with previoulsy published results. The best performing word vector model is ivLBL (Mnih and Kavukcuoglu, 2013) with an accuracy of 55.5, while the best performing single language model is LBL (Mnih and Teh, 2012) with an accuracy of 54.7. Both approaches are based on the log-bilinear language model (Mnih and Hinton, 2007). A combination of several recurrent neural networks and the skip-gram model holds the state of the art with an accuracy of 58.9 (Mikolov et al., 2013b). To fairly compare with existing models, we restrict the layer size of our models to 1. We observe that LdTreeLSTM consistently outperforms TreeLSTM, which indicates the importance of modeling the interaction between left and right dependents. In fact, LdTreeLSTM ($d = 400$) achieves a new state-of-the-art on this task, despite being a single model. We also implement LSTM and bidirectional LSTM language models.[3] An LSTM with $d = 400$ outperforms its smaller counterpart ($d = 300$), however performance decreases with $d = 450$. The bidirectional LSTM is worse than the LSTM (see Mnih and Teh (2012) for a similar observation). The best performing LSTM is worse than a LdTreeLSTM ($d = 300$). The input and output embeddings ($\mathbf{W}_e$ and $\mathbf{W}_{ho}$) dominate the number of parameters in all neural models except for RNNME, depRNN+3gram and ldepRNN+4gram, which include a ME model that contains 1 billion sparse n-gram features (Mikolov, 2012; Mirowski and Vlachos, 2015). The number of parameters in TreeLSTM and LdTreeLSTM is not much larger compared to LSTM due to the tied $\mathbf{W}_e$ and $\mathbf{W}_{ho}$ matrices.

3.3 Dependency Parsing

In this section we demonstrate that our model can be also used for parse reranking. This is not possible for sequence-based language models since they cannot estimate the probability of a tree. We use our models to rerank the top K dependency trees produced by the second order MSTParser (McDon-

[3] LSTMs and BiLSTMs were also trained with NCE ($s = d/2$; hyperparameters were tuned on the development set).

ald and Pereira, 2006).[4] We follow closely the experimental setup of Chen and Manning (2014) and Dyer et al. (2015). Specifically, we trained TreeLSTM and LdTreeLSTM on Penn Treebank sections 2–21. We used section 22 for development and section 23 for testing. We adopted the Stanford basic dependency representations (De Marneffe et al., 2006); part-of-speech tags were predicted with the Stanford Tagger (Toutanova et al., 2003). We trained TreeLSTM and LdTreeLSTM as language models (singletons were replaced with UNK) and did not use any POS tags, dependency labels or composition features, whereas these features are used in Chen and Manning (2014) and Dyer et al. (2015). We tuned d, the number of layers, and K on the development set.

Table 2 reports unlabeled attachment scores (UAS) and labeled attachment scores (LAS) for the MSTParser, TreeLSTM (d = 300, 1 layer, K = 2), and LdTreeLSTM (d = 200, 2 layers, $K = 4$). We also include the performance of two neural network-based dependency parsers; Chen and Manning (2014) use a neural network classifier to predict the correct transition (NN parser); Dyer et al. (2015) also implement a transition-based dependency parser using LSTMs to represent the contents of the stack and buffer in a continuous space. As can be seen, both TreeLSTM and LdTreeLSTM outperform the baseline MSTParser, with LdTreeLSTM performing best. We also initialized the word embedding matrix $\mathbf{W}_e$ with pre-trained GLOVE vectors (Pennington et al., 2014). We obtained a slight improvement over TreeLSTM (TreeLSTM* in Table 2; d = 200, 2 layer, K = 4) but no improvement over LdTreeLSTM. Finally, notice that LdTreeLSTM is slightly better than the NN parser in terms of UAS but worse than the S-LSTM parser. In the future, we would like to extend our model so that it takes labeled dependency information into account.

3.4 Tree Generation

This section demonstrates how to use a trained LdTreeLSTM to generate tree samples. The generation starts at the Root node. At each time step t, for each node w_t, we add a new edge and node to the tree. Unfortunately during generation, we do not know which type of edge to add. We therefore use four binary classifiers (Add-Left, Add-Right, Add-Nx-Left and Add-Nx-Right) to predict whether we should add a Left, Right, Nx-Left or Nx-Right edge.[5] Then when a classifier predicts true, we use the corresponding LSTM to generate a new node by sampling from the predicted word distribution in Equation (3). The four classifiers take the previous hidden state $\mathbf{H}[:, t']$ and the output embedding of the current node $\mathbf{W}_{ho} \cdot e(w_t)$ as features.[6] Specifically, we use a trained LdTreeLSTM to go through the training corpus and generate hidden states and embeddings as input features; the corresponding class labels (true and false) are “read off” the training dependency trees. We use two-layer rectifier networks (Glorot et al., 2011) as the four classifiers with a hidden size of 300. We use the same LdTreeLSTM model as in Section 3.3 to generate dependency trees. The classifiers were trained using AdaGrad (Duchi et al., 2011) with a learning rate of 0.01. The accuracies of Add-Left, Add-Right, Add-Nx-Left and Add-Nx-Right are 94.3%, 92.6%, 93.4% and 96.0%, respectively. Fig-

[4] http://www.seas.upenn.edu/ strctlrn/MSTParser

[5] It is possible to get rid of the four classifiers by adding START/STOP symbols when generating left and right dependents as in (Eisner, 1996). We refrained from doing this for computational reasons. For a sentence with N words, this approach will lead to $2N$ additional START/STOP symbols (with one START and one STOP symbol for each word). Consequently, the computational cost and memory consumption during training will be three times as much rendering our model less scalable.

[6] The input embeddings have lower dimensions and therefore result in slightly worse classifiers.

ure 5 shows examples of generated trees.

4 Conclusions

In this paper we developed TREELSTM (and LDTREELSTM), a neural network model architecture, which is designed to predict tree structures rather than linear sequences. Experimental results on the MSR sentence completion task show that LDTREELSTM is superior to sequential LSTMs. Dependency parsing reranking experiments highlight our model's potential for dependency parsing. Finally, the ability of our model to generate dependency trees holds promise for text generation applications such as sentence compression and simplification (Filippova et al., 2015). Although our experiments have focused exclusively on dependency trees, there is nothing inherent in our formulation that disallows its application to other types of tree structure such as constituent trees or even taxonomies.

Abstract

Recurrent Neural Networks (RNNs) have obtained excellent result in many natural language processing (NLP) tasks. However, understanding and interpreting the source of this success remains a challenge. In this paper, we propose Recurrent Memory Network (RMN), a novel RNN architecture, that not only amplifies the power of RNN but also facilitates our understanding of its internal functioning and allows us to discover underlying patterns in data. We demonstrate the power of RMN on language modeling and sentence completion tasks. On language modeling, RMN outperforms Long Short-Term Memory (LSTM) network on three large German, Italian, and English dataset. Additionally we perform in-depth analysis of various linguistic dimensions that RMN captures. On Sentence Completion Challenge, for which it is essential to capture sentence coherence, our RMN obtains 69.2% accuracy, surpassing the previous state of the art by a large margin.[1]

1 Introduction

Recurrent Neural Networks (RNNs) (Elman, 1990; Mikolov et al., 2010) are remarkably powerful models for sequential data. Long Short-Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), a specific architecture of RNN, has a track record of success in many natural language processing tasks such as language modeling (Józefowicz et al., 2015), dependency parsing (Dyer et al., 2015), sentence compression (Filippova et al., 2015), and machine translation (Sutskever et al., 2014).

Within the context of natural language processing, a common assumption is that LSTMs are able to capture certain linguistic phenomena. Evidence supporting this assumption mainly comes from evaluating LSTMs in downstream applications: Bowman et al. (2015) carefully design two artificial datasets where sentences have explicit recursive structures. They show empirically that while processing the input linearly, LSTMs can implicitly exploit recursive structures of languages. Filippova et al. (2015) find that using explicit syntactic features within LSTMs in their sentence compression model hurts the performance of overall system. They then hypothesize that a basic LSTM is powerful enough to capture syntactic aspects which are useful for compression.

To understand and explain which linguistic dimensions are captured by an LSTM is non-trivial. This is due to the fact that the sequences of input histories are compressed into several dense vectors by the LSTM's components whose purposes with respect to representing linguistic information is not evident. To our knowledge, the only attempt to better understand the reasons of an LSTM's performance and limitations is the work of Karpathy et al. (2015) by means of visualization experiments and cell activation statistics in the context of character-level language modeling.

Our work is motivated by the difficulty in understanding and interpreting existing RNN architectures from a linguistic point of view. We propose Recurrent Memory Network (RMN), a novel RNN architecture that combines the strengths of both LSTM

[1] Our code and data are available at https://github.com/ketranm/RMN

Proceedings of NAACL-HLT 2016, pages 321–331,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

and Memory Network (Sukhbaatar et al., 2015). In RMN, the Memory Block component—a variant of Memory Network—accesses the most recent input words and selectively attends to words that are relevant for predicting the next word given the current LSTM state. By looking at the attention distribution over history words, our RMN allows us not only to interpret the results but also to discover underlying dependencies present in the data.

In this paper, we make the following contributions:

1. We propose a novel RNN architecture that complements LSTM in language modeling. We demonstrate that our RMN outperforms competitive LSTM baselines in terms of perplexity on three large German, Italian, and English datasets.

2. We perform an analysis along various linguistic dimensions that our model captures. This is possible only because the Memory Block allows us to look into its internal states and its explicit use of additional inputs at each time step.

3. We show that, with a simple modification, our RMN can be successfully applied to NLP tasks other than language modeling. On the Sentence Completion Challenge (Zweig and Burges, 2012), our model achieves an impressive 69.2% accuracy, surpassing the previous state of the art 58.9% by a large margin.

2 Recurrent Neural Networks

Recurrent Neural Networks (RNNs) have shown impressive performances on many sequential modeling tasks due to their ability to encode unbounded input histories. However, training simple RNNs is difficult because of the vanishing and exploding gradient problems (Bengio et al., 1994; Pascanu et al., 2013). A simple and effective solution for exploding gradients is gradient clipping proposed by Pascanu et al. (2013). To address the more challenging problem of vanishing gradients, several variants of RNNs have been proposed. Among them, Long Short-Term Memory (Hochreiter and Schmidhuber, 1997) and Gated Recurrent Unit (Cho et al., 2014) are widely regarded as the most successful variants. In this work, we focus on LSTMs because they have been shown to outperform GRUs on language modeling tasks (Józefowicz et al., 2015). In the following, we will detail the LSTM architecture used in this work.

Long Short-Term Memory

Notation: Throughout this paper, we denote matrices, vectors, and scalars using bold uppercase (e. g., $\mathbf{W}$), bold lowercase (e. g., $\mathbf{b}$) and lowercase (e. g., α) letters, respectively.

The LSTM used in this work is specified as follows:

$$\begin{aligned}
\mathbf{i}_t &= \text{sigm}(\mathbf{W}_{xi}\mathbf{x}_t + \mathbf{W}_{hi}\mathbf{h}_{t-1} + \mathbf{b}_i) \\
\mathbf{j}_t &= \text{sigm}(\mathbf{W}_{xj}\mathbf{x}_t + \mathbf{W}_{hj}\mathbf{h}_{t-1} + \mathbf{b}_j) \\
\mathbf{f}_t &= \text{sigm}(\mathbf{W}_{xf}\mathbf{x}_t + \mathbf{W}_{hf}\mathbf{h}_{t-1} + \mathbf{b}_f) \\
\mathbf{o}_t &= \tanh(\mathbf{W}_{xo}\mathbf{x}_t + \mathbf{W}_{ho}\mathbf{h}_{t-1} + \mathbf{b}_o) \\
\mathbf{c}_t &= \mathbf{c}_{t-1} \odot \mathbf{f}_t + \mathbf{i}_t \odot \mathbf{j}_t \\
\mathbf{h}_t &= \tanh(\mathbf{c}_t) \odot \mathbf{o}_t
\end{aligned}$$

where $\mathbf{x}_t$ is the input vector at time step t, $\mathbf{h}_{t-1}$ is the LSTM hidden state at the previous time step, $\mathbf{W}_*$ and $\mathbf{b}_*$ are weights and biases. The symbol $\odot$ denotes the Hadamard product or element-wise multiplication.

Despite the popularity of LSTM in sequential modeling, its design is not straightforward to justify and understanding why it works remains a challenge (Hermans and Schrauwen, 2013; Chung et al., 2014; Greff et al., 2015; Józefowicz et al., 2015; Karpathy et al., 2015). There have been few recent attempts to understand the components of an LSTM from an empirical point of view: Greff et al. (2015) carry out a large-scale experiment of eight LSTM variants. The results from their 5,400 experimental runs suggest that forget gates and output gates are the most critical components of LSTMs. Józefowicz et al. (2015) conduct and evaluate over ten thousand RNN architectures and find that the initialization of the forget gate bias is crucial to the LSTM's performance. While these findings are important to help choosing appropriate LSTM architectures, they do not shed light on what information is captured by the hidden states of an LSTM.

Bowman et al. (2015) show that a vanilla LSTM, such as described above, performs reasonably well compared to a recursive neural network (Socher et al., 2011) that explicitly exploits tree structures on two artificial datasets. They find that LSTMs can effectively exploit recursive structure in the artificial datasets. In contrast to these simple datasets containing a few logical operations in their experiments, natural languages exhibit highly complex patterns. The extent to which linguistic assumptions about syntactic structures and compositional semantics are reflected in LSTMs is rather poorly understood. Thus it is desirable to have a more principled mechanism allowing us to inspect recurrent architectures from a linguistic perspective. In the following section, we propose such a mechanism.

3 Recurrent Memory Network

It has been demonstrated that RNNs can retain input information over a long period. However, existing RNN architectures make it difficult to analyze what information is exactly retained at their hidden states at each time step, especially when the data has complex underlying structures, which is common in natural language. Motivated by this difficulty, we propose a novel RNN architecture called Recurrent Memory Network (RMN). On linguistic data, the RMN allows us not only to qualify which linguistic information is preserved over time and why this is the case but also to discover dependencies within the data (Section 5). Our RMN consists of two components: an LSTM and a *Memory Block* (MB) (Section 3.1). The MB takes the hidden state of the LSTM and compares it to the most recent inputs using an attention mechanism (Gregor et al., 2015; Bahdanau et al., 2014; Graves et al., 2014). Thus, analyzing the attention weights of a trained model can give us valuable insight into the information that is retained over time in the LSTM.

In the following, we describe in detail the MB architecture and the combination of the MB and the LSTM to form an RMN.

3.1 Memory Block

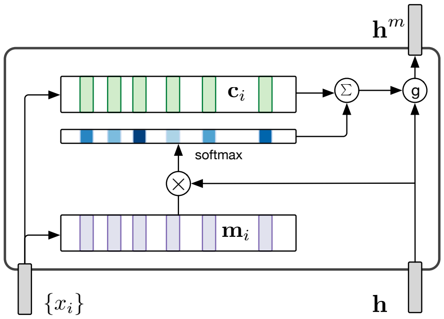

Figure 1: A graphical representation of the MB.

The Memory Block (Figure 1) is a variant of Memory Network (Sukhbaatar et al., 2015) with one hop (or a single-layer Memory Network). At time step t, the MB receives two inputs: the hidden state $\mathbf{h}_t$ of the LSTM and a set $\{x_i\}$ of n most recent words including the current word x_t. We refer to n as the memory size. Internally, the MB consists of two lookup tables $\mathbf{M}$ and $\mathbf{C}$ of size $|V| \times d$, where $|V|$ is the size of the vocabulary. With a slight abuse of notation we denote $\mathbf{M}_i = \mathbf{M}(\{x_i\})$ and $\mathbf{C}_i = \mathbf{C}(\{x_i\})$ as $n \times d$ matrices where each row corresponds to an input memory embedding $\mathbf{m}_i$ and an output memory embedding $\mathbf{c}_i$ of each element of the set $\{x_i\}$. We use the matrix $\mathbf{M}_i$ to compute an attention distribution over the set $\{x_i\}$:

$$\mathbf{p}_t = \text{softmax}(\mathbf{M}_i \mathbf{h}_t) \tag{1}$$

When dealing with data that exhibits a strong temporal relationship, such as natural language, an additional temporal matrix $\mathbf{T} \in \mathbb{R}^{n \times d}$ can be used to bias attention with respect to the position of the data points. In this case, equation 1 becomes

$$\mathbf{p}_t = \text{softmax}\big((\mathbf{M}_i + \mathbf{T})\mathbf{h}_t\big) \tag{2}$$

We then use the attention distribution $\mathbf{p}_t$ to compute a context vector representation of $\{x_i\}$:

$$\mathbf{s}_t = \mathbf{C}_i^{\mathsf{T}} \mathbf{p}_t \tag{3}$$

Finally, we combine the context vector $\mathbf{s}_t$ and the hidden state $\mathbf{h}_t$ by a function $g(\cdot)$ to obtain the output $\mathbf{h}_t^m$ of the MB. Instead of using a simple addition function $g(\mathbf{s}_t, \mathbf{h}_t) = \mathbf{s}_t + \mathbf{h}_t$ as in Sukhbaatar et al. (2015), we propose to use a gating unit that decides how much it should trust the hidden state $\mathbf{h}_t$ and context $\mathbf{s}_t$ at time step t. Our gating unit is a form of Gated Recurrent Unit (Cho et al., 2014; Chung et al., 2014):

$$\mathbf{z}_t = \text{sigm}(\mathbf{W}_{sz}\mathbf{s}_t + \mathbf{U}_{hz}\mathbf{h}_t) \tag{4}$$

$$\mathbf{r}_t = \text{sigm}(\mathbf{W}_{sr}\mathbf{s}_t + \mathbf{U}_{hr}\mathbf{h}_t) \tag{5}$$

$$\tilde{\mathbf{h}}_t = \tanh(\mathbf{W}\mathbf{s}_t + \mathbf{U}(\mathbf{r}_t \odot \mathbf{h}_t)) \tag{6}$$

$$\mathbf{h}_t^m = (\mathbf{1} - \mathbf{z}_t) \odot \mathbf{h}_t + \mathbf{z}_t \odot \tilde{\mathbf{h}}_t \tag{7}$$

where $\mathbf{z}_t$ is an update gate, $\mathbf{r}_t$ is a reset gate.

The choice of the composition function $g(\cdot)$ is crucial for the MB especially when one of its input comes from the LSTM. The simple addition function might overwrite the information within the LSTM's hidden state and therefore prevent the MB from keeping track of information in the distant past. The gating function, on the other hand, can control the degree of information that flows from the LSTM to the MB's output.

3.2 RMN Architectures

As explained above, our proposed MB receives the hidden state of the LSTM as one of its input. This leads to an intuitive combination of the two units by stacking the MB on top of the LSTM. We call this architecture Recurrent-Memory (RM). The RM architecture, however, does not allow interaction between Memory Blocks at different time steps. To enable this interaction we can stack one more LSTM layer on top of the RM. We call this architecture Recurrent-Memory-Recurrent (RMR).

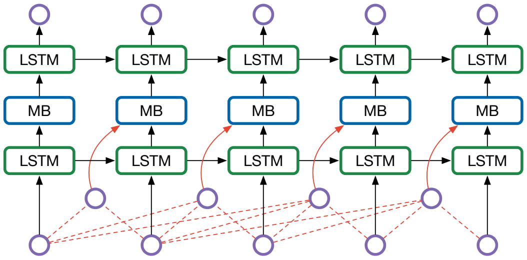

Figure 2: A graphical illustration of an unfolded RMR with memory size 4. Dashed line indicates concatenation. The MB takes the output of the bottom LSTM layer and the 4-word history as its input. The output of the MB is then passed to the second LSTM layer on top. There is no direct connection between MBs of different time steps. The last LSTM layer carries the MB's outputs recurrently.

4 Language Model Experiments

Language models play a crucial role in many NLP applications such as machine translation and speech recognition. Language modeling also serves as a standard test bed for newly proposed models (Sukhbaatar et al., 2015; Kalchbrenner et al., 2015). We conjecture that, by explicitly accessing history words, RMNs will offer better predictive power than the existing recurrent architectures. We therefore evaluate our RMN architectures against state-of-the-art LSTMs in terms of perplexity.

4.1 Data

We evaluate our models on three languages: English, German, and Italian. We are especially interested in German and Italian because of their larger vocabularies and complex agreement patterns. Table 1 summarizes the data used in our experiments.

Lang	Train	Dev	Test	$\lvert s\rvert$	$\lvert V\rvert$
En	26M	223K	228K	26	77K
De	22M	202K	203K	22	111K
It	29M	207K	214K	29	104K

Table 1: Data statistics. $|s|$ denotes the average sentence length and $|V|$ the vocabulary size.

The training data correspond to approximately 1M sentences in each language. For English, we use all the News Commentary data (8M tokens) and 18M tokens from News Crawl 2014 for training. Development and test data are randomly drawn from the concatenation of the WMT 2009-2014 test sets (Bojar et al., 2015). For German, we use the first 6M tokens from the News Commentary data and 16M tokens from News Crawl 2014 for training. For development and test data we use the remaining part of the News Commentary data concatenated with the WMT 2009-2014 test sets. Finally, for Italian, we use a selection of 29M tokens from the PAISÀ corpus (Lyding et al., 2014), mainly including Wikipedia pages and, to a minor extent, Wikibooks and Wikinews documents. For development and test we randomly draw documents from the same corpus.

4.2 Setup

Our baselines are a 5-gram language model with Kneser-Ney smoothing, a Memory Network (MemN) (Sukhbaatar et al., 2015), a vanilla single-layer LSTM, and two stacked LSTMs with two and three layers respectively. N-gram models have been used intensively in many applications for their excellent performance and fast training. Chen et al. (2015) show that n-gram model outperforms a popular feed-forward language model (Bengio et al.,

2003) on a one billion word benchmark (Chelba et al., 2013). While taking longer time to train, RNNs have been proven superior to n-gram models.

We compare these baselines with our two model architectures: RMR and RM. For each of our models, we consider two settings: with or without temporal matrix (+tM or –tM), and linear vs. gating composition function. In total, we experiment with eight RMN variants.

For all neural network models, we set the dimension of word embeddings, the LSTM hidden states, its gates, the memory input, and output embeddings to 128. The memory size is set to 15. The bias of the LSTM's forget gate is initialized to 1 (Józefowicz et al., 2015) while all other parameters are initialized uniformly in $(-0.05, 0.05)$. The initial learning rate is set to 1 and is halved at each epoch after the forth epoch. All models are trained for 15 epochs with standard stochastic gradient descent (SGD). During training, we rescale the gradients whenever their norm is greater than 5 (Pascanu et al., 2013).

Sentences with the same length are grouped into buckets. Then, mini-batches of 20 sentences are drawn from each bucket. We do not use truncated back-propagation through time, instead gradients are fully back-propagated from the end of each sentence to its beginning. When feeding in a new mini-batch, the hidden states of LSTMs are reset to zeros, which ensures that the data is properly modeled at the sentence level. For our RMN models, instead of using padding, at time step $t < n$, we use a slice $\mathbf{T}[1:t] \in \mathbb{R}^{t \times d}$ of the temporal matrix $\mathbf{T} \in \mathbb{R}^{n \times d}$.

4.3 Results

Perplexities on the test data are given in Table 2. All RMN variants largely outperform n-gram and MemN models, and most RMN variants also outperform the competitive LSTM baselines. The best results overall are obtained by RM with temporal matrix and gating composition (+tM-g).

Our results agree with the hypothesis of mitigating prediction error by explicitly using the last n words in RNNs (Karpathy et al., 2015). We further observe that using a temporal matrix always benefits the RM architectures. This can be explained by seeing the RM as a principled way to combine an LSTM and a neural n-gram model. By contrast, RMR works better without temporal matrix but its overall performance is not as good as RM. This suggests that we need a better mechanism to address the interaction between MBs, which we leave to future work. Finally, the proposed gating composition function outperforms the linear one in most cases.

Model		**De**	**It**	**En**
5-gram	–	225.8	167.5	219.0
MemN	1 layer	169.3	127.5	188.2
LSTM	1 layer	135.8	108.0	145.1
	2 layers	128.6	105.9	139.7
	3 layers	125.1	106.5	136.6
RMR	+tM-l	127.5	109.9	133.3
	–tM-l	126.4	106.1	134.5
	+tM-g	126.2	99.5	135.2
	–tM-g	**122.0**	**98.6**	**131.2**
RM	+tM-l	121.5	92.4	**127.2**
	–tM-l	122.9	94.0	130.4
	+tM-g	**118.6**	**88.9**	128.8
	–tM-g	129.7	96.6	135.7

Table 2: Perplexity comparison including RMN variants with and without temporal matrix (tM) and linear (l) versus gating (g) composition function.

For historical reasons, we also run a stacked three-layer LSTM and a RM(+tM-g) on the much smaller Penn Treebank dataset (Marcus et al., 1993) with the same setting described above. The respective perplexities are 126.1 and 123.5.

5 Attention Analysis

The goal of our RMN design is twofold: (i) to obtain better predictive power and (ii) to facilitate understanding of the model and discover patterns in data. In Section 4, we have validated the predictive power of the RMN and below we investigate the source of this performance based on linguistic assumptions of word co-occurrences and dependency structures.

5.1 Positional and lexical analysis

As a first step towards understanding RMN, we look at the average attention weights of each history word position in the MB of our two best model variants (Figure 3). One can see that the attention mass tends to concentrate at the rightmost position (the current

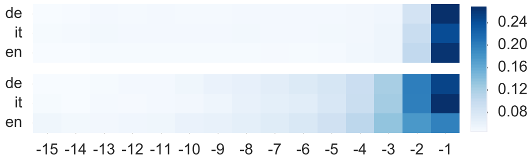

Figure 3: Average attention per position of RMN history. Top: RMR(–tM-g), bottom: RM(+tM-g). Rightmost positions represent most recent history.

word) and decreases when moving further to the left (less recent words). This is not surprising since the success of n-gram language models has demonstrated that the most recent words provide important information for predicting the next word. Between the two variants, the RM average attention mass is less concentrated to the right. This can be explained by the absence of an LSTM layer on top, meaning that the MB in the RM architecture has to pay more attention to the more distant words in the past. The remaining analyses described below are performed on the RM(+tM-g) architecture as this yields the best perplexity results overall.

Beyond average attention weights, we are interested in those cases where attention focuses on distant positions. To this end, we randomly sample 100 words from test data and visualize attention distributions over the last 15 words. Figure 4 shows the attention distributions for random samples of German and Italian. Again, in many cases attention weights concentrate around the last word (bottom row). However, we observe that many long distance words also receive noticeable attention mass. Interestingly, for many predicted words, attention is distributed evenly over memory positions, possibly indicating cases where the LSTM state already contains enough information to predict the next word.

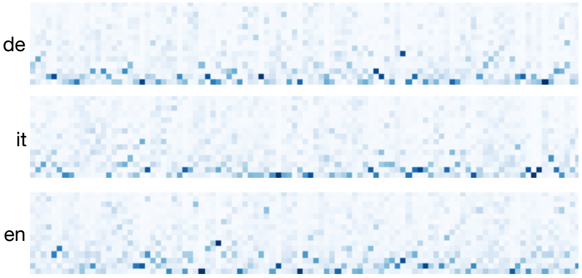

Figure 4: Attention visualization of 100 word samples. Bottom positions in each plot represent most recent history. Darker color means higher weight.

To explain the long-distance dependencies, we first hypothesize that our RMN mostly memorizes frequent co-occurrences. We run the RM(+tM-g) model on the German development and test sentences, and select those pairs of (*most-attended-word, word-to-predict*) where the MB's attention concentrates on a word more than six positions to the left. Then, for each set of pairs with equal distance, we compute the mean frequency of corresponding co-occurrences seen in the training data (Table 3). The lack of correlation between frequency and memory location suggests that RMN does more than simply memorizing frequent co-occurrences.

d	7	8	9	10	11	12	13	14	15
μ	54	63	42	67	87	47	67	44	24

Table 3: Mean frequency (μ) of (*most-attended-word, word-to-predict*) pairs grouped by relative distance (d).

Previous work (Hermans and Schrauwen, 2013; Karpathy et al., 2015) studied this property of LSTMs by analyzing simple cases of closing brackets. By contrast RMN allows us to discover more interesting dependencies in the data. We manually inspect those high-frequency pairs to see whether they display certain linguistic phenomena. We observe that RMN captures, for example, *separable verbs* and *fixed expressions* in German. Separable verbs are frequent in German: they typically consist of preposition+verb constructions, such *ab+hängen* ('to depend') or *aus+schließen* ('to exclude'), and can be spelled together (*abhängen*) or apart as in '*hängen von der Situation ab*' ('depend on the situation'), depending on the grammatical construction. Figure 5a shows a long-dependency example for the separable verb *abhängen (to depend)*. When predicting the verb's particle *ab*, the model correctly attends to the verb's core *hängt* occurring seven words to the left. Figure 5b and 5c show fixed expression examples from German and Italian, respectively: *schlüsselrolle ... spielen (play a key role)* and *insignito ... titolo (awarded title)*. Here too, the model correctly attends to the key word despite its long distance from the word to predict.

Other interesting examples found by the RMN in the test data include:

German: findet *statt* (takes *place*), kehrte *zurück* (came *back*), fragen *antworten* (questions *answers*), kämpfen *gegen* (fight *against*), bleibt *erhalten* (remains *intact*), verantwortung *übernimmt* (*takes* responsibility);

Italian: sinistra *destra* (left *right*), latitudine *longitudine* (latitude *longitude*), collegata *tramite* (connected *through*), sposò *figli* (got-married *children*), insignito *titolo* (awarded *title*).

5.2 Syntactic analysis

It has been conjectured that RNNs, and LSTMs in particular, model text so well because they capture syntactic structure implicitly. Unfortunately this has been hard to prove, but with our RMN model we can get closer to answering this important question.

We produce dependency parses for our test sets using (Sennrich et al., 2013) for German and (Attardi et al., 2009) for Italian. Next we look at how much attention mass is concentrated by the RM(+tM-g) model on different dependency types. Figure 6 shows, for each language, a selection of ten dependency types that are often long-distance.[2] Dependency direction is marked by an arrow: e.g. →*mod* means that the word to predict is a modifier of the attended word, while *mod*← means that the attended word is a modifier of the word to predict.[3] White cells denote combinations of position and dependency type that were not present in the test data.

While in most of the cases closest positions are attended the most, we can see that some dependency types also receive noticeably more attention than the average (ALL) on the long-distance positions. In German, this is mostly visible for the head of separable verb particles (→*avz*), which nicely supports our observations in the lexical analysis (Section 5.1). Other attended dependencies include: auxiliary verbs (→*aux*) when predicting the second element of a complex tense (*hat… gesagt / has said*); subordinating conjunctions (*konj*←) when predicting the clause-final inflected verb (*dass sie sagen sollten / that they should say*); control verbs (→*obji*) when predicting the infinitive verb (*versucht ihr zu helfen / tries to help her*). Out of the Italian dependency types selected for their frequent long-distance occurrences (bottom of Figure 6), the most attended are argument heads (→*arg*), complement heads (→*comp*), object heads (→*obj*) and subjects (*subj*←). This suggests that RMN is mainly capturing predicate argument structure in Italian. Notice that syntactic annotation is never used to train the model, but only to analyze its predictions.

We can also use RMN to discover which complex dependency paths are important for word prediction. To mention just a few examples, high attention on

[2] The full plots are available at `https://github.com/ketranm/RMN`. The German and Italian tag sets are explained in (Simi et al., 2014) and (Foth, 2006) respectively.

[3] Some dependency directions, like *obj*← in Italian, are almost never observed due to order constraints of the language.

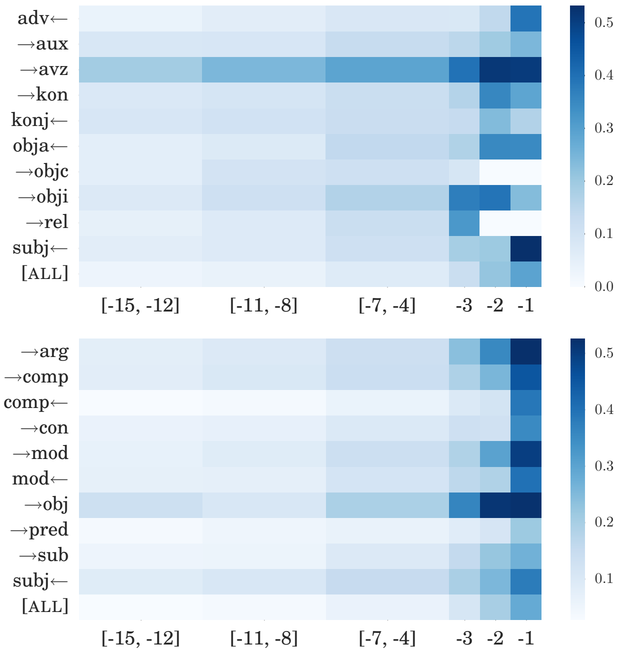

Figure 6: Average attention weights per position, broken down by dependency relation type+direction between the attended word and the word to predict. Top: German. Bottom: Italian. More distant positions are binned.

the German path *[subj←,→kon,→cj]* indicates that the model captures morphological agreement between coordinate clauses in non-trivial constructions of the kind: *spielen die Kinder im Garten und singen / the children play in the garden and sing*. In Italian, high attention on the path *[→obj,→comp,→prep]* denotes cases where the semantic relatedness between a verb and its object does not stop at the object's head, but percolates down to a prepositional phrase attached to it (*passò buona parte della sua vita / spent a large part of his life*). Interestingly, both local n-gram context and immediate dependency context would have missed these relations.

While much remains to be explored, our analysis shows that RMN discovers patterns far more complex than pairs of opening and closing brackets, and suggests that the network's hidden state captures to a large extent the underlying structure of text.

6 Sentence Completion Challenge

The Microsoft Research Sentence Completion Challenge (Zweig and Burges, 2012) has recently become a test bed for advancing statistical language modeling. We choose this task to demonstrate the effectiveness of our RMN in capturing sentence coherence. The test set consists of 1,040 sentences selected from five Sherlock Holmes novels by Conan Doyle. For each sentence, a content word is removed and the task is to identify the correct missing word among five given candidates. The task is carefully designed to be non-solvable for local language models such as n-gram models. The best reported result is 58.9% accuracy (Mikolov et al., 2013)[4] which is far below human accuracy of 91% (Zweig and Burges, 2012).

As baseline we use a stacked three-layer LSTM. Our models are two variants of RM(+tM-g), each consisting of three LSTM layers followed by a MB. The first variant (unidirectional-RM) uses n words preceding the word to predict, the second (bidirectional-RM) uses the n words preceding *and* the n words following the word to predict, as MB input. We include bidirectional-RM in the experiments to show the flexibility of utilizing future context in RMN.

We train all models on the standard training data of the challenge, which consists of 522 novels from Project Gutenberg, preprocessed similarly to (Mnih and Kavukcuoglu, 2013). After sentence splitting, tokenization and lowercasing, we randomly select 19,000 sentences for validation. Training and validation sets include 47M and 190K tokens respectively. The vocabulary size is about 64,000.

We initialize and train all the networks as described in Section 4.2. Moreover, for regularization, we place dropout (Srivastava et al., 2014) after each LSTM layer as suggested in (Pham et al., 2014). The dropout rate is set to 0.3 in all the experiments.

Table 4 summarizes the results. It is worth to mention that our LSTM baseline outperforms a dependency RNN making explicit use of syntactic information (Mirowski and Vlachos, 2015) and performs on par with the best published result (Mikolov et al., 2013). Our unidirectional-RM sets a new state of the art for the Sentence Completion Challenge with 69.2% accuracy. Under the same setting of d we observe that using bidirectional context does not

[4] The authors use a weighted combination of skip-ngram and RNN without giving any technical details.

The stage lost a fine ____ , even as science lost an acute reasoner , when he became a specialist in crime
a) linguist b) hunter c) **actor**♣ d) estate e) horseman♢

What passion of hatred can it be which leads a man to ____ in such a place at such a time

That is his ____ fault , but on the whole he's a good worker
a) **main** b) successful c) mother's♣ d) generous e) favourite♢

Figure 7: Examples of sentence completion. The correct option is in boldface. Predictions by the LSTM baseline and by our best RMN model are marked by ♢ and ♣ respectively.

Model	n	d	**Accuracy**
LSTM	–	256	56.0
unidirectional-RM	15	256	64.3
	15	512	**69.2**
bidirectional-RM	7	256	59.6
	10	512	67.0

Table 4: Accuracy on 1,040 test sentences. We use perplexity to choose the best model. Dimension of word embeddings, LSTM hidden states, and gate g parameters are set to d.

bring additional advantage to the model. Mnih and Kavukcuoglu (2013) also report a similar observation. We believe that RMN may achieve further improvements with hyper-parameter optimization.

Figure 7 shows some examples where our best RMN beats the already very competitive LSTM baseline, or where both models fail. We can see that in some sentences the necessary clues to predict the correct word occur only to its *right*. While this seems to conflict with the worse result obtained by the bidirectional-RM, it is important to realize that prediction corresponds to the whole sentence probability. Therefore a badly chosen word can have a negative effect on the score of future words. This appears to be particularly true for the RMN due to its ability to directly access (distant) words in the history. The better performance of unidirectional versus bidirectional-RM may indicate that the attention in the memory block can be distributed reliably only on words that have been already seen and summarized by the current LSTM state. In future work, we may investigate whether different ways to combine two RMNs running in opposite directions further improve accuracy on this challenging task.

7 Conclusion

We have proposed the Recurrent Memory Network (RMN), a novel recurrent architecture for language modeling. Our RMN outperforms LSTMs in terms of perplexity on three large dataset and allows us to analyze its behavior from a linguistic perspective. We find that RMNs learn important co-occurrences regardless of their distance. Even more interestingly, our RMN implicitly captures certain dependency types that are important for word prediction, despite being trained without any syntactic information. Finally RMNs obtain excellent performance at modeling sentence coherence, setting a new state of the art on the challenging sentence completion task.

Abstract

This paper presents a novel latent variable recurrent neural network architecture for jointly modeling sequences of words and (possibly latent) discourse relations between adjacent sentences. A recurrent neural network generates individual words, thus reaping the benefits of discriminatively-trained vector representations. The discourse relations are represented with a latent variable, which can be predicted or marginalized, depending on the task. The resulting model can therefore employ a training objective that includes not only discourse relation classification, but also word prediction. As a result, it outperforms state-of-the-art alternatives for two tasks: implicit discourse relation classification in the Penn Discourse Treebank, and dialog act classification in the Switchboard corpus. Furthermore, by marginalizing over latent discourse relations at test time, we obtain a discourse informed language model, which improves over a strong LSTM baseline.

1 Introduction

Natural language processing (NLP) has recently experienced a neural network "tsunami" (Manning, 2016). A key advantage of these neural architectures is that they employ discriminatively-trained distributed representations, which can capture the meaning of linguistic phenomena ranging from individual words (Turian et al., 2010) to longer-range linguistic contexts at the sentence level (Socher et al., 2013) and beyond (Le and Mikolov, 2014). Because they are discriminatively trained, these methods can learn representations that yield very accurate predictive models (e.g., Dyer et al, 2015).

However, in comparison with the probabilistic graphical models that were previously the dominant machine learning approach for NLP, neural architectures lack flexibility. By treating linguistic annotations as random variables, probabilistic graphical models can marginalize over annotations that are unavailable at test or training time, elegantly modeling multiple linguistic phenomena in a joint framework (Finkel et al., 2006). But because these graphical models represent uncertainty for every element in the model, adding too many layers of latent variables makes them difficult to train.

In this paper, we present a hybrid architecture that combines a recurrent neural network language model with a latent variable model over shallow discourse structure. In this way, the model learns a discriminatively-trained distributed representation of the local contextual features that drive word choice at the intra-sentence level, using techniques that are now state-of-the-art in language modeling (Mikolov et al., 2010). However, the model treats shallow discourse structure — specifically, the relationships between pairs of adjacent sentences — as a latent variable. As a result, the model can act as both a discourse relation classifier and a language model. Specifically:

- If trained to maximize the conditional likelihood of the discourse relations, it outperforms state-of-the-art methods for both implicit discourse relation classification in the Penn Discourse Treebank (Rutherford and Xue, 2015) and dialog act classification in Switch-

Proceedings of NAACL-HLT 2016, pages 332–342,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

board (Kalchbrenner and Blunsom, 2013). The model learns from both the discourse annotations as well as the language modeling objective, unlike previous recursive neural architectures that learn only from annotated discourse relations (Ji and Eisenstein, 2015).

- If the model is trained to maximize the joint likelihood of the discourse relations and the text, it is possible to marginalize over discourse relations at test time, outperforming language models that do not account for discourse structure.

In contrast to recent work on continuous latent variables in recurrent neural networks (Chung et al., 2015), which require complex variational autoencoders to represent uncertainty over the latent variables, our model is simple to implement and train, requiring only minimal modifications to existing recurrent neural network architectures that are implemented in commonly-used toolkits such as Theano, Torch, and CNN.

We focus on a class of *shallow discourse relations*, which hold between pairs of adjacent sentences (or utterances). These relations describe how the adjacent sentences are related: for example, they may be in CONTRAST, or the latter sentence may offer an answer to a question posed by the previous sentence. Shallow relations do not capture the full range of discourse phenomena (Webber et al., 2012), but they account for two well-known problems: implicit discourse relation classification in the Penn Discourse Treebank, which was the 2015 CoNLL shared task (Xue et al., 2015); and dialog act classification, which characterizes the structure of interpersonal communication in the Switchboard corpus (Stolcke et al., 2000), and is a key component of contemporary dialog systems (Williams and Young, 2007). Our model outperforms state-of-the-art alternatives for implicit discourse relation classification in the Penn Discourse Treebank, and for dialog act classification in the Switchboard corpus.

2 Background

Our model scaffolds on recurrent neural network (RNN) language models (Mikolov et al., 2010), and recent variants that exploit multiple levels of linguistic detail (Ji et al., 2015; Lin et al., 2015).

RNN Language Models Let us denote token n in a sentence t by $y_{t,n} \in \{1 \ldots V\}$, and write $\boldsymbol{y}_t = \{y_{t,n}\}_{n \in \{1 \ldots N_t\}}$ to indicate the sequence of words in sentence t. In an RNN language model, the probability of the sentence is decomposed as,

$$p(\boldsymbol{y}_t) = \prod_{n}^{N_t} p(y_{t,n} \mid \boldsymbol{y}_{t,<n}), \tag{1}$$

where the probability of each word $y_{t,n}$ is conditioned on the entire preceding sequence of words $\boldsymbol{y}_{t,<n}$ through the summary vector $\boldsymbol{h}_{t,n-1}$. This vector is computed recurrently from $\boldsymbol{h}_{t,n-2}$ and from the *embedding* of the current word, $\mathbf{X}_{y_{t,n-1}}$, where $\mathbf{X} \in \mathbb{R}^{K \times V}$ and K is the dimensionality of the word embeddings. The language model can then be summarized as,

$$\boldsymbol{h}_{t,n} = \boldsymbol{f}(\mathbf{X}_{y_{t,n}}, \boldsymbol{h}_{t,n-1}) \tag{2}$$

$$p(y_{t,n} \mid \boldsymbol{y}_{t,<n}) = \text{softmax}\left(\mathbf{W}_o \boldsymbol{h}_{t,n-1} + \boldsymbol{b}_o\right), \tag{3}$$

where the matrix $\mathbf{W}_o \in \mathbb{R}^{V \times K}$ defines the *output embeddings*, and $\boldsymbol{b}_o \in \mathbb{R}^V$ is an offset. The function $\boldsymbol{f}(\cdot)$ is a deterministic non-linear transition function. It typically takes an element-wise non-linear transformation (e.g., $\tanh$) of a vector resulting from the sum of the word embedding and a linear transformation of the previous hidden state.

The model as described thus far is identical to the recurrent neural network language model (RNNLM) of Mikolov et al. (2010). In this paper, we replace the above simple hidden state units with the more complex Long Short-Term Memory units (Hochreiter and Schmidhuber, 1997), which have consistently been shown to yield much stronger performance in language modeling (Pham et al., 2014). For simplicity, we still use the term RNNLM in referring to this model.

Document Context Language Model One drawback of the RNNLM is that it cannot propagate long-range information between the sentences. Even if we remove sentence boundaries, long-range information will be attenuated by repeated application of the non-linear transition function. Ji et al. (2015) propose the Document Context Language Model (DCLM) to address this issue. The core idea is to represent context with *two* vectors: $\boldsymbol{h}_{t,n}$, representing *intra*-sentence word-level context, and $\boldsymbol{c}_t$, representing *inter*-sentence context. These two vectors

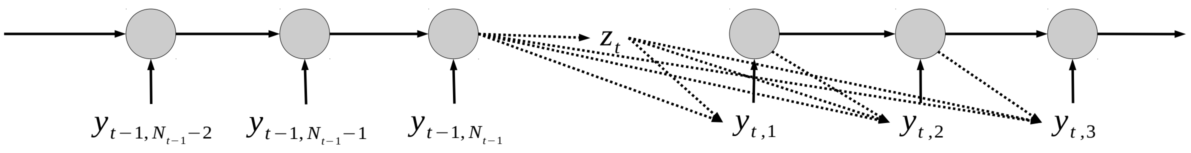

Figure 1: A fragment of our model with latent variable z_t, which only illustrates discourse information flow from sentence $(t-1)$ to t. The information from sentence $(t-1)$ affects the distribution of z_t and then the words prediction within sentence t.

$$p(y_{t,n+1} \mid z_t,\ \boldsymbol{y}_{t,<n},\ \boldsymbol{y}_{t-1}) = g\Big(\underbrace{\mathbf{W}_o^{(z_t)}\boldsymbol{h}_{t,n}}_{\substack{\text{relation-specific}\\ \text{intra-sentential context}}} + \underbrace{\mathbf{W}_c^{(z_t)}\boldsymbol{c}_{t-1}}_{\substack{\text{relation-specific}\\ \text{inter-sentential context}}} + \underbrace{\boldsymbol{b}_o^{(z_t)}}_{\substack{\text{relation-specific}\\ \text{bias}}} \Big) \qquad (4)$$

Figure 2: Per-token generative probabilities in the discourse relation language model

are then linearly combined in the generation function for word $y_{t,n}$,

$$\begin{aligned} & p(y_{t,n} \mid \boldsymbol{y}_{t,<n}, \boldsymbol{y}_{<t}) \\ & = \text{softmax}\left(\mathbf{W}_o \boldsymbol{h}_{t,n-1} + \mathbf{W}_c \boldsymbol{c}_{t-1} + \boldsymbol{b}_o\right), \end{aligned} \qquad (5)$$

where $\boldsymbol{c}_{t-1}$ is set to the last hidden state of the previous sentence. Ji et al. (2015) show that this model can improve language model perplexity.

3 Discourse Relation Language Models

We now present a probabilistic neural model over sequences of words and shallow discourse relations. Discourse relations z_t are treated as latent variables, which are linked with a recurrent neural network over words in a *latent variable recurrent neural network* (Chung et al., 2015).

3.1 The Model

Our model (see Figure 1) is formulated as a two-step generative story. In the first step, context information from the sentence $(t-1)$ is used to generate the discourse relation between sentences $(t-1)$ and t,

$$p(z_t \mid \boldsymbol{y}_{t-1}) = \text{softmax}\left(\boldsymbol{U}\boldsymbol{c}_{t-1} + \boldsymbol{b}\right), \qquad (6)$$

where z_t is a random variable capturing the discourse relation between the two sentences, and $\boldsymbol{c}_{t-1}$ is a vector summary of the contextual information from sentence $(t-1)$, just as in the DCLM (Equation 5). The model maintains a default context vector $\boldsymbol{c}_0$ for the first sentences of documents, and treats it as a parameter learned with other model parameters during training.

In the second step, the sentence $\boldsymbol{y}_t$ is generated, conditioning on the preceding sentence $\boldsymbol{y}_{t-1}$ and the discourse relation z_t:

$$p(\boldsymbol{y}_t \mid z_t, \boldsymbol{y}_{t-1}) = \prod_{n}^{N_t} p(y_{t,n} \mid \boldsymbol{y}_{t,<n}, \boldsymbol{y}_{t-1}, z_t), \qquad (7)$$

The generative probability for the sentence $\boldsymbol{y}_t$ decomposes across tokens as usual (Equation 7). The per-token probabilities are shown in Equation 4, in Figure 2. Discourse relations are incorporated by parameterizing the output matrices $\mathbf{W}_o^{(z_t)}$ and $\mathbf{W}_c^{(z_t)}$; depending on the discourse relation that holds between $(t-1)$ and t, these matrices will favor different parts of the embedding space. The bias term $\boldsymbol{b}_o^{(z_t)}$ is also parametrized by the discourse relation, so that each relation can favor specific words.

Overall, the joint probability of the text and discourse relations is,

$$p(\boldsymbol{y}_{1:T}, \boldsymbol{z}_{1:T}) = \prod_{t}^{T} p(z_t \mid \boldsymbol{y}_{t-1}) \times p(\boldsymbol{y}_t \mid z_t, \boldsymbol{y}_{t-1}). \qquad (8)$$

If the discourse relations z_t are not observed, then our model is a form of latent variable recurrent neural network (LVRNN). Connections to recent work on LVRNNs are discussed in § 6; the key difference is that the latent variables here correspond to linguistically meaningful elements, which we may wish to predict or marginalize, depending on the situation.

Parameter Tying As proposed, the Discourse Relation Language Model has a large number of parameters. Let K, H and V be the input dimension, hidden dimension and the size of vocabulary in language modeling. The size of each prediction matrix $\mathbf{W}_o^{(z)}$ and $\mathbf{W}_c^{(z)}$ is $V \times H$; there are two such matrices for each possible discourse relation. We reduce the number of parameters by factoring each of these matrices into two components:

$$\mathbf{W}_o^{(z)} = \mathbf{W}_o \cdot \mathbf{V}^{(z)}, \quad \mathbf{W}_c^{(z)} = \mathbf{W}_c \cdot \mathbf{M}^{(z)}, \quad (9)$$

where $\mathbf{V}^{(z)}$ and $\mathbf{M}^{(z)}$ are relation-specific components for intra-sentential and inter-sentential contexts; the size of these matrices is $H \times H$, with $H \ll V$. The larger $V \times H$ matrices $\mathbf{W}_o$ and $\mathbf{W}_c$ are shared across all relations.

3.2 Inference

There are two possible inference scenarios: inference over discourse relations, conditioning on words; and inference over words, marginalizing over discourse relations.

Inference over Discourse Relations The probability of discourse relations given the sentences $p(\boldsymbol{z}_{1:T} \mid \boldsymbol{y}_{1:T})$ is decomposed into the product of probabilities of individual discourse relations conditioned on the adjacent sentences $\prod_t p(z_t \mid \boldsymbol{y}_t, \boldsymbol{y}_{t-1})$. These probabilities are computed by Bayes' rule:

$$p(z_t \mid \boldsymbol{y}_t, \boldsymbol{y}_{t-1}) = \frac{p(\boldsymbol{y}_t \mid z_t, \boldsymbol{y}_{t-1}) \times p(z_t \mid \boldsymbol{y}_{t-1})}{\sum_{z'} p(\boldsymbol{y}_t \mid z', \boldsymbol{y}_{t-1}) \times p(z' \mid \boldsymbol{y}_{t-1})}. \quad (10)$$

The terms in each product are given in Equations 6 and 7. Normalizing involves only a sum over a small finite number of discourse relations. Note that inference is easy in our case because all words are observed and there is no probabilistic coupling of the discourse relations.

Inference over Words In discourse-informed language modeling, we marginalize over discourse relations to compute the probability of a sequence of sentence $\boldsymbol{y}_{1:T}$, which can be written as,

$$p(\boldsymbol{y}_{1:T}) = \prod_t^T \sum_{z_t} p(z_t \mid \boldsymbol{y}_{t-1}) \times p(\boldsymbol{y}_t \mid z_t, \boldsymbol{y}_{t-1}), \quad (11)$$

because the word sequences are observed, decoupling each z_t from its neighbors z_{t+1} and z_{t-1}. This decoupling ensures that we can compute the overall marginal likelihood as a product over local marginals.

3.3 Learning

The model can be trained in two ways: to maximize the joint probability $p(\boldsymbol{y}_{1:T}, \boldsymbol{z}_{1:T})$, or to maximize the conditional probability $p(\boldsymbol{z}_{1:T} \mid \boldsymbol{y}_{1:T})$. The joint training objective is more suitable for language modeling scenarios, and the conditional objective is better for discourse relation prediction. We now describe each objective in detail.

Joint likelihood objective The joint likelihood objective function is directly adopted from the joint probability defined in Equation 8. The objective function for a single document with T sentences or utterances is,

$$\begin{aligned}\ell(\boldsymbol{\theta}) = &\sum_t^T \log p(z_t \mid \boldsymbol{y}_{t-1}) \\ &+ \sum_n^{N_t} \log p(y_{t,n} \mid \boldsymbol{y}_{t,<n}, \boldsymbol{y}_{t-1}, z_t), \quad (12)\end{aligned}$$

where $\boldsymbol{\theta}$ represents the collection of all model parameters, including the parameters in the LSTM units and the word embeddings.

Maximizing the objective function $\ell(\boldsymbol{\theta})$ will jointly optimize the model on both language language and discourse relation prediction. As such, it can be viewed as a form of multi-task learning (Caruana, 1997), where we learn a shared representation that works well for discourse relation prediction and for language modeling. However, in practice, the large vocabulary size and number of tokens means that the language modeling part of the objective function tends to dominate.

Conditional objective This training objective is specific to the discourse relation prediction task, and based on Equation 10 can be written as:

$$\begin{aligned}\ell_r(\boldsymbol{\theta}) = &\sum_t^T \log p(z_t \mid \boldsymbol{y}_{t-1}) + \log p(\boldsymbol{y}_t \mid z_t, \boldsymbol{y}_{t-1}) \\ &- \log \sum_{z'} p(z' \mid \boldsymbol{y}_{t-1}) \times p(\boldsymbol{y}_t \mid z', \boldsymbol{y}_{t-1}) \\ &\quad (13)\end{aligned}$$

The first line in Equation 13 is the same as $\ell(\boldsymbol{\theta})$, but the second line reflects the normalization over all possible values of z_t. This forces the objective function to attend specifically to the problem of maximizing the conditional likelihood of the discourse relations and treat language modeling as an auxiliary task (Collobert et al., 2011).

3.4 Modeling limitations

The discourse relation language model is carefully designed to decouple the discourse relations from each other, after conditioning on the words. It is clear that text documents and spoken dialogues have sequential discourse structures, and it seems likely that modeling this structure could improve performance. In a traditional hidden Markov model (HMM) generative approach (Stolcke et al., 2000), modeling sequential dependencies is not difficult, because training reduces to relative frequency estimation. However, in the hybrid probabilistic-neural architecture proposed here, training is already expensive, due to the large number of parameters that must be estimated. Adding probabilistic couplings between adjacent discourse relations $\langle z_{t-1}, z_t \rangle$ would require the use of dynamic programming for both training and inference, increasing time complexity by a factor that is quadratic in the number of discourse relations. We did not attempt this in this paper; we do compare against a conventional HMM on the dialogue act prediction task in § 5.

Ji et al. (2015) propose an alternative form of the document context language model, in which the contextual information $\boldsymbol{c}_t$ impacts the hidden state $\boldsymbol{h}_{t+1}$, rather than going directly to the outputs $\boldsymbol{y}_{t+1}$. They obtain slightly better perplexity with this approach, which has fewer trainable parameters. However, this model would couple z_t with *all* subsequent sentences $\boldsymbol{y}_{>t}$, making prediction and marginalization of discourse relations considerably more challenging. Sequential Monte Carlo algorithms offer a possible solution (de Freitas et al., ; Gu et al., 2015), which may be considered in future work.

4 Data and Implementation

We evaluate our model on two benchmark datasets: (1) the Penn Discourse Treebank (Prasad et al., 2008, PDTB), which is annotated on a corpus of Wall Street Journal acticles; (2) the Switchboard dialogue act corpus (Stolcke et al., 2000, SWDA), which is annotated on a collections of phone conversations. Both corpora contain annotations of discourse relations and dialogue relations that hold between adjacent spans of text.

