- We propose an automatic method to build a large-scale DP training corpus. Given that the DPs are annotated in the parallel corpus, models trained on this data are more appropriate to the translation task;
- Benefiting from representation learning, our deep learning-based generation models are able to avoid ignore the complex feature-engineering work while still yielding encouraging results;
- To decrease the negative effects on translation caused by inserting incorrect DPs, we force the SMT system to arbitrate between multiple ambiguous hypotheses from the DP predictions.

The rest of the paper is organized as follows. In Section 2, we describe our approaches to building the DP corpus, DP generator and SMT integration. Related work is described in Section 3. The experimental results for both the DP generator and translation are reported in Section 4. Section 5 analyses some real examples which is followed by our conclusion in Section 6.

2 Methodology

The architecture of our proposed method is shown in Figure 2, which can be divided into three phases: DP corpus annotation, DP generation, and SMT integration.

2.1 DP Training Corpus Annotation

We propose an approach to automatically annotate DPs by utilizing alignment information. Given a parallel corpus, we first use an unsupervised word alignment method (Och and Ney, 2003; Tu et al., 2012) to produce a word alignment. From observing of the alignment matrix, we found it is possible to detect DPs by projecting misaligned pronouns from the non-pro-drop target side (English) to the pro-drop source side (Chinese). In this work, we focus on nominative and accusative pronouns including personal, possessive and reflexive instances, as listed in Table 1.

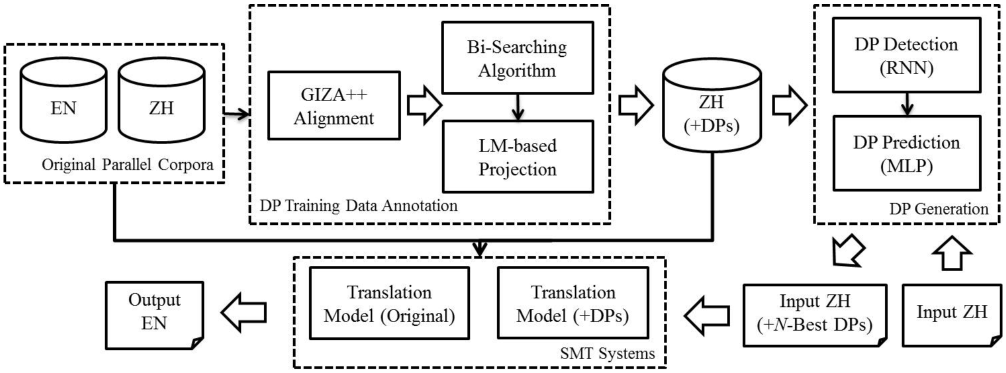

Figure 2: Architecture of proposed method.

Category	Pronouns
Subjective Personal	我 (*I*), 我们 (*we*), 你/你们 (*you*), 他 (*he*), 她 (*she*), 它 (*it*), 他们/她们/它们 (*they*).
Objective Personal	我 (*me*), 我们 (*us*), 你/你们 (*you*), 他 (*him*), 她 (*her*), 它 (*it*), 她们/他们/它们 (*them*).
Possessive	我的 (*my*), 我们的 (*our*), 你的/你们的 (*your*), 他的 (*his*), 她的 (*her*), 它的 (*its*), 他们的/她们的/它们的 (*their*).
Objective Possessive	我的 (*mine*), 我们的 (*ours*), 你的/你们的 (*yours*), 他的 (*his*), 她的 (*hers*), 它的 (*its*), 她们的/他们的/它们的 (*theirs*).
Reflexive	我自己 (*myself*), 我们自己 (*ourselves*), 你自己 (*yourself*), 你们自己 (*yourselves*), 他自己 (*himself*), 她自己 (*herself*), 它自己 (*itself*), 他们自己/她们自己/它们自己 (*themselves*).

Table 1: Pronouns and their categories.

We use an example to illustrate our idea. Figure 3 features a dropped pronoun "我" (not shown) on the source side, which is aligned to the second "*I*" (in red) on the target side. For each pronoun on the target side (e.g. "*I*", "*you*"), we first check whether it has an aligned pronoun on the source side. We find that the second "*I*" is not aligned to any source word and possibly corresponds to a DP_I (e.g. "我"). To determine the possible positions of DP_I on the source side, we employ a *diagonal* heuristic based on the observation that there exists a diagonal rule in the local area of the alignment matrix. For example, the alignment blocks in Figure 3 generally follow a diagonal line. Therefore, the pronoun "*I*" on the target side can be projected to the purple area (i.e. "你 说 过 想") on the source side, according to the preceding and following alignment blocks (i.e. "*you*-你" and "*want*-想").

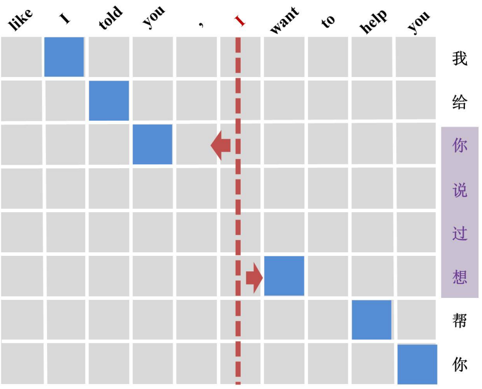

Figure 3: Example of DP projection using alignment results (i.e. blue blocks).

However, there are still three possible positions to insert DP_I (i.e. the three gaps in the purple area). To further determine the exact position of DP_I, we generate possible sentences by inserting the corresponding Chinese DPs[1] into every possible position. Then we employ an n-gram language model (LM) to score these candidates and select the one with the lowest perplexity as final result. This LM-based projection is based on the observation that the amount and type of DPs are very different in different gen-

[1] The Chinese DP can be determined by using its English pronouns according to Table 1. Note that some English pronouns may correspond to different Chinese pronouns, such as "*they* - 他们 / 她们 / 它们". In such cases, we use all the corresponding Chinese pronouns as the candidates.

res. We hypothesize that the DP position can be determined by utilizing the inconsistency of DPs in different domains. Therefore, the LM is trained on a large amount of webpage data (detailed in Section 3.1). Considering the problem of incorrect DP insertion caused by incorrect alignment, we add the original sentence into the LM scoring to reduce impossible insertions (noise).

2.2 DP Generation

In light of the recent success of applying deep neural network technologies in natural language processing (Raymond and Riccardi, 2007; Mesnil et al., 2013), we propose a neural network-based DP generator via the DP-inserted corpus (Section 2.1). We first employ an RNN to predict the DP position, and then train a classifier using multilayer perceptrons to generate our N-best DP results.

2.2.1 DP detection

The task of DP position detection is to label words if there are pronouns missing before the words, which can intuitively be regarded as a sequence labelling problem. We expect the output to be a sequence of labels $y^{(1:n)} = (y^{(1)}, y^{(2)}, \cdots, y^{(t)}, \cdots, y^{(n)})$ given a sentence consisting of words $w^{(1:n)} = (w^{(1)}, w^{(2)}, \cdots, w^{(t)}, \cdots, w^{(n)})$, where $y^{(t)}$ is the label of word $w^{(t)}$. In our task, there are two labels $L = \{NA, DP\}$ (corresponding to non-pro-drop or pro-drop pronouns), thus $y^{(t)} \in L$.

Word embeddings (Mikolov et al., 2013) are used for our generation models: given a word $w^{(t)}$, we try to produce an embedding representation $\mathbf{v}^{(t)} \in \mathbb{R}^d$ where d is the dimension of the representation vectors. In order to capture short-term temporal dependencies, we feed the RNN unit a window of context, as in Equation (1):

$$\mathbf{x_d}^{(t)} = \mathbf{v}^{(t-k)} \oplus \cdots \oplus \mathbf{v}^{(t)} \oplus \cdots \oplus \mathbf{v}^{(t+k)} \quad (1)$$

where k is the window size.

We employ an RNN (Mesnil et al., 2013) to learn the dependency of sentences, which can be formulated as Equation (2):

$$\mathbf{h}^{(t)} = f(\mathbf{U}\mathbf{x_d}^{(t)} + \mathbf{V}\mathbf{h}^{(t-1)}) \quad (2)$$

where $f(x)$ is a sigmoid function at the hidden layer. $\mathbf{U}$ is the weight matrix between the raw input and the hidden nodes, and $\mathbf{V}$ is the weight matrix between the context nodes and the hidden nodes. At the output layer, a softmax function is adopted for labelling, as in Equation (3):

$$y^{(t)} = g(\mathbf{W_d}\mathbf{h}^{(t)}) \quad (3)$$

where $g(z_m) = \frac{e^{z_m}}{\sum_k e^{z_k}}$, and $\mathbf{W_d}$ is the output weight matrix.

ID.	Description
	Lexical Feature Set
1	S surrounding words around p
2	S surrounding POS tags around p
3	preceding pronoun in the same sentence
4	following pronoun in the same sentence
	Context Feature Set
5	pronouns in preceding X sentences
6	pronouns in following X sentences
7	nouns in preceding Y sentences
8	nouns in following Y sentences
	Syntax Feature Set
9	path from current word (p) to the root
10	path from preceding word ($p-1$) to the root

Table 2: List of features.

2.2.2 DP prediction

Once the DP position is detected, the next step is to determine which pronoun should be inserted based on this result. Accordingly, we train a 22-class classifier, where each class refers to a distinct Chinese pronoun in Table 1. We select a number of features based on previous work (Xiang et al., 2013; Yang et al., 2015), including lexical, contextual, and syntax features (as shown in Table 2). We set p as the DP position, S as the window size surrounding p, and X, Y as the window size surrounding current sentence (the one contains p). For Features 1–4, we extract words, POS tags and pronouns around p. For Features 5–8, we also consider the pronouns and nouns between X/Y surrounding sentences. For Features 9 and 10, in order to model the syntactic relation, we use a path feature, which is the combined tags of the sub-tree nodes from p/$(p-1)$ to the root. Note that Features 3–6 consider all pronouns that were not dropped. Each unique feature is treated as a word, and assigned a "word embedding". The embeddings of the features are then fed to the neural network. We fix the number of features for the variable-length features, where missing ones are tagged as None. Accordingly, all training instances share the same feature length. For the training data, we sample all DP instances from the corpus (annotated by the method in Section 2.1). During decoding, p can be given by our DP detection model.

We employ a feed-forward neural network with four layers. The input $\mathbf{x_p}$ comprises the embeddings of the set of all possible feature indicator names. The middle two layers $\mathbf{a}^{(1)}$, $\mathbf{a}^{(2)}$ use Rectified Linear function R as the activation function, as in Equation (4)–(5):

$$\mathbf{a}^{(1)} = R(\mathbf{b}^{(1)} + \mathbf{W_p}^{(1)}\mathbf{x_p}) \quad (4)$$

$$\mathbf{a}^{(2)} = R(\mathbf{b}^{(2)} + \mathbf{W_p}^{(2)}\mathbf{a}^{(1)}) \quad (5)$$

where $\mathbf{W_p}^{(1)}$ and $\mathbf{b}^{(1)}$ are the weights and bias connecting the first hidden layer to second hidden layer; and so on. The last layer $\mathbf{y_p}$ adopts the softmax function g, as in Equation (6):

$$\mathbf{y_p} = g(\mathbf{W_p}^{(3)}\mathbf{a}^{(2)}) \quad (6)$$

2.3 Integration into Translation

The baseline SMT system uses the parallel corpus and input sentences without inserting/generating DPs. As shown in Figure 2, the integration into SMT system is two fold: DP-inserted translation model (*DP-ins. TM*) and DP-generated input (*DP-gen. Input*).

2.3.1 DP-inserted TM

We train an additional translation model on the new parallel corpus, whose source side is inserted with DPs derived from the target side via the alignment matrix (Section 2.1). We hypothesize that DP insertion can help to obtain a better alignment, which can benefit translation. Then the whole translation process is based on the boosted translation model, i.e. with DPs inserted. As far as TM combination is concerned, we directly feed Moses the multiple phrase tables. The gain from the additional TM is mainly from complementary information about the recalled DPs from the annotated data.

2.3.2 DP-generated input

Another option is to pre-process the input sentence by inserting possible DPs with the DP generation model (Section 2.2) so that the DP-inserted input (Input ZH+DPs) is translated. The predicted DPs would be explicitly translated into the target language, so that the possibly missing pronouns in the translation might be recalled. This makes the input sentences and DP-inserted TM more consistent in terms of recalling DPs.

2.3.3 N-best inputs

However, the above method suffers from a major drawback: it only uses the 1-best prediction result for decoding, which potentially introduces translation mistakes due to the propagation of prediction errors. To alleviate this problem, an obvious solution is to offer more alternatives. Recent studies have shown that SMT systems can benefit from widening the annotation pipeline (Liu et al., 2009; Tu et al., 2010; Tu et al., 2011; Liu et al., 2013). In the same direction, we propose to feed the decoder N-best prediction results, which allows the system to arbitrate between multiple ambiguous hypotheses from upstream processing so that the best translation can be produced. The general method is to make the input with N-best DPs into a confusion network. In our experiment, each prediction result in the N-best list is assigned a weight of $1/N$.

3 Related Work

There is some work related to DP generation. One is zero pronoun resolution (ZP), which is a sub-direction of co-reference resolution (CR). The difference to our task is that ZP contains three steps (namely ZP detection, anaphoricity determination and co-reference link) whereas DP generation only contains the first two steps. Some researchers (Zhao and Ng, 2007; Kong and Zhou, 2010; Chen and Ng, 2013) propose rich features based on different machine-learning methods. For example, Chen and Ng (2013) propose an SVM classifier using 32 features including lexical, syntax and grammatical roles etc., which are very useful in the ZP task. However, most of their experiments are conducted on a small-scale corpus (i.e. OntoNotes)[2] and performance drops correspondingly when using a system-parse tree compared to the gold standard one. Novak and Zabokrtsky (2014) explore cross-language

[2] It contains 144K coreference instances, but only 15% of them are dropped subjects.

differences in pronoun behavior to affect the CR results. The experiment shows that bilingual feature sets are helpful to CR. Another line related to DP generation is using a wider range of empty categories (EC) (Yang and Xue, 2010; Cai et al., 2011; Xue and Yang, 2013), which aims to recover long-distance dependencies, discontinuous constituents and certain dropped elements[3] in phrase structure treebanks (Xue et al., 2005). This work mainly focus on sentence-internal characteristics as opposed to contextual information at the discourse level. More recently, Yang et al. (2015) explore DP recovery for Chinese text messages based on both lines of work.

These methods can also be used for DP translation using SMT (Chung and Gildea, 2010; Le Nagard and Koehn, 2010; Taira et al., 2012; Xiang et al., 2013). Taira et al. (2012) propose both simple rule-based and manual methods to add zero pronouns in the source side for Japanese–English translation. However, the BLEU scores of both systems are nearly identical, which indicates that only considering the source side and forcing the insertion of pronouns may be less principled than tackling the problem head on by integrating them into the SMT system itself. Le Nagard and Koehn (2010) present a method to aid English pronoun translation into French for SMT by integrating CR. Unfortunately, their results are not convincing due to the poor performance of the CR method (Pradhan et al., 2012). Chung and Gildea (2010) systematically examine the effects of EC on MT with three methods: pattern, CRF (which achieves best results) and parsing. The results show that this work can really improve the end translation even though the automatic prediction of EC is not highly accurate.

4 Experiments

4.1 Setup

For dialogue domain training data, we extract around 1M sentence pairs (movie or TV episode subtitles) from two subtitle websites.[4] We manually create both development and test data with DP annotation. Note that all sentences maintain their contextual information at the discourse level, which can be used for feature extraction in Section 2.1. The detailed statistics are listed in Table 3. As far as the DP training corpus is concerned, we annotate the Chinese side of the parallel data using the approach described in Section 2.1. There are two different language models for the DP annotation (Section 2.1) and translation tasks, respectively: one is trained on the 2.13TB Chinese Web Page Collection Corpus[5] while the other one is trained on all extracted 7M English subtitle data (Wang et al., 2016).

Corpus	Lang.	Sentents	Pronouns	Ave. Len.
Train	ZH	1,037,292	604,896	5.91
	EN	1,037,292	816,610	7.87
Dev	ZH	1,086	756	6.13
	EN	1,086	1,025	8.46
Test	ZH	1,154	762	5.81
	EN	1,154	958	8.17

Table 3: Statistics of corpora.

We carry out our experiments using the phrase-based SMT model in Moses (Koehn et al., 2007) on a Chinese–English dialogue translation task. Furthermore, we train 5-gram language models using the SRI Language Toolkit (Stolcke, 2002). To obtain a good word alignment, we run GIZA++ (Och and Ney, 2003) on the training data together with another larger parallel subtitle corpus that contains 6M sentence pairs.[6] We use minimum error rate training (Och, 2003) to optimize the feature weights.

The RNN models are implemented using the common Theano neural network toolkit (Bergstra et al., 2010). We use a pre-trained word embedding via a lookup table. We use the following settings: windows = 5, the size of the single hidden layer = 200, iterations = 10, embeddings = 200. The MLP classifier use random initialized embeddings, with the following settings: the size of the single hidden layer = 200, embeddings = 100, iterations = 200.

For end-to-end evaluation, case-insensitive BLEU (Papineni et al., 2002) is used to measure

[3] EC includes trace markers, dropped pronoun, big PRO etc, while we focus only on dropped pronoun.

DP	Set	P	R	F1
DP Detection	Dev	0.88	0.84	0.86
	Test	0.88	0.87	0.88
DP Prediction	Dev	0.67	0.63	0.65
	Test	0.67	0.65	0.66

Table 4: Evaluation of DP generation quality.

translation performance and micro-averaged F-score is used to measure DP generation quality.

4.2 Evaluation of DP Generation

We first check whether our DP annotation strategy is reasonable. To this end, we follow the strategy to automatically and manually label the source sides of the development and test data with their target sides. The agreement between automatic labels and manual labels on DP prediction are 94% and 95% on development and test data and on DP generation are 92% and 92%, respectively. This indicates that the automatic annotation strategy is relatively trustworthy.

We then measure the accuracy (in terms of words) of our generation models in two phases. "DP Detection" shows the performance of our sequence-labelling model based on RNN. We only consider the tag for each word (pro-drop or not pro-drop before the current word), without considering the exact pronoun for DPs. "DP Prediction" shows the performance of the MLP classifier in determining the exact DP based on detection. Thus we consider both the detected and predicted pronouns. Table 4 lists the results of the above DP generation approaches. The F1 score of "DP Detection" achieves 88% and 86% on the Dev and Test set, respectively. However, it has lower F1 scores of 66% and 65% for the final pronoun generation ("DP Prediction") on the development and test data, respectively. This indicates that predicting the exact DP in Chinese is a really difficult task. Even though the DP prediction is not highly accurate, we still hypothesize that the DP generation models are reliable enough to be used for end-to-end machine translation. Note that we only show the results of 1-best DP generation here, but in the translation task, we use N-best generation candidates to recall more DPs.

Systems	Dev Set	Test set
Baseline	20.06	18.76
+DP-ins. TM	20.32 (+0.26)	19.37 (+0.61)
+DP-gen. Input		
1-best	20.49 (+0.43)	19.50 (+0.74)
2-best	20.15 (+0.09)	18.89 (+0.13)
4-best	20.64 (+0.58)	19.68 (+0.92)
6-best	21.61 (+1.55)	20.34 (+1.58)
8-best	20.94 (+0.88)	19.83 (+1.07)
Manual Oracle	24.27 (+4.21)	22.98 (+4.22)
Auto Oracle	23.10 (+3.04)	21.93 (+3.17)

Table 5: Evaluation of DP translation quality.

4.3 Evaluation of DP Translation

In this section, we evaluate the end-to-end translation quality by integrating the DP generation results (Section 3.3). Table 5 summaries the results of translation performance with different sources of DP information. "Baseline" uses the original input to feed the SMT system. "+DP-ins. TM" denotes using an additional translation model trained on the DP-inserted training corpus, while "+DP-gen. Input N" denotes further completing the input sentences with the N-best pronouns generated from the DP generation model. "Oracle" uses the input with manual ("Manual") or automatic ("Auto") insertion of DPs by considering the target set. Taking "Auto Oracle" for example, we annotate the DPs via alignment information (supposing the reference is available) using the technique described in Section 2.1.

The baseline system uses the parallel corpus and input sentences without inserting/generating DPs. It achieves 20.06 and 18.76 in BLEU score on the development and test data, respectively. The BLEU scores are relatively low because 1) we have only one reference, and 2) dialogue machine translation is still a challenge for the current SMT approaches.

By using an additional translation model trained on the DP-inserted parallel corpus as described in Section 2.1, we improve the performance consistently on both development (+0.26) and test data (+0.61). This indicates that the inserted DPs are helpful for SMT. Thus, the gain in the "+DP-ins TM" is mainly from the improved alignment quality.

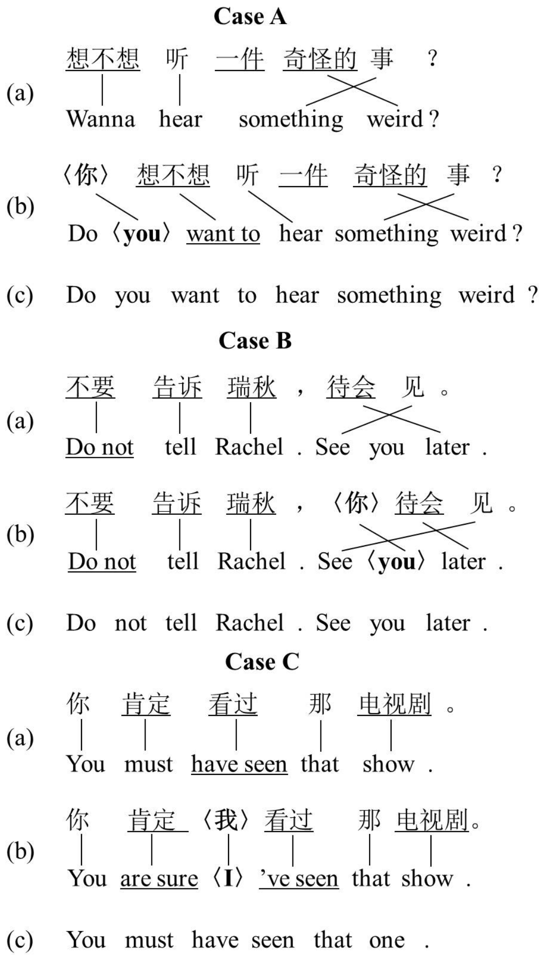
We can further improve translation performance by completing the input sentences with our DP generation model as described in Section 2.2. We test N-best DP insertion to examine the performance, where N $=\{1, 2, 4, 6, 8\}$. Working together with “DP-ins. TM”, 1-best generated input already achieves +0.43 and + 0.74 BLEU score improvements on development and test set, respectively. The consistency between the input sentences and the DP-inserted parallel corpus contributes most to these further improvements. As N increases, the BLEU score grows, peaking at 21.61 and 20.34 BLEU points when N=6. Thus we achieve a final improvement of 1.55 and 1.58 BLEU points on the development and test data, respectively. However, when adding more DP candidates, the BLEU score decreases by 0.97 and 0.51. The reason for this may be that more DP candidates add more noise, which harms the translation quality.

The oracle system uses the input sentences with manually annotated DPs rather than “DP-gen. Input”. The performance gap between “Oracle” and “+DP-gen. Input” shows that there is still a large space (+4.22 or +3.17) for further improvement for the DP generation model.

5 Case Study

We select sample sentences from the test set to further analyse the effects of DP generation on translation.

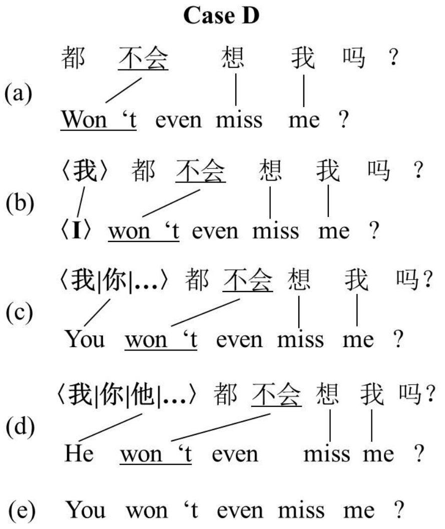
In Figure 4, we show an improved case (Case A), an unchanged case (Case B), and a worse case (Case C) of translation no-/using DP insertion (i.e. “+DP-gen. Input 1-best”). In each case, we give (a) the original Chinese sentence and its translation, (b) the DP-inserted Chinese sentence and its translation, and (c) the reference English sentence. In Case A, “*Do you*” in the translation output is compensated by adding DP 〈你〉 (you) in (b), which gives a better translation than in (a). In contrast, in case C, our DP generator regards the simple sentence as a compound sentence and insert a wrong pronoun 〈我〉 (I) in (b), which causes an incorrect translation output (worse than (a)). This indicates that we need a highly accurate parse tree of the source sentences for more correct completion of the antecedent of the DPs. In Case B, the translation results are the same in (a) and (b). This kind of unchanged case always occurs in “fixed” linguistic chunks such as preposition phrases (“on *my* way”), greetings (“see *you* later” , “thank *you*”) and interjections (“*My* God”). However, the alignment of (b) is better than that of (a) in this case.



Case A
(a) 想不想 听 一件 奇怪的 事 ？
Wanna hear something weird ?
(b) 〈你〉 想不想 听 一件 奇怪的 事 ？
Do 〈you〉 want to hear something weird ?
(c) Do you want to hear something weird ?
Case B
(a) 不要 告诉 瑞秋 ， 待会 见 。
Do not tell Rachel . See you later .
(b) 不要 告诉 瑞秋 ， 〈你〉 待会 见 。
Do not tell Rachel . See 〈you〉 later .
(c) Do not tell Rachel . See you later .
Case C
(a) 你 肯定 看过 那 电视剧 。
You must have seen that show .
(b) 你 肯定 〈我〉 看过 那 电视剧。
You are sure 〈I〉 ’ve seen that show .
(c) You must have seen that one .

Figure 4: Effects of DP generation for translation.

Figure 5 shows an example of “+DP-gen. Input N-best” translation. Here, (a) is the original Chinese sentence and its translation; (b) is the 1-best DP-generated Chinese sentence and its MT output; (c) stands for 2-best, 4-best and 6-best DP-generated Chinese sentences and their MT outputs (which are all the same); (d) is the 8-best DP-generated Chinese sentence and its MT output; (e) is the reference. The N-best DP candidate list is 〈我〉 (I), 〈你〉 (You), 〈他〉 (He), 〈我们〉 (We), 〈他们〉 (They), 〈你们〉 (You), 〈它〉 (It) and 〈她〉 (She). In (b), when integrating an incorrect 1-best DP into MT, we obtain the wrong translation. However, in (c), when considering more DPs (2-/4-/6-best), the SMT system generates a perfect translation by weighting the DP candidates during decoding. When further increasing N (8-best), (d) shows a wrong translation again due to increased noise.



Case D
(a)
都 不会 想 我 吗 ?
Won ‘t even miss me ?
(b)
〈我〉 都 不会 想 我 吗 ?
〈I〉 won ‘t even miss me ?
(c)
〈我|你|...〉 都 不会 想 我 吗?
You won ‘t even miss me ?
(d)
〈我|你|他|...〉 都 不会 想 我 吗?
He won ‘t even miss me ?
(e)
You won ‘t even miss me ?

Figure 5: Effects of N-best DP generation for translation.

6 Conclusion and Future Work

We have presented a novel approach to recall missing pronouns for machine translation from a pro-drop language to a non-pro-drop language. Experiments show that it is crucial to identify the DP to improve the overall translation performance. Our analysis shows that insertion of DPs affects the translation in a large extent.

Our main findings in this paper are threefold:

- Bilingual information can help to build monolingual models without any manually annotated training data;
- Benefiting from representation learning, neural network-based models work well without complex feature engineering work;
- N-best DP integration works better than 1-best insertion.

In future work, we plan to extend our work to different genres, languages and other kinds of dropped words to validate the robustness of our approach.

Learning Global Features for Coreference Resolution

Abstract

There is compelling evidence that coreference prediction would benefit from modeling global information about entity-clusters. Yet, state-of-the-art performance can be achieved with systems treating each mention prediction independently, which we attribute to the inherent difficulty of crafting informative cluster-level features. We instead propose to use recurrent neural networks (RNNs) to learn latent, global representations of entity clusters directly from their mentions. We show that such representations are especially useful for the prediction of pronominal mentions, and can be incorporated into an end-to-end coreference system that outperforms the state of the art without requiring any additional search.

1 Introduction

While structured, non-local coreference models would seem to hold promise for avoiding many common coreference errors (as discussed further in Section 3), the results of employing such models in practice are decidedly mixed, and state-of-the-art results can be obtained using a completely local, mention-ranking system.

In this work, we posit that global context is indeed necessary for further improvements in coreference resolution, but argue that informative *cluster*, rather than mention, level features are very difficult to devise, limiting their effectiveness. Accordingly, we instead propose to learn representations of mention clusters by embedding them sequentially using a recurrent neural network (shown in Section 4). Our model has no manually defined cluster features, but instead learns a global representation from the individual mentions present in each cluster. We incorporate these representations into a mention-ranking style coreference system.

The entire model, including the recurrent neural network and the mention-ranking sub-system, is trained end-to-end on the coreference task. We train the model as a local classifier with fixed context (that is, as a history-based model). As such, unlike several recent approaches, which may require complicated inference during training, we are able to train our model in much the same way as a vanilla mention-ranking model.

Experiments compare the use of learned global features to several strong baseline systems for coreference resolution. We demonstrate that the learned global representations capture important underlying information that can help resolve difficult pronominal mentions, which remain a persistent source of errors for modern coreference systems (Durrett and Klein, 2013; Kummerfeld and Klein, 2013; Wiseman et al., 2015; Martschat and Strube, 2015). Our final system improves over 0.8 points in CoNLL score over the current state of the art, and the improvement is statistically significant on all three CoNLL metrics.

2 Background and Notation

Coreference resolution is fundamentally a clustering task. Given a sequence $(x_n)_{n=1}^{N}$ of (intra-document) mentions – that is, syntactic units that can refer or be referred to – coreference resolution involves partitioning (x_n) into a sequence of clusters $(X^{(m)})_{m=1}^{M}$ such that all the mentions in any particular cluster

Proceedings of NAACL-HLT 2016, pages 994–1004,
San Diego, California, June 12-17, 2016.

$X^{(m)}$ refer to the same underlying entity. Since the mentions within a particular cluster may be ordered linearly by their appearance in the document,[1] we will use the notation $X_j^{(m)}$ to refer to the j'th mention in the m'th cluster.

A valid clustering places each mention in exactly one cluster, and so we may represent a clustering with a vector $\boldsymbol{z} \in \{1, \dots, M\}^N$, where $z_n = m$ iff x_n is a member of $X^{(m)}$. Coreference systems attempt to find the best clustering $\boldsymbol{z}^* \in \mathcal{Z}$ under some scoring function, with $\mathcal{Z}$ the set of valid clusterings.

One strategy to avoid the computational intractability associated with predicting an entire clustering $\boldsymbol{z}$ is to instead predict a single *antecedent* for each mention x_n; because x_n may not be anaphoric (and therefore have no antecedents), a "dummy" antecedent ϵ may also be predicted. The aforementioned strategy is adopted by "mention-ranking" systems (Denis and Baldridge, 2008; Rahman and Ng, 2009; Durrett and Klein, 2013), which, formally, predict an antecedent $\hat{y} \in \mathcal{Y}(x_n)$ for each mention x_n, where $\mathcal{Y}(x_n) = \{1, \dots, n-1, \epsilon\}$. Through transitivity, these decisions induce a clustering over the document.

Mention-ranking systems make their antecedent predictions with a *local* scoring function $f(x_n, y)$ defined for any mention x_n and any antecedent $y \in \mathcal{Y}(x_n)$. While such a scoring function clearly ignores much structural information, the mention-ranking approach has been attractive for at least two reasons. First, inference is relatively simple and efficient, requiring only a left-to-right pass through a document's mentions during which a mention's antecedents (as well as ϵ) are scored and the highest scoring antecedent is predicted. Second, from a linguistic modeling perspective, mention-ranking models learn a scoring function that requires a mention x_n to be compatible with only *one* of its coreferent antecedents. This contrasts with mention-pair models (e.g., Bengtson and Roth (2008)), which score all pairs of mentions in a cluster, as well as with certain cluster-based models (see discussion in Culotta et al. (2007)). Modeling each mention as having a single antecedent is particularly advantageous for pronominal mentions, which we might like to model as linking to a single nominal or proper antecedent, for example, but not necessarily to all other coreferent mentions.

Accordingly, in this paper we attempt to maintain the inferential simplicity and modeling benefits of mention ranking, while allowing the model to utilize global, structural information relating to $\boldsymbol{z}$ in making its predictions. We therefore investigate objective functions of the form

$$\underset{y_1,\dots,y_N}{\arg\max} \sum_{n=1}^{N} f(x_n, y_n) + g(x_n, y_n, \boldsymbol{z}_{1:n-1}) \qquad ,$$

where g is a global function that, in making predictions for x_n, may examine (features of) the clustering $\boldsymbol{z}_{1:n-1}$ induced by the antecedent predictions made through y_{n-1}.