The Penn Discourse Treebank (PDTB) provides a low-level discourse annotation on written texts. In the PDTB, each discourse relation is annotated between two argument spans, `Arg1` and `Arg2`. There are two types of relations: explicit and implicit. Explicit relations are signalled by discourse markers (e.g., "*however*", "*moreover*"), and the span of `Arg1` is almost totally unconstrained: it can range from a single clause to an entire paragraph, and need not be adjacent to either `Arg2` nor the discourse marker. However, automatically classifying these relations is considered to be relatively easy, due to the constraints from the discourse marker itself (Pitler et al., 2008). In addition, explicit relations are difficult to incorporate into language models which must generate each word exactly once. On the contrary, *implicit* discourse relations are annotated only between adjacent sentences, based on a semantic understanding of the discourse arguments. Automatically classifying these discourse relations is a challenging task (Lin et al., 2009; Pitler et al., 2009; Rutherford and Xue, 2015; Ji and Eisenstein, 2015). We therefore focus on implicit discourse relations, leaving to the future work the question of how to apply our modeling framework to explicit discourse relations. During training, we collapse all relation types other than implicit (explicit, ENTREL, and NOREL) into a single dummy relation type, which holds between all adjacent sentence pairs that do not share an implicit relation.

As in the prior work on first-level discourse relation identification (e.g., Park and Cardie, 2012), we use sections 2-20 of the PDTB as the training set, sections 0-1 as the development set for parameter tuning, and sections 21-22 for testing. For preprocessing, we lower-cased all tokens, and substituted all numbers with a special token "*NUM*". To build the vocabulary, we kept the 10,000 most frequent words from the training set, and replaced low-frequency words with a special token "*UNK*". In prior work that focuses on detecting individual relations, balanced training sets are constructed so that there are an equal number of instances with and without each relation type (Park and Cardie, ; Biran and McKeown, 2013; Rutherford and Xue, 2014). In this paper, we target the more challenging multi-way classification problem, so this strategy is not applicable; in any case, since our method deals with entire documents, it is not possible to balance the training set in this way.

The Switchboard Dialog Act Corpus (SWDA) is annotated on the Switchboard Corpus of human-human conversational telephone speech (Godfrey et al., 1992). The annotations label each utterance with one of 42 possible speech acts, such as AGREE, HEDGE, and WH-QUESTION. Because these speech acts form the structure of the dialogue, most of them pertain to both the preceding and succeeding utterances (e.g., AGREE). The SWDA corpus includes 1155 five-minute conversations. We adopted the standard split from Stolcke et al. (2000), using 1,115 conversations for training and nineteen conversations for test. For parameter tuning, we randomly select nineteen conversations from the training set as the development set. After parameter tuning, we train the model on the full training set with the selected configuration. We use the same preprocessing techniques here as in the PDTB.

4.1 Implementation

We use a single-layer LSTM to build the recurrent architecture of our models, which we implement in the CNN package.[1] Our implementation is available on `https://github.com/jiyfeng/drlm`. Some additional details follow.

Initialization Following prior work on RNN initialization (Bengio, 2012), all parameters except the relation prediction parameters $\mathbf{U}$ and $\boldsymbol{b}$ are initialized with random values drawn from the range $[-\sqrt{6/(d_1+d_2)}, \sqrt{6/(d_1+d_2)}]$, where d_1 and d_2 are the input and output dimensions of the parameter matrix respectively. The matrix $\mathbf{U}$ is initialized with random numbers from $[-10^{-5}, 10^{-5}]$ and $\boldsymbol{b}$ is initialized to $\mathbf{0}$.

Learning Online learning was performed using AdaGrad (Duchi et al., 2011) with initial learning rate $\lambda = 0.1$. To avoid the exploding gradient problem, we used norm clipping trick with a threshold of $\tau = 5.0$ (Pascanu et al., 2012). In addition, we used value dropout (Srivastava et al., 2014) with rate 0.5, on the input $\mathbf{X}$, context vector $\boldsymbol{c}$ and hidden state $\boldsymbol{h}$, similar to the architecture proposed by Pham et al. (2014). The training procedure is monitored by the performance on the development set. In our experiments, 4 to 5 epochs were enough.

Hyper-parameters Our model includes two tunable hyper-parameters: the dimension of word representation K, the hidden dimension of LSTM unit H. We consider the values $\{32, 48, 64, 96, 128\}$ for both K and H. For each corpus in experiments, the best combination of K and H is selected via grid search on the development set.

5 Experiments

Our main evaluation is discourse relation prediction, using the PDTB and SWDA corpora. We also evaluate on language modeling, to determine whether incorporating discourse annotations at training time and then marginalizing them at test time can improve performance.

5.1 Implicit discourse relation prediction on the PDTB

We first evaluate our model with implicit discourse relation prediction on the PDTB dataset. Most of the prior work on first-level discourse relation prediction focuses on the "one-versus-all" binary classification setting, but we attack the more general four-way classification problem, as performed by Rutherford and Xue (2015). We compare against the following methods:

Rutherford and Xue (2015) build a set of feature-rich classifiers on the PDTB, and then augment these classifiers with additional automatically-labeled training instances. We compare against their published results, which are state-of-the-art.

Ji and Eisenstein (2015) employ a recursive neural network architecture. Their experimental setting is different, so we re-run their system using the same setting as described in § 4.

5. Joint training	74.0
6. Conditional training	**77.0***

* significantly better than line 4 with $p < 0.01$

Table 2: The results of dialogue act tagging.

Results As shown in Table 1, the conditionally-trained discourse relation language models (DrLM) outperforms all alternatives, on both metrics. While the jointly-trained DrLM is at the same level as the previous state-of-the-art, conditional training on the same model provides a significant additional advantage, indicated by a binomial test.

5.2 Dialogue Act tagging

Dialogue act tagging has been widely studied in both NLP and speech communities. We follow the setup used by Stolcke et al. (2000) to conduct experiments, and adopt the following systems for comparison:

Stolcke et al. (2000) employ a hidden Markov model, with each HMM state corresponding to a dialogue act.

Kalchbrenner and Blunsom (2013) employ a complex neural architecture, with a convolutional network at each utterance and a recurrent network over the length of the dialog. To our knowledge, this model attains state-of-the-art accuracy on this task, outperforming other prior work such as (Webb et al., 2005; Milajevs and Purver, 2014).

Results As shown in Table 2, the conditionally-trained discourse relation language model (DrLM) outperforms all competitive systems on this task. A binomial test shows the result in line 6 is significantly better than the previous state-of-the-art (line 4). All comparisons are against published results, and Macro-F_1 scores are not available. Accuracy is more reliable on this evaluation, since no single class dominates, unlike the PDTB task.

5.3 Discourse-aware language modeling

As a joint model for discourse and language modeling, DrLM can also function as a language model, assigning probabilities to sequences of words while marginalizing over discourse relations. To determine whether discourse-aware language modeling can improve performance, we compare against the following systems:

RNNLM+LSTM This is the same basic architecture as the RNNLM proposed by (Mikolov et al., 2010), which was shown to outperform a Kneser-Ney smoothed 5-gram model on modeling Wall Street Journal text. Following Pham et al. (2014), we replace the Sigmoid nonlinearity with a long short-term memory (LSTM).

DCLM We compare against the Document Context Language Model (DCLM) of Ji et al. (2015). We use the "context-to-output" variant, which is identical to the current modeling approach, except that it is not parametrized by discourse relations. This model achieves strong results on language modeling for small and medium-sized corpora, outperforming RNNLM+LSTM.

Results The perplexities of language modeling on the PDTB and the SWDA are summarized in Table 3. The comparison between line 1 and line 2 shows the benefit of considering multi-sentence context information on language modeling. Line 3 shows that adding discourse relation information

	PDTB			SWDA		
Model	K	H	PPLX	K	H	PPLX
Baseline						
1. RNNLM	96	128	117.8	128	96	56.0
2. DCLM	96	96	112.2	96	96	45.3
Our work						
3. DrLM	64	96	108.3	128	64	39.6

Table 3: Language model perplexities (PPLX), lower is better. The model dimensions K and H that gave best performance on the dev set are also shown.

yields further improvements for both datasets. We emphasize that discourse relations in the test documents are marginalized out, so no annotations are required for the test set; the improvements are due to the disambiguating power of discourse relations in the training set.

Because our training procedure requires discourse annotations, this approach does not scale to the large datasets typically used in language modeling. As a consequence, the results obtained here are somewhat academic, from the perspective of practical language modeling. Nonetheless, the positive results here motivate the investigation of training procedures that are also capable of marginalizing over discourse relations at training time.

6 Related Work

This paper draws on previous work in both discourse modeling and language modeling.

Discourse and dialog modeling Early work on discourse relation classification utilizes rich, handcrafted feature sets (Joty et al., 2012; Lin et al., 2009; Sagae, 2009). Recent representation learning approaches attempt to learn good representations jointly with discourse relation classifiers and discourse parsers (Ji and Eisenstein, 2014; Li et al., 2014). Of particular relevance are applications of neural architectures to PDTB implicit discourse relation classification (Ji and Eisenstein, 2015; Zhang et al., 2015; Braud and Denis, 2015). All of these approaches are essentially classifiers, and take supervision only from the 16,000 annotated discourse relations in the PDTB training set. In contrast, our approach is a probabilistic model over the entire text.

Probabilistic models are frequently used in dialog act tagging, where hidden Markov models have been a dominant approach (Stolcke et al., 2000). In this work, the emission distribution is an n-gram language model for each dialogue act; we use a conditionally-trained recurrent neural network language model. An alternative neural approach for dialogue act tagging is the combined convolutional-recurrent architecture of Kalchbrenner and Blunsom (2013). Our modeling framework is simpler, relying on a latent variable parametrization of a purely recurrent architecture.

Language modeling There are an increasing number of attempts to incorporate document-level context information into language modeling. For example, Mikolov and Zweig (2012) introduce LDA-style topics into RNN based language modeling. Sordoni et al. (2015) use a convolutional structure to summarize the context from previous two utterances as context vector for RNN based language modeling. Our models in this paper provide a unified framework to model the context and current sentence. Wang and Cho (2015) and Lin et al. (2015) construct bag-of-words representations of previous sentences, which are then used to inform the RNN language model that generates the current sentence. The most relevant work is the Document Context Language Model (Ji et al., 2015, DCLM); we describe the connection to this model in § 2. By adding discourse information as a latent variable, we attain better perplexity on held-out data.

Latent variable neural networks Introducing latent variables to a neural network model increases its representational capacity, which is the main goal of prior efforts in this space (Kingma and Welling, 2014; Chung et al., 2015). From this perspective, our model with discourse relations as latent variables shares the same merit. Unlike this prior work, in our approach, the latent variables carry a linguistic interpretation, and are at least partially observed. Also, these prior models employ continuous latent variables, requiring complex inference techniques such as variational autoencoders (Kingma and Welling, 2014; Burda et al., 2016; Chung et al., 2015). In contrast, the discrete latent variables in our model are easy to sum and maximize over.

7 Conclusion

We have presented a probabilistic neural model over sequences of words and shallow discourse relations between adjacent sequences. This model combines positive aspects of neural network architectures with probabilistic graphical models: it can learn discriminatively-trained vector representations, while maintaining a probabilistic representation of the targeted linguistic element: in this case, shallow discourse relations. This method outperforms state-of-the-art systems in two discourse relation detection tasks, and can also be applied as a language model, marginalizing over discourse relations on the test data. Future work will investigate the possibility of learning from partially-labeled training data, which would have at least two potential advantages. First, it would enable the model to scale up to the large datasets needed for competitive language modeling. Second, by training on more data, the resulting vector representations might support even more accurate discourse relation prediction.

Questioning Arbitrariness in Language: a Data-Driven Study of Conventional Iconicity

Ekaterina Abramova
Radboud University Nijmegen
e.abramova@ftr.ru.nl

Raquel Fernández
University of Amsterdam
raquel.fernandez@uva.nl

Abstract

This paper presents a data-driven investigation of *phonesthemes*, phonetic units said to carry meaning associations, thus challenging the traditionally assumed arbitrariness of language. Phonesthemes have received a substantial amount of attention within the cognitive science literature on sound iconicity, but nevertheless remain a controversial and understudied phenomenon. Here we employ NLP techniques to address two main questions: How can the existence of phonesthemes be tested at a large scale with quantitative methods? And how can the meaning arguably carried by a phonestheme be induced automatically from word embeddings? We develop novel methods to make progress on these fronts and compare our results to previous work, obtaining substantial improvements.

1 Introduction

It has long been held in linguistics that since the same concept can be expressed with words whose forms do not resemble each other (e.g., English *dog* vs. Italian *cane* vs. German *Hund*), there is no intrinsic link between how words sound and what they mean. This feature—*arbitrariness*—is often considered a hallmark of human language (Saussure, 1916; Hockett, 1959). At the same time, however, over the last decades, mounting evidence from psycholinguistic studies (Markel and Hamp, 1960; Ohala, 1984; Fordyce, 1989) has shown that speakers do in fact associate words that contain a particular form with certain meaning—that is, there is a degree of *iconicity* in language in addition to arbitrariness, which has been claimed to benefit language learning (Monaghan and Christiansen, 2006; Monaghan et al., 2014).

Non-arbitrary form-meaning associations come in two basic varieties: primary iconicity (also called 'true') and secondary (or 'conventional') iconicity. In the former, the sound is thought to directly resemble the meaning, as in onomatopoeia.[1] In the latter, the relationship is a statistical regularity according to which words that share similar sounds tend to be also similar in meaning, such as a large proportion of English words that end with the sound /-æʃ/ (e.g., *crash*, *slash*, *mash*, *trash*, *dash*) being related to destructive action or collision (Hutchins, 1998). The phonetic units that exhibit conventional meaning regularities of this latter kind are called *phonesthemes* and are the focus of the present paper. In particular, we investigate two main questions: (1) how can the existence of phonesthemes be tested at a large scale by means of a data-driven method? and (2) how can the meaning arguably conveyed by a phonestheme be derived automatically?

Phonesthemes are traditionally distinguished from morphemes in being non-compositional. That is, *unthinkable* can be thought of as being composed of morphemes *un-* (meaning *not*), *think*, and *-able* (meaning *capable of*), all contributing to the overall meaning of "incapable of being thought" and susceptible of being combined with other units with predictable semantic effects (e.g., *un-drinkable, think-er*). On the other hand, *crash* is not con-

[1] Although, the relationship can still be modified by phonetic features of a particular language, e.g., the rooster says *cock-a-doodle-doo* in English but *kikiriki* in German.

Proceedings of NAACL-HLT 2016, pages 343–352,

sidered to be formed compositionally from *cr-* and *-ash*, since these components do not possesses an easily identifiable independent meaning that can be combined productively with other morphemes.

Because phonesthemes challenge defining features of language such as arbitrariness and compositionality, they remain a rather controversial and poorly understood phenomenon. To a large extent, this is due to methodological issues. Early evidence for the existence of phonesthemes consisted primarily in linguists pointing out instances of intuitive correlations between a phonetic unit and the meaning of words containing that unit (Marchand, 1959; Reid, 1967), while early psycholinguistic experiments attempted to elicit meaning definitions for predefined lists of (real or nonsense) words sharing a phonetic unit traditionally considered to be a phonestheme (Fordyce, 1989; Abelin, 1999; Magnus, 2000). More systematic studies have subsequently been carried out by Hutchins (1998) and Bergen (2004), but overall the phenomenon of conventional linguistic iconicity as reflected in phonesthemes remains largely understudied, certainly within the computational linguistics community.

In this paper, we investigate phonesthemes by analyzing their orthographic correlates in a large corpus of written English, leveraging word embeddings constructed with `word2vec` and made available by Baroni et al. (2014). In particular, we make the following contributions:

- We develop a stricter test than previously done in the literature for deciding whether a unit exhibits conventional iconicity.
- We propose a new unsupervised method to induce the meaning conveyed by a phonesthemic unit.
- We evaluate our meaning induction method with new automatic evaluation techniques and compare its performance to a WordNet-based method proposed by Abramova et al. (2013), obtaining a very substantial improvement.
- We additionally evaluate our automatically derived meanings with human judgments collected via a crowdsourcing experiment.

We believe phonesthemes deserve thorough investigation for both theoretical and practical reasons. Theoretically, adding more data-driven methods can substantially enhance work in linguistics and psycholinguistics. Within computational linguistics itself, cross-fertilization with computational morphology (Wang et al., 2012; Marelli and Baroni, 2015), is an exciting avenue to be pursued. With respect to potential applications of automatic phonestheme meaning induction, creative brand naming (Klink, 2000; Özbal and Strapparava, 2012), sentiment analysis (Sokolova and Bobicev, 2009) and construction of more appropriate language teaching materials (Imai et al., 2008) are viable possibilities.

2 Related Work

Psycholinguistic studies on the nature of phonesthemes have shown that people tend to associate certain sounds with a particular meaning. Such studies were conducted on different languages, employing different methods and exhibiting various degrees of scale and systematicity (Fordyce, 1989; Abelin, 1999; Magnus, 2000; Hutchins, 1998). Recently, it has also been shown that phonesthemes affect online implicit language processing (Bergen, 2004) and language learning (Parault and Schwanenflugel, 2006).

What also emerged from these studies is that phonesthemes are not a homogeneous phenomenon. They can vary in terms of the number of words that contain a given phonestheme, their frequencies, the strength of their association with the core meaning of a phonestheme (for example measured as an average of human ratings for all the words that comprise the given phonesthemic cluster) and the regularity of that association (what proportion of words in the whole cluster are highly related to the predicted meaning). However, psycholinguistic data is to some extent ambiguous on how these features of phonesthemes affect their productivity, learnability and their effect on language processing, which could partly be due the methods being employed. For example, in order to determine the regularity of sound-meaning association, Bergen (2004) consults word definitions in Websters 7th collegiate dictionary and counts how many of those words bear the required meaning for a given phonestheme. The procedure requires an intuitive judgment from the experimenter in determining the meaning of a phonestheme and estimating whether a given word has that meaning, and as a result is prone to experimenter bias and does not allow for large-scale testing. Finding a more automatic method for assessing phonestheme features and determining their meaning could thus alleviate this type of research liabilities.

Otis and Sagi (2008) and Abramova et al. (2013) are two studies that attempted to test for the existence of phonesthemes in a corpus-based automatic manner. For both the guiding question was: are words that contain a given phonetic unit, thought to be a phonestheme, more semantically similar than would be expected by chance? Using distributional models they compared the average cosine similarity of the vectors that correspond to phonestheme-bearing words to similarly sized groups of random words. Both studies found support for a sizable proportion of phonetic units tested. However, it could still be questioned whether the comparison was sufficiently strict, given that sets of random words which do not overlap in form have a priori lower chance of being semantically related than sets of words that share a phonestheme. Therefore, in the first part of our study (Section 4) we present a stricter validation method for candidate phonesthemes that also includes considerations related to morphological diversity, which were ignored in previous work.

Abramova et al. (2013) presented the first attempt to automatically assign meaning to sets of phonestheme-bearing words. The authors viewed the task as an instance of unsupervised ontology acquisition in the style of Widdows (2003) and used WordNet to assign over-arching labels to phonesthemic groups of words. While the approach was moderately successful in inducing WordNet labels that were in the direction predicted by the literature for a few phonesthemes (e.g., *gl*-containing words were assigned light-related labels), most phonesthemes did not receive meaningful labels according to the meanings typically associated with phonesthemes in the sound iconicity literature. The authors surmise that the failure could be due to the nature of WordNet, e.g., that it reflects only one type of semantic relation (hypernymy) which might not exhaust the links between words that share a phonestheme. In Section 5, we present a different approach to phonestheme meaning induction that exploits the properties of word embeddings in a fully unsupervised manner and yields substantially better results.

3 Data

Candidate phonesthemes. Following the studies of Hutchins (1998), we compile a list of possible phonesthemes of interest and their respective semantic glosses (more on the latter in Section 5). We will refer to these units as "candidate phonesthemes" because they all have been considered phonesthemes by previous qualitative studies and our aim is to investigate whether their alleged phenesthemic status is warranted quantitatively. Specifically, we focus on two-consonant units in word-initial position, which we will often call prefixes.[2] We focus on the 16 prefix candidate phonesthemes listed in Table 1. Since we work with orthographic correlates of phonetic units, we restrict ourselves to prefixes that have clear orthographic–phonetic mappings, discarding prefixes that allow for variation, such as *sc-/sk-*.[3]

bl-	*cl-*	*cr-*	*dr-*	*fl-*	*gl -*	*gr-*	*sl-*
sm-	*sn-*	*sp-*	*st-*	*sw-*	*tr-*	*tw-*	*wr-*

Table 1: Candidate phonesthemes considered.

Word embeddings. For our experiments, we use existing, high-quality word embeddings created and made available by Baroni et al. (2014).[4] We use the best performing model amongst those tested by Baroni and colleagues, which has been constructed with `word2vec`[5] using the CBOW approach proposed by Mikolov et al. (2013). The model contains 400-dimension vectors generated by considering the 300K most frequent word tokens (without lemmatization) in a large corpus comprising the English Wikipedia, the web-based corpus ukWaC (Baroni et al., 2009), and the BNC (Burnard, 2007).

Unfamiliar or very technical words are unlikely to contribute to the formation of sound-meaning associations (Hutchins, 1998). Accordingly, from the 300K target words present in the distributional model, we discard those that are not recognized by a

[2] Recall, however, that they do not correspond to morphological prefixes.

[3] Such alternation-susceptible prefixes are excluded from all analyses, including the baseline clusters introduced later on in Section 4.

[4] `http://clic.cimec.unitn.it/composes/semantic-vectors.html`

[5] `https://code.google.com/p/word2vec/`

comprehensive off-the-shelf English spell-checking dictionary. This results in a substantial reduction of the target vocabulary: 61,122 tokens remain after the filtering.[6] We use this restricted set of words and corresponding embeddings in all our experiments.

4 Phonestheme Validation

The aim of the first experiment is to investigate which of the candidate prefixes in Table 1 have phonesthemic character and thus evince conventional iconicity.

4.1 Methods

For a prefix to exhibit conventional iconicity, the words sharing that prefix must be semantically similar, while being morphologically diverse—i.e., their semantic relatedness must stem from their shared sound (as captured by the prefix's orthographic form), and not from their sharing of a common morpheme.

Semantic similarity factors. We start by assessing the degree of semantic similarity exhibited by all the words in the vocabulary that share a candidate phonestheme, which we refer to as candidate *phonesthemic clusters*. Our aim is to conduct a stricter test than previously done in the literature. Therefore, rather than comparing candidate phonesthemic clusters to sets of random words, as done by Otis and Sagi (2008) and Abramova et al. (2013), we compare them to words that share a random two-consonant prefix that is non-phonesthemic, i.e., not present in our list of candidate phonesthemes. Our vocabulary contains a total of 307 non-phonesthemic two-consonant prefixes. We refer to the sets of words sharing these prefixes as *baseline clusters*. For our subsequent analyses we use only 191 baseline clusters which contain between 10 and 2000 words. Naturally, such baseline clusters will contain words that are morphologically and hence semantically related, which offers a more challenging baseline.

In our first similarity test, we compute cosine similarities for all possible pairs of words within every phonesthemic and baseline cluster. We then run 191 independent-samples one-tailed Welch's t-tests for each candidate phonestheme, comparing its pair-wise similarity to the pair-wise similarity of each of the baseline clusters. For each candidate phonesthemic cluster, we record how many t-tests indicated significantly higher similarity than the baseline (using a Bonferroni-corrected threshold of $\alpha = .05/191$) as well as the effect size (Cohen's d) of the successful t-tests. Based on the binomial distribution (with α=.05), we obtain a significance threshold of 108—we hence judge a candidate prefix to exhibit significantly higher similarity than the baseline if more than 108 out of 191 t-tests are successful.

Our second similarity test is a check on the overall semantic cohesiveness of the candidate phonesthemic clusters. We calculate the average of all the pairwise similarities within our 191 baseline clusters. We then compare the average pairwise similarity of each candidate phonesthemic cluster to the distribution of the average similarity of the baseline clusters. We expect a positive correlation between the number of successful t-test per candidate phonestheme and their average similarity.

Morphological diversity factors. Since high semantic similarity could be due to the presence of a large proportion of morphologically related words rather than to a sound-meaning association, we want to balance similarity-based factors with considerations about the morphological diversity of the word clusters we investigate. In general, the larger the size of a cluster, the higher the chance for morphological diversity and the lower the chance for finding high semantic cohesiveness. Hence, we would expect a negative correlation between cluster size and semantic similarity.

In previous studies (Hutchins, 1998; Otis and Sagi, 2008) the impact of morphology is counteracted by manually removing morphologically related words before testing for semantic cohesiveness. Since one of our aims is to minimize manual intervention, we instead take into account morphological relatedness at the validation phase. To that end, we implement a crude lemmatization procedure and use the ratio between the number of words and

[6] In particular, we use the spell-checking Python library PyEnchant for English; see `https://pythonhosted.org/pyenchant/api/enchant.html`. Many of the terms removed with this filtering mechanism correspond to non-words or named entities present in the corpus.

the number of lemmas in a cluster to estimate morphological diversity.[7]

The higher this ratio, the lower the morphological diversity—with the maximum value being equal to the size of the cluster when all words are reducible to a single lemma. We calculate this proxy of morphological diversity for candidate phonesthemic clusters and baseline clusters.

Validation constraints. Given the factors described above, we judge a candidate prefix to be a phonestheme if all the following conditions hold:

- *pairwise semantic similarity* is significantly higher than the baseline (according to our first semantic similarity analysis test)
- *average effect size* (Cohen's d) of pairwise similarity tests is at least 0.2
- *average semantic similarity* is higher than 2 standard errors above the average baseline similarity ($\mu = 0.1260, SE = 0.0038$)
- *ratio words/lemmas* is lower than 3 standard errors above the average ratio calculated for baseline clusters ($\mu = 2.93, SE = 0.0615$)

We have chosen each of the thresholds to be reasonably strong but not too restrictive since we rely on a combination of constraints. We deemed an average effect size of 0.2 sufficient given the strictness of our comparison method. The average semantic similarity of the phonesthemic cluster was required to be at least 2 standard errors above average similarity of the baseline clusters to approximate the conventional one-tailed alpha level of 0.025. Finally, a stricter threshold of 3 standard errors was chosen for the lemma ratio just to exclude cases of prefixes that have abnormally low morphological diversity. A stricter condition (requiring high diversity) does not seem justified since there is no reason to expect phonestheme-bearing words to be *more* morphologically diverse than average. The candidate phonestheme was judged to be significant when all constraints were simultaneously satisfied.

4.2 Results

We apply the validation methods to our data. As a sanity check, we test whether the information encoded in the word embeddings is consistent with the data used in previous experiments: Indeed, the average similarity of the 16 candidate prefixes tested is positively correlated with the human ratings for semantic cohesiveness collected by Hutchins (1998) ($r = .46$), and with the similarity values reported by Otis and Sagi (2008) ($r = .68$) and Abramova et al. (2013) ($r = .58$).[8]

As predicted, the correlation between the average number of successful t-tests and average similarity is high ($r = .93$), suggesting that both methods are equally valid for evaluating semantic cohesiveness of phonesthemic clusters. Cluster size (both raw and as the number of lemmas) is negatively correlated with all semantic similarity measures, i.e. average pairwise similarity, average number of successful t-tests, and average effect size ($r \approx -.7$). This is consistent with the experimental finding by Hutchins (1998), who obtained lower human ratings for larger clusters of words.

Regarding evidence for conventional iconicity, the following six prefixes meet all our validation constraints: *bl-*, *gl-*, *sm-*, *sn-*, *sw-*, and *tw-*. Of the remaining 10 prefixes tested, 3 fail all constraints (*cl-*, *cr-*, *tr-*), 3 fail only the morphological diversity constraint (*gr-*, *sp-*, *st-*), and the rest fail some combination of constraints.[9] The 6 validated prefixes are a proper subset of the candidate phonesthemes validated according to the less strict methods used in earlier approaches: Otis and Sagi (2008) found support for *dr-* and *wr-* in addition to our 6 supported phonesthemes and Abramova et al. (2013) discarded only *cr-*, *sp-*, and *tr-* amongst our 16 candidates. This shows that our proposed validation procedure provides a compatible as well as stricter test for evidence of phonesthemic conventional iconicity.

5 Phonestheme Meaning Induction

The quantitative results presented so far show that, according to our validation constraints, some can-

[7] Since our data consists of word embeddings (generalizing over contexts), an off-the-shelf lemmatizer is not effective. Instead we implement a lemmatizer dictionary based on the raw and lemmatized versions of the British National Corpus (Burnard, 2007). The lemma is retrieved if a given word is in the dictionary. Otherwise, we apply two state-of-the-art stemmers, first Lancaser, then Porter (this order was chosen after qualitative examination of a few examples).

[8] Recall that each of these studies uses a different corpus.

Table 2: Meaning glosses from Hutchins (1998, pp. 66–70) for the six validated phonesthemic prefixes, with example words.

didate phonesthemes do have phonesthemic character: they are present in words that are semantically similar while not being highly morphologically related. But what is the 'meaning' that these phonetic units convey? In this section, we aim at investigating whether the kind of meanings that have been informally proposed for these units in the sound iconicity literature can be derived using fully unsupervised methods.

In addition, we present ways for automatically evaluating the derived meanings, and finally conduct a human evaluation experiment via crowdsourcing.

5.1 Methods

Gold standard. We construct a set of gold standard meaning labels for each validated phonestheme by taking as a starting point the informal glosses provided by Hutchins (1998), who, in turn, compiled them by inspecting previous literature by Firth (1930), Marchand (1959), Wescott (1971) and others. The glosses for our validated phonesthemes are given in Table 2.[10] From each gloss, we extract the content words (ignoring words that bear the given phonestheme to avoid circular results) and manually discard words that play only an instrumental role in the definition. For example, in the following gloss for the phonestheme *sn-*, we keep the words in italics and discard the rest: "related to the *nose*, or *breathing*; or by metaphorical extension to snobbishness, *inquisitiveness*". Since the resulting lists of words are to some extent arbitrary (derived from intuitions of a single scholar), we extend them by manually adding synonyms of each of the initial seed words until each phonestheme is associated with 25 gold labels.[11]

Meaning induction. We generate an abstract meaning representation for a phonestheme by computing the centroid of the phonestheme-bearing word cluster. Our method for inducing the core meaning conveyed by a phonestheme is then very simple: We extract the nearest neighbors of the phonestheme centroid, with the constraint that these neighboring words cannot be members of the cluster themselves (i.e., must not exhibit the prefix in question). This method outputs an ordered set of words or *meaning labels*, which we can then evaluate against the gold standard labels.

As described in Section 2, the only previous attempt at automatically deriving the meaning of phonesthemes is due to Abramova et al. (2013). Their approach is inspired by the work of Widdows (2003) on ontology acquisition and it consists in assigning to a phonesthemic cluster the WordNet synsets that subsume as many as possible of the cluster words as closely as possible (i.e., within as few as possible intervening levels in the WordNet hierarchy). As discussed in that paper, this method does not only have the disadvantage of relying on a handcrafted ontology. Other shortcomings include WordNet's limited coverage in terms of vocabulary and type of semantic relations considered (mostly, hyponymy and synonymy).

For comparison purposes, we apply the WordNet meaning induction method of Abramova et al. (2013) and compare its performance to the unsupervised centroid method we propose.

[10] The semantic glosses for the remaining candidate phonesthemes can be found at `http://tinyurl.com/phonesthemes-naacl2016`.

[11] We consult an online edition of Roget's thesaurus (`thesaurus.com`) and retrieve only the synonyms that correspond to the relevant sense of a seed word, e.g., *light* in the sense of *illuminated*, not in the sense of *blond*.

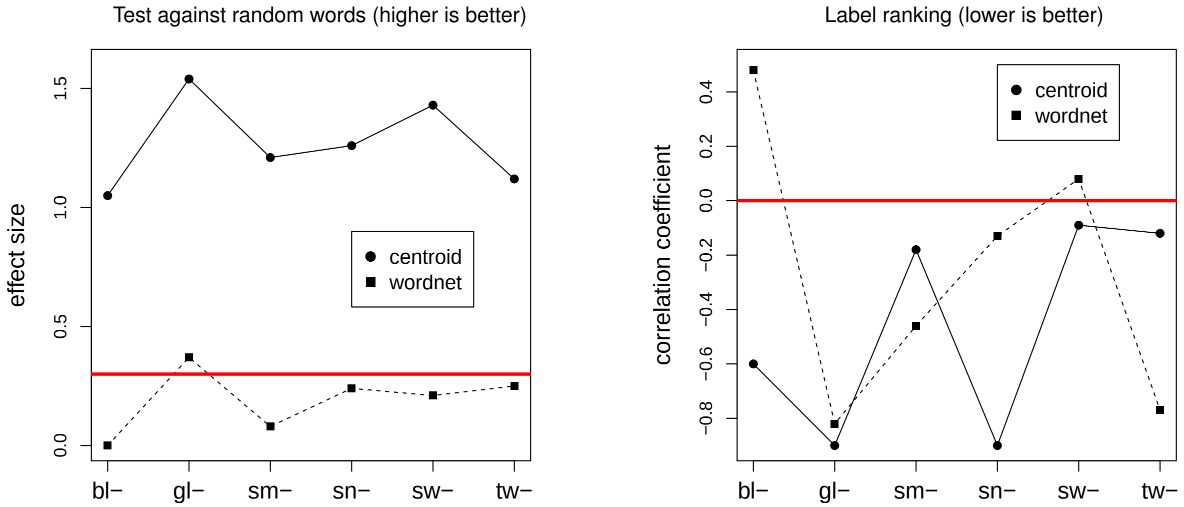

Figure 1: Evaluation of meaning induction methods. Left: only labels induced for prefixes above the horizontal line are significantly better than random labels. Right: negative coefficient scores shown below the line indicate better labels at the top of the list.

Automatic evaluation measures. Abramova et al. (2013) only offer an informal qualitative evaluation of their WordNet-based meaning labels. Here we propose two complementary ways of quantitatively evaluating induced phonesthemic meanings.

For our first meaning label evaluation test, we use a Monte Carlo analysis to determine whether generated labels are closer in vector space to gold labels than random sets of words. More specifically, for each phonesthemic cluster, we compute the *generated–gold similarities*, i.e., pairwise cosine similarities between all the generated labels and the gold set. We then create 100 sets of words, each composed of 25 words randomly drawn from the vocabulary and compute the *random–gold similarities*, i.e., pairwise cosine similarities between these sets of random words and the gold set. Next, we run 100 independent-samples one-tailed Welch's t-tests recording how many t-tests indicated significantly higher generated-gold similarity than random-gold (using a Bonferroni-corrected threshold of $\alpha = .05/100$). We also record the effect sizes (Cohen's d) of the successful t-tests. We repeat the procedure 3 times and take the average of these measures. Based on the binomial distribution (with $\alpha = .05$ and $p = .5$), we judge obtaining at least 59 successful t-tests to indicate that the generated labels are better than random baseline at capturing the phonesthemic meaning.

Our second evaluation test exploits the fact that both our centroid method and the WordNet method output ordered sets of labels (from more to less suitable). We are interested in testing whether the generated meaning labels are more similar to the gold labels the closer they are to the top of the list. To that end, we again compute the pairwise average similarity of each generated label with the gold label set and look at the correlation of that measure with the position k of the generated label. We expect similarity to decrease as k increases: Hence a strongly negative correlation indicates that the method retrieves the best labels first.

5.2 Results

Automatic analysis. We compare the meaning labels induced with our unsupervised centroid method to those generated with the WordNet method. An overview of the results can be seen in Figure 1. Regarding the first label evaluation test (*generated–gold similarities* vs. *random–gold similarities*; left plot in the figure), centroid overwhelmingly outperforms WordNet: Our method obtains significant results with high effect size for all phonestheme prefixes considered, while with the WordNet method only the labels derived for *gl-* are significantly more similar to the gold standard than random words.[12]

Regarding the order-sensitive evaluation measure

[12] In line with the informal evaluation by Abramova et al. (2013), who find that their meaning labels only seem to make sense for *gl-*.

(ranking of induced labels, right plot in Figure 1), with the centroid method we obtain negative correlations for all phonesthemes, although rather weak for *sw- tw-*, and *sm-*. This shows that the top induced labels tend to be closer to the gold meaning. Although the WordNet method again obtains results that are poorer overall, there are strong negative correlations for two phonesthemes: *gl-* and *tw-*.

Taken together, the results indicate that the WordNet method might be able to generate a few of good labels at the top of the list, especially when these labels are associated with the phonestheme-bearing words by hypernymy (e.g., the top *gl-* labels are *brightness, flash, radiance, lightness, look*). However, the remaining labels are mostly generic concepts such as *entity* and *object*, which do not produce significant results when compared as a group to the gold labels. The centroid method produces better labels overall as well as better labels at the top of the list. For example, the top *gl-* labels are *shimmered, twinkled, satiny* but it is also able to capture the meaning of other phonesthemes: the pejorative *sm-* receives *stunk* and *leered* as the top two and twisting and oscillating *tw-*'s top label is *waggled*.

Human evaluation. In addition to the automatic label evaluation procedures we have developed, we test our induced meaning labels against human judgments. What we aim at testing here is whether the semantic closeness to the gold standard meaning that we have been able to detect in vector space can actually be perceived by speakers.

We conducted a data collection study using the crowdsourcing platform CrowdFlower.[13] To prepare the stimuli, for each of the six validated phonesthemes we selected the 10 most frequent gold labels,[14] the 10 top labels induced with our centroid method, and 10 words randomly drawn from the vocabulary, with a BNC frequency of at least 100 to try to minimize the presence of words possibly unknown to the participants. The 100 cut-off is justified given that the average frequency of the gold labels is not significantly higher than the average frequency of all words above this threshold ($t = 1.876$, $p < 0.05$).

Prefix	AvgCount	Stats
bl-	5.53	$t(29) = 1.35$
gl-	6.57	$t(29) = 4.37$**
sm-	5.93	$t(29) = 2.04$*
sn-	6.7	$t(29) = 4.12$**
sw-	4.93	$t(29) = -0.18$
tw-	7.8	$t(29) = 5.66$**

Table 3: Results of human evaluation: avg. number of times an induced label was selected (N=30). *=p<0.05, **=p<0.001

An annotation item consisted of the set of gold words and 10 pairs of induced-vs-random labels (randomized in order). The participants were asked to judge which of the words in each pair was more related to the set of gold words.[15] We constructed 10 annotation items per phonestheme (including the same top 10 induced labels but paired with different random words) and for each annotation item we collected judgments from three different subjects (thus $N = 30$ items per phonestheme).

To analyze the results, we counted how many times an automatically induced label was selected as more similar to the gold label set than a random word. We performed a t-test with an alternative hypothesis that the mean number of selected induced labels per item is greater than 5 (i.e., greater than chance since there were 10 pairs to be judged per item). Automatically induced labels for 4 out of 6 phonesthemes (*gl-*, *sm-*, *sn-* and *tw-*) were judged to be related to the gold meaning to a higher degree than random words. Detailed results are in Table 3.

The fact that we obtain significant results indicates that our generated labels are meaningful not only according to automatic evaluation measures but also in terms of what speakers can perceive. However, the pattern of which phonesthemic labels receive better human judgments is somewhat less clear. For example, the appropriateness of the *gl-* labels is highly significant according to human judgment as well as both automatic tests (effect size and average similarity correlation with k). At the same time, while the *sw-* labels achieve a high effect size (see left plot in Figure 1), they are not judged signif-

[15] A screenshot of the instructions given to the participants can be found at http://tinyurl.com/phonesthemes-naacl2016.

icant in our human study. The pattern is reversed for *tw-*. Whether this exposes a real difference in sensitivity to phonesthemic meanings in human judgments compared to vector-based methods, remains an open question.

6 Conclusions

The analysis we have presented in this paper confirms that the connection between sound and meaning is not always entirely arbitrary and shows that this can be detected using the properties of word embeddings. We find, in line with previous computational and psycholinguistic studies, that words that share certain phonetic prefixes without being morphologically related are more semantically similar that would be expected by chance. In particular, our phonestheme validation procedure is stricter compared to previous work since we use sets of words that share a random two-consonant prefix as baseline and, importantly, take into account morphological relatedness. According to our more principled and stricter constraints, the following six consonant prefixes exhibit symptoms of conventional sound iconicity: *bl-*, *gl-*, *sm-*, *sn-*, *sw-*, and *tw-*. The validation method we employ could serve as a starting point for discovering new phonesthemes. For example, we could inquire whether any of the two-consonant clusters that we consider a baseline is in fact a previously unrecognized phonestheme.

The second aspect we have addressed concerns the automatic induction of the meaning conveyed by a phonestheme. Up to now, the arguable meanings of phonesthemes have been approximated informally by scholars (Hutchins, 1998; Bergen, 2004). To make progress on this front, we have proposed a fully unsupervised meaning induction method that relies on extracting semantic nearest neighbors of a phonesthemic cluster centroid in vector space. We have shown that this method achieves substantially better results than the WordNet-based method of our previous work (Abramova et al., 2013), generating meaning labels that are closer to the meanings proposed in the theoretical literature. For a subset of phonesthemes (4 out of 6: *gl-*, *sm-*, *sn-* and *tw-*), the higher suitability of the centroid-based meaning labels (as compared to random words) was also detected by human evaluators. Although there is obviously room for improvement, we think that these results are very promising given that this is the first data-driven study addressing this problem in an unsupervised manner.

Distinguishing Literal and Non-Literal Usage of German Particle Verbs

Maximilian Köper **Sabine Schulte im Walde**
Institut für Maschinelle Sprachverarbeitung
Universität Stuttgart, Germany
{maximilian.koeper,schulte}@ims.uni-stuttgart.de

Abstract

This paper provides a binary, token-based classification of German particle verbs (PVs) into literal vs. non-literal usage. A random forest improving standard features (e.g., bag-of-words; affective ratings) with PV-specific information and abstraction over common nouns significantly outperforms the majority baseline. In addition, PV-specific classification experiments demonstrate the role of shared particle semantics and semantically related base verbs in PV meaning shifts.

1 Introduction

Automatic detection of non-literal expressions (including metaphors and idioms) is critical for many natural language processing (NLP) tasks such as information extraction, machine translation, and sentiment analysis. For this reason, the last decade has seen an increase in research on identifying literal vs. non-literal meaning (Birke and Sarkar, 2006; Birke and Sarkar, 2007; Li and Sporleder, 2009; Sporleder and Li, 2009; Turney et al., 2011; Shutova et al., 2013; Tsvetkov et al., 2014), as well as the establishment of workshops on metaphorical language in NLP.[1]

In this paper, we explore the prediction of literal vs. non-literal language usage of a computationally challenging class of multiword expressions: German particle verbs (PVs) such as *anlachen* (laugh at) are compositions of a base verb (BV) such as *lachen* (smile/laugh) and a verb particle such as *an*. German PVs are highly productive (Springorum et al., 2013b; Springorum et al., 2013a), and the particles are notoriously ambiguous (Lechler and Roßdeutscher, 2009; Haselbach, 2011; Springorum, 2011). Furthermore, the particles often trigger (regular) meaning shifts when they combine with base verbs (Springorum et al., 2013b), so the resulting PVs represent frequent cases of non-literal meaning. The contributions of this paper are as follows:

1. We present a random forest classifier that correctly identifies 86.8% of literal vs. non-literal language usage within a novel dataset of 6 436 annotated sentences, in comparison to a majority baseline of 64.9%.

2. We successfully incorporate salient PV-specific features and noun clusters in addition to standard bag-of-words features and affective ratings.

3. We demonstrate that PVs with semantically similar particles and semantically similar base verbs can predict each others' literal vs. non-literal language usage.

4. We illustrate the potential and the limits of the most salient classification features in predicting PV non-literal language usage.

In the remainder of this paper we describe previous work on non-literal language identification and computational models of German particle verbs (Section 2), before we introduce our dataset

on German particle verbs (Section 3), the particle verb features (Section 4), and the experiments, results and analyses (Section 5).

2 Related Work

Previous work relevant to this paper includes research on identifying non-literal language usage, and computational work on (German) particle verb meaning.

Identification of non-literal language usage: Birke and Sarkar (2006), Birke and Sarkar (2007), Li and Sporleder (2009) and Sporleder and Li (2009) performed binary token-based classifications for English datasets, relying on various contextual indicators. Birke & Sarkar exploited seed sets of literal vs. non-literal sentences, and used distributional similarity to classify English verbs. Li & Sporleder defined two models of text cohesion (a cohesion chain and a cohesion graph) to classify V+NP and V+PP combinations. Shutova et al. (2013) performed both metaphor identification and interpretion (by paraphrasing), focusing on English verbs. She relied on a seed set of annotated metaphors and standard verb and noun clustering, to classify literal vs. metaphorical verb senses. Gedigian et al. (2006) also predicted metaphorical meanings of English verb tokens, however heavily relying on manual rather than unsupervised data (i.e. labeled sentences and PropBank annotation) and a maximum entropy classifier. Turney et al. (2011) assumed that metaphorical word usage is correlated with the degree of abstractness of the word's context, and classified word senses in a given context as either literal or metaphorical. Their targets were adjective–noun combinations and verbs. Tsvetkov et al. (2014) presented a language-independent approach to metaphor identification. They used affective ratings, WordNet categories and vector-space word representations to train a metaphor-detecting classifier on English samples, and then applied it to a different target language using bilingual dictionaries.

Computational research on particle verbs was initially concerned with the automatic acquisition of particle verbs from corpora (Baldwin and Villavicencio, 2002; Baldwin, 2005; Villavicencio, 2005). Afterwards, the main focus has been on modelling the degree of compositionality of particle verbs as based on distributional features (McCarthy et al., 2003; Baldwin et al., 2003; Bannard, 2005). All these approaches were type-based, and predicting the compositionality was mainly concerned with PV–BV similarity, not taking the contribution of the particle into account. In cases where the particle semantics was respected (such as Bannard (2005)), the results were disappointing because modelling particle senses is still an unsolved problem.

Regarding German particle verbs, there has also been a focus on modelling PV compositionality (Kühner and Schulte im Walde, 2010; Bott and Schulte im Walde, 2014; Bott and Schulte im Walde, 2015). As in English, the approaches were all type-based and mainly concerned with PV–BV similarity. Another line of research categorized particle meanings by relating formal semantic definitions to automatic classifications (Rüd, 2012; Springorum et al., 2012). Furthermore, Springorum et al. (2013b) recently provided a corpus-based study on regular meaning shift conditions for German particle verbs.

3 Particle Verb Dataset

We selected 165 particle verbs across 10 particles, based on previous experiments and datasets that incorporated German particle verbs with regular meaning shifts, various degrees of ambiguity, and across frequency ranges (Springorum et al., 2013b; Springorum et al., 2013a; Bott and Schulte im Walde, 2015). For the 165 PVs, we randomly extracted 50 sentences from *DECOW14AX*, a German web corpus containing 12 billion tokens (Schäfer and Bildhauer, 2012; Schäfer, 2015). The sentences were morphologically annotated and parsed using *SMOR* (Faaß et al., 2010), *MarMoT* (Müller et al., 2013) and the MATE dependency parser (Bohnet, 2010). Combining part-of-speech and dependency information, we were able to reliably sample both separated and non-separated PV occurrences ("Der␣Ast␣**bricht␣ab**" vs. "Der␣Ast␣ist␣**abgebrochen**").

Three German native speakers with a linguistic background annotated each of the 8128 sentences[2] on a 6-point scale [0,5], ranging from clearly literal (0) to clearly non-literal (5) usage. The total agreement of the annotators on all six categories was 43%, Fleiss' κ = 0.35. Dividing the scale into two disjunctive ranges with three categories each ([0,2] and [3,5]), the total agreement of the annotators on the two categories was 79%, Fleiss' κ = 0.70. In the experiments we used the binary-class distinction, and disregarded all cases of disagreement. This final dataset comprises 6 436 sentences: 4 174 literal and 2 262 non-literal uses across 159 particle verbs and 10 particles.[3] Figure 1 shows the distribution of literal and non-literal sentences across the particles.

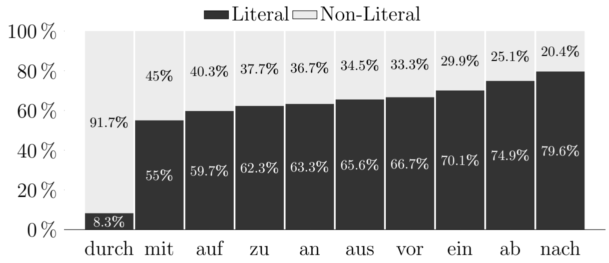

Figure 1: Lit/Non-lit distribution across particles.

4 Particle Verb Features

Our feature space includes standard features to detect non-literal language uses (bags-of-words and affective ratings) as well as PV-specific features and abstraction over common nouns.

4.1 Unigrams

As a standard feature in vector space models, we used all words in the particle verb sentences, i.e., a bag-of-words model relying on unigrams. We expected this standard information to be useful, because some words such as the abstract noun *Hoffnung* (hope) and the concrete noun *Geld* (money) frequently occur with non-literal rather than literal language usage:

1. (non-lit.) "Die Hoffnung **keimte** früh **auf**." *That hope **arose (lit: sprouted)** early.*

2. (non-lit.) "Er versucht das Geld **abzugraben**." *He tries to **demand (lit: dig off)** the money.*

To overcome data sparseness, we did not use the unigrams as individual features ($|V|$ = feature space), but implemented this feature as the output of a text-classifier. We relied on the Multinomial Naive Bayes (MNB) classifier by McCallum and Nigam (1998). While the classifier was designed for document classification, we considered a sentence as a document and the possible class outcomes were literal and non-literal.

Noun Clusters Because of the severe data sparseness in our PV feature sets, we performed noun generalization and applied the generalized information to all nouns in our PV contexts. Using all approx. 430 000 nouns that appeared >100 times in the *DECOW14AX* corpus, we applied k-Means clustering with $k \in [2, 10\,000]$. As an alternative to the standard unigrams, we then replaced every noun in the PV sentences with its corresponding cluster tag.

4.2 Affective Ratings

Previous work on detecting non-literal language often makes use of psycholinguistic attributes, namely abstractness and concreteness ratings (Turney et al., 2011), and imageability ratings (Tsvetkov et al., 2014). Words with high abstractness ratings refer to entities that cannot be perceived with our senses; a large subset of which are non-visual (i.e., receive low imageability). It has been shown that non-literal expressions tend to occur with abstract words (*dark humor* versus *dark hair*). We thus expected affective ratings to be useful for particle verbs as well:

1. (lit.) "Den Lippenstift kannst du dir **abschminken**." *You can **remove** the lipstick.*

2. (non-lit.) "'Den Job kannst du dir **abschminken**." *You can **forget about** the job.*

We reimplemented the algorithm from (Turney and Littman, 2003) to create large-scale abstractness and imageability ratings for German (Köper and Schulte im Walde, 2016). Based on these ratings, we defined the following (partially redundant) features for the PV sentential contexts:

1. Rating of the PV subject
2. Rating of the PV object

[2] Some PVs appeared < 50 times in the corpus.

[3] The dataset is accessible from http://www.ims.uni-stuttgart.de/data/pv_nonlit.

3. Average rating of all nouns (excluding proper names)
4. Average rating of all proper names
5. Average rating of all verbs, excluding the PV
6. Average rating of all adjectives
7. Average rating of all adverbs

While features 3–7 have been adopted from (Turney et al., 2011), features 1–2 represent additional, PV-specific features.

4.3 Distributional Fit of PV, BV and Context

Particle verbs with a meaning shift are non-compositional regarding their base verbs. We thus implemented a PV-specific feature that measures the distributional fit of PVs and their BVs in the PV contexts. For example, looking at the following two PV sentences containing the BV *klingen* (to sound), the context of the first, literal sentence fits well to the BV meaning, but the context of the second, non-literal sentence does not. The distributional fit of the BV in the literal context should therefore be high, but the distributional fit of the BV in the non-literal context should be low.

1. (lit.) "Der Ton der Gitarre **klingt aus**."
   *The tone of the guitar **fades**.*

2. (non-lit.) "Den Abend lassen wir mit Wein **ausklingen**." *We **end** the evening with wine.*

To measure the distributional fit of PVs and BVs to PV contexts, we created 400-dimensional word representations using the *hyperwords* toolkit (Levy et al., 2015) and the *DECOW14AX* corpus. We relied on a symmetrical window of size 3 and applied positive pointwise mutual (PPMI) feature weighting together with singular value decomposition (SVD). Based on the word representations, we calculated cosine similarities between the PVs and their contexts, and likewise between the respective BVs and the PV contexts. The contexts we used were the same seven dimensions we used for the affective ratings (cf. Section 4.2). For example, regarding the sentence "Die Katze **springt** auf den Tisch" (*The cat **jumps** on the table*), we calculated the distributional similarity between the PV "aufspringen" and the subject "Katze", and the distributional similarity between the BV "springen" and the subject "Katze", etc. Each PV–context and each BV–context dimension represents an individual feature.

5 Classification Experiments

In this section, we present a series of binary classification experiments to distinguish literal and non-literal PV usage. Section 5.1 presents the main experiments comparing our features in a global classification setup, and Section 5.2 presents PV-specific additional experiments that zoom into the role of particle types and into the role of semantically related PVs and BVs. Section 5.3 provides a qualitative analysis of the features.

5.1 Main Experiments

We used a random forest with multiple (in our case 100) random decision trees,[4] with each tree voting for an overall classification result. The unigram information was represented by stacking the output of a multinomial naive bayes text classifier as a single feature into the random forest. For all machine learning algorithms we relied on the WEKA toolkit (Witten et al., 2011).

The experiments were performed in two modes, (a) without knowledge of the particle (i.e., the individual particle was not provided as a feature), and (b) with explicit knowledge of the particle. In this way, we could identify the contribution of the particle.

The classification results are shown in Table 1. We report on the feature type, and on the size[5] of the feature set f. We further present literal and non-literal f-scores F_1, and accuracy with and without particle knowledge. We compare against the majority baseline (literal). The right-most columns indicate whether the differences in performance are statistically significant, using the χ^2

[4] Experiments with other classification methods showed similar but inferior performance. Simple Logistic Regression performed 2nd best.

[5] Remember from Section 4.1 that the unigram information is based on all tokens (12 427) but we implemented the unigrams as a single feature (using the output of a classifier), thus the combined setting is only based on 22 features.

	Feature Type	$\|f\|$	Lit. F_1	Non-Lit. F_1	*Acc.*	*Acc.* + *P*
1	Majority Baseline	0	78.7	0.0	64.9	-

Table 1: Main classification results.

test and $*$ for $p < 0.001$ and $\circ$ for $p < 0.05$ to mark significance.

The results demonstrate that the classification results across all feature types are significantly better than the majority baseline. The single best performing feature type (cf. lines 1–6) is the unigram information; in combination with the particle information (+*P*), the distributional PV/BV–context fit is best. Combining the best feature types (2+4+6) once more improves the results, and ditto when adding noun cluster information.[6] We can also see that abstractness (AC) ratings outperform imageability (IMG) ratings.

So overall, the best performing feature set successfully combines unigrams that incorporate clusters for noun generalization; abstractness ratings; and PV-specific information regarding the distributional PV/BV–context fit and knowledge about the particle. This setup correctly classifies literal sentences with an f-score of 88.8 and non-literal sentences with an f-score of 77.3; overall accuracy is 86.8 over a baseline of 64.9.

It is difficult to compare our results against previous approaches on different datasets and in different languages. Regarding the closest approaches to our work, Tsvetkov et al. (2014) report an accuracy score of 82.0 using 10-fold cross-validation on a training dataset with a majority baseline of 59.2, combining multiple lexical semantic features on a dataset of 1 609 English subject–verb–object triples. Birke and Sarkar (2007) trained a single classifier for each of twenty-five verbs in the English TroFi verb dataset and reported only an average f-score: 64.9 against a majority baseline of 62.9. Turney et al. (2011) obtained an average f-score of 63.9 and additionally report an accuracy score of 73.4 on the same dataset, using abstractness ratings.

In contrast to our work, the two approaches by Birke and Sarkar (2007) and Turney et al. (2011) treated each group of sentences for a given target verb as a separate learning problem, while we learn one classifier across different verbs. Our method 4 (AC Ratings) can be considered a German re-implementation of the approach by Turney et al. (2011). In comparison to the results of previous work, our approach can safely be considered state-of-the-art.

5.2 PV-Specific Experiments

5.2.1 Incorporating Standard Measures of Multiword Idiomaticity

One traditional line of research to identify type-based multiword collocations or idiomatic expressions relies on the association strength between the multiword parts (Evert and Krenn, 2001; Krenn and Evert, 2001; Stevenson et al., 2004): The stronger the association between the parts of a multiword expression (as determined by raw frequency, some variant of mutual information, etc.), the stronger the collocation/idiomaticity of the combination of the parts. Based on this assumption, we calculated the association strength between PVs and their contextual subjects/objects, using *local mutual information (LMI)*, cf. Evert (2005). The LMI scores were based on type-based frequency counts in the *DECOW14AX* corpus and added as features to the respective contexts, assuming that large LMI scores indicate non-literal PV usage.

[6] The best cluster analysis in our experiments contained 750 noun clusters.

Adding the LMI values to the overall best feature set from the main experiments decreased accuracy from 86.8 → 86.0. Using the LMI association strength values of the PV–subject and PV–object pairs by themselves provided slightly but non-significantly better results in comparison to the majority baseline: 65.9 > 64.9.[7] Manual investigations revealed that verb–noun pairs with high LMI scores represent collocations in many cases, but the collocations are not only used in non-literal language but also in literal language, e.g., ”Sendung ausstrahlen” (“broadcast a program”).

5.2.2 Non-Literality across Particles

In order to explore the predicability of literal vs. non-literal uses with respect to specific particles, we trained the best classifier from the main experiments on all particle verbs with particle X and applied the classifier to all particle verbs with particle Y. Our hypothesis was that pairs of particles with similar ambiguities might predict each other better than pairs with different particle meanings.

This PV-specific setup could also be applied within a PV group with the same particle: We trained the classifier on all PVs with particle X except for one, and then applied the trained classifier to the missing PV with particle X. The setup was repeated for all PVs with particle X, and the average accuracy was calculated.

Figure 2 provides the results as a heat map, with red indicating high and blue indicating low accuracy scores. The vertical particles on the left correspond to the training particles, and the horizontal particles at the bottom correspond to the test particles. The bottom line shows the majority baseline. For example, training a classifier on ”ein” PVs and evaluating it on ”aus” PVs results in an accuracy of 76.56, which is significantly better ($***$ for $p < 0.001$) than the baseline for ”aus” (65.55).

The diagonal in the heat map (showing the within-particle setup) provides particularly high accuracy scores, so the PVs with the same particle predict (non-)literality within the group very well. This demonstrates that the meanings and the meaning shifts across PVs with the same particle (e.g., *aufdecken* and *auftischen*) are quite regular. A comparably strong prediction is found between ”vor” (before/in front of) and ”nach” (after/behind), with both particles carrying highly similar temporal and local senses. Other examples of strongly related antonymous particle pairs are ”auf”/”zu”, ”ein”/”aus”, and ”aus”/”an”. Examples of strongly related synonymous particle pairs are ”an”/”ein”, and ”aus”/”zu”. ”durch” correlates poorly with all other particles, which is probably due to the few sentences we collected from the corpus. ”mit” also correlates poorly with all other particles, because it is the only particle with little ambiguity. So overall, the heat map corresponds to intuitions about semantic relatedness across particle pairs.

5.2.3 Non-Literality across Particle Verbs

An even more fine-grained experiment setting explored the predictability of a specific particle verb based on the classifier trained on a different particle verb. Our hypothesis was that pairs of PVs that predict each other particularly well share some meaning aspects, either (i) because the training and the test verb share the same BV (**SameBV**: ab*graben*:auf*graben*), or (ii) the PVs are synonymous according to the German *Duden*[8]

[7] We also experimented with the other five contextual feature dimensions, but the results were even worse.

[8] `http://www.duden.de`

dictionary (**PVSyn**: *auftragen*:*auftischen*), or (iii) because the BVs of two PVs with identical particles are synonymous according to the *Duden* (**BVSyn**: auf*reissen*:auf*platzen*).

Figure 3 shows the f-scores for predicting literality and non-literality across the three settings, in comparison to the main experiments ("All"). The number of PV pairs in the settings and the majority accuracy for these PV pairs are also provided, because the experiment sets differ in size. We can see that PVs with the same BV (**SameBV**) predict each other's classifications well regarding literal but not regarding non-literal sentences. This behaviour illustrates the contribution of the particle to the PV meaning: The same BVs with different particles potentially differ strongly, if the particles do not agree on one or more senses. Synonymous PVs (**PVSyn**) predict each other as well in literal as in non-literal cases. Since the PVs in all cases are supposed to have the same meaning, this behaviour is also reasonable. An increase in both literal and non-literal F1 is reached for PV pairs with the same particle and synonymous BVs (**BVSyn**), because the BVs are supposed to carry the same meaning, and the identical particles trigger similar meaning shifts. Overall, the experiment demonstrates that synonymous verbs undergo similar meaning shifts, and that a particle initiates similar meaning shifts when applied to synonymous BVs.

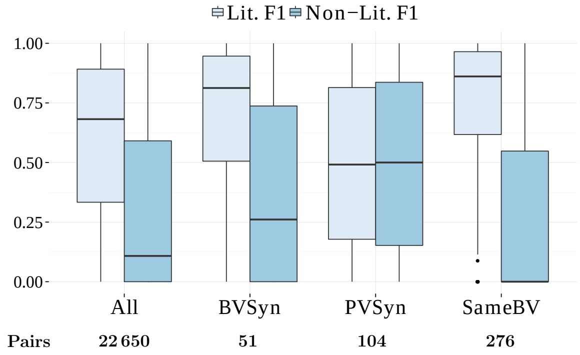

Figure 3: Prediction for semantically related PVs.

5.3 Indicators of Non-Literality

In the final part of the paper, we perform a qualitative analysis of the most salient features.

5.3.1 Information Gain

First of all, we looked into the feature space by computing the information gain within the best random forest classifier. The information gain (*I-Gain*) provides the improvement in information entropy regarding our feature space and the class labels, as defined by equation (1).

$$I\text{-}Gain(Class,Feat) = H(Class) - H(Class|Feat) \quad (1)$$

The information gain does not take feature interaction into account, but determines the importance of the individual features. Applying this method reveals the three most salient features: unigrams (0.31), abstractness ratings of the context nouns (0.17), and distributional fit of the base verbs (0.11). The information gain therefore confirms our results from the main experiments, where these three features worked best.

In addition, we noticed that for all features higher weights were given to dimensions that depend on nouns (such as the common nouns in the PV contexts, and the subject and object nouns), in comparison to proper names, verbs, adjectives and adverbs. For example, the abstractness ratings of the adverbs were ranked second lowest with a score of 0.005, and the distributional fit between BVs and adjectives was ranked last with a zero score, indicating that this feature provides no additional information for our dataset.

5.3.2 Distributional Fit

We now take a look at the distributional fit feature, which was the best performing feature in the main experiments, when combined with particle knowledge. Figure 4 focusing on the distributional fit between BVs and common nouns (as determined third best by the information gain) confirms that the feature is helpful in distinguishing literal vs. non-literal PV sentences across particles: The medians in the boxplots for literal sentences are clearly above those for non-literal sentences. The plots confirm that BVs can be exploited to identify compositional uses of PVs (which in turn refer to literal usage).

Looking into individual PVs confirms that this feature distinguishes well between the literal and non-literal sentences. On the other hand, we also find PVs where this feature is not able to identify non-literal language use. Figure 5 presents the boxplots with cosine values for *aufblühen* (blossom out) and *auflodern* (burn up), where the feature works well, in comparison to *absaufen* (drown), where the feature cannot distinguish (non-)literal language usage.

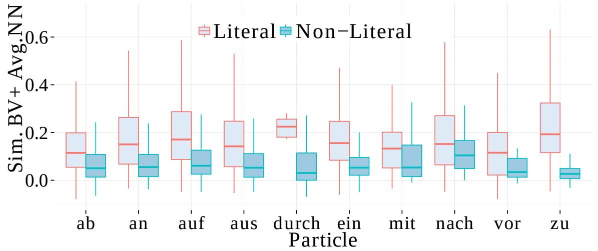

Figure 4: Distributional fit of BVs and context nouns in (non-)literal sentences across particles.

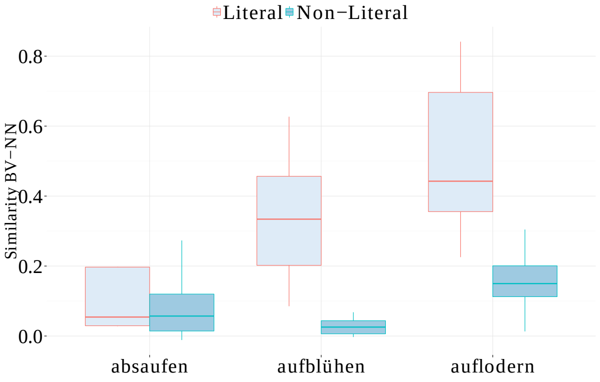

Figure 5: Example PVs and their distributional fit of BVs and context nouns in (non-)literal use.

5.3.3 Abstractness of Contexts

Finally, we take a look at the abstractness feature, which was also among the best performing features in the main experiments, and which is generally assumed to represent a salient indicator of non-literal language usage. Figure 6 focusing on the abstractness of common nouns in the PV sentences[9] (as determined second best by the information gain) confirms that the feature is also helpful in distinguishing literal vs. non-literal PV sentences across particles: Again, the medians in the boxplots for literal sentences are clearly above those for non-literal sentences. The plots confirm that contextual abstractness is a salient indicator of non-literal language usage.

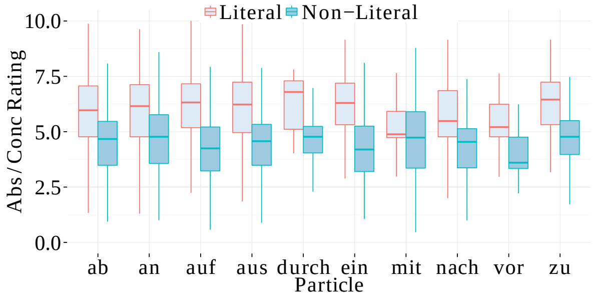

Figure 6: Average abstractness ratings of context nouns in (non-)literal sentences across particles.

Looking into individual PVs again confirms that this feature distinguishes well between the literal and non-literal sentences but also that there are PVs where this feature is not able to identify non-literal language use. Figure 7 presents the boxplots with abstractness ratings for *anstauen* (accumulate) and *durchsickern* (leak through), where the feature works well, in comparison to *antanzen* (waltz in) and especially *ausklingen* (fade/finish), where the feature cannot distinguish (non-)literal language usage.

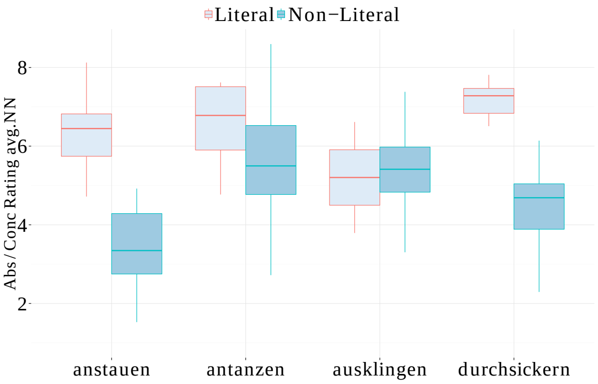

Figure 7: Example PVs and their average abstractness ratings of context nouns in (non-)literal use.

Two example sentences where the abstractness feature goes wrong for a good reason are as follows. In (1) ”Aber wir sollten doch um fünf zum Essen **antanzen**.” (*But we should **show up (lit: waltz in)** for dinner at five*), the context nouns are concrete (*we; dinner*) but the language usage is non-literal. In contrast, in (2) ”Ich liebe Emotionen, deshalb **summen** alle **mit**.” (*I love emotions, there-*

[9] High values indicate concreteness.

fore everyone ***hums along***), the object noun in the sentence is highly abstract (*emotion*), but the language usage is literal. These examples illustrate that contextual abstractness is not a perfect indicator of non-literal language usage.

6 Conclusion

We presented a classifier that predicts literal vs. non-literal language usage for German particle verbs, a semantically challenging type of multiword expressions. The classifier significantly outperformed the baseline by improving standard features with noun clusters and a PV-specific distributional fit feature. PV-specific experiments indicated that PVs whose particles share aspects of ambiguity and which incorporate semantically related BVs seem to undergo similar meaning shifts.

Phrasal Substitution of Idiomatic Expressions

Changsheng Liu and **Rebecca Hwa**

Abstract

Idioms pose a great challenge to natural language understanding. A system that can automatically paraphrase idioms in context has applications in many NLP tasks. This paper proposes a phrasal substitution method to replace idioms with their figurative meanings in literal English. Our approach identifies relevant replacement phrases from an idiom's dictionary definition and performs appropriate grammatical and referential transformations to ensure that the idiom substitution fits seamlessly into the original context. The proposed method has been evaluated both by automatic metrics and human judgments. Results suggest that high quality paraphrases of idiomatic expressions can be achieved.

1 Introduction

An idiom is a combination of words that has a figurative meaning which differs from its literal meaning. Idioms pose a great challenge to many NLP tasks, such as machine translation, word sense disambiguation, and sentiment analysis (Volk, 1998; Korkontzelos et al., 2013; Zanzotto et al., 2010; Williams et al., 2015). Previous work (Salton et al., 2014) has shown that a typical statistical machine translation system might achieve only half of the BLEU score (Papineni et al., 2002) on sentences that contain idiomatic expressions than on those that do not. Idioms are also problematic for second language learners. In a pilot study we have surveyed seven non-native speakers on 100 Tweets containing idioms; we have found that, on average, the participants had trouble understanding 70% of them due to the inclusion of idioms.

This work explores the possibility of automatically replacing idiomatic expressions in sentences. The full pipeline of a successful system has to solve many problems. First, it has to determine that an expression is, in fact, being used as an idiom in a sentence (Fazly et al., 2009; Korkontzelos et al., 2013; Sporleder and Li, 2009). Moreover, the system has to *sense disambiguate* the idiom – it has to pick the correct interpretation when more than one is possible. Second, it has to generate an appropriate phrasal replacement for the idiom using literal English. Third, it has to ensure that the replacement phrase will fit seamlessly back into the original sentence. This paper focuses on the second and third problem, which have not been studied as extensively in previous works.

We propose to extract the phrasal replacement for an idiom from its definition, assuming the existence of an up-to-date dictionary of broad coverage and high quality.[1] Because a typical definition is quite long, it cannot directly serve as a replacement for the idiom. A major challenge of our work is in identifying the right nugget to extract from the definition. Another major challenge is the smooth integration of the substitution phrase into the sentence. We consider both grammatical fluency as well as references resolution in our automatic Post-Editing technique. These phrasal challenges set our goals apart from related work on lexical simplification and substitution (Specia et al., 2012; Jauhar and Specia, 2012; McCarthy, 2002; McCarthy and Navigli, 2007) and

from general sentence simplification (Wubben et al., 2012; Siddharthan, 2014; Zhu et al., 2010; Coster and Kauchak, 2011) methods.

We validate the plausibility of the proposed methods with empirical experiments on a manually annotated corpus.[2] Results from both automatic evaluations and user studies show that the proposed approach can generate high-quality paraphrases of sentences containing idiomatic expressions. A successful idiom paraphrase generator may not only benefit non-native speakers, but may also facilitate other NLP applications.

2 Background

The main idea of this work is to produce a fluent and meaningful paraphrase of the original sentence similar to how a human non-native reader might approach the problem. Suppose the reader encounters the following sentence:

> **Sentence:** This kind of language really barfs me out and *gets my blood up*.[3]

If they do not understand the expression *gets my blood up*, they may look it up in a dictionary:

> **Definition:** Fig. to get someone or oneself angry. (Fixed order.)[4]

Then they might try to reconcile the definition with the context of the sentence and arrive at:

> **Paraphrased :** This kind of language really barfs me out and *gets me angry*.

In the example above, only a portion of the full definition is needed. One possible way to identify this relevant nugget is to apply sentence compression techniques (McDonald, 2006; Siddharthan, 2011; Štajner et al., 2013; Filippova et al., 2015; Filippova and Strube, 2008; Narayan and Gardent, 2014; Cohn and Lapata, 2009). However, all these methods have been developed for standard texts with complete sentences, and it is not clear whether they are suited to dictionary definitions. Consider Table 1, in which a corpus of 1000 randomly selected idiom definitions is compared with samples from two normal text corpora (CLwritten and CLspoken) used by Clarke and Lapata (2008). The CLwritten corpus comes from written sources in the British National Corpus and the American News Text corpus; the CLspoken corpus comes from transcribed broadcast news stories. We see that on average, definitions are shorter than complete sentences; arguably, each word in a definition carries more information. The density of punctuation per sentence shows that definitions are more fragmented. These factors are problematic for sentence compression techniques that rely heavily on the syntactic parse trees of complete, well-formed sentences (Cohn and Lapata, 2009; Narayan and Gardent, 2014). One recent compression method that does not rely as heavily on syntax is the work of Filippova et al. (2015). However, their approach requires a training set of considerable size, which is not practical for the domain of idiom definitions. The most likely to succeed text compression method for our domain is the work of McDonald (2006) as they only use syntactic information as soft evidence to compress target sentences. We choose this method as a comparative baseline in our experimental evaluation.

Corpus	Average length	Punctuation density
CLspoken	17	2.16
CLwritten	18	2.07
Definition	12	2.86

Table 1: Some statistics over normal text corpora and an idiom definition corpus.

After obtaining an appropriately shortened definition, *get someone angry*, more operations are needed to properly replace the idiom with it in the original sentence. First, we need to convert *get* to *gets* to make the tense consistent. Second, we need to resolve the reference *someone* to the appropriate person in the context of the original sentence: *me*. These operations are important to fit the shortened definition seamlessly into the original context, which will be covered in the Post Editing section.

3 Our Method

As outlined in the previous section, our proposed method consists of two components: *substitution*

[2] https://github.com/liucs1986/idiom_corpus

[3] https://twitter.com/ezzwanaezwnd/status/231992426548559872

[4] http://idioms.thefreedictionary.com/get+blood+up

generation and *post editing*.

3.1 Substitution Generation

This component aims to extract relevant replacement phrases from an idiom's dictionary definition. Rather than using generic sentence compression techniques, we argue that the taxonomy of a definition follows certain conventions that can be exploited. In most definitions, the *core meaning* is presented first; it is then optionally followed by additional information that supports, explains, and/or exemplifies the main point. The relationship between the core meaning and different types of addition information is akin to relationships between nucleus and surrounding sentences as described by the rhetorical structure theory (Mann and Thompson, 1988). Using a development set of idiom definition, we have identified four types of additional information:

Type	Example
Coordination	to discover **or apprehend** someone with something
Reason	to be feeling happy **because you are satisfied with your life**
Supplement	time is very important.**(Used especially when time is limited)**
Example	to apply thick soapsuds to something, **such as part of the body**

Table 2: Different types of additional information.

Below, we present two methods for extracting the core meaning from a full definition. We first consider a rule-based approach, under the assumption that definitions can be fully described by a small set of regular patterns. We also present a supervised machine-learning approach, showing that these regular patterns do not have to be predefined, thus opening up for possibilities of adapting the method to different dictionaries and languages.

3.1.1 A Rule-based Method

Analyzing the development set, we observe that additional information are often signaled by a small sets of lexical cues[5]; we call them *boundary words*. Using these boundary words and some shallow syntactic features[6], we have hand-crafted a small set of rules to pare down the definition. Below are five main types of rules:

1. **Delete coordinated phrase after the word ”or” or ”and”**. We consider that phrase to be an equivalent alternative and discard it.
2. **Delete subordinate clause after ”because” or ”since”**. The subordinate clause is used to elaborate the reason for a fact or event.
3. **Delete the clause after words such as ”so that”, ”when”, ”if” and ”especially”**. These are often extraneous supplemental information.
4. **Delete sentence after words such as ”for instance”, ”e.g.”, etc.**. The clause following these words usually gives further examples.
5. **Delete sentences in bracket**. This is often just supplemental information.

If multiple rules are applicable, we start from the rule that covers the widest range first, then to rules covering smaller ranges. After all these steps, if the output has more than one sentence, we always keep the first sentence for simplicity.

There is also a case of keyword ambiguity with respect to the word ”as:” it could signal an explanation (like ”because”) or an example (like ”such as”). Because TheFree Dictionary rarely use ”as” by itself to signal an explanation, we have only encoded the ”such as” sense in our rule-set to avoid the ambiguity.

3.1.2 A ML-based Method

Not every definition follows the schema expected by the rule-based system. To generalize the patterns, we cast substitution generation as a binary classification problem. The most straightforward way is to decide whether each word in a definition should be deleted or kept, but this will degrade the sequential fluency of the shortened definition.

A better alternative is to segment the definition into syntactic chunks such as non-embedded NP, VP, ADJP, ADVP and PP phrases using off-the-shelf

[5] We have identified 23 words and punctuation marks: and, or, because, since, ’cause, especially, if, for example, for instance, such as, e.g., i.e., etc., in particular, like, particularly, namely, viz. , specifically, so that, when, (,).

[6] These are obtained by using the shallow parser in Natural Language Tool Kit (NLTK) (Bird, 2006) and the parts-of-speech tagger in Stanford Parser (De Marneffe et al., 2006).

shallow parsers (e.g., NLTK). Chunks have been shown to minimize the generation of discontinuous sentences in previous works in machine translation (Zhang et al., 2007; Watanabe et al., 2003). We apply a trained binary Support Vector Machine (SVM) classifier to each chunk to predict whether it should be kept or discarded. The shortened definition consists of only chunks that are kept.

Lexical and syntactical features are extracted from definition chunks as well as the sentence containing the original idiom. We have also incorporated features that related previous works have found to be beneficial (Štajner et al., 2013; Narayan and Gardent, 2014). The following is a brief description of our feature set.

Features from the Sentence: These features encode the syntactic context of the idiom. One feature is the constituent label of the entire idiom from the sentence's full parse. It aims to show the big picture of the grammatical function of the idiom in the original sentence. Another feature is the part-of-speech (POS) tag of the word preceding the idiom. These features help to select definition chunks that fit better into the sentence context in which the idiom is used. Due to data sparsity and overfitting concerns, we do not extract lexical features from the sentences.

Features from the Definition: These features encode the syntactic information extracted from all the chunks that made up the definition. In addition to chunking, we also apply a full parser on the definition to obtain its dependency and constituency tree. Although the parse trees may not be reliable enough to serve as hard constraints, they offer useful syntactic information as soft evidences. For example, the dependency tree helps us to identify the head word of every chunk (denoted here as w_h). The constituency tree helps us to determine whether w_h is a node in a subordinate clause (subtree with its root labeled as 'SBAR'). This feature is useful because two adjacent chunks in a relative clause tend to be kept or discarded together. We also include features indicating the relation of the typed dependency of the chunks. Thus, if a verb chunk is kept, its arguments are also likely to be kept. Other features includes whether w_h is the root, whether w_h is the leaf node in the dependency tree. Since certain adjacent words tend to be discarded or kept together, we reinforce this property by adding a bigram POS feature of w_h to encode its context. Additionally, we extract various surface features from the chunks such as their lengths, their positions in the definition, POS of w_h, etc. Some definitions are very long and have several sub-sentences, while a good shortened definition is usually extracted from one sub-sentence. Thus, we have also included a feature indicating whether the definition has more than one sub-sentence, and if the definition has more than one sub-sentence, whether the chunk is in the first sub-sentence.

Features adapted from the Rule-Based method: These include: whether the chunk contains a boundary word, whether the preceding word of the chunk is a boundary word, whether the following word of the chunk is a boundary word, whether the chunk is in a bracket.

3.2 Post Editing

To ensure that the shortened definition is a fluent replacement for the idiom in the context of the original sentence, we must make grammatical adjustments, resolve references, and smooth over the replacement boundaries.

3.2.1 Grammatical Adjustments

We perform several agreement checks. For example, when replacing a noun phrase idiom, we need to make sure that the grammatical number of the replacement phrase agrees with how it is used in the sentence. Similarly, when replacing a verb phrase idiom, we need to perform verb tense, person and number agreement checks, such as converting *get someone angry* to *gets someone angry* in the example mentioned in Section 2.

3.2.2 Reference Resolution

Reference expression is common in definition of idiom. For example, the idiom *see eye to eye* has a shortened definition of *they agree with each other*. The referent *they* has to be resolved when we substitute the idiom with it. The general reference resolution problem is a long-standing challenge in NLP (Mitkov, 1998; Hobbs, 1978; Hobbs, 1979); even in the limited context of our idiom substitution problem, it is not trivial. While regular expression matching may work for idioms that contain simple slot replacements (e.g., the idiom *lather something up* with the definition *to apply thick soapsuds to* something), further analyses on the idiom's sentential context are necessary for many idioms (e.g., *see eye to eye* has no obvious slot).

Typical reference expressions in a definition include *something*, *someone*, *somebody*, *you*, *they*, which often refer to noun phrases (NPs) in and around the idiom in the sentence. When the sentence context contains multiple NPs, we need to choose the right one to resolve the reference. To do so, we rely on two commonly used factors: recency and syntactic agreement (Lappin and Leass, 1994). Similar to the work of Siddharthan (2006), we extract all NPs in the original sentence with their agreement types and grammatical functions; for each NP, we assign it a score with equal weights of recency and syntactic factors. We choose the NP that satisfy the agreements and grammatical functions with the highest score, breaking ties by selecting the closest NP. When no contextual NP is suitable, we replace the reference expression with generics such as "it," "people," or "person" instead.

There is one subtle difference between reference resolution in our work and typical cases. In addition to deriving the correct interpretation of a reference expression, our system has to actually insert the referent to the shortened definition and make the paraphrased sentence grammatical. This means that we need to make the appropriate PRP (personal pronoun) and PRP$ (possessive pronouns) conversions. Consider the example from Section 2 again. the *someone* in the shortened definition is initially resolved to *my* in the original sentence, but to make the substitution grammatical, it has to be transformed to *me*. In addition, special processing is also needed when the substitution is in the form of *subordinate clause*. For example:

> **Tweet:** Maybe if the NFL stopped treating him as such, he wouldn't act like *a prima Donna.*[7]
> **Substitution:** *someone* who demands to be treated in a special way[8]

Although *someone* refers to *he* in the original sentence, no pronoun substitution is plausible. Therefore, *someone* is replaced by a generic expression, "a person."

3.2.3 Boundary Smoothing

Boundary smoothing is the last step of the Post-Editing process to improve the fluency of the resulting sentence. We rely on a standard n-gram language model to evaluate the "smoothness" of the transitions between the original sentence and the substitution phrase. For the left boundary, we begin by checking the bigram probability of the word immediately before the substitution and the first word of the substitution. If it is 0, we would drop the first word and recheck until we find a bigram with non-zero probability or until we have reached the fourth word, whichever occurs first. If a non-zero bigram cannot be found within the first three words, we substitute the original shortened definition as is, without any word deletion. The range of three word is chosen based on our analysis of the development set. A mirror image process is applied to the right boundary. The language model is trained via NLTK using the Brown corpus[9].

4 Evaluation

To determine the performance of the definition shortening methods and post editing operations, we have carried out two experiments. The first (Section 4.2) evaluates the quality of the substitution generation methods; we also argument the evaluation with statistical analysis of post-editing as a reference for future work. The second (Section 4.3) evaluates whether the resulting paraphrased sentence is grammatical and preserves the original meaning.

4.1 Corpus

To evaluate our method on real data, we chose to select Tweets that contain idioms. The reasons are twofold. First, the inspiration for our problem formulation was to help non-native speakers understand social media contents. The limited context of a Tweet makes it harder for someone who does not know an embedded idiom to induce its meaning from the rest of the text. Second, Tweet are self-contained, making the paraphrase task as well as its evaluation (by human judges) more stand-alone. The short context limits the set of mentioned en-

Dataset	Agree	MED_{avg}	
		Disagree	Total
Training	32.9%	**3.25**	2.18
Testing	36.9%	3.42	**2.15**
All data	34.8%	3.33	2.17

Table 3: Agreement between the two annotators. MED_{avg} represents the average minimum edit distance (by word).

tities, which helps with pronoun resolution; otherwise, we foresee no significant hurdles in applying our system to regular sentences.

To build the dataset, we randomly selected 200 idioms (100 for train and 100 for test) and automatically collected tweets in which they appeared using the query API[10]. There were six idioms for which no exact match was found; so we included the usage examples from TheFreeDictionary.com instead. We presented these sentences along with each idiom's definition and asked a volunteer native speaker (Annotator #1) to manually shorten the definition. After filtering out sentences that do not exemplify the idioms[11], we had a total of 88 instances for training and 84 for testing. Next, a near-native speaker (Annotator #2) also performed the same task so that we may compute the inter-annotator agreement. The shortened definitions from Annotator #1 are used as the gold standard.

Table 3 shows the agreement between two annotators. The overall average edit distance is 2.17 words; since the average length of the definitions is about twelve words long (cf. Table 1), the annotators have significant overlaps with each other (the Cohen's kappa is 0.64, suggesting that the inter-annotator agreement is within an acceptable range (Viera et al., 2005)). However, although the annotators extracted the exact same phrase 34.8% of the times, in general they do not completely agree. Some people may select more words to convey a more precise meaning while others sacrifice some precision in meaning for a greater fluency. Thus, in addition to measuring against the gold standard (Annotator #1) using automatic metrics, we also need to perform a human evaluation to directly judge the qualities of the paraphrases.

4.2 Automatic evaluation

In this experiment, we compare different approaches for substitution generation using automatic metrics. We wish to determine: 1) How well does each method replicate human annotators' phrasal extractions? 2) Do we need specialized methods for extracting core meanings from idiom definitions? 3) Is the ML-based method more general and flexible?

The training data contains 88 definitions for a total of 645 chunks that have been labeled as "keep" or "discard" according to the gold standards. The test data consists of 84 unique idioms used in tweets. The evaluation metric is the minimum edit distance of each proposed substitution from the gold standard. We also calculate the *compression rate*, the ratio between numbers of tokens kept with total numbers of tokens in original sentence.

We compare our proposed methods with McDonald (2006). Specifically we use an adapted version described in Filippova et al. (2015). We also implemented two simpler baselines:

Equal-POS: Extract those words from the definition that have the same POS tags as the idiom. For example, if the idiom consists of a VB and an NN, then the first two words tagged as VB and NN in the definition are returned as the substitution. When POS matching fails, the whole definition is returned.

First-Six: Always return the first six words. We choose six because the average length of the gold standard extractions from the training set is six words long.

From the results presented in Table 4, we see that the problem of extracting the core explanation from a long definition is not trivial. The average minimum edit distances from the gold standard are high for the two simple baselines (6.29 for First-Six, 4.92 for Equal-POS). The text compression baseline, McDonald, is only a little better, at 4.86. Because the proposed methods are developed especially for idiom definitions, they are closer to the gold standard. Considering the inter-annotator agreement as an upper-bound (with an average minimum edit distance of 2.15 for the test set), the ML-based approach comes the closest to the upper-bound (with an average distance of 2.75).

[10] https://dev.twitter.com/rest/public/search

[11] For example, "the bitter end" was used in reference to the name of a club.

Method	Agree	MED_{avg}		Compression Rate
		Disagree	Total	
First-Six	0%	6.29	6.29	37%
Equal-POS	6.0%	5.10	4.92	49%
McDonald	6.0%	5.14	4.86	**22%**
Rule-Based	23.8%	4.04	3.27	59%
ML-based	25.0%	**3.5**	**2.75**	51%

Table 4: A comparison of different substitution generation methods with gold standard. MED_{avg} denotes the average minimum edit distance of the method's extraction from the gold standard.

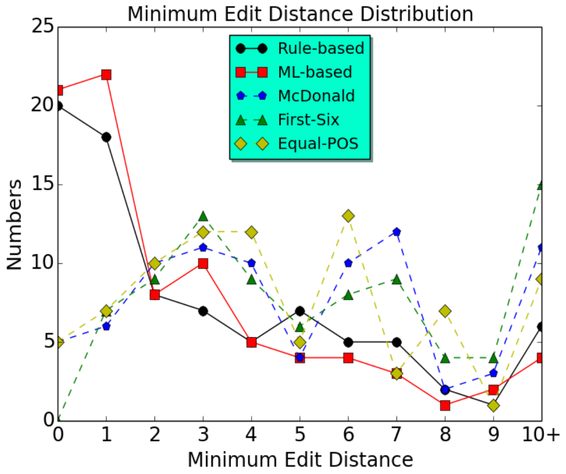

Figure 1: A distribution of edit distances for individual instances.

	Method	Grammaticality	Meaning
Def	McDonald	3.74	3.32
	Rule-Based	**4.92**	**4.71**
	ML-based	4.79	4.68
Sen	McDonald	3.44	3.27
	Rule-Based	4.25	4.31
	ML-based	**4.61**	**4.64**

Table 5: Human evaluation of the different methods in terms of the grammaticality and meaning preservation. In *Def* only the shortened definition are evaluated; in *Sen* the final paraphrased sentences are evaluated.

Figure 1 plots a distribution of each method's minimum edit distances for the instances in the test set. While the rule-based approach has a similar distribution as the trained classifier, it is almost always slightly worse. We see that half of the extractions based on the keep/discard classification are within a one word difference from the gold standard, and there are fewer than five instances for which the edit distance is at least 10; in contrast, the rule-based approach has fewer cases of (nearly) perfect matches and more cases of large mismatches (with the exception of an edit distance of 9). These results suggest that specialized methods are necessary for processing idiom definitions and that an ML-based approach is more general and flexible.

We have also measured the compression rate (CR) of each method; however, this may not be an appropriate metric for our domain in the sense that lower is not necessarily better. The CR of gold standard is 45%, while the ML-based method is 51%. Although the McDonald method has the lowest CR, at 22%, it is lower than that of the gold standard; this suggests that its approach is too aggressive.

To evaluate the contribution of the post-editing component, we have performed data analyses on each step individually: grammatical adjustment, reference resolution and boundary smoothing (using the outputs of the ML-based method). In terms of grammatical adjustments, there are two cases of noun number adjustment and five verb related adjustment.

In terms of reference resolution, we need to address not only the typical reference expressions, but also special cases relating to PRP and PRP$ conversions and subordinate clauses that was discussed in section 3.2.2. We have found fifteen cases of typical reference resolution and nine special cases, out of which, seven were related to subordinate clause (cf. Example 2 in Table 6). Finally, there are three cases for which reference expression cannot be resolved due to the lack of an appropriate noun phrase (cf. Example 5 in Table 6).

Sentence	French and British police are working *in harness* to solve the problem.
Definition	*if two or more people work in harness, they work together to achieve something*
ML-based	French and British police are *working together* to solve the problem.
Rule-Based	French and British police are *working together to achieve it* to solve the problem.
McDonald	French and British police are *working to achieve* to solve the problem.
Sentence	Don’t buy *a pig in a poke*.
Definition	*something that you buy without knowing if it is good or not*
ML-based	Don’t buy *something without knowing if it is good.*
Rule-Based	Don’t buy *something that you buy without knowing if it is good.*
McDonald	Don’t buy *without is good.*
Sentence	*Band-Aid solutions* for a homeless Senate worker.
Definition	*a temporary solution to a problem, or something that seems to be a solution but has no real effect*
ML-based	*Temporary solutions* for a homeless Senate worker.
Rule-Based	*Temporary solutions to a problem* for a homeless Senate worker.
McDonald	Or to be a for a homeless Senate worker.
Sentence	I’ve said all I had to say, *the ball is in your court* .
Definition	*if the ball is in someone’s court, they have to do something before any progress can be made in a situation.*
ML-based	I’ve said all I had to say, *you have to do something.*
Rule-Based	I’ve said all I had to say, *you have to do something before any progress can be made in a situation.*
McDonald	I’ve said all I had to say, *do before can made.*
Sentence	I had to *spill my guts* about the broken window.
Definition	*to tell someone all about yourself, especially your problems*
ML-based	I had to *tell me all about myself* about the broken window .
Rule-Based	I had to *tell me all about myself* about the broken window .
McDonald	I had to *tell* about the broken window .

Table 6: Example of paraphrased sentences. The underlined pronouns in Examples 4&5 have to be resolved. Example 5 shows a failure of reference resolution.

With respect to boundary smoothing, there are many more cases of left boundary smoothing than right boundary smoothing (39 vs. 2 cases). Although many of the left boundary cases simply involve deleting the word ”to” from the shortened definitions, some boundary smoothing cases do address the more severe redundancy disfluencies (cf. Example 1 in Table 6).

4.3 Human evaluation

Minimum edit distance to the gold standard cannot fully indicate the grammaticality and meaning preservation of the extracted phrase. In this experiment, we follow standard human evaluation procedures (McDonald, 2006) to verify our findings from the first experiment. The results will answer two questions: 1) Are the shortened definitions grammatical and are they representative of the core meanings? 2) Are the final paraphrased sentences grammatical and do they retain their original meanings?

We used the same 84 idioms which were the test set in the automatic evaluation. Four native speakers were recruited to evaluate the grammaticality and meaning of the shortened definitions and paraphrased sentences on a five-point scale. Each person took approximately 90 minutes to finish the study. We did not evaluate the simple baselines (First-Six and Equal-POS) because their qualities were obviously low; including them may bias the human subjects to give inflated scores to the better methods. The results are presented in Table 5.

In terms of shortening the definition, the rule-based method obtains the highest scores in both grammaticality and meaning; this is because it tends to be relatively conservative. The compression rate is 59%, while the ML-based method is 51%. Keeping more words in the definition reduces the chance of introducing grammar error and meaning loss; however, a longer definition makes poorer substitution in the full sentence because it introduces redundancy and thwarts post-editing efforts. This is validated in our experimental results – in terms of the paraphrased sentences, the rule-based method is outperformed by the ML-based method, which achieves the best result, with 4.61 in grammaticality and 4.64 in meaning.

Table 6 shows some typical examples of the paraphrases produced using substitution generation from the ML-based method, the rule-based method, and the McDonald method followed by processing with the proposed post-editing techniques. The first example features the effect of boundary smoothing. The shortened definition from the ML-based method is *work together to*. Direct replacement into the original sentence creates a disfluent bigram ”working work”, which has a probability of 0; thus the first word in the shortened definition (*work*) is deleted automatically. Similarly, the word *to* is deleted for the right boundary. In the third example, an automatic grammar adjustment is applied during substitution: *a temporary solution* is converted to *Temporary solutions* to keep the number consistent. In the forth example, the reference *they* is successfully resolved to *you* in the definition. The fifth example features a challenging rare case that results in a failed reference resolution.

Shortening the definition is a trade off between length and meaning. In these examples, the rule-based method keeps as many words as possible from the definition and leads to redundancy in the final output. It has a negative impact on the readability of the paraphrase. The McDonald method is too aggressive for short text such as definition, so the outputs are often discontinuous. The ML-based method offers a reasonable balance between length and meaning, and produces paraphrases that people seem to prefer.

5 Conclusion

We have proposed a phrasal substitution method for paraphrasing idiomatic expressions. Our system extracts the core meaning of an idiom from its dictionary definition and replaces the idiom with it. Empirical evaluations shows that the proposed method produces grammatical paraphrases that preserves the idioms' meanings, and it outperforms other methods such as sentence compression. In the future, we will explore the uses of the idiom paraphrases in NLP applications such as machine translation and intelligent tutor for second-language learners.

Leverage Financial News to Predict Stock Price Movements Using Word Embeddings and Deep Neural Networks

Abstract

Financial news contains useful information on public companies and the market. In this paper we apply the popular word embedding methods and deep neural networks to leverage financial news to predict stock price movements in the market. Experimental results have shown that our proposed methods are simple but very effective, which can significantly improve the stock prediction accuracy on a standard financial database over the baseline system using only the historical price information.

1 Introduction

In the past few years, deep neural networks (DNNs) have achieved huge successes in many data modelling and prediction tasks, ranging from speech recognition, computer vision to natural language processing. In this paper, we are interested in applying the powerful deep learning methods to financial data modelling to predict stock price movements.

Traditionally neural networks have been used to model stock prices as time series for the forecasting purpose, such as in (Kaastra and Boyd, 1991; Adya and Collopy, 1991; Chan et al., 2000; Skabar and Cloete, 2002; Zhu et al., 2008). In these earlier work, due to the limited training data and computing power available back then, normally shallow neural networks were used to model various types of features extracted from stock price data sets, such as historical prices, trading volumes, etc, in order to predict future stock yields and market returns.

More recently, in the community of natural language processing, many methods have been proposed to explore additional information (mainly online text data) for stock forecasting, such as financial news (Xie et al., 2013; Ding et al., 2014), twitter sentiments (Si et al., 2013; Si et al., 2014), financial reports (Lee et al., 2014). For example, (Xie et al., 2013) has proposed to use semantic frame parsers to generalize from sentences to scenarios to detect the roles of specific companies (positive or negative), where support vector machines with tree kernels are used as predictive models. On the other hand, (Ding et al., 2014) has proposed to use various lexical and syntactic constraints to extract event features for stock forecasting, where they have investigated both linear classifiers and deep neural networks as predictive models.

In this paper, we propose to use the recent word embedding methods (Mikolov et al., 2013b; Liu et al., 2015; Chen et al., 2015) to select features from on-line financial news corpora, and employ deep neural networks (DNNs) to predict the future stock movements based on the extracted features. Experimental results have shown that the features derived from financial news are very useful and they can significantly improve the prediction accuracy over the baseline system that only relies on the historical price information.

2 Our Approach

In this paper, we use deep neural networks (DNNs) as our predictive models, which provide us with the advantage of easily combining various types of features from different domains with the minimum

Proceedings of NAACL-HLT 2016, pages 374–379,
San Diego, California, June 12-17, 2016.

pre-processing and normalization effort. The DNN model takes as input the features extracted from both historical price information and on-line financial news to predict the stock movements in the future (either up or down) (Peng and Jiang, 2015).

2.1 Deep Neural Networks

The structure of DNNs used in this paper is a conventional multi-layer perceptron with many hidden layers. An L-layer DNN consisting of $L - 1$ hidden nonlinear layers and one output layer. The output layer is used to model the posterior probability of each output target. In this paper, we use the rectified linear activation function, i.e., $f(x) = \max(0, x)$, to compute from activations to outputs in each hidden layer, which are in turn fed to the next layer as inputs. For the output layer, we use the *softmax* function to compute posterior probabilities between two nodes, standing for *stock-up* and *stock-down*.

2.2 Features from historical price data

In this paper, for each target stock on a target date, we choose the previous five days' closing prices and concatenate them to form an input feature vector for DNNs: $P = (p_{t-5}, p_{t-4}, p_{t-3}, p_{t-2}, p_{t-1})$, where t denotes the target date, and p_m denotes the closing price on the date m. We then normalize all prices by the mean and variance calculated from all closing prices of this stock in the training set. In addition, we also compute first and second order differences among the five days' closing prices, which are appended as extra feature vectors. For example, we compute the first order difference as follows: $\Delta P = (p_{t-4}, p_{t-3}, p_{t-2}, p_{t-1}) - (p_{t-5}, p_{t-4}, p_{t-3}, p_{n-2})$. In the same way, the second order difference is calculated by taking the difference between two adjacent values in each ΔP: $\Delta\Delta P = (\Delta P_{t-3}, \Delta P_{t-2}, \Delta P_{t-1}) - (\Delta P_{t-4}, \Delta P_{t-3}, \Delta P_{t-2})$. Finally, for each target stock on a particular date, the feature vector representing the historical price information consists of P, ΔP and $\Delta\Delta P$.

2.3 Financial news features

In order to extract fixed-size features suitable to DNNs from financial news corpora, we need to pre-process the text data. For all financial articles, we first split them into sentences. We only keep those sentences that mention at least a stock name or a public company. Each sentence is labelled by the publication date of the original article and the mentioned stock name. It is possible that multiple stocks are mentioned in one sentence. In this case, this sentence is labeled several times for each mentioned stock.

We then group these sentences by the publication dates and the underlying stock names to form the samples. Each sample contains a list of sentences that were published on the same date and mention the same stock or company. Moreover, each sample is labelled as *positive* ("price-up") or *negative* ("price-down") based on its next day's closing price consulted from the CRSP financial database (Booth, 2012). In the following, we introduce our method to extract three types of features from each sample.

(1) Bag of keywords (BoK): We first select the keywords based on the recent word embedding methods in (Mikolov et al., 2013a; Mikolov et al., 2013b). Using the popular word2vec method [1], we first compute the vector representations for all words occurring in the training set. Secondly, we manually select a small set of seed words, namely, nine seed words of {*surge*, *rise*, *shrink*, *jump*, *drop*, *fall*, *plunge*, *gain*, *slump*} in this work, which are believed to have a strong indication to the stock price movements. Next, we will repeat an iterative searching process to collect other useful keywords. In each iteration, we compute the cosine distance between other words occurring in the training set and each seed word. The cosine distance represents the similarity between two words in the word vector space. For example, based on the pre-calculated word vectors, we have found other words, such as *rebound*, *decline*, *tumble*, *slowdown*, *climb*, which are very close to at least one of the above seed words. The top 10 most similar words are chosen and added back into the set of seed words at the end of each iteration. The updated seed words will be used to repeat the searching process again to find another top 10 most similar words, the size of the seed words will increase as we repeat the procedure. In this way, we have searched all words occurring in training set and finally selected 1,000 words (including the nine initial seed words) as the keywords for our prediction

[1] https://code.google.com/p/word2vec/

task. In this iterative process to collect keywords, we have found that the final set of the derived keywords is usually very similar as long as we start from a small set of seed words that all strongly indicate the stock price movements.

Finally, a 1000-dimension feature vector, called *bag-of-keywords* or *BoK*, is generated for each sample. Each dimension of the *BoK* vector is the *TFIDF* score computed for each selected keyword from the whole training corpus.

(2) Polarity score (PS): We further compute so-called *polarity* scores (Turney and Littman, 2003; Turney and Pantel, 2010) to measure how each keyword is related to stock movements and how each keyword applies to a target stock in each sentence. To do this, we first compute the point-wise mutual information for each keyword w:

$$\text{PMI}(w, pos) = \log \frac{\text{freq}(w, pos) \times N}{\text{freq}(w) \times \text{freq}(pos)},$$

where freq(w, pos) denotes the frequency of the keyword w occurring in all positive samples, N denotes the total number of samples in the training set, freq(w) denotes the total number of keyword w occurring in the whole training set and freq(pos) denotes the total number of positive samples in the training set. Furthermore, we calculate the polarity score for each keyword w as:

$$\text{PS}(w) = \text{PMI}(w, pos) - \text{PMI}(w, neg).$$

Obviously, the above polarity score PS(w) measures how each keyword is related to stock movements (either positively or negatively) and by how much.

Next, for each sentence in all samples, we need to detect how each keyword is related to the mentioned stock. To do this, we use the Stanford parser (Marneffe et al., 2006) to detect whether the target stock is a subject of the keyword or not. If the target stock is the direct object of the keyword, we assume the keyword is *oppositely* related to the underlying stock. As a result, we need to flip the sign of the polarity score. Otherwise, if the target stock is the subject of the keyword, we keep the keyword's polarity score as it is. For example, in a sentence like *"Apple slipped behind Samsung and Microsoft in a 2013 customer experience survey from Forrester Research"*, which contains an identified keyword *slip*. Based on the parsing result, we know *Apple* is the subject of *slip* while *Samsung* and *Microsoft* are the object of *slip*. Therefore, if this sentence is used as a sample for *Apple*, the above polarity score of *slip* is directly used. However, if this sentence is used as a sample for *Samsung* or *Microsoft*, the polarity score of *slipped* is flipped by multiplying -1. Finally, the resultant polarity scores are multiplied to the *TFIDF* scores to generate another 1000-dimension feature vector for each sample.

(3) Category tag (CT): During the preprocessing of the financial news data, we have discovered that certain type of events are frequently described in the financial news, and the stock price will change significantly after the publication of such financial news. In order to discover the impact of these specific events on the stock price, we further define a list of categories that may indicate the specific events or activities of a public company, which we call as category tags. In this paper, the defined category tags include: *new-product*, *acquisition*, *price-rise*, *price-drop*, *law-suit*, *fiscal-report*, *investment*, *bankrupt*, *government*, *analyst-highlights*. Each category is first manually assigned with a few words that are closely related to the category. For example, we have chosen *released*, *publish*, *presented*, *unveil* as a list of seed words for the category *new-product*, which indicates the company's announcement of new products. Similarly, we use the above word embedding model to automatically expand the word list by searching for more words that have closer cosine distances with the selected seed words. At last, we choose the top 100 words to assign to each category tag.

After we have collected all key words for each category, for each sample, we count the total number of occurrences of all words under each category, and then we take the logarithm to obtain a feature vector as $V = (\log N_1, \log N_2, \log N_3, ..., \log N_c)$, where N_c denotes the total number of times the words in category c appear in the sample. In the case where N_c is zero, it is replaced by a large negative number, for example -99.0 in this work.

2.4 Predicting Unseen Stocks via Correlation Graph

There are a large number of stocks trading in the market. However, we normally can only find a

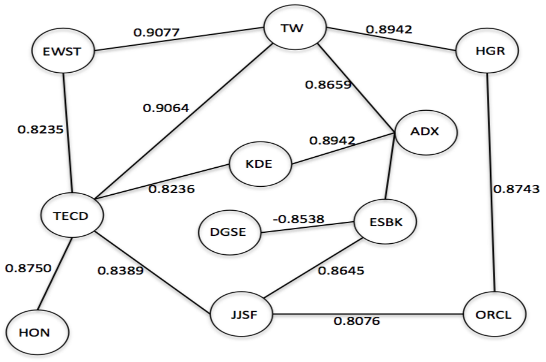

Figure 1: Illustration of a part of correlation graph

fraction of them mentioned in daily financial news. Hence, for each date, the above method can only predict those stocks mentioned in the news. In this section, we propose a new method to extend to predict more stocks that may not be directly mentioned in the financial news. Here we propose to use a stock correlation graph, shown in Figure 1, to predict those unseen stocks. The stock correlation graph is an undirected graph, where each node represents a stock and the arc between two nodes represents the correlation between these two stocks. In this way, if some stocks in the graph are mentioned in the news on a particular day, we first use the above method to predict these mentioned stocks. Afterwards, the predictions are propagated along the arcs in the graph to generate predictions for those unseen stocks.

(1) Build the graph: We choose the top 5,000 stocks from the CRSP database (Booth, 2012) to construct the correlation graph. At each time, any two stocks in the collection are selected to align their closing prices based on the related dates (between 2006/01/01 - 2012/12/31), and we only keep the stock pairs that have an overlapped trading period of at least 252 days (number of trading days in one year). Then we calculate the correlation coefficients between the closing prices of these two stocks. The computed correlation coefficients (between -1 and 1) are attached to the arc connecting these two stocks in the graph, indicating their price correlation. The correlation coefficients are calculated for all stock pairs from the collection of 5,000 stocks. In this paper, we only keep the arcs with an absolute correlation value greater than 0.8, all other edges are considered to be unreliable and pruned from the graph.

(2) Predict unseen stocks: In order to predict price movements of unseen stocks, we first take the prediction results of those mentioned stocks from the DNN outputs, by which we construct a 5000-dimension vector $\mathbf{x}$. The value of each dimension in this vector is set to indicate the probability of price moving up or down. For the dimensions corresponding to the stocks that are mentioned in the financial news, we set the values using the prediction outputs of the DNN. Since the DNN has two outputs, each of which represents the probabilities of two categories, i.e. stock price moving up or down. If a sample is recognized as price-up, we set this dimension as its probability. Otherwise, if it is recognized as price-down, we set this dimension as its probability multiplied by -1.0. Next, we set zeros for all other dimensions corresponding to unseen stocks. The graph propagation process can be mathematically represented as a matrix multiplication:

$$\mathbf{x}' = \mathbf{A}\mathbf{x}$$

where $\mathbf{A}$ is a symmetric 5000-by-5000 matrix denoting all arc correlation weights in the graph. Of course, this graph propagation may be repeated for several times until the prediction $\mathbf{x}'$ converges.

3 Dataset

The financial news data we used in this paper are provided by (Ding et al., 2014), which contains 106,521 articles from Reuters and 447,145 from Bloomberg. The news articles were published in the time period from October 2006 to December 2013. The historical stock security data are obtained from the Centre for Research in Security Prices (CRSP) database (Booth, 2012), which is published by the Chicago Business School and is widely used in the financial modelling. The CRSP database is properly adjusted for all special price events such as stock splits as well as dividend yields. We only use the security data from 2006 to 2013 to match the time period of the financial news. Base on the samples' publication dates, we split the dataset into three sets: a training set (all samples between 2006-10-01 and 2012-12-31), a validation set (2013-01-01 and 2013-06-15) and a test set (2013-06-16 to 2013-12-31). The training set contains 65,646 samples, the validation set contains 10,941 samples, and the test set contains 9,911 samples.

4 Experiments

4.1 Stock Prediction using DNNs

In the first set of experiments, we use DNNs to predict stock price movements based on a variety of features, namely producing a polar prediction of the price movement on next day (either *price-up* or *price-down*). Here we have trained a set of DNNs using different combinations of feature vectors and found that the DNN structure of 4 hidden layers (with 1024 hidden nodes in each layer) yields the best performance in the validation set. We use the historical price feature alone to create the baseline and various features derived from the financial news are added on top of it. We measure the final performance by calculating the error rate on the test set. As shown in Table 1, the features derived from financial news can significantly improve the prediction accuracy and we have obtained the best performance (an error rate of 43.13%) by using all the features discussed in Sections 2.2 and 2.3. We have also applied the structured event features proposed in (Ding et al., 2014) to our samples and the result is also listed in Table 1, which shows that our proposed features produce better performance in predicting a pool of individual stock prices.

feature combination	*error rate*
price	48.12%
price + BoK	46.02%
price + BoK + PS	43.96%
price + BoK + CT	45.86%
price + PS	45.00%
price + CT	46.10%
price + PS +CT	46.03%
price + BoK + PS + CT	**43.13%**
structured events (Ding et al., 2014)	44.79%

Table 1: Stock prediction error rates on the test set.

4.2 Predict Unseen Stocks via Correlation

Here we group all outputs from DNNs based on the dates of all samples on the test set. For each date, we create a vector $\mathbf{x}$ based on the DNN prediction results for all observed stocks and zeros for all unseen stocks, as described in section 2.4. Then, the vector is propagated through the correlation graph to generate another set of stock movement prediction. During the propagation, we compute the results from different iterations by multiplying the vector with the correlation matrix ($\mathbf{x}' = \mathbf{A}\mathbf{x}$). Our experimental results show that the prediction accuracy stops to increase after the 4th iteration. After the propagation converges, we may apply a threshold on the propagated vector to prune all low-confidence predictions. The remaining ones may be used to predict some stocks unseen on the test set. The prediction of all unseen stocks is compared with the actual stock movement on next day. Experimental results are shown in Figure 2, where the left y-axis denotes the prediction accuracy and the right y-axis denotes the percentage of stocks predicted out of all 5000 per day under various pruning thresholds. For example, using a large threshold (0.9), we may predict with an accuracy of 52.44% on 354 extra unseen stocks per day, in addition to predicting only 110 stocks per day on the test set.

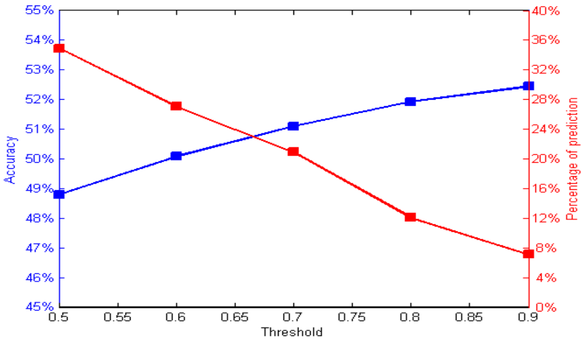

Figure 2: Predict unseen stocks via correlation

5 Conclusion

In this paper, we have proposed a simple method to leverage financial news to predict stock movements based on the popular word embedding and deep learning techniques. Our experiments have shown that the financial news is very useful in stock prediction and the proposed methods can improve the prediction accuracy on a standard financial data set.

Grammatical error correction using neural machine translation

Abstract

This paper presents the first study using neural machine translation (NMT) for grammatical error correction (GEC). We propose a two-step approach to handle the rare word problem in NMT, which has been proved to be useful and effective for the GEC task. Our best NMT-based system trained on the CLC outperforms our SMT-based system when testing on the publicly available FCE test set. The same system achieves an $F_{0.5}$ score of 39.90% on the CoNLL-2014 shared task test set, outperforming the state-of-the-art and demonstrating that the NMT-based GEC system generalises effectively.

1 Introduction

Grammatical error correction (GEC) is the task of detecting and correcting grammatical errors in text written by non-native English writers. Unlike building machine learning classifiers for specific error types (e.g. determiner or preposition errors) (Tetreault and Chodorow, 2008; Rozovskaya and Roth, 2011; Dahlmeier and Ng, 2011), the idea of 'translating' a grammatically incorrect sentence into a correct one has been proposed to handle all error types simultaneously (Felice et al., 2014; Junczys-Dowmunt and Grundkiewicz, 2014). Statistical machine translation (SMT) has been successfully used for GEC, as demonstrated by the top-performing systems in the CoNLL-2014 shared task (Ng et al., 2014).