3 The Role of Global Features

Here we motivate the use of global features for coreference resolution by focusing on the issues that may arise when resolving pronominal mentions in a purely local way. See Clark and Manning (2015) and Stoyanov and Eisner (2012) for more general motivation for using global models.

3.1 Pronoun Problems

Recent empirical work has shown that the resolution of pronominal mentions accounts for a substantial percentage of the total errors made by modern mention-ranking systems. Wiseman et al. (2015) show that on the CoNLL 2012 English development set, almost 59% of mention-ranking precision errors and almost 24% of recall errors involve pronominal mentions. Martschat and Strube (2015) found a similar pattern in their comparison of mention-ranking, mention-pair, and latent-tree models.

To see why pronouns can be so problematic, consider the following passage from the "Broadcast Conversation" portion of the CoNLL development set (bc/msnbc/0000/018); below, we enclose mentions in brackets and give the same subscript to coclustered mentions. (This example is also shown in Figure 2.)

> **DA:** um and [I]$_1$ think that is what's - Go ahead [Linda]$_2$.
>
> **LW:** Well and uh thanks goes to [you]$_1$ and to [the media]$_3$ to help [us]$_4$...So [our]$_4$ hat is off to all of [you]$_5$ as well.

[1] We assume nested mentions are ordered by their syntactic heads.

This example is typical of Broadcast Conversation, and it is difficult because local systems learn to myopically link pronouns such as [you]$_5$ to other instances of the same pronoun that are close by, such as [you]$_1$. While this is often a reasonable strategy, in this case predicting [you]$_1$ to be an antecedent of [you]$_5$ would result in the prediction of an incoherent cluster, since [you]$_1$ is coreferent with the singular [I]$_1$, and [you]$_5$, as part of the phrase "all of you," is evidently plural. Thus, while there is enough information in the text to correctly predict [you]$_5$, doing so crucially depends on having access to the *history* of predictions made so far, and it is precisely this access to history that local models lack.

More empirically, there are non-local statistical regularities involving pronouns we might hope models could exploit. For instance, in the CoNLL training data over 70% of pleonastic "it" instances and over 74% of pleonastic "you" instances follow (respectively) previous pleonastic "it" and "you" instances. Similarly, over 78% of referential "I" instances and over 68% of referential "he" instances corefer with previous "I" and "he" instances, respectively.

Accordingly, we might expect non-local models with access to global features to perform significantly better. However, models incorporating nonlocal features have a rather mixed track record. For instance, Björkelund and Kuhn (2014) found that cluster-level features improved their results, whereas Martschat and Strube (2015) found that they did not. Clark and Manning (2015) found that incorporating cluster-level features *beyond* those involving the precomputed mention-pair and mention-ranking probabilities that form the basis of their agglomerative clustering coreference system did not improve performance. Furthermore, among recent, state-of-the-art systems, mention-ranking systems (which are completely local) perform at least as well as their more structured counterparts (Durrett and Klein, 2014; Clark and Manning, 2015; Wiseman et al., 2015; Peng et al., 2015).

3.2 Issues with Global Features

We believe a major reason for the relative ineffectiveness of global features in coreference problems is that, as noted by Clark and Manning (2015), cluster-level features can be hard to define. Specifically, it is difficult to define discrete, fixed-length features on clusters, which can be of variable size (or shape). As a result, global coreference features tend to be either too coarse or too sparse. Thus, early attempts at defining cluster-level features simply applied the coarse quantifier predicates *all*, *none*, *most* to the mention-level features defined on the mentions (or pairs of mentions) in a cluster (Culotta et al., 2007; Rahman and Ng, 2011). For example, a cluster would have the feature 'most-female=true' if more than half the mentions (or pairs of mentions) in the cluster have a 'female=true' feature.

On the other extreme, Björkelund and Kuhn (2014) define certain cluster-level features by concatenating the mention-level features of a cluster's constituent mentions in order of the mentions' appearance in the document. For example, if a cluster consists, in order, of the mentions (*the president*, *he*, *he*), they would define a cluster-level "type" feature 'C-P-P=true', which indicates that the cluster is composed, in order, of a common noun, a pronoun, and a pronoun. While very expressive, these concatenated features are often quite sparse, since clusters encountered during training can be of any size.

4 Learning Global Features

To circumvent the aforementioned issues with defining global features, we propose to learn cluster-level feature representations implicitly, by identifying the state of a (partial) cluster with the hidden state of an RNN that has consumed the sequence of mentions composing the (partial) cluster. Before providing technical details, we provide some preliminary evidence that such learned representations capture important contextual information by displaying in Figure 1 the learned final states of all clusters in the CoNLL development set, projected using T-SNE (van der Maaten and Hinton, 2012). Each point in the visualization represents the learned features for an entity cluster and the head words of mentions are shown for representative points. Note that the model learns to roughly separate clusters by simple distinctions such as predominant type (nominal, proper, pronominal) and number (it, they, etc), but also captures more subtle relationships such as grouping geographic terms and long strings of pronouns.

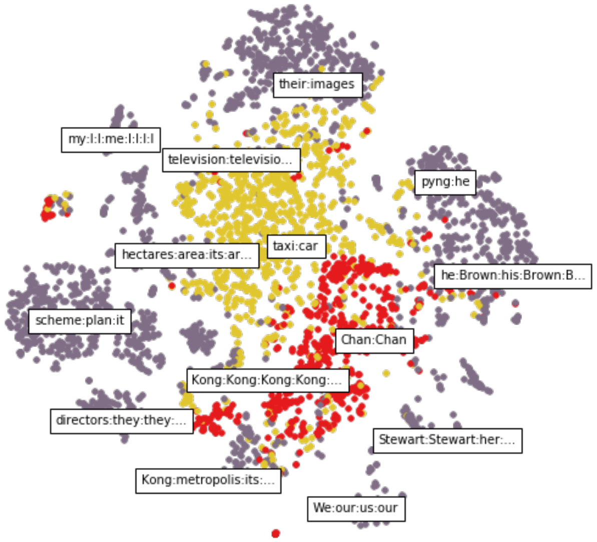

Figure 1: T-SNE visualization of learned entity representations on the CoNLL development set. Each point shows a gold cluster of size > 1. Yellow, red, and purple points represent predominantly common noun, proper noun, and pronoun clusters, respectively. Captions show head words of representative clusters' mentions.

4.1 Recurrent Neural Networks

A recurrent neural network is a parameterized non-linear function **RNN** that recursively maps an input sequence of vectors to a sequence of hidden states. Let $(\boldsymbol{m}_j)_{j=1}^{J}$ be a sequence of J input vectors $\boldsymbol{m}_j \in \mathbb{R}^D$, and let $\boldsymbol{h}_0 = \boldsymbol{0}$. Applying an RNN to any such sequence yields

$$\boldsymbol{h}_j \leftarrow \mathbf{RNN}(\boldsymbol{m}_j, \boldsymbol{h}_{j-1}; \boldsymbol{\theta}) \qquad ,$$

where $\boldsymbol{\theta}$ is the set of parameters for the model, which are shared over time.

There are several varieties of RNN, but by far the most commonly used in natural-language processing is the Long Short-Term Memory network (LSTM) (Hochreiter and Schmidhuber, 1997), particularly for language modeling (e.g., Zaremba et al. (2014)) and machine translation (e.g., Sutskever et al. (2014)), and we use LSTMs in all experiments.

4.2 RNNs for Cluster Features

Our main contribution will be to utilize RNNs to produce feature representations of entity clusters which will provide the basis of the global term g. Recall that we view a cluster $X^{(m)}$ as a sequence of mentions $(X_j^{(m)})_{j=1}^{J}$ (ordered in linear document order). We therefore propose to embed the state(s) of $X^{(m)}$ by running an RNN over the cluster in order.

In order to run an RNN over the mentions we need an embedding function $\boldsymbol{h}_{\mathrm{c}}$ to map a mention to a real vector. First, following Wiseman et al. (2015) define $\boldsymbol{\phi}_{\mathrm{a}}(x_n) : \mathcal{X} \rightarrow \{0,1\}^F$ as a standard set of local indicator features on a mention, such as its head word, its gender, and so on. (We elaborate on features below.) We then use a non-linear feature embedding $\boldsymbol{h}_{\mathrm{c}}$ to map a mention x_n to a vector-space representation. In particular, we define

$$\boldsymbol{h}_{\mathrm{c}}(x_n) \triangleq \tanh(\boldsymbol{W}_{\mathrm{c}}\, \boldsymbol{\phi}_{\mathrm{a}}(x_n) + \boldsymbol{b}_{\mathrm{c}}) \qquad ,$$

where $\boldsymbol{W}_{\mathrm{c}}$ and $\boldsymbol{b}_{\mathrm{c}}$ are parameters of the embedding.

We will refer to the j'th hidden state of the RNN corresponding to $X^{(m)}$ as $\boldsymbol{h}_j^{(m)}$, and we obtain it according to the following formula

$$\boldsymbol{h}_j^{(m)} \leftarrow \mathbf{RNN}(\boldsymbol{h}_{\mathrm{c}}(X_j^{(m)}), \boldsymbol{h}_{j-1}^{(m)}; \boldsymbol{\theta}) \qquad ,$$

again assuming that $\boldsymbol{h}_0^{(m)} = \boldsymbol{0}$. Thus, we will effectively run an RNN over each (sequence of mentions corresponding to a) cluster $X^{(m)}$ in the document, and thereby generate a hidden state $\boldsymbol{h}_j^{(m)}$ corresponding to each step of each cluster in the document. Concretely, this can be implemented by maintaining M RNNs – one for each cluster – that all share the parameters $\boldsymbol{\theta}$. The process is illustrated in the top portion of Figure 2.

5 Coreference with Global Features

We now describe how the RNN defined above is used within an end-to-end coreference system.

5.1 Full Model and Training

Recall that our inference objective is to maximize the score of both a local mention ranking term as well as a global term based on the current clusters:

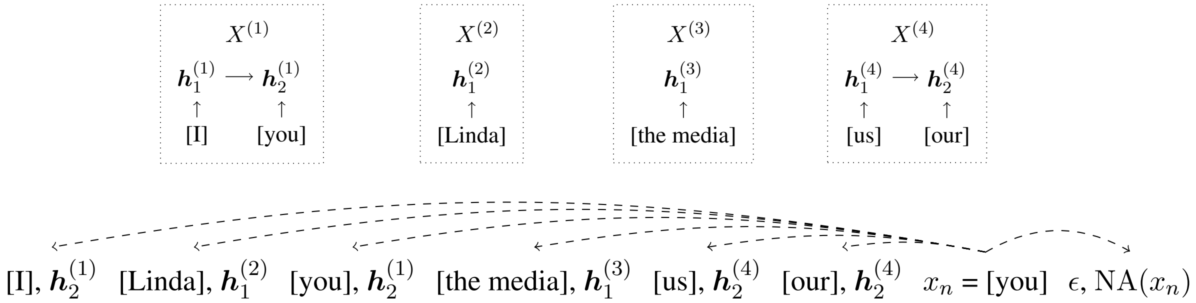
$$\operatorname*{arg\,max}_{y_1,\ldots,y_N} \sum_{n=1}^{N} f(x_n, y_n) + g(x_n, y_n, \boldsymbol{z}_{1:n-1})$$

We begin by defining the local model $f(x_n, y)$ with the two layer neural network of Wiseman et al. (2015), which has a specialization for the non-anaphoric case, as follows:

$$f(x_n, y) \triangleq \begin{cases} \boldsymbol{u}^{\mathsf{T}} \begin{bmatrix} \boldsymbol{h}_{\mathrm{a}}(x_n) \\ \boldsymbol{h}_{\mathrm{p}}(x_n, y) \end{bmatrix} + u_0 & \text{if } y \neq \epsilon \\ \boldsymbol{v}^{\mathsf{T}} \boldsymbol{h}_{\mathrm{a}}(x_n) + v_0 & \text{if } y = \epsilon \end{cases} \qquad .$$

DA: um and [I]$_1$ think that is what's - Go ahead [Linda]$_2$.

LW: Well and thanks goes to [you]$_1$ and to [the media]$_3$ to help [us]$_4$...So [our]$_4$ hat is off to all of [you]$_5$...



$X^{(1)}$
$\boldsymbol{h}_1^{(1)} \longrightarrow \boldsymbol{h}_2^{(1)}$
[I]
[you]
$X^{(2)}$
$\boldsymbol{h}_1^{(2)}$
[Linda]
$X^{(3)}$
$\boldsymbol{h}_1^{(3)}$
[the media]
$X^{(4)}$
$\boldsymbol{h}_1^{(4)} \longrightarrow \boldsymbol{h}_2^{(4)}$
[us]
[our]
[I], $\boldsymbol{h}_2^{(1)}$
[Linda], $\boldsymbol{h}_1^{(2)}$
[you], $\boldsymbol{h}_2^{(1)}$
[the media], $\boldsymbol{h}_1^{(3)}$
[us], $\boldsymbol{h}_2^{(4)}$
[our], $\boldsymbol{h}_2^{(4)}$
x_n = [you]
$\epsilon, \mathrm{NA}(x_n)$

Figure 2: Full RNN example for handling the mention x_n = [you]. There are currently four entity clusters in scope $X^{(1)}, X^{(2)}, X^{(3)}, X^{(4)}$ based on unseen previous decisions (y). Each cluster has a corresponding RNN state, two of which ($\boldsymbol{h}^{(1)}$ and $\boldsymbol{h}^{(4)}$) have processed multiple mentions (with $X^{(1)}$ notably including a singular mention [I]). At the bottom, we show the complete mention-ranking process. Each previous mention is considered as an antecedent, and the global term considers the antecedent clusters' current hidden state. Selecting ϵ is treated with a special case $\mathrm{NA}(x_n)$.

Above, $\boldsymbol{u}$ and $\boldsymbol{v}$ are the parameters of the model, and $\boldsymbol{h}_{\mathrm{a}}$ and $\boldsymbol{h}_{\mathrm{p}}$ are learned feature embeddings of the local mention context and the pairwise affinity between a mention and an antecedent, respectively. These feature embeddings are defined similarly to $\boldsymbol{h}_{\mathrm{c}}$, as

$$\begin{aligned}\boldsymbol{h}_{\mathrm{a}}(x_n) &\triangleq \tanh(\boldsymbol{W}_{\mathrm{a}}\, \boldsymbol{\phi}_{\mathrm{a}}(x_n) + \boldsymbol{b}_{\mathrm{a}})\\ \boldsymbol{h}_{\mathrm{p}}(x_n, y) &\triangleq \tanh(\boldsymbol{W}_{\mathrm{p}}\, \boldsymbol{\phi}_{\mathrm{p}}(x_n, y) + \boldsymbol{b}_{\mathrm{p}})\end{aligned} \quad ,$$

where $\boldsymbol{\phi}_{\mathrm{a}}$ (mentioned above) and $\boldsymbol{\phi}_{\mathrm{p}}$ are "raw" (that is, unconjoined) features on the context of x_n and on the pairwise affinity between mentions x_n and antecedent y, respectively (Wiseman et al., 2015). Note that $\boldsymbol{h}_{\mathrm{a}}$ and $\boldsymbol{h}_{\mathrm{c}}$ use the same raw features; only their weights differ.

We now specify our global scoring function g based on the history of previous decisions. Define $\boldsymbol{h}_{<n}^{(m)}$ as the hidden state of cluster m before a decision is made for x_n – that is, $\boldsymbol{h}_{<n}^{(m)}$ is the state of cluster m's RNN after it has consumed all mentions in the cluster *preceding* x_n. We define g as

$$g(x_n, y, \boldsymbol{z}_{1:n-1}) \;\triangleq\; \begin{cases}\boldsymbol{h}_{\mathrm{c}}(x_n)^{\mathsf{T}} \boldsymbol{h}_{<n}^{(z_y)} & \text{if } y \neq \epsilon\\ \mathrm{NA}(x_n) & \text{if } y = \epsilon\end{cases} \quad ,$$

where NA gives a score for assigning ϵ based on a non-linear function of all of the current hidden states:

$$\mathrm{NA}(x_n) = \boldsymbol{q}^{\mathsf{T}} \tanh\left(\boldsymbol{W}_s \begin{bmatrix}\boldsymbol{\phi}_{\mathrm{a}}(x_n)\\ \sum_{m=1}^{M} \boldsymbol{h}_{<n}^{(m)}\end{bmatrix} + \boldsymbol{b}_s\right).$$

See Figure 2 for a diagram. The intuition behind the first case in g is that in considering whether y is a good antecedent for x_n, we add a term to the score that examines how well x_n matches with the mentions already in $X^{(z_y)}$; this matching score is expressed via a dot-product.[2] In the second case, when predicting that x_n is non-anaphoric, we add the NA term to the score, which examines the (sum of) the current states $\boldsymbol{h}_{<n}^{(m)}$ of all clusters. This information is useful both because it allows the non-anaphoric score to incorporate information about potential antecedents, and because the occurrence of certain singleton-clusters often predicts the occurrence of future singleton-clusters, as noted in Section 3.

The whole system is trained end-to-end on coreference using backpropagation. For a given training document, let $\boldsymbol{z}^{(o)}$ be the oracle mapping from mention to cluster, which induces an oracle clustering. While at training time we do have oracle clusters, we do not have oracle antecedents $(y)_{n=1}^{N}$, so following past work we treat the oracle antecedent as latent (Yu and Joachims, 2009; Fernandes et al., 2012; Chang et al., 2013; Durrett and Klein, 2013). We train with the following slack-rescaled, margin objective:

[2] We also experimented with other non-linear functions, but dot-products performed best.

$$\sum_{n=1}^{N} \max_{\hat{y}\in\mathcal{Y}(x_n)} \Delta(x_n,\hat{y})(1+f(x_n,\hat{y})+g(x_n,\hat{y},\boldsymbol{z}^{(o)}) - f(x_n,y_n^{\ell}) - g(x_n,y_n^{\ell},\boldsymbol{z}^{(o)})),$$

where the latent antecedent y_n^{ℓ} is defined as

$$y_n^{\ell} \triangleq \operatorname*{arg\,max}_{y\in\mathcal{Y}(x_n):z_y^{(o)}=z_n^{(o)}} f(x_n,y)+g(x_n,y,\boldsymbol{z}^{(o)})$$

if x_n is anaphoric, and is ϵ otherwise. The term $\Delta(x_n,\hat{y})$ gives different weight to different error types. We use a Δ with 3 different weights $(\alpha_1,\alpha_2,\alpha_3)$ for "false link" (FL), "false new" (FN), and "wrong link" (WL) mistakes (Durrett and Klein, 2013), which correspond to predicting an antecedent when non-anaphoric, ϵ when anaphoric, and the wrong antecedent, respectively.

Note that in training we use the oracle clusters $\boldsymbol{z}^{(o)}$. Since these are known a priori, we can precompute all the hidden states $\boldsymbol{h}_j^{(m)}$ in a document, which makes training quite simple and efficient. This approach contrasts in particular with the work of Björkelund and Kuhn (2014) — who also incorporate global information in mention-ranking — in that they train against latent *trees*, which are not annotated and must be searched for during training. On the other hand, training on oracle clusters leads to a mismatch between training and test, which can hurt performance.

5.2 Search

When moving from a strictly local objective to one with global features, the test-time search problem becomes intractable. The local objective requires $O(n^2)$ time, whereas the full clustering problem is NP-Hard. Past work with global features has used integer linear programming solvers for exact search (Chang et al., 2013; Peng et al., 2015), or beam search with (delayed) early update training for an approximate solution (Björkelund and Kuhn, 2014). In contrast, we simply use greedy search at test time, which also requires $O(n^2)$ time.[3] The full algorithm is shown in Algorithm 1. The greedy search algorithm is identical to a simple mention-ranking system, with the exception of line 11, which updates the current RNN representation based on the previous decision that was made, and line 4, which then uses this cluster representation as part of scoring.

Algorithm 1 Greedy search with global RNNs

```
 1: procedure GreedyCluster($x_1,\ldots,x_N$)
 2:     Initialize clusters $X^{(1)}\ldots$ as empty lists, hidden states
        $\boldsymbol{h}^{(0)},\ldots$ as $\mathbf{0}$ vectors in $\mathbb{R}^D$, $\boldsymbol{z}$ as map from mention to
        cluster, and cluster counter $M \leftarrow 0$
 3:     for $n = 2\ldots N$ do
 4:         $y^* \leftarrow \operatorname{arg\,max}_{y\in\mathcal{Y}(x_n)} f(x_n,y)+g(x_n,y,\boldsymbol{z}_{1:n-1})$
 5:         $m \leftarrow z_{y^*}$
 6:         if $y^* = \epsilon$ then
 7:             $M \leftarrow M + 1$
 8:             $m \leftarrow M$
 9:         append $x_n$ to $X^{(m)}$
10:         $z_n \leftarrow m$
11:         $\boldsymbol{h}^{(m)} \leftarrow \mathbf{RNN}(\boldsymbol{h}_{\mathrm{c}}(x_n),\boldsymbol{h}^{(m)})$
12:     return $X^{(1)},\ldots,X^{(M)}$
```

6 Experiments

6.1 Methods

We run experiments on the CoNLL 2012 English shared task (Pradhan et al., 2012). The task uses the OntoNotes corpus (Hovy et al., 2006), consisting of 3,493 documents in various domains and formats. We use the experimental split provided in the shared task. For all experiments, we use the Berkeley Coreference System (Durrett and Klein, 2013) for mention extraction and to compute features $\boldsymbol{\phi}_{\mathrm{a}}$ and $\boldsymbol{\phi}_{\mathrm{p}}$.

Features We use the raw BASIC+ feature sets described by Wiseman et al. (2015), with the following modifications:

- We remove all features from $\boldsymbol{\phi}_{\mathrm{p}}$ that concatenate a feature of the antecedent with a feature of the current mention, such as bi-head features.

- We add true-cased head features, a current speaker indicator feature, and a 2-character

[3] While beam search is a natural way to decrease search error at test time, it may fail to help if training involves a *local* margin objective (as in our case), since scores need not be calibrated across local decisions. We accordingly attempted to train various locally normalized versions of our model, but found that they underperformed. We also experimented with training approaches and model variants that expose the model to its own predictions (Daumé III et al., 2009; Ross et al., 2011; Bengio et al., 2015), but found that these yielded a negligible performance improvement.

Table 1: Results on CoNLL 2012 English test set. We compare against recent state of the art systems, including (in order) Bjorkelund and Kuhn (2014), Martschat and Strube (2015), Clark and Manning (2015), Peng et al. (2015), and Wiseman et al. (2015). F$_1$ gains are significant ($p < 0.05$ under the bootstrap resample test (Koehn, 2004)) compared with Wiseman et al. (2015) for all metrics.

genre (out of {bc,bn,mz,nw,pt,tc,wb}) indicator to $\boldsymbol{\phi}_{\text{p}}$ and $\boldsymbol{\phi}_{\text{a}}$.

- We add features indicating if a mention has a substring overlap with the current speaker ($\boldsymbol{\phi}_{\text{p}}$ and $\boldsymbol{\phi}_{\text{a}}$), and if an antecedent has a substring overlap with a speaker distinct from the current mention's speaker ($\boldsymbol{\phi}_{\text{p}}$).

- We add a single centered, rescaled document position feature to each mention when learning $\boldsymbol{h}_{\text{c}}$. We calculate a mention x_n's rescaled document position as $\frac{2n-N-1}{N-1}$.

These modifications result in there being approximately 14K distinct features in $\boldsymbol{\phi}_{\text{a}}$ and approximately 28K distinct features in $\boldsymbol{\phi}_{\text{p}}$, which is far fewer features than has been typical in past work.

For training, we use document-size minibatches, which allows for efficient pre-computation of RNN states, and we minimize the loss described in Section 5 with AdaGrad (Duchi et al., 2011) (after clipping LSTM gradients to lie (elementwise) in $(-10, 10)$). We find that the initial learning rate chosen for AdaGrad has a significant impact on results, and we choose learning rates for each layer out of $\{0.1, 0.02, 0.01, 0.002, 0.001\}$.

In experiments, we set $\boldsymbol{h}_{\text{a}}(x_n)$, $\boldsymbol{h}_{\text{c}}(x_n)$, and $\boldsymbol{h}^{(m)}$ to be $\in \mathbb{R}^{200}$, and $\boldsymbol{h}_{\text{p}}(x_n, y) \in \mathbb{R}^{700}$. We use a single-layer LSTM (without "peep-hole" connections), as implemented in the `element-rnn` library (Léonard et al., 2015). For regularization, we apply Dropout (Srivastava et al., 2014) with a rate of 0.4 before applying the linear weights $\boldsymbol{u}$, and we also apply Dropout with a rate of 0.3 to the LSTM states before forming the dot-product scores.

RNN, OH	74.26	63.89	59.54	65.90

Table 2: F$_1$ scores of models described in text on CoNLL 2012 development set. Rows in grey highlight models using oracle history.

Following Wiseman et al. (2015) we use the cost-weights $\boldsymbol{\alpha} = \langle 0.5, 1.2, 1 \rangle$ in defining Δ, and we use their pre-training scheme as well. For final results, we train on both training and development portions of the CoNLL data. Scoring uses the official CoNLL 2012 script (Pradhan et al., 2014; Luo et al., 2014). Code for our system is available at `https://github.com/swiseman/nn_coref`. The system makes use of a GPU for training, and trains in about two hours.

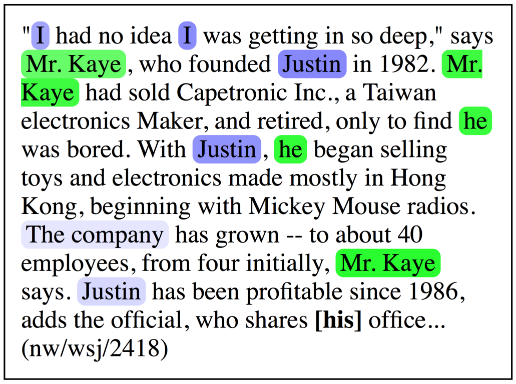
6.2 Results

In Table 1 we present our main results on the CoNLL English test set, and compare with other recent state-of-the-art systems. We see a statistically significant improvement of over 0.8 CoNLL points over the previous state of the art, and the highest F$_1$ scores to date on all three CoNLL metrics.

We now consider in more detail the impact of global features and RNNs on performance. For these experiments, we report MUC, B^3, and CEAF$_e$ F$_1$-scores in Table 2 as well as errors broken down by mention type and by whether the mention is anaphoric or not in Table 3. Table 3 further partitions errors into FL, FN, and WL categories, which

	Non-Anaphoric (FL)		
	Nom. HM	Nom. No HM	Pron.
MR	1061	130	1075
Avg, OH	983	140	1011
RNN, GH	914	125	893
RNN, OH	913	130	842
# Mentions	9.0K	22.2K	3.1K
	Anaphoric (FN + WL)		
Model	Nom. HM	Nom. No HM	Pron.
MR	665+326	666+56	533+796
Avg, OH	781+300	641+60	578+744
RNN, GH	767+303	648+57	664+727
RNN, OH	750+289	648+52	611+686
# Mentions	4.7K	1.0K	7.3K

Table 3: Number of "false link" (FL) errors on non-anaphoric mentions (top) and number of "false new" (FN) and "wrong link" (WL) errors on anaphoric mentions (bottom) on CoNLL 2012 development set. Mentions are categorized as nominal or proper with (previous) head match (Nom. HM), nominal or proper with no head match (Nom. No HM), and pronominal. Models are described in the text, and rows in grey highlight models using oracle history.



"I had no idea I was getting in so deep," says Mr. Kaye, who founded Justin in 1982. Mr. Kaye had sold Capetronic Inc., a Taiwan electronics Maker, and retired, only to find he was bored. With Justin, he began selling toys and electronics made mostly in Hong Kong, beginning with Mickey Mouse radios. The company has grown -- to about 40 employees, from four initially, Mr. Kaye says. Justin has been profitable since 1986, adds the official, who shares **[his]** office... (nw/wsj/2418)

Figure 3: Cluster predictions of greedy RNN model; co-clustered mentions are of the same color, and intensity of mention x_j corresponds to $\boldsymbol{h}_c(x_n)^\top \boldsymbol{h}^{(i)}_{<k}$, where $k = j+1$, $i \in \{1, 2\}$, and x_n = "his." See text for full description.

are defined in Section 5.1. We typically think of FL and WL as representing precision errors, and FN as representing recall errors.

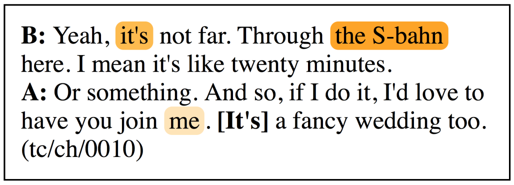
Our experiments consider several different settings. First, we consider an oracle setting ("RNN, OH" in tables), in which the model receives $\boldsymbol{z}^{(o)}_{1:n-1}$, the oracle partial clustering of all mentions preceding x_n in the document, and is therefore not forced to rely on its own past predictions when predicting x_n. This provides us with an upper bound on the performance achievable with our model. Next, we consider the performance of the model under a greedy inference strategy (RNN, GH), as in Algorithm 1. Finally, for baselines we consider the mention-ranking system (MR) of Wiseman et al. (2015) using our updated feature-set, as well as a non-local baseline with oracle history (Avg, OH), which averages the representations $\boldsymbol{h}_c(x_j)$ for all $x_j \in X^{(m)}$, rather than feed them through an RNN; errors are still backpropagated through the $\boldsymbol{h}_c$ representations during learning.

In Table 3 we see that the RNN improves performance overall, with the most dramatic improvements on non-anaphoric pronouns, though errors are also decreased significantly for non-anaphoric nominal and proper mentions that follow at least one mention with the same head. While WL errors also decrease for both these mention-categories under the RNN model, FN errors increase. Importantly, the RNN performance is significantly better than that of the Avg baseline, which barely improves over mention-ranking, even with oracle history. This suggests that modeling the sequence of mentions in a cluster is advantageous. We also note that while RNN performance degrades in both precision and recall when moving from the oracle history upper-bound to a greedy setting, we are still able to recover a significant portion of the possible performance improvement.

6.3 Qualitative Analysis

In this section we consider in detail the impact of the g term in the RNN scoring function on the two error categories that improve most under the RNN model (as shown in Table 3), namely, pronominal WL errors and pronominal FL errors. We consider an example from the CoNLL development set in each category on which the baseline MR model makes an error but the greedy RNN model does not.

The example in Figure 3 involves the resolution of the ambiguous pronoun "his," which is bracketed and in bold in the figure. Whereas the baseline MR model *incorrectly* predicts "his" to corefer with the closest gender-consistent antecedent "Justin" — thus making a WL error — the greedy RNN model



B: Yeah, it's not far. Through the S-bahn here. I mean it's like twenty minutes.
A: Or something. And so, if I do it, I'd love to have you join me . **[It's]** a fancy wedding too. (tc/ch/0010)

Figure 4: Magnitudes of gradients of NA score applied to bold "It's" with respect to final mention in three preceding clusters. See text for full description.

correctly predicts "his" to corefer with "Mr. Kaye" in the previous sentence. (Note that "the official" also refers to Mr. Kaye). To get a sense of the greedy RNN model's decision-making on this example, we color the mentions the greedy RNN model has predicted to corefer with "Mr. Kaye" in green, and the mentions it has predicted to corefer with "Justin" in blue. (Note that the model incorrectly predicts the initial "I" mentions to corefer with "Justin.") Letting $X^{(1)}$ refer to the blue cluster, $X^{(2)}$ refer to the green cluster, and x_n refer to the ambiguous mention "his," we further shade each mention x_j in $X^{(1)}$ so that its intensity corresponds to $\boldsymbol{h}_c(x_n)^{\mathsf{T}}\boldsymbol{h}_{<k}^{(1)}$, where $k = j + 1$; mentions in $X^{(2)}$ are shaded analogously. Thus, the shading shows how highly g scores the compatibility between "his" and a cluster $X^{(i)}$ as each of $X^{(i)}$'s mentions is added. We see that when the initial "Justin" mentions are added to $X^{(1)}$ the g-score is relatively high. However, after "The company" is correctly predicted to corefer with "Justin," the score of $X^{(1)}$ drops, since companies are generally not coreferent with pronouns like "his."

Figure 4 shows an example (consisting of a telephone conversation between "A" and "B") in which the bracketed pronoun "It's" is being used pleonastically. Whereas the baseline MR model predicts "It's" to corefer with a previous "it" — thus making a FL error — the greedy RNN model does not. In Figure 4 the final mention in three preceding clusters is shaded so its intensity corresponds to the magnitude of the gradient of the NA term in g with respect to that mention. This visualization resembles the "saliency" technique of Li et al. (2016), and it attempts to gives a sense of the contribution of a (preceding) cluster in the calculation of the NA score.

We see that the potential antecedent "S-Bahn" has a large gradient, but also that the initial, obviously pleonastic use of "it's" has a large gradient, which may suggest that earlier, easier predictions of pleonasm can inform subsequent predictions.

7 Related Work

In addition to the related work noted throughout, we add supplementary references here. Unstructured approaches to coreference typically divide into mention-pair models, which classify (nearly) every pair of mentions in a document as coreferent or not (Soon et al., 2001; Ng and Cardie, 2002; Bengtson and Roth, 2008), and mention-ranking models, which select a single antecedent for each anaphoric mention (Denis and Baldridge, 2008; Rahman and Ng, 2009; Durrett and Klein, 2013; Chang et al., 2013; Wiseman et al., 2015). Structured approaches typically divide between those that induce a clustering of mentions (McCallum and Wellner, 2003; Culotta et al., 2007; Poon and Domingos, 2008; Haghighi and Klein, 2010; Stoyanov and Eisner, 2012; Cai and Strube, 2010), and, more recently, those that learn a latent tree of mentions (Fernandes et al., 2012; Björkelund and Kuhn, 2014; Martschat and Strube, 2015).

There have also been structured approaches that merge the mention-ranking and mention-pair ideas in some way. For instance, Rahman and Ng (2011) rank clusters rather than mentions; Clark and Manning (2015) use the output of both mention-ranking and mention pair systems to learn a clustering.

The application of RNNs to modeling (the trajectory of) the state of a cluster is apparently novel, though it bears some similarity to the recent work of Dyer et al. (2015), who use LSTMs to embed the state of a transition based parser's stack.

8 Conclusion

We have presented a simple, state of the art approach to incorporating global information in an end-to-end coreference system, which obviates the need to define global features, and moreover allows for simple (greedy) inference. Future work will examine improving recall, and more sophisticated approaches to global training.

Search Space Pruning: A Simple Solution for Better Coreference Resolvers

Nafise Sadat Moosavi and **Michael Strube**
Heidelberg Institute for Theoretical Studies gGmbH
Schloss-Wolfsbrunnenweg 35
69118 Heidelberg, Germany

Abstract

There is a significant gap between the performance of a coreference resolution system on gold mentions and on system mentions. This gap is due to the large and unbalanced search space in coreference resolution when using system mentions. In this paper we show that search space pruning is a simple but efficient way of improving coreference resolvers. By incorporating our pruning method in one of the state-of-the-art coreference resolution systems, we achieve the best reported overall score on the CoNLL 2012 English test set. A version of our pruning method is available with the Cort coreference resolution source code.

1 Introduction

Coreference resolution is the task of clustering referring expressions in a text so that each resulting cluster represents an entity. It is a very challenging task in natural language processing and it is still far from being solved, i.e. the best reported overall CoNLL score on the CoNLL 2012 English test set is 63.39 (Wiseman et al., 2015).

Text spans referring to an entity are called mentions. Mentions are the primary objects in a coreference resolution system. As with most previous work on coreference resolution, we only consider mentions that are noun phrases. However, not all of the noun phrases are mentions. A noun phrase may not refer to any entity at all. The pronoun *it* in the sentence *it is raining* is an example of a non-referential noun phrase. Noun phrases which do refer to an entity (mentions) can be further divided into two categories: mentions referring to entities which only appear once in the discourse (i.e. singletons), and mentions realizing entities that have been referred to more than once in the text (i.e. coreferent mentions). Henceforth, we refer to both singletons and non-referential phrases as non-coreferent mentions. A large number of mentions that appear in a text are non-coreferent. For instance, more than 80% of mentions are singletons in the OntoNotes English development set (Marneffe et al., 2015).

The latent ranking model is the best performing model for coreference resolution to date (Wiseman et al., 2015; Martschat and Strube, 2015). If we use gold mentions, the latent ranking model of Martschat and Strube (2015) achieves an overall score of 80% on the CoNLL 2012 English test set. This result shows that once we have the ideal pruned search space, the ranking model with the current set of features is reasonably capable of finding corresponding entities of mentions. The substantial gap (17%) between the results of the gold mentions and system mentions implies that search space pruning is a promising direction for further improvements in coreference resolution.

Marneffe et al. (2015) examine different search space pruning methods that exist for coreference resolution. Among those, anaphoricity detection is the most popular method (e.g. Ng and Cardie (2002), Denis and Baldridge (2007), Ng (2009), Zhou and Kong (2009), Durrett and Klein (2013), Martschat and Strube (2015), Wiseman et al. (2015), Peng et al. (2015), and Lassalle and Denis (2015)), while singleton detection is a more recent method (Recasens et al., 2013; Ma et al., 2014; Marneffe et al., 2015).

Proceedings of NAACL-HLT 2016, pages 1005–1011,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

Anaphoricity detection examines whether a phrase is anaphoric. Singleton detection examines whether a phrase belongs to a coreference chain regardless of being anaphor or antecedent. Therefore, anaphoricity detection only prunes the search space of anaphors while singleton detection prunes the search space of both anaphors and antecedents.

Except for Clark and Manning (2015), all of the state-of-the-art coreference resolvers explicitly model anaphoricity detection (Martschat and Strube, 2015; Wiseman et al., 2015; Peng et al., 2015). Therefore, modeling search space pruning as singleton detection can provide additional information for the state-of-the-art coreference resolution systems.

In this paper we propose a simple but efficient singleton detection model. We first perform intrinsic evaluations and show that our simple model significantly improves the state-of-the-art results in singleton detection by a large margin. We then evaluate our singleton model extrinsically on coreference resolution showing that search space pruning improves different coreference resolution models.

2 Simple but Efficient Singleton Detection

In this section we show that pruning the coreference resolution search space is not a very difficult task. By using a simple set of features and a standard classifier, we achieve new state-of-the-art results for classifying coreferent and non-coreferent mentions.

Unlike Marneffe et al. (2015) who use both surface (i.e. part-of-speech and n-gram based) features and a large number (123) of carefully designed linguistic features, we select a simple and small set of shallow features:

1. lemmas of all words included in the mention;
2. lemmas of the two previous/next words before/after the mention;
3. part-of-speech tags of all words of the mention;
4. part-of-speech tags of the two previous/next words before/after the mention;
5. complete mention string;
6. length of the mention in words;
7. mention type (proper, nominal, pronominal);
8. whether the whole string of the mention appears again in the document;
9. whether the head of the mention appears again in the document.

We use an anchored SVM (Goldberg and Elhadad, 2007) with a polynomial kernel of degree two for classification. When only few features are available, anchored SVMs generalize much better than soft-margin-SVMs (Goldberg and Elhadad, 2009). In our experiments, we use a count threshold for discarding vary rare lexical features that occur fewer than 10 times.

Similar to Marneffe et al. (2015), we use three different configurations for evaluation. The *Surface* configuration only uses the shallow features. The *Combined* configuration uses the surface features plus the linguistic features introduced by Marneffe et al. (2015). The linguistic features of Marneffe et al. (2015) also include some pairwise combinations of the single features. Since our SVM with a polynomial kernel of degree two implicitly models feature pairs, we only include the single features in our *Combined* configuration. When removing mentions that are classified as non-coreferent during preprocessing, precision matters more than recall in order not to over prune coreferent mentions. To achieve higher precision, the *Confident* configuration uses high confidence predictions of SVM (i.e. classifying a mention as non-coreferent if the SVM output is less or equal to -1, and as coreferent if the output is greater or equal to +1). We use the same set of shallow features as *Surface* for *Confident*. However, Marneffe et al. (2015) use their combined feature set for *Confident*.

2.1 Results

Table 2 shows the results of our singleton detection model in comparison to that of Marneffe et al. (2015). We train our model on the CoNLL 2012 English training set and evaluate it on the development set using recall, precision, F1 measure and accuracy for both coreferent and non-coreferent mentions. Unlike Marneffe et al. (2015) that also use some gold annotations for their features, we extract all of our surface features from `'auto_conll'` files. Therefore, only predicted annotations are used.

The incorporation of linguistic features in Marneffe et al. (2015) improves the classification of both coreferent and non-coreferent mentions by about 1

			Non-Coreferent			Coreferent			
		#Features	R	P	F1	R	P	F1	Accuracy
Marneffe et al.	Surface	73,393	80.2	79.9	80.0	75.3	75.6	75.4	78.0
	Confident	73,516	56.0	89.8	69.0	48.2	90.7	62.9	52.2
	Combined	73,516	81.1	80.8	80.9	76.4	76.6	76.5	79.0
This work	Surface	8,331	89.37	87.08	88.21	80.32	83.59	81.92	85.73
	Confident	8,331	65.08	94.44	77.06	55.14	93.55	69.38	61.08
	Combined	8,446	89.48	87.16	88.30	80.45	83.76	82.07	85.85

Table 1: Results on the the CoNLL 2012 English development set.

percent in comparison to the *Surface* results. However, in our case, the linguistic features only improve the results by about 0.1 percent.

As the results show, by only using shallow features, we achieve a new state-of-the-art performance for singleton detection that improves the results of Marneffe et al. (2015) by a large margin for classifying both coreferent and non-coreferent mentions.

2.2 Error Analysis

For a singleton detector, precision errors (classifying a coreferent mention as non-coreferent) are more harmful than recall errors. If a coreferent mention is classified as non-coreferent, the recall of the coreference resolver that uses the singleton detector will decrease. On the other hand, recall errors only affect the singleton detector itself and not coreference resolvers.

The precision error ratios of our *Surface* and *Confident* systems for proper name (NAM), nominal (NOM) and pronominal (PRO) mentions are listed in Table 2. For each mention type, Table 2 also shows the precision error ratio by mention type related to the mentions that are first mentions of their corresponding entities. For example, in the *Confident* system 73.45% of the nominal mentions that are incorrectly classified as non-coreferent are first mentions of their corresponding entities. As can be seen, many of the precision errors in both *Surface* and *Confident* systems are errors in which the first mention of an entity is detected as non-coreferent. Detecting whether a mention will be referred to later, is indeed very hard and requires more context information. Features (8) and (9) from our feature set are designed to address the correct detection of the first mentions of entities to a limited degree. These features only address first mentions of entities that are referred to by later mentions with head or complete string match. More features considering properties of other mentions, rather than the examined mention itself, are required in order to improve the correct detection of the first mentions of entities.

		NAM	NOM	PRO
Surface	Error rate	23.17	70.61	6.22
	First mentions	57.68	65.54	20.19
Confident	Error rate	23.52	74.70	1.78
	First mentions	62.63	73.45	33.33

Table 2: Precision error ratio.

	NAM	NOM	PRO
Surface	30.48	34.07	35.45
Confident	23.65	58.25	13.50

Table 3: Recall error ratio.

Table 3 shows the ratio of recall errors for each mention type. For our *Surface* system, this ratio is more or less the same for different mention types. However, *Confident*'s main source of recall errors is the detection of non-coreferent nominal mentions.

2.3 Discussion

Our results significantly outperform the results of Marneffe et al. (2015) who use both surface features and a set of hand-engineered features targeting different linguistic phenomena related to the task. Our findings are mirrored by Durrett and Klein (2013)'s work on the coreference resolution task. Durrett and Klein (2013) show that a coreference resolution system that uses surface features can outperform those using hand-engineered linguistic features.

Linguistic features like syntactic nearness (on which Hobbs' algorithm (Hobbs, 1978) is based), morpho-syntactic and semantic agreement (e.g. number, gender and semantic class agreements), re-

cency, focus (Grosz and Sidner, 1986), and centering (Brennan et al., 1987) are examples of useful linguistic features for coreference resolution which have the additional benefit of being applicable to different languages. For example, Hobbs' algorithm and agreement features are being used successfully in the Stanford system (Lee et al., 2013). However, apart from features like these, a large number of linguistically motivated features have been proposed which either do not have a significant impact or are only applicable to a specific language or domain. Therefore, designing general linguistic features which provide information that is not captured by surface features deserve more attention in order to gain higher recall and better generalization.

We combine a simple set of surface features with a standard machine learning model that can handle a large number of surface features. This leads to a new state-of-the-art singleton detection with high precision that can easily be incorporated in a coreference resolution system for pruning non-coreferent mentions.

3 Pruning = Better Coreference Resolvers

In this section, we investigate the effect of search space pruning on coreference resolution. We choose the Stanford rule-based system (Lee et al., 2013) and the Cort[1] system (Martschat and Strube, 2015) as our baselines for coreference resolution. Wiseman et al. (2015) is the best performing coreference resolution system to date. However, we choose Cort as our learning-based baseline because Cort is a framework that allows evaluations on various coreference resolution models, i.e. ranking, antecedent trees, and pairwise. The pairwise model is the most commonly used model in coreference resolution, and latent ranking is the best performing model for coreference resolution to date (Wiseman et al., 2015; Martschat and Strube, 2015).

3.1 Results

Table 4 shows the results of integrating singleton detection into different coreference resolution approaches. We evaluate the systems on the CoNLL 2012 English test set using the MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and $CEAF_e$ (Luo, 2005) measures as provided by the CoNLL coreference scorer version 8.01 (Pradhan et al., 2014). According to the approximate randomization test (Noreen, 1989), all of the improvements made by our singleton detection module are statistically significant ($p < 0.05$).

Baseline shows the result of the Stanford system without using singleton detection. *+Stanford Singleton* is the result of the Stanford system including its singleton detection module (Recasens et al., 2013). *+Preprocess Pruning* is the result when our *Confident* model from Section 2 is used.

The singleton detection modules of Recasens et al. (2013) and Marneffe et al. (2015) are incorporated in the Stanford system in a heuristic way: if both anaphor and antecedent are classified as singleton, and none of them is a named entity, then those mentions will be disregarded. However, since our *Confident* model does have a high precision, we use it for removing all non-coreferent mentions in a preprocessing step. As shown in Table 4, our singleton detection improves the overall score of the *Baseline*

[1] http://github.com/smartschat/cort

system by about 2 percent on the test set.

Cort uses a perceptron for learning. Therefore, we use a perceptron in Cort while an anchored SVM would have performed slightly better. We also include all the additional features that are used in Cort for our Cort singleton detection model. SVM accuracy with surface features on the development set is about 0.1 percent better than that of the perceptron with Cort's additional features.

For the pairwise model, singleton detection is performed in a preprocessing step. The singleton detection module improves the overall performance of the pairwise model by about 1 percent on the test set.

The Cort latent model already performs search space pruning in the form of anaphoricity detection. Additional pruning of potential anaphors in the preprocessing step by the singleton model hurts the recall of the latent model. Therefore, we add the output of the singleton model as a new feature for both anaphor and antecedent. For obtaining these features for training, we split the training data into two halves and train a singleton perceptron separately on each half. The values of the singleton feature for the first half are computed based on the model that is trained on the second half, and vice versa. This way, the accuracy of singleton features on both training and testing is similar. If we would train the singleton model on the whole training data, we would overfit the model seriously. The values of the singleton feature would be very accurate on the training data, and the learner would overestimate the importance of this feature.

The new feature improves the overall performance of the latent ranking model by about 0.5 percent on the test set. This result is the best reported overall score for coreference resolution on the CoNLL 2012 English test set to date.

The singleton feature support is added to the Cort source code. It is available at http://github.com/smartschat/cort.

3.2 Discussion

Recent improvements in coreference resolution have been made by exploring more complex learning and inference strategies, a larger number of features, and joint processing. There are also technically viable solutions for improving the performance of a coreference resolver which do not work in practice. For instance, since coreference resolution is a set partitioning problem, entity-based models seem to be more suitable for coreference resolution than mention-pair models. However, entity-based models do not necessarily perform better than mention-pair models (e.g. Ng (2010) and Moosavi and Strube (2014)). The same is true for incorporating more semantic-level information in a coreference resolution system (e.g. Durrett and Klein (2013)).

In this paper, we show that coreference resolution can also simply be improved by performing search space pruning. The significant gap between the performance of the latent ranking model on gold mentions and on system mentions indicates that there is still room for further improvements in search space pruning.

4 Conclusions

We achieve new state-of-the-art results for singleton detection by only using shallow features and simple classifiers. We also show that search space pruning significantly improves different coreference resolution models. The substantial gap between the performance on gold mentions and on system mentions indicates that there is still plenty of room for further improvements in singleton detection. Therefore, search space pruning is a promising direction for further improvements in coreference resolution. The proposed singleton detector as a feature for coreference resolvers is implemented for the Cort coreference resolver. It is available with the Cort source code.

Acknowledgments

The authors would like to thank Sebastian Martschat for his help to use the proposed singleton detector in the Cort coreference resolver. We would also like to thank Mark-Christoph Müller, Benjamin Heinzerling, Mohsen Mesgar, Daraksha Parveen and Alex Judea for their helpful comments. Abstract

Coreference resolution is one of the first stages in deep language understanding and its importance has been well recognized in the natural language processing community. In this paper, we propose a generative, unsupervised ranking model for entity coreference resolution by introducing resolution mode variables. Our unsupervised system achieves 58.44% F1 score of the CoNLL metric on the English data from the CoNLL-2012 shared task (Pradhan et al., 2012), outperforming the Stanford deterministic system (Lee et al., 2013) by 3.01%.

1 Introduction

Entity coreference resolution has become a critical component for many Natural Language Processing (NLP) tasks. Systems requiring deep language understanding, such as information extraction (Wellner et al., 2004), semantic event learning (Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009), and named entity linking (Durrett and Klein, 2014; Ji et al., 2014) all benefit from entity coreference information.

Entity coreference resolution is the task of identifying mentions (i.e., noun phrases) in a text or dialogue that refer to the same real-world entities. In recent years, several supervised entity coreference resolution systems have been proposed, which, according to Ng (2010), can be categorized into three classes — mention-pair models (McCarthy and Lehnert, 1995), entity-mention models (Yang et al., 2008a; Haghighi and Klein, 2010; Lee et al., 2011) and ranking models (Yang et al., 2008b; Durrett and Klein, 2013; Fernandes et al., 2014) — among which ranking models recently obtained state-of-the-art performance. However, the manually annotated corpora that these systems rely on are highly expensive to create, in particular when we want to build data for resource-poor languages (Ma and Xia, 2014). That makes unsupervised approaches, which only require unannotated text for training, a desirable solution to this problem.

Several unsupervised learning algorithms have been applied to coreference resolution. Haghighi and Klein (2007) presented a mention-pair nonparametric fully-generative Bayesian model for unsupervised coreference resolution. Based on this model, Ng (2008) probabilistically induced coreference partitions via EM clustering. Poon and Domingos (2008) proposed an entity-mention model that is able to perform joint inference across mentions by using Markov Logic. Unfortunately, these unsupervised systems' performance on accuracy significantly falls behind those of supervised systems, and are even worse than the deterministic rule-based systems. Furthermore, there is no previous work exploring the possibility of developing an unsupervised ranking model which achieved state-of-the-art performance under supervised settings for entity coreference resolution.

In this paper, we propose an unsupervised generative ranking model for entity coreference resolution. Our experimental results on the English data from the CoNLL-2012 shared task (Pradhan et al., 2012) show that our unsupervised system outperforms the Stanford deterministic system (Lee et al., 2013) by 3.01% absolute on the CoNLL official metric. The

Proceedings of NAACL-HLT 2016, pages 1012–1018,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

contributions of this work are (i) proposing the first unsupervised ranking model for entity coreference resolution. (ii) giving empirical evaluations of this model on benchmark data sets. (iii) considerably narrowing the gap to supervised coreference resolution accuracy.

2 Unsupervised Ranking Model

2.1 Notations and Definitions

In the following, $D = \{m_0, m_1, \ldots, m_n\}$ represents a generic input document which is a sequence of coreference mentions, including the artificial root mention (denoted by m_0). The method to detect and extract these mentions is discussed later in Section 2.6. Let $C = \{c_1, c_2, \ldots, c_n\}$ denote the coreference assignment of a given document, where each mention m_i has an associated random variable c_i taking values in the set $\{0, i, \ldots, i-1\}$; this variable specifies m_i's selected antecedent ($c_i \in \{1, 2, \ldots, i-1\}$), or indicates that it begins a new coreference chain ($c_i = 0$).

2.2 Generative Ranking Model

The following is a straightforward way to build a generative model for coreference:

$$\begin{aligned} P(D, C) &= P(D|C)P(C) \\ &= \prod_{j=1}^{n} P(m_j|m_{c_j}) \prod_{j=1}^{n} P(c_j|j) \end{aligned} \qquad (1)$$

where we factorize the probabilities $P(D|C)$ and $P(C)$ into each position j by adopting appropriate independence assumptions that given the coreference assignment c_j and corresponding coreferent mention m_{c_j}, the mention m_j is independent with other mentions in front of it. This independent assumption is similar to that in the IBM 1 model on machine translation (Brown et al., 1993), where it assumes that given the corresponding English word, the aligned foreign word is independent with other English and foreign words. We do not make any independent assumptions among different features (see Section 2.4 for details).

Inference in this model is efficient, because we can compute c_j separately for each mention:

$$c_j^* = \operatorname*{argmax}_{c_j} P(m_j|m_{c_j})P(c_j|j)$$

The model is a so-called ranking model because it is able to identify the most probable candidate antecedent given a mention to be resolved.

2.3 Resolution Mode Variables

According to previous work (Haghighi and Klein, 2009; Ratinov and Roth, 2012; Lee et al., 2013), antecedents are resolved by different categories of information for different mentions. For example, the Stanford system (Lee et al., 2013) uses string-matching sieves to link two mentions with similar text and precise-construct sieve to link two mentions which satisfy special syntactic or semantic relations such as apposition or acronym. Motivated by this, we introduce resolution mode variables $\Pi = \{\pi_1, \ldots, \pi_n\}$, where for each mention j the variable $\pi_j \in \{str, prec, attr\}$ indicates in which mode the mention should be resolved. In our model, we define three resolution modes — string-matching (*str*), precise-construct (*prec*), and attribute-matching (*attr*) — and Π is deterministic when D is given (i.e. $P(\Pi|D)$ is a point distribution). We determine π_j for each mention m_j in the following way:

- $\pi_j = str$, if there exists a mention $m_i, i < j$ such that the two mentions satisfy the *String Match* sieve, the *Relaxed String Match* sieve, or the *Strict Head Match A* sieve in the Stanford multi-sieve system (Lee et al., 2013).

- $\pi_j = prec$, if there exists a mention $m_i, i < j$ such that the two mentions satisfy the *Speaker Identification* sieve, or the *Precise Constructs* sieve.

- $\pi_j = attr$, if there is no mention $m_i, i < j$ satisfies the above two conditions.

Now, we can extend the generative model in Eq. 1 to:

$$\begin{aligned} &P(D, C) = P(D, C, \Pi) \\ &= \prod_{j=1}^{n} P(m_j|m_{c_j}, \pi_j)P(c_j|\pi_j, j)P(\pi_j|j) \end{aligned}$$

where we define $P(\pi_j|j)$ to be uniform distribution. We model $P(m_j|m_{c_j}, \pi_j)$ and $P(c_j|\pi_j, j)$ in the fol-

Mode π	Feature	Description
prec	Mention Type	the type of a mention. We use three mention types: $Proper, Nominal, Pronoun$
str	Mention Type	the same as the mention type feature under *prec* mode.
	Exact Match	boolean feature corresponding to String Match sieve in Stanford system.
	Relaxed Match	boolean feature corresponding to Relaxed String Match sieve in Stanford system.
	Head Match	boolean feature corresponding to Strict Head Match A sieve in Stanford system.
attr	Mention Type	the same as the mention type feature under *prec* mode.
	Number	the number of a mention similarly derived from Lee et al. (2013).
	Gender	the gender of a mention from Bergsma and Lin (2006) and Ji and Lin (2009).
	Person	the person attribute from Lee et al. (2013). We assign person attributes to all mentions, not only pronouns.
	Animacy	the animacy attribute same as Lee et al. (2013).
	Semantic Class	semantic classes derived from WordNet (Soon et al., 2001).
	Distance	sentence distance between the two mentions. This feature is for parameter $q(k\|j, \pi)$

Table 1: Feature set for representing a mention under different resolution modes. The *Distance* feature is for parameter q, while all other features are for parameter t.

Algorithm 1: Learning Model with EM

```
Initialization: Initialize $\theta_0 = \{t_0, q_0\}$
for $t = 0$ to $T$ do
    set all counts $c(\ldots) = 0$
    for each document $D$ do
        for $j = 1$ to $n$ do
            for $k = 0$ to $j - 1$ do
                $L_{jk} = \frac{t(m_j|m_k,\pi_j)q(k|\pi_j,j)}{\sum_{i=0}^{j-1} t(m_j|m_i,\pi_j)q(i|\pi_j,j)}$
                $c(m_j, m_k, \pi_j) += L_{jk}$
                $c(m_k, \pi_j) += L_{jk}$
                $c(k, j, \pi_j) += L_{jk}$
                $c(j, \pi_j) += L_{jk}$
    // Recalculate the parameters
    $t(m|m', \pi) = \frac{c(m,m',\pi)}{c(m',\pi)}$
    $q(k, j, \pi) = \frac{c(k,j,\pi)}{c(j,\pi)}$
```

lowing way:

$$P(m_j|m_{c_j}, \pi_j) = t(m_j|m_{c_j}, \pi_j)$$
$$P(c_j|\pi_j, j) = \begin{cases} q(c_j|\pi_j, j) & \pi_j = attr \\ \frac{1}{j} & \text{otherwise} \end{cases}$$

where $\theta = \{t, q\}$ are parameters of our model. Note that in the attribute-matching mode ($\pi_j = attr$) we model $P(c_j|\pi_j, j)$ with parameter q, while in the other two modes, we use the uniform distribution. It makes sense because the position information is important for coreference resolved by matching attributes of two mentions such as resolving pronoun coreference, but not that important for those resolved by matching text or special relations like two mentions referring the same person and matching by the name.

Corpora	# Doc	# Sent	# Word	# Entity	# Mention
Gigaword	3.6M	75.4M	1.6B	-	-
ON-Dev	343	9,142	160K	4,546	19,156
ON-Test	348	9,615	170K	4,532	19,764

Table 2: Corpora statistics. "ON-Dev" and "ON-Test" are the development and testing sets of the OntoNotes corpus.

2.4 Features

In this section, we describe the features we use to represent mentions. Specifically, as shown in Table 1, we use different features under different resolution modes. It should be noted that only the *Distance* feature is designed for parameter q, all other features are designed for parameter t.

2.5 Model Learning

For model learning, we run EM algorithm (Dempster et al., 1977) on our Model, treating D as observed data and C as latent variables. We run EM with 10 iterations and select the parameters achieving the best performance on the development data. Each iteration takes around 12 hours with 10 CPUs parallelly. The best parameters appear at around the 5th iteration, according to our experiments.The detailed derivation of the learning algorithm is shown in Appendix A. The pseudo-code is shown is Algorithm 1. We use uniform initialization for all the parameters in our model.

Several previous work has attempted to use EM for entity coreference resolution. Cherry and Bergsma (2005) and Charniak and Elsner (2009) applied EM for pronoun anaphora resolution. Ng (2008) probabilistically induced coreference partitions via EM clustering. Recently, Moosavi and Strube (2014) proposed an unsupervised model uti-

lizing the most informative relations and achieved competitive performance with the Stanford system.

2.6 Mention Detection

The basic rules we used to detect mentions are similar to those of Lee et al. (2013), except that their system uses a set of filtering rules designed to discard instances of pleonastic *it*, partitives, certain quantified noun phrases and other spurious mentions. Our system keeps partitives, quantified noun phrases and *bare NP* mentions, but discards pleonastic *it* and other spurious mentions.

3 Experiments

3.1 Experimental Setup

Datasets. Due to the availability of readily parsed data, we select the APW and NYT sections of Gigaword Corpus (years 1994-2010) (Parker et al., 2011) to train the model. Following previous work (Chambers and Jurafsky, 2008), we remove duplicated documents and the documents which include fewer than 3 sentences. The development and test data are the English data from the CoNLL-2012 shared task (Pradhan et al., 2012), which is derived from the OntoNotes corpus (Hovy et al., 2006). The corpora statistics are shown in Table 2. Our system is evaluated with automatically extracted mentions on the version of the data with automatic preprocessing information (e.g., predicted parse trees).

Evaluation Metrics. We evaluate our model on three measures widely used in the literature: MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and Entity-based CEAF (CEAF$_e$) (Luo, 2005). In addition, we also report results on another two popular metrics: Mention-based CEAF (CEAF$_m$) and BLANC (Recasens and Hovy, 2011). All the results are given by the latest version of CoNLL-2012 scorer [1]

3.2 Results and Comparison

Table 3 illustrates the results of our model together as baseline with two deterministic systems, namely **Stanford**: the Stanford system (Lee et al., 2011) and **Multigraph**: the unsupervised multigraph system (Martschat, 2013), and one unsupervised system, namely **MIR**: the unsupervised system using most informative relations (Moosavi and Strube, 2014). Our model outperforms the three baseline systems on all the evaluation metrics. Specifically, our model achieves improvements of 2.93% and 3.01% on CoNLL F1 score over the Stanford system, the winner of the CoNLL 2011 shared task, on the CoNLL 2012 development and test sets, respectively. The improvements on CoNLL F1 score over the Multigraph model are 1.41% and 1.77% on the development and test sets, respectively. Comparing

[1] `http://conll.cemantix.org/2012/software.html`

with the MIR model, we obtain significant improvements of 2.62% and 3.02% on CoNLL F1 score.

To make a thorough empirical comparison with previous studies, Table 3 (below the dashed line) also shows the results of some state-of-the-art supervised coreference resolution systems — **IMS**: the second best system in the CoNLL 2012 shared task (Björkelund and Farkas, 2012); **Latent-Tree**: the latent tree model (Fernandes et al., 2012) obtaining the best results in the shared task; **Berkeley**: the Berkeley system with the final feature set (Durrett and Klein, 2013); **LaSO**: the structured perceptron system with non-local features (Björkelund and Kuhn, 2014); **Latent-Strc**: the latent structure system (Martschat and Strube, 2015); **Model-Stack**: the entity-centric system with model stacking (Clark and Manning, 2015); and **Non-Linear**: the non-linear mention-ranking model with feature representations (Wiseman et al., 2015). Our unsupervised ranking model outperforms the supervised IMS system by 1.02% on the CoNLL F1 score, and achieves competitive performance with the latent tree model. Moreover, our approach considerably narrows the gap to other supervised systems listed in Table 3.

4 Conclusion

We proposed a new generative, unsupervised ranking model for entity coreference resolution into which we introduced resolution mode variables to distinguish mentions resolved by different categories of information. Experimental results on the data from CoNLL-2012 shared task show that our system significantly improves the accuracy on different evaluation metrics over the baseline systems.

One possible direction for future work is to differentiate more resolution modes. Another one is to add more precise or even event-based features to improve the model's performance.

Appendix A. Derivation of Model Learning

Formally, we iteratively estimate the model parameters θ, employing the following EM algorithm:

E-step: Compute the posterior probabilities of C, $P(C|D;\theta)$, based on the current θ.

M-step: Calculate the new θ' that maximizes the expected complete log likelihood, $E_{P(C|D;\theta)}[\log P(D,C;\theta')]$

For simplicity, we denote:

$$\begin{aligned} P(C|D;\theta) &= \tilde{P}(C|D) \\ P(C|D;\theta') &= P(C|D) \end{aligned}$$

In addition, we use $\tau(\pi_j|j)$ to denote the probability $P(\pi_j|j)$ which is uniform distribution in our model. Moreover, we use the following notation for convenience:

$$\theta(m_j, m_k, j, k, \pi_j) = t(m_j|m_k, \pi_j)q(k|\pi_j, j)\tau(\pi_j|j)$$

Then, we have

$$\begin{aligned} & E_{\tilde{P}(c|D)}[\log P(D,C)] \\ = & \sum_C \tilde{P}(C|D)\log P(D,C) \\ = & \sum_C \tilde{P}(C|D)\big(\sum_{j=1}^{n} \log t(m_j|m_{c_j},\pi_j) + \log q(c_j|\pi_j, j) + \log\tau(\pi_j|j)\big) \\ = & \sum_{j=1}^{n}\sum_{k=0}^{j-1} L_{jk}\big(\log t(m_j|m_k,\pi_j) + \log q(k|\pi_j, j) + \log\tau(\pi_j|j)\big) \end{aligned}$$

Then the parameters t and q that maximize $E_{\tilde{P}(c|D)}[\log P(D,C)]$ satisfy that

$$\begin{aligned} t(m_j|m_k,\pi_j) &= \frac{L_{jk}}{\sum\limits_{i=1}^{n} L_{ik}} \\ q(k|\pi_j, j) &= \frac{L_{jk}}{\sum\limits_{i=0}^{j-1} L_{ji}} \end{aligned}$$

where L_{jk} can be calculated by

$$\begin{aligned} L_{jk} &= \sum_{C,c_j=k} \tilde{P}(C|D) = \frac{\sum\limits_{C,c_j=k} \tilde{P}(C,D)}{\sum\limits_{C} \tilde{P}(C,D)} \\ &= \frac{\sum\limits_{C,c_j=k}\prod\limits_{i=1}^{n}\tilde{\theta}(m_i,m_{c_i},c_i,i,\pi_i)}{\sum\limits_{C}\prod\limits_{i=1}^{n}\tilde{\theta}(m_i,m_{c_i},c_i,i,\pi_i)} \\ &= \frac{\tilde{\theta}(m_j,m_k,k,j,\pi_j)\sum\limits_{C(-j)}\tilde{P}(C(-j)|D)}{\sum\limits_{i=0}^{j-1}\tilde{\theta}(m_j,m_i,i,j,\pi_j)\sum\limits_{C(-j)}\tilde{P}(C(-j)|D)} \\ &= \frac{\tilde{\theta}(m_j,m_k,k,j,\pi_j)}{\sum\limits_{i=0}^{j-1}\tilde{\theta}(m_j,m_i,i,j,\pi_j)} \\ &= \frac{\tilde{t}(m_j|m_k,\pi_j)\tilde{q}(k|\pi_j,j)\tilde{\tau}(\pi_j|j)}{\sum\limits_{i=0}^{j-1}\tilde{t}(m_j|m_i,\pi_j)\tilde{q}(i|\pi_j,j)\tilde{\tau}(\pi_j|j)} \\ &= \frac{\tilde{t}(m_j|m_k,\pi_j)\tilde{q}(k|\pi_j,j)}{\sum\limits_{i=0}^{j-1}\tilde{t}(m_j|m_i,\pi_j)\tilde{q}(i|\pi_j,j)} \end{aligned}$$

where $C(-j) = \{c_1, \ldots, c_{j-1}, c_{j+1}, \ldots, c_n\}$. The above derivations correspond to the learning algorithm in Algorithm 1.