Recently, several neural machine translation (NMT) models have been developed with promising results (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Sutskever et al., 2014; Bahdanau et al., 2014). Unlike SMT, which consists of components that are trained separately and combined during decoding (i.e. the translation model and language model) (Koehn, 2010), NMT learns a single large neural network which inputs a sentence and outputs a translation. NMT is appealing for GEC as it may be possible to correct erroneous word phrases and sentences that have not been seen in the training set more effectively (Luong et al., 2015). NMT-based systems thus may help ameliorate the lack of large error-annotated learner corpora for GEC.

However, NMT models typically limit vocabulary size on both source and target sides due to the complexity of training (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015; Jean et al., 2015). Therefore, they are unable to translate rare words, and out-of-vocabulary (OOV) words are replaced with *UNK* symbol. This problem is more serious for GEC as non-native text contains not only rare words (e.g. proper nouns), but also misspelled words (i.e. spelling errors). By replacing all the OOV words with the same *UNK* symbol, useful information is discarded, resulting in systems that are not able to correct misspelled words or even keep some of the error-free original words, as in the following examples (OOV words are underlined):

Original sentence

... I am ***goign*** *to make a plan ...*

System hypothesis

... I am UNK to make a plan ...

Gold standard

Proceedings of NAACL-HLT 2016, pages 380–386,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

... I am ***going*** *to make a plan ...*

Original sentence

I suggest you visit first the cathedral of " Le Seu d'Mrgell " because it is the most emblematic building in the area .

System hypothesis

I suggest you visit first the cathedral of " Le UNK UNK " because it is the most UNK building in the area .

Gold standard

I suggest you visit first the cathedral of " Le Seu d'Mrgell " because it is the most emblematic building in the area . (unchanged)

Inspired by the work of Luong et al. (2015), we propose a similar but much simpler two-step approach to address the rare word problem: rather than annotating the training data with alignment information, we apply unsupervised alignment models to find the sources of the words in the target sentence. Once we know the source words that are responsible for the unknown target words, a word level translation model learnt from parallel sentences is used to translate these source words.

This paper makes the following contributions. First, we present the first study using NMT for GEC, outperforming the state-of-the-art. Second, we propose a two-step approach to address the rare word problem in NMT for GEC, which we show yields a substantial improvement. Finally, we report results on two well-known publicly available test sets that can be used for cross-system comparisons.

2 Neural machine translation

NMT systems apply the so-called *encoder-decoder* mechanism proposed by Cho et al. (2014) and Sutskever et al. (2014). An encoder reads and encodes an entire source sentence $\mathbf{x} = (x_1, x_2, ..., x_T)$ into a vector c:

$$c = q(h_1, h_2, ..., h_T) \tag{1}$$

where a hidden state h_t at time t is defined as:

$$h_t = f(x_t, h_{t-1}) \tag{2}$$

A decoder then outputs a translation $\mathbf{y} = (y_1, y_2, ..., y_{T'})$ by predicting the next word y_t based on the encoded vector c and all the previously predicted words $\{y_1, y_2, ..., y_{t-1}\}$:

$$p(\mathbf{y}) = \prod_{t=1}^{T'} p(y_t | \{y_1, y_2, ..., y_{t-1}\}, c) = \prod_{t=1}^{T'} g(y_{t-1}, s_t, c) \tag{3}$$

where s_t is the hidden state of the decoder.

Different neural network models have been proposed, for example, Kalchbrenner and Blunsom (2013) proposed a hybrid of a recurrent neural network (RNN) and a convolutional neural network, Sutskever et al. (2014) used a Long Short-Term Memory (LSTM) model, Cho et al. (2014) proposed a similar but simpler gated RNN model, and Bahdanau et al. (2014) introduced an attentional-based architecture.

In this work, we use the *RNNsearch* model of Bahdanau et al. (Bahdanau et al., 2014), which contains a bidirectional RNN as an encoder and an attention-based decoder. The bidirectional RNN encoder has a forward and a backward RNN. The forward RNN reads the source sentence from the first word to the last, and the backward RNN reads the source sentence in reverse order. By doing this, it captures both historical and future information. The attention-based model allows the decoder to focus on the most relevant information in the source sentence, rather than remembering the entire source sentence.

3 Handling rare words

The rare word problem in NMT has been noticed by (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015; Jean et al., 2015). Jean et al. (2015) proposed a method based on importance sampling that uses a very large target vocabulary without increasing training complexity. However, no matter how large the target vocabulary size is, there are still OOV words. We also notice that in GEC, the source side vocabulary size is much larger than that of the target side as there are many incorrect words in the source (e.g. spelling mistakes and word form errors) (see Section 4.1). Luong et al. (2015) introduced three new annotation strategies to annotate the training data, so that unknown words in the output can be traced back to their origins. The training data was first re-annotated using the output of a word alignment algorithm. NMT systems were then built using this new data. Finally, information about the OOV words in the target sentence and their corresponding words in the source sentence was extracted from the NMT systems and used in a post-processing step to translate these OOV words using a dictionary.

We propose a similar two-step approach: 1) aligning the unknown words (i.e. *UNK* tokens) in the target sentence to their origins in the source sentence with an unsupervised aligner; 2) building a word level translation model to translate those words in a post-processing step. In order to locate the source words that are responsible for the unknown target words, we apply unsupervised aligners directly and use only the NMT model output instead of first re-annotating training data, and then building new NMT models using this newly annotated data as proposed by Luong et al. (2015). Our approach is much simpler as we avoid re-annotating any data and train only one NMT model. Due to the nature of error correction (i.e. both source and target sentences are in the same language), most words translate as themselves, and errors are often similar to their correct forms. Thus, unsupervised aligners can be successfully used to align the unknown target words. Two automatic alignment tools are used: GIZA++ (Och and Ney, 2003) and METEOR (Banerjee and Lavie, 2005). GIZA++ is an implementation of IBM Models 1-5 (Brown et al., 1993) and a Hidden-Markov alignment model (HMM) (Vogel et al., 1996), which can align two sentences from any languages. Unlike GIZA++, METEOR aligns two sentences from the same language. The latest METEOR 1.5 only supports a few languages, and English is one of them. METEOR identifies not only words with exact matches, but also words with identical stems, synonyms, and unigram paraphrases. This is useful for GEC as it can deal with word form, noun number, and verb form corrections that share identical stems, as well as word choice corrections with synonyms or unigram paraphrases. To build a word level translation model for translating the source words that are responsible for the target unknown words, we need word-aligned data. The IBM Models are used to learn word alignment from parallel sentences.

4 Experiments

4.1 Dataset

We use the publicly available FCE dataset (Yannakoudakis et al., 2011), which is a part of the Cambridge Learner Corpus (CLC) (Nicholls, 2003). The FCE dataset contains 1,244 scripts produced by learners taking the First Certificate in English (FCE) examination between 2000 and 2001. The texts have been manually annotated by linguists using a taxonomy of approximately 80 error types. The publicly available FCE dataset contains about 30,995 pairs of parallel sentences for training (approx. 496,567 tokens on the target side) and about 2,691 pairs of parallel sentences for testing (approx. 41,986 tokens on the target side). Since the FCE training set is too small to build good MT systems, we add training examples extracted from the CLC. Overall, there are 1,965,727 pairs of parallel sentences in our training set. The source side contains 28,823,615 words with 248,028 unique words, and the target side contains 29,219,128 words with 143,852 unique words. As we can see, the source side vocabulary size is much larger than that of the target side. Training and test data is pre-processed using RASP (Briscoe et al., 2006).

4.2 Evaluation

System performance is evaluated using three automatic evaluation metrics: I-measure (Felice and Briscoe, 2015), M^2 Scorer (Dahlmeier and Ng, 2012) and GLEU (Napoles et al., 2015). In the I-measure, an Improvement (I) score is computed by comparing system performance with that of a baseline which leaves the original text uncorrected (i.e. the source). The M^2 Scorer was the official scorer in the CoNLL shared tasks (Ng et al., 2013; Ng et al., 2014), with $F_{0.5}$ being the reported metric in the 2014 edition. GLEU is a simple variant of BLEU (Papineni et al., 2002), which shows better correlation with human judgments on the CoNLL-2014 shared task test set.

4.3 SMT baseline

Following previous work (e.g. Brockett et al. (2006), Yuan and Felice (2013)), we build a phrase-based SMT error correction system as the baseline. Pialign (Neubig et al., 2011) is used to create a phrase translation table. In addition to default features, we add character-level Levenshtein distance to each mapping in the phrase table as proposed by Felice et al. (2014). Decoding is performed using Moses (Koehn et al., 2007). The language model used during decoding is built from the corrected sentences in the learner corpus, to make sure that the final system outputs fluent English sentences. The IRSTLM Toolkit (Federico et al., 2008) is used to buid a 5-gram language model with modified Kneser-Ney smoothing (Kneser and Ney, 1995).

4.4 NMT training details

Our training procedure and hyper-parameters for the NMT system are similar to those used by Bahdanau et al. (2014). We train models with sentences of length up to 100 words, which covers about 99.96% of all the training examples. In terms of vocabulary size, we limit the target vocabulary size to 30K, and experiment with three different source vocabulary sizes: 30K, 50K and 80K.[1] Each model is trained for approximately 5 days using a Tesla K20 GPU.

The output sentences from the NMT systems are aligned with their source sentences using GIZA++. In addition, alignment information learnt by METEOR is used by GIZA++ during aligning. All the *UNK* tokens in the output sentences are replaced with the translation of the source words that are responsible for those *UNK* tokens. The translation is performed using a word level model learnt from IBM Model 4.

4.5 Results

From the results in Table 1, we can see that NMT-based systems alone are not able to achieve comparable results to an SMT-based system. It is probably because of the rare word problem, as increasing the source side vocabulary size helps. The performance of the best NMT system alone (*NMT 80K-30K*), without replacing *UNK* tokens, is still worse than the SMT baseline. When we replace the *UNK* tokens in the NMT output, using GIZA++ for unknown word alignment improves the system performance for all three NMT systems in all three evaluation metrics. We can see that our proposed approach is more useful for NMT systems trained on a small source side vocabulary (e.g. 30K) than a large vocabulary (e.g. 50K, 80K). The larger the vocabulary size, the smaller the gain after replacing *UNK* tokens. The introduction of the METEOR alignment information to GIZA++ yields further improvements. Our best system (*NMT 30K-30K + GIZA++ + METEOR*) achieves an $F_{0.5}$ score of 53.49%, an I score of 3.94%, and a GLEU score of 71.16%, outperforming the SMT baseline in all three evaluation metrics.

System	**GLEU**	**$F_{0.5}$ (M^2)**	**I-measure**
Source	60.39	0	0
SMT baseline	70.15	52.90	2.87
NMT-based systems			
NMT 30K-30K	69.04	46.10	-1.30
+ GIZA++	70.89	52.79	3.89
+ METEOR	**71.16**	**53.49**	**3.94**
NMT 50K-30K	68.95	46.78	-1.14
+ GIZA++	70.31	52.02	2.86
+ METEOR	70.40	52.35	2.89
NMT 80K-30K	70.02	49.17	-1.04
+ GIZA++	71.18	53.48	2.40
+ METEOR	71.18	53.49	2.41

Table 1: System performance on the FCE test set (in percentages). The results of our best system are marked in **bold**.

Comparing the output of the SMT baseline with that of the NMT system reveals that there are some learner errors which are missed by the SMT system but are captured by the NMT system. One possible reason is that the phrase-based SMT system is trained on surface forms and therefore unaware of syntactic structure. In order to make a correction, it has to have seen the exact correction rule in the training data. Since the NMT system does not rely on any correction rules, in theory, it should be able to make any changes as long as it has seen the words in the training data. For example:

> **Original sentence**
>
> *There are* ***kidnaps*** *everywhere and not all of the* ***family*** *can afford the ransom ...*
>
> **SMT hypothesis**
>
> *There are* ***kidnaps*** *everywhere and not all of the* ***families*** *can afford the ransom ...*
>
> **NMT hypothesis**

[1] Preliminary experiments show that increasing the source side vocabulary size is more useful than target side.

> *There are* ***kidnappings*** *everywhere and not all of the* ***families*** *can afford the ransom ...*
>
> **Gold standard**
>
> *There are* ***kidnappings*** *everywhere and not all of the* ***families*** *can afford the ransom ...*

The SMT system fails to correct the word form error as the correction rule (*kidnaps* → *kidnappings*) is not in the SMT phrase table learnt from the training data. Since these two words (*kidnaps* and *kidnappings*) have been seen in the training data, the NMT system corrects this error successfully.

5 CoNLL-2014 shared task

The CoNLL-2014 shared task on grammatical error correction required participating systems to correct all errors present in learner English text. The official training and test data comes from the National University of Singapore Corpus of Learner English (NUCLE) (Dahlmeier et al., 2013). $F_{0.5}$ was adopted as the evaluation metric, as reported by the M^2 Scorer. In order to test how well our system generalises, we apply our best system trained on the CLC to the CoNLL-2014 shared task test data directly without adding the NUCLE training data or tuning for the NUCLE. The state-of-the-art $F_{0.5}$ score was reported by Susanto et al. (2014) after the shared task. By combining the outputs from two classification-based systems and two SMT-based systems, they achieved an $F_{0.5}$ score of 39.39%. Results of the uncorrected baseline, our best NMT-based system, Susanto et al. (2014)'s system and the top three systems in the shared task are presented in Table 2. We can see that our NMT-based system outperforms the top three teams, achieving the highest $F_{0.5}$, I and GLEU scores. It also outperforms the state-of-the-art combined system from Susanto et al. (2014). Our system achieves the best $F_{0.5}$ score of 39.90% even though it is not trained on the NUCLE data. This result shows that our system generalises well to other datasets. We expect these results might be further improved by retokenising the test data to be consistent with the tokenisation of the CLC.[2]

System	**GLEU**	**$F_{0.5}$ (M^2)**	**I-measure**
Source	64.19	0	0
Our NMT-based system			
30K-30K + GIZA++ + METEOR	65.59	39.90	-3.11
Top 3 systems in CoNLL-2014			
CAMB (Felice et al., 2014)	64.32	37.33	-5.58
CUUI (Rozovskaya et al., 2014)	64.64	36.79	-3.91
AMU (Junczys-Dowmunt and Grundkiewicz, 2014)	64.56	35.01	-3.31
State-of-the-art			
Susanto et al. (2014)	n/a	39.39	n/a

Table 2: System performance on the CoNLL-2014 test set without alternative answers (in percentages).

6 Conclusions

We have shown that NMT can be successfully applied to GEC once we address the rare word problem. Our proposed two-step approach for *UNK* replacement has been proved to be effective, and to provide a substantial improvement. We have developed an NMT-based system that generalises well to another dataset. Our NMT system achieves an $F_{0.5}$ score of 53.49%, an I score of 3.94%, and a GLEU score of 71.16% on the publicly available FCE test set, outperforming an SMT-based system in all three metrics. When testing on the official CoNLL-2014 test set without alternative answers, our system achieves an $F_{0.5}$ score of 39.90%, outperforming the current state-of-the-art. In future work, we would like to explore other ways to address the rare word problem in NMT-based GEC, such as incorporating the soft-alignment information generated by the attention-based decoder, or using character-based models instead of word-based ones.

Acknowledgements

We would like to thank Cambridge English Language Assessment and Cambridge University Press for granting us access to the CLC for research purposes as well as the anonymous reviewers for their comments and suggestions. We acknowledge NVIDIA for an Academic Hardware Grant. This work also used the Wilkes GPU cluster at the University of Cambridge High Performance Computing Service, provided by Dell Inc., NVIDIA and Mellanox, and part funded by STFC with industrial sponsorship from Rolls Royce and Mitsubishi Heavy Industries.

[2] The NUCLE data was preprocessed using the NLTK toolkit, whereas the CLC was tokenised with RASP.

Abstract

Children learn the meaning of words by being exposed to perceptually rich situations (linguistic discourse, visual scenes, etc). Current computational learning models typically simulate these rich situations through impoverished symbolic approximations. In this work, we present a *distributed* word learning model that operates on child-directed speech paired with realistic *visual scenes*. The model integrates linguistic and extra-linguistic information (visual and social cues), handles referential uncertainty, and correctly learns to associate words with objects, even in cases of limited linguistic exposure.

1 Introduction

Computational models of word learning typically approximate the perceptual context that learners are exposed to through artificial proxies, e.g., representing a visual scene via a collection of symbols such as cat and dog, signaling the presence of a cat, a dog, etc. (Yu and Ballard, 2007; Fazly et al., 2010, *inter alia*).[1] While large amounts of data can be generated in this way, they will not display the complexity and richness of the signal found in the natural environment a child is exposed to. We take a step towards a more realistic setup by introducing a model that operates on naturalistic images of the objects present in a communicative episode. Inspired by recent computational models of meaning (Bruni et al., 2014; Kiros et al., 2014; Silberer and Lapata, 2014), that integrate distributed linguistic and visual information, we build upon the Multimodal Skip-Gram (MSG) model of Lazaridou et al. (2015). and enhance it to handle cross-referential uncertainty. Moreover, we extend the cues commonly used in multimodal learning (e.g., objects in the environment) to include *social cues* (e.g., eyegaze, gestures, body posture, etc.) that reflect speakers' intentions and generally contribute to the unfolding of the communicative situation (Stivers and Sidnell, 2005). As a first step towards developing full-fleged learning systems that leverage all signals available within a communicative setup, in our extended model we incorporate information regarding the objects that caregivers are holding.

2 Attentive Social MSG Model

Like the original MSG, our model learns multimodal word embeddings by reading an utterance sequentially and making, for each word, two sets of predictions: (a) the preceding and following words, and (b) the visual representations of objects co-occurring with the utterance. However, unlike Lazaridou et al. (2015), we do not assume we know the right object to be associated with a word. We consider instead a more realistic scenario where multiple words in an utterance co-occur with multiple objects in the corresponding scene. Under this *referential uncertainty*, the model needs to induce word-object associations as part of learning, relying on current knowledge about word-object affinities as well as on any social clues present in the scene.

Similar to the standard skipgram, the model's parameters are context word embeddings $\mathbf{W}'$ and tar-

[1] See Kádár et al. (2015) for a recent review of this line of work, and another learning model using, like ours, real visual input.

Proceedings of NAACL-HLT 2016, pages 387–392,
San Diego, California, June 12-17, 2016.

get word embeddings $\mathbf{W}$. The model aims at optimizing these parameters with respect to the following multi-task loss function for an utterance w with associated set of objects U:

$$L(w, U) = \sum_{t=1}^{T} (\ell_{ling}(w, t) + \ell_{vis}(w_t, U)) \quad (1)$$

where t ranges over the positions in the utterance w, such that w_t is t^{th} word. The linguistic loss function is the standard skip-gram loss (Mikolov et al., 2013). The visual loss is defined as:

$$\begin{aligned} \ell_{vis}(w_t, U) = \sum_{s=1}^{S} & \lambda\alpha(\mathbf{w}_t, \mathbf{u}_s) g(\mathbf{w}_t, \mathbf{u}_s) \\ & + (1-\lambda) h(\mathbf{u}_s) g(\mathbf{w}_t, \mathbf{u}_s) \end{aligned} \quad (2)$$

where $\mathbf{w}_t$ stands for the column of $\mathbf{W}$ corresponding to word w_t, $\mathbf{u}_s$ is the vector associated with object U_s, and g the penalty function

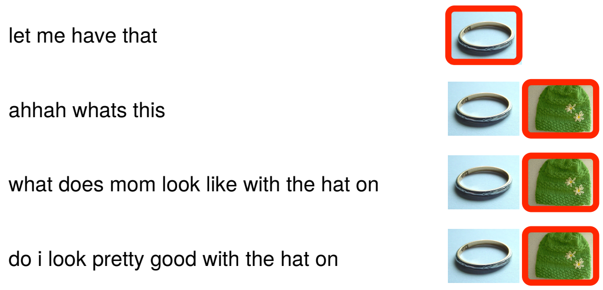
$$\begin{aligned} g(\mathbf{w}_t, \mathbf{u}_s) = \sum_{\mathbf{u}'} & \max(0, \gamma - \cos(\mathbf{w}_t, \mathbf{u}_s) \\ & + \cos(\mathbf{w}_t, \mathbf{u}')), \end{aligned} \quad (3)$$

which is small when projections to the visual space $\mathbf{w}_t$ of words from the utterance are similar to the vectors representing co-occurring objects, and at the same time they are dissimilar to vectors $\mathbf{u}'$ representing randomly sampled objects. The first term in Eq. 2 is the penalty g weighted by the current word-object affinity α, inspired by the "attention" of Bahdanau et al. (2015). If α is set to a constant 1, the model treats all words in an utterance as equally relevant for each object. Alternatively it can be used to encourage the model to place more weight on words which it already knows are likely to be related to a given object, by defining it as the (exponentiated) cosine similarity between word and object normalized over all words in the utterance:

$$\alpha(\mathbf{w}_t, \mathbf{u}_s) = \frac{\exp(\cos(\mathbf{w}_t, \mathbf{u}_s))}{\sum_r \exp(\cos(\mathbf{w}_r, \mathbf{u}_s))} \quad (4)$$

The second term of Eq. 2 is the penalty weighted by the social salience h of the object, which could be based on various cues in the scene. In our experiments we set it to 1 if the caregiver holds the object, 0 otherwise.

We experiment with three versions of the model. With $\lambda = 1$ and α frozen to 1, the model reduces to the original **MSG**, but now trained with referential uncertainty. The **Attentive MSG** sets $\lambda = 1$ and calculates $\alpha(\mathbf{w}_t, \mathbf{u}_s)$ using Equation 4 (we use the term "attentive" to emphasize the fact that, when processing a word, the model will pay more attention to the more relevant objects). Finally, **Attentive Social MSG** further sets $\lambda = \frac{1}{2}$, boosting the importance of socially salient objects.



let me have that

ahhah whats this

what does mom look like with the hat on

do i look pretty good with the hat on

Figure 1: Fragment of the IFC corpus where symbolic labels `ring` and `hat` have been replaced by real images. Red frames mark objects being touched by the caregiver.

All other hyperparameters are set to the values found by Lazaridou et al. (2015) to be optimal after tuning, except hidden layer size that we set to 200 instead of 300 due to the small corpus (see Section 3). We train the MSG models with stochastic gradient descent for one epoch.

3 The Illustrated Frank et al. Corpus

Frank et al. (2007) present a Bayesian cross-situational learning model for simulating early word learning in first language acquisition. The model is tested on a portion of the Rollins section of the CHILDES Database (MacWhinney, 2000) consisting of two transcribed video files (`me03` and `di06`), of approximately 10 minutes each, where a mother and a pre-verbal infant play with a set of toys. By inspecting the video recordings, the authors manually annotated each utterance in the transcripts with a list of object labels (e.g., `ring`, `hat`, `cow`) corresponding to all midsize objects judged to be visible to the infant while the utterance took place, as well as various social cues. The dataset includes a gold-standard lexicon consisting of 36 words paired with 17 object labels (e.g., *hat*=`hat`, *pig*=`pig`, *piggie*=`pig`).[2]

[2] `http://langcog.stanford.edu/materials/nipsmaterials.html`

Aiming at creating a more realistic version of the original dataset, akin to simulating a real visual scene, we replaced symbolic object labels with actual visual representations of objects. To construct such visual representations, we sample for each object 100 images from the respective ImageNet (Deng et al., 2009) entry, and from each image we extract a 4096-dimensional visual vector using the Caffe toolkit (Jia et al., 2014), together with the pretrained convolutional neural network of Krizhevsky et al. (2012).[3] These vectors are finally averaged to obtain a single visual representation of each object. Concerning social cues, since infants rarely follow the caregivers' eye gaze but rather attend to objects held by them (Yu and Smith, 2013), we include in our corpus only information on whether the caregiver is holding any of the objects present in the scene. Note however that this signal, while informative, can also be ambiguous or even misleading with respect to the actual referents of a statement. Figure 1 exemplifies our version of the corpus, the Illustrated Frank et al. Corpus (IFC).

Several aspects make IFC a challenging dataset. Firstly, we are dealing with language produced in an interactive setting rather than written discourse. For example, compare the first sentence in the Wikipedia entry for *hat* (*"A hat is a head covering"*) to the third utterance in Figure 1, corresponding to the first occurrence of *hat* in our corpus. Secondly, there is a large amount of referential uncertainty, with up to 7 objects present per utterance (2 on average) and with only 33% of utterances explicitly including a word directly associated with a possible referent (i.e., not taking into account pronouns). For instance, the first, second and last utterances in Figure 1 do not explicitly mention any of the objects present in the scene. This uncertainty also extends to social cues: only in 23% of utterances does the mother explicitly name an object that she is holding in her hands. Finally, models must induce word–object associations from minimal exposure to input rather than from large amounts of training data. Indeed, the IFC is extremely small by any standards: 624 utterances making up 2,533 words in total, with 8/37 test words occurring only once.

Model	*Best-F*
MSG	.64 (.04)
AttentiveMSG	.70 (.04)
AttentiveSocialMSG	.73 (.03)
ASMSG+shuffled visual vectors	.65 (.06)
ASMSG+randomized sentences	.59 (.03)
BEAGLE	.55
PMI	.53
Bayesian CSL	.54
BEAGLE+PMI	.83

Table 1: Best-F results for the MSG variations and alternative models on word-object matching. For all MSG models, we report Best-F mean and standard deviation over 100 iterations.

4 Experiments

We follow the evaluation protocol of Frank et al. (2007) and Kievit-Kylar et al. (2013). Given 37 test words and the corresponding 17 objects (see Table 2), all found in the corpus, we rank the objects with respect to each word. A mean *Best-F* score is then derived by computing, for each word, the top F score across the precision-recall curve, and averaging it across the words. MSG rankings are obtained by directly ordering the visual representations of the objects by cosine similarity to the MSG word vectors.

Table 1 reports our results compared to those in earlier studies, all of which did not use actual visual representations of objects but rather arbitrary symbolic IDs. Bayesian CSL is the original Bayesian cross-situational model of Frank et al. (2007), also including social cues (not limited, like us, to mother's touch). BEAGLE is the best semantic-space result across a range of distributional models and word-object matching methods from Kievit-Kylar et al. (2013). Their distributional models were trained in a *batch mode*, and by treating object IDs as words so that standard word-vector-based similarity methods could be used to rank objects with respect to words. Plain MSG is outperforming nearly all earlier approaches by a large margin. The only method bettering it is the BEAGLE+PMI combination of Kievit-Kylar et al. (PMI measures direct co-occurrence of test words and object IDs). The latter was obtained through a grid search of all possible model combinations performed directly on the test set, and relied on a weight parameter optimized on the corpus by assuming access to gold annotation.

[3] To match the hidden layer size, we average every k = 4096/200 original non-overlapping visual dimensions into a single dimension.

It is thus not comparable to the untuned MSG.

Plain MSG, then, performs remarkably well, even without any mechanism attempting to track word-object matching across scenes. Still, letting the model pay more attention to the objects currently most tightly associated to a word (AttentiveMSG) brings a large improvement over plain MSG, and a further improvement is brought about by giving more weight to objects touched by the mother (AttentiveSocialMSG). As concrete examples, plain MSG associated the word *cow* with a pig, whereas AttentiveMSG correctly shifts attention to the cow. In turn, AttentiveSocialMSG associates to the right object several words that AttentiveMSG wrongly pairs with the hand holding them, instead.

One might fear the better performance of our models might be due to the skip-gram method being superior to the older distributional semantic approaches tested by Kievit-Kylar et al. (2013), independently of the extra visual information we exploit. In other words, it could be that MSG has simply learned to treat, say, the *lamb* visual vector as an arbitrary signature, functioning as a semantically opaque ID for the relevant object, without exploiting the visual resemblance between lamb and sheep. In this case, we should obtain similar performance when arbitrarily shuffling the visual vectors across object types (e.g., consistently replacing each occurrence of the *lamb* visual vector with, say, the *hand* visual vector). The lower results obtained in this control condition (ASMSG+shuffled visual vector) confirm that our performance boost is largely due to exploitation of genuine visual information.

Since our approach is incremental (unlike the vast majority of traditional distributional models that operate on batch mode), it can in principle exploit the fact that the linguistic and visual flows in the corpus are meaningfully ordered (discourse and visual environment will evolve in a coherent manner: a hat appears on the scene, it's there for a while, in the meantime a few statements about hats are uttered, etc.). The dramatic quality drop in the ASMSG+randomized sentences condition, where AttentiveSocialMSG was trained on IFC after randomizing sentence order, confirms the coherent situation flow is crucial to our good performance.

word	*gold*	*17 objects*		*5.1K objects*	
	object	*nearest*	*r*	*nearest*	*r*
bunny	bunny	bunny	**1**	bunny	**1**
cows	cow	cow	**1**	lea	**7**
duck	duck	duck	**1**	mallard	**4**
duckie	duck	duck	**1**	mallard	**3**
kitty	kitty	book	**2**	bookcase	**66**
lambie	lamb	lamb	**1**	lamb	**1**
moocows	cow	cow	**1**	ranch	**4**
rattle	rattle	rattle	**1**	rattle	**1**

Table 2: Test words occurring only once in IFC, together with corresponding gold objects, AttentiveSocialMSG top visual neighbours among the test items and in a larger 5.1K-objects set, and ranks of gold object in the two confusion sets.

Minimal exposure. Given the small size of the input corpus, good performance on the word-object association already counts as indirect evidence that MSG, like children, can learn from small amounts of data. In Table 2 we take a more specific look at this challenge by reporting AttentiveSocialMSG performance on the task of ranking object visual representations for test words that occurred *only once* in IFC, considering both the standard evaluation set and a much larger confusion set including visual vectors for 5.1K distinct objects (those of Lazaridou et al. (2015)). Remarkably, in all but one case, the model associates the test word to the right object from the small set, and to either the right object or another relevant visual concept (e.g., a ranch for *moocows*) when the extended set is considered. The exception is *kitty*, and even for this word the model ranks the correct object as second in the smaller set, and well above chance for the larger one. Our approach, just like humans (Trueswell et al., 2013), can often get a word meaning right based on a single exposure to it.

Generalization. Unlike the earlier models relying on arbitrary IDs, our model is learning to associate words to actual feature-based visual representations. Thus, once the model is trained on IFC, we can test its generalization capabilities to associate known words with new object instances that belong to the right category. We focus on 19 words in our test set corresponding to objects that were normed for visual similarity to other objects by Silberer and Lapata (2014). Each test word was paired with 40 ImageNet pictures evenly divided between images of the gold object (*not* used in IFC), of a highly visually similar object, of a mildly visually similar object and of a dissimilar one (for *duck*: *duck*, *chicken*, *finch* and *garage*, respectively). The pictures were represented by vectors obtained with the same method outlined in Section 3, and were ranked by similarity to a test word AttentiveSocialMSG representation.

Average Precision@10 for retrieving gold object instances is at 62% (chance: 25%). In the majority of cases the top-10 intruders are instances of the most visually related concepts (60% of intruders, vs. 33% expected by chance). For example, the model retrieves pictures of sheep for the word *lamb*, or bulls for *cow*. Intriguingly, this points to classic overextension errors that are commonly reported in child language acquisition (Rescorla, 1980).

5 Related Work

While there is work on learning from multimodal data (Roy, 2000; Yu, 2005, a.o.) as well as work on learning distributed representations from child-directed speech (Baroni et al., 2007; Kievit-Kylar and Jones, 2011, a.o.), to the best of our knowledge ours is the first method which learns distributed representations from multimodal child-directed data. For example, in comparison to Yu (2005)'s model, our approach (1) induces distributed representations for words, based on linguistic and visual context, and (2) operates entirely on distributed representations through similarity measures without positing a categorical level on which to learn word-symbol/category-symbol associations. This leads to rich multimodal conceptual representations of words in terms of distributed multimodal features, while in Yu's approach words are simply distributions over categories. It is therefore not clear how Yu's approach could capture phenomena such as predicting appearance from a verbal description or representing abstract words–all tasks that our model is at least in principle well-suited for. Note also that Frank et al. (2007)'s Bayesian model we compare against could be extended to include realistic visual data in a similar vein to Yu's, but it would then have the same limitations.

Our work is also related to research on reference resolution in dialogue systems, such as Kennington and Schlangen (2015). However, unlike Kennington and Schlangen, who explicitly train an object recognizer associated with each word of interest, with at least 65 labeled positive training examples per word, our model does not have any comparable form of supervision and our data exhibits much lower frequencies of object and word (co-)occurrence. Moreover, reference resolution is only an aspect of what we do: Besides being able to associate a word with a visual extension, our model is simultaneously learning word representations that allow us to deal with a variety of other tasks—for example, as mentioned above, guessing the appearance of the object denoted by a new word from a purely verbal description, grouping concepts into categories by their similarity, or having both abstract and concrete words represented in the same space.

6 Conclusion

Our very encouraging results suggest that multimodal distributed models are well-suited to simulating human word learning. We think the most pressing issue to move ahead in this direction is to construct larger corpora recording the linguistic and visual environment in which children acquire language, in line with the efforts of the Human Speechome Project (Roy, 2009; Roy et al., 2015). Having access to such data will enable us to design agents that acquire semantic knowledge by leveraging all available cues present in multimodal communicative setups, such as learning agents that can automatically predict eye-gaze (Recasens* et al., 2015) and incorporate this knowledge into the semantic learning process.

Abstract

We propose recurrent support vector machine (RSVM) for slot tagging. This model is a combination of the recurrent neural network (RNN) and the structured support vector machine. RNN extracts features from the input sequence. The structured support vector machine uses a sequence-level discriminative objective function. The proposed model therefore combines the sequence representation capability of an RNN with the sequence-level discriminative objective. We have observed new state-of-the-art results on two benchmark datasets and one private dataset. RSVM obtained statistical significant 4% and 2% relative average F1 score improvement on ATIS dataset and Chunking dataset, respectively. Out of eight domains in Cortana live log dataset, RSVM achieved F1 score improvement on seven domains. Experiments also show that RSVM significantly speeds up the model training by skipping the weight updating for non-support vector training samples, compared against training using RNN with CRF or minimum cross-entropy objectives.

1 Introduction

One of the key tasks in natural language understanding (Hemphill et al., 1990a; He and Young, 2003; De Mori, 2007; Dinarelli et al., 2008; Wang et al., 2005) is slot tagging that labels user queries with semantic tags. It is a sequence labeling problem that transcribes a sequence of observations $X = [x(1), x(2), ..., x(M)]$ to a sequence of discrete labels $Y = [y(1), y(2), ..., y(M)]$. For example, in the query "show me flights from Seattle to Boston", the words "Seattle" and "Boston" should be labeled, respectively, as the *from-city-name* slot and the *to-city-name* slot.

Recently recurrent neural networks (RNNs) and their variants achieved state-of-the-art performances on slot tagging tasks (Yao et al., 2013; Yao et al., 2014b; Yao et al., 2014a; Graves, 2012; Shi et al., 2015; Mesnil et al., 2015; Peng and Yao, 2015). One direction to improve the sequence labeling is to strengthen the model memorization capability by designing dedicated special structures, for example, using long-short-term-memory (LSTM) networks (Hochreiter and Schmidhuber, 1997; Graves et al., 2013; Yao et al., 2014a), gated RNN and RNN with external memory (RNN-em) (Peng and Yao, 2015). The other direction is to optimize the sequence-level discrimination criterion. For example, recurrent conditional random fields (RCRFs) (Yao et al., 2014b) is trained to optimize the sequence conditional likelihood rather than minimizing frame level cross-entropy applied in conventional RNN based sequence labeling (Prez-ortiz et al., 2001; Yao et al., 2013; Mikolov et al., 2010; Shi et al., 2015; Mesnil et al., 2015).

In this paper, we propose recurrent support vector machines (RSVMs) to improve the discrimination ability of RNNs. Different from RCRFs and conventional RNNs that in essence apply the multinomial logistic regression on the output layer, RSVMs optimize the sequence-level max-margin training criterion used by structured support vector machines (Tsochantaridis et al., 2005) on the output layer of RNNs. There are several advantages of using sequence-level max-margin training over maximum likelihood or minimum cross-entropy. Firstly, the sequence-level max-margin criterion is a *global un-normalized* criterion in which there is no computation cost for normalization. Secondly, using max-margin training, only training samples from support vectors generate non zero errors. In other words, model training can be sped up by skipping the weight updating for non-support vector training samples. Finally, as proven in (Vapnik, 1995), margin maximization is equivalent to minimization of an upper bound on the generalization errors. Max-margin training has no assumption about the model distribution. To use maximum likelihood or minimum cross-entropy, it assumes that the model distribution is peaked. However, especially in natural language processing where the ambiguity is ubiquitous, this assumption does not hold.

Proceedings of NAACL-HLT 2016, pages 393–399,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

For example, "seven eleven" can be labeled as time tag or place name (super market name) tag. The conditional probability of tag given "seven eleven" should not be sharp for time or place name.

Recently, SVM is also applied on top of a deep neural network for speech recognition (Zhang et al., 2015). In their work, a cutting-plane algorithm (Joachims et al., 2009) is used, which is computationally expensive for speech recognition tasks. In this paper, we use the stochastic gradient descent algorithm (SGD) (Panagiotakopoulos and Tsampouka, 2013) for model training. The loss function is critical to the sequence level max-margin training criterion, which defines the margin. In this paper, we apply the sequence level hard loss function rather than traditional Hamming loss function (Nguyen and Guo, 2007). In sequence level hard loss function, the wrong sequence is assigned loss one without considering the number of wrong slot labels in the sequence. In the experiments on two bench mark datasets, namely the ATIS (Airline Travel Information Systems) dataset (Hemphill et al., 1990b; Yao et al., 2014b) and the CoNLL 2000 Chunking dataset [1], and private Cortana live log dataset, RSVMs outperformed previous results.

2 Recurrent Support Vector Machines

In this section, we propose RSVM that uses the structured SVM algorithm (Tsochantaridis et al., 2005) to estimate the weights for RNN and label transition probabilities based on the entire training sequence. The training objective in RSVM is the following constrained optimization.

$$\min_{W,A} \frac{1}{2}||W||_2^2 + \frac{1}{2}||A||_2^2 + C\sum_{k=1}^{K}\zeta_k$$

$$s.t.\, f(Y^{(k)^*}) + \zeta_k \geq f(Y^{(k)}) + L(Y^{(k)}) \quad \forall Y^{(k)} \tag{1}$$

$$L(Y^{(k)}) \geq 0 \quad \forall Y^{(k)} \tag{2}$$

$$\zeta_k \geq 0 \tag{3}$$

where

$$f(Y^{(k)}) = \sum_{t=1}^{T} a_{y_k(t-1)y_k(t)} + W_{y_k(t)}^T H(t) \tag{4}$$

where C is regularization weight for empirical loss. $Y^{(k)}$ represents the slot label sequence $y^{(k)}(1:T)$ for training sample $X^{(k)}$. $Y^{(k)^*}$ is the ground truth slot sequence $y^{(k)^*}(1:T)$ for $X^{(k)}$. $a_{y^{(k)}(t-1)y^{(k)}(t)}$ is one element in matrix A, representing the weight for the slot label transition features from $y^{(k)}(t-1)$ to $y^{(k)}(t)$. $L(Y^{(k)})$ defines the loss function of a possible slot label sequence for a training sample $X^{(k)}$, which is actually used as a margin to separate the score $f(Y^{(k)^*})$ for ground truth slot label sequence with all other possible slot sequences in Eq. (1). $\zeta^{(k)}$ is the slack variable that penalize the slot label sequence that violates the margin constraint.

The constrained optimization problem can be transformed to an unconstrained optimization problem as

$$\min_{W,A} \quad F(W,A) = \frac{1}{2C}||W||_2^2 + \frac{1}{2C}||A||_2^2$$
$$+\sum_{k=1}^{K}[\max_{Y^{(k)}\neq Y^{(k)^*}}\big(f(Y^{(k)}) + L(Y^{(k)})\big) - f(Y^{(k)^*})]_+. \tag{5}$$

where $[x]_+$ is the Hinge function that maps x to zero when x is smaller than zero, otherwise $[x]_+ = x$.

The loss function $L(Y^{(k)})$ is critical to the structured SVM training. The following two types of loss functions have been investigated:

$$L(Y^{(k)}) = \sum_{t=1}^{T} 1\big(y^{(k)}(t) \neq y^{(k)^*}(t)\big) \tag{6}$$

$$L(Y^{(k)}) = 1\big(y^{(k)}(1:T) \neq y^{(k)^*}(1:T)\big) \tag{7}$$

Eq. (6) is Hamming loss that is applied by (Nguyen and Guo, 2007) for structured SVM sequence labeling. Eq. (7) is sequence level hard loss function that always give loss one to wrong slot label sequences no matter how many words are labeled with wrong slot labels. In our experiment, we find that the margin defined by Eq. (7) gives the best performance.

2.1 Training Procedure For Recurrent Support Vector Machines

Fig. 1 depicts the architecture of RSVM that can be viewed as the conventional RNN unrolled over the sequence $x(1:T)$. For each single training sample $x(1:T)$, a forward inference and a backward learning are carried out to sweep over the network shown in Fig. 1.

In the forward inference, an unnormalized slot score vector $y(t)$ is computed based on each word input $x(t)$ and its corresponding auxiliary feature $Cx(t)$. The word input and auxiliary feature are encoded in one-hot representation. As shown in Fig. 1, a slot label lattice is generated for the training sample $x(1:T)$. Using Viterbi algorithm, two best slot label sequences $Y^{(k)^{\text{top}}}$ and $Y^{(k)^{\text{second}}}$ are derived from the lattice. In the decoding phase, only the best slot label sequence is computed.

In backward learning, the sub-gradient (Ratliff et al., 2007) are calculated to update the weights for RSVMs. When $Y^{(k)^{\text{top}}} \neq Y^{(k)^*}$ the sub-gradient is

$$\frac{\partial \zeta_k}{\partial \theta} = \frac{\partial f(Y^{(k)^{\text{top}}})}{\partial \theta} - \frac{\partial f(Y^{(k)^*})}{\partial \theta}. \tag{8}$$

When $Y^{(k)^{\text{top}}} = y^{(k)^*}$ and $y^{(k)^*} - Y^{(k)^{\text{second}}} < L(Y^{(k)})$, the

[1] See http://www.cnts.ua.ac.be/conll2000/chunking.

sub-gradient is

$$\frac{\partial \zeta_k}{\partial \theta} = \frac{\partial f(Y^{(k)^{\text{second}}})}{\partial \theta} - \frac{\partial f(Y^{(k)^*})}{\partial \theta}. \tag{9}$$

When $Y^{(k)^{\text{top}}} = Y^{(k)^*}$ and $y^{(k)^*} - Y^{(k)^{\text{second}}} \geq L(Y^{(k)})$, the subgradient is zero. Our experiment show that the RSVM training can be substantially sped up by skipping the backward weight updating for non-support vector training samples that obtain zero subgradient.

In Eq. (8) and (9), θ represents the weights in RSVMs. Specifically, the weights W, A, U and V are updated using sequence level mini-batch method. The weights O connecting hidden layers are updated using Backpropagation Through Time (BPTT) (Werbos, 1990).

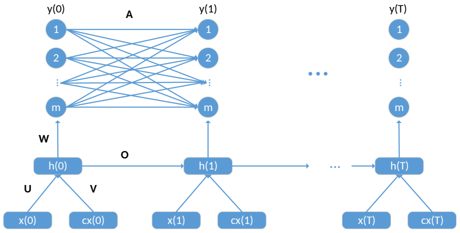

Figure 1: Recurrent support vector machines for slot tagging. U is the weight matrix connecting the word input to the hidden layer, V is the weight matrix connecting auxiliary feature input to the hidden layer, O is the weight matrix connecting previous hidden state to the current hidden state and W is the weight matrix connecting the hidden layer to the output layer. A represents the weight for slot label transition features.

3 Experiments

3.1 Data

To evaluate performances of the proposed model, three sets of experiments were conducted. The first set of experiments are based on ATIS dataset (Hemphill et al., 1990b; Yao et al., 2014b). There are 893 queries from ATIS-III, Nov93 and Dec94 for testing, and 4978 utterances from the rest of ATIS-III and ATIS-II used for training. The training data contains 127 unique slot tags.

The second dataset used in the experiment is CoNLL 2000 Chunking dataset. Chunking is also called shallow parsing that assigns syntactic labels to segments of a sequence of words. Chunking and slot tagging are typical sequence labeling problems. In this paper, we use the chunking task to further verify the performance of the proposed RSVM model. In the CoNLL 2000 Chunking task, the training data are from sections 15-18 of WSJ data and the test data are from section 20. In the training data, there are 220663 tokens with 19123 unique words and additional 45 different types of Part-Of-Speech (POS).

The last dataset is Cortana live log dataset which is constituted by 8 domains, namely alarm, calender, communication, note, ondevice, places, reminder and weather. In total, there are 71 slots. There are 42506 queries used for training and 5290 queries for testing. The data distribution is described in Table. 1. The last column of Table. 1 shows the average query length (the number of words in one query) on different domains.

domain	train	test	length
alarm	3816	452	4.3
calendar	4138	475	4.5
communication	9551	1262	3.8
note	829	139	4.6
ondevice	4384	572	2.4
places	6167	753	4.7
reminder	5359	720	4.1
weather	8270	917	3.4

Table 1: Cortana live log data distribution.

3.2 Settings

In this paper, we use a predefined maximum iteration number to terminate the training. The learning rate is dynamically adjusted using AdaGrad (Duchi et al., 2011).

In all the experiments, we set the hidden layer size to 300 and initial learning rate to 0.1. In RSVMs, the surrounding two words of the current word are used as auxiliary feature which is represented as bag of words. We set the maximum iteration to 20 for ATIS and 30 for Chunking and Cortana live log. For each dataset, we trained 10 models with the same parameter settings except using different random initialization.

3.3 Results on ATIS

ATIS is a well studied benchmark dataset. Table. 2 gives the slot tagging F1 scores achieved by different models in the literature, using the same data settings. There are three blocks in Table. 2. The top block gives the F1 score obtained by CRF and simple RNN. The middle block gives the results obtained by applying advanced RNN architectures such as LSTM, Gated RNN and RNN with external memories (RNN-em) (Peng and Yao, 2015). These advanced RNNs improves RNN by enhancing its memory (sequence representation capability). The bottom block gives results using the proposed RSVMs.

The bottom part gives F1 scores of the proposed RSVM method. We show results generated by 10 models with different random seeds. The average F1 score of RSVM is similar to the best score of RNN-em. F1 score distribution of 10 RSVM models gets significant improvement over the average score of RNN-em (z-test $p - value = 0.0002 << 0.05$). Fundamentally, the proposed RSVM

model	F1(%)
CRF (Mesnil et al., 2015)	92.9
DBN (Deoras and Sarikaya, 2013)	93.2
RNN (Yao et al., 2013)	94.1
RNN-Jordan(Mesnil et al., 2015)	94.3
RNN-embed(Xu and Sarikaya, 2013)	94.4
RNN-joint (Shi et al., 2015)	94.6
RNN-hybrid(Mesnil et al., 2015)	95.1
deep-LSTM (Yao et al., 2014a)	95.0
GRNN-max(Peng and Yao, 2015)	94.7
RNN-em-min(Peng and Yao, 2015)	94.7
RNN-em-average(Peng and Yao, 2015)	95.0
RNN-em-max(Peng and Yao, 2015)	95.2
RSVM-min	94.9
RSVM-average	95.2
RSVM-max	95.5

Table 2: F1 score (in %) for slot tagging on ATIS achieved by different models using only lexical feature. "-min", "-max", and "-average" each denotes mininum, maximum and average F1 scores for a corresponding method.

is based on simple RNN. Comparing LSTM and RNN-em, the proposed model has simpler topology. Note that in (Yao et al., 2014a) and (Peng and Yao, 2015), their advanced models are trained using local normalization method without using sequence level optimization. So the superiority of the proposed RSVM may come from the sequence training and the powerful discriminant capability of SVM. Applying the proposed RSVM method to LSTM or other advanced RNN can be a promising direction for future work.

3.4 Results on CoNLL 2000 Chunking

Table. 3 gives the F1 scores of different models on CoNLL 2000 chunking experiment. To our best knowledge, the first neural network (NN) based chunking model is proposed in (Collobert et al., 2011). Using four basic natural language processing tasks, namely POS tagging, chunking, name entity recognition and semantic role labeling, they demonstrate the ability of NN to discover hidden representations. In their work, only simple input feature is used. There is not any task-specific feature engineering work in their proposed system. Their model purely relies on the NN feature representation that are learned from large amount of unlabeled data. As shown in Table. 3, their system performs better than all the previous systems on CoNLL 2000 chunking dataset.

The performance of Bidirectional LSTM (BLSTM), RCRF and the proposed RSVM on chunking task further confirms the conclusion in (Collobert et al., 2011) that NN is able to discover the internal representations that are useful for different natural language processing tasks. Additionally, the results of BLSTM, RCRF and RSVM, indicate that RNNs have better capabilities to discover the sequence representation than NN. The average F1 score of RCRF and RSVM are 94.9% and 95.0%, respectively. Comparing the F1 score distribution, RSVM achieves the significant improvement over RCRF (paired t-test $p - value = 0.012 < 0.05$). As shown in Table. 3, replacing the CRF objective function with structured SVM max-margin criterion could generate further improvement. The average performance of RSVM is better than the best result of RCRF shown in the table.

model	F1(%)
SVM (Kudo and Matsumoto, 2000)	93.5
gen-Winnow(Zhang et al., 2001)	93.9
SVM (Kudo and Matsumoto, 2001)	93.9

BLSTM (Wang et al., 2015)	94.6
RCRF-min	94.7
RCRF-average	94.9
RCRF-max	94.9
RSVM-min	94.7
RSVM-average	95.0
RSVM-max	95.1

Table 3: F1 score (in %) for chunking on CoNLL 2000 shared task using different models. All these models use word features as well as POS features. "-min", "-max", and "-average" each denotes minimum, maximum and average F1 scores for a corresponding method.

3.5 Results on Internal Live dataset

In this section, we compare different slot models on different domains based on Cortana live log data.

Table. 4 compares the F1 score on CRF, RNN, RCRF, joint-RNN and the proposed RSVM on alarm, calendar, communication, and note. Table. 5 presents the F1 score of different models on the rest domains. "RNN" denotes the Elman type of RNN for slot tagging which uses current word information, previous slot output information and context window information (surrounding four words) (Yao et al., 2013). "RCRF" represents the RCRF slot tagging models that use the same feature as "RNN" (Yao et al., 2014b). "joint-RNN" (Shi et al., 2015) also uses the same features as "RNN" and "RCRF". However, "joint-RNN" implicitly makes use of query domain, intent and slot information by training the domain classifier, intent classifier and slot labeling jointly via multi-task learning.

Overall, the proposed RSVM obtains significant improvement over CRF, RNN,RCRF and joint-RNN on alarm, communication, note and reminder (z-test $p - value < 5E - 5$). On the calendar, places and weather, RSVM achieves similar performance as joint-RNN. Even joint-

RNN is built on the basis of conventional RNN using local normalization, it actually takes the sequence representation information implicitly from domain and intent classification. However, in ondevice domain, RCRF performs the best and the proposed RSVM model performs even worse than CRF. We notice that, in ondevice model, user queries tend to be short, with on average 2.4 words in a query, shown in Table. 1. Also the loss function in the proposed model only uses the top and the second most hypothesis, which may be less informative, especially with short sentences, as compared to using all hypothesis in RCRF.

model	alarm	calen	commu	note
CRF	93.2	93.7	91.6	76.5
RNN	93.8	95.2	92.5	77.0
RCRF	93.9	95.9	93.2	76.9
joint-RNN	94.9	96.4	92.9	74.9
RSVM-min	95.8	95.8	93.3	86.9
RSVM-aver	95.9	96.3	93.9	88.3
RSVM-max	96.2	96.6	94.9	89.7

Table 4: F1 score comparison on different slot tagging models on alarm, calendar, communication and note.

model	ondev	place	remin	weath
CRF	98.2	87.5	93.3	95.7
RNN	98.4	88.4	90.5	95.0
RCRF	98.8	88.3	91.9	94.6
joint-RNN	98.6	90.6	92.4	96.7
RSVM-min	97.4	88.2	94.3	96.2
RSVM-aver	97.7	89.7	94.5	96.6
RSVM-max	97.9	90.8	95.1	96.8

Table 5: F1 score comparison on different slot tagging models on ondevice, places, reminder and weather.

Table. 6 gives the overall performance comparison of different models in internal live log dataset using the weighted average F1 score over all domains. In this table, we can find that the proposed RSVM on average can achieve 0.6% and 0.7% F1 score improvement over joint-RNN and RCRF, respectively.

3.6 Training Speed Up In RSVM

Using max-margin criteria, backward weight updating only happens to support vector samples. While using cross-entropy or maximum likelihood based training criteria, backward weight updating has to sweep over the whole training data. Fig. 2 shows that RSVM can substantially speed up the model training by skipping the backward weight updating for non-support vector samples. As depicted in Fig. 2, RSVM only executes backward weight updating for 337 training samples (7% of whole training data) at epoch 20.

model	F1(%)
CRF	92.6
RNN	92.8
RCRF	93.9

4 Conclusions

We have proposed a recurrent support vector machine (RSVM) which applies the structured SVM on top of the conventional RNN for slot tagging. Different from previous RNN sequence training approaches that use maximum conditional likelihood as objective function, the proposed method uses sequence level max-margin criterion with hard loss function. The model is trained to discriminate the score of ground-truth slot sequences with respect to other competing slot sequences by a margin. Viterbi algorithm is used in decoding to select a slot sequence that gives the largest score. To verify the performance of the proposed method, three datasets, namely ATIS dataset, CoNLL 2000 Chunking dataset and Cortana live log dataset, were used. The proposed RSVM achieved a new state-of-the-art performances on these datasets. In addition, RSVM showed substantial training speed up by skipping the weight updating for non-support vector training samples. On ATIS data, after 20 epoches, backward weight updating only happened for almost 7% of whole training samples.

The proposed RSVM is built on top of conventional RNN structure. Though RSVM doesn't have advanced topology used in LSTM and RNN-em, it achieves comparable or better performances. Therefore, the improvement comes from its sequence level max-margin criterion. For future works, we plan to apply the structured SVM on top of other advanced models.

Abstract

We tackle the task of extracting tweets that mention a specific event from all tweets that contain relevant keywords, for which the main challenges include unbalanced positive and negative cases, and the unavailability of manually labeled training data. Existing methods leverage a few manually given seed events and large unlabeled tweets to train a classifier, by using expectation regularization training with discrete ngram features. We propose a LSTM-based neural model that learns tweet-level features automatically. Compared with discrete ngram features, the neural model can potentially capture non-local dependencies and deep semantic information, which are more effective for disambiguating subtle semantic differences between true event mentions and false cases that use similar wording patterns. Results on both tweets and forum posts show that our neural model is more effective compared with a state-of-the-art discrete baseline.

1 Introduction

A Distributed Denial of Service (DDoS) attack employs multiple compromised systems to interrupt or suspend services of a host connected to the Internet. Victims are often high-profile web servers such as banks or credit card payment gateways, and therefore a single attack may cause considerable loss. The aim of this paper is to build an automatic system which can extract DDoS event mentions from social media, a timely information source for events taking place around the world, so that the mined emerging incidents can serve as early DDoS warnings or signs for Internet service providers.

Ritter et al. (2015) proposed the first work to extract cybersecurity event mentions from raw Twitter stream. They investigated three different event categories, namely *DDoS attacks*, *data breaches* and *account hijacking*, by tracking the keywords *ddos*, *breach* and *hacked*, respectively. Not all tweets containing the keywords describe events. For example, the tweet "give me paypall or i will tell my mum and *ddos* u" shows a metaphor rather than a DDoS event. As a result, the event mention extraction task involves a classification task that filters out true events from all tweets that contain event keywords. Two main challenges exist for this task. First, the numbers of positive and negative examples are typically unbalanced. In our datasets, only about 22% of the tweets that contain the term *ddos* are mentions to DDoS attack events. Second, there is typically little manual annotation available. Ritter et al. (2015) tackled the challenges by weakly supervising a classification model with a small number of human-provided seed events.

In particular, Ritter et al. exploit expectation regularization (ER; Mann and McCallum (2007)) for semi-supervised learning from large amounts of raw tweets that contain the event keyword. They show that the ER approach outperforms semi-supervised expectation-maximization and one-class support vector machine on the task. They build a logistic regression classifier, using few human-labeled seed events and domain knowledge on the ratio between positive and negative examples for ER in training. Results show that the regulariza-

Proceedings of NAACL-HLT 2016, pages 400–410,
San Diego, California, June 12-17, 2016.

tion method was effective on classifying unbalanced datasets.