Embedding Lexical Features via Low-Rank Tensors

Abstract

Modern NLP models rely heavily on engineered features, which often combine word and contextual information into complex lexical features. Such combination results in large numbers of features, which can lead to over-fitting. We present a new model that represents complex lexical features—comprised of parts for words, contextual information and labels—in a tensor that captures conjunction information among these parts. We apply low-rank tensor approximations to the corresponding parameter tensors to reduce the parameter space and improve prediction speed. Furthermore, we investigate two methods for handling features that include n-grams of mixed lengths. Our model achieves state-of-the-art results on tasks in relation extraction, PP-attachment, and preposition disambiguation.

1 Introduction

Statistical NLP models usually rely on hand-designed features, customized for each task. These features typically combine lexical and contextual information with the label to be scored. In relation extraction, for example, there is a parameter for the presence of a specific relation occurring with a feature conjoining a word type (lexical) with dependency path information (contextual). In measuring phrase semantic similarity, a word type is conjoined with its position in the phrase to signal its role. Figure 1b shows an example in dependency parsing, where multiple types (words) are conjoined with POS tags or distance information.

To avoid model over-fitting that often results from features with lexical components, several smoothed lexical representations have been proposed and shown to improve performance on various NLP tasks; for instance, word embeddings (Bengio et al., 2006) help improve NER, dependency parsing and semantic role labeling (Miller et al., 2004; Koo et al., 2008; Turian et al., 2010; Sun et al., 2011; Roth and Woodsend, 2014; Hermann et al., 2014).

However, using only word embeddings is not sufficient to represent complex lexical features (e.g. ϕ in Figure 1c). In these features, the same word embedding conjoined with different non-lexical properties may result in features indicating different labels; the corresponding lexical feature representations should take the above interactions into consideration. Such important interactions also increase the risk of over-fitting as feature space grows exponentially, yet how to capture these interactions in representation learning remains an open question.

To address the above problems,[1] we propose a general and unified approach to reduce the feature space by constructing low-dimensional feature representations, which provides a new way of combining word embeddings, traditional non-lexical properties, and label information. Our model exploits the inner structure of features by breaking the feature into multiple parts: lexical, non-lexical and (optional) label. We demonstrate that the full feature is an outer product among these parts. Thus, a parameter tensor scores each feature to produce a prediction. Our model then reduces the number of param-

[*] Paper submitted during Mo Yu's PhD study at HIT.

[1] Our paper only focuses on lexical features, as non-lexical features usually suffer less from over-fitting.

Proceedings of NAACL-HLT 2016, pages 1019–1029,
San Diego, California, June 12-17, 2016.

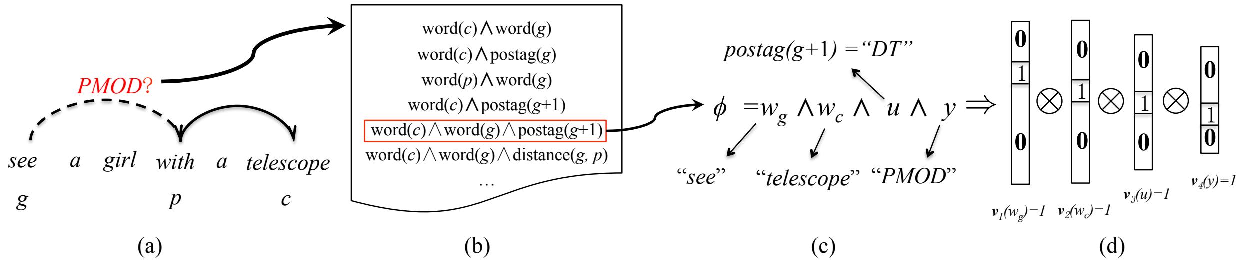

Figure 1: An example of lexical features used in dependency parsing. To predict the "PMOD" arc (the dashed one) between "see" and "with" in (a), we may rely on lexical features in (b). Here p, c, g are indices of the word "with", its child ("telescope") and a candidate head. Figure (c) shows what the fifth feature (ϕ) is like, when the candidate is "see". As is common in multi-class classification tasks, each template generates a different feature for each label y. Thus a feature $\phi = \mathrm{w}_g \wedge \mathrm{w}_c \wedge \mathrm{u} \wedge \mathrm{y}$ is the conjunction of the four parts. Figure (d) is the one-hot representation of ϕ, which is equivalent to the outer product (i.e. a 4-way tensor) among the four one-hot vectors. $\mathbf{v}(x) = 1$ means the vector $\mathbf{v}$ has a single non-zero element in the x position.

eters by approximating the parameter tensor with a low-rank tensor: the Tucker approximation of Yu et al. (2015) but applied to each embedding type (view), or the **C**anonical/**P**arallel-Factors Decomposition (CP). Our models use fewer parameters than previous work that learns a separate representation for each feature (Ando and Zhang, 2005; Yang and Eisenstein, 2015). CP approximation also allows for much faster prediction, going from a method that is cubic in rank and exponential in the number of lexical parts, to a method linear in both. Furthermore, we consider two methods for handling features that rely on n-grams of mixed lengths.

Our model makes the following contributions when contrasted with prior work:

Lei et al. (2014) applied CP to combine different views of features. Compared to their work, our usage of CP-decomposition is different in the application to feature learning: (1) We focus on dimensionality reduction of existing, well-verified features, while Lei et al. (2014) generates new features (usually different from ours) by combining some "atom" features. Thus their work may ignore some useful features; it relies on binary features as supplementary but our model needs not. (2) Lei et al. (2014)'s factorization relies on views with explicit meanings, e.g. head/modifier/arc in dependency parsing, making it less general. Therefore its applications to tasks like relation extraction are less obvious.

Compared to our previous work (Gormley et al., 2015; Yu et al., 2015), this work allows for higher-order interactions, mixed-length n-gram features, lower-rank representations. We also demonstrate the strength of our new model via applications to new tasks.

The resulting method learns smoothed feature representations combining lexical, non-lexical and label information, achieving state-of-the-art performance on several tasks: relation extraction, preposition semantics and PP-attachment.

2 Notation and Definitions

We begin with some background on notation and definitions. Let $\mathcal{T} \in \mathbb{R}^{d_1 \times \cdots \times d_K}$ be a K-way tensor (i.e., a tensor with K views). In this paper, we consider the tensor k-mode product, i.e. multiplying a tensor $\mathcal{T} \in \mathbb{R}^{d_1 \times \cdots \times d_K}$ by a matrix $\mathbf{x} \in \mathbb{R}^{d_k \times J}$ (or a vector if $J = 1$) in mode (view) k. The product is denoted by $\mathcal{T} \times_k \mathbf{x}$ and is of size $d_1 \times \cdots \times d_{k-1} \times J \times d_{k+1} \times \cdots \times d_K$. Element-wise, we have

$$(\mathcal{T} \times_k \mathbf{x})_{i_1 \ldots i_{k-1}\, j\, i_{k+1} \ldots i_K} = \sum_{i_k=1}^{d_k} \mathcal{T}_{i_1 \ldots i_k \ldots i_K} \mathbf{x}_{i_k j},$$

for $j = 1, \ldots, J$. A mode-k fiber $\mathcal{T}_{i_1 \ldots i_{k-1} \bullet i_{k+1} \ldots i_K}$ of $\mathcal{T}$ is the d_k dimensional vector obtained by fixing all but the kth index. The mode-k unfolding $\mathcal{T}_{(k)}$ of $\mathcal{T}$ is the $d_k \times \prod_{i \neq k} d_i$ matrix obtained by concatenating all the $\prod_{i \neq k} d_i$ mode-k fibers along columns.

Given two matrices $\mathrm{W}_1 \in \mathbb{R}^{d_1 \times r_1}$, $\mathrm{W}_2 \in \mathbb{R}^{d_2 \times r_2}$, we write $\mathrm{W}_1 \otimes \mathrm{W}_2$ to denote the Kronecker product between W_1 and W_2 (outer product for vectors). We define the Frobenius product (matrix dot product) $\mathbf{A} \odot \mathbf{B} = \sum_{i,j} A_{ij} B_{ij}$ between two matrices with the same sizes; and define element-wise (Hadamard) multiplication $\mathbf{a} \circ \mathbf{b}$ between vectors with the same sizes.

Tucker Decomposition: Tucker Decomposition represents a $d_1 \times d_2 \times \ldots \times d_K$ tensor $\mathcal{T}$ as:

$$\mathcal{T} = g \times_1 \mathrm{W}_1 \times_2 \mathrm{W}_2 \ldots \times_K \mathrm{W}_K \quad (1)$$

where each $\times_i$ is the tensor i-mode product and each W_i is a $r_i \times d_i$ matrix. Tensor g with size $r_1 \times r_2 \times \ldots \times r_K$ is called the *core tensor*. We say that $\mathcal{T}$ has a Tucker rank $(r_{(1)}, r_{(2)}, \ldots, r_{(K)})$, where $r_{(i)} = \text{rank}(\mathcal{T}_{(i)})$ is the rank of mode-i unfolding. To simplify learning, we define the Tucker rank as $r_{(i)}$=rank($\mathbf{g}_{(i)}$), which can be bounded simply by the dimensions of g, i.e. $r_{(i)} \leq r_i$; this allows us to enforce a rank constraint on $\mathcal{T}$ simply by restricting the dimensions r_i of g, as described in §6.

CP Decomposition: CP decomposition represents a $d_1 \times d_2 \times \ldots \times d_K$ tensor $\mathcal{T}$ as a sum of rank-one tensors (i.e. a sum of outer products of K vectors):

$$\mathcal{T} = \sum_{j=1}^{r} \mathrm{W}_1[j,:] \otimes \mathrm{W}_2[j,:] \otimes \ldots \otimes \mathrm{W}_K[j,:] \quad (2)$$

where each W_i is an $r \times d_i$ matrix and $\mathrm{W}_i[j,:]$ is the vector of its j-th row. For CP decomposition, the rank r of a tensor $\mathcal{T}$ is defined to be the number of rank-one tensors in the decomposition. CP decomposition can be viewed as a special case of Tucker decomposition in which $r_1 = r_2 = \ldots = r_K = r$ and g is a superdiagonal tensor.

3 Factorization of Lexical Features

Suppose we have feature ϕ that includes information from a label y, multiple lexical items $\mathrm{w}_1, \ldots, \mathrm{w}_n$ and non-lexical property u. This feature can be factorized as a conjunction of each part: $\phi = \mathrm{y} \wedge \mathrm{u} \wedge \mathrm{w}_1 \wedge \ldots \wedge \mathrm{w}_n$. The feature fires when all $(n+2)$ parts fire in the instance (reflected by the $\wedge$ symbol in ϕ). The one-hot representation of ϕ can then be viewed as a tensor $e_\phi = \mathrm{y} \otimes \mathrm{u} \otimes \mathrm{w}_1 \otimes \cdots \otimes \mathrm{w}_n$, where each feature part is also represented as a one-hot vector.[2] Figure 1d illustrates this case with two lexical parts.

Given an input instance $\mathbf{x}$ and its associated label y, we can extract a set of features $S(\mathbf{x}, \mathrm{y})$. In a traditional log-linear model, we view the instance $\mathbf{x}$ as a bag-of-features, i.e. a feature vector $F(\mathbf{x}, \mathrm{y})$. Each dimension corresponds to a feature ϕ, and has value 1 if $\phi \in S(\mathbf{x}, \mathrm{y})$. Then the log-linear model scores the instance as $s(\mathbf{x}, \mathrm{y}; \mathbf{w}) = \mathbf{w}^T F(\mathbf{x}, \mathrm{y}) = \sum_{\phi \in S(\mathbf{x}, \mathrm{y})} s(\phi; \mathbf{w})$, where $\mathbf{w}$ is the parameter vector. We can re-write $s(\mathbf{x}, \mathrm{y}; \mathbf{w})$ based on the factorization of the features using tensor multiplication; in which $\mathbf{w}$ becomes a parameter tensor $\mathcal{T}$:

$$s(\mathbf{x}, \mathrm{y}; \mathbf{w}) = s(\mathbf{x}, \mathrm{y}; \mathcal{T}) = \sum_{\phi \in S(\mathbf{x}, \mathrm{y})} s(\phi; \mathcal{T}) \quad (3)$$

Here each ϕ has the form $(\mathrm{y}, \mathrm{u}, \mathrm{w}_1, \ldots, \mathrm{w}_n)$, and

$$s(\phi; \mathcal{T}) = \mathcal{T} \times_l \mathrm{y} \times_f \mathrm{u} \times_{\mathrm{w}_1} \mathrm{w}_1 \ldots \times_{\mathrm{w}_n} \mathrm{w}_n. \quad (4)$$

Note that one-hot vectors w_i of words themselves are large ($|\mathrm{w}_i| > 500\text{k}$), thus the above formulation with parameter tensor $\mathcal{T}$ can be very large, making parameter estimation difficult. Instead of estimating only the values of the dimensions which appear in training data as in traditional methods, we will reduce the size of tensor $\mathcal{T}$ via a low-rank approximation. With different approximation methods, (4) will have different equivalent forms, e.g. (6), (7) in §4.1.

Optimization objective: The loss function ℓ for training the log-linear model uses (3) for scores, e.g., the log-loss $\ell(\mathbf{x}, \mathrm{y}; \mathcal{T}) = -\log \frac{\exp\{s(\mathbf{x}, \mathrm{y}; \mathcal{T})\}}{\sum_{\mathrm{y}' \in L} \exp\{s(\mathbf{x}, \mathrm{y}'; \mathcal{T})\}}$. Learning can be formulated as the following optimization problem:

$$\begin{aligned} \underset{\mathcal{T}}{\text{minimize:}} \quad & \sum_{(\mathbf{x}, y) \in \mathcal{D}} \ell(\mathbf{x}, y; \mathcal{T}) \\ \text{subject to:} \quad & \begin{cases} \text{rank}(\mathcal{T}) \leq (r_1, r_2, ..., r_{n+2}) \\ \qquad\qquad \text{(Tucker-form)} \\ \text{rank}(\mathcal{T}) \leq r \quad \text{(CP-form)} \end{cases} \end{aligned} \quad (5)$$

where the constraints on rank($\mathcal{T}$) depend on the chosen tensor approximation method (§2).

The above framework has some advantages: First, as discussed in §1 and here, we hope the representations capture rich interactions between different parts of the lexical features; the low-rank tensor approximation methods keep the most important interaction information of the original tensor, while significantly reducing its size. Second, the low-rank structure will encourage weight-sharing among lexical features with similar decomposed parts, leading

[2] u, y, w_i denote one-hot vectors instead of symbols.

to better model generalization. Note that there are examples where features have different numbers of multiple lexical parts, such as both unigram and bigram features in PP-attachment. We will use two different methods to handle these features (§5).

Remarks (advantages of our factorization) Compared to prior work, e.g. (Lei et al., 2014; Lei et al., 2015), the proposed factorization has the following advantages:

1. **Parameter explosion** when mapping a view with lexical properties to its representation vector (as will be discussed in 4.3): Our factorization allows the model to treat word embeddings as inputs to the views of lexical parts, dramatically reducing the parameters. Prior work cannot do this since its views are mixtures of lexical and non-lexical properties. Note that Lei et al. (2014) uses embeddings by *concatenating* them to specific views, which increases dimensionality, but the improvement is limited.

2. **No weight-sharing** among conjunctions with same lexical property, like the child-word "word(c)" and its conjunction with head-postag "word(c) $\wedge$ word(g)" in Figure 1(b). The factorization in prior work treats them as *independent* features, greatly increasing the dimensionality. Our factorization builds representations of both features based on the embedding of "word(c)", thus utilizing their connections and reducing the dimensionality.

The above advantages are also key to overcome the problems of prior work mentioned at the end of §1.

4 Feature Representations via Low-rank Tensor Approximations

Using one-hot encodings for each of the parts of feature ϕ results in a very large tensor. This section shows how to compute the score in (4) without constructing the full feature tensor using two tensor approximation methods (§4.1 and §4.2).

We begin with some intuition. To score the original (full rank) tensor representation of ϕ, we need a parameter tensor $\mathcal{T}$ of size $d_1 \times d_2 \times \ldots \times d_{n+2}$, where $d_3 = \cdots = d_{n+2} = |V|$ is the vocabulary size, n is the number of lexical parts in the feature and $d_1 = |L|$ and $d_2 = |F|$ are the number of different labels and non-lexical properties, respectively. (§5 will handle n varying across features.) Our methods reduce the tensor size by embedding each part of ϕ into a lower dimensional space, where we represent each label, non-lexical property and words with an $r_1, r_2, r_3, \ldots, r_{n+2}$ dimensional vector respectively ($r_i \ll d_i$, $\forall i$). These embedded features can then be scored by much smaller tensors. We denote the above transformations as matrices $\mathrm{W}_l \in \mathbb{R}^{r_1 \times d_1}$, $\mathrm{W}_f \in \mathbb{R}^{r_2 \times d_2}$, $\mathrm{W}_i \in \mathbb{R}^{r_{i+2} \times d_{i+2}}$ for $i = 1, \ldots, n$, and write corresponding low-dimensional hidden representations as $\mathbf{h}_{\mathrm{y}}^{(l)} = \mathrm{W}_l \mathrm{y}$, $\mathbf{h}_{\mathrm{u}}^{(f)} = \mathrm{W}_f \mathrm{u}$ and $\mathbf{h}_{\mathrm{w}}^{(i)} = \mathrm{W}_i \mathrm{w}$.

In our methods, the above transformations of embeddings are *parts of low-rank tensors* as in (5), so the embeddings of non-lexical properties and labels can be trained simultaneously with the low-rank tensors. Note that for one-hot input encodings the transformation matrices are essentially lookup tables, making the computation of these transformations sufficiently fast.

4.1 Tucker Form

For our first approximation, we assume that tensor $\mathcal{T}$ has a low-rank Tucker decomposition: $\mathcal{T} = g \times_l \mathrm{W}_l \times_f \mathrm{W}_f \times_{\mathrm{w}_1} \mathrm{W}_1 \times_{\mathrm{w}_2} \cdots \times_{\mathrm{w}_n} \mathrm{W}_n$. We can then express the scoring function (4) for a feature $\phi = (\mathrm{y}, \mathrm{u}, \mathrm{w}_1, \ldots \mathrm{w}_n)$ with n-lexical parts, as:

$$\begin{aligned} & s(\mathrm{y}, \mathrm{u}, \mathrm{w}_1, \cdots, \mathrm{w}_n; g, \mathrm{W}_l, \mathrm{W}_f, \{\mathrm{W}_i\}_{i=1}^{n}) \\ & = g \times_l \mathbf{h}_{\mathrm{y}}^{(l)} \times_f \mathbf{h}_{\mathrm{u}}^{(f)} \times_{\mathrm{w}_1} \mathbf{h}_{\mathrm{w}_1}^{(1)} \cdots \times_{\mathrm{w}_n} \mathbf{h}_{\mathrm{w}_n}^{(n)}, \quad (6) \end{aligned}$$

which amounts to first projecting u, y, and w_i (for all i) to lower dimensional vectors $\mathbf{h}_{\mathrm{u}}^{(f)}, \mathbf{h}_{\mathrm{y}}^{(l)}, \mathbf{h}_{\mathrm{w}_i}^{(i)}$, and then weighting these hidden representations using the flattened core tensor g. The low-dimensional representations and the corresponding weights are learned jointly using a discriminative (supervised) criterion. We call the model based on this representation the *Low-Rank Feature Representation with Tucker form*, or LRFR$_n$-TUCKER.

4.2 CP Form

For the Tucker approximation the number of parameters in (6) scale exponentially with the number of lexical parts. For instance, suppose each $\mathbf{h}_{\mathrm{w}_i}^{(i)}$ has dimensionality r, then $|g| \propto r^n$. To address scalability and further control the complexity of our tensor based model, we approximate the parameter tensor using CP decomposition as in (2), resulting in the following scoring function:

$$s(\mathrm{y}, \mathrm{u}, \mathrm{w}_1, \cdots, \mathrm{w}_n; \mathrm{W}_l, \mathrm{W}_f, \{\mathrm{W}_i\}_{i=1}^n) = \sum_{j=1}^{r} \left(\mathbf{h}_{\mathrm{y}}^{(l)} \circ \mathbf{h}_{\mathrm{u}}^{(\mathbf{f})} \circ \mathbf{h}_{\mathrm{w}_1}^{(1)} \circ \cdots \circ \mathbf{h}_{\mathrm{w}_n}^{(n)}\right)_j. \quad (7)$$

We call this model *Low-Rank Feature Representation with CP form* (LRFR$_n$-CP).

4.3 Pre-trained Word Embeddings

One of the computational and statistical bottlenecks in learning these LRFR$_n$ models is the vocabulary size; the number of parameters to learn in each matrix W_i scales linearly with $|V|$ and would require very large sets of labeled training data. To alleviate this problem, we use pre-trained continuous word embeddings (Mikolov et al., 2013) as input embeddings rather than the one-hot word encodings. We denote the m-dimensional word embeddings by e_{w}; so the transformation matrices W_i for the lexical parts are of size $r_i \times m$ where $m \ll |V|$.

We note that when sufficiently large labeled data is available, our model allows for fine-tuning the pre-trained word embeddings to improve the expressive strength of the model, as is common with deep network models.

Remarks Our LRFRs introduce embeddings for non-lexical properties and labels, making them better suit the common setting in NLP: rich linguistic properties; and large label sets such as open-domain tasks (Hoffmann et al., 2010). The LRFR-CP better suits n-gram features, since when n increases 1, the only new parameters are the corresponding W_i. It is also very efficient during prediction ($O(nr)$), since the cost of transformations can be ignored with the help of look-up tables and pre-computing.

5 Learning Representations for n-gram Lexical Features of Mixed Lengths

For features with n lexical parts, we can train an LRFR$_n$ model to obtain their representations. However, we often have features of varying n (e.g. both unigrams (n=1) and bigrams (n=2) as in Figure 1). We require representations for features with arbitrary different n simultaneously.

We propose two solutions. The first is a straightforward solution based on our framework, which handles each n with a $(n+2)$-way tensor. This strategy is commonly used in NLP, e.g. Taub-Tabib et al. (2015) have different kernel functions for different order of dependency features. The second is an approximation method which aims to use a single tensor to handle all ns.

Multiple Low-Rank Tensors Suppose that we can divide the feature set $S(\mathbf{x}, \mathrm{y})$ into subsets $S_1(\mathbf{x}, \mathrm{y}), S_2(\mathbf{x}, \mathrm{y}), \ldots, S_n(\mathbf{x}, \mathrm{y})$ which correspond to features with one lexical part (unigram features), two lexical parts (bigram features),... and n lexical parts (n-gram features), respectively. To handle these types of features, we modify the training objective as follows:

$$\underset{\mathcal{T}_1, \mathcal{T}_2, \cdots, \mathcal{T}_n}{\text{minimize}} \sum_{(\mathbf{x}, \mathrm{y}) \in D} \ell(\mathbf{x}, \mathrm{y}; \mathcal{T}_1, \mathcal{T}_2, \ldots, ...\mathcal{T}_n), \quad (8)$$

where the score of a training instance $(\mathbf{x}, \mathrm{y})$ is defined as $s(\mathbf{x}, \mathrm{y}; \mathcal{T}) = \sum_{i=1}^{n} \sum_{\phi \in S_i(\mathbf{x}, \mathrm{y})} s(\phi; \mathcal{T}_i)$. We use the Tucker form low-rank tensor for $\mathcal{T}_1$, and the CP form for $\mathcal{T}_i$ $(\forall i > 1)$. We refer to this method as LRFR$_1$-TUCKER & LRFR$_2$-CP.

Word Clusters Alternatively, to handle different numbers of lexical parts, we replace some lexical parts with discrete word clusters. Let $c(\mathrm{w})$ denote the word cluster (e.g. from Brown clustering) for word w. For bigram features we have:

$$\begin{aligned} & s(\mathrm{y}, \mathrm{u}, \mathrm{w}_1, \mathrm{w}_2; \mathcal{T}) \\ &= s(\mathrm{y}, \mathrm{u} \wedge c(\mathrm{w}_1), \mathrm{w}_2; \mathcal{T}) + s(\mathrm{y}, \mathrm{u} \wedge c(\mathrm{w}_2), \mathrm{w}_1; \mathcal{T}) \\ &= \mathcal{T} \times_l \mathrm{y} \times_f (\mathrm{u} \wedge c(\mathrm{w}_1)) \times_{\mathrm{w}} e_{\mathrm{w}_2} \\ &\quad + \mathcal{T} \times_l \mathrm{y} \times_f (\mathrm{u} \wedge c(\mathrm{w}_2)) \times_{\mathrm{w}} e_{\mathrm{w}_1} \quad (9) \end{aligned}$$

where for each word we have introduced an additional set of non-lexical properties that are conjunctions of word clusters and the original non-lexical properties. This allows us to reduce an n-gram feature representation to a unigram representation. The advantage of this method is that it uses a single low-rank tensor to score features with different numbers of lexical parts. This is particularly helpful when we have very limited labeled data. We denote this method as LRFR$_1$-BROWN, since we use Brown clusters in practice. In the experiments we use the

Tucker form for LRFR$_1$-BROWN.

6 Parameter Estimation

The goal of learning is to find a tensor $\mathcal{T}$ that solves problem (5). Note that this is a non-convex objective, so compared to the convex objective in a traditional log-linear model, we are trading better feature representations with the cost of a harder optimization problem. While stochastic gradient descent (SGD) is a natural choice for learning representations in large data settings, problem (5) involves rank constraints, which require an expensive proximal operation to enforce the constraints at each iteration of SGD. We seek a more efficient learning algorithm. Note that we fixed the size of each transformation matrix $\mathrm{W}_i \in \mathbb{R}^{r_i \times d_i}$ so that the smaller dimension ($r_i < d_i$) matches the upper bound on the rank. Therefore, the rank constants are always satisfied through a run of SGD and we in essence have an unconstrained optimization problem. Note that in this way we do not guarantee orthogonality and full-rank of the learned transformation matrices. These properties are assumed in general, but are not necessary according to (Kolda and Bader, 2009).

The gradients are computed via the chain-rule. We use AdaGrad (Duchi et al., 2011) and apply L2 regularization on all W_is and g, except for the case of r_i=d_i, where we will start with $\mathrm{W}_i = \mathbf{I}$ and regularize with $\|\mathrm{W}_i$ - $\mathbf{I}\|_2$. We use early-stopping on a development set.

7 Experimental Settings

We evaluate LRFR on three tasks: relation extraction, PP attachment and preposition disambiguation (see Table 1 for a task summary). We include detailed feature templates in Table 2.

PP-attachment and relation extraction are two fundamental NLP tasks, and we test our models on the largest English data sets. The preposition disambiguation task was designed for compositional semantics, which is an important application of deep learning and distributed representations. On all these tasks, we compare to the state-of-the-art.

We use the same word embeddings in Belinkov et al. (2014) on PP-attachment for a fair comparison. For the other experiments, we use the same 200-d word embeddings in Yu et al. (2015).

Relation Extraction We use the English portion of the ACE 2005 relation extraction dataset (Walker et al., 2006). Following Yu et al. (2015), we use both gold entity spans and types, train the model on the news domain and test on the broadcast conversation domain. To highlight the impact of training data size we evaluate with all 43,518 relations (entity mention pairs) and a reduced training set of the first 10,000 relations. We report precision, recall, and F1.

We compare to two baseline methods: 1) a log-linear model with a rich binary feature set from Sun et al. (2011) and Zhou et al. (2005) as described in Yu et al. (2015) (BASELINE); 2) the embedding model (FCM) of Gormley et al. (2015), which uses rich linguistic features for relation extraction. We use the same feature templates and evaluate on fine-grained relations (sub-types, 32 labels) (Yu et al., 2015). This will evaluate how LRFR can utilize non-lexical linguistic features.

PP-attachment We consider the prepositional phrase (PP) attachment task of Belinkov et al. (2014),[3] where for each PP the correct head (verbs or nouns) must be selected from content words before the PP (within a 10-word window). We formulate the task as a ranking problem, where we optimize the score of the correct head from a list of candidates with varying sizes.

PP-attachment suffers from data sparsity because of bi-lexical features, which we will model with methods in §5. Belikov et al. show that rich features – POS, WordNet and VerbNet – help this task. The combination of these features give a large number of non-lexical properties, for which embeddings of non-lexical properties in LRFR should be useful.

We extract a dev set from section 22 of the PTB following the description in Belinkov et al. (2014).

Preposition Disambiguation We consider the preposition disambiguation task proposed by Ritter et al. (2014). The task is to determine the spatial relationship a preposition indicates based on the two objects connected by the preposition. For example, "the apple on the refrigerator" indicates the "support by Horizontal Surface" relation, while "the apple on the branch" indicates the "Support from Above" relation. Since the meaning of a preposition depends

Preposition	$p, p \,\&\, w_m, p \,\&\, w_h, p \,\&\, w_m \,\&\, w_h$

Set	Template
Bag of Words	w (w is w_m or w_h), $w_m\&w_h$
Distance	Dis(w_h, w_m) & $\{w_m, w_h, w_m\&w_h\}$
Prep	w_p & $\{w_m, w_h, w_m\&w_h\}$
POS	$t(w_h)$ & $\{w_m, w_h, w_m\&w_h\}$
NextPOS	$t(w_{h+1})$ & $\{w_m, w_h, w_m\&w_h\}$
VerbNet	$P=\{p(w_h)\}$ & $\{w_m, w_h, w_m\&w_h\}$ $I[w_p \in P]$ & $\{w_m, w_h, w_m\&w_h\}$
WordNet	$R_h=\{r(w_h)\}$ & $\{w_m, w_h, w_m\&w_h\}$ $R_m=\{r(w_m)\}$ & $\{w_m, w_h, w_m\&w_h\}$

Table 2: **Up-left**: Unigram lexical features (only showing non-lexical parts) for **relation extraction** (from Yu et al. (2014)). We denote the two target entities as M_1, M_2 (with head indices h_1, h_2, NE types t_{h_1}, t_{h_2}), and their dependency path as P. **Right**: Uni/bi-gram feature for **PP-attachment**: Each feature is defined on tuple (w_m, w_p, w_h), where w_p is the preposition word, w_m is the child of the preposition, and w_h is a candidate head of w_p. $t(w)$: POS tag of word w; $p(w)$: a preposition collocation of verb w from VerbNet; $r(w)$: the root hypernym of word w in WordNet. Dis$(\cdot,\cdot)$: the number of candidate heads between two words. **Down-left**: Uni/bi-gram feature for **preposition disambiguation** (for each preposition word p, its modifier noun w_m and head noun w_h). Since the sentences are different from each other on only p, w_m and w_h, we ignore the words on the other positions.

on the combination of both its head and child word, we expect conjunctions between these word embeddings to help, i.e. features with two lexical parts.

We include three baselines: point-wise addition (SUM) (Mitchell and Lapata, 2010), concatenation (Ritter et al., 2014), and an SVM based on hand-crafted features in Table 2. Ritter et al. show that the first two methods beat other compositional models.

Hyperparameters are all tuned on the dev set. The chosen values are learning rate $\eta = 0.05$ and the weight of L2 regularizer $\lambda = 0.005$ for LRFR, except for the third LRFR in Table 3 which has $\lambda = 0.05$. We select the rank of LRFR-TUCKER with a grid search from the following values: $r_1 = \{10, 20, d_1\}$, $r_2 = \{20, 50, d_2\}$ and $r_3 = \{50, 100, 200\}$. For LRFR-CP, we select $r = \{50, 100, 200\}$. For the *PP-attachement* task there is no r_1 since it uses a ranking model. For the *Preposition Disambiguation* we do not choose r_1 since the number of labels is small.