Ritter et al. use manually-defined discrete features. However, the event mention extraction task is highly semantic-driven, and simple textual patterns may suffer limitations in representing subtle semantic differences between true event mentions and false cases with similar word patterns. Recently, deep learning received increasing research attention in the NLP community (Bengio, 2009; Mikolov et al., 2013; Pennington et al., 2014; Kalchbrenner et al., 2014; Vo and Zhang, 2015). One important advantage of deep learning is automatic representation learning, which can effectively encodes syntactic and information about words, phrases and sentences in low-dimensional dense vectors.

In this paper we exploit a deep neural model for event mention extraction, using word embeddings and a novel LSTM-based neural network structure to automatically obtain features for a tweet. Results on two human-annotated datasets show that the proposed LSTM-based representation yields significant improvements over Ritter et al. (2015).

2 Related Work

In terms of scope, our work falls into the area of information extraction from social media (Guo et al., 2013; Li et al., 2015). The proposed event mention extraction system is domain-specific, similar to works that aim at detecting categorized events such as disaster outbreak (Sakaki et al., 2010; Neubig et al., 2011; Li and Cardie, 2013) and cybersecurity events (Ritter et al., 2015). Such work typically trains semi-supervised classifiers to determine events of interest due to the limitation of annotated data. On the other hand, a few studies devote to open domain event extraction (Benson et al., 2011; Ritter et al., 2012; Petrović et al., 2010; Diao et al., 2012; Chierichetti et al., 2014; Li et al., 2014; Qiu and Zhang, 2014), in which an event category is not predefined, and clustering models are applied to automatically induce event types.

In terms of method, the proposed model is in line with recent methods on deep learning for neural feature representations, which have seen success in some NLP tasks (Collobert and Weston, 2008; Collobert et al., 2011; Chen and Manning, 2014). Competitive results have been obtained in sentiment analysis (Kalchbrenner et al., 2014; Kim, 2014; Socher et al., 2013b), semantic relation classification (Hashimoto et al., 2013; Liu et al., 2015), and question answering (Dong et al., 2015; Iyyer et al., 2014). In addition, deep learning models have shown promising results on syntactic parsing (Dyer et al., 2015; Zhou et al., 2015) and machine translation (Cho et al., 2014). Compared to syntactic problems, semantic tasks see relatively larger improvements by using neural architectures, possible because of the capability of neural features in better representing semantic information, which is relatively more difficult to capture by discrete indicator features. We consider event mention extraction as a semantic-heavy task and demonstrate that it can benefit significantly from neural feature representations.

3 Baseline

We take the method of Ritter et al. (2015) as a baseline. Given a tweet containing the keyword *ddos*, the task is to determine whether a DDoS attack event is mentioned in the tweet. A logistic regression classifier is used, which is trained by maximum-likelihood with ER on unlabeled tweets, and automatically generated positive examples from a few seed events.

3.1 Seed Events

Ritter et al. (2015) manually pick seed events, represented as (ENTITY, DATE) tuples, and treated tweets published on DATE referencing ENTITY as positive training instances. For example, (*GitHub*, 2013 July 29)[1] is defined as a seed DDoS event, and the tweet "@amosie *GitHub* is experiencing a large DDos https://t.co/cqEIR6Rz6t" posted on 2013 July 29 is seen as an event mention since it contains the ENTITY *GitHub* as well as matches the DATE 2013 July 29. Those tweets with the word *ddos* but not matching any seed events are grouped as unlabeled data.

3.2 Sparse Feature Representation

Each tweet is represented by a sparse binary vector for feature extraction, where the features consist of bi- to five-grams containing a name entity or the event keyword. For better generalization, all

words other than common nouns and verbs are replaced with their part-of-speech (POS) tags. Table 1 shows an example of contextual features extracted from the tweet "@amosie GitHub is experiencing a large DDos https://t.co/cqEIR6Rz6t". As can be seen from the table, the features contain shallow wording patterns from a tweet, which are local to a 5-word window. In contrast, the observed average tweet length is 16 words, with the longest tweet containing 48 words, which is difficult to fully represent using only a local window. Our neural model addresses the limitations by learning global tweet-level syntactic and semantic features automatically.

3.3 Logistic Regression Classification with Expectation Regularization

With the feature vector $\vec{f_s} \in \mathbb{R}^d$ defined for a given tweet s, the probability of s being an event mention is defined as:

$$p_\theta(y=1|s) = \frac{1}{1+e^{-\vec{\theta}\vec{f_s}}} \quad (1)$$

where $\vec{\theta} \in \mathbb{R}^d$ is a weight vector.

Given a set of event mentions $M = \langle m_1, m_2, ..., m_j \rangle$ and a set of unlabeled instances $U = \langle u_1, u_2, ..., u_k \rangle$, Ritter et al. (2015) train an ER model that maximizes the log-likelihood of positive data while keeping the conditional probabilities on unlabeled data consistent with the human-provided expectations. The objective function is defined as:

$$\begin{aligned} O(\theta; M, U) = & \underbrace{\sum_{m \in M} \log p_\theta(y=1|m)}_{Log\ Likelihood} \\ - & \underbrace{\lambda^U \Delta(\tilde{p}, \hat{p}^U_\theta)}_{Expectation\ Regularization} \quad (2) \\ - & \underbrace{\lambda^{L^2} \|\theta\|^2}_{L^2\ Regularization} \end{aligned}$$

The expectation regularization term $\Delta(\tilde{p}, \hat{p}^U_\theta)$ is defined as the KL divergence between the model's posterior predictions on unlabeled data, $\hat{p}^U_\theta$, and the human-provided label expectation priors, $\tilde{p}$:

$$\begin{aligned} \Delta(\tilde{p}, \hat{p}^U_\theta) &= D(\tilde{p}||\hat{p}^U_\theta) \\ &= \tilde{p}\ \log \frac{\tilde{p}}{\hat{p}^U_\theta} + (1-\tilde{p})\ \log \frac{1-\tilde{p}}{1-\hat{p}^U_\theta} \end{aligned} \quad (3)$$

4 Distant Seed Event Extraction

We follow Ritter et al. (2015), using a set of seed events and large raw tweets for ER. However, we take a fully-automated approach to find seed events, since manual listing of seed DDoS events can be a costly and time consuming process, and requires a certain level of expert knowledge.

We leverage news articles to collect seed events, representing events as (ENTITY, DATE RANGE) tuples. The ENTITY in our seed events is defined as a name entity that appears in either the *assailant* or *victim* role of an *attack* event labeled by frame-semantic parsing, and the DATE RANGE is a date window around the news publication date. We use a date window rather than a definite news publication date because news articles are not always published on the day a DDoS attack happened. Some examples are given in Figure 1.

We parse DDoS attack news collected from http://www.ddosattacks.net[2] with a state-of-the-art frame-semantic parsing system (SEMAFOR; Das et al. (2010)). Tweets are gathered using the Twitter Streaming API[3] with a case-insensitive track keyword *ddos*. Name entities are extracted from both news articles and tweets using a Twitter-tuned NLP pipeline (Ritter et al., 2011).[4]

Table 2 shows two example DDoS attack news, where the ENTITY values are included in the victim roles, *RBS*, *Ulster Bank*, *GovCERT* and *FBI* in the first news, and *Essex* in the second. It is worth noting that the DDoS attack on RBS, Ulster Bank and Natwest was actually on 2015 July 31. The correlation between tweet mentions and news reports are shown in Figure 1, where each bar indicates the

[2] Most of the articles are about DDoS attack events, while a smaller number discusses the nature of DDoS attacks and related issues.

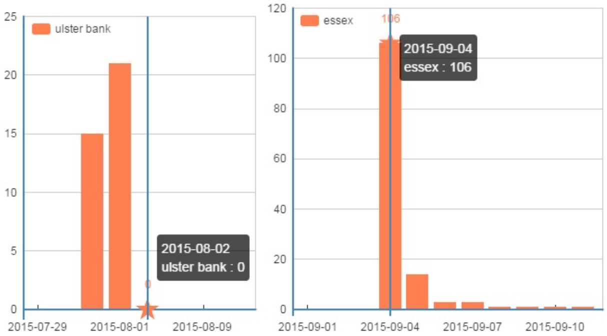

Figure 1: Visualization of the numbers of tweets mentioning Ulster bank (on the left) and Essex (on the right) around the news publication dates.

number of tweets (y-axis) containing a certain ENTITY posted on a certain DATE (x-axis). According to these, we used a 11-day (-3,7) window centered at the news publication date for extracting positive training instances. Experiments show that our method can find seed events with 97% accuracy.

5 Neural Event Mention Extraction

The overall structure of our representation learning model is shown in Figure 2. Given a tweet, two LSTM models (Section 5.1) are used to capture its sequential semantic information in the left-to-right and right-to-left directions, respectively. For deep

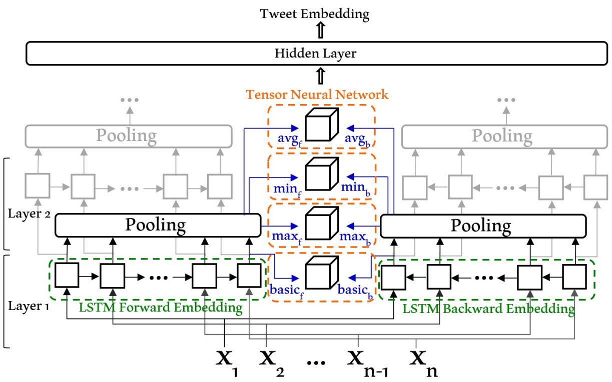

Figure 2: Architecture of the proposed neural tweet representation model.

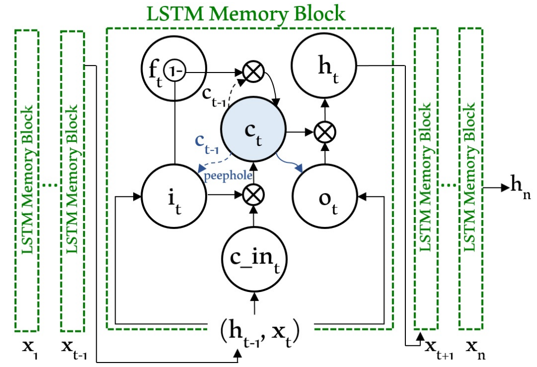

Figure 3: LSTM-based text embedding for word vectors $x_1, x_2, \ldots, x_n$.

semantic representation, each LSTM model can include multiple stacked layers. Neural pooling (Section 5.2) is performed on each LSTM layer to extract rich features. Finally, features from the left-to-right and right-to-left components are combined using neural tensors (Section 5.3), and the resulting features are used as inputs to a feed-forward neural network for classification (Section 5.4).

5.1 LSTM Models

The main goal of our neural model is to find dense vector representations for tweets, which are effective features for event mention extraction. Starting from word embeddings (Mikolov et al., 2013; Pennington et al., 2014), a natural way of modeling a tweet is to treat it as a sequence and use a recurrent neural network (RNN) structure (Pearlmutter, 1989). LSTM (Hochreiter and Schmidhuber, 1997) is a variant of RNNs, which is better at exploiting long range context thanks to purpose-built units called *memory blocks* to store history information.

LSTM has shown improvements over conventional RNN in many NLP tasks (Jozefowicz et al., 2015; Graves et al., 2013b; Cho et al., 2014).

A typical LSTM memory block consists of three gates (i.e. *input*, *forget* and *output*), which control the flow of information, and a *memory cell* to store the temporal state of the network (Gers et al., 2000). While traditionally the values of gates are decided by the input and hidden states in a RNN, we take a variation with *peephole connections* (Gers and Schmidhuber, 2000), which allows gates in the same memory block to learn from the current cell state. In addition, to simplify model complexity, we use coupled *forget* and *input* gates (Cho et al., 2014).

Figure 3 illustrates the memory block used for our tweet representation. The network unit activations for input x_t at time step t are defined by the following set of equations:

Gates at step t:

$$i_t = \sigma(W_{ix}x_t + W_{ih}h_{t-1} + W_{ic}c_{t-1} + b_i) \quad (4)$$

$$f_t = 1 - i_t \quad (5)$$

$$o_t = \sigma(W_{ox}x_t + W_{oh}h_{t-1} + W_{oc}c_t + b_o) \quad (6)$$

Cell:

$$\begin{aligned} c_t &= f_t \otimes c_{t-1} \\ &+ \; i_t \otimes tanh(W_{cx}x_t + W_{ch}h_{t-1} + b_{c\_in}) \end{aligned} \quad (7)$$

Hidden State:

$$h_t = o_t \otimes tanh(c_t) \quad (8)$$

The W terms in Equations 4–7 are the weight matrices (W_{ic} and W_{oc} are diagonal weight matrices for peephole connections); the b terms denote bias vectors; σ is the logistic sigmoid function; and $\otimes$ computes element-wise multiplication of two vectors. i_t, f_t and o_t are *input*, *forget* and *output* gates, respectively; c_t stores the cell state, and h_t is the output of the current memory block.

Inputs For the inputs $x_1, x_2, ..., x_n$, we learn 50-dimension word representations using the skip-gram algorithm (Mikolov et al., 2013). The training corpus was collected from the tweet archive site, and a total of 604,926,764 tweets were used. Each tweet was tokenized using a tweet-adapted tokenizer (Owoputi et al., 2013), and stopwords and punctuations are removed. The trained model contains 5,251,332 words.

Layers Recent research has shown that both RNNs and LSTMs can benefit from depth in space (Graves et al., 2013a; Graves et al., 2013b; Sak et al., 2014; Sak et al., 2015). A deep LSTM is built by stacking multiple LSTM layers, with the output sequence of one layer forming the input sequence for the next, as shown in Figure 2. At each time step the input goes through multiple non-linear layers, which progressively build up higher level representations from the current level. In our tweet representation model, we embody a deep LSTM architecture with up to 3 layers.

5.2 Pooling

Given a LSTM and an input sequence $x_1, x_2, ..., x_n$, using the last state h_n as features is a *basic* representation strategy for the sequence. Apart from this approach, another common feature extraction strategy is to apply pooling (Boureau et al., 2011) over all the states $h_1, h_2, ..., h_n$ to capture the most characteristic information. Pooling extracts fixed dimensional features from $h_1, h_2, ..., h_n$, which has variable length. In our model we consider different pool strategies, including *max*, *average* and *min* poolings. For convenience of writing, we refer to the *basic* feature strategy also as *basic* pooling in later sections. When there are multiple LSTM layers, the features consist of the pooling results from each layer, concatenated to give a single vector.

5.3 Neural Tensor Network for Feature Combination

Given the pooling methods, we extract features r_f and r_b for the forward and backward multi-layer LSTMs, respectively. Inspired by Socher et al. (2013a), we use a neural tensor network (NTN) to combine the bi-directional r_f and $r_b \in \mathbb{R}^d$. The network can be formalized as follows:

$$V = tanh(r_f^T \, T^{[1:q]} \, r_b + W_{ntn} \begin{bmatrix} r_f \\ r_b \end{bmatrix} + b_{ntn}) \quad (9)$$

where $T^{[1:q]} \in \mathbb{R}^{d \times d \times q}$ is a tensor, $W_{ntn} \in \mathbb{R}^{q \times 2d}$ and $b_{ntn} \in \mathbb{R}^q$ are the weight matrix and bias vector, respectively, as that in the standard form of a neural network. The bilinear tensor product $r_f^T \, T^{[1:q]} \, r_b$ is a vector $v \in \mathbb{R}^q$, where each entry is computed by one slice of the tensor:

$$v_i = r_f^T \, T^{[i]} \, r_b \qquad (i = 1, 2, \ldots, q) \quad (10)$$

1. **NSA** site went down due to ‘internal error’, not DDoS attack, agency claims http://t.co/B7AzoLPsKf < isn’t that the same thing
2. **NSA** denies DDOS attack took place on website, claims internal error http://t.co/WW7uFM4Xk5
3. @HostingSocial True Shikha,**Enterprises** are at a greater risk with increased DDoS attacks & #cloud solns need to take measures for prevention

Table 3: The three false positives in the 100 automatically extracted mentions, where EVENT ENTITIES are in bold.

The NTN combined features are concatenated, and fed into a *tanh* hidden layer. The output of the layer, $\vec{f_s}$, becomes the final representation of a tweet, and is used to compute the probability of the tweet being an event mention, as shown in Equation 1.

5.4 Classification

The final classifier of the neural network model is Equation 1, consistent with the baseline model. As a result, ER is applied in the same way as Equation 2. The main difference between our model and the baseline is in the definition of $\vec{f_s}$, the former being a deep neural network and the latter being manual features. Consequently, Equation 1 can be regarded as a softmax layer in our deep neural model, for which all the features and parameters are trained automatically and consistently.

For training, the parameters are initialized uniformly within the interval $[-a,a]$, where

$$a = \sqrt{\frac{6}{H_k + H_{k+1}}} \tag{11}$$

H_k and H_{k+1} are the numbers of rows and columns of the parameter, respectively (Glorot and Bengio, 2010). The parameters are learned using stochastic gradient descent with momentum (Rumelhart et al., 1988). The model is trained by 500 iterations, in each of which unlabeled instances are randomly sampled so that the same numbers of positives and unlabeled data are used.

6 Experiments and Results

6.1 Data

We streamed tweet with the track kayword *ddos* for five months from April 13 to September 13, 2015. In addition, we extracted tweets containing the word *ddos* from a tweet archive[5] in the period from September 2011 to September 2014. Using the distant seed event extraction scheme described in Section 4, a total number of 930 mentions covering 45 ENTITY were automatically derived. In order to examine whether the automatically-collected instances are true positives and hence form a useful training set, an author of this paper annotated 100 extracted mentions finding that that 3 are false positives, as listed in Table 3. The result suggests that the automatically extracted mentions are reliable.

	Training	Dev	Test	Dark Web Test
Positive	930	43	160	82
Negative	–	157	640	318
Unlabeled	127,774	–	–	–

Table 4: Statistics of the datasets.

The remaining tweets were randomly split into a 200-instance development set, a 800-instance test set, and an unlabeled training set.[6] Both the development and test sets were annotated by a human judge and an author of this paper. The inter-annotator agreement on the binary labeled 1000 instances was measured by using Fleiss’ kappa (Fleiss et al., 2013), and the score, which is 0.85 for the data, represents *almost perfect agreement* according to Landis and Koch (1977). There were 47 out of the 1,000 tweets that received different labels, for which another human judge made the final decision.

To test the applicability of the proposed mention extraction system on other domains, we collected 400 sentences containing the keyword *ddos* from dark web. Again each sentence was annotated by two human judges, and the third person made the final decision on conflicting cases. The inter-annotator agreement kappa score on this dataset is 0.85, consistent with the tweet annotation. Table 4 presents the statistics of the datasets.

6.2 Evaluation

We follow Ritter et al. (2015) and evaluate the performance by the area under the precision-recall curve (AUC), where *precision* is the fraction of retrieved instances that are event mentions, and *re-*

max+avg	0.48
max+min	0.50
max+basic	**0.51**
max+basic+min	0.50
max+basic+min+avg	0.47

Table 6: AUCs of different pooling methods.

call is the fraction of gold event mention instances that are retrieved. Precision-recall (PR) curves offer informative pictures on the classification of unbalanced classes (Davis and Goadrich, 2006).

6.3 Development Experiments

For the proposed model, we empirically set the LSTM output vector h_t, the NTN output V, and the size of the hidden layer to 32.[7] For the ER model, the human-provided label expectation prior $\tilde{p}$ is set to 0.22 since the percentage of positives in the development set is 22%, and the parameter λ^U is set to one-tenth of the positive training data.[8]

6.3.1 Feature Combination

We first test whether using a NTN to combine the bi-directional representations can give a better performance compared to simply concatenating the two representation vectors. Table 5 gives AUCs of one-layer *basic*, *max*, *avg* and *min* pooling strategies tested on the tweet development set. We can see that all the four different pooling strategies perform better when the NTN combination is used. As a result, for the following experiments we only consider using NTNs to combine bi-directional representations.

Next we observe the effect of using different numbers of LSTM layers in our model. AUCs of *basic*, *max*, *avg* and *min* pooling strategies with respect to 1, 2 and 3 LSTM layers are presented in Table 5. In most of the cases, the performance of the model increases when the LSTM architecture goes deeper, and we build our final models using 3 LSTM layers.

6.3.2 Pooling Strategies

In the previous experiments, *max* pooling achieves the highest AUC with the architecture 3-LSTM-layer+NTN, we are interested in whether combining *max* with other pooling strategies would further increase the performance. Table 6 summarizes the AUC of various combinations, according to which we choose *max+basic* for final tests.

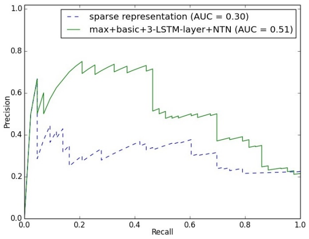

Figure 4: Development PR curves.

Finally, we test the performance of sparse feature representations as used in the model of Ritter et al. (2015). Figure 4 shows the PR curves of the sparse representation and the best setting *max+basic* evaluated on the development set. The AUC of using sparse representation is 0.30 while that of the *max+basic* model is 0.51. The runtime performances of training with sparse feature representations and neural feature representations are 276.17 and 1137.87 seconds, respectively, running on a single thread of an Intel Core i7-4790 3.60GHz CPU.

6.4 Final Test

Figure 5 presents the PR curves of the baseline sparse feature representation and the final neural model evaluated on the datasets, and Table 7 gives the AUC for these test-set evaluations. From the curves we can see that the sparse representation is comparatively less efficient in picking out negative examples, since at a lower recall the model does not gain a higher precision. In contrast, LSTM-based representation demonstrates a better trade-off between recall and precision. We do not have a strong intuition on why the performance on dark web test set is better than that on tweet test set for the proposed model.

[7] The hidden layer size is chosen by comparing development test scores using the sizes of 16, 32 and 64.

[8] Mann and McCallum (2007) found that λ^U does not require tuning for different data set.

Table 7: Final AUCs.

6.5 Analysis

Table 8 shows the top 5 and bottom 5 ranked dark web sentences[9] as scored by the baseline and the proposed LSTM-based model, respectively. For each sentence, the human judgment (*P* for event mentions and *N* for non-event mentions) is given, followed by the probability values output by the baseline and the proposed system.

Only one of the top five most probable event-mentioning sentences as decided by the baseline is true positive. On the other hand, all of the top five sentences indicated by the proposed model are true positives. We investigate the contextual features that contribute to the false positive case "They dealt with the ddos attacks with grace and confidence." determined by the baseline, and find that the patterns "DT ddos", "ddos attack|NN", "DT ddos attack|NN IN" and "IN DT ddos" are ranked 2nd, 18th, 111th, 127th among the 15,355 contextual patterns, respectively, which have relatively high weights but only carry

[9] The sentence boundary was detected by NLTK PunktSentenceTokenizer.

(b) Dark web test set.

Figure 6: Probability distributions on the test sets.

limited information. In contrast, the LSTM-based model can capture global syntactic and semantic features other than words surrounding *ddos* to distinguish mentions from non-mentions. From the table we can see that those high-confidence sentences determined by the LSTM-based model are more informative compared with those lower ranked sentences.

Figure 6 presents the probability distributions of positive and negative test cases as obtained by the baseline (x-axis) and the LSTM-based model (y-axis), respectively. It can be seen from the figures that the probabilities determined by the LSTM-based model are scattered between 0.0 and 1.0, while those by the baseline are gathered between 0.5 and 0.9, which shows that the proposed neural model can achieve better confidence on classifying event mentions. This demonstrates its stronger differentiating power as compared with discrete indicator features, as hypothesized in the introduction. In addition, for the proposed model a large portion of true positives (▲) are close to the top in both test sets, while more negatives (×) gather at the bottom of the dark web test set plot, compared to that in the tweet test set. As for the baseline model, many negatives locate around the horizontal centre, with a probability of 0.5, in the tweet test set, which explains why the baseline is relatively less effective on the precision-recall trade-off.

7 Conclusion

We investigated LSTM-based text representation for event mention extraction, finding that automatic features from the deep neural network largely improve the sparse representation method on the task. The model performance can further benefit by exploiting deep LSTM structures and tensor combination of bidirectional features. Results on tweets and dark web forum posts show the effectiveness of the method.

Abstract

Neural machine translation (NMT) with recurrent neural networks, has proven to be an effective technique for end-to-end machine translation. However, in spite of its promising advances over traditional translation methods, it typically suffers from an issue of unbalanced outputs, that arise from both the nature of recurrent neural networks themselves, and the challenges inherent in machine translation. To overcome this issue, we propose an agreement model for neural machine translation and show its effectiveness on large-scale Japanese-to-English and Chinese-to-English translation tasks. Our results show the model can achieve improvements of up to 1.4 BLEU over the strongest baseline NMT system. With the help of an ensemble technique, this new end-to-end NMT approach finally outperformed phrase-based and hierarchical phrase-based Moses baselines by up to 5.6 BLEU points.

1 Introduction

Recurrent neural network (RNN) has achieved great successes on several structured prediction tasks (Graves, 2013; Watanabe and Sumita, 2015; Dyer et al., 2015), in which RNNs are required to make a sequence of dependent predictions. One of its advantages is that an unbounded *history* is available to enrich the context for the prediction at the current time-step.

Despite its successes, recently, (Liu et al., 2016) pointed out that the RNN suffers from a fundamental issue of generating unbalanced outputs: that is to say the suffixes of its outputs are typically worse than the prefixes. This is due to the fact that later predictions directly depend on the accuracy of previous predictions. They empirically demonstrated this issue on two simple sequence-to-sequence learning tasks: machine transliteration and grapheme-to-phoneme conversion.

On the more general sequence-to-sequence learning task of machine translation (MT), neural machine translation (NMT) based on RNNs has recently become an active research topic (Sutskever et al., 2014; Bahdanau et al., 2014). Compared to those two simple tasks, MT involves in much larger vocabulary and frequent reordering between input and output sequences. This makes the prediction at each time-step far more challenging. In addition, sequences in MT are much longer, with averaged length of 36.7 being about 5 times longer than that in grapheme-to-phoneme conversion. Therefore, we believe that the history is more likely to contain incorrect predictions and the issue of unbalanced outputs may be more serious. This hypothesis is supported later (see Table 1 in §4.1), by an analysis that shows the quality of the prefixes of translation hypotheses is much higher than that of the suffixes.

To address this issue for NMT, in this paper we extend the agreement model proposed in (Liu et al., 2016) to the task of machine translation. Its key idea is to encourage the agreement between a pair of target-directional (left-to-right and right-to-left) NMT models in order to produce more balanced translations and thus improve the overall translation quality. Our contribution is two-fold:

- We introduce a simple and general method to address the issue of unbalanced outputs for

Proceedings of NAACL-HLT 2016, pages 411–416,
San Diego, California, June 12-17, 2016.

NMT (§3). This method is robust without any extra hyperparameters to tune and is easy to implement. In addition, it is general enough to be applied on top of any of the existing RNN translation models, although it was implemented on top of the model in (Bahdanau et al., 2014) in this paper.

- We provide an empirical evaluation of the technique on large scale Japanese-to-English and Chinese-to-English translation tasks. The results show our model can generate more balanced translation results, and achieves substantial improvements (of up to 1.4 BLEU points) over the strongest NMT baseline (§4). With the help of an ensemble technique, our new end-to-end NMT gains up to 5.6 BLEU points over phrase-based and hierarchical phrase-based Moses (Koehn et al., 2007) systems. [1]

2 Overview of Neural Machine Translation

Suppose $\mathbf{x} = \langle x_1, x_2, \cdots, x_m \rangle$ denotes a source sentence, $\mathbf{y} = \langle y_1, y_2, \cdots, y_n \rangle$ denotes a target sentence. In addition, let $x_{<t} = \langle x_1, x_2, \cdots, x_{t-1} \rangle$ denote a prefix of $\mathbf{x}$. Neural Machine Translation (NMT) directly maps a source sentence into a target within a probabilistic framework. Formally, it defines a conditional probability over a pair of sequences $\mathbf{x}$ and $\mathbf{y}$ via a recurrent neural network as follows:

$$\begin{aligned} p(\mathbf{y} \mid \mathbf{x}; \theta) &= \prod_{t=1}^{n} p(y_t \mid y_{<t}, \mathbf{x}; \theta) \\ &= \prod_{t=1}^{n} \mathbf{softmax}\big(g(h_t)\big)[y_t] \end{aligned} \tag{1}$$

where θ is the set of model parameters; h_t denotes a hidden state (i.e. a vector) of $\mathbf{y}$ at timestep t; g is a transformation function from a hidden state to a vector with dimension of the target-side vocabulary size; $\mathbf{softmax}$ is the softmax function, and $[i]$ denotes the i_{th} component in a vector.[2] Furthermore, $h_t = f(h_{t-1}, c(\mathbf{x}, y_{<t}))$ is defined by a recurrent function over both the previous hidden state h_{t-1} and the context $c(\mathbf{x}, y_{<t})$. [3] Note that both h_t and $c(\mathbf{x}, y_{<t})$ have dimension d for all t.

In this paper, we develop our model on top of the neural machine translation approach of (Bahdanau et al., 2014), and we refer the reader this paper for a complete description of the model, for example, the definitons of f and c. The proposed method could just as easily been implemented on top of any other RNN models such as that in (Sutskever et al., 2014).

3 Agreement on Target-bidirectional NMT

In this section, we extend the method in (Liu et al., 2016) to address this issue of unbalanced outputs for NMT. The key idea is to: 1) train two kinds of NMT, i.e. one generating targets from *left-to-right* while the other from *right-to-left*; 2) encourage the agreement between them by joint search.

3.1 Training

The training objective function for our **agreement** (or **joint**) model is formalized as follows:

$$\ell = \sum_{\langle \mathbf{x}, \mathbf{y} \rangle} \log p(\mathbf{y} \mid \mathbf{x}; \theta_1) + \log p(\mathbf{y}^r \mid \mathbf{x}; \theta_2) \tag{2}$$

where $\mathbf{y}^r = \langle y_n, y_{n-1} \cdots, y_1 \rangle$ is the reverse of sequence $\mathbf{y}$; $p(\mathbf{y} \mid \mathbf{x}; \theta_1)$ denotes the **left-to-right** model with parameters θ_1, while $p(\mathbf{y}^r \mid \mathbf{x}; \theta_2)$ denotes the **right-to-left** model with parameters θ_2, as defined in Eq.(1); and $\langle \mathbf{x}, \mathbf{y} \rangle$ ranges over a given training dataset. Following (Bahdanau et al., 2014), we employ AdaDelta (Zeiler, 2012) to minimize the loss ℓ.

Note that, in parallel to our efforts, Cheng et al. (2016) has explored the agreement idea for NMT close to ours. However, unlike their work on the agreement between source and target sides in the spirit of the general idea in (Liang et al., 2006), we focus on the agreement between left and right directions on the target side oriented to the natural issue of NMT itself. Although our model is orthogonal to theirs, one of our advantage is that our model does not rely on any additional hyperparameters to

[1] The absolute gains of our model can be expected to be further increased by applying the well-known techniques in (Jean et al., 2015; Luong et al., 2015) that address the problems presented by unknown words, but these techniques are beyond the scope of this paper.

[2] In that sense, y_t in Eq.(1) also denotes the index of this word in its vocabulary.

[3] Both hidden states and context vectors are dependent on the model parameter θ, but we remove it from the expressions here for simplicity.

encourage agreement, given that tuning such hyperparameters for NMT is too costly.

3.2 Approximate Joint Search

Given a source sentence $\mathbf{x}$ and model parameters $\langle\theta_1, \theta_2\rangle$, decoding can be formalized as follows:

$$\hat{\mathbf{y}} = \underset{\mathbf{y}}{\mathbf{argmax}}\, p(\mathbf{y} \mid \mathbf{x}; \theta_1) \times p(\mathbf{y}^r \mid \mathbf{x}; \theta_2)$$

As pointed out by (Liu et al., 2016), it is NP-hard to perform an exact search, and so we adapt one of their approximate search methods for the machine translation scenario. The basic idea consists of two steps: 1) run beam search for forward and reverse models independently to obtain two k-best lists; 2) re-score the union of two k-best lists using the joint model to find the best candidate. We refer to the reader to (Liu et al., 2016) for further details.

4 Experiments

We conducted experiments on two challenging translation tasks: Japanese-to-English (JP-EN) and Chinese-to-English (CH-EN), using case-insensitive BLEU for evaluation.

For the JP-EN task, we use the data from NTCIR-9 (Goto et al., 2011): the training data consisted of 2.0M sentence pairs, The development and test sets contained 2K sentences with a single referece, respectively. For the CH-EN task, we used the data from the NIST2008 Open Machine Translation Campaign: the training data consisted of 1.8M sentence pairs, the development set was nist02 (878 sentences), and the test sets are were nist05 (1082 sentences), nist06 (1664 sentences) and nist08 (1357 sentences).

Four baselines were used. The first two were the conventional state-of-the-art translation systems, phrase-based and hierarchical phrase-based systems, which are from the latest version of well-known Moses (Koehn et al., 2007) and are respectively denoted as Moses and Moses-hier. The other two were neural machine translation systems implemented using the open source NMT toolkit (Bahdanau et al., 2014):[4] left-to-right NMT (**NMT-l2r**) and right-to-left NMT (**NMT-r2l**). The proposed joint model (**NMT-J**) was also implemented using NMT (Bahdanau et al., 2014).

Systems	Prefix	Suffix
NMT-l2r	29.4	25.4
NMT-r2l	26.2	26.7
NMT-J	29.5	28.6

Table 1: Quality of 5-word prefixes and suffices of translations in the JP-EN test set, evaluated using partial BLEU.

We followed the standard pipeline to train and run Moses. GIZA++ (Och and Ney, 2000) with grow-diag-final-and was used to build the translation model. We trained 5-gram target language models using the training set for JP-EN and the Gigaword corpus for CH-EN, and used a lexicalized distortion model. All experiments were run with the default settings except for a distortion-limit of 12 in the JP-EN experiment, as suggested by (Goto et al., 2013).[5] To alleviate the negative effects of randomness, the final reported results are averaged over five runs of MERT.

To ensure a fair comparison, we employed the same settings for all NMT systems. Specifically, except for the maximum sequence length (seqlen, which was to 80), and the stopping iteration which was selected using development data, we used the default settings set out in (Bahdanau et al., 2014) for all NMT-based systems: the dimension of word embedding was 620, the dimension of hidden units was 1000, the batch size was 80, the source and target side vocabulary sizes were 30000, and the beam size for decoding was 12. Training was conducted on a single Tesla K80 GPU, and it took about 6 days to train a single NMT system on our large-scale data.

4.1 Results and Analysis on the JP-EN Task

In §1, it was claimed that NMT generates unbalanced outputs. To demostrate this, we have to evaluate the partial translations, which is not trivial (Liu and Huang, 2014). Inspired by (Liu and Huang, 2014), we employ the idea of partial BLEU rather than potential BLEU, as there is no future string concept during NMT decoding. In addition, since the lower n-gram (for example, 1-gram) is easier to be aligned to the uncovered words in source side,

[4] See https://github.com/lisa-groundhog/GroundHog/tree/master/experiments/nmt.

[5] This configuration achieved the significant improvements over the default setting on JP-EN.

Systems	dev	test
Moses	27.9	29.4
Moses-hier	28.6	30.2
NMT-l2r	31.5	32.4
NMT-r2l	31.5	32.6
NMT-J	33.0	34.1
NMT-l2r-5	32.6	33.7
NMT-r2l-5	33.0	34.3
NMT-J-5	**33.8**	**35.0**
NMT-l2r-10	32.5	33.6
NMT-r2l-10	33.0	34.2

Table 2: BLEU comparison of the proposed model NMT-Joint with three baselines on JP-EN task.

which might negatively affect the absolute statistics of evaluation,[6] we employ the partial 4-gram as the metric to evaluate the quality of partial translations (both prefixes and suffixes). In Table 1, we can see that the prefixes are of higher quality than the suffixes for a single left-to-right model (NMT-l2r). In contrast to this, it can be seen that our joint model (NMT-J) that includes one left-to-right and one right-to-left model, successfully addresses this issue, producing balanced outputs.

Table 2 shows the main results on the JP-EN task. From this table, we can see that, although a single NMT model (either left-to-right or right-to-left) comfortably outperforms the Moses and Moses-hier baselines, our simple NMT-J (with one l2r and one r2l NMT model) obtain gains of 1.5 BLEU points over a single NMT. In addition, the more powerful joint model NMT-J-5, which is an ensemble of five l2r and five r2l NMT models, gains 0.7 BLEU points over the strongest NMT ensemble NMT-r2l-5, i.e. an ensemble of five r2l NMT models. The ensemble of joint models achieved considerable gains of 5.6 and 4.8 BLEU points over the state-of-the-art Moses and Moses-hier, respectively. To the best of our knowlege, it is the first time that an end-to-end neural machine translation system has achieved such improvements on the very challenging task of JP-EN translation.

Systems	nist05	nist06	nist08
Moses	35.4	33.7	25.0
Moses-hier	35.6	33.8	25.3
NMT-l2r	34.2	34.9	27.7
NMT-r2l	34.0	34.1	26.9
NMT-J	36.8	36.9	28.5
NMT-l2r-5	37.0	37.5	28.2
NMT-r2l-5	36.9	37.1	27.3
NMT-J-5	**37.5**	**38.9**	**28.8**

Table 3: BLEU comparison of the proposed model NMT-Joint with baselines on CH-EN task.

One might argue that our NMT-J-5 contained ten NMT models in total, while the NMT-l2r-5 or NMT-r2l-5 only used five models, and thus such a comparison is unfair. Therefore, we integrated ten NMT models into the NMT-r2l-10 ensemble. In Table 2, we can see that NMT-r2l-10 is not necessarily better than NMT-r2l-5, which is consistent with the findings reported in (Zhou et al., 2002).

4.2 Results on the CH-EN Task

Table 3 shows the comparison between our method and the baselines on the CH-EN task.[7] The results were similar in character to the results for JP-EN. The proposed joint model (NMT-J-5) consistently outperformed the strongest neural baseline (NMT-l2r-5), an ensemble of five l2r NMT models, on all the test sets with gains up to 1.4 BLEU points. Furthermore, our model again achieved substantial gains over the Moses and Moses-hier systems, in the range 1.9∼5.2 BLEU points, depending on the test set.

5 Related Work

Target-bidirectional transduction techniques were pioneered in the field of machine translation (Watanabe and Sumita, 2002; Finch and Sumita, 2009; Zhang et al., 2013). They used the techniques for traditional SMT models, under the IBM framework (Watanabe and Sumita, 2002) or the feature-driven linear models (Finch and Sumita, 2009; Zhang et al., 2013). However, the target-bidirectional techniques

[6] In training SMT (Liu and Huang, 2014), we update weights towards higher BLEU translations and thus we care more about the relative statistics of BLEU; but in this paper, we care more about the absolute statistics, in order to show how severe the problem of unbalanced outputs is.

[7] We did not run NMT-l2r-10 and NMT-r2l-10, because it is too time-consuming to train 10 NMT models on both target directions and especially NMT-r2l-10 is not necessarily better than NMT-r2l-5 as shown in Table 2.

we have developed for the unified neural network framework, target a pressing need directly motivated by a fundamental issue suffered by recurrent neural networks.

Target-directional neural network models have also been successfully employed in (Devlin et al., 2014). However, their approach was concerned with feedforward networks, which can not make full use of rich contextual information. As a result, their models could only be used as features (i.e. submodels) to augment traditional translation techniques in contrast to the end-to-end neural network framework for machine translation in our proposal.

Our approach is related to that in (Bengio et al., 2015) in some sense. Both approaches can alleviate the mismatch between the training and testing stages: the history predictions are always correct in training while may be incorrect in testing. Bengio et al. (2015) introduce noise into history predictions in training to balance the mistmatch, while we try to make the history predictions in testing as accurate as those in training by using of two directional models. Therefore, theirs focuses on this problem from the view of training instead of both modeling and training as ours, but it is possible and promising to apply their approach to optimize our joint model.

6 Conclusion

In this paper, we investigate the issue of unbalanced outputs suffered by recurrent neural networks, and empirically show its existence in the context of machine translation. To address this issue, we propose an easy to implement agreement model that extends the method of (Liu et al., 2016) from simple sequence-to-sequence learning tasks to machine translation.

On two challenging JP-EN and CH-EN translation tasks, our approach was empirically shown to be effective in addressing the issue; by generating balanced outputs, it was able to consistently outperform a respectable NMT baseline on all test sets, delivering gains of up to 1.4 BLEU points. To put these results in the broader context of machine translation research, our approach (even without special handling of unknown words) achieved gains of up to 5.6 BLEU points over strong phrase-based and hierarchical phrase-based Moses baselines, with the help of an ensemble technique.

Acknowledgments

We would like to thank the three anonymous reviewers for helpful comments and suggestions. In addition, we would like to thank Rico Sennrich for fruitful discussions.

Abstract

We tackle the problem of identifying deceptive agents in highly-motivated high-conflict dialogues. We consider the case where we only have textual information. We show the usefulness of psycho-linguistic deception and persuasion features on a small dataset for the game of Werewolf. We analyse the role of syntax and we identify some characteristics of players in deceptive roles.

1 Introduction

Deception detection has gained some attention in the NLP community (Mihalcea and Strapparava, 2009; Ott et al., 2011; Jindal and Liu, 2008). The focus has mostly been on detecting insincere reviews or arguments. However, there has been little work (Hung and Chittaranjan, 2010) in detecting deception and manipulation in dialogues.

When the agents involved in a dialogue have conflicting goals, they are often motivated to use deception and manipulation in order to reach those goals. Examples include trials and negotiations. The high motivation for using deception and the possiblity of tracking the effects on participants throughout the dialogue sets this problem apart from identifying deception in nonce text fragment where motivation is not immediately relevant.

The Werewolf game is an instance of such a dialogue where people are motivated to deceive and manipulate in order to reach their goals. The setting is a village where at least one of the villagers is secretly a werewolf. Each night, a villager falls prey to the werewolves. Each day, the remaining villagers discuss to find the most likely werewolf to execute.

Players are assigned roles that define their goals and available actions. For our purpose, all roles are collapsed together as either werewolf or non-werewolf. There are other important roles in Werewolf, such as seer, vigilante, etc, the goals and available actions of which are not the focus of this paper. (Barnwell, 2012) provides a broader description of the game and roles.

Each player only knows her own role, as assigned by an impartial judge who overlooks the game. The players with a *werewolf* role learn each other's roles in the first round of the game. Every round, they pick another non-werewolf player to be removed from the game. This happens during a *night phase*, and is hidden from the other players. The judge announces the identity and role of the removed player.

All players are then allowed to remove one other player from the game before the next night phase. They discuss and vote during a *day phase*. The *non-werewolves* are motivated to remove the werewolves from the game. The werewolves are motivated to hide their roles, as in every round there is a majority of non-werewolves. Any time werewolves become a majority, they win the game. Any time all werewolves are eliminated, they lose the game.

In this paper we define the task as binary classification of deceptive and non-deceptive roles in Werewolf. Werewolf roles are deceptive, as they rely on deception to win the game, whereas all the

other roles are nondeceptive (Hung and Chittaranjan, 2010). For our purpose, all these roles are collapsed together according to whether they help the werewolves or not. We consider all the utterances of each player in each game as one distinct instance.

This is a first step towards building a model of deception in the Werewolf game, and more generally in scenarios where deception can be used to achieve goals. The model can then be used to predict future actions, e.g. the vote outcomes in Werewolf.

We show that by analyzing this dialogue genre we can gain some insights into the dynamics of manipulation and deception. These insights would then be useful in detecting hidden intentions and predicting decisions in important, real-life scenarios.

2 Previous Work

There has been little work on deception detection in written language and most of it has focused on either discriminating between sincere and insincere arguments (Mihalcea and Strapparava, 2009) or opinion spam (Ott et al., 2011; Jindal and Liu, 2008). One method of data collection has been to ask subjects to argue for both sides of a debate (Mihalcea and Strapparava, 2009). While lies about one's beliefs are also present, the manipulative behaviour and the motivation are missing. Since none of the previous work focuses on dialogue, the change in participants' beliefs, intentions, and plans reflected in the interaction between players is also absent.

More related is the work of (Hung and Chittaranjan, 2010), who recorded a total of 81.17 hours of people playing the Werewolf game, and used phonetic features to detect werewolves. While their results are promising, our focus is on written text only.

We have also been inspired by psycho-linguistic studies of deception detection (Porter and Yuille, 1996) as well as by psycho-linguistic research on persuasive or powerless language (Greenwald et al., 1968; Hosman, 2002; Sparks and Areni, 2008). We build upon findings from both of these lines of research, as Werewolf players use both deception, to hide their roles and intentions, and persuasion, to manipulate other players' beliefs and intentions.

3 Experiments

3.1 Data

The raw data consists of 86 game transcripts collected by Barnwell (Barnwell, 2012). The transcripts have an average length of 205 messages per transcript, including judge comments.

In the transcripts, the judge is a bot, which means there is a small fixed set of phrases it uses to make announcements. As part of the system, the judge knows all the roles as they are assigned. It reveals those roles in an annoucement as follows: every time a player is removed from the game, their role is made known; and the roles of the remaining players are revealed after the game is concluded.

We automatically extracted role assignments by looking for phrases such as *was a, is a, turns out to have been, carried wolfsbane*. We manually checked the assignments and found the werewolf roles were correctly assigned for 72 out of the 86 transcripts. The remaining 14 games end before they should because the judge bot breaks down. However, the players do reveal their own roles after the game ends. By looking at their comments, we manually annotated these remaining games.

All the utterances from each player in each transcript translate to one data instance. The label is 1 or 0, for whether the player is or isn't a werewolf. We do not consider the judge as part of the data. The resulting data set consists of 701 instances, of which 116 are instances of a werewolf role.

Given the small size and the skewed distribution of the dataset, we balanced the data with resampling so that we have enough instances to learn from.

3.2 Features

3.2.1 Psycholinguistic Features

(Tausczik and Pennebaker, 2010) suggest word count and use of negative emotions, motion, and sense words are indicative of deception.

We counted the negative emotion words using the MPQA subjectivity lexicon of (Wilson et al., 2005). We also experimented with the NRC word-emotion association lexicon of (Mohammad and Yang, 2011), but found the MPQA lexicon to perform better. Since we didn't have access to LIWC (Tausczik and Pennebaker, 2010), we used manually created lists of motion (*arrive, run, walk*) and sense (*see, sense, appearance*) words. The lists are up to 50 words long. We also considered the number of verbs, based on our intuition that heavy use of verbs can be associated to motion. However, we don't expect the number of motion words to be as important in our domain. This is because deception in the Werewolf game does not refer to a fabricated story that other players have to be convinced to believe, but rather to hiding one's identity and intentions.

(Tausczik and Pennebaker, 2010) also talk about honesty features : number of exclusion words (*but, without, exclude, except, only, just, either*) and number of self references (we used a list of first person singular pronoun forms). They claim that cognitive complexity is also correlated with honesty. This is because maintaining the coherence of a fabricated story is cognitively taxing. Cognitive complexity manifests in the use of: long words (longer than 6 letters), exclusion words (differentiating between competing solutions), conjunctions, disjunctions, connectives (integrating different aspects of a task), and cognitive words (*think, plan, reason*).

(Porter and Yuille, 1996) observe that for highly motivated deception, people use longer utterances, more self references, and more negative statements. We used those as features, as the average number of words per utterance and the number of dependencies of type *negation* from the Stanford parser.

Another set of features cited by (Porter and Yuille, 1996) comes for ex-polygrapher Sapir's training program for police investigators. He notes that liars use too many unneeded connectors, and display deviations in pronoun usage – most of the times by avoiding first-person singular. This seems to contradict the discussion on highly motivated deception (Porter and Yuille, 1996), and is aligned with (Tausczik and Pennebaker, 2010)'s findings. It is possible that the natural tendency of a liar is to avoid self references (e.g. due to cognitive dissonance), but that a strong motivation can cause one to purposefully act against this tendency, ignoring any mental discomfort it may cause. In our experiments, we didn't observe any tendency of werewolf to either avoid or increase use of self references.

There are differences in language when used to recount a true memory versus a false one (reality monitoring) (Porter and Yuille, 1996). In this context, a true memory means a memory of reality, i.e. of a story that actually happened, whereas a false memory is a mental representation of a fabricated story. People talking about a true memory tend to focus on the attributes of the stimulus that generated the memory (e.g. shape, location, color), whereas people talking about a false memory tend to use more cognitive words (e.g. *believe*, *think*, *recall*) and hedges (e.g. *kind of*, *maybe*, *a little*). An explanation is that the process of fabricating a story engages reasoning more than it does memory, and people tend to resist committing to a lie. We used the noun and adjective count as a rough approximation of the number of stimulus attributes, as adjectives and nouns in prepositional phrases can be used to enrich a description, e.g. of a memory. However, it is important to note that Werewolf players do not actively lie, in the sense that the discussion does not involve events not directly accessible to all players. Therefore it's impossible for players to lie about the course of events, so there is no false memory to recount.

Another characteristic of the game is that the werewolves actively try to *persuade* other players that their intentions are not harmful. (Hosman, 2002) notes that language complexity is indicative of persuasive power. A measure of language complexity is the type-token ratio (TTR). On the other hand, hesitations (*um, er, uh*), hedges (*sort of, kind of, almost*), and polite forms are markers of powerless language (Sparks and Areni, 2008). We did not find any polite forms in our data, the context being a game where players adopt a familiar tone.

The complete list of features is as follows (words are stemmed): *TTR* (type-token ratio), *number of hesitations, number of negative emotions, number of words, number of words longer than 6 letters, number of self references, number of negations, number of hedges* (50 hedge words), *number of cognitive words* (50 words), *number of motion words* (20 words), *number of sense words* (17 words), *number of exclusion words, number of connectors* (prepositions and conjunctions), *number of pronouns, number of adjectives, number of nouns, number of verbs, number of conjunctions, number of prepositions*.

3.2.2 POS and Syntactic Features

Following the intuition that cognitive complexity can also be reflected in sentence structure, we decided to look beyond lexical level for markers of deception and persuasion and experimented with POS and syntactic features. We used the Stanford POS parser (Lee et al., 2011) to extract part of speech labels as well as dependencies and production rules.

The syntactic features are based on both constituency and dependency parses, i.e. both production rules and dependency types.

3.3 Results

We used Weka and 10-fold cross-validation. We experimented with: logistic regression (LR, 10^8 ridge), SVM, Naive Bayes, perceptron, decision trees (DT), voted perceptron (VP), and random forest (RF).

The results are summarized in Table 1. DT and LR performed best among basic classifiers. DT outperforms LR, and the ensemble methods (VP and RF) far outperform both. An explanation is that there are deeper nonlinear dependencies between features. We believe such dependencies are worth further investigation beyond the scope of this paper. We plan to address this in future work.

In Table 1, we underlined the results for the two best *basic* classifiers, since we further analyze the features for these. Given space constraints, ensemble methods (VP and RF) are left to future work as analyzing the features and interactions based on their internal structure needs special attention.

Table 2 summarizes the feature selection results. We used Weka's feature selection. The selected features (with a positive/negative association with a deceptive role) were: number of words (negative); number of pronouns, adjectives, nouns (positive).

In order to observe each feature's individual contribution, we also performed manual feature selection, removing one feature at a time. Removing the following features improved or did not affect the performance, increasing the F1 score from 64.9 to 66.1 : number of self references, number of adjectives, number of long words, number of conjunctions or of connectors (but not both), number of cognitive words, number of pronouns.

3.4 POS and Syntactic Features

We repeated the experiments with POS tags as features (POS model), and then with syntactic features, i.e. dependency types and production rules (POS+dep, POS+con, and POS+syn models). For each model, the *baseline* feature set is the set of psycholinguistic features used in the previous section. The subsequent models use both the baseline features and the syntactic features, e.g. POS+con uses lexical-level psycholinguistic features, POS tags, and production rules. We also used tf-idf weighting.

Model	Acc.	F1	Prec.	Rec.	AUC
SVM	57.2	56.2	58.9	57.2	57.9
Perc	62.77	62.6	63.5	62.8	67
LR	**64.91**	**64.9**	**65.1**	**64.9**	66.8
NB	55.92	53.7	58.9	55.9	68.6
DT	**84.45**	**84.4**	**84.9**	**84.5**	**87.4**
VP	65.34	62.2	70.7	65.3	65.6

Table 3 suggests that production rules highly improve performance. An explanation is that complex syntax reflects cognitive complexity. For example, the utterance: *Player A said that I was innocent, which I know to be true* has many subordinates (SBAR nodes , SBAR → IN S, SBAR → WHNP S), whereas *Anyone feeling particularly lupine?* has elliptical structure (missing S → NP VP). There is also overlap with lexical features (IN nodes).

4 Discussion and Conclusions

Inspecting the decision tree, we found that most non-werewolf players used few words, no connectors, and no negations. Most werewolves use more words, adjectives, few negative emotion words, and not many words greater than 6 letters. Some werewolves use sense words and few negative emotion words, whereas others use no sense words and few or no hedges, self references, or cognitive words.

Feature set	Acc.	F1	Prec.	Rec.	AUC
baseline	64.91	64.9	65.1	64.9	66.8

The conclusion is that werewolves are more verbose and moderately emotional, whereas non-werewolves are usually quiet, non-confrontational players. Werewolves also use moderately complex language, which can be explained by the fact that they are both actively trying to persuade other players, and under the cognitive load of constantly adjusting their plans to players' comments, and maintaining a false image of themselves and others.

This aligns with previous findings on low cognitive complexity for maintaining a lie (Tausczik and Pennebaker, 2010) and verbosity for highly motivated deception (Porter and Yuille, 1996).

Inspecting the odds ratios (OR) of the features in the logistic regression classifier, we found the following features to be most relevant: *TTR* (3.49), *number of hesitations* (0.91), *number of negative emotions* (1.16), *number of motion words* (1.25), *number of sense words* (0.76), *number of exclusions* (1.31), *number of connectors* (0.92), *number of conjunctions* (0.92), *number of prepositions* (1.32).

On the connection between werewolf roles and persuasion, TTR is indicative of persuasive power as well as of a werewolf, and the number of hesitations is a marker of powerless language, and is negatively associated with a werewolf role.

The fact that the number of prepositions is indicative of a werewolf role aligns with Sapir's findings, whereas the positive influence of negative emotion and motion words and the negative influence of connectors and conjunctions is as predicted by (Tausczik and Pennebaker, 2010). However, (Tausczik and Pennebaker, 2010) cite the number of sense words as highly associated with deception and the number of exclusions, with honesty. We found that in our case these associations are reversed.

One possible explanation regarding the number of sense words can be the fact that *seeing*, a family of sense words, is overloaded in this data set, since *seer* is a legitimate game role, with actions (*seeing*) that carry a specific meaning. Another explanation is that, since the transcripts are from online game, there is no actual sensing involved.

As for the number of exclusions, (Tausczik and Pennebaker, 2010) list it as a marker of cognitive complexity, which should be affected by any attempt to maintain a false story. But here most players do not actively lie, so there is no false story to maintain, and therefore no toll on cognitive complexity.

Another observation is that features suggested for highly motivated deception (longer utterances, more self references, and more negations) are not important for this data set. It is possible that we do not have highly motivated deception, since any motivation is mitigated by the context, which is a game. This suggests that deception in dialogue contexts as well as game contexts is different than in the storytelling contexts analyzed in previous work in psycholinguistics (Hosman, 2002; Porter and Yuille, 1996). On the other hand, *identity concealment* is different than other kinds of highly motivated deception – in this particular case it might be more helpful to appear logical, rather than emotional.

In this paper we presented a simple model to serve as a baseline for further models of deception detection in dialogues. We did not consider word sequence, player interaction, individual characteristics of players, or non-literal meaning. However, the data set is too small for any more complex models. We believe our results shed light on some mechanisms of deception in the Werewolf game in particular, and of deception and manipulation in dialogues in general. We plan to collect more data on which we can employ richer models that also take into account utterance sequence and dialogue features.

Individual Variation in the Choice of Referential Form

Abstract

This study aims to measure the variation between writers in their choices of referential form by collecting and analysing a new and publicly available corpus of referring expressions. The corpus is composed of referring expressions produced by different participants in identical situations. Results, measured in terms of normalized entropy, reveal substantial individual variation. We discuss the problems and prospects of this finding for automatic text generation applications.

1 Introduction

Automatic text generation is the process of automatically converting data into coherent text - practical applications range from weather reports (Goldberg et al., 1994) to neonatal intensive care reports (Portet et al., 2009). One important way to achieve coherence in texts is by generating appropriate referring expressions throughout the text (Krahmer and van Deemter, 2012). In this generation process, the choice of referential form is a crucial task (Reiter and Dale, 2000): when referring to a person or object in a text, should the system use a proper name ("Phillip Anschutz"), a definite description ("the American entrepreneur") or a pronoun ("he")?