8 Results

Relation Extraction All LRFR-TUCKER models improve over BASELINE and FCM (Table 3), making these the best reported numbers for this task. However, LRFR-CP does not work as well on the features with only one lexical part. The Tucker-form does a better job of capturing interactions between different views. In the limited training setting, we find that LRFR-CP does best.

Additionally, the primary advantage of the CP approximation is its reduction in the number of model parameters and running time. We report each model's running time for a single pass on the development set. The LRFR-CP is by far the fastest. The first three LRFR-TUCKER models are slightly slower than FCM, because they work on dense non-lexical property embeddings while FCM benefits from sparse vectors.

PP-attachment Table 4 shows that LRFR (89.6 and 90.3) improves over the previous best standalone system HPCD (88.7) by a large margin, with exactly the same resources. Belinkov et al. (2014) also reported results of parsers and parser re-rankers, which can access to additional resources (complete parses for training and complete sentences as inputs) so it is unfair to compare them with the standalone systems like HPCD and our LRFR. Nonethe-

Method	Parameters			Full Set ($\|D\|$=43,518)			Reduced Set ($\|D\|$=10,000)			Prediction

Table 3: Results on test for relation extraction. Y(es)/N(o) indicates whether embeddings are updated during training.

System	Resources Used	Acc
SVM (Belinkov et al., 2014)	distance, word, embedding, clusters, POS, WordNet, VerbNet	86.0
HPCD (Belinkov et al., 2014)	distance, embedding, POS, WordNet, VerbNet	88.7
LRFR$_1$-TUCKER & LRFR$_2$-CP	distance, embedding, POS, WordNet, VerbNet	**90.3**
LRFR$_1$-BROWN	distance, embedding, clusters, POS, WordNet, VerbNet	89.6
RBG (Lei et al., 2014)	dependency parser	88.4
Charniak-RS (McClosky et al., 2006)	dependency parser + re-ranker	88.6
RBG + HPCD (combined model)	dependency parser + distance, embedding, POS, WordNet, VerbNet	90.1

Table 4: PP-attachment test accuracy. The baseline results are from Belinkov et al. (2014).

less LRFR$_1$-TUCKER & LRFR$_2$-CP (90.3) still outperforms the state-of-the-art parser RBG (88.4), reranker Charniak-RS (88.6), and the combination of the state-of-the-art parser and compositional model RBG + HPCD (90.1). Thus, even with fewer resources, LRFR becomes the new best system.

Not shown in the table: we also tried LRFR$_1$-TUCKER & LRFR$_2$-CP with *postag features only* (89.7), and with grand-head-modifier conjunctions removed (89.3) . Note that compared to LRFR, RBG benefits from binary features, which also exploit grand-head-modifier structures. Yet the above reduced models still work better than RBG (88.4) without using additional resources.[4] Moreover, the results of LRFR can still be potentially improved by combining with binary features. The above results show the advantage of our factorization method, which allows for utilizing pre-trained word embeddings, and thus can benefit from semi-supervised learning.

Method	Accuracy
SVM - Lexical Features	85.09
SUM	80.55
Concatenation	86.73
LRFR$_1$-TUCKER & LRFR$_2$-CP	87.82
LRFR$_1$-BROWN	**88.18**
LRFR$_1$-BROWN - Control	84.18

Table 5: Accuracy for spatial classification of PPs.

Preposition Disambiguation LRFR improves (Table 5) over the best methods (SUM and Concatenation) in Ritter et al. (2014) as well as the SVM based on the original lexical features (85.1). In this task LRFR$_1$-BROWN better represents the unigram and bigram lexical features, compared to the usage of two low-rank tensors (LRFR$_1$-TUCKER & LRFR$_2$-CP). This may be because LRFR$_1$-BROWN has fewer parameters, which is better for smaller training sets.

We also include a control setting (LRFR$_1$-BROWN - Control), which has a full rank parameter tensor with the same inputs on each view as LRFR$_1$-BROWN, but represented as one hot vectors without transforming to the hidden representations $\mathbf{h}$s. This is equivalent to an SVM with the compound cluster features as in Koo et al. (2008). It performs much worse than LRFR$_1$-BROWN, showing the advantage of using word embeddings and low-rank tensors.

Summary For unigram lexical features, LRFR$_n$-TUCKER achieves better results than LRFR$_n$-CP. However, in settings with fewer training examples,

[4] Still this is not a fair comparison since we have different training objectives. Using RBG's factorization and training with our objective will give a fair comparison and we leave it to future work.

features with more lexical parts (n-grams), or when faster predictions are advantageous, LRFR$_n$-CP does best as it has fewer parameters to estimate. For n-grams of variable length, LRFR$_1$-TUCKER & LRFR$_2$-CP does best. In settings with fewer training examples, LRFR$_1$-BROWN does best as it has only one parameter tensor to estimate.

9 Related Work

Dimensionality Reduction for Complex Features is a standard technique to address high-dimensional features, including PCA, alternating structural optimization (Ando and Zhang, 2005), denoising autoencoders (Vincent et al., 2008), and feature embeddings (Yang and Eisenstein, 2015). These methods treat features as atomic elements and ignore the inner structure of features, so they learn separate embedding for each feature without shared parameters. As a result, they still suffer from large parameter spaces when the feature space is very huge.[5]

Another line of research studies the inner structures of lexical features: e.g. Koo et al. (2008), Turian et al. (2010), Sun et al. (2011), Nguyen and Grishman (2014), Roth and Woodsend (2014), and Hermann et al. (2014) used pre-trained word embeddings to replace the lexical parts of features ; Srikumar and Manning (2014), Gormley et al. (2015) and Yu et al. (2015) propose splitting lexical features into different parts and employing tensors to perform classification. The above can therefore be seen as special cases of our model that only embed a certain part (view) of the complex features. This restriction also makes their model parameters form a full rank tensor, resulting in data sparsity and high computational costs when the tensors are large.

Composition Models (Deep Learning) build representations for structures based on their component word embeddings (Collobert et al., 2011; Bordes et al., 2012; Socher et al., 2012; Socher et al., 2013b). When using only word embeddings, these models achieved successes on several NLP tasks, but sometimes fail to learn useful syntactic or semantic patterns beyond the strength of combinations of word embeddings, such as the dependency relation in Figure 1(a). To tackle this problem, some work designed their model structures according to a specific kind of linguistic patterns, e.g. dependency paths (Ma et al., 2015; Liu et al., 2015), while a recent trend enhances compositional models with linguistic features. For example, Belinkov et al. (2014) concatenate embeddings with linguistic features before feeding them to a neural network; Socher et al. (2013a) and Hermann and Blunsom (2013) enhanced Recursive Neural Networks by refining the transformation matrices with linguistic features (e.g. phrase types). These models are similar to ours in the sense of learning representations based on linguistic features and embeddings.

Low-rank Tensor Models for NLP aim to handle the conjunction among different views of features (Cao and Khudanpur, 2014; Lei et al., 2014; Chen and Manning, 2014). Yu and Dredze (2015) proposed a model to compose phrase embeddings from words, which has an equivalent form of our CP-based method under certain restrictions. Our work applies a similar idea to exploiting the inner structure of complex features, and can handle n-gram features with different ns. Our factorization (§3) is general and easy to adapt to new tasks. More importantly, it makes the model benefit from pre-trained word embeddings as shown by the PP-attachment results.

10 Conclusion

We have presented LRFR, a feature representation model that exploits the inner structure of complex lexical features and applies a low-rank tensor to efficiently score features with this representation. LRFR attains the state-of-the-art on several tasks, including relation extraction, PP-attachment, and preposition disambiguation. We make our implementation available for general use.[6]

Abstract

We provide the first extensive evaluation of how using different types of context to learn skip-gram word embeddings affects performance on a wide range of intrinsic and extrinsic NLP tasks. Our results suggest that while intrinsic tasks tend to exhibit a clear preference to particular types of contexts and higher dimensionality, more careful tuning is required for finding the optimal settings for most of the extrinsic tasks that we considered. Furthermore, for these extrinsic tasks, we find that once the benefit from increasing the embedding dimensionality is mostly exhausted, simple concatenation of word embeddings, learned with different context types, can yield further performance gains. As an additional contribution, we propose a new variant of the skip-gram model that learns word embeddings from weighted contexts of substitute words.

1 Introduction

Word embeddings have become increasingly popular lately, proving to be valuable as a source of features in a broad range of NLP tasks with limited supervision (Turian et al., 2010; Collobert et al., 2011; Socher et al., 2013; Bansal et al., 2014). `word2vec`[1] skip-gram (Mikolov et al., 2013a) and `GloVe`[2] (Pennington et al., 2014) are among the most widely used word embedding models today. Their success is largely due to an efficient and user-friendly implementation that learns high-quality word embeddings from very large corpora.

Both `word2vec` and `GloVe` learn low-dimensional continuous vector representations for words by considering window-based contexts, i.e., context words within some fixed distance of each side of the target word. However, the underlying models are equally applicable to different choices of context types. For example, Bansal et al. (2014) and Levy and Goldberg (2014) showed that using syntactic contexts rather than window contexts in `word2vec` captures *functional* similarity (as in *lion:cat*) rather than *topical* similarity or *relatedness* (as in *lion:zoo*). Further, Bansal et al. (2014) and Melamud et al. (2015b) showed the benefits of such modified-context embeddings in dependency parsing and lexical substitution tasks. However, to the best of our knowledge, there has not been an extensive evaluation of the effect of multiple, diverse context types on a wide range of NLP tasks.

Word embeddings are typically evaluated on *intrinsic* and *extrinsic* tasks. Intrinsic tasks mostly include predicting human judgments of semantic relations between words, e.g., as in WordSim-353 (Finkelstein et al., 2001), while extrinsic tasks include various 'real' downstream NLP tasks, such as coreference resolution and sentiment analysis. Re-

cent works have shown that while intrinsic evaluations are easier to perform, their correlation with results on extrinsic evaluations is not very reliable (Schnabel et al., 2015; Tsvetkov et al., 2015), stressing the importance of the latter.

In this work, we provide the first extensive evaluation of word embeddings learned with different types of context, on a wide range of intrinsic similarity and relatedness tasks, and extrinsic NLP tasks, namely dependency parsing, named entity recognition, coreference resolution, and sentiment analysis. We employ contexts based of different word window sizes, syntactic dependencies, and a lesser-known substitute words approach (Yatbaz et al., 2012). Finally, we experiment with combinations of the above word embeddings, comparing two approaches: (1) simple vector concatenation that offers a wider variety of features for a classifier to choose and learn weighted combinations from, and (2) dimensionality reduction via either Singular Value Decomposition or Canonical Correlation Analysis, which tries to find a smaller subset of features.

Our results suggest that it is worthwhile to carefully choose the right type of word embeddings for an extrinsic NLP task, rather than rely on intrinsic benchmark results. Specifically, picking the optimal context type and dimensionality is critical. Furthermore, once the benefit from increasing the embedding dimensionality is mostly exhausted, concatenation of word embeddings learned with different context types can yield further performance gains.

2 Word Embedding Context Types

2.1 Learning Corpus

We use a fixed learning corpus for a fair comparison of all embedding types: a concatenation of three large English corpora: (1) English Wikipedia 2015, (2) UMBC web corpus (Han et al., 2013), and (3) English Gigaword (LDC2011T07) newswire corpus (Parker et al., 2011). Our concatenated corpus is diverse and substantial in size with approximately 10B words. This allows us to learn high quality embeddings that cover a large vocabulary. After extracting clean text from these corpora, we used Stanford CoreNLP (Manning et al., 2014) for sentence splitting, tokenization, part-of-speech tagging and dependency parsing.[3] Then, all tokens were lowercased, and sentences were shuffled to prevent structured bias. When learning word embeddings, we ignored words with corpus frequency lower than 100, yielding a vocabulary of about 500K words.[4]

2.2 Window-based Word Embeddings

We used `word2vec`'s skip-gram model with negative sampling (Mikolov et al., 2013b) to learn window-based word embeddings.[5] This popular method embeds both target words and contexts in the same low-dimensional space, where the embeddings of a target and context are pushed closer together the more frequently they co-occur in a learning corpus. Indirectly, this also results in similar embeddings for target words that co-occur with similar contexts. More formally, this method optimizes the following objective function:

$$L = \sum_{(t,c) \in PAIRS} L_{t,c} \tag{1}$$

$$L_{t,c} = \log \sigma(v'_c \cdot v_t) + \sum_{neg \in NEGS_{(t,c)}} \log \sigma(-v'_{neg} \cdot v_t) \tag{2}$$

where v_t and v'_c are the vector representations of target word t and context word c. $PAIRS$ is the set of window-based co-occurring target-context pairs considered by the model that depends on the window size, and $NEGS_{(t,c)}$ is a set of randomly sampled context words used with the pair (t, c).[6]

We experimented with window sizes of 1, 5, and 10, and various dimensionalities. We denote a window-based word embedding with window size of n and dimensionality of m with Wn^m. For example, W5^{300} is a word embedding learned using a window size of 5 and dimensionality of 300.

2.3 Dependency-based Word Embeddings

We used `word2vecf`[7] (Levy and Goldberg, 2014), to learn dependency-based word embeddings from

[3] Parses follow the Universal Dependencies formalism and were produced by Stanford CoreNLP, version 3.5.2

[4] Our word embeddings are available at: `www.cs.biu.ac.il/nlp/resources/downloads/embeddings-contexts/`

[5] We used negative sampling = 5 and iterations = 3 in all of the experiments described in this paper.

[6] For more details refer to Mikolov et al. (2013b).

[7] `http://bitbucket.org/yoavgo/word2vecf`

the parsed version of our corpus, similar to the approach of Bansal et al. (2014). `word2vecf` accepts as its input arbitrary target-context pairs. In the case of dependency-based word embeddings, the context elements are the syntactic contexts of the target word, rather than the words in a window around it. Specifically, following Levy and Goldberg (2014), we first 'collapsed' prepositions (as implemented in `word2vecf`). Then, for a target word t with modifiers m_1,...,m_k and head h, we paired the target word with the context elements (m_1, r_1),...,(m_k, r_k),(h, r_h^{-1}), where r is the type of the dependency relation between the head and the modifier (e.g., *dobj*, *prep_of*) and r^{-1} denotes an inverse relation. We denote a dependency-based word embedding with dimensionality of m by DEP^m. We note that under this setting `word2vecf` optimizes the same objective function described in Equation (1), with $PAIRS$ now comprising dependency-based pairs instead of window-based ones.

2.4 Substitute-based Word Embeddings

Substitute vectors are a recent approach to representing contexts of target words, proposed in Yatbaz et al. (2012). Instead of the neighboring words themselves, a substitute vector includes the potential filler words for the target word slot, weighted according to how 'fit' they are to fill the target slot *given* the neighboring words. For example, the substitute vector representing the context of the word *love* in "I love my job", could look like: [*quit* 0.5, *love* 0.3, *hate* 0.1, *lost* 0.1]. Substitute-based contexts are generated using a language model and were successfully used in distributional semantics models for part-of-speech induction (Yatbaz et al., 2012), word sense induction (Baskaya et al., 2013), functional semantic similarity (Melamud et al., 2014) and lexical substitution tasks (Melamud et al., 2015a).

Similar to Yatbaz et al. (2012), we consider the words in a substitute vector, as a weighted set of contexts 'co-occurring' with the observed target word. For example, the above substitute vector is considered as the following set of weighted target-context pairs: $\{$(*love*, *quit*, 0.5), (*love*, *love*, 0.3), (*love*, *hate*, 0.1), (*love*, *lost*, 0.1)$\}$. To learn word embeddings from such weighted target-context pairs, we extended `word2vecf` by modifying the objective function in Equation (1) as follows:

$$L = \sum_{(t,c)\in PAIRS} \alpha_{t,c} \cdot L_{t,c} \tag{3}$$

where $\alpha_{t,c}$ is the weight of the target-context pair (t, c). With this simple modification, the effect of target-context pairs on the learned word representations becomes proportional to their weights.

W10^{300}	DEP^{300}	SUB^{300}
played	play	singing
play	played	rehearsing
plays	understudying	performing
professionally	caddying	composing
player	plays	running

Table 1: The top five words closest to target word *playing* in different embedding spaces.

To generate the substitute vectors we followed the methodology in (Yatbaz et al., 2012; Melamud et al., 2015a). We learned a 4-gram Kneser-Ney language model from our learning corpus using KenLM (Heafield et al., 2013). Then, we used FASTSUBS (Yuret, 2012) with this language model to efficiently generate substitute vectors, where the weight of each substitute s is the conditional probability $p(s|C)$ for this substitute to fill the target slot given the sentential context C. For efficiency, we pruned the substitute vectors to their top-10 substitutes, $s_1..s_{10}$, and normalized their probabilities such that $\sum_{i=1..10} p(s_i|C) = 1$. We also generated only up to 20,000 substitute vectors for each target word type. Finally, we converted each substitute vector into weighted target-substitute pairs and used our extended version of `word2vecf` to learn the substitute-based word embeddings, denoted SUB^m.

2.5 Qualitative Effect of Context Type

To motivate the rest of our work, we first qualitatively inspect the top most-similar words to some target words, using cosine similarity of their respective embeddings. As illustrated in Table 1, in embeddings learned with large window contexts, we see both functionally similar words and topically similar words, sometimes with a different part-of-speech. With small windows and dependency contexts, we generally see much fewer topically similar words, which is consistent with previous findings (Bansal et al., 2014; Levy and Goldberg, 2014). Finally, with substitute-based contexts, there appears to be even a stronger preference for functional similarity, with a tendency to also strictly preserve verb tense.

3 Word Embedding Combinations

As different choices of context type yield word embeddings with different properties, we hypothesize that combinations of such embeddings could be more informative for some extrinsic tasks. We experimented with two alternative approaches to combine different sets of word embeddings: (1) Simple vector concatenation, which is a lossless combination that comes at the cost of increased dimensionality, and (2) SVD and CCA, which are lossy combinations that attempt to capture the most useful information from the different embeddings sets with lower dimensionality. The methods used are described in more detail next.

3.1 Concatenation

Perhaps the simplest way to combine two different sets of word embeddings (sharing the same vocabulary) is to concatenate their word vectors for every word type. We denote such a combination of word embedding set A with word embedding set B using the symbol (+). For example W10+DEP^{600} is the concatenation of W10^{300} with DEP^{300}. Naturally, the dimensionality of the concatenated embeddings is the sum of the dimensionalities of the component embeddings. In our experiments, we only ever combine word embeddings of equal dimensionality.

The motivation behind concatenation relates primarily to supervised models in extrinsic tasks. In such settings, we hypothesize that using concatenated word embeddings as input features to a classifier could let it choose and combine (i.e., via learned weights) the most suitable features for the task. Consider a situation where the concatenated embedding W10+DEP^{600} is used to represent the word inputs to a named entity recognition classifier. In this case, the classifier could choose, for instance, to represent entity words mostly with dependency-based embedding features (reflecting functional semantics), and surrounding words with large window-based embedding features (reflecting topical semantics).

3.2 Singular Value Decomposition

Singular Value Decomposition (SVD) has been shown to be effective in compressing sparse word representations (Levy et al., 2015). In this work, we use this technique in the same way to reduce the dimensionality of concatenated word embeddings.

3.3 Canonical Correlation Analysis

Recent work used Canonical Correlation Analysis (CCA) to derive an improved set of word embeddings. The main idea is that two distinct sets of word embeddings, learned with different types of input data, are considered as multi-views of the same vocabulary. Then, CCA is used to project each onto a lower dimensional space, where correlation between the two is maximized. The correlated information is presumably more reliable. Dhillon et al. (2011) considered their two CCA views as embeddings learned from the left and from the right context of the target words, showing improvements on chunking and named entity recognition. Faruqui and Dyer (2014) and Lu et al. (2015) considered multilingual views, showing improvements in several intrinsic tasks, such as word and phrase similarity.

Inspired by this prior work, we consider pairs of word embedding sets, learned with different types of context, as different views and correlate them using linear CCA.[8] We use either the SimLex-999 or WordSim-353-R intrinsic benchmark (section 4.1) to tune the CCA hyperparameters[9] with the Spearmint Bayesian optimization tool[10] (Snoek et al., 2012). This results in different projections for each of these tuning objectives, where SimLex-999/WordSim-353-R is expected to give some bias towards functional/topical similarity, respectively.

4 Evaluation

4.1 Intrinsic Benchmarks

We employ several commonly used intrinsic benchmarks for assessing how well word embeddings mimic human judgements of semantic similarity of words. The popular **WordSim-353** dataset (Finkelstein et al., 2001) includes 353 word pairs manually

[8] See Faruqui and Dyer (2014), Lu et al. (2015) for details.

[9] These are projection dimensionality and regularization.

[10] `github.com/JasperSnoek/spearmint`

annotated with a degree of similarity. For example, *computer*:*keyboard* is annotated with 7.62, indicating a relatively high degree of similarity. While WordSim-353 does not make a distinction between different 'flavors' of similarity, Agirre et al. (2009) proposed two subsets of this dataset, **WordSim-353-S** and **WordSim-353-R**, which focus on functional and topical similarities, respectively. **SimLex-999** (Hill et al., 2014) is a larger word pair similarity dataset with 999 annotated pairs, purposely built to focus on functional similarity. We evaluate our embeddings on these datasets by computing a score for each pair as the cosine similarity of two word vectors. The Spearman's correlation[11] between the ranking of word pairs induced from the human annotations and that from the embeddings is reported.

The **TOEFL** task contains 80 synonym selection items, where a synonym of a target word is to be selected out of four possible choices. We report the overall accuracy of a system that uses cosine distance between the embeddings of the target word and each of the choices to select the one most similar to the target word as the answer.

4.2 Extrinsic Benchmarks

The following four diverse downstream NLP tasks serve as our extrinsic benchmarks.[12]

1) Dependency Parsing (PARSE) The Stanford Neural Network Dependency (NNDEP) parser (Chen and Manning, 2014) uses dense continuous representations of words, parts-of-speech and dependency labels. While it can learn these representations entirely during the training on labeled data, Chen and Manning (2014) show that initialization with word embeddings, which were pre-trained on unlabeled data, yields improved performance. Hence, we used our different types of embeddings to initialize the NNDEP parser and compared their performance on a standard Penn Treebank benchmark. We used WSJ sections 2–21 for training and 22 for development. We used predicted tags produced via 20-fold jackknifing on sections 2–21 with the Stanford CoreNLP tagger.

2) Named Entity Recognition (NER) We used the NER system of Turian et al. (2010), which allows adding word embedding features (on top of various other features) to a regularized averaged perceptron classifier, and achieves near state-of-the-art results using several off-the-shelf word representations. We varied the type of word embeddings used as features when training the NER model, to evaluate their effect on NER benchmarks results. Following Turian et al. (2010), we used the CoNLL-2003 shared task dataset (Tjong Kim Sang and De Meulder, 2003) with 204K/51K train/dev words, as our main benchmark. We also performed an out-of-domain evaluation, using CoNLL-2003 as the train set and the MUC7 formal run (59K words) as the test set.[13]

3) Coreference Resolution (COREF) We used the Berkeley Coreference System (Durrett and Klein, 2013), which achieves near state-of-the-art results with a log-linear supervised model. Most of the features in this model are associated with pairs of *current* and *antecedent* reference mentions, for which a coreference decision needs to be made. To evaluate the contribution of different word embedding types to this model, we extended it to support the following additional features: $\{a_i\}_{i=1..m}$, $\{c_i\}_{i=1..m}$ and $\{a_i \cdot c_i\}_{i=1..m}$, where a_i or c_i is the value of the ith dimension in a word embedding vector representing the antecedent or current mention, respectively. We considered two different word embedding representations for a mention: (1) the embedding of the head word of the mention and (2) the average embedding of all words in the mention. The features of both types of representations were presented to the learning model as inputs at the same time. They were added on top of Berkeley's full feature list ('FINAL') as described in Durrett and Klein (2013). We evaluated our features on the CoNLL-2012 coreference shared task (Pradhan et al., 2012).

4) Sentiment Analysis (SENTI) Following Faruqui et al. (2014), we used a sentence-level binary decision version of the sentiment analysis task from Socher et al. (2013). In this setting, neutral sentences were discarded and all remaining sentences were labeled coarsely as positive or negative. Maintaining the original split into train/dev

[11] We used `spearmanr`, SciPy version 0.15.1.

[12] Since our goal is to explore performance trends, we mostly experimented with the tasks' development sets.

[13] See Turian et al. (2010) for more details on this setting.

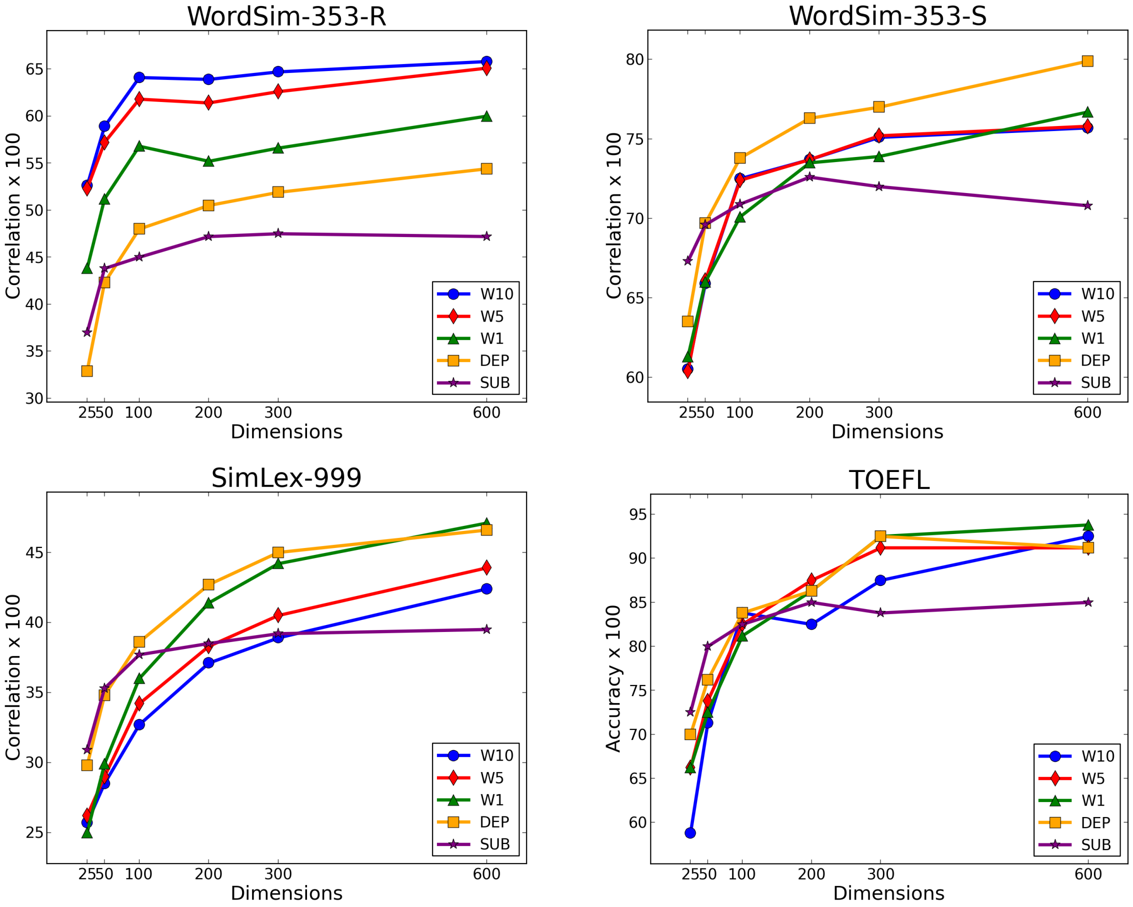

Figure 1: Intrinsic tasks' results for embeddings learned with different types of contexts.

results, we get a dataset containing 6920/872 sentences. To evaluate different types of word embeddings, we represented each sentence as an average of its word embeddings and then used an L2-regularized logistic regression classifier trained on these features to predict the sentiment labels.

5 Results

5.1 Intrinsic Results for Context Types

The results on the intrinsic tasks are illustrated in Figure 1. First, we see that the performance on all tasks generally increases with the number of dimensions, reaching near-optimal performance at around 300 dimensions, for all types of contexts. This is in line with similar observations on skip-gram word embeddings (Mikolov et al., 2013a).

Looking further, we observe that there are significant differences in the results when using different types of contexts. The effect of context choice is perhaps most evident in the WordSim-353-R task, which captures topical similarity. As might be expected, in this benchmark, the largest-window word embeddings perform best. The performance decreases with the decrease in window size and then reaches significantly lower levels for dependency (DEP) and substitute-based (SUB) embeddings. Conversely, in WordSim-353-S and SimLex-999, both of which capture a more functional similarity, the DEP embeddings are the ones that perform best, strengthening similar observations in Levy and Goldberg (2014). Finally, in the TOEFL benchmark, all contexts except for SUB, perform comparably.

5.2 Extrinsic Results for Context Types

The extrinsic tasks results are illustrated in Figure 2. A first observation is that optimal extrinsic results may be reached with as few as 50 dimensions. Furthermore, performance may even degrade when us-

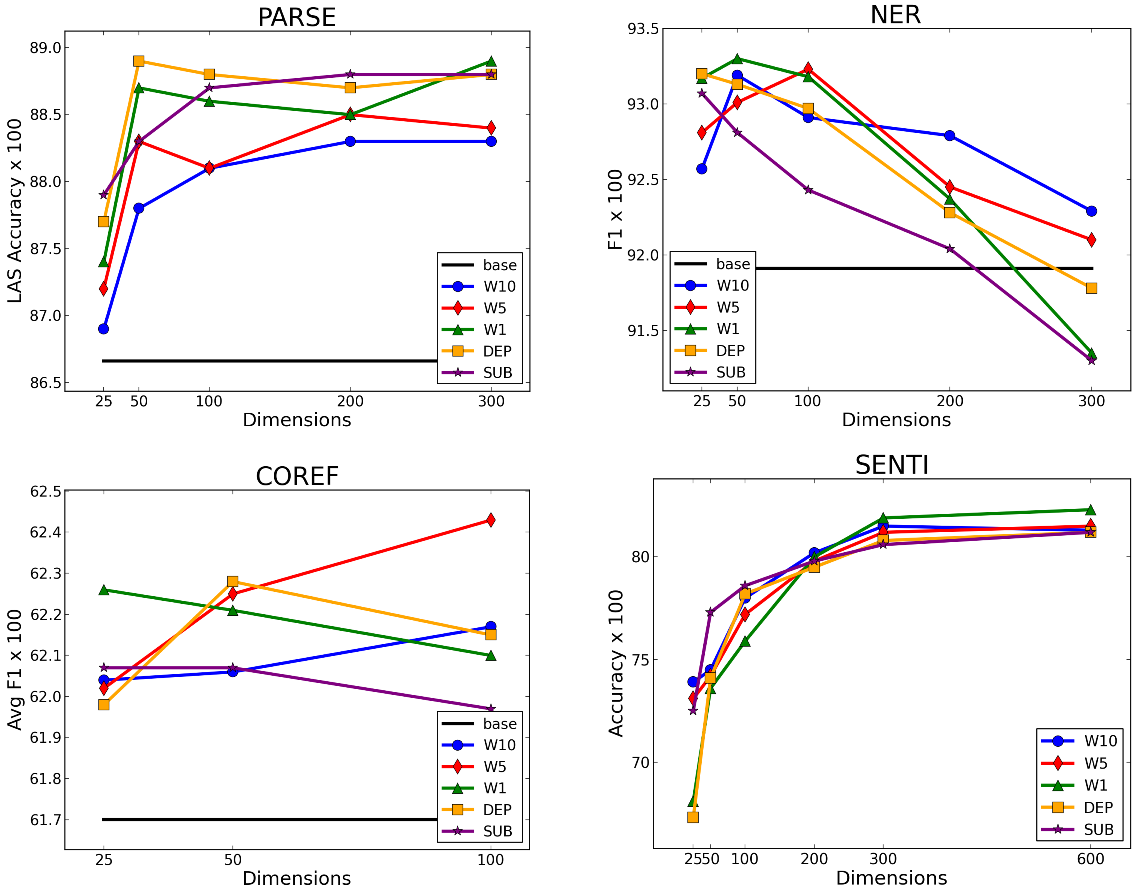

Figure 2: Extrinsic tasks' development set results for embeddings learned with different types of contexts. 'base' denotes the results with no word embedding features. Due to computational limitations we tested NER and PARSE with only up to 300 dimensions embeddings, and COREF with up to 100.

ing too many dimensions, as is most evident in the NER task. This behavior presumably depends on various factors, such as the size of the labeled training data or the type of classifier used, and highlights the importance of tuning the dimensionality of word embeddings in extrinsic tasks. This is in contrast to intrinsic tasks, where higher dimensionality typically yields better results.