Despite the large amount of algorithms developed for deciding upon the form of a referring expression (Callaway and Lester, 2002; Greenbacker and McCoy, 2009; Gupta and Bandopadhyay, 2009; Orăsan and Dornescu, 2009; Greenbacker et al., 2010), it is difficult to know how well these algorithms actually perform. Typically, such algorithms are evaluated against a corpus of human written texts, predicting what form each reference should have in a given context. Now consider a situation in which the algorithm predicts that a reference should be a description, while this same reference is a pronoun in the corpus text. Should this count as an error? The answer is: it depends. The use of a pronoun does not necessarily mean that the use of a description is incorrect. In fact, other writers might have used a description as well.

In general, corpora of referring expressions have only *one* gold standard referential form for each situation, while different writers may conceivably vary in the referential form they would use. This complicates the development and evaluation of text generation algorithms, since these will typically attempt to predict the corpus gold standard, which may not always be representative of the choices of different writers. Although recent work in text generation has explored individual variation in the content determination of definite descriptions (Viethen and Dale, 2010; Ferreira and Paraboni, 2014), to the best of our knowledge this has not been systematically explored for choosing referential forms.

In this paper, we collect and analyze a new corpus to address this issue. In the collection, we presented different writers with texts in which all references to the main topic of the text have been replaced with gaps. The task of the participants was to fill each of those gaps with a reference to the topic. In the analysis, we estimated to what extent different writers agree with each other in terms of normalized entropy. In addition, we study whether this variation depends on the text genre, compar-

ing encyclopedic texts with news and product reports. Moreover, we discuss the implications of our findings for automatic text generation, exploring whether factors such as syntactic structure, referential status and recency affect the variation between the writers' choices. The annotated corpus is made publicly available[1].

2 Data Gathering

2.1 Material

For our study, we used 36 English texts, equally distributed over three different genres: news texts, reviews of commercial products and encyclopedic texts. The encyclopedic texts were selected from the GREC corpus (Belz et al., 2010), which is a standard corpus for testing and evaluating models for choice of referential form. The news and review texts were selected from the AQUAINT-2 corpus[2] and the SFU Review corpus (Konstantinova et al., 2012), respectively.

Note that, depending on the genre, texts may address different kinds of topics. For instance, the news texts usually are about a person, a company or a group; the product reviews may be about a book, a movie or a phone; and the encyclopedic texts about a mountain, a river or a country. In all texts, all expressions referring to the topic were replaced with gaps, which the participants should fill in.

2.2 Participants

Participants were recruited through CrowdFlower[3]. 78 participants completed the survey. 53 were female and 25 were male. Their average age was 37 years old. Most were native speakers (73 participants) or fluent in English (5 participants).

2.3 Procedure

The participants were first presented with an introduction to the experiment, explaining the procedure and asking their consent. Next, they were asked for their age, demographic information and English language proficiency. After this, participants were randomly assigned to a list, containing 9 texts (3 per genre).

The task of the participants was to fill in each gap with a reference to the topic of the text. To inform the participants about the entities, a short description - extracted from the Wikipedia page about the topic - was provided before each text.

Participants were encouraged to fill in the gaps according to their preferences, so that they felt the texts would be easy to understand. We made sure that participants did not fill all the gaps in a text with only one referring expression (to avoid copy/paste behaviour). Participants could also not leave any gap empty (they were instructed to use the "-" symbol for empty references).

2.4 Annotation

The first author of this study annotated the referring expressions produced by participants for referential form, syntactic position, referential status, and recency. Coding was straightforward, and the few difficult cases were resolved in discussions between the co-authors.

The referring expressions were assigned to one of five forms: **proper names** ("*Philip Anschutz*, 66, will have no trouble keeping busy."); **pronouns** ("*It* is the highest peak [...]", "Huffman, *who* spoke at the sentencing phase [...]"); **definite descriptions** ("[...] *the Russian President* defended the country's contribution [...]"); **demonstratives** ("You'll probably have screaming kids who want to see *this movie*."); and **empty references** ("He rarely grants on-the-record media interviews and __ seldom allows himself to be photographed.").

Following the GREC Project scheme (Belz et al., 2010), referring expressions were annotated for three syntactic positions: subject noun phrases, object noun phrases, and genitive noun phrases that function as determiners (***Google's*** *stock*). Referential status refers to whether a referring expression is a first mention to the topic (new) or not (old). We annotated this at the level of the text, paragraph and sentence, so that a reference can be new in paragraph, but old in the text. Recency, finally, is the distance between a given referring expression and the last, previous reference to the same topic, measured in terms of number of words within a paragraph. If the referring expression was the first mention to the topic in the paragraph, its recency is set to 0.

In total, 10,977 referring expressions were col-

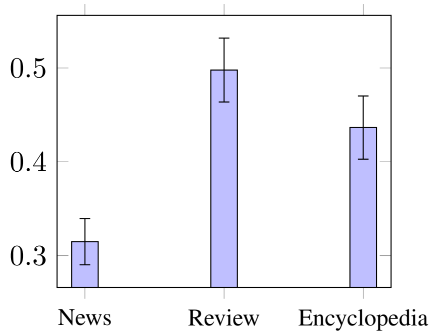

Figure 1: Average entropy per gap as a function of text genre. The error bars represent the 95% confidence intervals.

lected in 563 referential gaps. 3,682 were annotated as proper names, 4,662 as pronouns, 768 as definite descriptions, 318 as demonstratives and 158 as empty references. The remaining 1,389 were ruled out of the corpus, since they did not consist of a reference to the target entity or changed the meaning of the original sentence.

2.5 Analysis

We measured variation between participants' choices for each gap, using the normalized entropy measure, defined in Equation 1, where X corresponds to the references in a given gap, and $n = 5$ the number of referential forms annotated.

$$H(X) = -\sum_{i=1}^{n=5} \frac{p(x_i)\log(p(x_i))}{\log(n)} \qquad (1)$$

The measure ranges from 0 to 1, where 0 indicates the complete agreement among the participants for a particular referential form, and 1 indicates the complete variation among their choices.

3 Results

Figure 1 presents the main result, depicting the amount of individual variation in referential forms, measured in terms of entropy, as a function of text genre. The averaged entropies are significantly higher than 0 for all three genres according to a Wilcoxon signed-rank test (News: $V = 20,910.0$, $p < .001$; Reviews: $V = 11,476.0$, $p < .001$; and Encyclopedic texts: $V = 10,153.0$, $p < .001$). This clearly shows that different writers can vary substantially in their choices for a referential form. Comparing the three different genres, we find that writers' choices of referential form varied most in review texts and least in news texts, with encyclopedic texts sandwiched in between (Kruskal-Wallis $H = 70.73$, $p < .001$).

In comparison with the original texts, 44% of the referring expressions produced by the writers differ from the original ones in a same referential gap. Furthermore, the form of the original referring expressions differs from the major choice of the writers in 38% of the referential gaps.

To get a better understanding of factors potentially influencing individual variation, we investigate the effects of three linguistic factors: syntactic position, referential status and recency. Figure 2 depicts the average entropies for each of these.

Comparing the three syntactic positions, Figure 2a suggests that the highest variation is found when writers need to choose referential forms in the object position of a sentence, whereas the lowest variation is found for references that function as a genitive noun phrase determiner (Kruskal-Wallis $H = 52.53$, $p < .001$).

Figure 2b depicts individual variation in the choice of referential form for old and new references in the text, paragraph and sentence. The data suggests a higher amount of individual variation when writers need to refer to a topic already mentioned in the text rather than a first mention (Mann-Whitney $U = 3,916.0$, $p < .001$), presumably because for a topic which is new in the text, writers were more likely to agree to use proper names (91% of the choices). Looking at old and new references within paragraphs reveals no significant differences in individual variation (Mann-Whitney $U = 32,669.5$, $p < .094$). At the sentence level, finally, there is more individual variation for references to a new topic than for references to a previously mentioned one (Mann-Whitney $U = 21,873.0$, $p < .001$). When writers referred to a previously mentioned referent in the sentence, they tended to agree on the use of a pronoun (76% of the choices).

Figure 2c shows the individual variation in referential form as a function of recency. Except for the relatively nearby intervals (between 0 and 10 words, and between 11 and 20 words), the data suggests that when the distance between two consecutive references gets larger, the variation among writ-

In Figure 2c, the bars represent the average entropies for the group of references where the most recent prior reference is 10 or less words away, between 11 and 20 words, between 21 and 30 words, between 31 and 40 words and more than 40 words away.

ers' choices increases (Kruskal-Wallis $H = 35.31$, $p < .001$).

4 Discussion

In this paper, we studied individual variation in the choice of referential form by collecting a new (and publicly available) dataset in which different participants (writers) were asked to refer to the same referent throughout a text. This was done for different genres (news, product review and encyclopedic texts) by measuring the variation between participants in terms of normalized entropy. If participants would all use the same referential form in the same gap, we would expect entropy values of 0 (no individual variation), but instead we found a clearly different pattern in all three text genres. Moreover, we also saw a considerably difference in form among the original referring expressions and the ones generated by the participants. This reveals that substantial individual variation between writers exists in terms of referential form.

To get a better understanding of which factors influence individual variation, we analysed to what extent three linguistic factors had an impact on the entropy scores: syntactic position, referential status and recency. We found a higher amount of individual variation when writers had to choose referential forms in the direct object position, referring to previously mentioned topics in the text and first mentioned ones in the sentence, and references that were relatively distant from the most recent antecedent reference to the same topic.

These findings can be related to theories of reference involving the salience of a referent (Gundel et al., 1993; Grosz et al., 1995, among others). Brennan (1995), for example, argued that references in the role of the subject of a sentence are more likely to be salient than references in the role of the object. Chafe (1994), to give a second example, pointed out that references to previously mentioned referents in the discourse and ones that are close to their antecedent are more likely to be salient than references to new referents or ones that are distant from their antecedents. Note, incidentally, that none of these earlier studies address the issue of individual variation in referential form.

Arguably, the amount of individual variation is even larger than the data reported here suggest. To illustrate this, consider, for instance, that different participants referred to *Phillip Frederick Anschutz* - the main topic of one of the texts used - as *Phillip Frederick Anschutz*, *Mr. Phillip Frederick Anschutz*, *Anschutz*, *Mr. Anschutz* and *Phillip Anschutz*. Even though these all have the same referential form (proper names), there is also a lot of variation *within* this category. Indeed, it would be interesting in future research to explore which factors account for this within-form variation.

The current findings are important for automatic text generation algorithms in two ways. First, they are beneficial for developers of text generation systems, since they allow for a better understanding of the range of variation that is possible in referring expression generation. Second, they allow for a more principled evaluation of algorithms predicting referential form. In fact, the collected corpus paves the way for developing models which predict frequency distributions over referential forms, rather than merely predicting a single form in particular context (as current models do).

Joint Learning Templates and Slots for Event Schema Induction

Lei Sha, Sujian Li, Baobao Chang, Zhifang Sui

Abstract

Automatic event schema induction (*AESI*) means to extract meta-event from raw text, in other words, to find out what types (templates) of event may exist in the raw text and what roles (slots) may exist in each event type. In this paper, we propose a joint entity-driven model to learn templates and slots simultaneously based on the constraints of templates and slots in the same sentence. In addition, the entities' semantic information is also considered for the inner connectivity of the entities. We borrow the *normalized cut* criteria in image segmentation to divide the entities into more accurate template clusters and slot clusters. The experiment shows that our model gains a relatively higher result than previous work.

1 Introduction

Event schema is a high-level representation of a bunch of similar events. It is very useful for the traditional information extraction (*IE*)(Sagayam et al., 2012) task. An example of event schema is shown in Table 1. Given the bombing schema, we only need to find proper words to fill the slots when extracting a bombing event.

Bombing Template	
Perpetrator:	person
Victim:	person
Target:	public
Instrument:	bomb

Table 1: The event schema of bombing event in MUC-4, it has a bombing template and four main slots

There are two main approaches for *AESI* task. Both of them use the idea of clustering the potential event arguments to find the event schema. One of them is probabilistic graphical model (Chambers, 2013; Cheung, 2013). By incorporating templates and slots as latent topics, probabilistic graphical models learns those templates and slots that best explains the text. However, the graphical models considers the entities independently and do not take the interrelationship between entities into account. Another method relies on ad-hoc clustering algorithms (Filatova et al., 2006; Sekine, 2006; Chambers and Jurafsky, 2011). (Chambers and Jurafsky, 2011) is a pipelined approach. In the first step, it uses pointwise mutual information(PMI) between any two clauses in the same document to learn events, and then learns syntactic patterns as fillers. However, the pipelined approach suffers from the error propagation problem, which means the errors in the template clustering can lead to more errors in the slot clustering.

This paper proposes an entity-driven model which jointly learns templates and slots for event schema induction. The main contribution of this paper are as follows:

- To better model the inner connectivity between entities, we borrow the normalized cut in image segmentation as the clustering criteria.

- We use constraints between templates and between slots in one sentence to improve *AESI* result.

Figure 1: An entity example

2 Task Definition

Our model is an entity-driven model. This model represents a document d as a series of entities $E_d = \{e_i | i = 1, 2, \cdots\}$. Each entity is a quadruple $e = (h, p, d, f)$. Here, h represents the head word of an entity, p represents its predicate, and d represents the dependency path between the predicate and the head word, f contains the features of the entity (such as the **direct** hypernyms of the head word), the sentence id where e occurred and the document id where e occurred. A simple example is Fig 1.

Our ultimate goal is to assign two labels, a slot variable s and a template variable t, to each entity. After that, we can summarize all of them to get event schemas.

3 Automatic Event Schema Induction

3.1 Inner Connectivity Between Entities

We focus on two types of inner connectivity: (1) the likelihood of two entities to belong to the same template; (2) the likelihood of two entities to belong to the same slot;

3.1.1 Template Level Connectivity

It is easy to understand that entities occurred near each other are more likely to belong to the same template. Therefore, (Chambers and Jurafsky, 2011) uses PMI to measure the correlation of two words in the same document, but it cannot put two words from different documents together. In the Bayesian model of (Chambers, 2013), p(predicate) is the key factor to decide the template, but it ignores the fact that entities occurring nearby should belong to the same template. In this paper, we try to put two measures together. That is, if two entities occurred nearby, they can belong to the same template; if they have similar meaning, they can also belong to the same template. We use PMI to measure the distance similarity and use word vector (Mikolov et al., 2013) to calculate the semantic similarity.

A word vector can well represent the meaning of a word. So we concatenate the word vector of the j-th entity's head word and its predicate, denoted as $vec_{hp}(i)$. We use the cosine distance $\cos_{hp}(i, j)$ to measure the difference of two vectors.

Then we can get the template level connectivity formula as shown in Eq 1. The $PMI(i, j)$ is calculated by the head words of entity mention i and j.

$$W_T(i, j) = PMI(i, j) + \cos_{hp}(i, j) \qquad (1)$$

3.1.2 Slot Level Connectivity

If two entities can play similar role in an event, they are likely to fill the same slot. We know that if two entities can play similar role, their head words may have the same hypernyms. We only consider the **direct** hypernyms here. Also, their predicates may have similar meaning and the entities may have the same dependency path to their predicate. Therefore, we give the factors equal weights and add them together to get the slot level similarity.

$$\begin{aligned} W_S(i, j) = \cos_p(i, j) + \delta(depend_i = depend_j) \\ + \delta(hypernym_i \cap hypernym_j \neq \phi) \end{aligned} \qquad (2)$$

Here, the $\delta(\cdot)$ has value 1 when the inner expression is true and 0 otherwise. The "hypernym" is derived from Wordnet(Miller, 1995), so it is a set of direct hypernyms. If two entities' head words have at least one common direct hypernym, then they may belong to the same slot. And again $\cos_p(i, j)$ represents the cosine distance between the predicates' word vector of entity i and entity j.

3.2 Template and Slot Clustering Using Normalized Cut

Normalized cut intend to maximize the intra-class similarity while minimize the inter class similarity, which deals well with the connectivity between entities.

We represent each entity as a point in a high-dimension space. The edge weight between two points is their template level similarity / slot level similarity. Then the larger the similarity value is, the more likely the two entities (point) belong to the same template / slot, which is also our basis intuition.

For simplicity, denote the entity set as $E = \{e_1, \cdots, e_{|E|}\}$, and the template set as T. We use the $|E| \times |T|$ partition matrix X_T to represent the template clustering result. Let $X_T = [X_{T_1}, \cdots, X_{T_{|T|}}]$, where X_{T_l} is a binary indicator for template $l(T_l)$.

$$X_T(i,l) = \begin{cases} 1 & e_i \in T_l \\ 0 & otherwise \end{cases} \tag{3}$$

Usually, we define the degree matrix D_T as: $D_T(i,i) = \sum_{j \in E} W_T(i,j), i = 1, \cdots, |E|$. Obviously, D_T is a diagonal matrix. It contains information about the weight sum of edges attached to each vertex. Then we have the template clustering optimization as shown in Eq 4 according to (Shi and Malik, 2000).

$$\begin{aligned} \max \quad & \varepsilon_1(X_T) = \frac{1}{|T|} \sum_{l=1}^{|T|} \frac{X_{T_l}^T W_T X_{T_l}}{X_{T_l}^T D_T X_{T_l}} \\ s.t. \quad & X_T \in \{0,1\}^{|E| \times |T|} \quad X_T \mathbf{1}_{|T|} = \mathbf{1}_{|E|} \end{aligned} \tag{4}$$

where $\mathbf{1}_{|E|}$ represents the $|E| \times 1$ vector of all 1's.

For the slot clustering, we have a similar optimization as shown in Eq 5.

$$\begin{aligned} \max \quad & \varepsilon_2(X_S) = \frac{1}{|S|} \sum_{l=1}^{|S|} \frac{X_{S_l}^T W_S X_{S_l}}{X_{S_l}^T D_S X_{S_l}} \\ s.t. \quad & X_S \in \{0,1\}^{|E| \times |S|} \quad X_S \mathbf{1}_{|S|} = \mathbf{1}_{|E|} \end{aligned} \tag{5}$$

where S represents the slot set, X_S is the slot clustering result with $X_S = [X_{S_1}, \cdots, X_{S_{|S|}}]$, where X_{S_l} is a binary indicator for slot $l(S_l)$.

$$X_S(i,l) = \begin{cases} 1 & e_i \in S_l \\ 0 & otherwise \end{cases} \tag{6}$$

3.3 Joint Model With Sentence Constraints

For event schema induction, we find an important property and we name it "Sentence constraint". The entities in one sentence often belong to one template but different slots.

The sentence constraint contains two types of constraint, "template constraint" and "slot constraint".

1. **Template constraint**: Entities in the same sentence are usually in the same template. Hence we should make the templates taken by a sentence as few as possible.

2. **Slot constraint**: Entities in the same sentence are usually in different slots. Hence we should make the slots taken by a sentence as many as possible.

Based on these consideration, we can add an extra item to the optimization object. Let $N_{sentence}$ be the number of sentences. Define $N_{sentence} \times |E|$ matrix J as the sentence constraint matrix, the entries of J is as following:

$$J(i,j) = \begin{cases} 1 & e_i \in Sentence_j \\ 0 & otherwise \end{cases} \tag{7}$$

Easy to show, the product $G_T = J^T X_T$ represents the relation between sentences and templates. In matrix G_T, the (i,j)-th entry represents how many entities in sentence i are belong to T_j.

Using G_T, we can construct our objective. To represent the two constraints, the best objective we have found is the trace value: $tr(G_T G_T^T)$. Each entry on the diagonal of matrix $G_T G_T^T$ is the square sum of all the entries in the corresponding line in G_T, and the larger the trace value is, the less templates the sentence would taken. Since $tr(G_T G_T^T)$ is the sum of the diagonal elements, we only need to maximize the value $tr(G_T G_T^T)$ to meet the template constraint. For the same reason, we need to minimize the value $tr(G_S G_S^T)$ to meet the slot constraint.

Generally, we have the following optimization objective:

$$\varepsilon_3(X_T, X_S) = \frac{tr\left(X_T^T J J^T X_T\right)}{tr\left(X_S^T J J^T X_S\right)} \tag{8}$$

The whole joint model is shown in Eq 9. The detailed derivation[1] is shown in the supplement file.

$$
\begin{aligned}
X_T, X_S = \underset{X_T, X_S}{\operatorname{argmax}}\, & \varepsilon_1(X_T) + \varepsilon_2(X_S) + \varepsilon_3(X_T, X_S) \\
s.t.\ X_T \in \{0,1\}^{|E| \times |T|} & \quad X_T \mathbf{1}_{|T|} = \mathbf{1}_{|E|} \\
X_S \in \{0,1\}^{|E| \times |S|} & \quad X_S \mathbf{1}_{|S|} = \mathbf{1}_{|E|}
\end{aligned} \tag{9}
$$

4 Experiment

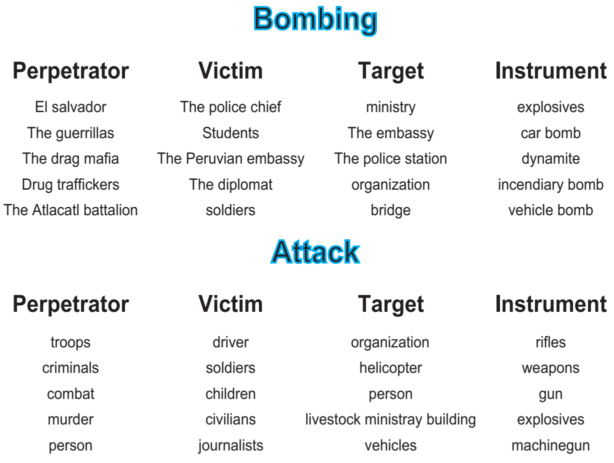
4.1 Dataset

In this paper, we use MUC-4(Sundheim, 1991) as our dataset, which is the same as previous works (Chambers and Jurafsky, 2011; Chambers, 2013). MUC-4 corpus contains 1300 documents in the training set, 200 in development set (TS1, TS2) and 200 in testing set (TS3, TS4) about Latin American news of terrorism events. We ran several times on the 1500 documents (training/dev set) and choose the best $|T|$ and $|S|$ as $|T| = 6$, $|S| = 4$. Then we report the performance of test set. For each document, it provides a series of hand-constructed event schemas, which are called gold schemas. With these gold schemas we can evaluate our results. The MUC-4 corpus contains six template types: **Attack, Kidnapping, Bombing, Arson, Robbery, and Forced Work Stoppage**, and for each template, there are 25 slots. Since most previous works do not evaluate their performance on all the 25 slots, they instead focus on 4 main slots like Table 1, we will also focus on these four slots. We use the Stanford CoreNLP toolkit to parse the MUC-4 corpus.

4.2 Performance

Fig 2 shows two examples of our learned schemas: Bombing and Attacking. The five words in each slot are the five randomly picked entities from the mapped slots. The templates and slots that were joint learned seem reasonable.

Induced schemas need to map to gold schemas before evaluation. Previous works used two methods of mapping. The first ignores the schema type, and simply finds the best performing slot for each gold template slot. For instance, a perpetrator of a bombing and a perpetrator of an attack are treated the same. We call this the **slot-only mapping** evaluation. The second approach is to map each template t to the best gold template g, and limit the slot mapping so that only the slots under t can map to slots under g. We call this the **strict template mapping** evaluation. The slot-only mapping can result in higher scores since it is not constrained to preserve schema structure in the mapping.



Bombing

Perpetrator	Victim	Target	Instrument
El salvador	The police chief	ministry	explosives
The guerrillas	Students	The embassy	car bomb
The drag mafia	The Peruvian embassy	The police station	dynamite
Drug traffickers	The diplomat	organization	incendiary bomb
The Atlacatl battalion	soldiers	bridge	vehicle bomb

Attack

Perpetrator	Victim	Target	Instrument
troops	driver	organization	rifles
criminals	soldiers	helicopter	weapons
combat	children	person	gun
murder	civilians	livestock ministray building	explosives
person	journalists	vehicles	machinegun

Table 2: Slot-only mapping comparison to state-of-the-art unsupervised systems, "-SC" means without sentence constraint

We compare our results with four works (Chambers and Jurafsky, 2011; Cheung, 2013; Chambers, 2013; Nguyen et al., 2015) as is shown in Table 2 and Table 3. Our model has outperformed all of the previous methods. The improvement of recall is due to the normalized cut criteria, which can better use the inner connectivity between entities. The sentence constraint improves the result one step further.

Note that after adding the sentence constraint, the slot-only performance has increased a little, but the strict *template mapping* performance has increased a lot as is shown in Table 3. This phenomenon can be explained by the following facts: We count the

[1] At https://github.com/shalei120/ESI_1_2 can the code be found.

	Prec	Recall	F1
Chambers (2013)	**0.42**	0.27	0.33
Our Model-SC	0.26	**0.55**	0.35
Our Model	0.33	0.50	**0.40**

Table 3: strict template mapping comparison to state-of-the-art unsupervised systems, "-SC" means without sentence constraint

amount of entities which has been assigned different templates or different slots in "Our Model-SC" and "Our Model". Of all the 11465 entities, 2305 entities has been assigned different templates in the two methods while only 108 entities has different slots. This fact illustrates that the sentence constraint can affect the assignment of templates much more than the slots. Therefore, the sentence constraint leads largely improvement to the strict mapping performance and very little increase to the slot-only performance.

5 Related Works

The traditional information extraction task is to fill the event schema slots. Many slot filling algorithms requires the full information of the event schemas and the labeled corpus. Among them, there are rule-based method (Rau et al., 1992; Chinchor et al., 1993), supervised learning method (Baker et al., 1998; Chieu et al., 2003; Bunescu and Mooney, 2004; Patwardhan and Riloff, 2009; Maslennikov and Chua, 2007), bootstrapping method (Yangarber et al., 2000) and cross-document inference method (Ji and Grishman, 2008). Also there are many semi-supervised solutions, which begin with unlabeled, but clustered event-specific documents, and extract common word patterns as extractors (Riloff and Schmelzenbach, 1998; Sudo et al., 2003; Riloff et al., 2005; Patwardhan and Riloff, 2007; Filatova et al., 2006; Surdeanu et al., 2006)

Other traditional information extraction task learns binary relations and atomic facts. Models can learn relations like "Jenny is married to Bob" with unlabeled data (Banko et al., 2007; Etzioni et al., 2008; Yates et al., 2007; Fader et al., 2011), or ontology induction (dog is an animal) and attribute extraction (dogs have tails) (Carlson et al., 2010a; Carlson et al., 2010b; Huang and Riloff, 2010; Van Durme and Pasca, 2008), or rely on predefined patterns (Hearst, 1992).

Shinyama and Sekine (2006) proposed an approach to learn templates with unlabeled corpus. They use *unrestricted relation discovery* to discover relations in unlabeled corpus as well as extract their fillers. Their constraints are that they need redundant documents and their relations are binary over repeated named entities. (Chen et al., 2011) also extract binary relations using generative model.

Kasch and Oates (2010), Chambers and Jurafsky (2008), Chambers and Jurafsky (2009), Balasubramanian et al. (2013) captures template-like knowledge from unlabeled text by large-scale learning of scripts and narrative schemas. However, their structures are limited to frequent topics in a large corpus. Chambers and Jurafsky (2011) uses their idea, and their goal is to characterize a specific domain with limited data using a three-stage clustering algorithm.

Also, there are some state-of-the-art works using probabilistic graphic model (Chambers, 2013; Cheung, 2013; Nguyen et al., 2015). They use the Gibbs sampling and get good results.

6 Conclusion

This paper presented a joint entity-driven model to induct event schemas automatically.

This model uses word embedding as well as PMI to measure the inner connection of entities and uses normalized cut for more accurate clustering. Finally, our model uses sentence constraint to extract templates and slots simultaneously. The experiment has proved the effectiveness of our model.

Inferring Psycholinguistic Properties of Words

Gustavo Henrique Paetzold and **Lucia Specia**
Department of Computer Science
University of Sheffield, UK
{ghpaetzold1,l.specia}@sheffield.ac.uk

Abstract

We introduce a bootstrapping algorithm for regression that exploits word embedding models. We use it to infer four psycholinguistic properties of words: Familiarity, Age of Acquisition, Concreteness and Imagery and further populate the MRC Psycholinguistic Database with these properties. The approach achieves 0.88 correlation with human-produced values and the inferred psycholinguistic features lead to state-of-the-art results when used in a Lexical Simplification task.

1 Introduction

Throughout the last three decades, much has been found on how the psycholinguistic properties of words influence cognitive processes in the human brain when a subject is presented with either written or spoken forms. A word's Age of Acquisition is an example. The findings in (Carroll and White, 1973) reveal that objects whose names are learned earlier in life can be named faster in later stages of life. Zevin and Seidenberg (2002) show that words learned in early ages are orthographically or phonologically very distinct from those learned in adult life.

Other examples of psycholinguistic properties, such as Familiarity and Concreteness, influence one's proficiency in word recognition and text comprehension. The experiments in (Connine et al., 1990; Morrel-Samuels and Krauss, 1992) show that words with high Familiarity yield lower reaction times in both visual and auditory lexical decision, and require less hand gesticulation in order to be described. Begg and Paivio (1969) found that humans are less sensitive to changes in wording made to sentences with high Concreteness words.

When quantified, these aspects can be used as features for various Natural Language Processing (NLP) tasks. The Lexical Simplification approach in (Jauhar and Specia, 2012) is an example. By combining various collocational features and psycholinguistic measures extracted from the MRC Psycholinguistic Database (Coltheart, 1981), they trained a ranker (Joachims, 2002) that reached first place in the English Lexical Simplification task at SemEval 2012. Semantic Classification tasks have also benefited from the use of such features: by combining Concreteness with other features, (Hill and Korhonen, 2014) reached the state-of-the-art performance in Semantic Composition (*denotative/connotative*) and Semantic Modification (*intersective/subsective*) prediction.

Despite the evident usefulness of psycholinguistic properties of words, resources describing such properties are rare. The most extensively developed resource for English is the MRC Psycholinguistic Database (Section 2). However, it is far from complete, most likely due to the inherent cost of manually entering such properties. In this paper we propose a method to automatically infer these missing properties. We train regressors by performing bootstrapping (Yarowsky, 1995) over the existing features in the MRC database, exploiting word embedding models and other linguistic resources for that (Section 3). This approach outperform various strong baselines (Section 4) and the resulting properties lead to significant improvements when used in Lexical Simplification models (Section 5).

2 The MRC Psycholinguistic Database

Introduced by Coltheart (1981), the MRC (Machine Readable Dictionary) Psycholinguistic Database is a digital compilation of lexical, morphological and psycholinguistic properties for 150,837 words. The 27 psycholinguistic properties in the resource range from simple frequency measures (Rudell, 1993) to elaborate measures estimated by humans, such as Age of Acquisition and Imagery (Gilhooly and Logie, 1980). However, despite various efforts to populate the MRC Database, these properties are only available for small subsets of the 150,837 words.

We focus on four manually estimated psycholinguistic properties in the MRC Database:

- **Familiarity**: The frequency with which a word is seen, heard or used daily. Available for 9,392 words.
- **Age of Acquisition**: The age at which a word is believed to be learned. Available for 3,503 words.
- **Concreteness**: How "palpable" the object the word refers to is. Available for $8,228$ words.
- **Imagery**: The intensity with which a word arouses images. Available for 9,240 words.

All four properties are real values, determined based on different quantifiable metrics. We focus on these properties since they have been proven useful and are some of the most scarce in the MRC Database. As we discussed in Section 1, these properties have been successfully used in various approaches for Lexical Simplification and Semantic Classification, and yet are available for no more than 6% of the words in the MRC Database.

3 Bootstrapping with Word Embeddings

In order to automatically estimate missing psycholinguistic properties in the MRC Database, we resort to bootstrapping. We base our approach on that by (Yarowsky, 1995), a bootstrapping algorithm which aims to learn a classifier over a reduced set of annotated training instances (or "seeds"). It does so by performing the following five steps:

1. Initialise training set S with the seeds available.
2. Train a classifier over S.
3. Predict values for a set of unlabelled instances U.
4. Add to S all instances from U for which the prediction confidence c is equal or greater than ζ.
5. If at least one instance was added to S, go to step 2, otherwise, return the resulting classifier.

One critical difference between this approach and ours is that our task requires regression algorithms instead of classifiers. In classification, the prediction confidence c is often calculated as the maximum signed distance between an instance and the estimated hyperplanes. There is, however, no analogous confidence estimation technique for regression problems. We address this problem by using word embedding models.

Embedding models have been proved effective in capturing linguistic regularities of words (Mikolov et al., 2013b). In order to exploit these regularities, we assume that the quality of a regressor's prediction on an instance is directly proportional to how similar the instance is to the ones in the labelled set. Since the input for the regressors are words, we compute the similarity between a test word and the words in the labelled dataset as the maximum cosine similarity between the test word's vector and the vectors in the labelled set.

Let M be an embeddings model trained over vocabulary V, S a set of training seeds, ζ a minimum confidence threshold, $sim(w, S, M)$ the maximum cosine similarity between word w and S with respect to model M, R a regression model, and $R(w)$ its prediction for word w. Our bootstrapping algorithm is depicted in Algorithm 1.

Algorithm 1: Regression Bootstrapping

```
input: $M$, $V$, $S$, $\zeta$;
output: $R$;
repeat
    Train $R$ over $S$;
    for $w \in V - S$ do
        if $sim(w, S, M) \geq \zeta$ then
            Add $\langle w, R(w) \rangle$ to $S$;
        end
    end
until $||S||$ converges ;
```

We found that 64,895 out of the 150,837 words in the MRC database were not present in either WordNet or our word embedding models. Since our bootstrappers use features extracted from both these resources, we were only able to predict the Familiarity, Age of Acquisition, Concreteness and Imagery values of the remaining 85,942 words in MRC.

4 Evaluation

Since we were not able to find previous work for this task, in these experiments, we compare the performance of our bootstrapping strategy to various baselines. For training, we use the Ridge regression algorithm (Tikhonov, 1963). As features, our regressor uses the word's raw embedding values, along with the following 15 lexical features:

- Word's length and number of syllables, as determined by the Morph Adorner module of LEXenstein (Paetzold and Specia, 2015).
- Word's frequency in the Brown (Francis and Kucera, 1979), SUBTLEX (Brysbaert and New, 2009), SubIMDB (Paetzold and Specia, 2016), Wikipedia and Simple Wikipedia (Kauchak, 2013) corpora.
- Number of senses, synonyms, hypernyms and hyponyms for word in WordNet (Fellbaum, 1998).
- Minimum, maximum and average distance between the word's senses in WordNet and the thesaurus' root sense.
- Number of images found for word in the Getty Images database[1].

We train our embedding models using word2vec (Mikolov et al., 2013a) over a corpus of 7 billion words composed by the SubIMDB corpus, UMBC webbase[2], News Crawl[3], SUBTLEX (Brysbaert and New, 2009), Wikipedia and Simple Wikipedia (Kauchak, 2013). We use 5-fold cross-validation to optimise parameters: ζ, embeddings model architecture (CBOW or Skip-Gram), and word vector size (from 300 to 2,500 in intervals of 200). We include four strong baseline systems in the comparison:

- **Max. Similarity**: Test word is assigned the property value of the closest word in the training set, i.e. the word with the highest cosine similarity according to the word embeddings model.
- **Avg. Similarity**: Test word is assigned the average property value of the n closest words in the training set, i.e. the words with the highest cosine similarity according to the word embeddings model. The value of n is decided through 5-fold cross validation.
- **Simple SVM**: Test word is assigned the property value as predicted by an SVM regressor (Smola and Vapnik, 1997) with a polynomial kernel trained with the 15 aforementioned lexical features.
- **Simple Ridge**: Test word is assigned the property value as predicted by a Ridge regressor trained with the 15 aforementioned lexical features.
- **Super Ridge**: Identical to Simple Ridge, the only difference being that it also includes the words embeddings in the feature set. We note that this baseline uses the exact same features and regression algorithm as our bootstrapped regressors.

The parameters of all baseline systems are optimised following the same method as with our approach. We also measure the correlation between each of the aforementioned lexical features and the psycholinguistic properties. For each psycholinguistic property, we create a training and a test set by splitting the labelled instances available in the MRC Database in two equally sized portions. All training instances are used as seeds in our approach. As evaluation metrics, we use Spearman's (ρ) and Pearson's (r) correlation. Pearson's correlation is the most important indicator of performance: an effective regressor would predict values that change linearly with a given psycholinguistic property.

The results are illustrated in Table 1. While the similarity-based approaches tend to perform well for Concreteness and Imagery, typical regressors capture Familiarity and Age of Acquisition more effectively. Our approach, on the other hand, is consistently superior for all psycholinguistic properties, with both Spearman's and Pearson's correlation

Table 1: Regression correlation scores. In bold are the highest scores within a group (features, baselines, proposed approach), and underlined the highest scores overall.

scores varying between 0.82 and 0.88. The difference in performance between the Super Ridge baseline and our approach confirm that our bootstrapping algorithm can in fact improve on the performance of a regressor.

The parameters used by our bootstrappers, which are reported below, highlight the importance of parameter optimization in out bootstrapping strategy: its performance peaked with very different configurations for most psycholinguistic properties:

- **Familiarity**: 300 word vector dimensions with a Skip-Gram model, and $\zeta = 0.9$.

- **Age of Acquisition**: 700 word vector dimensions with a CBOW model, and $\zeta = 0.7$.

- **Concreteness**: 1,100 word vector dimensions with a Skip-Gram model, and $\zeta = 0.7$.

- **Imagery**: 1,100 word vector dimensions with a Skip-Gram model, and $\zeta = 0.7$.

Interestingly, frequency in the SubIMDB corpus[4], composed of over 7 million sentences extracted from subtitles of "family" movies and series, has good linear correlation with Familiarity and Age of Acquisition, much higher than any other feature. For Concreteness and Imagery, on the other hand, the results suggest something different: the further a word is from the root of a thesaurus, the most likely it is to refer to a physical object or entity.

5 Psycholinguistic Features for LS

Here we assess the effectiveness of our bootstrappers in the task of Lexical Simplification (LS). As shown in (Jauhar and Specia, 2012), psycholinguistic features can help supervised ranking algorithms capture word simplicity. Using the parameters described in Section 4, we train bootstrappers for these two properties using all instances in the MRC Database as seeds. We then train three rankers with (W) and without (W/O) psycholinguistic features:

[4] http://ghpaetzold.github.io/subimdb

- **Horn** (Horn et al., 2014): Uses an SVM ranker trained on various n-gram probability features.
- **Glavas** (Glavaš and Štajner, 2015): Ranks candidates using various collocational and semantic metrics, and then re-ranks them according to their average rankings.
- **Paetzold** (Paetzold and Specia, 2015): Ranks words according to their distance to a decision boundary learned from a classification setup inferred from ranking examples. Uses n-gram frequencies as features.

We use data from the English Lexical Simplification task of SemEval 2012 to assess systems' performance. The goal of the task is to rank words in different contexts according to their simplicity. The training and test sets contain 300 and 1,710 instances, respectively. The official metric from the task – TRank (Specia et al., 2012) – is used to measure systems' performance. As discussed in (Paetzold, 2015), this metric best represents LS performance in practice. The results in Table 2 show that the addition of our features lead to performance increases with all rankers. Performing F-tests over the rankings estimated for the simplest candidate in each instance, we have found these differences to be statistically significant ($p < 0.05$). Using our features, the **Paetzold** ranker reaches the best published results for the dataset, significantly superior to the best system in SemEval (Jauhar and Specia, 2012).

	TRank	
Ranker	W/O	W
Best SemEval	-	0.602
Horn	0.625	**0.635**
Glavas	0.623	**0.636**
Paetzold	0.653	**0.657**

Table 2: Results on SemEval 2012 LS task dataset

6 Conclusions

Overall, the proposed bootstrapping strategy for regression has led to very positive results, despite its simplicity. It is therefore a cheap and reliable alternative to manually producing psycholinguistic properties of words. Word embedding models have proven to be very useful in bootstrapping, both as surrogates for confidence predictors and as regression features. Our findings also indicate the usefulness of individual features and resources: word frequencies in the SubIMDB corpus have a much stronger correlation with Familiarity and Age of Acquisition than previously used corpora, while the depth of a word's in a thesaurus hierarchy correlates well with both its Concreteness and Imagery.

In future work we plan to employ our bootstrapping solution in other regression problems, and to further explore potential uses of automatically learned psycholinguistic features.

Abstract

This paper proposes a variability normalization algorithm to reduce the variability between intra-topic documents for topic classification. Firstly, an optimization problem is constructed based on linear variability removable assumption. Secondly, a new feature space for document representation is found by solving the optimization problem with kernel principle component analysis (KPCA). Finally, effective feature transformation is taken through linear projection. As for experiments, state-of-the-art SVM and KNN algorithm are adopted for topic classification respectively. Experimental results on a free-style conversational corpus show that the proposed variability normalization algorithm for topic classification achieves 3.8% absolute improvement for micro-F_1 measure.

1 Introduction

Topic classification is now faced with the problem of enormous variability between documents due to the exponential growth of free-style unstructured texts in recent years. This paper treats variability as differences between text documents and aims at reducing the intra-topic document variability for better topic classification. There are various factors to cause the intra-topic variability problem, such as the different language usages of different persons (Chambers, 1995; Fillmore et al., 2014). In free-style conversations experimented in this paper, different people would use very different words to express their opinions. Therefore, documents in a same topic could be quite different because of the intra-topic variability problem.

In this work, we are interested in finding a robust document representation strategy to address the intra-topic variability problem. Traditional method represents document by a high-dimensional TF-IDF vector based on the bag-of-word approach (Salton and McGill, 1986; Salton and Buckley, 1988). However, the TF-IDF feature reveals little semantic similarity information between terms, which would increase the differences between intra-topic documents when different words are used. Beyond the TF-IDF strategy, there are two class of techniques, i.e., unsupervised technique and supervised technique for document representations. The unsupervised technique includes some latent semantic analysis methods. The typical method is Latent Semantic Indexing (LSI) while the features estimated by LSI are linear combinations of the original features (Deerwester et al., 1990; Wang et al., 2013). Meanwhile, the popular Latent Dirichlet Allocation (Blei et al., 2003; Morchid et al., 2014) algorithm was proposed to represent document by a generative probabilistic model (Blei et al., 2003). Moreover, in recent years, many neural network based methods have been investigated for document representations (Hinton and Salakhutdinov, 2006; Srivastava et al., 2013; Le and Mikolov, 2014). For example, in (Le and Mikolov, 2014), a model called *paragraph vector* was designed to represent each document by a dense vector while the vector is trained by predicting all words in the corresponding document. On the other hand, supervised technique for document representation includes some discrim-

Proceedings of NAACL-HLT 2016, pages 441–446,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

inative approaches, e.g., Linear Discriminant Analysis (Berry et al., 1995; Chakrabarti et al., 2003; Torkkola, 2004) and supervised latent semantic indexing (Sun et al., 2004; Chakraborti et al., 2007; Bai et al., 2009). Meanwhile, some improved linear analysis methods were proposed for encoding documents with a reliable similarity information (Y-ih et al., 2011; Chang et al., 2013). However, all those works for document representation paid little attention to the variability of intra-topic documents. Therefore, they could hardly solve the intra-topic variability problem in a direct way.

This paper makes a preliminary investigation to deal with the intra-topic variability problem. The main purpose of this work is to find a new feature space with minimized intra-topic variability. An objective criterion is constructed for optimization. Mathematically, we make use of the topic label information of the training set to create a weighting matrix, and then sum over all the differences of intra-topic documents. Then a robust feature space with minimized intra-topic variability is generated by solving the optimization problem with effective KPCA based algorithm. Finally, we accomplish the variability normalization operations for the baseline features. We also employ the linear discriminant analysis as a supplementary algorithm. As for experiments, state-of-the-art SVM and KNN algorithms are employed for topic classification. System performances are evaluated on a challenging free-style conversational database.

The rest of this paper is organized as follows. In section 2, we introduce the proposed variability normalization algorithm for topic classification in detail. After it, section 3 presents experimental setup and results. Finally, conclusions and future work would be given in section 4.

2 Variability Normalization Algorithm

2.1 Motivation for variability normalization

This work aims to find a robust document representation strategy for topic classification. The proposed algorithm is motivated by the Nuisance Attribute Projection (NAP) algorithm in speaker verification field (Solomonoff et al., 2005; Solomonoff et al., 2007). We firstly make a **linear variability removable assumption** for document representation. Mathematically, given a document, it could be denoted by a column vector $\mathbf{x}$ with dimensionality of d as follows

$$\mathbf{x} = \mathbf{x}_t + \mathbf{x}_v \qquad (1)$$

where $\mathbf{x}_t$ denotes the useful signal information in current document, $\mathbf{x}_v$ stands for the remaining noise. It is very difficult to model the noise signal in a document since it could come from various sources. Therefore, in this paper, we focus on the noise created by the variability among intra-topic documents. Our goal is to find a new document representation through linear projection:

$$\tilde{\mathbf{x}} = \mathbf{P}\mathbf{x} \qquad (2)$$

where $\mathbf{P}$ is the projection matrix. Since the goal of this paper is not dimensionality reduction, the dimensionality of the new document representation is the same as the source document representation. Therefore, the size of $\mathbf{P}$ is $d \times d$. This paper proposes to learn $\mathbf{P}$ by minimizing the following intra-topic variability

$$\mathcal{Q} = \sum_{i,j} w_{ij} \|\mathbf{P}(\mathbf{x}_i - \mathbf{x}_j)\|^2 \qquad (3)$$

where w_{ij} is the *i*-th row and *j*-th column element of a weighting matrix $\mathbf{W}$ created in this work. The matrix is determined by the topic label information of training set as follows

$$w_{ij} = \begin{cases} 1 & \text{if } \mathbf{x}_i \text{ and } \mathbf{x}_j \text{ belong to a same topic} \\ 0 & \text{othervise} \end{cases} \qquad (4)$$

2.2 Variability normalization algorithm

For deriving the variability normalization algorithm, we follow the work of (Solomonoff et al., 2007) and re-write the projection matrix $\mathbf{P}$ by the variability space (denoted as a unit vector $\mathbf{v}$ here) as follows

$$\mathbf{P} = \mathbf{I} - \mathbf{v}\mathbf{v}^{\mathrm{T}} \qquad (5)$$

where $\mathbf{I}$ is a ($d \times d$) dimensional identity matrix. Combining (3) and (5), we get

$$\mathcal{Q} = \sum_{i,j} w_{ij}(\|\mathbf{x}_i - \mathbf{x}_j\|^2 - (\mathbf{v}^{\mathrm{T}}(\mathbf{x}_i - \mathbf{x}_j))^2). \qquad (6)$$

Since the first part of $\mathcal{Q}$ in (6) is independent on $\mathbf{v}$, we discard it and create the final criterion

$$\mathcal{Q} = -\sum_{i,j} w_{ij}(\mathbf{v}^{\mathrm{T}}(\mathbf{x}_i - \mathbf{x}_j))^2). \quad (7)$$

Unfolding (7) by linear operation, we get

$$\mathcal{Q} = 2\mathbf{v}^{\mathrm{T}}\mathbf{X} \cdot (\mathbf{W} - \mathrm{diag}(\mathbf{W} \cdot \mathbf{1})) \cdot \mathbf{X}^{\mathrm{T}}\mathbf{v}. \quad (8)$$

where $\mathbf{X}$ denotes the training set matrix, each row of $\mathbf{X}$ represents one document vector, $\mathbf{1}$ is a vector with all elements equal to 1. Minimizing (8) is equivalent to solving the flowing eigenvalue decomposition problem

$$\mathbf{X} \cdot (\mathrm{diag}(\mathbf{W} \cdot \mathbf{1}) - \mathbf{W})\mathbf{X}^{\mathrm{T}}\mathbf{v} = \lambda\mathbf{v}. \quad (9)$$

Here we apply the idea of KPCA (Solomonoff et al., 2007; Schölkopf et al., 1997) to solve (9). Denoting $\mathbf{v}$ by a new vector $\mathbf{Xu}$, finding $\mathbf{u}$ turns to solving a generalized eigenvalue problem in kernel space as

$$\begin{cases} \mathbf{KZKu} = \lambda\mathbf{Ku} \\ \mathbf{K} = \mathbf{X}^{\mathrm{T}}\mathbf{X} \\ \mathbf{Z} = \mathrm{diag}(\mathbf{W} \cdot \mathbf{1}) - \mathbf{W}. \end{cases} \quad (10)$$

The variability space is then constructed by selecting a set of eigenvectors corresponding to the d_1 largest eigenvalues.

$$\mathbf{U} = [\mathbf{u}_1, \mathbf{u}_2, ..., \mathbf{u}_{d_1}] \quad (11)$$

Finally, a $(d \times d)$ projection matrix is obtained by combining (5), (11) and $\mathbf{v} = \mathbf{Xu}$.

Based on this variability normalization algorithm, the baseline document vectors could be transformed to a new feature space with minimized intra-topic variability. The main procedure to implement intra-topic variation normalization could be divided into the following steps:

- Generate sample matrix $\mathbf{X}$ using the whole n documents of training set.
- Construct weighting matrix $\mathbf{W}$ according to (4) with the use of topic label information.
- Estimate a projection matrix $\mathbf{P}$ by solving the aforementioned eigenvalue problem.
- Transform all documents to new feature space through linear projection according to (2).

It should be noticed that after making feature transformation by the proposed variability normalization algorithm, the dimensionality of document representation has not been changed. This is different with all the existing dimensionality reduction methods since our goal is to re-define the feature representation space for topic document representation. To prove the effectiveness of the proposed algorithm, this paper presents experimental results on a challenging conversational dataset.

3 Experiments

In this section, we evaluate the proposed variability normalization method in a typical topic classification problem. We will firstly introduce the experimental setup, including dataset, evaluation criteria and system description. After it, all the experimental results would be reported in detail.

3.1 Experimental setup

3.1.1 Dataset

The data set used in this paper is the text transcripts of free-style conversational speech database, Fisher English corpus released by LDC, which contains 11699 recorded conversations (Cieri et al., 2004). This corpus is collected from 40 different topics, and each document includes relatively a distinct topic (e.g. “Comedy”, “Smoking”, “Terrorism”, etc.) as well as topics covering similar subject areas (e.g. “Airport Security”, “Bioterrorism”, “Issues in the Middle East”). This paper randomly chooses 60 documents and 50 documents per topic for the training set and testing set respectively. Another 50 documents for each topic are randomly selected to for the development set.

3.1.2 Evaluation criteria

We use two types of criteria to make a comprehensive evaluations for this work. The first evaluation creterion is F_1 measure corresponding to the recall and precision rates for a typical classification system. In detail, we would report micro-average F_1 and macro-average F_1 results. In consideration of topic classification is similar to topic verification, we choose equal error rate (EER) to be the second criterion, which is the equal value of miss probability and false probability.

3.1.3 System description

Module	Methods
Text processing	stop-word removal, stemming
Representation	TF-IDF feature
Classification	KNN, SVM algorithm

Table 1: Baseline system modules for topic classification.

This paper constructs several systems for comparison. The configurations of our baseline system are shown in Table 1. Porter algorithm (Porter, 1980) is adopted for word stemming after stop-words removal. Then a vocabulary with 19534 unique words is determined according to the occurrence frequency information of training set. Documents in the baseline system are represented by using the popular TF-IDF term weighting strategy (Salton and Buckley, 1988). Two popular algorithms SVM and KNN are used for classification separately. The SVM classification is implemented using the LIBSVM toolkit (Chang and Lin, 2011).

Based on the baseline system, descriptions of other systems are given as below.

(1) *LSI*: documents are represented in latent semantic space estimated by the LSI algorithm (Deerwester et al., 1990) based on the baseline features.

(2) *LDA*: document features are transformed by linear discriminant analysis. We select 50 eigenvectors for the low dimensional feature space.

(3) *VarNorm*: document features are transformed from the baseline TF-IDF vectors by the approach proposed in this paper. We select 60 eigenvectors for generating the project matrix.

(4) *VarNorm-LDA*: system combined *VarNorm* with *LDA*, which employs feature transformation operations twice on the original TF-IDF document features. The number of eigenvectors for *VarNorm* and *LDA* are set to 60 and 50 respectively.

All the parameters suggested in this paper are tuned on the development set. However, the eigenvector number is not restricted to 50 or 60. It is recommended to set the eigenvector num from 45 to 75 since we have 40 topics for experiments.

3.2 Experimental Results

3.2.1 Variability normalization performance

According to (3), we compare the intra-topic variability for the baseline and the *VarNorm* system. The difference for variability calculation is whether to use the projection matrix $\mathbf{P}$ or not. Figure 1 shows the intra-topic variability on 40 topics of the training set. The vertical axis represents the variability for each topic, while the horizontal axis stands for 40 topics in the conversation corpus. As we can see clearly, the variability of baseline system is high. After conducting variability normalization, it could be reduced effectively.

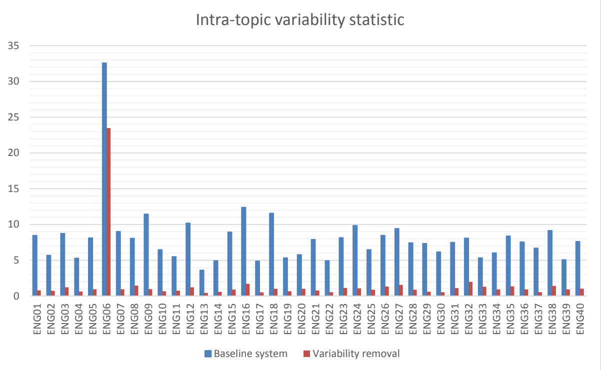

Figure 1: Variability normalization performance.

After making detailed analysis, we find for the topic ENG06, the theme is "*Hypothetical Situations: Perjury – Do either of you think that you would commit perjury for a close friend or family member?*", the variability among documents from this topic is largest in the whole corpus. However, for the topic ENG13, "*Movies: Do each of you enjoy going to the movies in a theater, or would you rather rent a movie and stay home? What was the last movie that you saw? Was it good or bad and why?*", the variability is the lowest. This is the difference between common topics and infrequent topics. Since people would use various words to express their ideas, it is reasonable to find the variability problem is more serious for infrequent topics than common topics.

3.2.2 Classification Results using KNN

Experimental results using KNN classification algorithm are given in Table 2. The results show that, compared to the baseline system, the variability normalization system *VarNorm* achieves 2% absolute F_1 improvement, and 29% relative improvement for EER. When taking the variability removing as a preliminary process, and employing LDA as the secondary transformation, the system *VarNorm-LDA* achieves the best performance. The EER is im-

Table 2: Classification results using KNN algorithm

System	EER	macro-F_1	micro-F_1
Baseline	6.10	84.72	83.15
LSI	4.25	86.24	85.45
LDA	4.49	88.94	88.15
VarNorm	4.30	86.46	85.60
VarNorm-LDA	**2.51**	**90.29**	**90.00**

Table 3: Classification results using SVM algorithm

System	EER	macro-F_1	micro-F_1
Baseline	3.40	88.86	88.40
LSI	3.35	89.59	89.25
LDA	3.05	90.81	90.55
VarNorm	**2.90**	**91.04**	**90.80**
VarNorm-LDA	**2.50**	**92.28**	**92.15**

proved by 65% relatively, and the micro-F_1 measure is improved by 6.85% absolutely. The reason for this performance is straightforward. Since the proposed algorithm effectively reduce the differences among intra-topic documents, the LDA algorithm would be more easier and effective to maximize the ratio of between-class-variance to within-class-variance.

3.2.3 Classification Results using SVM

Similarly, the experimental results using SVM classification algorithm are shown in Table 3. The baseline performance is better than system using KNN algorithm. The improvements achieved by *LSI* in KNN sytem almost vanish here, while the *VarNorm* system keeps its improvement. The *VarNorm* system even works better than the *LDA* system, with nearly 15% relative improvement on EER, and 3.4% absolute improvement on micro-F_1 measure. The best results are obtained by the *VarNorm-LDA* system. There are 36% relative improvement for EER, and 3.75% absolute improvement for micro-F_1 measure.

4 Conclusions and Future Work

In this paper, we investigated the intra-topic variability problem for topic classification. The major contribution of this work is that we proposed a effective variability normalization approach for robust document representation. An optimization problem was constructed after making a linear variability removable assumption. In order to take a deep insight into the performance of the proposed variability normalization algorithm, we conducted experiments on a challenge free-style conversation corpus. Experimental results based on the SVM and KNN classification algorithm all confirmed the robustness of the proposed approach. As a conclusion, the variability normalization algorithm could be used as a front-end feature transformation strategy, and we also suggest to combine it with linear discriminant analysis algorithm or some other algorithms to further improve system performances.