Next, comparing the results of different types of contexts, we see, as might be expected, that dependency embeddings work best in the PARSE task. More generally, embeddings that do well in functional similarity intrinsic benchmarks and badly in topical ones (DEP, SUB and W1) work best for PARSE, while large window contexts perform worst, similar to observations in Bansal et al. (2014).

In the rest of the tasks it's difficult to say which context works best for what. One possible explanation to this in the case of NER and COREF is that the embedding features are used as add-ons to an already competitive learning system. Therefore, the total improvement on top of a 'no embedding' baseline is relatively small, leaving little room for significant differences between different contexts.

Context type	F1 x 100
DEP	79.8
W1	79.3
SUB	79.0
W10	78.1
W5	77.4
None	71.8

Table 2: NER MUC out-of-domain results for different embeddings with dimensionality = 25.

We did find a more notable contribution of word

embedding features to the overall system performance in the out-of-domain NER MUC evaluation, described in Table 2. In this out-of-domain setting, all types of contexts achieve at least five points improvement over the baseline. Presumably, this is because continuous word embedding features are more robust to differences between train and test data, such as the typical vocabulary used. However, a detailed investigation of out-of-domain settings is out of scope for this paper and left for future work.

5.3 Extrinsic Results for Combinations

A comparison of the results obtained on the extrinsic tasks using the word embedding concatenations (*concats*), described in section 3.1, versus the original single context word embeddings (*singles*), appears in Table 3. To control for dimensionality, concats are always compared against singles with identical dimensionality. For example, the 200-dimensional concat W10+DEP^{200}, which is a concatenation of W10^{100} and DEP^{100}, is compared against 200-dimensional singles, such as W10^{200}.

Looking at the results, it seems like the benefit from concatenation depends on the dimensionality and task at hand, as also illustrated in Figure 3. Given task X and dimensionality d, if $\frac{d}{2}$ is in the range where increasing the dimensionality yields significant improvement on task X, then it’s better to simply increase dimensionality of singles from $\frac{d}{2}$ to d rather than concatenate. The most evident example for this are the results on the SENTI task with $d = 50$. In this case, the benefit from concatenating two 25-dimensional singles is notably lower than that of using a single 50-dimensional word embedding. On the other hand, if $\frac{d}{2}$ is in the range where near-optimal performance is reached on task X, then concatenation seems to pay off. This can be seen in SENTI with $d = 600$, PARSE with $d = 200$, and NER with $d = 50$. More concretely, looking at the best performing concatenations, it seems like combinations of the topical W10 embedding with one of the more functional ones, SUB, DEP or W1, typically perform best, suggesting that there is added value in combining embeddings of different nature.

Finally, our experiments with the methods using SVD (section 3.2) and CCA (section 3.3) yielded degraded performance compared to single word embeddings for all extrinsic tasks and therefore are not reported for brevity. These results seem to further strengthen the hypothesis that the information captured with varied types of context is different and complementary, and therefore it is beneficial to preserve these differences as in our concatenation approach.

6 Related Work

There are a number of recent works whose goal is a broad evaluation of the performance of different word embeddings on a range of tasks. However, to the best of our knowledge, none of them focus on embeddings learned with diverse context types as we do. Levy et al. (2015), Lapesa and Evert (2014), and Lai et al. (2015) evaluate several design choices when learning word representations. However, Levy et al. (2015) and Lapesa and Evert (2014)

Dimensions	Result	SENTI	PARSE	NER	COREF
50	best+	74.3 (W10+W1)	88.7 (W10+SUB)	**93.6** (W1+DEP)	**62.4** (W10+W1)
	best	**77.3** (SUB)	**88.9** (W1)	93.3 (W1)	62.3 (DEP)
	mean+	72.7	88.3	**93.3**	62.1
	mean	**74.7**	**88.4**	93.1	**62.2**
200	best+	**81.0** (W10+SUB)	**89.1** (W1+DEP)	**93.1** (W10+DEP)	
	best	80.2 (W10)	88.8 (SUB)	92.8 (W10)	
	mean+	79.1	**88.9**	**92.8**	
	mean	**79.9**	88.6	92.4	
600	best+	**82.6** (W10+SUB)			
	best	82.3 (W1)			
	mean+	**82.0**			
	mean	81.5			

Table 3: Extrinsic tasks development set results obtained with word embeddings concatenations. 'best' and 'best+' are the best results achieved across all single context types and context concatenations, respectively (best performing embedding indicated in parenthesis). 'mean' and 'mean+' are the mean results for the same. Due to computational limitations of the employed systems, some of the evaluations were not performed.

perform only intrinsic evaluations and restrict context representation to word windows, while Lai et al. (2015) do perform extrinsic evaluations, but restrict their context representation to a word window with the default size of 5. Schnabel et al. (2015) and Tsvetkov et al. (2015) report low correlation between intrinsic and extrinsic results with different word embeddings (they did not evaluate different context types), which is consistent with differences we found between intrinsic and extrinsic performance patterns in all tasks, except parsing. Bansal et al. (2014) show that functional (dependency-based and small-window) embeddings yield higher parsing improvements than topical (large-window) embeddings, which is consistent with our findings.

Several works focus on particular types of contexts for learning word embeddings. Cirik and Yuret (2014) investigates S-CODE word embeddings based on substitute word contexts. Ling et al. (2015b) and Ling et al. (2015a) propose extensions to the standard window-based context modeling. Alternatively, another recent popular line of work (Faruqui et al., 2014; Kiela et al., 2015) attempts to improve word embeddings by using manually-constructed resources, such as WordNet. These techniques could be complementary to our work. Finally, Yin and Schütze (2015) and Goikoetxea et al. (2016) propose word embeddings combinations, using methods such as concatenation and CCA, but evaluate mostly on intrinsic tasks and do not consider different types of contexts.

7 Conclusions

In this paper we evaluated skip-gram word embeddings on multiple intrinsic and extrinsic NLP tasks, varying dimensionality and type of context. We show that while the best practices for setting skip-gram hyperparameters typically yield good results on intrinsic tasks, success on extrinsic tasks requires more careful thought. Specifically, we suggest that picking the optimal dimensionality and context type are critical for obtaining the best accuracy on extrinsic tasks and are typically task-specific. Further improvements can often be achieved by combining complementary word embeddings of different context types with the right dimensionality.

Improve Chinese Word Embeddings by Exploiting Internal Structure

hchen@ustc.edu.cn

Abstract

Recently, researchers have demonstrated that both Chinese word and its component characters provide rich semantic information when learning Chinese word embeddings. However, they ignored the semantic similarity across component characters in a word. In this paper, we learn the semantic contribution of characters to a word by exploiting the similarity between a word and its component characters with the semantic knowledge obtained from other languages. We propose a similarity-based method to learn Chinese word and character embeddings jointly. This method is also capable of disambiguating Chinese characters and distinguishing non-compositional Chinese words. Experiments on word similarity and text classification demonstrate the effectiveness of our method.

1 Introduction

Distributed representations of knowledge has received wide attention in recent years. Researchers have proposed various models to learn it at different granularity levels. Distributed word representations, also known as word embeddings, were learned in (Rumelhart et al., 1988; Bengio et al., 2006; Mnih and Hinton, 2009; Mikolov et al., 2013a). Larger granularity levels than words have also been investigated, including phrase level (Socher et al., 2010; Zhang et al., 2014; Yu and Dredze, 2015), sentence level (Le and Mikolov, 2014; Socher et al., 2013; Kalchbrenner et al., 2014; Kiros et al., 2015), and document level (Le and Mikolov, 2014; Hermann and Blunsom, 2014; Srivastava et al., 2013).

For language like Chinese, some smaller units than word also provide rich semantic information. For example, Chinese characters in word, Chinese radicals in character. These internal structures have been proved to be useful for Chinese word and character embeddings (Chen et al., 2015; Li et al., 2015). Chen et al. (2015) took Chinese characters in a word into account when modeling the semantic meaning of the word. They proposed a character-enhanced word embeddings model (CWE) by adding the embedding of component characters in a word with the same weight to the word embedding. However, the internal characters in a Chinese word have different semantic contributions to its meaning. Take Chinese word “青蛙” (frog) as an example. The character “青” (blue or green) is to decorate character “蛙” (frog). It is obvious that the latter character contributes more than the former one to the word meaning. In Li et al. (2015), they proposed a component-enhanced Chinese character embeddings model based on the feature that most Chinese characters are phono-semantic compounds. They considered characters and bi-characters as the basic embedding units. However, some bi-characters are meaningless, and may not form a Chinese word. These bi-characters may undermine embeddings of others.

This paper, motivated by Chen et al. (2015), exploits the internal structures of Chinese word, namely the Chinese characters. We propose a method to calculate the semantic contribution of characters to a word in a cross-lingual manner. The basic

San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

idea is that the semantic contribution of Chinese characters in most Chinese words can be learned from their translations in other languages. Such as the word “青蛙” we mentioned above. The word embeddings of other languages are used to calculate semantic contribution of characters to the word they compose. Moreover, Chinese characters are more ambiguous than words. To tackle this problem, multiple-prototype character embeddings is proposed. Different meanings of characters will be represented by different embeddings. Our contributions can be summarized as follows:

1. We provide a method to calculate the semantic contribution of Chinese characters to the word they compose with English translation. Compared with English, there are fewer human-made resources to supervise the learning process of Chinese word and character embeddings. While translation resources are always easy to be accessed on the Internet.

2. We propose a novel way to disambiguate Chinese characters with translating resources. There are some limitations in existing cluster-based algorithms (Huang et al., 2012; Neelakantan et al., 2015; Chen et al., 2015). They either fixed the number of clusters or proposed a nonparametric way to learn it for each word. However, the number of clusters for words varies a lot. For nonparametric method, different hyperparameters have to be tune to control the number of clusters for different datasets.

3. We provide a method to distinguish whether a Chinese word is semantically compositional automatically. Not all Chinese words exhibit semantic compositions from their component characters. For example, entity names, transliterated words like “沙发” (sofa), single-morpheme multi-character words like “徘徊” (wander). In Chen et al. (2015), they performed part-of-speech tagging to identify entity names. The transliterated words are tagged manually, which requires human work and need to be updated when new words are created.

The evaluations on word similarity, text classification, Chinese characters disambiguation, and qualitative analysis of word embeddings demonstrate the effectiveness of our method.

2 Related Work

2.1 Word2vec

Word2vec (Mikolov et al., 2013a) is an algorithm to learn distributed word representations using a neural language model. Word2vec has two models, the continuous bag-of-words model (CBOW) and the skip-gram model. In this paper, we propose a new model based on the CBOW, hence we focus attention on it. CBOW aims at predicting the target word given context words in a slide window. Given a word sequence $D = \{x_1, x_2, \ldots, x_T\}$, the objective of CBOW is to maximize the average log probability

$$L = \frac{1}{T}\sum_{i=1}^{T} \log p(x_i | x_{i-j}^{i+j}), \tag{1}$$

where x_{i-j}^{i+j} is the context words centered at x_i, $p(x_i|x_{i-j}^{i+j})$ is defined as:

$$\frac{\exp(v_{x_i}^{'\ T} \sum_{-j\le k\le j, k\ne 0} v_{x_{i+k}})}{\sum_{x=1}^{W} \exp(v_x^{'\ T} \sum_{-j\le k\le j, k\ne 0} v_{x_{i+k}})}, \tag{2}$$

where v_{x_i} and $v_{x_i}^{'}$ are the input and output vector representations of word x_i. Since the size of English vocabulary W may be up to 10^6 scale, hierarchical softmax and negative sampling (Mikolov et al., 2013b) are applied during training to learn the model efficiently. However, using CBOW to learn Chinese word embeddings directly may have some limitations. It fails to capture the internal structure of words. In (Botha and Blunsom, 2014; Luong et al., 2013; Trask et al., 2015; Chen et al., 2015), they demonstrated the usefulness to exploit the internal structure of words, and proposed some morphological-based methods. For example, Chen et al. (2015) exploit the internal structure in Chinese words.

2.2 The CWE model

The basic idea of CWE is that both external context words and internal component characters in words provide rich information in modeling the semantic meaning of the target word. In CWE, they learned word embeddings with its component characters embeddings. Let C denotes the Chinese characters set, and the word x_t in context x_{i-j}^{i+j} is composed by several characters in C, let $x_t = \{c_1, c_2, \ldots, c_{N_t}\}$, c_k denotes the k-th character in x_t,

$$\widehat{v}_{x_t} = v_{x_t} + \frac{1}{N_t}\sum_{k=1}^{N_t} v_{c_k}, \tag{3}$$

where $\widehat{v}_{x_t}$ is the modified word embedding, N_t denotes the number of Chinese characters in x_t. To address the issue of ambiguity in Chinese characters, they proposed several approaches for multiple-prototype character embeddings: position-based, cluster-based, nonparametric methods, and position-cluster-based character embeddings. These methods are denoted as CWE+P, CWE+L, CWE+N, CWE+LP respectively. However, this model has some limitations. The internal characters are of the same contribution to the semantic meaning of the word in CWE, which is not the case for most Chinese words.

3 Methodology

Our method can be described as three stages:

- **Obtain translations of Chinese words and characters**
  Chinese words segmentation tool is used to segment words in Chinese corpus. Then we use an online English-Chinese translation tool to translate all the Chinese characters and segmented words.

- **Perform Chinese character sense disambiguation**
  We train an English corpus with CBOW to get English word embeddings. Then, we merge some meanings of Chinese characters with small difference, and disambiguate the meanings of characters in words by computing the similarity between their English translation words.

- **Learn word and character embeddings with our model**
  Based on the character sense disambiguation process, we modify the objective of CWE to learn Chinese word and character embeddings. Then we analyse the complexity of our model briefly.

3.1 Obtain translations of Chinese words and characters

We use segmentation tools to segment words in Chinese training corpus, and perform part-of-speech tagging to recognize all the entity names. Since entity name words do not exhibit semantic compositions, they are identified as non-compositional words. We count the times of characters appearing in different words. Words with Chinese characters rarely combined with other characters are classified as single-morpheme multi-character words and identified as non-compositional.

Then programming interface of online translation tool is used to translate Chinese words and characters into English. For non-compositional Chinese words, they are not included in the translation list. Table 1 shows the English meanings of Chinese word “音乐”, “沙发” and their component characters “音” and “ 乐”, “沙” and “发”.

3.2 Perform Chinese character sense disambiguation

We train an English corpus with CBOW to get English word embeddings. Then, the meanings of characters with small difference are merged.

In Table 1, we observe that the difference between some meanings of character “乐” is very small, some of them differ only in their part-of-speech. In Chinese, the same characters and words are used in different part-of-speech but express the same semantic meaning. Hence these meanings are merged as one semantic meaning. Let $\mathrm{Sim}(\cdot)$ denotes the function to calculate the similarity between meanings of Chinese words and characters, we use cosine distance as the distance metric. The i-th and j-th meanings of Chinese character c are c^i and c^j. Their similarity is defined as:

$$\begin{aligned}&\mathrm{Sim}(c^i, c^j) = \max(cos(v_{x_m}, v_{x_n})),\\ &s.t.\;\; x_m \in \mathrm{Trans}(c^i), x_n \in \mathrm{Trans}(c^j),\\ &\qquad x_m, x_n \notin \mathrm{stop\_words(en)},\end{aligned} \tag{4}$$

where $\mathrm{Trans}(c^i)$ denotes the English translation words set of c^i, $\mathrm{stop\_words(en)}$ denotes the stop words in English, x_m and x_n are not in these stop words. For example, the Chinese word “音乐” in Table 1, c_2 denotes the second character

Word	English Explanation
音乐	music;
音	(声音) sound; (消息) news, tidings; (音质) tone; (姓氏) a surname;
乐	N. (音乐) music; (姓氏) a surname; (愉快; 满足) pleasure, enjoyment; JJ. (快乐) happy,glad,joyful,cheerful; V. (喜欢) enjoy, be glad to, love, find pleasure in; (笑) laugh, be amused; RB. (乐意) gladly, happily, willingly;
沙发	sofa, settee;
沙	N. (沙子) sand; (某些呈沙状的食物) granulated, powdered; (姓氏) a surname; JJ. (嗓音不清脆) (of voice) hoarse, husky;
发	N. (头发) hair; V. (送出;交付) send out, distribute, deliver; (发射) launch, discharge, shoot, emit; (产生, 发生) produce, generate, come into existence; (表达) express, utter; (扩大, 开展) expand, develop; (因得财物而兴旺) flourish; (放散, 散开) spread out, disperse, diffuse; etc.;

Table 1: English Translation of Chinese words and characters in ICIBA. V., N., JJ., RB. denote their verb, noun, adjective and adverb meaning respectively. Different meanings of word and character are separated by semicolon.

“乐” in the word. $\mathrm{Trans}(c_2^3)$ is the third translation English words set of character “乐”, which is $\{pleasure, enjoyment\}$. Therefore x_m can be pleasure or enjoyment here.

If the $\mathrm{Sim}(c^i, c^j)$ is above a threshold δ, then they are merged as one semantic meaning. For simplicity, we use the union of English translation words set. One character may be translated into several English words. We may average all the translation word embeddings and then compute the similarity, or select the maximum value of the similarity between all English word pairs. In our experiments, maximum method works better.

Finally, we perform Chinese character sense disambiguation. In Chinese, characters may have multiple meanings, but for a certain word, their meanings are determined. For exmaple, the word “音乐”, the English translation is music. For character “乐”, the first translation “music” matches the meaning of the word. For character “音”, the best match is the first translation “sound”. For transliterated word like “沙发”, the English translations are sofa and settee, neither sofa nor settee have high similarity with English translation words of character “沙” and character “发”. Formally, if $\max(\mathrm{Sim}(x_t, c_k)) > \lambda, c_k \in x_t$, then x_t is identified as compositional word, and belongs to the compositional set COMP. For compositional words, we build a set

$$F = \{(x_t, s_t, n_t) \mid x_t \in \mathrm{COMP}\}, \tag{5}$$

where

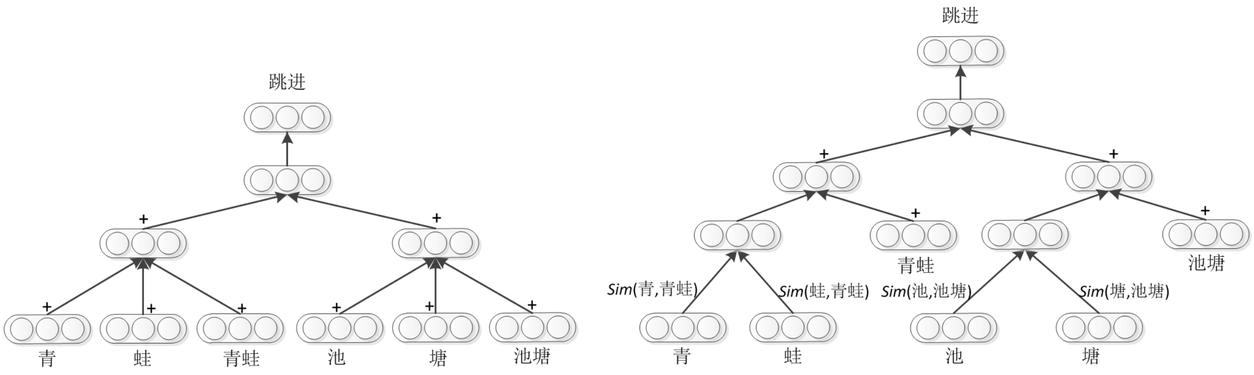
$$\begin{aligned} s_t &= \{\mathrm{Sim}(x_t, c_k) \mid c_k \in x_t\}, \\ n_t &= \{\max_i \mathrm{Sim}(x_t, c_k^i) \mid c_k \in x_t\} \end{aligned} \tag{6}$$

For example, the word “音乐” is defined as (“音乐”, $\{$Sim(“音乐”, “音”), Sim(“音乐”, “乐”)$\}$,$\{$1,1$\}$) in F.

3.3 Learn word and character vectors with SCWE

The internal characters in a word make different contributions to its semantic meaning. However, in Chen et al. (2015), the contribution of component characters to the semantic meaning of word are treated equally. They add character embeddings to the word embeddings with the same weight, which may undermine the quality of word embeddings. Based on this point, we propose a similarity-based character-enhanced word embedding model, which takes the contribution of characters into account. We name it SCWE for ease of reference in the later part. The architecture of CWE and SCWE are shown in Fig. 1.

Similarity-Based Character-Enhanced word Embedding In the character sense disambiguation stage, we build a set F, which contains compositional words, the similarity between words and its component characters, and the meaning order number of characters in the word. Suppose x_t in W is a



(a) CWE

(b) SCWE

Figure 1: Architecture of models. The left is CWE and right is SCWE. "青蛙 (frog) 跳进 (jump into) 池塘 (pond)" is the word sequence. The word "青蛙" is composed of characters "青 (blue or green)" and "蛙 (frog)", and the word "池塘 (pond) is composed of characters "池 (pond, pool)" and "塘 (pond)".

compositional word, in SCWE,

$$\widehat{v}_{x_t} = \frac{1}{2}\{v_{x_t} + \frac{1}{N_t}\sum_{k=1}^{N_t}\text{Sim}(x_t, c_k)v_{c_k}\} \qquad (7)$$

To deal with ambiguity problem of Chinese characters, we propose multiple-prototype character embeddings and denote it as SCWE+M model. Since the meaning of a character is determined in a given word, we utilize the information provided by the last element in set F, and use different character embeddings for different meanings of characters. Then, in SCWE+M,

$$\widehat{v}_{x_t} = \frac{1}{2}\{v_{x_t} + \frac{1}{N_t}\sum_{k=1}^{N_t}\text{Sim}(x_t, c_k)v_{c_k^i}\} \qquad (8)$$

Complexity analysis We analyze the complexities of CBOW, CWE, SCWE and SCWE+M. Let S denotes the size of corpus, $|W|$ denotes the size of vocabulary, $|C|$ denotes the number of Chinese characters in corpus. And d is the dimensions of Chinese word and character embeddings, k is the context window size, f is the time spend in computing hierarchical softmax or negative sampling, n is the average number of characters in a Chinese word, m is the average meaning number of Chinese characters. The results are shown in Table 2.

In Chinese, most of words are composed by two Chinese characters, and the meaning number of commonly used characters are usually less than five. Moreover, according to *CJK Unified Ideographs*[1], the total number of Chinese characters is 20913, the commonly used characters are less than 10000. Therefore, our model is competitive to other methods in model parameters and computational complexity.

Method	Model parameters	Computational complexity
CBOW	$\|W\|d$	$2kSf$
CWE	$(\|W\| + \|C\|)d$	$2kS(f + n)$
SCWE	$(\|W\| + \|C\|)d$	$2kS(f + n)$
SCWE + M	$(\|W\| + m\|C\|)d$	$2kS(f{+}n{+}mn)$

Table 2: Complexity analysis

4 Experiments and Analysis

4.1 Experiments Settings

We select *English Wikipedia Dump*[2] to train English word embeddings with CBOW, and set dimensions to 200. For Chinese word embeddings, we select *Chinese Wikipedia Dump*[3] to train character and word embeddings. Before training, pure digits and non-Chinese characters are removed. We use an open-source Chinese segment tool called *ANSJ*[4] to

[1] https://en.wikipedia.org/wiki/CJK_Unified_Ideographs

[2] http://download.wikipedia.com/enwiki/

[3] http://download.wikipedia.com/zhwiki/

[4] https://github.com/NLPchina/ansj_seg

segment words in corpus. ANSJ is a java implementation of ICTCLAS (Institute of Computing Technology, Chinese Lexical Analysis System). It can process about one million words in a second, and get up to 96 percent accuracy in segmentation task. The part-of-speech tagging and name entity recognition tasks are also done in this process. We select *ICIBA*[5] as English-Chinese translation tool, which provides us with an application programming interface. CBOW and CWE are used as baseline methods. Context window size is set as 5 and both Chinese word and character embeddings are set as 100 dimension. After some cross validation steps, our threshold δ and λ are set as 0.5 and 0.4 in character disambiguation process. The influence of λ and δ is report in the later part.

Model	wordsim-240	wordsim-296
CBOW	51.78	60.82
CWE	52.57	60.36
SCWE	54.92	60.85
SCWE + M	**55.10**	**62.86**

Table 3: Evaluation on wordsim-240 and wordsim-296

4.2 Word Similarity

Word similarity is a task to compute semantic relatedness between given word pairs. The relatedness between word pairs have been scored by human in advance. The correlation between model results and human judgement can be used to evaluate the performance of models. In this paper, wordsim-240 and wordsim-296 (Jin and Wu, 2012) are used as evaluation datasets. The Spearman's rank correlation (Myers et al., 2010) is applied to compute the correlation. The experimental results are summarized in Table 3.

We observe that on wordsim-240, SCWE and SCWE+M outperform the baseline methods, which indicates the effectiveness of exploiting the internal structure. On dataset wordsim-296, we can see that CBOW, CWE, SCWE perform similarly. This may be explained by some highly ambiguous Chinese characters in this dataset. In SCWE and CWE, representing these ambiguous characters with the same embeddings may undermine word embeddings. Therefore, SCWE+M achieves a better performance by applying multiple-prototype character embeddings.

Fudan-large	Size	Fudan-small	Size
Environment	1218	Education	59
Agriculture	1022	Philosophy	44
Economy	1601	Transport	58
Politics	1025	Medical	52
Sports	1254	Military	75

Table 4: 2 groups datasets of text classification, the first column denotes the category of documents and the second denotes number of documents in each category.

4.3 Text Classification

In this experiment, we use *Fudan Corpus*[6] as datasets, which contains 20 categories of documents, including economy, politics, sports and etc.. The number of documents in each category ranges from 27 to 1061. To avoid imbalance, we select 10 categories and organize them into 2 groups. One group is named *Fudan-large* and each category in this group contains more than 1000 documents. The other is named *Fudan-small* and each category contains less than 100 documents. In each category, 80 percent of documents are used as training set, the rest are used as testing set to evaluate the performance. The detailed information for two datasets are reported in Table 4.

Similar to the way we deal with Chinese training corpus, pure digits and non-Chinese characters are removed and ANSJ is used to do word segmentation on these datasets. The publish information of each document is removed. We represent each document by averaging word embeddings in the document. The classifiers are trained using LIBLINEAR package(Fan et al., 2008) with the embeddings obtained from different methods. The performance of each method is evaluated by predicting accuracy on testing set. Experiment results are given in Table 5.

It is observed that our methods outperform the baseline methods on both datasets. This can be explained that the semantic relatedness of a word with the component characters which have more contribution to its semantic meaning is strengthen in our methods. Such as, in sports documents, the word

SCWE	91.53	92.68
SCWE + M	**93.22**	**92.89**

Table 5: Evaluation accuracies (%) on text classification.

"球" (ball) is used frequently. For Chinese words like "篮球" (basketball) and "网球" (tennis), the character "球" contributes more to their semantic meaning than other characters. Therefore, they lie closer to character "球" in embedding space obtained by our model than CBOW and CWE, and tend to form a cluster in embedding space.

Characters	Words
道1 (say, speak)	说道 (say) 称道 (speak)
道2 (Taoism, Taoist)	道经 (Taoist scriptures) 道教徒 (Taoist)
道3 (road, path)	岔道 (branch road) 驰道 (royal road)
光1 (scenery)	湖光山色 (a landscape of lakes and mountains) 明媚 (bright and beautiful)
光2 (time)	时光 (time, year) 光阴 (time)
光3 (light,ray)	光强 (light intensity) 透光率 (light transmittance)

Table 6: English explanatory of characters and their nearest words in vector space.

4.4 Multiple Prototype of Chinese Charaters

To tackle the ambiguity of Chinese characters, we propose multiple-prototype character embeddings. To evaluate the effectiveness of our method, we use PCA to conduct dimensionality reduction on word and character embeddings. The results are illustrated in Fig 2. We take 3 different meanings of Chinese characters "道" and "光", and 2 of their top-related words as examples. The character followed by a digit i denotes the i-th meanings of it.

We can observe that characters and words, which have similar meanings are gathered together. For example, "光3", "光强" and "透光率" are all related to the light. Thus, they get closer in the embedding space.

We also develop a dataset to compare our method with the disambiguation methods in Chen et al. (2015). We select some ambiguous Chinese characters, and then use *online Xinhua Dictionary*[7] as our standard to disambiguate the words that contain these ambiguous characters. Each word is assigned a number according to their explanation in the dictionary. We use KNN as classifier to evaluate all the methods. The results are shown in Table 7. It is observed that our method outperforms the methods proposed in Chen et al. (2015).

Model	Accuracy
CWE + P	84.9
CWE + L	81.0
CWE + LP	85.4
CWE + N	73.5
SCWE + M	**91.1**

Table 8: Nearest words example of Chinese words.

4.5 Qualitative analysis of word embeddings

In this part, we take two Chinese words as examples, and list their nearest words to examine the quality of word embeddings obtained by CWE and SCWE. The results are shown in Table 8. We can observe the most similar words return by CWE and SCWE both tend to share common characters with the given word. In CWE, characters with little semantic contribution to the word may undermine the quality of word embeddings. For example, the character “青” in word “青蛙”. The semantic relatedness of words with character “青” to the given word are overestimated in CWE. In our model, by calculating the semantic contribution of internal characters to the word, we alleviate this misjudgement greatly, which demonstrates the effectiveness of our model.

4.6 Parameter Analysis

In this part, the influence of parameters on our model is investigated. The parameters include the compositional word similarity threshold λ, character disambiguation threshold δ.

Compositional word similarity To investigate how λ influence the process of non-compositional word detection, we build a word list of transliterated words manually, which consists of 161 words. Then 161 of most frequent semantic compositional words with more than one Chinese characters are added to the list in the corpus. In Table 9, the performance of our method in classifying transliterated words when λ ranges from 0.25 to 0.55 are reported. From Table 9, we can observe as λ increases, more compositional words will be classified as non-compositional words, while transliterated words are more likely to be classified correctly. Our method achieves best F-Score when $\lambda = 0.4$.

Character disambiguation threshold In Table 10, we show the performance of our model in disambiguating Chinese characters. We adopted the same datasets in Section 4.4 with different δ. From Table 1, we can observe some meanings of a character are very close, therefore, a high δ are adopted in our model. When $\delta = 0.5$, our model gets the best result in our dataset.

Parameter λ	Precision	Recall	F-Score
0.25	97.0	60.9	74.8
0.30	96.5	68.9	80.4
0.35	94.6	75.8	84.2
0.40	92.0	78.9	**85.0**
0.45	88.9	80.1	84.3
0.50	84.0	84.5	84.2
0.55	82.5	85.1	83.8

Table 9: Precision, recall, F-score of transliterated words when λ ranges from 0.25 to 0.55

Parameter δ	Precision
0.35	87.5
0.40	89.0
0.45	89.5
0.50	**91.1**
0.55	89.9
0.60	89.5
0.65	88.5

Table 10: Evaluation accuracies (%) on ambiguous characters when λ ranges from 0.35 to 0.65.

5 Conclusion

In this paper, we exploit the internal structure in Chinese words by learning the semantic contribution of internal characters to the word. We propose a method to improve Chinese word and character embeddings with a similarity-based character-enhanced word embeddings model. Ambiguity problem of Chinese characters can also be tackled in our method. Moreover, we build a way to classify whether a Chinese word is compositional automatically, which requires to be labelled manually in CWE. We argue that our method may be used to improve word embeddings of other language whose internal structure is similar to Chinese. The code and datasets we use is available at: `https://github.com/JianXu123/SCWE`.

Abstract

Given a pair of sentences, we present computational models to assess if one sentence is simpler to read than the other. While existing models explored the usage of phrase structure features using a non-incremental parser, experimental evidence suggests that the human language processor works incrementally. We empirically evaluate if syntactic features from an incremental CCG parser are more useful than features from a non-incremental phrase structure parser. Our evaluation on Simple and Standard Wikipedia sentence pairs suggests that incremental CCG features are indeed more useful than phrase structure features achieving 0.44 points gain in performance. Incremental CCG parser also gives significant improvements in speed (12 times faster) in comparison to the phrase structure parser. Furthermore, with the addition of psycholinguistic features, we achieve the strongest result to date reported on this task. Our code and data can be downloaded from https://github.com/bharatambati/sent-compl.

1 Introduction

The task of assessing text readability aims to classify text into different levels of difficulty, e.g., text comprehensible by a particular age group or second language learners (Petersen and Ostendorf, 2009; Feng, 2010; Vajjala and Meurers, 2014). There have been efforts to automatically simplify Wikipedia to cater its content for children and English language learners (Zhu et al., 2010; Woodsend and Lapata, 2011; Coster and Kauchak, 2011; Wubben et al., 2012; Siddharthan and Mandya, 2014). A related attempt of Vajjala and Meurers (2016) studied the usage of linguistic features for automatic classification of a pair of sentences – one from Standard Wikipedia and the other its corresponding simplification from Simple Wikipedia – into COMPLEX and SIMPLE. As syntactic features, they use information from phrase structure trees produced by a non-incremental parser, and found them useful.