Further study will investigate the adaptive methods for constructing robust feature spaces. We would also combine this work with more document representations methods as well. Moreover, it would be very interesting to extend and combine our work to some novel unsupervised machine learning techniques, like the work of (Zhang and Jiang, 2015) while they proposed a model for high-dimensional data by combineing a linear orthogonal projection and a finite mixture model under a unified generative modeling framework.

Abstract

We present a neural network based shift-reduce CCG parser, the first neural-network based parser for CCG. We also study the impact of neural network based tagging models, and greedy versus beam-search parsing, by using a structured neural network model. Our greedy parser obtains a labeled F-score of 83.27%, the best reported result for greedy CCG parsing in the literature (an improvement of 2.5% over a perceptron based greedy parser) and is more than three times faster. With a beam, our structured neural network model gives a labeled F-score of 85.57% which is 0.6% better than the perceptron based counterpart.

1 Introduction

Shift-reduce parsing is interesting for practical real-world applications like parsing the web, since parsing can be achieved in linear time. Although greedy parsers are fast, accuracies of these parsers are typically much lower than graph-based parsers. Conversely, beam-search parsers achieve accuracies comparable to graph-based parsers (Zhang and Nivre, 2011) but are much slower than their greedy counterparts. Recently, Chen and Manning (2014) have showed that fast and accurate parsing can be achieved using neural network based parsers. Improving their work, Weiss et al. (2015) presented a structured neural network model which gave state-of-the-art results for English dependency parsing.

There has been increasing interest in Combinatory Categorial Grammar (CCG) (Steedman, 2000) parsing due to the simplicity of its interface between syntax and semantics. In addition to predicate-argument structure, CCG captures the unbounded dependencies found in grammatical constructions like relativization, coordination, etc. We present a neural network based shift-reduce CCG parser, the first neural network based parser for CCG. We first adapt Chen and Manning (2014)'s shift-reduce dependency parser for CCG parsing. We then develop a structured neural network model based on Weiss et al. (2015), in order to explore the impact of a beam-search on the parser. We also analyze the impact of neural network taggers (for both POS-tagging and CCG supertagging) as compared to maximum entropy taggers. Our greedy neural network parser achieves unlabeled and labeled F-scores of 89.78% and 83.27% respectively, an improvement of around 2.5% over a perceptron based greedy parser, and is more than three times faster. Due to its relevance for large-scale parsing, we make this parser available for public usage. By using a beam search, our structured neural network model gave even better results of 91.95% and 85.57% unlabeled and labeled F-scores respectively. To the best of our knowledge, ours is the first neural network based parser for CCG and also the first work on exploring neural network taggers for shift-reduce CCG parsing.

2 Related Work

2.1 CCG Parsers

Due to the availability of English CCGbank (Hockenmaier and Steedman, 2007), several wide-coverage CCG parsers have been developed (Hockenmaier and Steedman, 2002; Clark and Curran, 2007; Auli and Lopez, 2011; Zhang and Clark,

Proceedings of NAACL-HLT 2016, pages 447–453,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

2011; Lewis and Steedman, 2014a). While the majority of CCG parsers are chart-based (Clark and Curran, 2007; Lewis and Steedman, 2014a), there has been some work on shift-reduce CCG parsing (Zhang and Clark, 2011; Xu et al., 2014; Ambati et al., 2015). Zhang and Clark (2011) used a global linear model trained discriminatively with the averaged perceptron (Collins, 2002) and beam search for their shift-reduce CCG parser. A dependency model for shift-reduce CCG parsing using a dynamic oracle technique (Goldberg and Nivre, 2012) was developed by Xu et al. (2014). Ambati et al. (2015) presented an incremental algorithm for transition based CCG parsing which introduced two novel revealing actions to overcome the consequences of the greedy nature of the previous parsers.

2.2 Neural Network Parsers

Neural Network parsers are attracting interest for both speed and accuracy. There has been some work on neural networks for constituent based parsing (Collobert, 2011; Socher et al., 2013; Watanabe and Sumita, 2015). Chen and Manning (2014) developed a neural network architecture for dependency parsing. This parser was fast and accurate, parsing around 1000 sentences per second and achieving an unlabeled attachment score of 92.0% on the standard Penn Treebank test data for English. Chen and Manning (2014)'s parser used a feed forward neural network. Several improvements were made to this architecture in terms of using Long Short-Term Memory (LSTM) networks (Dyer et al., 2015), deep neural networks (Weiss et al., 2015) and structured neural networks (Weiss et al., 2015; Zhou et al., 2015; Alberti et al., 2015).

3 Our Neural Network Parser (NNPar)

The architecture of our neural network based shift-reduce CCG parser is similar to that of Chen and Manning (2014). We present the details of the network and the model settings in this section. We also discuss our structured neural network model.

3.1 Architecture

Figure 1 shows the architecture of our neural network parser. There are three layers in the parser: input, hidden and output layers. We first extract discrete features like words, POS-tags and CCG supertags from the parser configuration. For each of these discrete features we obtain a continuous vector representation in the form of their corresponding embeddings and use them in the input layer. Following Chen and Manning (2014), we use a cube activation function and softmax for output layer.

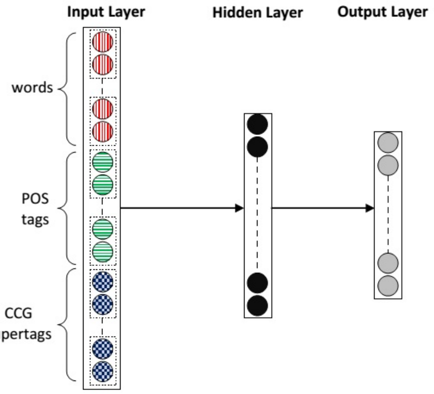

Figure 1: Our Neural Network Architecture (adapted from Chen and Manning (2014)).

3.2 Feature and Model Settings

We extract features from a) top four nodes in the stack, b) next four nodes in the input and c) left and right children of the top two nodes in the stack. We obtain words and POS-tags of all these 12 nodes. In case of CCG supertags, in addition to the CCG categories of the nodes in the stack (top four nodes, left and right children of top two nodes), we also obtain the lexical head categories for the top two nodes. We use a special token 'NULL' if a feature is not present in the parser configuration. So, in total we have 34 features: 12 word, 12 POS-tag and 10 CCG supertag features. For each of these 34 features we obtain their corresponding embeddings. We use Turian embeddings of dimensionality 50 (Turian-50)[1]. For the words which are not in the word embeddings dictionary, embeddings of '-UNKNOWN-' token are used as a backoff. For POS-tags and CCG supertags, the parameters are randomly initialized with values between -0.01 and 0.01.

Our input layer is a 34 (feature templates) X 50 (embedding size) dimensional vector. We use 200

[1] Lewis and Steedman (2014b) explored different publicly available word embeddings (Mnih and Hinton, 2009; Turian et al., 2010; Collobert et al., 2011; Mikolov et al., 2013) for CCG supertagging and showed that Turian-50 gave best results.

hidden units in the the hidden layer. For the output layer we compute softmax probabilities only for the actions which are possible in a particular parser configuration instead of all the actions. We use the training settings of Chen and Manning (2014) for our parser. The training objective is to minimize the cross-entropy loss with an l_2-regularization and the training error derivatives are backpropagated during training. For optimization we use AdaGrad (Duchi et al., 2011). 10^{-8} and 0.01 are the values for regularization parameter and Adagrad initial learning rate respectively. Parameters that give the best labeled F-score on the development data are used for testing data.

3.3 Structured Neural Network

Chen and Manning (2014)'s parser is a greedy parser and it is not straight forward to add a beam during training into their parser. As a way of introducing a beam, Weiss et al. (2015) presented a structured perceptron training for the neural network parser. They first pre-trained their neural network model. For the final layer, they trained a structured perceptron using beam search decoding which takes the neural network hidden and output layers as the input. This method, known as a structured neural network, gave the state-of-the-art results for English dependency parsing. In addition to using a softmax for the output layer, we also applied this structured neural network approach for our experiments using a beam. Unlike Weiss et al. (2015)'s neural network architecture, which consists of two hidden layers with 2048 hidden units each, we use the Chen and Manning (2014) style architecture described in the previous sections.

3.4 Comparison to Chen and Manning (2014)

Our neural network parser differs from Chen and Manning (2014) in a number of respects. We use CCG supertags in the input layer rather than dependency labels. For word embeddings, we use Turian embeddings (Turian et al., 2010) whereas they use Collobert et al. (2011). We have a slightly smaller set of 34 feature templates as compared to their 48 templates. Our parser has 2296 actions when instantiated by specific categorial types: 1285 `Shift`, 340 `Reduce-Left`, 593 `Reduce-Right` and 78 `Reduce-Unary` actions. In comparison, Chen and Manning (2014) have a much smaller number of actions (35 for CoNLL and 91 for Stanford dependencies). Because there are many more CCG categories ($\sim$ 500) compared to dependency labels, there are relatively more operations in a CCG parser.

4 Experiments and Results

We first compare our neural network parser (NNPar)[2] with a perceptron based parser in the greedy settings. Then we analyze the impact of beam using neural network (NNPar) and structured neural network (Structured NNPar) models.

The perceptron based parser is a reimplementation of Zhang and Clark (2011)'s parser (Z&C*). A global linear model trained with the averaged perceptron (Collins, 2002) is used for this parser and an early-update (Collins and Roark, 2004) strategy is used during training. In the greedy setting (beam=1), when the predicted action differs from the gold action, decoding stops and weights are updated accordingly. When a beam is used (beam=16), weights are updated when the gold parse configuration falls out of the beam. For Z&C*, the feature set of Zhang and Clark (2011), which comprises of 64 feature templates is used. For NNPar, the 34 feature templates described in section 3.2 are used. We employ an arc-standard style shift-reduce algorithm for CCG parsing, similar to Zhang and Clark (2011), for all our experiments.

4.1 Data and Settings

We use the standard CCGbank training (sections 02 – 21), development (section 00) and testing (section 23) splits for our experiments. All the experiments are performed using automatic POS-tags and CCG supertags. We compare performance using two types of taggers: maximum entropy and neural network based taggers (NNT). The C&C taggers [3] (Clark and Curran, 2004) are used for maximum entropy taggers. For neural network taggers, SENNA tagger[4] (version 3.0) (Collobert et al., 2011) is used

[2] We used Chen and Manning (2014)'s classifier for implementing our NNPar

[3] `http://svn.ask.it.usyd.edu.au/trac/candc/wiki`

[4] `http://ronan.collobert.com/senna/`

for POS-tagging and EasyCCG tagger[5] (Lewis and Steedman, 2014a) is used for supertagging. Both these taggers use a feed-forward neural network architecture with a single hidden layer similar to our NNPar architecture.

In the case of POS-tags, we consider the first best tag given by the POS tagger. For CCG supertags, we use a multitagger which gives n-best supertags for a word. Following Zhang and Clark (2011) and Xu et al. (2014), only during training, the gold CCG lexical category is added to the list of supertags for a word if it is not present in the list assigned by the multitagger.

4.2 Greedy Setting

In this section, we compare the performance of perceptron (Z&C*) and neural network (NNPar) parsers in the greedy setting. Table 1 presents the unlabeled F-score (UF), labeled F-score (LF) and lexical category accuracy (Cat.) for the Z&C* and NNPar on the CCGbank development data.

NNPar outperformed Z&C* on all the metrices. There is an improvement of 2.14% in UF and 2.4% in LF, when both the parsers used maximum-entropy (C&C) taggers. We also experimented with the revealing based incremental algorithm of Ambati et al. (2015). Neural network parser gave better results than the perceptron parser for the incremental algorithm as well. Using the incremental algorithm, our NNPar obtained UF and LF of 89.08% and 81.07% which is 0.3% and 1.6% respectively lower than the results with the non-incremental algorithm. So, for the rest of the experiments we use non-incremental parsing algorithm of Z&C*.

Using neural network based taggers (NNT) didn't give any improvement for Z&C* in the greedy settings. Performance of NNT is slightly lower than C&C tagger which could be the reason for this (Lewis and Steedman, 2014a). But for NNPar, NNT improved the performance over C&C by 0.7%. Lewis and Steedman (2014a) and Xu et al. (2015) showed improvements in the performance of C&C, a graph based parser, by using neural network taggers. Our result with NNPar is in line with theirs and shows that neural network taggers can improve the performance of shift-reduce CCG parsers as well. We obtained final unlabeled and labeled F-scores of 90.09% and 83.33% respectively on the development data. To the best of our knowledge these are the best reported results for greedy shift-reduce CCG parsing.

Model	*Tagger*	*UF*	*LF*	*Cat.*
Z&C*	C&C	87.24	80.25	91.09
Our NNPar	C&C	89.38	82.65	91.72
Z&C*	NNT	87.00	79.78	90.52
Our NNPar	NNT	**90.09**	**83.33**	**92.03**

Table 1: Performance of greedy CCG parsers on CCGbank development data (Sec. 00).

4.3 Beam Search

We next analyze the impact of beam-search on the various parsers. For Z&C* and Structured NNPar, we use a beam of size 16 both during training and testing; for NNPar, a beam (of 16) can be used only during testing. Table 2 presents the results using a beam size of 16. Results are presented with a beam of size 16 to enable direct comparison with Zhang and Clark (2011), since our parsing algorithm is similar to theirs.

The top 3 rows of the table show the results of our experiments and the last 2 rows contain published results of Zhang and Clark (2011) and Xu et al. (2014). Using a beam improved the performance of both the perceptron and neural network parsers. Since NNPar uses a beam only during testing, there is only slight improvement in the f-score. Using a structured neural network gave a significant boost in performance. Structured NNPar is better than NNPar on all the metrices which shows that Structured NNPar is a stronger model than NNPar. We obtained a final LF of 85.69% on the development data which is 1.3% better than the Z&C*, the structured perceptron counter part, and 1.1% better than NNPar. This is the best published result on the development data for shift-reduce CCG parsing.

4.4 Final Test Results

Table 3 presents the results for the final test data. The top 2 rows of the table present the results in the greedy settings. The middle 3 rows of the table show the results with a beam. The last 2 rows give the published results of Zhang and Clark (2011)

[5] `http://homepages.inf.ed.ac.uk/s1049478/easyccg.html`

Model	*Beam*	*UF*	*LF*	*Cat.*
Z&C*	1	87.28	80.78	91.44
Our NNPar	1	89.78	83.27	91.89
Z&C*	16	91.28	85.00	92.79
Our NNPar	16	91.14	84.44	92.22
Our Structured NNPar	16	**91.95**	85.57	**92.86**
Zhang and Clark (2011)	16	-	85.48	92.77
Xu et al. (2014)	128	-	**86.00**	92.75

Table 3: Results on CCGbank test data (Sec. 23).

Model	*UF*	*LF*	*Cat.*
Z&C*	91.17	84.34	92.42
Our NNPar	91.46	84.55	92.35
Our Structured NNPar	**92.19**	**85.69**	**93.02**
Zhang and Clark (2011)		85.00	92.77
Xu et al. (2014)		85.18	92.75

Table 2: Impact of the beam on CCGbank development data (Sec. 00).

and Xu et al. (2014). With the greedy setting, our NNPar outperformed Z&C* by around 2.5%, obtaining 89.78% and 83.27% UF and LF respectively. These are the best reported result for greedy shift-reduce CCG parsing.

In the case of the beam search parsers, we achieved final best scores of 91.95% in UF and 85.57% in LF with our Structured NNPar. Structured NNPar gave improvements of 1.1% over the NNPar and 0.6% over the structured perceptron model, Z&C*. Structured NNPar gets better category accuracy, but lower LF than Xu et al.(2014). Note however that we use a much smaller beam size of 16 (similar to Z&C) as compared to theirs (128). Increasing the beam size improved the accuracy but significantly reduced the parsing speed. Testing with a beam of size 128 gave 0.2% improvement in labelled F-score but slowed the parser by ten times.

4.5 Speed

Beam-search parsers are more accurate than greedy parsers but are very slow. With neural network models we can build parsers which give a nice trade-off between speed and accuracy. Table 4 present the speed comparison for both Z&C* and our NNPar in greedy settings. NNPar is much faster, parsing 350 sentences per second compared to Z&C* which parses 110 sentences per second. Parsers with a beam of size 16 parse around 10 sentences per second and parsers with a beam of size 128 parse around 1 sentence per second. These numbers don't include POS tagging and supertagging time.

Model	*Sentences/Second*
Z&C*	110
NNPar	350

Table 4: Speed comparison of perceptron and neural network based greedy parsers.

5 Conclusion

We presented the first neural network based shift-reduce parsers for CCG, a greedy and a beam-search parser. On the standard CCGbank test data, we achieved a labeled F-score of 85.57% with our structured neural network parser, an improvement of 0.6% over the structured perceptron parser (Z&C*). Our greedy parser gets UF and LF of 89.78% and 83.27% respectively, the best reported results for a greedy CCG parser, and is more than three times faster. In future we plan to explore more sophisticated tagging and parsing models like deep neural networks (Weiss et al., 2015), recurrent neural networks (Dyer et al., 2015), and bi-directional LSTMs (Lewis et al., 2016) for shift-reduce CCG parsing.

The parser code can be downloaded at `https://github.com/bharatambati/tranccg`.

Abstract

For topic models, such as LDA, that use a bag-of-words assumption, it becomes especially important to break the corpus into appropriately-sized "documents". Since the models are estimated solely from the term cooccurrences, extensive documents such as books or long journal articles lead to diffuse statistics, and short documents such as forum posts or product reviews can lead to sparsity. This paper describes practical inference procedures for hierarchical models that smooth topic estimates for smaller sections with hyperpriors over larger documents. Importantly for large collections, these online variational Bayes inference methods perform a single pass over a corpus and achieve better perplexity than "flat" topic models on monolingual and multilingual data. Furthermore, on the task of detecting document translation pairs in large multilingual collections, polylingual topic models (PLTM) with multi-level hyperpriors (mlhPLTM) achieve significantly better performance than existing online PLTM models while retaining computational efficiency.

1 Introduction

Bag of words models simplify the representation of documents by discarding grammatical information and simply relying on document-level word cooccurrence statistics. Topic models, such as latent Dirichlet allocation (LDA) (Blei et al., 2003), use this representation. A major drawback of the bag of words representation, especially in collections of large documents, is that the word co-occurrence statistics are computed on a document level and as such they do not capture the effect of words co-occurring close to each other versus words co-occurring further apart.

One alternative approach to longer documents that has received attention in the past has been to directly model local—i.e., Markov—dependencies among tokens. For example, the topical n-gram model (TNG) introduced by Wang et al. (2007) models unigram and n-gram phrases as mixture of topics based on the nearby word context. More recently, Jameel & Lam (2013) proposed an LDA extension that uses word sequence information to generate topic distribution over n-grams and performs topic segmentation using segment and paragraph information. While these and many other approaches offer a better and more realistic modeling of word sequences, they don't model topical variations across document sections either in mono- or multilingual collections.

In this paper, we focus on hierarchical models for improving topic models of long documents. In the past, document-topic based hierarchical prior structures have been explored for LDA. For example, Wallach et al. (2009) showed that Gibbs sampling implementation of asymmetric Dirichlet priors provide better modeling of documents, across the whole collection, compared to the original LDA approach. More recently, Kim et al. (2013) introduced tiLDA, a topic model of monolingual document collections with nested hierarchies. In order to achieve reasonable performance over large document collections with deep hierarchies, tiLDA utilizes parallel variational Bayes (VB) inference. While VB is known to converge faster than Gibbs sampling, and paral-

Proceedings of NAACL-HLT 2016, pages 454–459,
San Diego, California, June 12-17, 2016.

lel implementations are even faster, they, as with Gibbs sampling, still require multiple iterations over the whole collection besides the overhead of parallelizing the model parameters. Furthermore these approaches focus on monolingual collections.

We propose an online VB inference approach for topic models that captures the document specific effect of local and long range word co-occurrence by modeling individual document sections using multilevel Dirichlet prior structure. The proposed models assign Dirichlet priors to individual document sections that are coupled by a document level hierarchical Dirichlet prior which facilitates explicit modeling of the variation in topics across documents in mono- and multilingual collections. This in turn streamlines the use of topic models in collections of large documents where there is a predetermined section structure. Our contribution is twofold: (1) we present an online VB inference approach for topic models with multi-level Dirchlet prior structure and more importantly (2) introduce a polylingual topic model (PLTM) with multi-level hyperpriors (mlhPLTM) which is capable of efficiently modeling topical variations across document sections in large multilingual collections.

2 Efficient Multi-level Hyperpriors

The original LDA model and its multilingual variant, PLTM, use symmetric Dirichlet priors over the document-topic distributions θ_d and topic-word distributions φ_k which means that the concentration parameter α of the Dirichlet distribution is fixed and that the base measure u across all topics is uniform. Symmetric Dirichlet priors assume that all documents in the collection are drawn from the same family of distributions. This assumption is not suitable for collections of documents that cover a diverse set of topics. In the past this issue has been addressed with asymmetric priors where the base measures are non-uniform. One way to assign asymmetric priors to individual documents is to treat the base measures vector u as a hidden variable and assign a symmetric Dirichlet prior to it which creates a hierarchical Dirichlet prior structure over all document-topic distributions in the collection. This approach was used by Wallach et al. (2009). Unlike Wallach et al. (2009), who use a single document-topic distribution θ_d, we introduce section-topic distributions θ_s. The existing symmetric Dirichlet prior over θ_d creates a hierarchical Dirichlet prior over θ_s ($\theta = \theta_d, \theta_{s_1}, \theta_{s_2}, ..., \theta_{s_S}$):

$$p(\theta|\alpha_d u, \alpha_s) \propto p(\theta_d|\alpha_d u) \prod_s p(\theta_s|\alpha_s \theta_d) \qquad (1)$$

In this setting the most widely used approach for estimating θ_d is Minka's (2000) fixed-point iteration approach which is also used in (Kim et al., 2013). Instead we use a more efficient approach for estimating the Dirichlet-multinomial hyperparameters by approximating the digamma differences in Minka's approach which was showcased in (Wallach, 2008) to be more efficient. Figure 1 shows the graphical model representation (left) of our model, which we refer to as multi-level hyperpriors LDA (mlhLDA), along with the free variational parameters for approximating the posteriors (right).

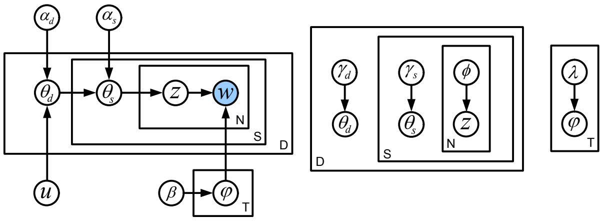

Figure 1: mlhLDA: Graphical representation (left); Free variational parameters for the online VB approximation (right).

2.1 Inference using Online VB

Due to its ease of implementation, the most widely used approach for inferring LDA posterior distributions is Gibbs sampling (Griffiths and Steyvers, 2004). For example, this approach was used by Wallach et al. (2009) and was originally used for PLTM. On the other hand the VB approach (Blei et al., 2003) offers more efficient computation but as in the case of Gibbs sampling requires iterating over the whole collection multiple times (e.g. Kim et al. (2013)). More recently Hoffman et al. (2010) introduced online LDA (oLDA) that relies on online stochastic optimization and requires a single pass over the whole collection. The same approach was also extended to PLTM (oPLTM) (Krstovski and Smith, 2013). In our work we also utilize online VB to implement multi-level hyperprior (mlh) structure in LDA and PLTM. Similar to batch VB, in online

VB locally optimal values of the free variational parameters γ and ϕ, which are used to approximate the posterior θ and z, are computed in the E step of the algorithm but on a batch b of documents d_i (rather than the whole collection D as in the case of batch VB) while holding the topic-word variational parameter λ fixed. In the M step, λ is updated using stochastic gradient algorithm by first computing the optimal values of $\tilde{\lambda}$ using the batch optimal values of ϕ^b: $\tilde{\lambda}_{kw} = \eta + \frac{D}{|b|} \sum_{i=1}^{|b|} n_{d_i w} \phi_{wk}^{d_i}$. This value is then combined with value of λ computed on the previous batch through weighted average:

$$\lambda_{kw}^{b} \leftarrow (1 - \rho_b)\, \lambda_{kw}^{b-1} + \rho_b \tilde{\lambda}_{kw} \qquad (2)$$

When computing the section-topic variational parameters we follow the proof of the lower bound which was derived by Kim et al. (2013). This lower bound, which is looser than the original VB Evidence Lower Bound (ELBO), allows for the batch VB approach to be used with asymmetric priors. More specifically, given the document-topic variational parameter γ_{dk} in the E step of our online VB approach the update for the section-topic variational parameter γ_{sk} becomes:

$$\gamma_{sk} = \alpha_s\left(\frac{\gamma_{dk}}{\sum_k \gamma_{dk}}\right) + \sum_w n_w^s\, \phi_{wk}^s \qquad (3)$$

3 Online PLTM with multi-level Dirichlet Priors

Given an aligned multilingual document tuple, PLTM assumes that: (1) there exists a single tuple-specific distribution across topics and (2) sets of language specific topic-word distributions. Each word is generated from a language- and topic-specific multinomial distribution φ_k^l as selected by the topic assignment variable z_n^l:

$$w_n^l \sim p\left(w_n^l \mid z_n^l, \varphi_k^l\right) \qquad (4)$$

We extend this model by introducing sections specific topic distributions θ_s across the different languages in the tuple which are coupled by the tuple specific document-topic distribution θ_d.

Given a collection of document tuples d where each tuple contains l documents that are translations of each other in different languages, mlhPLTM assumes the following generative process. For each language l in the collection the model first generates a set of $k \in \{1, 2, ..., K\}$ topic-word distributions, φ_k^l which are drawn from a Dirichlet prior with language specific hyperparameter β^l: $\varphi_k^l \sim Dirichlet(\beta^l)$. For each document d^l with s_d sections in tuple d, mlhPLTM then assumes the following generative process:

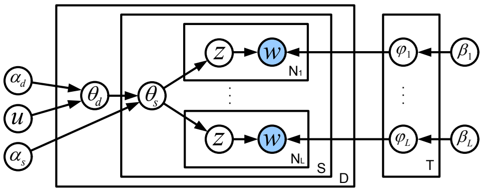

Figure 2: mlhPLTM: Graphical model representation.

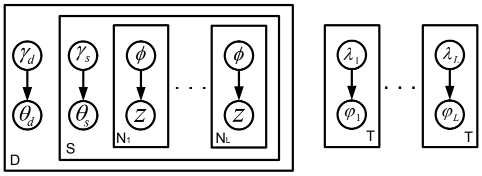

Figure 3: mlhPLTM: Graphical representation of the free variational parameters for the online VB approximation.

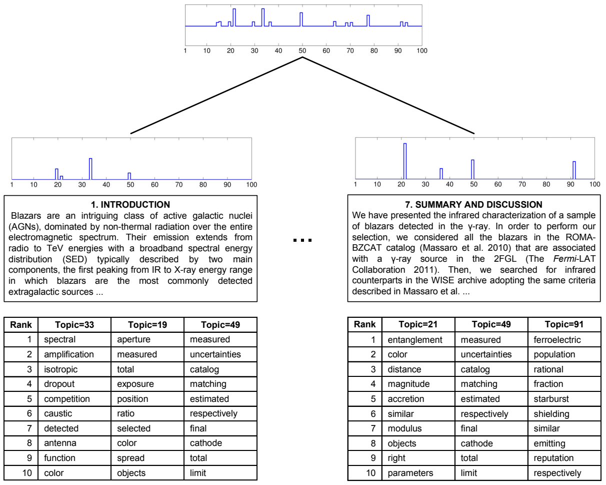
- Choose $\theta_d \sim Dir.(\alpha_d)$
- For each section s_d in document tuple d:
- Choose $\theta_s \sim Dir.(\alpha_s \theta_d)$
  - For each language l in section s:
    - ∗ For each word w in section s_d^l:
      - · Choose a topic $z \sim Multi.(\theta_s^l)$
      - · Choose a word $w \sim Multi.(\varphi_z^l)$

Figure 2 shows the graphical representation of mlhPLTM. The free variational parameters for the online VB approximation of the posteriors are shown in Figure 3.

4 Modeling Sections in Scientific Articles

We explore the ability of mlhLDA to model variations across document sections found in scientific articles using a collection of journal articles from the Astrophysics Data System (ADS) (Kurtz et al., 2000). Our collection consists of 130k training articles (888,346 sections) and a held-out set of 8,078 articles (54,502 sections). Figure 4 shows an example mlhLDA representation of an ApJ article with 100 topics. Shown on the top is the inferred topic representation of the whole document (θ_d) which, in the mlhLDA model, serves as a prior for the section-topic distributions (θ_s). Shown on the bottom are ex-



1. INTRODUCTION
Blazars are an intriguing class of active galactic nuclei (AGNs), dominated by non-thermal radiation over the entire electromagnetic spectrum. Their emission extends from radio to TeV energies with a broadband spectral energy distribution (SED) typically described by two main components, the first peaking from IR to X-ray energy range in which blazars are the most commonly detected extragalactic sources ...

7. SUMMARY AND DISCUSSION
We have presented the infrared characterization of a sample of blazars detected in the γ-ray. In order to perform our selection, we considered all the blazars in the ROMA-BZCAT catalog (Massaro et al. 2010) that are associated with a γ-ray source in the 2FGL (The *Fermi*-LAT Collaboration 2011). Then, we searched for infrared counterparts in the WISE archive adopting the same criteria described in Massaro et al. ...

amples of 2 article sections (out of 7), their inferred topic distributions along with the top 10 words for each of the top 3 section topics.

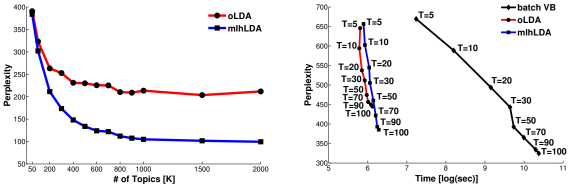

Figure 5: oLDA vs. mlhLDA: perplexity comparison (left); speed vs. perplexity comparisons with batch VB (right).

The left side of Figure 5 shows the held-out perplexity comparison between oLDA and mlhLDA across 13 different topic configurations. For this set of experiments we used the above training set of 130k articles and the set of 8,078 held-out articles. From these comparisons we clearly see the advantage of using the multi-level Dirchlet prior structure. Another way of evaluating topic models is through an extrinsic evaluation task which was not available for this collection. In the case of oLDA, article sections were treated as individual documents. In the original oLDA[1] implementation the per document concentration parameter α_d was set to $\frac{1}{K}$ which we also use in our case for both the symmetric θ_d and asymmetric θ_s (same goes for PLTM and mlhPLTM). Since in our case we perform relative comparison between oLDA and mlhLDA we weren't concerned with experimenting with different concentration parameters but we rather used the default one implemented in oLDA.

With a random subset of 10k training and 1k held-out articles we compared the performance of oLDA and mlhLDA with the original batch VB[2] implementation of Blei et al. (2003). Unlike the implementations of oLDA and mlhLDA which are written in Python the original VB algorithm is written in C and requires multiple iterations over the whole collection. The right side of Figure 5 shows the speed (in natural log scale) vs. perplexity comparison across the three models.

5 Modeling and Retrieving Speeches in Europarl Sessions

We compared the modeling performance of oPLTM and mlhPLTM on a subset of the English-Spanish Europarl collection (Koehn, 2005). The subset consists of ∼64k training pairs of English-Spanish speeches that are translations of each other which originate from 374 sessions of the European Parliament (Europarl) and a test set of ∼14k speech translation pairs from 112 sessions. With oPLTM we modeled individual speech pairs while with mlhPLTM we utilized the session hierarchy and modeled pairs of speeches as document sections. Comparisons were performed intrinsically (using perplexity) and extrinsically on a cross-language information retrieval (CLIR) task. This task, along with the Europarl subset, have been previously defined by Mimno et al. (2009) and used across other publications (Platt et al., 2010; Krstovski and Smith, 2013). Given a query English speech, the CLIR task is to retrieve its Spanish translation equivalent. It involves performing comparison across topic representations of all Spanish speeches using Jensen-Shannon divergence and sorting the results. Models are evaluated using precision at rank one (P@1). Figure 6 shows the CLIR task performance comparisons results using 13 different topic configurations. We performed comparisons across three different settings of the concentration parameters α_d and α_s (α_d=α_s=$\frac{1}{K}$, 0.4 and 1.0).

[1] http://www.cs.princeton.edu/~mdhoffma

[2] http://www.cs.princeton.edu/~blei/lda-c

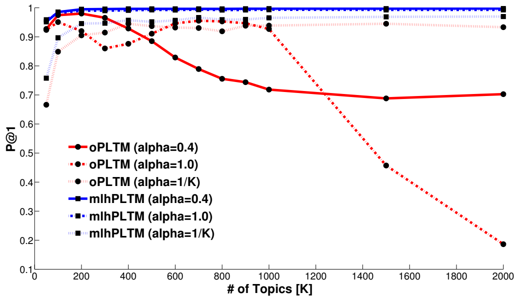

Figure 6: oPLTM vs. mlhPLTM: Performance comparison on the CLIR task using chronological ordering of sessions across different hyperparameter settings, α_d=α_s=$\frac{1}{K}$, 0.4 and 1.0 .

Across the different concentration parameter values and across the 13 different topic configurations we observe that the performance of oPLTM fluctuates as we increase the numbers of topics. On the other hand, across the three different concentration parameter settings, mlhPLTM performance is very steady and tends to increase with the number of topics. Across the different topic configurations both models provide the best performance with $\alpha_d = \alpha_s = 0.4$. Setting the concentration parameters to $\frac{1}{K}$ gives the overall worst performance.

In our initial experiments we unintentionally reordered our set of training Europarl sessions based on two digit years which was different from the experimental setup in (Mimno et al., 2009) and (Krstovski and Smith, 2013) where the order of the presentation data (Europarl speeches) was chronological. This emphasized the fact that in online VB, order of presentation of documents plays an important role especially in the training step where the model learns the per topic-word distributions. Figure 7 shows the performance comparison results between oPLTM and mlhPLTM when documents in the training and test steps are ordered numerically. In our initial experimental setup concentration parameters where set to $\alpha_d = \alpha_s = \frac{1}{K}$. To the left is the perplexity comparison between the two models. The CLIR task performance comparisons results are shown on the right. Unordered mlhPLTM achieves high P@1 after 2,000 topics. While it takes much longer in terms of the number of topics unordered mlhPLTM ultimately achieves similar performance results as ordered mlhPLTM.

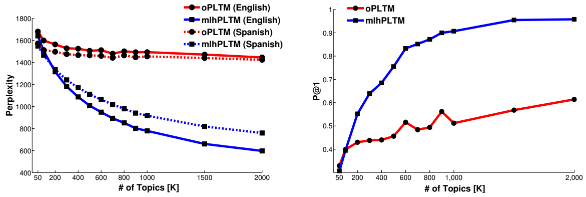

Figure 7: oPLTM vs. mlhPLTM: perplexity comparison (left); performance comparison on the CLIR task (right). Documents were presented out of chronological order and thus performance is lower, especially for oPLTM.

6 Conclusion

We presented online topic models with multi-level Dirichlet prior structure that provide better modeling of topical variations across document sections in mono- and multilingual collections. We showed that documents with rich sub-document level structure could be modeled with higher likelihood compared to regular online LDA and PLTM models while offering the same efficiency. Furthermore on the task of retrieving document translations we showed that mlhPLTM achieves significantly better retrieval results compared to online PLTM.

Abstract

Knowledge bases of real-world facts about entities and their relationships are useful resources for a variety of natural language processing tasks. However, because knowledge bases are typically incomplete, it is useful to be able to perform *link prediction*, i.e., predict whether a relationship not in the knowledge base is likely to be true. This paper combines insights from several previous link prediction models into a new embedding model *STransE* that represents each entity as a low-dimensional vector, and each relation by two matrices and a translation vector. STransE is a simple combination of the SE and TransE models, but it obtains better link prediction performance on two benchmark datasets than previous embedding models. Thus, STransE can serve as a new baseline for the more complex models in the link prediction task.

1 Introduction

Knowledge bases (KBs), such as WordNet (Fellbaum, 1998), YAGO (Suchanek et al., 2007), Freebase (Bollacker et al., 2008) and DBpedia (Lehmann et al., 2015), represent relationships between entities as triples $(\mathrm{head\ entity}, \mathrm{relation}, \mathrm{tail\ entity})$. Even very large knowledge bases are still far from complete (Socher et al., 2013; West et al., 2014). *Link prediction* or *knowledge base completion* systems (Nickel et al., 2015) predict which triples not in a knowledge base are likely to be true (Taskar et al., 2004; Bordes et al., 2011). A variety of different kinds of information is potentially useful here, including information extracted from external corpora (Riedel et al., 2013; Wang et al., 2014a) and the other relationships that hold between the entities (Angeli and Manning, 2013; Zhao et al., 2015). For example, Toutanova et al. (2015) used information from the external ClueWeb-12 corpus to significantly enhance performance.

While integrating a wide variety of information sources can produce excellent results, there are several reasons for studying simpler models that directly optimize a score function for the triples in a knowledge base, such as the one presented here. First, additional information sources might not be available, e.g., for knowledge bases for specialized domains. Second, models that don't exploit external resources are simpler and thus typically much faster to train than the more complex models using additional information. Third, the more complex models that exploit external information are typically extensions of these simpler models, and are often initialized with parameters estimated by such simpler models, so improvements to the simpler models should yield corresponding improvements to the more complex models as well.

Embedding models for KB completion associate entities and/or relations with dense feature vectors or matrices. Such models obtain state-of-the-art performance (Nickel et al., 2011; Bordes et al., 2011; Bordes et al., 2012; Bordes et al., 2013; Socher et al., 2013; Wang et al., 2014b; Guu et al., 2015) and generalize to large KBs (Krompa et al., 2015). Table 1 summarizes a number of prominent embedding models for KB completion.

Let (h, r, t) represent a triple. In all of the models

Model	Score function $f_r(h,t)$	**Opt.**
SE	$\lVert\mathbf{W}_{r,1}\mathbf{h} - \mathbf{W}_{r,2}\mathbf{t}\rVert_{\ell_{1/2}}$; $\mathbf{W}_{r,1}, \mathbf{W}_{r,2} \in \mathbb{R}^{k\times k}$	SGD
Unstructured	$\lVert\mathbf{h} - \mathbf{t}\rVert_{\ell_{1/2}}$	SGD
TransE	$\lVert\mathbf{h} + \mathbf{r} - \mathbf{t}\rVert_{\ell_{1/2}}$; $\mathbf{r} \in \mathbb{R}^{k}$	SGD
DISTMULT	$\mathbf{h}^{\top}\mathbf{W}_r\mathbf{t}$; $\mathbf{W}_r$ is a diagonal matrix $\in \mathbb{R}^{k\times k}$	AdaGrad
NTN	$\mathbf{u}_r^{\top}\, tanh(\mathbf{h}^{\top}\mathbf{M}_r\mathbf{t} + \mathbf{W}_{r,1}\mathbf{h} + \mathbf{W}_{r,2}\mathbf{t} + \mathbf{b}_r)$; $\mathbf{u}_r, \mathbf{b}_r \in \mathbb{R}^{d}$; $\mathbf{M}_r \in \mathbb{R}^{k\times k\times d}$; $\mathbf{W}_{r,1}, \mathbf{W}_{r,2} \in \mathbb{R}^{d\times k}$	L-BFGS
TransH	$\lVert(\mathbf{I} - \mathbf{r}_p\mathbf{r}_p^{\top})\mathbf{h} + \mathbf{r} - (\mathbf{I} - \mathbf{r}_p\mathbf{r}_p^{\top})\mathbf{t}\rVert_{\ell_{1/2}}$; $\mathbf{r}_p, \mathbf{r} \in \mathbb{R}^{k}$; $\mathbf{I}$: Identity matrix size $k \times k$	SGD
TransD	$\lVert(\mathbf{I} + \mathbf{r}_p\mathbf{h}_p^{\top})\mathbf{h} + \mathbf{r} - (\mathbf{I} + \mathbf{r}_p\mathbf{t}_p^{\top})\mathbf{t}\rVert_{\ell_{1/2}}$; $\mathbf{r}_p, \mathbf{r} \in \mathbb{R}^{d}$; $\mathbf{h}_p, \mathbf{t}_p \in \mathbb{R}^{k}$; $\mathbf{I}$: Identity matrix size $d \times k$	AdaDelta
TransR	$\lVert\mathbf{W}_r\mathbf{h} + \mathbf{r} - \mathbf{W}_r\mathbf{t}\rVert_{\ell_{1/2}}$; $\mathbf{W}_r \in \mathbb{R}^{d\times k}$; $\mathbf{r} \in \mathbb{R}^{d}$	SGD
Our STransE	$\lVert\mathbf{W}_{r,1}\mathbf{h} + \mathbf{r} - \mathbf{W}_{r,2}\mathbf{t}\rVert_{\ell_{1/2}}$; $\mathbf{W}_{r,1}, \mathbf{W}_{r,2} \in \mathbb{R}^{k\times k}$; $\mathbf{r} \in \mathbb{R}^{k}$	SGD

Table 1: The score functions $f_r(h,t)$ and the optimization methods (Opt.) of several prominent embedding models for KB completion. In all of these the entities h and t are represented by vectors $\mathbf{h}$ and $\mathbf{t} \in \mathbb{R}^k$ respectively.

discussed here, the head entity h and the tail entity t are represented by vectors $\mathbf{h}$ and $\mathbf{t} \in \mathbb{R}^k$ respectively. The *Unstructured* model (Bordes et al., 2012) assumes that $\mathbf{h} \approx \mathbf{t}$. As the Unstructured model does not take the relationship r into account, it cannot distinguish different relation types. The *Structured Embedding* (SE) model (Bordes et al., 2011) extends the unstructured model by assuming that h and t are similar only in a relation-dependent subspace. It represents each relation r with two matrices $\mathbf{W}_{r,1}$ and $\mathbf{W}_{r,2} \in \mathbb{R}^{k\times k}$, which are chosen so that $\mathbf{W}_{r,1}\mathbf{h} \approx \mathbf{W}_{r,2}\mathbf{t}$. The *TransE* model (Bordes et al., 2013) is inspired by models such as Word2Vec (Mikolov et al., 2013) where relationships between words often correspond to translations in latent feature space. The TransE model represents each relation r by a translation vector $\mathbf{r} \in \mathbb{R}^k$, which is chosen so that $\mathbf{h} + \mathbf{r} \approx \mathbf{t}$.

The primary contribution of this paper is that two very simple relation-prediction models, SE and TransE, can be combined into a single model, which we call *STransE*. Specifically, we use relation-specific matrices $\mathbf{W}_{r,1}$ and $\mathbf{W}_{r,2}$ as in the SE model to identify the relation-dependent aspects of both h and t, and use a vector $\mathbf{r}$ as in the TransE model to describe the relationship between h and t in this subspace. Specifically, our new KB completion model STransE chooses $\mathbf{W}_{r,1}$, $\mathbf{W}_{r,2}$ and $\mathbf{r}$ so that $\mathbf{W}_{r,1}\mathbf{h} + \mathbf{r} \approx \mathbf{W}_{r,2}\mathbf{t}$. That is, a TransE-style relationship holds in some relation-dependent subspace, and crucially, this subspace may involve very different projections of the head h and tail t. So $\mathbf{W}_{r,1}$ and $\mathbf{W}_{r,2}$ can highlight, suppress, or even change the sign of, relation-specific attributes of h and t. For example, for the "purchases" relationship, certain attributes of individuals h (e.g., age, gender, marital status) are presumably strongly correlated with very different attributes of objects t (e.g., sports car, washing machine and the like).

As we show below, STransE performs better than the SE and TransE models and other state-of-the-art link prediction models on two standard link prediction datasets WN18 and FB15k, so it can serve as a new baseline for KB completion. We expect that the STransE will also be able to serve as the basis for extended models that exploit a wider variety of information sources, just as TransE does.

2 Our approach

Let $\mathcal{E}$ denote the set of entities and $\mathcal{R}$ the set of relation types. For each triple (h,r,t), where $h,t \in \mathcal{E}$ and $r \in \mathcal{R}$, the STransE model defines a *score function* $f_r(h,t)$ of its implausibility. Our goal is to choose f such that the score $f_r(h,t)$ of a plausible triple (h,r,t) is smaller than the score $f_{r'}(h',t')$ of an implausible triple (h',r',t'). We define the STransE score function f as follows:

$$f_r(h,t) \quad = \quad \lVert\mathbf{W}_{r,1}\mathbf{h} + \mathbf{r} - \mathbf{W}_{r,2}\mathbf{t}\rVert_{\ell_{1/2}}$$

using either the ℓ_1 or the ℓ_2-norm (the choice is made using validation data; in our experiments we found that the ℓ_1 norm gave slightly better results). To learn the vectors and matrices we minimize the following margin-based objective function:

$$\mathcal{L} \;=\; \sum_{\substack{(h,r,t)\in\mathcal{G}\\(h',r,t')\in\mathcal{G}'_{(h,r,t)}}} [\gamma + f_r(h,t) - f_r(h',t')]_+$$

where $[x]_+ = \max(0,x)$, γ is the margin hyperparameter, $\mathcal{G}$ is the training set consisting of correct triples, and $\mathcal{G}'_{(h,r,t)} = \{(h',r,t) \mid h' \in \mathcal{E}, (h',r,t) \notin \mathcal{G}\} \cup \{(h,r,t') \mid t' \in \mathcal{E}, (h,r,t') \notin \mathcal{G}\}$ is the set of incorrect triples generated by corrupting a correct triple $(h,r,t) \in \mathcal{G}$.

We use Stochastic Gradient Descent (SGD) to minimize $\mathcal{L}$, and impose the following constraints during training: $\|\mathbf{h}\|_2 \leqslant 1$, $\|\mathbf{r}\|_2 \leqslant 1$, $\|\mathbf{t}\|_2 \leqslant 1$, $\|\mathbf{W}_{r,1}\mathbf{h}\|_2 \leqslant 1$ and $\|\mathbf{W}_{r,2}\mathbf{t}\|_2 \leqslant 1$.

3 Related work

Table 1 summarizes related embedding models for link prediction and KB completion. The models differ in the score functions $f_r(h,t)$ and the algorithms used to optimize the margin-based objective function, e.g., SGD, AdaGrad (Duchi et al., 2011), AdaDelta (Zeiler, 2012) and L-BFGS (Liu and Nocedal, 1989).

DISTMULT (Yang et al., 2015) is based on a Bilinear model (Nickel et al., 2011; Bordes et al., 2012; Jenatton et al., 2012) where each relation is represented by a diagonal rather than a full matrix. The neural tensor network (NTN) model (Socher et al., 2013) uses a bilinear tensor operator to represent each relation. Similar quadratic forms are used to model entities and relations in KG2E (He et al., 2015) and TATEC (Garcia-Duran et al., 2015b).

The TransH model (Wang et al., 2014b) associates each relation with a relation-specific hyperplane and uses a projection vector to project entity vectors onto that hyperplane. TransD (Ji et al., 2015) and TransR/CTransR (Lin et al., 2015b) extend the TransH model using two projection vectors and a matrix to project entity vectors into a relation-specific space, respectively. TransD learns a relation-role specific mapping just as STransE, but represents this mapping by projection vectors rather than full matrices, as in STransE. Thus STransE can be viewed as an extension of the TransR model, where head and tail entities are associated with their own project matrices, rather than using the same matrix for both, as in TransR and CTransR.

Dataset	#E	#R	#Train	#Valid	#Test
WN18	40,943	18	141,442	5,000	5,000
FB15k	14,951	1,345	483,142	50,000	59,071

Table 2: Statistics of the experimental datasets used in this study (and previous works). #E is the number of entities, #R is the number of relation types, and #Train, #Valid and #Test are the numbers of triples in the training, validation and test sets, respectively.

Recently, Lao et al. (2011), Neelakantan et al. (2015), Gardner and Mitchell (2015), Luo et al. (2015), Lin et al. (2015a), Garcia-Duran et al. (2015a) and Guu et al. (2015) showed that relation paths between entities in KBs provide richer information and improve the relationship prediction. Nickel et al. (2015) reviews other approaches for learning from KBs and multi-relational data.

4 Experiments

For link prediction evaluation, we conduct experiments and compare the performance of our STransE model with published results on the benchmark WN18 and FB15k datasets (Bordes et al., 2013). Information about these datasets is given in Table 2.

4.1 Task and evaluation protocol

The link prediction task (Bordes et al., 2011; Bordes et al., 2012; Bordes et al., 2013) predicts the head or tail entity given the relation type and the other entity, i.e. predicting h given $(?,r,t)$ or predicting t given $(h,r,?)$ where ? denotes the missing element. The results are evaluated using the ranking induced by the score function $f_r(h,t)$ on test triples.

For each test triple (h,r,t), we corrupted it by replacing either h or t by each of the possible entities in turn, and then rank these candidates in ascending order of their implausibility value computed by the score function. Following the protocol described in Bordes et al. (2013), we remove any corrupted triples that appear in the knowledge base, to avoid cases where a correct corrupted triple might be ranked higher than the test triple. We report the mean rank and the Hits@10 (i.e., the proportion of test triples in which the target entity was ranked in the top 10 predictions) for each model. Lower mean rank or higher Hits@10 indicates better link prediction performance.

Following TransR/CTransR (Lin et al., 2015b), TransD (Ji et al., 2015), TATEC (Garcia-Duran et al., 2015b), RTransE (Garcia-Duran et al., 2015a) and PTransE (Lin et al., 2015a), we used the entity and relation vectors produced by TransE (Bordes et al., 2013) to initialize the entity and relation vectors in STransE, and we initialized the relation matrices with identity matrices. Following Wang et al. (2014b), Lin et al. (2015b), He et al. (2015), Ji et al. (2015) and Lin et al. (2015a), we applied the "*Bernoulli*" trick for generating head or tail entities when sampling incorrect triples. We ran SGD for 2,000 epochs to estimate the model parameters. Following Bordes et al. (2013) we used a grid search on validation set to choose either the l_1 or l_2 norm in the score function f, as well as to set the SGD learning rate $\lambda \in \{0.0001, 0.0005, 0.001, 0.005, 0.01\}$, the margin hyper-parameter $\gamma \in \{1, 3, 5\}$ and the number of vector dimensions $k \in \{50, 100\}$. The lowest mean rank on the validation set was obtained when using the l_1 norm in f on both WN18 and FB15k, and when $\lambda = 0.0005, \gamma = 5$, and $k = 50$ for WN18, and $\lambda = 0.0001, \gamma = 1$, and $k = 100$ for FB15k.

4.2 Main results

Table 3 compares the link prediction results of our STransE model with results reported in prior work, using the same experimental setup. The first twelve rows report the performance of models that do not exploit information about alternative paths between head and tail entities. The next two rows report results of the RTransE and PTransE models, which are extensions of the TransE model that exploit information about relation paths. The last row presents results for the log-linear model Node+LinkFeat (Toutanova and Chen, 2015) which makes use of textual mentions derived from the large external ClueWeb-12 corpus.

It is clear that Node+LinkFeat with the additional external corpus information obtained best results. In future work we plan to extend the STransE model to incorporate such additional information. Table 3 also shows that models RTransE and PTransE employing path information achieve better results than models that do not use such information. In terms of models not exploiting path information or external information, the STransE model scores better than the other models on WN18 and produces the highest Hits@10 score on FB15k. Compared to the closely related models SE, TransE, TransR, CTransR and TransD, STransE does better than these models on both WN18 and FB15k.

Method	WN18		FB15k	
	MR	H10	MR	H10
SE (Bordes et al., 2011)	985	80.5	162	39.8
Unstructured (Bordes et al., 2012)	304	38.2	979	6.3
TransE (Bordes et al., 2013)	251	89.2	125	47.1
TransH (Wang et al., 2014b)	303	86.7	87	64.4
TransR (Lin et al., 2015b)	225	92.0	77	68.7
CTransR (Lin et al., 2015b)	218	92.3	75	70.2
KG2E (He et al., 2015)	348	93.2	59	74.0
TransD (Ji et al., 2015)	212	92.2	91	77.3
TATEC (Garcia-Duran et al., 2015b)	-	-	**58**	76.7
NTN (Socher et al., 2013)	-	66.1^{+}	-	41.4^{+}
DISTMULT (Yang et al., 2015)	-	94.2^{+}	-	57.7^{+}
Our STransE model	**206**	**93.4**	69	**79.7**
RTransE (Garcia-Duran et al., 2015a)	-	-	**50**	76.2
PTransE (Lin et al., 2015a)	-	-	58	84.6
NLFeat (Toutanova and Chen, 2015)	-	**94.3**	-	**87.0**

Table 3: Link prediction results. MR and H10 denote evaluation metrics of mean rank and Hits@10 (in %), respectively. "NLFeat" abbreviates Node+LinkFeat. The results for NTN (Socher et al., 2013) listed in this table are taken from Yang et al. (2015) since NTN was originally evaluated on different datasets. The results marked with $^{+}$ are obtained using the optimal hyper-parameters chosen to optimize Hits@10 on the validation set; trained in this manner, STransE obtains a mean rank of 244 and Hits@10 of **94.7**% on WN18, while producing the same results on FB15k.

Following Bordes et al. (2013), Table 4 analyzes Hits@10 results on FB15k with respect to the relation categories defined as follows: for each relation type r, we computed the averaged number a_h of heads h for a pair (r, t) and the averaged number a_t of tails t for a pair (h, r). If $a_h < 1.5$ and $a_t < 1.5$, then r is labeled **1-1**. If $a_h \geq 1.5$ and $a_t < 1.5$, then r is labeled **M-1**. If $a_h < 1.5$ and $a_t \geq 1.5$, then r is labeled as **1-M**. If $a_h \geq 1.5$ and $a_t \geq 1.5$, then r is labeled as **M-M**. 1.4%, 8.9%, 14.6% and 75.1% of the test triples belong to a relation type classified as **1-1**, **1-M**, **M-1** and **M-M**, respectively.

Table 4 shows that in comparison to prior models not using path information, STransE obtains highest Hits@10 result for **M-M** relation category at $(80.1\% + 83.1\%)/2 = 81.6\%$. In addition, STransE

Method	**Predicting head h**				**Predicting tail t**			
	1-1	1-M	M-1	M-M	1-1	1-M	M-1	M-M
SE	35.6	62.6	17.2	37.5	34.9	14.6	68.3	41.3
Unstr.	34.5	2.5	6.1	6.6	34.3	4.2	1.9	6.6

TATEC	79.3	93.2	42.3	77.2	78.5	51.5	92.7	80.7
STransE	82.8	94.2	50.4	**80.1**	82.4	56.9	93.4	**83.1**

Table 4: Hits@10 (in %) by the relation category on FB15k. "Unstr." abbreviates Unstructured.

also performs better than TransD for **1-M** and **M-1** relation categories. We believe the improved performance of the STransE model is due to its use of full matrices, rather than just projection vectors as in TransD. This permits STransE to model diverse and complex relation categories (such as **1-M**, **M-1** and especially **M-M**) better than TransD and other similiar models. However, STransE is not as good as TransD for the **1-1** relations. Perhaps the extra parameters in STransE hurt performance in this case (note that 1-1 relations are relatively rare, so STransE does better overall).

5 Conclusion and future work

This paper presented a new embedding model for link prediction and KB completion. Our STransE combines insights from several simpler embedding models, specifically the Structured Embedding model (Bordes et al., 2011) and the TransE model (Bordes et al., 2013), by using a low-dimensional vector and two projection matrices to represent each relation. STransE, while being conceptually simple, produces highly competitive results on standard link prediction evaluations, and scores better than the embedding-based models it builds on. Thus it is a suitable candidate for serving as future baseline for more complex models in the link prediction task.

In future work we plan to extend STransE to exploit relation path information in knowledge bases, in a manner similar to Lin et al. (2015a), Garcia-Duran et al. (2015a) or Guu et al. (2015).

An Unsupervised Model of Orthographic Variation for Historical Document Transcription

Dan Garrette

Abstract

Historical documents frequently exhibit extensive orthographic variation, including archaic spellings and obsolete shorthand. OCR tools typically seek to produce so-called *diplomatic* transcriptions that preserve these variants, but many end tasks require transcriptions with *normalized* orthography. In this paper, we present a novel joint transcription model that learns, unsupervised, a probabilistic mapping between modern orthography and that used in the document. Our system thus produces dual diplomatic and normalized transcriptions simultaneously, and achieves a 35% relative error reduction over a state-of-the-art OCR model on diplomatic transcription, and a 46% reduction on normalized transcription.