However, psycholinguistic theories suggest that humans process text incrementally, i.e., humans build syntactic analysis interactively by enhancing current analysis or choosing an alternative analysis on the basis of the plausibility with respect to context (Marslen-Wilson, 1973; Altmann and Steedman, 1988; Tanenhaus et al., 1995). Besides being cognitively possible, incremental parsing has shown to be useful for many real-time applications such as language modeling for speech recognition (Chelba and Jelinek, 2000; Roark, 2001), modeling text reading time (Demberg and Keller, 2008), dialogue systems (Stoness et al., 2004) and machine translation (Schwartz et al., 2011). Furthermore, incremental parsers offer linear time speed. Here we explore the usefulness of incremental parsing for predicting relative sentence readability.

Given a pair of sentences – one sentence a simplified version of the other – we aim to classify the sentences into SIMPLE or COMPLEX. We use the sentences from Standard Wikipedia (WIKI) paired with their corresponding simplifications in Simple Wikipedia (SIMPLEWIKI) as training and evaluation data. We pose this problem as a pairwise classification problem (Section 2). For feature extraction,

Proceedings of NAACL-HLT 2016, pages 1051–1057,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

we use an incremental CCG parser which provides a trace of each step of the parse derivation (Section 3). Our evaluation results show that incremental parse features are more useful than non-incremental parse features (Section 5). With the addition of psycholinguistic features, we attain the best reported results on this task. We make our system available for public usage.

2 Problem Formulation

Initially Vajjala and Meurers (2014) trained a binary classifier to classify sentences in SIMPLEWIKI to the class SIMPLE, and sentences in WIKI to the class COMPLEX. This model performed poorly on relative readability assessment. Noting that not all SIMPLEWIKI sentences are simpler than every other sentence in WIKI, Vajjala and Meurers (2016) reframed the problem as a ranking problem according to which given a pair of parallel SIMPLEWIKI and WIKI sentences, the former must be ranked better than the latter in terms of readability. Inspired by Vajjala and Meurers (2016), we also treat each pair together, and model relative readability assessment as a pairwise classification problem. Let a, b be a pair of parallel sentences. Let **a**, **b** represent their corresponding feature vectors. We define our classifier Φ as

$$\begin{aligned}\Phi(\mathbf{a}-\mathbf{b}) &= \quad 1 \quad \text{if} \quad a \in \text{SIMPLE} \;\; \& \; b \in \text{COMPLEX} \\ &= -1 \quad \text{if} \quad b \in \text{SIMPLE} \;\; \& \; a \in \text{COMPLEX}\end{aligned}$$

The motivation for our modelling is that relative features (difference) are more useful than absolute features, e.g., intuitively shorter sentences are simple to read, but length can only be defined in comparison with another sentence.

3 Incremental CCG Parse Features

Below we provide necessary background, and then present the features.

3.1 Combinatory Categorial Grammar (CCG)

CCG (Steedman, 2000) is a lexicalized formalism in which words are assigned syntactic types encoding subcategorization information. Figure 1 displays an incremental CCG derivation. Here, the syntactic type (category) $(\mathrm{S}\backslash\mathrm{NP})/\mathrm{NP}$ on *ate* indicates that it is a transitive verb looking for a NP (object) on the righthand side and a NP (subject) on the lefthand side. Due to its lexicalized and strongly typed nature, the formalism offers attractive properties like elegant composition mechanisms which impose context-sensitive constraints, efficient parsing algorithms, and a synchronous syntax-semantics interface. In Figure 1, the category of *with* $(\mathrm{NP}\backslash\mathrm{NP})/\mathrm{NP}$ combines with the category of *mushrooms* NP on its righthand side using the combinatory rule of *forward application* (indicated by $>$), to form the category $\mathrm{NP}\backslash\mathrm{NP}$ representing the phrase *with mushrooms*. This phrase in turn combines with other contextual categories using CCG combinators to form new categories representing larger phrases.

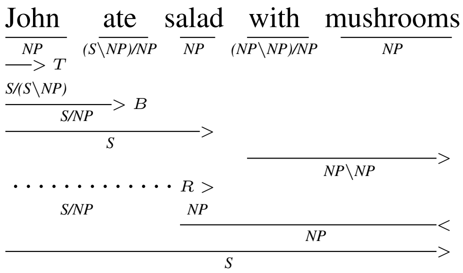

Figure 1: Incremental CCG derivation tree.

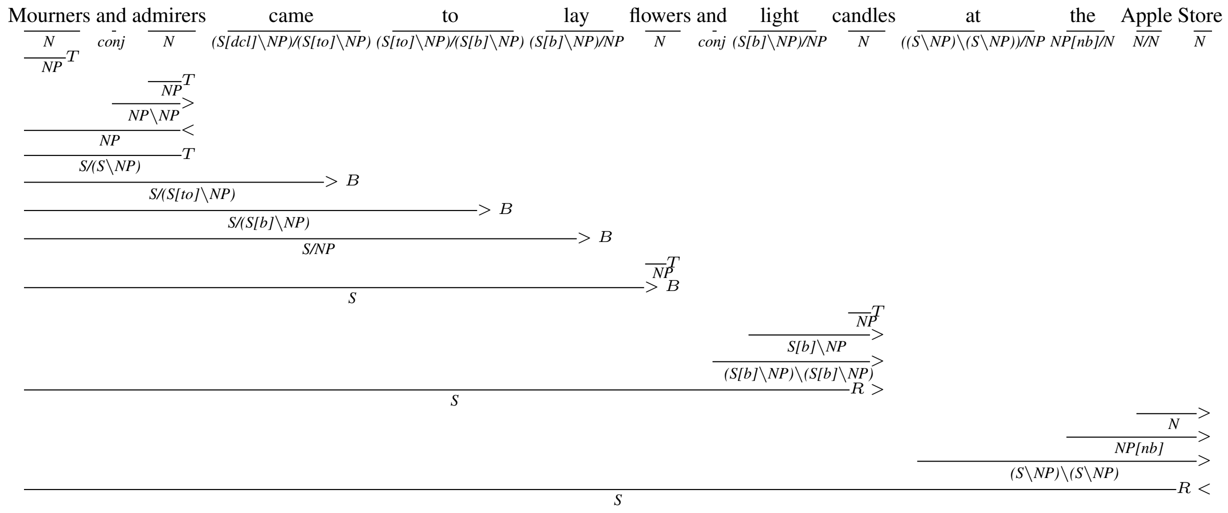
In contrast to phrase structure trees, CCG derivation trees encode a richer notion of syntactic type and constituency. For example, in a phrase structure tree, the category (constituency tag) of *ate* would be *VBD* irrespective of whether it is transitive or intransitive, whereas the CCG category distinguishes these types. As the linguistic complexity increases, the complexity of the CCG category may increase, e.g., the relative pronoun has the category $(\mathrm{NP}\backslash\mathrm{NP})/(\mathrm{S}\backslash\mathrm{NP})$ in relative clause constructions. In addition, CCG derivation trees have combinators annotated at each level which indicate the way in which the category is derived, e.g., in Figure 1 the category S/NP of *John ate* is formed by first *type-raising* (indicated by >T) *John* and then applying *forward composition* (indicated by >B) with *ate*. CCG combinators can throw light into the linguistic complexity of the construction, e.g., *crossed composition* is an indicator of long-range dependency. Phrase structure trees do not have this additional information encoded on their nodes.

3.2 Incremental CCG

Ambati et al. (2015) introduced a shift-reduce in-



Mourners and admirers came to lay flowers and light candles at the Apple Store
N conj N (S[dcl]\NP)/(S[to]\NP) (S[to]\NP)/(S[b]\NP) (S[b]\NP)/NP N conj (S[b]\NP)/NP N ((S\NP)\(S\NP))/NP NP[nb]/N N/N N

Figure 2: Incremental Derivation for a relatively complex sentence.

cremental CCG parser for English.[1] The main difference between this incremental version and standard non-incremental CCG parsers such as Zhang and Clark (2011) is that as soon as the grammar allows two types to combine, they are greedily combined. For example, in Figure 1, first *John* is pushed on the stack but is immediately reduced when its head *ate* appears on the stack (i.e., *John*'s category combines with *ate*'s category to form a new category), and similarly when *salad* is seen, it is reduced with *ate*. When *with* appears it waits to be reduced until its head *mushrooms* appears on the stack, and later *mushrooms* is reduced with *salad* via *ate* using a special *revealing* operation (indicated by R>) followed by a sequence of operations. The *revealing* operation is performed when a category has greedily consumed a head in advance of a subsequently encountered post-modifier to regenerate the head. In the non-incremental version, *salad* is not reduced with *ate* until *with mushrooms* is reduced with it.

Consider the following sentences (A) and (B) where (B) is a simpler version of (A).

(A)	Mourners and admirers came to lay flowers and light candles at the Apple Store.
(B)	People went to the Apple Store with flowers and candles.

Figures 2 and 3 present the incremental derivations for both these sentences. Consider the CCG category for *to* in both the sentences. In (A), the category of *to* is `(S[dcl]\NP)/(S[to]\NP)` which is more complex compared to the category of *to* in (B) which is `PP/NP`. Both the derivations have one right reveal action (indicated by $R >$). In (A), the depth of this action is two since it is a VP coordination.[2] Whereas in (B) the depth is only one. Such information can be useful in predicting the complexity of a sentence.

3.3 Features

As discussed above, as the complexity of a sentence increases, the complexity of CCG categories, combinators and the number of revealing operations increase in the incremental analysis. We exploit this information to assess the readability of a sentence. For each sentence, we build a feature vector using the features defined below extracted from its incremental CCG derivation.

Sentence Level Features. These features include sentence length, height of the CCG derivation, and the final number of constituents. A CCG derivation may have multiple constituents if none of the combinators allow the constituents to combine. This happens mainly in ungrammatical sentences.

CCG Rule Counts. These features include the number of applications, forward applications, back-

[1] This parser is not word by word (strictly) incremental but is incremental with respect to CCG derivational constituents following Strict Competence Hypothesis (Steedman, 2000).

[2] Please see Ambati et al. (2015) for additional information on the *depth* of revealing operations.

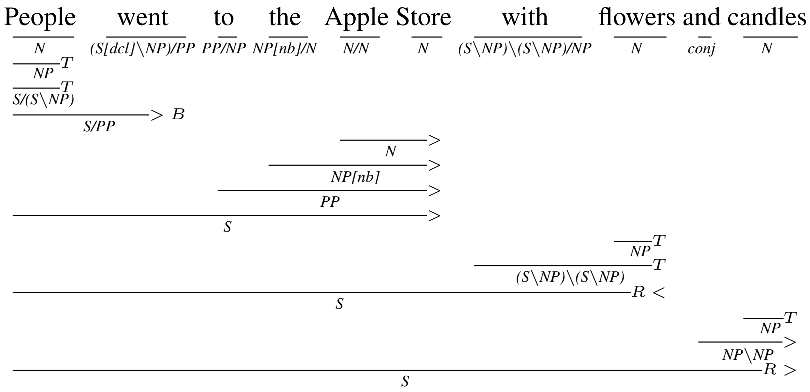

Figure 3: Incremental Derivation for a relatively simple sentence.

ward applications, compositions, forward compositions, backward compositions, left punctuations, right punctuations, coordinations, type-raisings, type-changing, left revealing, right revealing operations used in the CCG derivation. Each combinator is treated as a different feature dimension with its count as the feature value. For the revealing operations, we also add additional features which indicate the depth of the revealing which is analogous to surprisal (Hale, 2001).

CCG Categories. We define the complexity of a CCG category as the number of basic syntactic types used in the category, e.g., the complexity of (S[pss]\NP)/(S[to]\NP) is 4 since it has one S[pss], one $S[to]$, and two NPs. Note that CCG type S[pss] indicates a *sentence* but of the subtype *passive*. We use average complexity of all the CCG categories used in the derivation as a real valued feature. In addition, we define integer-valued features representing the frequency of specific subtypes (we have 21 subtypes each defined as a different dimension) and the frequency of the top 8 syntactic types (each as a different dimension).

4 Experimental Setup

4.1 Evaluation Data

As evaluation data, we use WIKI and SIMPLEWIKI parallel sentence pairs collected by Hwang et al. (2015), a newer and larger version compared to Zhu et al. (2010)'s collection. We only use the pairs from the section GOOD consisting of 150K pairs. We further removed pairs containing identical sentences which resulted in 117K clean pairs. We randomly divided the data into training (60%), development (20%) and test (20%) splits.

4.2 Implementation details

As our classifier (see Section 2) we use SVM with Sequential Minimal Optimization in Weka toolkit (Hall et al., 2009) following its popularity in readability literature (Feng, 2010; Hancke et al., 2012; Vajjala and Meurers, 2014).[3] We use Ambati et al. (2015)'s CCG parser for extracting CCG derivations. This parser requires a CCG supertagger to limit its search space for which we use EasyCCG tagger (Lewis and Steedman, 2014).

4.3 Baseline

NON-INCREMENTAL PST. Following Vajjala and Meurers (2016), we use features extracted from Phrase Structure Trees (PST) produced by the Stanford parser (Klein and Manning, 2003), a non-incremental parser. We use the exact code used by Vajjala and Meurers (2016) to extract these features which include part-of-speech tags, constituency features like the number of noun phrases, verb phrases and preposition phrases, and the average size of the constituent trees. Vajjala and Meurers (2016) used a total of 57 features.[4]

5 Results

First we analyze the impact of incremental CCG features (and so the name **INCREMENTAL CCG**).

[3] We also experimented with Naive Bayes and Logistic Regression and observed similar pattern in the results. But, SVM gave the best results among the classifiers we explored.

[4] Details of the features can be found in Vajjala and Meurers (2016).

Model	Accuracy
NON-INCREMENTAL PST	71.68
INCREMENTAL CCG	**72.12**

Table 1: Impact of different syntactic features.

Table 1 presents the results of predicting relative readability on the test data.[5] INCREMENTAL CCG achieves 72.12% accuracy, a significant[6] improvement of 0.44 points over NON-INCREMENTAL PST (71.68%) indicating that incremental CCG features are empirically more useful than non-incremental phrase structure features. We also evaluate if this result holds for incremental vs. non-incremental CCG parse features. Ambati et al. (2015) can also produce non-incremental CCG parses by turning off a flag. Note that in the non-incremental version, revealing features are absent. This version achieves an accuracy of 72.02%, around 0.1% lower than the winner INCREMENTAL CCG, yet higher than NON-INCREMENTAL PST showing that CCG derivation trees offer richer syntactic information than phrase structure trees. POS taggers used for Stanford and CCG parsers gave similar accuracy. This shows that the improvements are indeed due to the incremental CCG parse features rather than the POS features.

Apart from the syntactic features, Vajjala and Meurers (2016) have also used psycholinguistic features such as age of acquisition of words, word imagery ratings, word familiarity ratings, and ambiguity of a word, collected from the psycholinguistic repositories Celex (Baayen et al., 1995), MRC (Wilson, 1988), AoA (Kuperman et al., 2012) and WordNet (Fellbaum, 1998). These features are found to be highly predictive for assessing readability. We enhance our syntactic models NON-INCREMENTAL PST and INCREMENTAL CCG by adding these psycholinguistic features to build NON-INCREMENTAL PST++ and INCREMENTAL CCG++ respectively. Table 2 presents the final results along with the previous state-of-the-art results of Vajjala and Meurers (2016).[7] Psycholinguistic features gave a boost of around 6.75 points on the syntactic models.[8] Additionally the performance gap between our models decrease (from 0.44 to 0.19) showing some of the psycholinguistic features also model a subset of the syntactic features. INCREMENTAL CCG++ achieves an accuracy of 78.77% outperforming the previous best system of Vajjala and Meurers (2016) by a wide margin.

Model	Accuracy
Vajjala and Meurers (2016)	74.58
NON-INCREMENTAL PST++	78.68
INCREMENTAL CCG++	**78.87**

Table 2: Performance of models with both syntactic and psycholinguistic features.

Speed. In addition to accuracy, parsing speed is important in real-time applications. The Stanford parser took 204 minutes to parse the test data with a speed of 3.8 sentences per second. The incremental CCG parser took 16 minutes with an average speed of 47.5 sentences per second, a 12X improvement over the Stanford parser. These numbers include POS tagging time for the Stanford parser, and POS tagging and supertagging time for the incremental CCG parser. All the systems are run on the same hardware (Intel i5-2400 CPU @ 3.10GHz).

6 Conclusion

Our empirical evaluation on assessing relative sentence complexity suggests that syntactic features extracted from an incremental CCG parser are more useful than from a non-incremental phrase structure parser. This result aligns with psycholinguistic findings that human sentence processor is incremental. Our incremental model enhanced with psycholinguistic features achieves the best reported results on predicting relative sentence readability. We experimented with Simple Wikipedia and Wikipedia data from Hwang et al. (2015). We can explore the usefulness of our system on other datasets like OneStopEnglish (OSE) corpus (Vajjala and Meurers, 2016) or the dataset from Xu et al. (2015). We are also currently exploring the usefulness of incremental analysis for psycholinguistic data by switching off the lookahead feature.

[5] All feature engineering is done on the development data.

[6] Numbers in bold indicate significant results, significance measured using McNemar's test.

[7] We ran Vajjala and Meurers (2016)'s code on our dataset and get similar results reported on Zhu et al. (2010)'s dataset.

[8] Non-incremental CCG achieves an accuracy of 78.77%.

Abstract

In this paper, we present a straightforward strategy for transferring dependency parsers across languages. The proposed method learns a parser from partially annotated data obtained through the projection of annotations across unambiguous word alignments. It does not rely on any modeling of the reliability of dependency and/or alignment links and is therefore easy to implement and parameter free. Experiments on six languages show that our method is at par with recent algorithmically demanding methods, at a much cheaper computational cost. It can thus serve as a fair baseline for transferring dependencies across languages with the use of parallel corpora.

1 Introduction

Cross-lingual learning techniques enable to transfer useful supervision information from well-resourced to under-resourced languages, helping the development of NLP tools for a large number of languages. In this work, we present a simple method for transferring dependency parsers between languages.

Two main strategies have been considered to transfer syntactic annotations: (a) direct model transfer and (b) annotation transfer. The first approach assumes a common representation between the source and target languages (e.g. at the level of PoS tags), which enables to train a model on source data and to use it to parse target sentences. The performance of 'pure' delexicalized dependency transfer can be significantly improved using additional techniques such as self-training (Zeman and Resnik, 2008), smart data selection (Søgaard, 2011), relexicalization and/or multi-source model transfer (Cohen et al., 2011; Naseem et al., 2012; Täckström et al., 2013). The second approach (transfer of annotations) requires parallel sentences, in which word alignments are used to infer target syntactic structures from source dependencies. The main difficulty here is to cope with cases of non-isomorphism between the source and target structures as well as with the noise in source annotations and in alignments. Turning source trees into target trees indeed may require to filter poor alignments and to apply various heuristic transformation rules, such as the ones introduced in Hwa et al. (2005), later improved in Tiedemann (2014).

In this study, we consider a simple, yet effective approach to transfer annotations, which entirely dispenses from the transfer rules of Hwa et al. (2005), the sharp filtering of partially annotated trees (Tiedemann, 2014), the inclusion of fake root dependencies for unattached words (Spreyer and Kuhn, 2009), or the multi-step process of Rasooli and Collins (2015). Our proposal is, in fact, quite as straightforward (apart from the use of parallel texts) as the delexicalized transfer method of McDonald et al. (2013) while achieving performances that surpass this state-of-the-art method by a wide margin, and competing with recent algorithmically costly methods: it globally outperforms the scores of (Ma and Xia, 2014) and even achieves the same performance as (2015) for 1 language out of 5. It can thus be used as a fair and simple baseline when evaluating new transfer methodologies.

Proceedings of NAACL-HLT 2016, pages 1058–1063,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

Our method relies on the observation (Section 2) that transition-based dependency parsers using the dynamic oracle strategy can be trained from partially annotated trees (in which some words may not have a governor) *using exactly the same algorithm that is used to train from fully annotated tree*. As explained in Section 3, this observation allows us to design a simple transfer strategy that, first, (partially) projects syntactic annotations from a source language onto a target language via unambiguous word alignments and, second, learns a dependency parser from these partially annotated target data. We then apply this strategy for six language pairs.

2 Training Dependency Parsers on Partially Annotated Data

2.1 Training with a Dynamic Oracle

We consider a transition-based dependency parser based on the arc-eager algorithm (Nivre, 2003): this parser builds a dependency tree incrementally by performing a sequence of *actions*. At each step of the parsing process, a classifier scores each possible action and the highest scoring one is applied.

Training relies on the dynamic oracle of Goldberg and Nivre (2012): for each sentence, a parse tree is built incrementally; at each step, if the predicted action creates an erroneous dependency (or, equivalently, prevents the creation of a gold dependency), a weight vector is updated, according to the perceptron rule. The set of all 'correct' actions is built considering the (potentially wrong) predicted tree and the gold action is defined as the correct action with the highest model score.

It is crucial to notice that the training algorithm is an error-correction learning procedure that solely depends on its ability to detect when an action choice will result in an error: when no error is detected, the construction of the parse tree continues according to the model prediction. Consequently, this training procedure can also be used, unchanged, to train a dependency parser from partially annotated data: when no supervision information is available (no reference dependency is known), all actions are considered as correct; in this case, the predicted action is one of the correct actions, the weight vector is not updated, and the training process goes on.

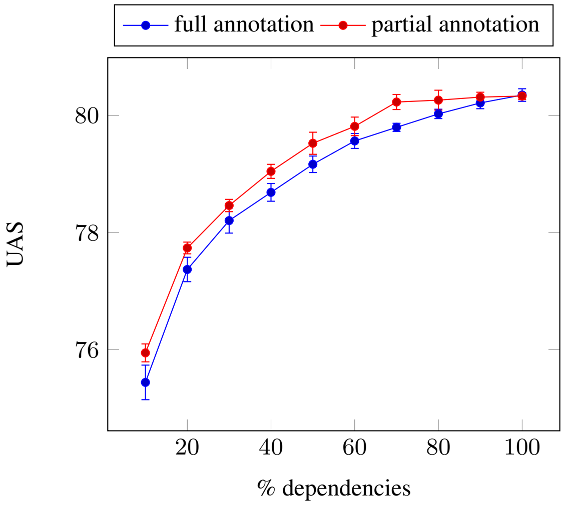

Figure 1: UAS achieved by a parser trained on $n\%$ of the dependencies on German.

This observation can be readily generalized to dependency parsers using a beam search procedure.[1] For the experiments in Section 3, we use a beam-search version of the parser trained with an early-update strategy (Collins and Roark, 2004).

2.2 Experiments on Artificial Datasets

We first carry out a control experiment on datasets in which dependencies have been artificially removed to show that learning from partially annotated data is possible. We compare the performance achieved by a parser trained on $n\%$ of the sentences of the train set with the performance of a parser trained on the whole train set, but in which only $n\%$ of the dependencies of each sentence are known. In both conditions, the total number of dependencies considered during training is roughly the same. Figure 1 plots the parsing performance for German, evaluated by the UAS, with respect to the percentage of dependencies that were kept. To avoid any bias, the reported scores have been averaged over 10 runs. Similar results are observed for 5 other languages of the Universal Dependency Treebank[2] (UDT) (McDonald et al., 2013).

Overall, these results show that learning a parser from partially annotated data is possible. Two other

[1] See (Aufrant and Wisniewski, 2016) for a detailed explanation.

[2] See Section 3.2 for more details on datasets.

conclusions can also be drawn. First, it appears that the number of training examples can be reduced without significantly hurting the performance: removing half the training sentences only reduces the UAS by 1.2 absolute. Second, for a similar number of annotations (i.e. number of dependencies known), better results are achieved when more sentences are annotated, even if this annotation is only partial: in Figure 1, the UAS of a parser trained on partially annotated sentences is higher than the UAS of a parser trained from a subset of the training set.

Indeed, in a partial structure, information on unknown dependencies can be inferred from neighbouring dependencies because of the projectivity constraints. Therefore, the set of gold actions is sometimes smaller than the set of possible actions and an update can happen even if the dependency is unknown. For instance, when training a German dependency parser, 35,382 updates are performed when only 60% of the dependencies are known, to be compared with the 31,339 updates that take place when training on 60% of the fully annotated sentences.

3 Application to Dependency Transfer

In this section, we show how learning from partially annotated data can be used for cross-lingual dependency transfer. A partial projection strategy is first applied to infer partially annotated data for a target language from a full-parsed source data. The target annotations are then used to learn an effective parsing model for the target language.

3.1 Partial Projection of Dependencies

Using sentence-aligned bitexts associating an automatically parsed text in a resource-rich language with its translation in target language, dependencies can readily be projected via alignment links, yielding 'cheap', albeit noisy, supervision data. The main difficulties with the projection arise with many-to-many links and un-aligned tokens. Hwa et al. (2005) have proposed several specific heuristics to deal with the different kinds of alignments and project a full dependency tree. However, this solution comes at the expense of deleting words or creating fake dependencies in the target sentence, which may introduce unreliable annotations in the target data.

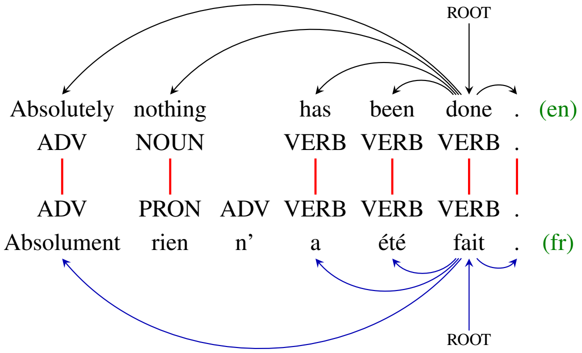

Figure 2: Partial dependency projection from English to French. Only English dependencies compatible with `1:1` alignments, and for which the POS of the aligned words are consistent, are transferred to French.

In this work, we advocate another approach and show that it is simpler and more effective to ignore unattached words and many-to-many alignments: we claim that training a parser from a corpus of high-quality annotated (albeit partially) data will result in better parsing performances than a parser trained from fully-annotated but noisy data.

In practice, parallel sentences are aligned in both directions with `Giza++` (Och and Ney, 2003) and these alignments are merged with the intersection heuristic. This heuristic only selects `1:1` alignment links that occur in the two directional alignments and, intuitively, contains only reliable alignment points, as they have been predicted by two independent models. Note that we do not try to model the reliability of dependency and/or alignment links, making our approach easy to implement and parameter free.

We additionally consider three simple heuristics to filter the transferred annotations and improve their precision: we first remove from the training set target sentences containing non-projective dependencies,[3] as well as sentences for which less than 80% of the words are attached. The latter case indeed corresponds to parallel sentences with few alignment links that are often not perfect translation of each other. Finally, following Rasooli and Collins (2015), we ignore all alignment links that associate words

[3] As shown in the work of (Mareček, 2011), sentences containing non-projective dependencies often results in low-quality projected dependency structures.

with different PoS tags. As shown in Figure 2, for each pair of aligned sentences, only the dependencies for which both the head and the dependent are each aligned to exactly one word (PoS-consistent) are projected.[4]

This approach finally produces an automatically annotated corpus for the target language that contains mostly accurate annotations, even if the dependency structure is incomplete.

3.2 Datasets and Experimental Setup

All our experiments are carried out on six languages[5] of the Universal Dependency Treebank Project: German, English, Spanish, French, Italian and Swedish. We considered as parallel corpora a subset of the Europarl corpus (Koehn, 2005) that have exactly the same English sentences, collecting $1,231,216$ parallel sentences for the 6 language pairs.

For training the target partial data, we used our own implementation of the arc-eager dependency parser with a dynamic oracle, using the features described in (Zhang and Nivre, 2011), with a beam size of 8. The beam-search strategy is used for training (20 iterations) and decoding.

3.3 Dependency Transfer Experiments

For each language pair, the source dataset (Europarl) is PoS-tagged and parsed using the transition-based version of the MateParser (Bohnet and Nivre, 2012), trained on the UDT corpus with a beam size of 40.[6] Dependencies are then (partially) projected onto the target side of the corpus and filtered using the method described above. As reported in Table 2, after filtering, the number of sentences in the train set varies between $15,191$ for German and $52,554$ for Swedish and the percentage of tokens receiving a dependency varies from 88.15% for French to 90.84% for German.

Our parser is then trained on the resulting partially annotated dataset and its performance evaluated on the target UDT test set by the Unlabeled Attachment Score, UAS (excluding punctuation). Gold PoS were used for evaluating in order to make results of our method comparable with state-of-art methods.

		# sentences		
source		**en**		**multi**
filter		100%	80%	80%
target	**de**	7,346	15,191	70,905
	es	9,293	27,700	178,147
	fr	6,626	21,381	144,755
	it	7,353	21,204	160,864
	sv	20,550	52,554	175,201

Table 2: Number of sentences in projected and filtered target data.

The proposed method is compared to three transfer method baselines: the relexicalisation procedure of McDonald et al. (2011), the method of Ma and Xia (2014) for transferring cross-lingual knowledge using entropy regularization, and the recent density-driven approach of Rasooli and Collins (2015) exploiting partially annotated data. The results are first compared for cross-lingual transfer from English and second, applying a voting method[7] for transferring from multiple sources. Note, however, that a direct comparison with these results is not completely fair as systems were not trained with the same exact conditions (less features, lower beam size, etc). As a baseline for comparing parsers, we also report the scores achieved by Rasooli and Collins (2015) and by our method on fully projected sentences ('en-100%').

3.4 Results

Table 1 reports the results of the various transfer methods. Our method achieves significantly better results than the relexicalisation procedure of McDonald et al. (2011) (up to +8.33 in Spanish) and outperforms the method of Ma and Xia (2014) for 3 languages (from +0.91 (fr) to +2.86 (sv)) and equalizes it for one (it). Finally, for Swedish, it achieves performance that are on a par with that of Rasooli

[4] To account for the root dependency, we consider that both the source and target sentences contain an additional ROOT token that is always aligned.

[5] These are the languages that are both in Europarl and UDT.

[6] Here are the supervised scores obtained with the MateParser (predicted PoS-tags) on the source languages: 92.4 (en), 80.4 (de), 83.1 (es), 83.8 (fr), 84.2 (it) and 85.7 (sv).

[7] The voting method chooses, for each token of a sentence, the most frequent head among the projected heads from the various source languages if it does not impede the projectivity of the resulted tree (otherwise the next most frequent head is chosen). The most frequent "head" may be null. Finally, the sentence may be partially annotated.

		M11	**MX14**	**RC15**			**this work**			**sup.**
source		(en)	(en)	(en)	(en-100%)	(multi)	(en)	(en-100%)	(multi)	
target	**de**	69.77	74.30	74.32	70.56	79.68	73.40	69.36	75.99	84.43
	es	68.72	75.53	78.17	75.69	80.86	77.05	73.98	78.94	85.51
	fr	73.13	76.53	79.91	77.03	82.72	77.44	75.89	80.80	85.81
	it	70.74	77.74	79.46	77.35	83.67	77.74	75.50	79.39	86.97
	sv	75.87	79.27	82.11	78.68	84.06	82.13	77.26	82.97	87.89

Table 1: Parsing quality (evaluated in UAS) of our method and previous works: M11 stands for McDonald et al. (2011), MX14 for Ma and Xia (2014), RC15 for Rasooli and Collins (2015) and 'sup' corresponds to the supervised scores. State-of-the-art scores are from (Rasooli and Collins, 2015).

and Collins (2015).

It therefore appears that, while being much simpler, the proposed approach achieves results very competitive with state-of-the-art methods at a much cheaper computational cost: our results have been obtained by training a single parser with a beam size of 8, while Ma and Xia (2014) use a parser with exact inference, the training and inference complexity of which is $\mathcal{O}(n^4)$ and the method of Rasooli and Collins (2015) requires the costly training of 4 different parsers each using a beam size of 64.

Results of Table 1 also show that Rasooli and Collins (2015) achieves better scores than our method when training on fully projected trees. This can be explained by the differing training conditions (as previously mentioned).[8] Finally, these results show the benefits of considering partial dependency trees and not only sentences for which a complete parse tree is transferred: a parser trained with partial dependencies improves the UAS up to 4.8 points.

4 Conclusion

In this paper, we have proposed and evaluated a very simple procedure to train a dependency parser with projected partial annotations. In fact, our training algorithm is virtually unchanged with respect to the fully supervised case. Yet, it has proved extremely effective when combined with an appropriate selection of the transferred annotations.[9]

Further improvements could be obtained using additional tricks, such as better data selection strategies or constrained parsing. Besides that, it is worth noting that our method is not only on a par with the method of Rasooli and Collins (2015) but could also be combined with it. Indeed, their first step can be substituted by our method. Since the latter outperforms the former, the combination of the two should improve their best final scores.

In our future work, we intend to study how this training strategy behaves for other transition-based systems or, more generally, for other NLP scenarios using partially annotated data.

Geolocation for Twitter: Timing Matters

Abstract

Automated geolocation of social media messages can benefit a variety of downstream applications. However, these geolocation systems are typically evaluated without attention to how changes in time impact geolocation. Since different people, in different locations write messages at different times, these factors can significantly vary the performance of a geolocation system over time. We demonstrate cyclical temporal effects on geolocation accuracy in Twitter, as well as rapid drops as test data moves beyond the time period of training data. We show that temporal drift can effectively be countered with even modest online model updates.