1 Introduction

Optical Character Recognition (OCR) for historical texts, a challenging problem due to unknown fonts and deteriorating documents, is made even more difficult by the fact that orthographic conventions including spelling, accent usage, and shorthands have not been consistent across the history of printing. For this reason, modern language models (LMs) yield poor performance when trying to recognize characters on the pages of these documents. Furthermore, transcription of the actual printed characters may not always be the most desirable output.

Greg (1950) describes two types of transcription: one that preserves variants and typographical errors, and another that records the *substantive* content, with this noise removed. Though in 1950 the substantive version was the norm, today these have become two distinct but equally valid tasks. *Diplomatic* transcription, the standard in contemporary OCR, preserves the variants of the document valuable to book historians and linguists. *Normalized* or modernized transcription recovers the substantive content, producing a text that adheres to modern standards. Normalized transcriptions are easier for users to read, and make large collections of historical texts indexable and searchable (Driscoll, 2006).

The current ideal for digital editions of historical texts has been described as a combination of diplomatic and normalized transcription (Pierazzo, 2014). This is generally achieved with a pipeline: first OCR is used to transcribe the document, then an (often manual) post-hoc normalization is performed. However, such a pipeline will result in cascading errors from OCR mistakes, and fails to make use of knowledge about modern language during the initial transcription. Additionally, post-processing tools are typically cumbersome language-specific, hand-built systems (Baron and Rayson, 2008; Burns, 2013; Hendrickx and Marquilhas, 2011).

In this work, we introduce a novel OCR model designed to jointly produce both diplomatic and normalized transcriptions. The model is an extension of Berg-Kirkpatrick et al.'s (2013) *Ocular*, the state of the art in historical OCR. Ocular's innovative ability to handle the material challenges of OCR (unknown fonts, uneven inking, etc.) depends on its use of a character n-gram LM. Our model improves the quality of Ocular's transcriptions by automatically learning a probabilistic mapping between the LM, which is trained on modern text, and the unique orthography of the document. This results in both an

Proceedings of NAACL-HLT 2016, pages 467–472,
San Diego, California, June 12-17, 2016.

improved orthographically-correct diplomatic transcription and a modern-style normalized transcription. To our knowledge, this represents the first OCR system that jointly produces both diplomatic and normalized transcriptions.

We evaluate our model on a multilingual collection of books exemplifying a high degree of orthographic variation. For diplomatic transcription, our unsupervised joint model achieves an error reduction of 35% over the baseline Ocular system without support for orthographic variation, and nearly matches the error rate of an approach proposed by earlier work that uses a hand-constructed ruleset of orthographic rewrites. However, for the new task of normalized transcription, we achieve a 46% error reduction over the baseline, as well as a 28% reduction over the hand-built ruleset approach.

2 Data

The *Primeros Libros* corpus dataset introduced in our previous work consists of multilingual (Spanish/Latin/Nahuatl) books printed in Mexico in the 1500s (Garrette et al., 2015). The original dataset includes gold diplomatic transcriptions of pages from five books of different time periods, regions, languages, and fonts. We additionally include two new monolingual Spanish *Primeros Libros* books annotated with both diplomatic and normalized transcriptions. Spanish-only texts were needed in order to find language-competent annotators skilled enough to create the more challenging normalized transcriptions. We used each of the seven books in isolation since they each have a different font. For each book, we used 20 pages for training and 10 for testing. For two of the books, an additional 10 pages were held out for tuning hyperparameters with grid search.

To produce the Spanish and Latin LMs, we used texts from Project Gutenberg; these documents were written during the target historical period, but all follow modernization standards including substitution for obsolete characters and expansion of shorthand. These texts were chosen because they are a realistic sample set that is freely and publicly available. In the Nahuatl case, scarce online resources made it necessary to supplement Project Gutenberg text with that from a private collection.

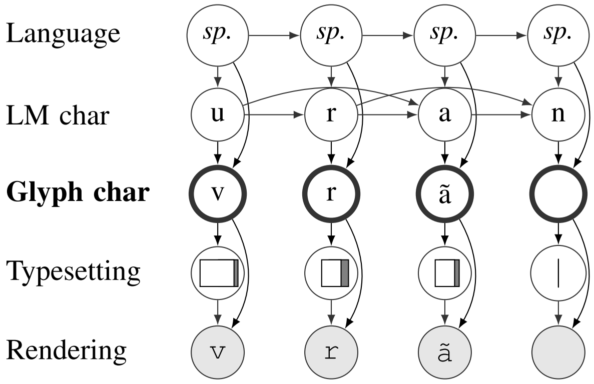

Figure 1: Our generative OCR model with the new *glyph* layer (bolded). The Spanish (*sp.*) n-gram language model (LM) generates a sequence of characters according to standard Spanish spellings, *uran* in this case, from the word *proc**uran**do* which may be written *proc**vrã**do*. Language-specific character-replacement probabilities are used to generate a *glyph char* from each LM char, producing *vrã* and a zero-width (elided) *n*. Finally, the model generates a bounding box and right-side padding (the typesetting) and a pixel-rendering of the glyph character.

3 Model

We extend Ocular, the generative model of Berg-Kirkpatrick et al. (2013), and its EM training procedure, to support our unsupervised approach to jointly modeling both diplomatic and normalized transcription. Ocular works by modeling the operation of a hand press in order to learn unknown fonts in the presence of the visual noise of the printing process: uneven inking and spacing in particular. Briefly, Ocular's generative story is as follows. First, a sequence of language states ℓ_i is generated according to $P^{\text{LANG}}(\ell_i \mid \ell_{i-1})$, where ℓ_{i-1} and ℓ_i may only differ on the start of a word. For each state, a character c_i is generated according to its language-specific n-gram LM: $P^{\text{CHAR}}_{\ell_i}(c_i \mid c_{i-n+1} \dots c_{i-1})$. Next, a state's *typesetting* t_i, consisting of a character's bounding box, vertical offset, and between-character padding, is generated according to $P^{\text{TYPE}}(t_i \mid c_i)$. Finally, the character image is rendered as a pixel-matrix inside the bounding box: $P^{\text{REND}}(x_i \mid c_i, t_i)$.[1]

A major downside to the Ocular model is that ren-

Table 1: Examples of automatic diplomatic and normalized transcriptions taken from actual system output.

dered image x_i is always generated directly from LM character c_i, resulting in transcription errors when printed characters don't follow the spellings in the LM. Our model (Figure 1) adds an additional layer to the generative model that de-couples the LM from the rendering by allowing the LM-generated character c_i to be replaced by a possibly different *glyph character* g_i which is rendered instead.

For the generative story of our new model, we again begin by generating pairs (ℓ_i, c_i). However, instead of typesetting c_i, we generate a distinct glyph character g_i as its replacement, according to $P^{\text{GLYPH}}_{\ell_i}(g_i \mid c_i)$. Orthographic substitution patterns are language-specific, and thus P^{GLYPH} is as well. Finally, we typeset and render g_i (instead of c_i) using $P^{\text{TYPE}}(t_i \mid g_i)$ and $P^{\text{REND}}(x_i \mid g_i, t_i)$.

We follow the previous Ocular work for the definitions of P^{LANG}, $P^{\text{CHAR}}_{\ell_i}$, P^{TYPE}, and P^{REND}. We define the new conditional distribution $P^{\text{GLYPH}}_{\ell_i}$, specifying the probability of rendering g when the LM generated c, given that the language is ℓ, as follows:

$$P^{\text{GLYPH}}_{\ell}(g \mid c) = \begin{cases} (1-\kappa) + \kappa \cdot p(g \mid c, \ell) & \text{if } g = c \\ \kappa \cdot p(g \mid c, \ell) & \text{else} \end{cases}$$

Constant κ defines a Bernoulli parameter specifying the fixed probability of deterministically choosing to render c_i directly (i.e., $g_i = c_i$). We set $\kappa = 0.9$ to bias the model away from substitutions in general. The remaining $(1 - \kappa)$ probability mass is then divided among all potential output glyph characters.

Table 1 shows some of the common substitution patterns that our model addresses. For a direct rendering of c_i, a letter substitution, or the dropping of an accent, g_i will be a simple character drawn from the language's set of valid characters (each language may have a different set of permitted characters, e.g. accented letters). In order to support the tilde-elision shorthand, we permit g_i to be a tilde-annotated version of c_i, and for doubled letters, we permit g_i to be $c_i c_i$, for which we typeset and render c_i twice. Finally, to allow for elided letters, including the dropping of a line-break hyphen, we allow g_i to be a special ELISION glyph that renders only as a zero-width space character.

The parameters of the glyph substitution model are learned in an unsupervised fashion as part of Ocular's EM procedure via a hard parameter update:

$$p(g \mid c, \ell) = \frac{\mathit{freq}(\ell, c, g) + 1}{\sum_{g'} (\mathit{freq}(\ell, c, g') + 1)}$$

where $\mathit{freq}(\ell, c, g)$ is the number of times in the training iteration that the model chose to replace c with g in a word (automatically) determined to be of language ℓ. The $+1$ term is Laplace smoothing.

To guide the model and improve efficiency, we employ a number of constraints governing which kinds of substitutions are valid. Among these, we stipulate that substitutions must be letter-to-letter, diacritics may only be added to lowercase letters, only *s* can replace long-*s*, and elision-tilde-marked letters must be followed by one or more elisions.

4 Experiments

As a first baseline, we compare against Ocular with no orthographic variation handling, in which characters generated by the LM are rendered directly.

As a second baseline, we compare to our previous work, which improved Ocular's diplomatic transcription accuracy by introducing orthographic variation directly into the LM with hand-constructed language-specific orthographic rules to rewrite the LM training data prior to n-gram estimation (Garrette et al., 2015). However, this rule-based preprocessing approach is inadequate in many ways. First, annotators do not know the full range of orthographic variations, or their frequencies, in each document, and it is impossible to write rules to handle typos. Furthermore, a highly language-proficient

annotator is required, which is not always feasible with, e.g, rare indigenous languages.

Each baseline model has a single output, evaluated against both diplomatic and normalized gold.

Our source code and evaluation data are freely available at *https://github.com/tberg12/ocular* and *https://github.com/dhgarrette/ocr-evaluation-data*.

5 Results and Discussion

Our results are shown in Table 3 and some correct example system outputs can be seen in Table 1.

Our model's accuracy in producing diplomatic transcriptions is substantially better than baseline Ocular performance, yielding a 35% relative character error rate reduction. Further, our model's diplomatic transcription accuracy is comparable to the LM replacement-rule approach of our previous work, but achieves this result with only unsupervised learning, as opposed to expert-produced rules. We can see in Table 4 that our model is able to discover and apply appropriate probabilities to relevant substitution rules. For the new normalized-transcription task, even larger gains were achieved: a 46% relative error reduction over Ocular, and a 28% reduction over the rule-based approach.

5.1 Error Analysis

Table 2 displays a sample of errors in our system output. (1) The word *días* is printed without an accent though it has one in modern Spanish. Our system is unable to distinguish between a dot and an accent above the *i*, and thus it opts to output the accented version since it is preferred by the LM. (2) The word *suplicar* does not have any accents in modern Spanish, but the model is over-eager in this case and attempts to revive an accent where there should not be one. (3) The word *salvo* is printed here as the variant *saluo*, but its under-inking leaves the *u* in disconnected pieces, resembling a pair of *i* characters. The LM model believes this to be the (valid) word *salió* with the accent dropped and the *i* doubled. (4) The model guesses incorrectly that the elision at the end of *alabã* is an *r* since *alabar* is a valid word. (5) The model correctly recognizes that the letters *ti* are printed, but the LM believes the normalized form is *te* even though *te pues* is not valid Spanish, perhaps because *te puedo* is a very common phrase and the six-gram context isn't enough to make that distinction. (6) Finally, there are some special idiomatic shorthands that our model is simply unable to understand because they have no clear

connection to what they are replacing. Here, *xp̃o* (from Greek letters *chi rho*) is shorthand for *Cristo*.

6 Conclusion

In this paper we presented a novel unsupervised OCR model for the joint production of diplomatic (variant-preserving) and normalized transcriptions of historical documents. The model is able to automatically learn a probabilistic mapping from a LM trained on modern text to the orthographic variants present in the document. This has the dual result of both considerably improving diplomatic transcription accuracy, while also enabling the model to simultaneously produce a normalized transcription.

Our model has the potential to significantly impact the work of scholars and librarians who wish to make digital texts easier to read, index, search, and study. Our approach also has the fortunate side-effect of producing metadata about orthographic variation in printed documents that may be valuable to scholars of book history. With our model, we are able to automatically induce sets of variation patterns used by printers, and the locations in the texts where those variants appear, without the need for labor-intensive page-by-page reading. Further, these induced mappings have probabilities attached, and are not simple rulebanks like those used in existing normalization work (Garrette et al., 2015; Baron and Rayson, 2008). Table 4, above, shows a sample of rules and their frequencies that resulted from training our model on Spanish documents.

Finally, our work helps to bridge the gap between historical text and mainline NLP. Orthographic variation lowers the accuracy of NLP tools due to high out-of-vocabulary rates and mismatched morphological features (Piotrowski, 2012). This is especially true when these tools are trained on the modern texts of the standard corpora used in NLP (Yang and Eisenstein, 2016). Normalization of historical texts have been shown to improve the quality of, for example, taggers (Rayson et al., 2007; Yang and Eisenstein, 2016) and parsers (Rayson et al., 2007). These techniques mirror those applied to the processing of text in social media, such as Twitter, where there is a high degree of slang and shorthand (Gimpel et al., 2011; Eisenstein, 2013; Yang and Eisenstein, 2013). Most approaches train off-the-shelf NLP tools on modern text and then apply normalization techniques to historical texts to transform them into something resembling the modern training input (Scheible et al., 2011). A joint model such as ours that automatically learns orthographic variations while training the NLP model might overcome some of the limitations of using such a pipeline approach.

Acknowledgments

Abstract

Sequence labeling for extraction of medical events and their attributes from unstructured text in Electronic Health Record (EHR) notes is a key step towards semantic understanding of EHRs. It has important applications in health informatics including pharmacovigilance and drug surveillance. The state of the art supervised machine learning models in this domain are based on Conditional Random Fields (CRFs) with features calculated from fixed context windows. In this application, we explored recurrent neural network frameworks and show that they significantly outperformed the CRF models.

1 Introduction

EHRs report patient's health, medical history and treatments compiled by medical staff at hospitals. It is well known that EHR notes contain information about medical events including medication, diagnosis (or Indication), and adverse drug events (ADEs) etc. A medical event in this context can be described as a change in patient's medical status. Identifying these events in a structured manner has many important clinical applications such as discovery of abnormally high rate of adverse reaction events to a particular drug, surveillance of drug efficacy, etc. In this paper we treat EHR clinical event detection as a task of sequence labeling.

Sequence labeling in the context of machine learning refers to the task of learning to predict a label for each data-point in a sequence of data-points. This learning framework has wide applications in many disciplines such as genomics, intrusion detection, natural language processing, speech recognition etc. However, sequence labeling in EHRs is a challenging task. Unlike text in the open domain, EHR notes are frequently noisy, containing incomplete sentences, phrases and irregular use of language. In addition, EHR notes incorporate abundant abbreviations, rich medical jargons, and their variations, which make recognizing semantically similar patterns in EHR notes difficult. Additionally, different events exhibit different patterns and possess different prevalences. For example, while a medication comprises of at most a few words of a noun, an ADE (e.g., "has not felt back to his normal self") may vary to comprise of a significant part of a sentence. While medication information is frequently described in EHRs, ADEs are typically rare events.

Rule-based and learning-based approaches have been developed to identify and extract information from EHR notes (Haerian et al., 2012), (Xu et al., 2010), (Friedman et al., 1994), (Aronson, 2001), (Polepalli Ramesh et al., 2014). Learning-based approaches use sequence labeling algorithms like Conditional Random Fields (Lafferty et al., 2001), Hidden Markov Models (Collier et al., 2000), and Max-entropy Markov Models (McCallum et al., 2000). One major drawback of these graphical models is that the label prediction at any time point only depends on its data instance and the immediate neighboring labels.

While this approach performs well in learning the distribution of the output labels, it has some limitations. One major limitation is that it is not designed to learn from dependencies which lie in the

Proceedings of NAACL-HLT 2016, pages 473–482,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

surrounding but not quite immediate neighborhood. Therefore, the feature vectors have to be explicitly modeled to include the surrounding contextual information. Traditionally, bag of words representation of surrounding context has shown reasonably good performance. However, the information contained in the bag of words vector is very sensitive to context window size. If the context window is too short, it will not include all the information. On the other hand if the context window is too large, it will compress the vital information with other irrelevant words. Usually a way to tackle this problem is to try different context window sizes and use the one that gives the highest validation performance. However, this method cannot be easily applied to our task, because different medical events like medication, diagnosis or adverse drug reaction require different context window sizes. For example, while a medication can be determined by a context of two or three words containing the drug name, an adverse drug reaction would require the context of the entire sentence. As an example, this is a sentence from one of the EHRs, "The follow-up needle biopsy results were consistent with *bronchiolitis obliterans*, which was likely due to the Bleomycin component of his *ABVD chemo*". In this sentence, the true labels are *Adverse Drug Event(ADE)* for "*bronchiolitis obliterans*" and *Drugname* for "*ABVD chemo*". However the ADE , "*bronchiolitis obliterans*" could be miss-labeled as just another disease or symptom, if the entire sentence is not taken into context.

Recent advancements in Recurrent Neural Networks (RNNs) have opened up new avenues of research in sequence labeling. Traditionally, recurrent neural networks have been hard to train through Back-Propagation, because learning long term dependencies using simple recurrent neurons lead to problems like exploding or vanishing gradients (Bengio et al., 1994), (Hochreiter et al., 2001). Recent approaches have modified the simple neuron structure in order to learn dependencies over longer intervals more efficiently. In this study, we evaluate the performance of two such neural networks, namely, Long Short Term Memory (LSTM) and Gated Recurrent Units (GRU).

Timely identification of new drug toxicities is an unresolved clinical and public health problem, costing people's lives and billions of US dollars. In this study, we empirically evaluated LSTM and GRU on EHR notes, focusing on the clinically important task of detecting medication, diagnosis, and adverse drug event. To our knowledge, we are the first group reporting the uses of RNN frameworks for information extraction in EHR notes.

2 Related Work

Medication and ADE detection is an important NLP task in biomedicine. Related existing NLP approaches can be grouped into knowledge or rule-based, supervised machine learning, and hybrid approaches. For example, Hazlehurst et al. (2005) developed MediClass, a knowledge-based system that deploys a set of domain-specific logical rules for medical concept extraction. Wang et al. (2015) , Humphreys et.al. (1993) and others map EHR notes to medical concepts to an external knowledge resource using hybrid rule-based and syntactic parsing approaches. Gurulingappa et al. (2010) detect two medical entities (*disease* and *adverse events*) in a corpus of annotated Medline abstracts. In contrast, our work uses a corpus of actual medical notes and detects additional events and attributes.

Rochefort et al. (2015) developed document classifiers to classify whether a clinical note contains deep venous thromboembolisms and pulmonary embolism. Haerian et al. (2012) applied distance supervision to identify terms (e.g., including "suicidal", "self harm", and "diphenhydramine overdose") associated with suicide events. Zuofeng Li et al. (2010) extracted medication information using CRFs.

Many named entity recognition systems in the biomedical domain have been driven by the Shared tasks of BioNLP (Kim et al., 2009), BioCreAtivE (Hirschman et al., 2005) i2b2 shared NLP tasks (Li et al., 2009) and ShARe/CLEF evaluation tasks (Pradhan et al., 2014). The best performing clinical NLP systems for named entity recognition includes Tang et al (2013) which applied CRF and structured SVM.

Neural Network models like Convolutional Neural Networks and Recurrent Neural Networks (LSTM, GRU) have recently been been successfully used to tackle various sequence labeling problems in NLP. Collobert (2011) used Convolutional

Labels	Annotations	Avg. Words / Annotations
ADE	905	1.51
Indication	1988	2.34
Other SSD	26013	2.14

Frequency	2801	2.35

Table 1: Annotation statistics for the corpus.

Neural Network for sequence labeling problems like POS tagging, NER etc. . Later, Huang et al. (2015) achieved comparable or better scores using bi-directional LSTM based models.

3 Dataset

The annotated corpus contains 780 English EHR notes or 613,593 word tokens (an average of 786 words per note) from cancer patients who have been diagnosed with hematological malignancy. Each note was annotated by at least two annotators with inter-annotator agreement of 0.93 kappa. The annotated events and attributes and their instances in the annotated corpus are shown in Table 1.

The annotated events can be broadly divided into two groups, *Medication*, and *Disease*. The *Medication* group contains *Drugname*, *Dosage*, *Frequency*, *Duration* and *Route*. It corresponds to information about medication events and their attributes. The attributes (Route, Frequency, Dosage, and Duration) of a medication (Drug name) occur less frequently than the Drugname tag itself, because few EHRs report complete attributes of an event.

The *Disease* group contains events related to diseases (*ADE*, *Indication*, *Other SSD*) and their attributes (*Severity*). An injury or disease can be labeled as *ADE*, *Indication*, or *Other SSD* depending on the semantic context. It is marked as *ADE* if it is the side effect of a drug. It is marked as *Indication* if it is being diagnosed currently by the doctor and a medication has been prescribed for it. Any sign, symptom or disease that does not fall into the aforementioned two categories is labeled as *Other SSD*. *Other SSD* is the most common label in our corpus, because it is frequently used to label conditions in the past history of the patient.

For each note, we removed special characters that do not serve as punctuation and then split the note into sentences using regular expressions.

4 Methods

4.1 Long Short Term Memory

Long Short Term Memory Networks (Hochreiter and Schmidhuber, 1997) are a type of Recurrent Neural Networks (RNNs). RNNs are modifications of feed-forward neural networks with recurrent connections. In a typical NN, the neuron output at time t is given by:

$$y_i^t = \sigma(W_i x_t + b_i) \tag{1}$$

Where W_i is the weight matrix, b_i is the bias term and σ is the sigmoid activation function. In an RNN, the output of the neuron at time $t-1$ is fed back into the neuron. The new activation function now becomes:

$$y_i^t = \sigma(W_i x_t + U_i y_i^{t-1} + b_i) \tag{2}$$

Since these RNNs use the previous outputs as recurrent connections, their current output depends on the previous states. This property remembers previous information about the sequence, making them useful for sequence labeling tasks. RNNs can be trained through back-propagation through time. Bengio et al. (1994) showed that learning long term dependencies in recurrent neural networks through gradient decent is difficult. This is mainly because the back-propagating error can frequently “blow-up” or explode which makes convergence infeasible, or it can vanish which renders the network incapable of learning long term dependencies (Hochreiter et al., 2001).

In contrast, LSTM networks were proposed as solutions for the vanishing gradient problem and were designed to efficiently learn long term dependencies. LSTMs accomplish this by keeping an internal state that represents the memory cell of the LSTM neuron. This internal state can only be read and written through gates which control the information flowing through the cell state. The updates of various gates can be computed as:

$$i_t = tanh(W_{xi} x_t + W_{hi} h_{t-1}) \tag{3}$$

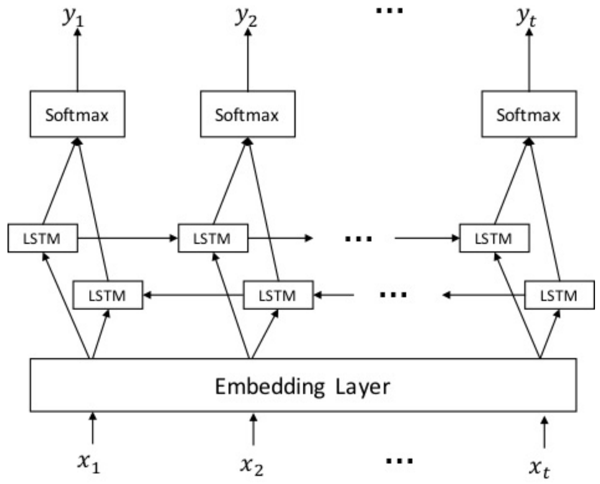

Figure 1: Sequence Labeling model for LSTM network

$$f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1}) \quad (4)$$

$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1}) \quad (5)$$

Here i_t , f_t and o_t denote input, forget and output gate respectively. The forget and input gate determine the contributions of the previous output and the current input, in the new cell state c_t. The output gate controls how much of c_t is exposed as the output. The new cell state c_t and the output h_t can be calculated as follows:

$$c_t = f_t \odot c_{t-1} + i_t \odot tanh(W_{xc}x_t + W_{hc}h_{t-1}) \quad (6)$$

$$h_t = o_t \odot tanh(c_t) \quad (7)$$

The cell state stores relevant information from the previous time-steps. It can only be modified in an additive fashion via the input and forget gates. Simplistically, this can be viewed as allowing the error to flow back through the cell state unchecked till it back propagates to the time-step that added the relevant information. This nature allows LSTM to learn long term dependencies.

We use LSTM cells in the Neural Network setup shown in figure 1. Here x_k,y_k are the input word, and the predicted label for the k^{th} word in the sentence. The embedding layer contains the word vector mapping from words to dense n-dimensional vector representations. We initialize the embedding layer at the start of the training with word vectors calculated on the larger data corpus described in section 4.4. This ensures that words which are not seen frequently in the labeled data corpus still have a reasonable vector representation. This step is necessary because our unlabeled corpus is much larger than the labeled one.

The words are mapped into their corresponding vector representations and fed into the LSTM layer. The LSTM layer consists of two LSTM chains, one propagating in the forward direction and other in the backward direction. We concatenate the output from the two chains to form a combined representation of the word and its context. This concatenated vector is then fed into a feed-forward neuron with Softmax activation function. The Softmax activation function normalizes the outputs to produce probability like outputs for each label type j as follows:

$$P(l_t = j|u_t) = \frac{exp(u_t W_j)}{\sum_{k=1}^{K} exp(u_t W_k)} \quad (8)$$

Here l_t and u_t are the label and the concatenated vector for each time step t. The most likely label at each word position is selected. The entire network is trained through back-propagation. The embedding vectors are also updated based on the back-propagated errors.

4.2 Gated Recurrent Units

Gated Recurrent Unit (GRU) is another type of recurrent neural network which was recently proposed for the purposes of Machine Translation by Cho et. al. (2014). Similar to LSTMs, Gated Recurrent Units also have an additive mechanism to update the cell state, with the current update. However, GRUs have a different mechanism to create the update. The candidate activation $\widetilde{h_t}$ is computed based on the previous cell state and the current input .

$$\widetilde{h_t} = \sigma(W_{xh}x_t + W_{hh}(r_t \odot h_{t-1})) \quad (9)$$

Here r_t is the reset gate and it controls the use of previous cell state while calculating the input activation. The reset gate itself is also computed based on the previous cell activation h_{t-1} and the current candidate activation .

$$\widetilde{r_t} = \sigma(W_{xr}x_t + W_{hr}h_{t-1}) \quad (10)$$

Models	Recall	Precision	F-score
CRF-nocontext	0.6562	0.7330	0.6925
CRF-context	0.6806	0.7711	0.7230
LSTM-sentence	0.8024	0.7803	0.7912
GRU-sentence	0.8013	0.7802	0.7906
LSTM-document	0.8050	0.7796	0.7921
GRU-document	**0.8126**	**0.7938**	**0.8031**

Table 2: Cross validated micro-average of Precision, Recall and F-score for all medical tags

The current cell state or activation is a linear combination of previous cell activation and the candidate activation.

$$h_t = (1 - z_t) \odot h_{t-1} + z_t \odot \widetilde{h}_t \qquad (11)$$

Here, z_t is the update gate which decides how much contribution the candidate activation and the previous cell state should have in the cell activation. The update gate is computed using the following equation:

$$z_t = (W_{hz}h_{t-1} + W_{xz}x_t) \qquad (12)$$

Gated recurrent units have some fundamental differences with LSTM. For example, there is no mechanism like the output gate which controls the exposure of the cell activation, instead the entire current cell activation is used as output. The mechanisms for using the previous output for the calculation of the current activation are also very different. Recent experiments (Chung et al., 2014), (Jozefowicz et al., 2015) comparing both these architectures have shown GRUs to have comparable or sometimes better performance than LSTM in several tasks with long term dependencies.

We use GRU with the same Neural Network structure as shown in Figure 1 by replacing the LSTM nodes with GRU. The embedding layer used here is also initialized in a similar fashion as the LSTM network.

4.3 The Baseline System

CRFs have been widely used for sequence labeling tasks in NLP. CRFs model the complex dependence of the outputs in a sequence using Probabilistic Graphical Models. Probabilistic Graphical Models represent relationships between variables through a product of factors where each factor is only influenced by a smaller subset of the variables. A particular factorization of the variables provides a specific set of independence relations enforced on the data. Unlike Hidden Markov Models which model the joint $p(x, y)$, CRFs model the posterior probability $p(y|x)$ directly. The conditional can be written as a product of factors as follows:

$$p(y|x) = \frac{1}{Z(x)} \prod_{t=1}^{T} \psi_t(y_t, y_{t-1}, x_t) \qquad (13)$$

Here Z is the partition function used for normalization, ψ_t are the local factor functions.

CRFs are fed the word inputs and their corresponding skip-gram word embedding (section 4.4). To compare CRFs with RNN, we add extra context feature for each word. This is done because our aim is to show that RNNs perform better than CRFs using context windows. This extra feature consists of two vectors that are bag of words representation of the sentence sections before and after the word respectively. We add this feature to explicitly provide a mechanism that is somewhat similar to the surrounding context that is generated in a Bi-directional RNN as shown in Figure 1. This CRF model is referred to as CRF-context in our paper. We also evaluate a CRF-nocontext model, which trains a CRF without the context features.

The tagging scheme used with both CRF models is BIO (Begin, Inside and Outside). We did not use the more detailed BILOU scheme (Begin, Inside, Last, Outside, Unit) due to data sparsity in some of the rarer labels.

4.4 Skip-Gram Word Embeddings

We use skip-gram word embeddings trained through a shallow neural network as shown by Mikolov et al., (2013) to initialize the embedding layer of the RNNs. This embedding is also used in the baseline CRF model as a feature. The embeddings are trained on a large unlabeled biomedical dataset, compiled from three sources, the English Wikipedia, an unlabeled EHR corpus, and PubMed Open Access articles. The English Wikipedia consists of text extracted from all the articles of English Wikipedia 2015. The unlabeled EHR corpus contains 99,700 electronic health record notes. PubMed Open Access articles are obtained by extracting the raw text from all openly available PubMed articles. This

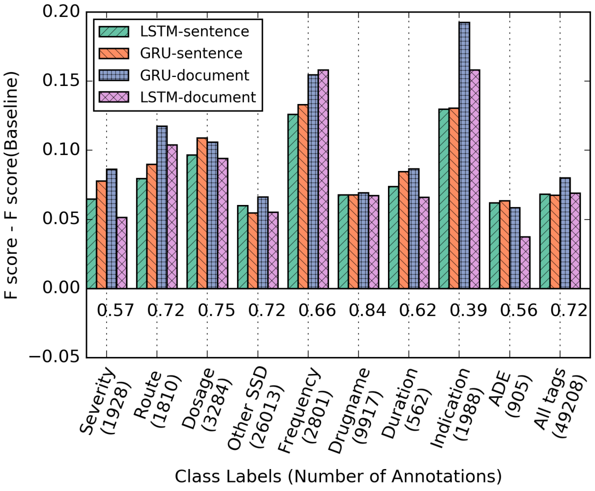

Figure 2: Change in F-score for RNN models with respect to CRF-context (baseline). The values below the plotted bars represent the baseline f-scores for each class label.

combined raw text corpus contains more than 3 billion word tokens. We convert all words to lowercase and use a context window of 10 words to train a 200 dimensional skip gram word embedding.

5 Experiments and Evaluation Metrics

For each word, the models were trained to predict either one of the nine medically relevant tags described in section 3, or the *Outside* label. The CRF tagger was run in two modes. The first mode (CRF–nocontext) used only the current word and its corresponding skip-gram representation. The second mode (CRF– context) used the extra context feature described in section 4.3. The extra features are basically the bag of words representation of the preceding and following sections of the sentence. The first mode was used to compare the performance of CRF and RNN models when using the same input data. It also serves as a method of contrasting with CRF's performance when context features are explicitly added. CRF Tagger uses L-BFGS optimizer with L2- regularization.

The RNN frameworks are trained on sentence level and document level. The sentence level neural networks are fed only one sentence at a time. This means that the LSTM and GRU states are only preserved and propagated within a sentence. The networks cell states are re-initialized before each sentence. The document level neural networks are fed one document at a time, so they can learn context cues that reside outside of the sentence boundary. We use 100 dimensional hidden layer for each directional RNN chain. Since we use bi-directional LSTMs and GRUs, this essentially amounts to a 200 dimensional recurrent hidden layer. The hidden layer activation functions for both RNN models are $tanh$. Output of this hidden layer is fed into a Softmax output layer which emits probabilities for each of the nine medical labels and the *Outside* label. We use categorical cross entropy as the objective function. Similar to the CRF implementation, the Neural Net cost function also contains an L2-regularization component. We also use dropout (Srivastava et al., 2014) as an additional measure to avoid over-fitting. Fifty percent dropout is used to manipulate the inputs to the RNN and the Softmax layer. We use AdaGrad (Duchi et al., 2011) to optimize the network cost.

We use ten-fold cross validation to calculate the performance metric for each model. The dataset is divided at the note level. We separate out 10 % of the training set to form the validation set. This validation set is used to evaluate the different parameter combinations for CRF and RNN models. We employ early stopping to terminate the training run if the validation error increases consistently. We use a maximum of 40 epochs to train each network. The batch sizes used were kept constant at 128 for sentence level RNNs and 16 for document level RNNs.

We report micro-averaged recall, precision and f-score. We use exact phrase matching to calculate the evaluation score for our experiments. Each phrase labeled by the learned models is considered a true positive only if it matches the exact true boundary of the phrase and correctly labels all the words in the phrase.

We use CRFsuite (Okazaki, 2007) for implementing the CRF tagger. We use Lasagne to setup the Neural Net framework. Lasagne[1] is a machine learning library focused towards neural networks that is build on top of Theano (Bergstra et al., 2010).

[1] https://github.com/Lasagne/Lasagne

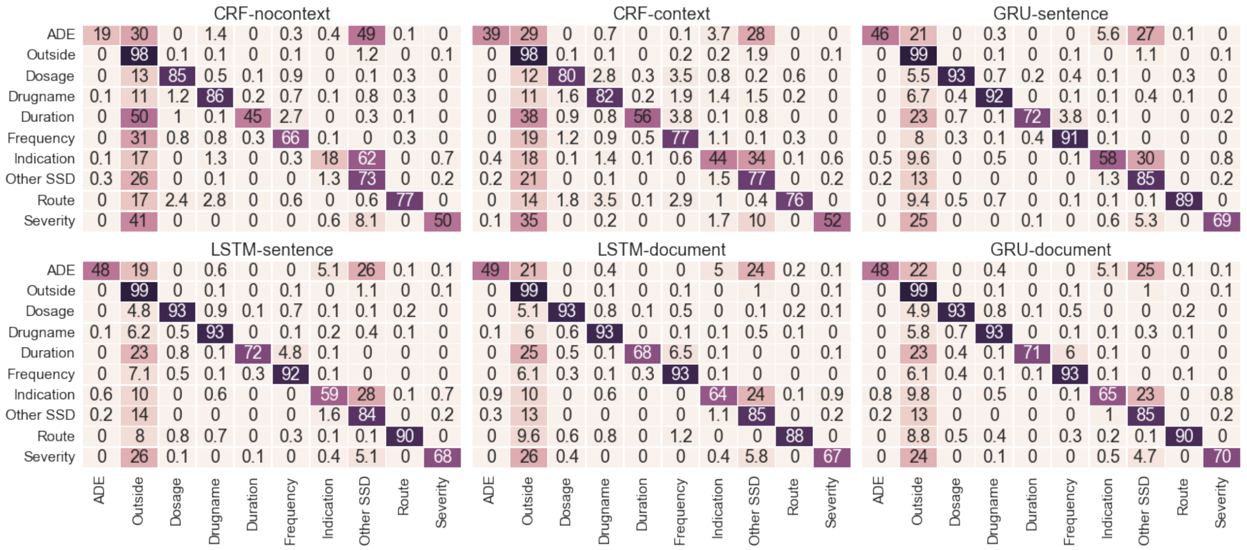

Figure 3: Heat-maps of Confusion Matrices of each method for the different class Labels. Rows are reference and columns are predictions. The value in cell (i, j) denotes the percentage of words in label i that were predicted as label j.

6 Results

Table 2 shows the micro averaged scores for each method. All RNN models significantly outperform the baseline (CRF-context). Compared to the baseline system, our best system (GRU-document) improved the recall (0.8126), precision (0.7938) and F-score (0.8031) by 19% , 2% and 11 % respectively. Clearly the improvement in recall contributes more to the overall increase in system performance. The performance of different RNN models is almost similar, except for the GRU model which exhibits an F-score improvement of at least one percentage point over the rest.

The changes (gain or loss) in label wise F-score for each RNN model relative to the baseline CRF-context method are plotted in Figure 2. GRU-document exhibits the highest gain overall in six of the nine tags: *indication* or diagnosis, *route*, *duration*, *severity*, *drug name*, and *other SSD*. For indication, its gain is about 0.19, a near 50% increase over the baseline. While the overall system performance of GRU-sentence, LSTM-sentence and LSTM-document are very similar, they do exhibit somewhat varied performance for different labels. The sentence level models clearly outperform the document level RNNs (both GRU and LSTM) for *ADE* and *Dosage*. Additionally, GRU sentence model shows the highest gain in *ADE* f-score.

Figure 3 shows the word level confusion matrix of different models for each label. Each cell shows the percentage of word tokens in row label i that were classified as column label j. The consistent increase of diagonal entries of RNN models for all ten labels, indicates an increase in the overall system accuracy when compared to the baseline. The most densely populated column in this figure is the *Outside* column, which denotes percentage of words that were erroneously labeled as *Outside*.

Figure 4 shows the change in average F-scores for each method with changing percentage of training data used. The setup for training, development and test data is kept the same as the ten-fold cross validation setup mentioned in Section 5. Only the training data is randomly down-sampled to achieve the reduced training data size. The figure shows that Recurrent Neural Network models perform better than traditional CRF models even with smaller training data sizes.

7 Discussion

We already discussed in the previous section how improved recall seems to be the major reason behind improvements in the RNN F-score. This trend can be observed in Figure 3 where RNN models lead to significant decreases in confusion values present in *Outside* column.

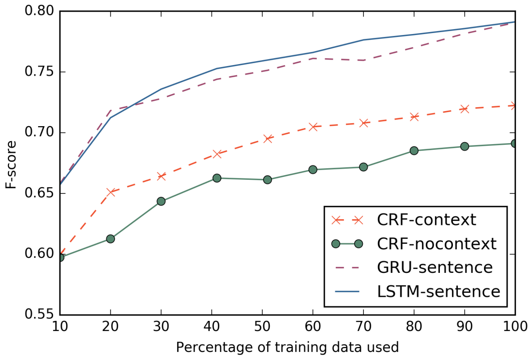

Figure 4: Change in F-score for all sentence models with respect to increasing training data size.

Further examination of Figure 3 shows two major sources of error in the CRF systems. The largest source of error is caused by confusing the relevant medical words as *Outside* (false negatives) and vice versa (false positives). The extent of false positives is not clear from Figure 3, but can be estimated if one takes into account that even a 1 % confusion in the *Outside* row represents about 5000 words. The second largest source of error is the confusion among *ADE*, *Indication* and *Other SSD* labels. As we discuss in the following paragraphs, RNNs manage to significantly reduce both these type of errors.

The large improvement in recall of all labels for RNN models seems to suggest that RNNs are able to recognize a larger set of relevant patterns than CRF baselines. This supports our hypothesis that learning dependencies with variable context ranges is crucial for our task of medical information extraction from EHR notes. This is also evident from the reduced confusion among *ADE*, *Indication* and *Other SSD*. Since these tags share a common vocabulary of Sign, Symptom and Disease Names, identifying the underlying word or phrase is not enough to distinguish between the three. Use of relevant patterns from surrounding context is often needed as a discriminative cue. Consequently, *ADE*, *Indication* confusion values in the *Other SSD* column for RNNs exhibit significant decreases when compared to CRF-nocontext and CRF-context. We also see large improvements in detecting *Duration*, *Frequency* and *Severity*. The vocabulary of these labels often lack specific medical jargon terms. Examples of these labels include “seven days”, “one week” for *duration*, “some”, “small”, “no significant” for *severity* and “as needed”, “twice daily” for *frequency*. Therefore, they are most likely to be confused with *Outside* label. This is indeed the case, as they have the highest confusion values in the *Outside* column of CRF-nocontext. Including context in CRF improves the performance, but not as much as RNN models which decrease the confusion by almost half or more in all cases. For example, GRU-document only confuses Frequency as an unlabeled word about 6.1 % of the time as opposed to 31 % and 19 % for CRF-nocontext and CRF-context respectively.

Document level models benefit by using context from outside the sentence. Since the label *Indication* requires the most use of surrounding context, it is clear that its performance would improve by using information from several sentences. Indications are diseases that are diagnosed by the medical staff, and the entire picture of the diagnosis is usually distributed across multiple sentences. Analysis of ADE is more complicated. Several ADE instances in a sentence also contain explicit cues similar to “secondary to” and “caused by”. When coupled with *Drugnames* this is enough to classify the ADE. Sentence level models might depend more on these local cues which leads to improved performance. Document models, on the other hand, have to recognize patterns from a larger context, using a very small dataset (total ADE annotations are just 905) which is quite difficult.

The LSTM-document model does not show the same improvement over the sentence models as GRU-document. One possible reason for this might be the simpler recurrence structure of GRU neuron as compared to LSTM. Since there are only 780 document sequences in the dataset, the GRU model with a smaller number of trainable parameters might learn faster than LSTM. It is possible that with a larger dataset, LSTM might perform comparable to or better than GRU. However, our experiments with reducing the hidden layer size of LSTM-document model to control for the number of trainable parameters did not produce any significant improvements.

Moreover, figure 4 seems to indicate that there is not much difference between the performances of LSTM and GRU with different data sizes. However it is clearly surprising that RNN models with a larger number of parameters can still perform better than CRF models on smaller dataset sizes. This might be because the embedding layer, which contributes to a very large section of the trainable parameters, is initialized with a suitably good estimate using skip-gram word embeddings described in section 4.4.

8 Conclusion

We have shown that RNNs models like LSTM and GRU are valuable tools for extracting medical events and attributes from noisy natural language text of EHR notes. We believe that the significant improvement provided by gated RNN models is due to their ability to remember information across different range of dependencies as and when required. As mentioned previously in the introduction, this is very important for our task because different labels have different contextual dependencies. CRF models with hand crafted features like bag of words representation, use fixed context windows and lose a lot of information in the process.

RNNs are excellent in extracting relevant patterns from sequence data. However, they do not explicitly enforce constraints or dependencies over the output labels. We believe that adding a probabilistic graphical model framework for structured output prediction would further improve the performance of our system. This experiment remains as our future work.

Acknowledgments

We thank the UMassMed annotation team, including Elaine Freund, Wiesong Liu and Steve Belknap, for creating the gold standard evaluation set used in this work. We also thank the anonymous reviewers for their comments and suggestions.

Abstract

When evaluating the quality of topics generated by a topic model, the convention is to score topic coherence — either manually or automatically — using the top-N topic words. This hyper-parameter N, or the *cardinality* of the topic, is often overlooked and selected arbitrarily. In this paper, we investigate the impact of this cardinality hyper-parameter on topic coherence evaluation. For two automatic topic coherence methodologies, we observe that the correlation with human ratings decreases systematically as the cardinality increases. More interestingly, we find that performance can be improved if the system scores and human ratings are aggregated over several topic cardinalities before computing the correlation. In contrast to the standard practice of using a fixed value of N (e.g. $N = 5$ or $N = 10$), our results suggest that calculating topic coherence over several different cardinalities and averaging results in a substantially more stable and robust evaluation. We release the code and the datasets used in this research, for reproducibility.[1]

1 Introduction

Latent Dirichlet Allocation ("LDA": Blei et al. (2003)) is an approach to document clustering, in which "topics" (multinomial distributions over terms) and topic allocations (multinomial distributions over topics per document) are jointly learned. When the topic model output is to be presented to humans, optimisation of the number of topics is a non-trivial problem. In the seminal paper of Chang et al. (2009), e.g., the authors showed that — contrary to expectations — extrinsically measured topic coherence correlates negatively with model perplexity. They introduced the word intrusion task, whereby a randomly selected "intruder" word is injected into the top-N words of a given topic and users are asked to identify the intruder word. Low reliability in identifying the intruder word indicates low coherence (and vice versa), based on the intuition that the more coherent the topic, the more clearly the intruder word should be an outlier.

Since then, several methodologies have been introduced to automate the evaluation of topic coherence. Newman et al. (2010) found that aggregate pairwise PMI scores over the top-N topic words correlated well with human ratings. Mimno et al. (2011) proposed replacing PMI with conditional probability based on co-document frequency. Aletras and Stevenson (2013) showed that coherence can be measured by a classical distributional similarity approach. More recently, Lau et al. (2014) proposed a methodology to automate the word intrusion task directly. Their results also reveal the differences between these methodologies in their assessment of topic coherence.

A hyper-parameter in all these methodologies is the number of topic words, or its *cardinality*. These methodologies evaluate coherence over the top-N topic words, where N is selected arbitrarily: for Chang et al. (2009), $N = 5$, whereas for Newman et al. (2010), Aletras and Stevenson (2013) and Lau et al. (2014), $N = 10$.

The germ of this paper came when using the automatic word intrusion methodology (Lau et al., 2014), and noticing that introducing one extra word to a given topic can dramatically change the accuracy of intruder word prediction. This forms the kernel of this paper: to better understand the impact of the topic cardinality hyper-parameter on the evaluation of topic coherence.

To investigate this, we develop a new dataset with human-annotated coherence judgements for a range of cardinality settings ($N = \{5, 10, 15, 20\}$). We experiment with the automatic word intrusion (Lau et al., 2014) and discover that correlation with human ratings decreases systematically as cardinality increases. We also test the PMI methodology (Newman et al., 2010) and make the same observation. To remedy this, we show that performance can be substantially improved if system scores and human ratings are aggregated over different cardinality settings before computing the correlation. This has broad implications for topic model evaluation.

2 Dataset and Gold Standard

To examine the relationship between topic cardinality and topic coherence, we require a dataset that has topics for a range of cardinality settings. Although there are existing datasets with human-annotated coherence scores (Newman et al., 2010; Aletras and Stevenson, 2013; Lau et al., 2014; Chang et al., 2009), these topics were annotated using a fixed cardinality setting (e.g. 5 or 10). We thus develop a new dataset for this experiment.

Following Lau et al. (2014), we use two domains: (1) WIKI, a collection of 3.3 million English Wikipedia articles (retrieved November 28th 2009); and (2) NEWS, a collection of 1.2 million New York Times articles from 1994 to 2004 (English Gigaword). We sub-sample approximately 50M tokens (100K and 50K articles for WIKI and NEWS respectively) from both domains to create two smaller document collections. We then generate 300 LDA topics for each of the sub-sampled collection.[2]

There are two primary approaches to assessing topic coherence: (1) via word intrusion (Chang et al., 2009); and (2) by directly measuring observed coherence (Newman et al., 2010; Lau et al., 2014). With the first method, Chang et al. (2009) injects an intruder word into the top-5 topic words, shuffles the topic words, and sets the task of selecting the single intruder word out of the 6 words. In preliminary experiments, we found that the word intrusion task becomes unreasonably difficult for human annotators when the topic cardinality is high, e.g. when $N = 20$. As such, we use the second approach as the means for generating our gold standard, asking users to judge topic coherence directly over different topic cardinalities.[3]

Domain	N			
	5	10	15	20
WIKI	2.42 (±0.54)	2.37 (±0.53)	2.35 (±0.51)	2.29 (±0.50)
NEWS	2.49 (±0.53)	2.46 (±0.53)	2.42 (±0.51)	2.39 (±0.51)

Table 1: Mean rating across different N (numbers in parentheses denote standard deviations)

Cardinality Pair	WIKI	NEWS
5 vs. 10	0.834	0.849
5 vs. 15	0.777	0.834
5 vs. 20	0.826	0.815
10 vs. 15	0.841	0.876
10 vs. 20	0.853	0.854
15 vs. 20	0.831	0.871
Mean	0.827	0.850

Table 2: Correlation between different pairwise cardinality settings.

To collect the coherence judgements, we used Amazon Mechanical Turk and asked Turkers to rate topics in terms of coherence using a 3-point ordinal scale, where 1 indicates incoherent and 3 very coherent (Newman et al., 2010). For each topic (600 topics in total) we experiment with 4 cardinality settings: $N = \{5, 10, 15, 20\}$. For example, for $N = 5$, we display the top-5 topic words for coherence judgement.

For annotation quality control, we embed a bad topic generated using random words into each HIT. Workers who fail to consistently rate these bad topics low are filtered out.[4] On average, we collected

[2] The sub-sampled document collections are lemmatised using OpenNLP and Morpha (Minnen et al., 2001) before topic modelling.

[3] This is not a major limitation, however, as Lau et al. (2014) found a strong correlation between the judgements generated by the two methodologies.

[4] We filter workers who rate bad topics with a rating > 1 in more than 30% of their HITs.

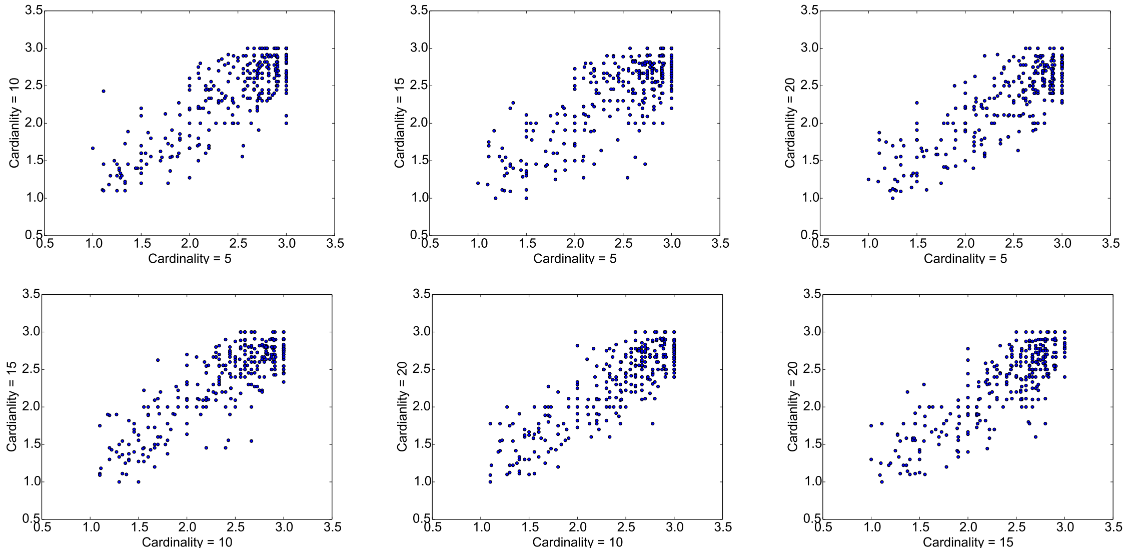

Figure 1: Scatter plots of human ratings for different pairwise cardinality settings for the WIKI topics.

approximately 9 ratings per topic in each cardinality setting (post-filtered), from which we generate the gold standard via the arithmetic mean.

To understand the impact of cardinality (N) on topic coherence, we analyse: (a) the mean topic rating for each N (Table 1), and (b) the pairwise Pearson correlation coefficient between the same topics for different values of N (Table 2).

Coherence decreases slightly but systematically as N increases, suggesting that users find topics less coherent (but marginally more consistently interpretable, as indicated by the slight drop in standard deviation) when more words are presented in a topic. The strong pairwise correlations, however, indicate that the ratings are relatively stable across different cardinality settings.

To better understand the data, in Figure 1 we present scatter plots of the ratings for all pairwise cardinality settings (where a point represents a topic). Note the vertical lines for $x = 3.0$ (cf. the weaker effect of horizontal lines for $y = 3.0$), in particular for the top 3 plots where we are comparing $N = 5$ against higher cardinality settings. This implies that topics that are rated as perfectly coherent (3.0) for $N = 5$ exhibit some variance in coherence ratings when N increases. Intuitively, it means that a number of perfectly coherent 5-word topics become less coherent as more words are presented.

3 Automated Method — Word Intrusion

Lau et al. (2014) proposed an automated approach to the word intrusion task. The methodology computes pairwise word association features for the top-N words, and trains a support vector regression model to rank the words. The top-ranked word is then selected as the predicted intruder word. Note that even though it is supervised, no manual annotation is required as the identity of the true intruder word is known. Following the original paper, we use as features normalised PMI (NPMI) and two conditional probabilities (CP1 and CP2), computed over the full collection of WIKI (3.3 million articles) and NEWS (1.2 million articles), respectively. We use 10-fold cross validation to predict the intruder words for all topics.

To generate an intruder for a topic, we select a random word that has a low probability ($P < 0.0005$) in the topic but high probability ($P > 0.01$) in another topic. We repeat this ten times to generate 10 different intruder words for a topic. The 4 cardinalities of a given topic share the same set of intruder words.

To measure the coherence of a topic, we compute *model precision*, or the accuracy of intruder word prediction. For evaluation we compute the Pearson correlation coefficient r of model precisions and human ratings for each cardinality setting. Results are summarised in Table 3.

Domain	N	In-domain Features	Out-of-Domain Features
WIKI	5	0.46	0.66
	10	0.41	0.54*
	15	0.32*	0.51*
	20	0.33*	0.43*
	Avg	0.46	0.65
NEWS	5	0.45*	0.65
	10	0.40*	0.60*
	15	0.38*	0.54*
	20	0.43*	0.47*
	Avg	0.50	0.65

Table 3: Pearson correlation between system model precision and human ratings across different values of N for word intrusion. '*' denotes statistical significance compared to aggregate correlation.

Domain	N	In-domain Features	Out-of-Domain Features
WIKI	5	0.02	0.59*
	10	−0.05*	0.58*
	15	0.00	0.56*
	20	0.06	0.55*
	Avg	0.00	0.63
NEWS	5	0.22*	0.62*
	10	0.27*	0.68*
	15	0.35	0.68*
	20	0.35	0.65*
	Avg	0.31	0.71

Table 4: Pearson correlation between system topic coherence and human ratings across different values of N for NPMI. "*" denotes statistical significance compared to aggregate correlation.

Each domain has 2 sets of correlation figures, based on in-domain and out-of-domain features. In-domain (out-of-domain) features are word association features computed using the same (different) domain as the topics, e.g. when we compute coherence of WIKI topics using word association features derived from WIKI (NEWS).

The correlations using in-domain features are in general lower than for out-of-domain features. This is due to idiosyncratic words that are closely related in the collection, e.g. remnant Wikipedia markup tags. The topic model discovers them as topics and the word statistics derived from the same collection supports the association, but these topics are generally not coherent, as revealed by out-of-domain statistics. This result is consistent with previous studies (Lau et al., 2014).

We see that correlation decreases systematically as N increases, implying that N has high impact on topic coherence evaluation and that if a single value of N is to be used, a lower value is preferable.

To test whether we can leverage the additional information from the different values of N, we aggregate the model precision values and human ratings per-topic before computing the correlation (Table 3: Cardinality = "Avg"). We also test the significance of difference for each N with the aggregate correlation using the Steiger Test (Steiger, 1980); they are marked with '*' in the table.[5]

The correlation improves substantially. In fact, for NEWS using in-domain features, the correlation is higher than that of any individual cardinality setting. This observation suggests that a better approach to automatically computing topic coherence is to aggregate coherence scores over different cardinality settings, and that it is sub-optimal to evaluate a topic by only assessing a single setting of N. Instead, we should repeat it several times, varying N.

4 Automated Method — NPMI

The other mainstream approach to evaluating topic coherence is to directly measure the average pairwise association between the top-N words. Newman et al. (2010) found PMI to be the best association measure, and later studies (Aletras and Stevenson, 2013; Lau et al., 2014) found that normalised PMI (NPMI: Bouma (2009)) improves PMI further.

To see if the benefit of aggregating coherence measures over several cardinalities transfers across to other methodologies, we test the NPMI methodology. We compute the topic coherence using the full collection of WIKI and NEWS, respectively, for varying N. Results are presented in Table 4.