1 Introduction

Geolocation – the task of identifying a social media message's location – can support a variety of downstream applications, such as advertising, personalization, event discovery, trend analysis and disease tracking (Watanabe et al., 2011; Hong et al., 2012; Kulshrestha et al., 2012; Broniatowski et al., 2013). Geolocation work has mostly focused on Twitter, since tweets are readily accessible and true location available from user geocoded tweets (*inter alia* (Eisenstein et al., 2010; Han et al., 2014; Rout et al., 2013; Compton et al., 2014; Cha et al., 2015; Jurgens et al., 2015; Osborne et al., 2014; Dredze et al., 2013)).

Most previous work consider the task of author geolocation, the identification of a author's primary (home) location (Eisenstein et al., 2010; Han et al., 2014). Author geolocation systems rely on multiple tweets from each author to identify the location. In this work, we consider the task of tweet geolocation, where a system identifies the location where a single tweet was written (Osborne et al., 2014; Dredze et al., 2013). This approach is necessary when geolocation decisions must be made quickly, with limited resources, or when the location of a specific tweet is required.

When focusing on a single tweet, time becomes relevant. Intuitively, tweets written in the morning might be in different locations (at home) than say tweets written during the day (at work). This information is often ignored but can provide important clues as to a tweet's location. Likewise, models built using historical data never adapt as time evolves. These factors may have a significant impact on geolocation accuracy, and downstream system's should be sensitive to these variations.

For the first time, we consider the impact of time on Twitter geolocation and predict where a post was made (rather than the more usual, and easier task of author location). We take a supervised learning approach, training a multi-class classifier to identify the city of a tweet. We train a system on 250 million tweets sampled from a 45 month period, perhaps the largest evaluation to date. We find that:

- Geolocation accuracy is cyclical, varying significantly with time.
- While access to massive training data improves accuracy, these effects are largely lost when models are deployed on new tweets, in large part due to new users and duplicate tweets.
- Periodically updating geolocation models, even with data available from the free Twitter API,

Proceedings of NAACL-HLT 2016, pages 1064–1069,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

can largely supplant massive training datasets.

Our study is similar to that of Pavalanathan and Eisenstein (2015), who called into question the accuracy of geolocation models due to mismatches between the behavior of users in available training data as compared to users encountered in live data. While our work provides a cautionary tale, it provides a guide for how these models can be used in practice.

2 Dataset

We start with *every geocoded tweet* (based on the "location" field) from January 1, 2012 to September 30, 2015: 8,530,693,792 tweets.[1] These tweets are associated with a specific location by Twitter (the "location" field is populated.)

We took several steps to remove tweets that were not relevant to the task. We removed tweets posted by location sharing services (FourSquare and jSwarm) since these are not written by users. We removed retweets for the same reason. We also remove tweets that do not have a specific latitude/longitude (geo) while nevertheless containing a location. Twitter allows user's to tag a tweet with a location (populating the location field) even when the user's device does not provide a latitude and longitude (geo field). To ensure we know the precise location of the user we only consider tweets with the geo field.

We matched each tweet to a city using the procedure of Han et al. (2014), with 3,709 cities derived from the geonames database[2]. Only 2983 locations contained a tweet; locations without tweets were mostly in Africa and China, which has low Twitter usage. Following Han et al. (2014) we focus on English tweets only, removing non-English tweets based on the metadata language code. We also identified the tweet's country for a country prediction task (161 labels). We divided this dataset into two time periods. We use tweets from January 1, 2012 to March 30, 2015 for a standard train/dev/test evaluation, selecting $\frac{2}{10{,}000}$ of the data for development and test sets. Data from March 31, 2015 to September 30, 2015 forms an "out of time" sample.

The most common cities were Los Angeles, London, Jakarta, Chicago, Kuala Lumpur and Dallas. The city clustering procedure of Han et al. (2014) greatly influences this list. For example, Los Angeles ends up as one large city, whereas the New York City area is divided into several smaller cities.

3 Geolocation Model

We treat geolocation as a multi-class task, with each city (or country) a label (Jurgens et al., 2015).

Features All of our features are extracted from a single tweet (text or metadata) without requiring additional queries to the Twitter API. [3] These include: **Text**: We extracted unigrams and bigrams from the text of each tweet after tokenizing with Twokenizer (O'Connor et al., 2010). We removed all punctuation, and replaced unique usernames and urls with placeholder tokens. Numbers were replaced with a NUM token. **Profile location**: Unigrams and bigrams extracted from the user supplied profile location field, as well as a feature for the entire location string. These fields often provide clues as to the user's location, e.g. "New York Living". **Timezone**: Each tweet has a timezone that reflects a specific location, e.g. "Pacific Time (US & Canada)", "Atlantic Time (Canada)", "Casablanca". We also include the UTC offset of the timezone. **Time**: We use a feature indicating the hour of the day (in UTC time) at which the tweet was posted.

Learning We used vowpal wabbit (version 8.1.1) (Agarwal et al., 2011), a linear classifier trained using stochastic gradient descent with adaptive, individual learning rates (Duchi et al., 2011) that minimizes the hinge loss. We used feature hashing with a 31-bit feature space. We selected the best model and parameters based on initial tests using *development data*. All other parameters used default settings.

[1] Data is available from third party resellers, such as *Gnip*.

[2] `http://www.geonames.org/`

[3] Our reliance on text features created a very large feature space, but only a small fraction of these occur with any regularity. Previous work has shown feature selection helpful for geolocation (Han et al., 2014). We tried L1 regularization for feature selection without a significant change to our results. It may be that our larger volume of training data removes the need for feature selection. Alternatively, we use feature hashing (to a 31-bit feature space) which can be a form of regularization as feature collisions mitigate overfitting (Ganchev and Dredze, 2008; Weinberger et al., 2009).

4 Evaluation

We report the four evaluation metrics of Han et al. (2014): city accuracy (AccCi), country accuracy (AccCo), accuracy within 161 km (100 miles) (Acc@161), and the median error in km (Median).

Baselines We include two baselines: (1) the majority predictor: always predicts the most popular label. (2) alias matching: we create a list of aliases for each of the 2983 cities from the genomes dataset, which includes the smaller cities clustered together by Han et al. (2014). We search each tweet and the user's profile location for these aliases, assigning a tweet with a matched alias to the corresponding city; unmatched tweets are assigned the majority label. When multiple cities match a tweet, we selected the correct one (if present) using oracle knowledge. About 90% of matches were in the profile. This strategy is similar to that of Dredze et al. (2013).

Duplicates A tweet may be duplicated in our dataset, appearing in both training and held out data, or appearing multiple times in held out data. We define duplicates as tweets with identical feature representations. We removed duplicates from dev and test splits, to ensure evaluation examples are unseen in training, yielding 22,966 dev and 23,240 test tweets.

5 Baseline Results

We begin by establishing the models' performance with a large training set, as measured on held out evaluation data drawn from the same time period. Here we use a standard setting, where there is no online adaptation. We include results for city and country models trained with the tweet text features alone (content). These evaluations train with a sample of 25,822,353 tweets, similar to previous large scale training for geolocation (Han et al., 2014).

Table 2 shows our model beating both baselines, with the additional features generally improving over content features alone. Interestingly, improvements from adding features appears to be additive: the final model's accuracy is nearly the sum of the individual improvements from each feature set. On the non-deduped test dataset (25,941 tweets), the accuracy was higher (city: 0.2920, country: 0.8777) but the trends of adding features remain unchanged. Our time feature, which captures a temporal prior over locations, does not seem to help, providing only a small boost.

We consider the impact of training data size in Figure 1, including a model trained on 258,222,490 tweets, an order of magnitude larger than Han et al. (2014), which improves accuracy by roughly 3%. This figure provides guidance on how much data is necessary to do well on this task.

To summarize: our approach yields tweet level geolocation accuracy similar to, or better than, state of the art user level geolocation.[4] We note that for small datasets (tens of millions of training examples, which can be obtained from the Twitter streaming API), one can obtain a reasonable model.

6 Temporal Factors in Geolocation

We now consider factors that influence geolocation temporal accuracy using our largest city model (258M training tweets), which has an accuracy of 0.3302 on test data (0.3062 excluding duplicates).

6.1 Question 1: How do daily and weekly patterns impact geolocation accuracy?

Twitter traffic varies over the course of a day and a week. User behavior may change at different times, and different locations are active at different times.

Figure 3 shows the number of tweets and test geolocation accuracy by the hour of the day (b) and day of the week (c). The day of the week has a minor impact on geolocation accuracy; the standard deviation of the 7 days is 2.7% of the total mean. Tweet volume has a negative correlation with accuracy (-0.435), i.e. more tweets may be indicative of more people from different locations tweeting, which makes the task harder. Notably, Monday is significantly harder, with an accuracy of 1.5 standard deviations below the mean. However, the hour of the day has much more significant impact on accuracy; some times of the day are significantly easier and harder than the average. The standard deviation is 6.8% of the mean, and tweet volume is strongly negatively correlated with accuracy (-0.647). Geolocation is easier during times when there are fewer locations actively tweeting. This is most apparent during

[4] Direct comparisons are not possible because of different datasets and tasks. However, our results are on par with the user-level geolocation system of Han et al. (2014).

Figure 3: (a) New users and tweets each day. Accuracy and number of tweets by hour (US eastern) (b) and day (c).

the nighttime in the US, where there are much fewer tweets overall and many fewer active locations. In short, the accuracy of a geolocation system depends on when it is running.

6.2 Question 2: How do changes over time impact a fixed geolocation model?

We now turn to our data sample taken after the training data: a 10% sample of 49,307,720 tweets from 2015/3/31 - 2015/9/30.[5] These tweets will demonstrate the accuracy of a trained model deployed on new data over time.

Evaluating on these tweets (duplicates included), our model yields an accuracy of 0.2661, down from 0.3302, a 19% relative drop. Surprisingly, this isn't a gradual change over time; the drop is quite rapid. The week immediately following the training period has an accuracy of 0.2884. Figure 4 shows the decline in accuracy over time.[6]

What factors contribute to this rapid drop? We consider two: new users and reposted tweets.

New Users One factor affecting geolocation performance might be new users joining, posting a few tweets and then no longer posting. In a sense, users have a temporal lifespan, after which information originating from them is of less predictive value. One measure of this is the number of users encountered in the evaluation data, which have never been previously encountered, either in training or earlier in the evaluation data. Over the six month evaluation period, the number of new tweets from geocoded users per day *increases*, even as a percentage of all tweets (Figure 3(a)).

We remove all tweets in the evaluation period from users that we have previously encountered, either in training or earlier in evaluation data. Accuracy drops to 0.1859, a 30% relative decrease from 0.2661, suggesting that the training data learns features specific to the users it observes. By comparison, the alias match baseline has an accuracy of 0.2113 on this data.

While trained models remain effective on users

[5] While training data is taken from the first 39 months, it is biased towards more recent months due to Twitter growth: the last 12 months (30% of the time) account for 37% of tweets. We evaluated with a 10% sample for efficiency.

[6] While accuracy continues to degrade over time, it begins to rise in August 2015. It may be that there are seasonal effects in geolocation accuracy, or recent changes by Twitter are making geolocation easier. However, we were unable to determine the source of this change.

present in training, it has difficulty generalizing to new users. Far from a small percentage of the total, new users make up a significant number of tweets, at a rate that does not appear to be slowing.

Reposted Tweets Users often repost content, which can include repeating simple message (e.g. “feeling good!”) or tweeting the same content to multiple users. Users are more likely to repost content shortly after it was first created, making the number of reposts go down over time. For example, while 8% of test tweets from the same time period as training data are duplicates (they appear in the training data), only 3.8% of tweets in the six month evaluation period are duplicates.

How much of an impact do these reposts have on accuracy? For the test data from the same time period, we saw model performance drop from 0.3302 to 0.3062, a fairly large difference. By comparison, removing reposts in the the six month evaluation period drops accuracy from 0.2661 to 0.2541, a more modest change. Reposts help to inflate geolocation accuracy, and their decrease as time progresses from training removes this accuracy inflation.

7 Question 3: Can periodic model updates maintain a trained geolocation system?

Our results so far are sobering: shortly after a static model is deployed performance degrades to a model using *two orders of magnitude less training data* (compare the drop in §6.2 with Figure 1). Increasing the amount of training data might be an option, but given our previous results on new users, etc., this is unlikely to be sufficient.

A simple method for addressing model degradation over time is to continuously update the model over time using online learning on new data as it becomes available. For example, we can continuously download a stream of (at least) 1% of geocoded tweets from the Twitter API to use as training for updating a deployed system. What is the impact on a system’s accuracy when it is updated on these geocoded tweets with SGD updates (§3)?

Figure 4 shows the performance of our system in an online setting (dashed black line). This model updates on every 100th example (1% of all geocoded tweets) encountered in the six-month evaluation period. When we update this previously trained static model, we see a quick recovery to accuracy levels that meet or exceed those on the test set from the same time period as training (horizontal line.)

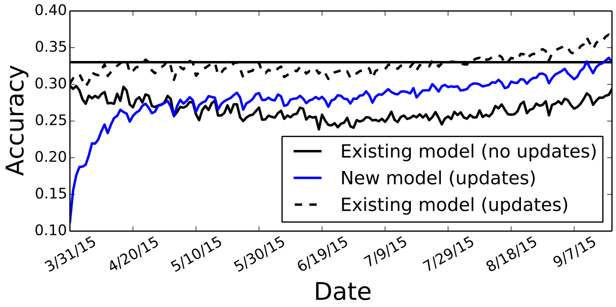

Figure 4: Accuracy over the six months following training. The horizontal line reflects the existing model’s performance on test from the same time period as training.

Finally, we consider the case where a practitioner starts from scratch with no training data, but updates using just 1% of geocoded tweets. Can someone with access to no prior training data build an effective model? Encouragingly, within 20 days the new model (solid blue line) catches the previously trained static model (solid black line, “Existing model: no updates“). This is an extremely promising result as it suggests that most practitioners **who do not have access to all geolocated data** can produce geolocation prediction models that approximate models trained using hundred of millions of examples.

8 Conclusion

We have presented a tweet geolocation system that considers an order of magnitude more data than any prior work. Despite hundreds of millions of training examples, the resulting system is sensitive to the time the tweet was authored. Additionally, accuracy suffers when deployed on data beyond the training period. We show that online updates can mitigate problems caused by concept drift. In short, sheer volume of data is not enough: geolocation models should adapt to new data. Encouragingly, starting from no training data and updating on just 1% of geocoded tweets, within 20 days we can recover a model that catches a static model previously trained on hundreds of millions of tweets.

Acknowledgments We thank Bo Han and Tim Baldwin for their help in reproducing their city labels.

Abstract

We present a fast, simple, and high-accuracy short answer grading system. Given a short-answer question and its correct answer, key measures of the correctness of a student response can be derived from its semantic similarity with the correct answer. Our supervised model (1) utilizes recent advances in the identification of short-text similarity, and (2) augments text similarity features with key grading-specific constructs. We present experimental results where our model demonstrates top performance on multiple benchmarks.

1 Introduction

Short-answer questions are a useful device for eliciting student understanding of specific concepts in a subject domain. Numerous automated graders have been proposed for short answers based on their semantic similarity with one or more expert-provided correct answers (Mohler et al., 2011; Heilman and Madnani, 2013; Ramachandran et al., 2015). From an application perspective, these systems vary considerably along a set of key dimensions: amount of human effort involved, accuracy, speed, and ease of implementation. We explore a design that seeks to optimize performance along all these dimensions.

Systems developed for the more general task of short-text semantic similarity provide a good starting point for such a design. Major progress has been made in this task in recent years, due primarily to the SemEval Semantic Textual Similarity (STS) task (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015). However, the utility of top STS systems has remained largely unexplored in the context of short answer grading. We seek to bridge this gap by adopting the feature set of the best performing STS system at SemEval-2015 (Sultan et al., 2015). Besides high accuracy, this system also has a simple design and fast runtime.

Textual similarity alone, however, is inadequate as a measure of answer correctness. For example, while the Sultan et al. (2015) system makes the general assumption that all content words[1] contribute equally to the meaning of a sentence, domain keywords (e.g., “mutation” for biological evolution) are clearly more significant than arbitrary content words (e.g., “consideration”) for academic text. As another example, *question demoting* (Mohler et al., 2011) proposes discarding words that are present in the question text as a preprocessing step for grading. We augment our generic text similarity features with such grading-specific measures.

We train supervised models with our final feature set; in two different grading tasks, these models demonstrate significant performance improvement over the state of the art. In summary, our contribution is a fast, simple, and high-performance short answer grading system which we also release as open-source software at: `https://github.com/ma-sultan/short-answer-grader`.

2 Related Work

A comprehensive review of automatic short answer grading can be found in (Burrows et al., 2015). Here

[1] meaning-bearing words (e.g., nouns and main verbs), as opposed to function words that play predominantly syntactic roles in a sentence (e.g., auxiliary verbs and prepositions).

Proceedings of NAACL-HLT 2016, pages 1070–1075,
San Diego, California, June 12-17, 2016.

we briefly discuss closely related work.

Early short answer grading work relied on patterns (e.g., regular expressions) manually extracted from expert-provided reference answers (Mitchell et al., 2002; Sukkarieh et al., 2004; Nielsen et al., 2009). Such patterns encode key concepts representative of good answers. Use of manually designed patterns continues to this day, e.g., in (Tandalla, 2012), the winning system at the ASAP answer scoring contest.[2] This is a step requiring human intervention that natural language processing can help to eliminate. Ramachandran et al. (2015) propose a mechanism to automate the extraction of patterns from the reference answer as well as high-scoring student answers. We adopt the simpler notion of semantic alignment to avoid explicitly generating complicated patterns altogether.

Direct semantic matching (as opposed to pattern generation) has been explored in early work like (Leacock and Chodorow, 2003). With advances in NLP techniques, this approach has gained popularity over time (Mohler et al., 2009; Mohler et al., 2011; Heilman and Madnani, 2013; Jimenez et al., 2013). Such systems typically use a large set of similarity measures as features for a supervised learning model. Features range from string similarity measures like word and character n-gram overlap to deeper semantic similarity measures based on resources like WordNet and distributional methods like latent semantic analysis (LSA). However, a large feature set contributes to higher system runtime and implementation difficulty. While following this generic framework, we seek to improve on these criteria by employing a minimal set of core similarity features adopted from (Sultan et al., 2015). Our features also yield higher accuracy by utilizing more recent measures of lexical similarity (Ganitkevitch et al., 2013; Baroni et al., 2014), which have been shown to outperform traditional resources and methods like WordNet and LSA.

Short-text semantic similarity has seen major progress in recent times, due largely to the SemEval Semantic Textual Similarity (STS) task (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015). STS systems can serve as a source of important new features and design elements for automatic short answer graders (Bär et al., 2012; Han et al., 2013; Lynum et al., 2014; Hänig et al., 2015).

Surprisingly, few existing grading systems utilize simple and computationally inexpensive grading-specific techniques like question demoting (Mohler et al., 2011) and term weighting. Our model augments the similarity features using these techniques.

3 Method

Following feature extraction, our system trains a supervised model for grading. As we discuss in Section 4, this can be a regressor or a classifier depending on the task. This section describes our features; specifics of the models are given in Section 4.

3.1 Features

3.1.1 Text Similarity

Given reference answer $R = (r_1, ..., r_n)$ and student response $S = (s_1, ..., s_m)$ (where each r and s is a word token), we compute three generic text similarity features.

Alignment. This feature measures the proportion of content words in R and S that have a semantically similar word in the other sentence. Such pairs are identified using a word aligner (Sultan et al., 2014). The semantic similarity of a word pair (r_i, s_j) is a weighted sum of their lexical and contextual similarities. A paraphrase database (PPDB, Ganitkevitch et al. (2013)) identifies lexically similar word pairs; contextual similarity is computed as average lexical similarity in (1) dependencies of r_i in R and s_j in S, and (2) content words in [-3, 3] windows around r_i in R and s_j in S. Lexical similarity scores of pairs in PPDB as well as weights of word and contextual similarities are optimized on an alignment dataset (Brockett, 2007).

To avoid penalizing long student responses that still contain the correct answer, we also employ a second version of this feature: the proportion of aligned content words only in R. We will refer to this feature as *coverage* of the reference answer's content by the student response.

Semantic Vector Similarity. This feature employs off-the-shelf word embeddings.[3] A sentence-level semantic vector is computed for each input

[2] https://www.kaggle.com/c/asap-sas/

[3] 400-dimensional word embeddings reported by Baroni et al. (2014).

sentence as the sum of its content word embeddings (lemmatized). The cosine similarity between the R and S vectors is then used as a feature. While the alignment features distinguish only between paraphrases and non-paraphrases, this feature enables integration of finer-grained lexical similarity measures between related concepts (e.g., *cell* and *organism*).

3.1.2 Question Demoting

We recompute each of the above similarity features after removing words that appear in the question text from both the reference answer and the student response. The objective is to avoid rewarding a student response for repeating question words.

3.1.3 Term Weighting

To be able to distinguish between domain keywords and arbitrary content words, in our next set of features we assign a weight to every content word in the reference and the student answer based on a variant of *tf-idf*. While general short-text similarity models typically use only *idf* (inverse document frequency) to penalize general words, the domain-specific nature of answer grading also enables the application of a *tf* (term frequency) measure.

To fully automate the process for a question and reference answer pair, we identify all content words in the pair. The top ten Wikipedia pages related to these words are retrieved using the Google API. Each page is read along with all linked pages crawled using Scrapy (Myers and McGuffee, 2015). The in-domain term frequency (tf_d) of a word in the answer is then computed by extracting its raw count in this collection of pages. We use the same set of tools to automatically extract Wikipedia pages in 25 different domains such as Art, Mathematics, Religion, and Sport. A total of 14,125 pages are retrieved, occurrences in which are used to compute the *idf* of each word.

We augment our alignment features—both original and question-demoted—with term weights to generate new features. Each word is assigned a weight equal to its $tf_d \times idf$ score. The sum of weights is computed for (1) aligned, and (2) all content words in the reference answer (after question demoting, if applicable). The ratio of these two numbers is then used as a feature. We compute only coverage features (Section 3.1.1) to avoid computing term weights for each student response. Thus the process of crawling and reading the documents is performed once per question; all the student responses can subsequently be graded quickly.

3.1.4 Length Ratio

We use the ratio of the number of words in the student response to that in the reference answer as our final feature. The aim is to roughly capture whether or not the student response contains enough detail.

4 Experiments

We evaluate our features on two grading tasks. The first task, proposed by Mohler et al. (2011), asks to compute a real-valued score for a student response on a scale of 0 to 5. The second task, proposed at SemEval-2013 (Dzikovska et al., 2013), asks to assign a label (e.g., *correct* or *irrelevant*) to a student response that shows how appropriate it is as an answer to the question. Thus from a machine learning perspective, the first is a regression task and the second is a classification task. We use the NLTK stopwords corpus (Bird et al., 2009) to identify function words. Results are discussed below.

4.1 The Mohler et al. (2011) Task

The dataset for this task consists of 80 undergraduate Data Structures questions and 2,273 student responses graded by two human judges. These questions are spread across ten different assignments and two tests, each on a related set of topics (e.g., programming basics, sorting algorithms). A reference answer is provided for each question. Inter-annotator agreement was 58.6% (Pearson's ρ) and .659 (RMSE on a 5-point scale). Average of the two human scores is used as the final gold score for each student answer.

We train a ridge regression model (Scikit-learn (Pedregosa et al., 2011)) for each assignment and test using annotations from the rest as training examples. A *dev* assignment or test is randomly held out for model selection. Out-of-range output scores, if any, are rounded to the nearest in-range integer. Following Mohler et al. (2011), we compute a single Pearson correlation and RMSE score over all student responses from all datasets. Average results across 1000 runs of the system are shown in Table 1. Our

System	Pearson's r	RMSE
tf-idf	.327	1.022
Lesk	.450	1.050
Mohler et al. (2011)	.518	.978
Our Model	**.592**	**.887**

Table 1: Performance on the Mohler et al. (2011) dataset with out-of-domain training. Performances of simpler bag-of-words models are reported by those authors.

System	r	RMSE
Ramachandran et al. (2015)	.61	.86
Our Model	**.63**	**.85**

Table 2: Performance on the Mohler et al. (2011) dataset with in-domain training.

model shows a large and significant performance improvement over the state-of-the-art model of Mohler et al. (two-tailed t-test, p <.001). Their system employs a support vector machine that predicts scores using a set of dependency graph alignment and lexical similarity measures. Our features are similar in intent, but are based on latest advances in identification of lexical similarity and monolingual alignment.

Ramachandran et al. (2015) adopt a different setup to evaluate their model on the same dataset. For each assignment/test, they use 80% of the data for training and the rest as test. This setup thus enables in-domain model training. Their system automatically generates regexp patterns intended to capture semantic variations and syntactic structures of good answers. Features derived from match with such patterns as well as term frequencies in the student response are used to train a set of random forest regressors, whose predictions are then combined to output a single score. Results in this setup are shown in Table 2. Again, averaged over 1000 runs, our model performs better on both evaluation metrics. The differences are smaller than before but still statistically significant (two-tailed t-test, p <.001).

4.2 The SemEval-2013 Task

Instead of a real-valued score, this task asks to assign one of five labels to a student response: *correct*, *partially correct/incomplete*, *contradictory*, *irrelevant*, and *non-domain* (an answer that contains no domain content). We use the SciEntsBank corpus, containing 9,804 answers to 197 questions in 15 science domains. Of these, 3,969 are used for model training and the remaining 5,835 for evaluation. A reference answer is provided for each question.

System	UA	UQ	UD	Wt. Mean
Lexical Overlap	.435	.402	.396	.400
Majority	.260	.239	.249	.249
ETS$_1$	.535	.487	.447	.460
SoftCardinality$_1$	.537	.492	.471	.480
Our Model	**.582**	**.554**	**.545**	**.550**

Table 3: F_1 scores on the SemEval-2013 datasets.

The test set is divided into three subsets with varying degrees of similarity with the training examples. The *Unseen Answers* (UA) dataset consists of responses to questions that are present in the training set. *Unseen Questions* (UQ) contains responses to in-domain but previously unseen questions. Three of the fifteen domains were held out for a final *Unseen Domains* (UD) test set, containing completely out-of-domain question-response pairs. For this task, we train a random forest classifier with 500 trees in Scikit-learn using our feature set.

Table 3 shows the performance of our model (averaged over 100 runs) along with that of top systems[4] at SemEval-2013 (and of simpler baselines). ETS (Heilman and Madnani, 2013) employs a logistic classifier combining lexical and text similarity features. SoftCardinality (Jimenez et al., 2013) employs decision tree bagging with similarity features derived from a set cardinality measure—soft cardinality—of the question, the reference answer, and the student response. These features effectively compute text similarity from commonalities and differences in character n-grams.

Each cell on columns 2–4 of Table 3 shows a weighted F_1-score on a test set computed over the five classes, where the weight of a class is proportional to the number of question-response pairs in that class. The final column shows a similarly weighted mean of scores computed over the three test sets. On each test set, our model outperforms the top-performing models from SemEval (significant at p <.001). Its performance also suffers less on out-of-domain test data compared to those models.

[4] Systems with best overall performance on SciEntsBank.

Features	Pearson's r	RMSE
All	.592	.887
w/o alignment	.519	.938
w/o embedding	.586	.892
w/o question demoting	.571	.903
w/o term weighting	.590	.889
w/o length ratio	.591	.888

Table 4: Ablation results on the Mohler et al. (2011) dataset.

4.3 Runtime Test

Given parsed input and having stop words removed, the most computationally expensive step in our system is the extraction of alignment features. Each content word pair across the two input sentences is assessed in constant time, giving the feature extraction process (and the whole system) a runtime complexity of $O(n_c \cdot m_c)$, where n_c and m_c are the number of content words in the two sentences. Note that all alignment features can be extracted from a single alignment of the input sentences.

Run on the Mohler et al. dataset (unparsed; about 18 words per sentence on average), our system grades over 33 questions/min on a 2.25GHZ core.

4.4 Ablation Study

Table 4 shows the performance of our regression model on the Mohler et al. dataset without different feature subsets. Performance falls with each exclusion, but by far the most without alignment-based features. Features implementing question demoting are the second most useful. Length ratio improves model performance the least.

Surprisingly, term weighting also has a rather small effect on model performance. Further inspection reveals two possible reasons for this. First, many reference answers are very short, only containing words or small phrases that are necessary to answer the question (e.g., "push", "enqueue and dequeue", "by rows"). In such cases, term weighting has little or no effect. Second, we observe that in many cases the key words in a correct answer are either not domain keywords or are unidentifiable using *tf-idf*. Consider the following:

- Question: What is a stack?
- Answer: A data structure that can store elements, which has the property that the last item added will be the first item to be removed (or last-in-first-out).

Important answer words like "last", "added", "first", and "removed" in this example are not domain keywords and/or are too common (across different domains) for a measure like *tf-idf* to work.

5 Conclusions and Future Work

We present a fast, simple, and high-performance short answer grading system. State-of-the-art measures of text similarity are combined with grading-specific constructs to produce top results on multiple benchmarks. There is, however, immense scope for improvement. Subtle factors like differences in modality or polarity might go undetected with coarse text similarity measures. Inclusion of text-level paraphrase and entailment features can help in such cases. Additional term weighting mechanisms are needed to identify important answer words in many cases. Our system provides a simple base model that can be easily extended with new features for more accurate answer grading.

Abstract

This paper presents an study of the use of interlocking phrases in phrase-based statistical machine translation. We examine the effect on translation quality when the translation units used in the translation hypotheses are allowed to overlap on the source side, on the target side and on both sides. A large-scale evaluation on 380 language pairs was conducted. Our results show that overall the use of overlapping phrases improved translation quality by 0.3 BLEU points on average. Further analysis revealed that language pairs requiring a larger amount of re-ordering benefited the most from our approach. When the evaluation was restricted to such pairs, the average improvement increased to up to 0.75 BLEU points with over 97% of the pairs improving. Our approach requires only a simple modification to the decoding algorithm and we believe it should be generally applicable to improve the performance of phrase-based decoders.

1 Introduction

In this paper we examine the effect on machine translation quality of using interlocking phrases to during the decoding process in phrase-based statistical machine translation (PBSMT). The motivation for this is two-fold.

Firstly, during the phrase-pair extraction process that occurs in the training of a typical PBSMT system, all possible alternative phrase-pairs are extracted that are consistent with a set of alignment points. As a consequence, the source and target sides of these extracted phrase pairs may overlap. However, in contrast to this, the decoding process traditionally proceeds by concatenating disjoint translation units; the process relies on the language model to eliminate awkward hypotheses with repeated words produced by sequences of translation units that overlap.

Secondly, the transduction process in PBSMT is carried out by generating hypotheses that are composed of sequences of translation units. These sequences are normally generated independently, as modeling the dependencies between them is difficult due to the data sparseness issues arising from modeling with word sequences. The process of interlocking is a way of introducing a form of dependency between translation units, effectively producing larger units from pairs of compatible units.

2 Related Work

(Karimova et al., 2014) presented a method to extract overlapping phrases offline for hierarchical phrase based SMT. They used the CDEC SMT decoder (Dyer et al., 2010) that offers several learners for discriminative tuning of weights for the new phrases. Their results showed improvements of 0.3 to 0.6 BLEU points over discriminatively trained hierarchical phrase-based SMT systems on two datasets for German-to-English translation. (Tribble and et al., 2003) proposed a method to generate longer new phrases by merging existing phrase-level alignments that have overlaping words on both source and target sides. Their experiments on translating Arabic-English text from the news domain were encouraging.

Proceedings of NAACL-HLT 2016, pages 1076–1081,
San Diego, California, June 12-17, 2016.

(Roth and McCallum, 2010) proposed a conditional-random-field approach to discriminatively train phrase based machine translation in which training and decoding are both cast in a sampling framework. Different with traditional PBSMT decoding that infers both a Viterbi alignment and the target sentence, their approach produced a rich overlapping phrase alignment. Their approach leveraged arbitrary features of the entire source sentence, target sentence and alignment. (Kääriäinen, 2009) proposed a novel phrase-based conditional exponential family translation model for SMT. The model operates on a feature representation in which sentence level translations are represented by enumerating all the known phrase level translations that occur inside them. The model automatically takes into account information provided by phrase overlaps. Although both of the latter two approaches were innovative the translation performance was lower than tranditional PBSMT baselines.

Our proposed approach is most similar to that of (Tribble and et al., 2003). Our approach differs in the interlocking process is less constrained; phrase pairs can interlock independently on source and target sides, and the interlocking process performed during the decoding process itself, rather than by augmenting the phrase-table.

3 Methodology

3.1 Target Interlocking

In the decoding process for PBSMT, the target is generated from left-to-right phrase-by-phrase. The process of interlocking the phrases is illustrated in Figure 1. The s_i are the source tokens, the t_j are the target tokens, the lower target token sequence on the left represents the partial translation hypothesis, and the upper target phrase is the target side of a translation unit $(s_3s_4, t_3t_4t_5)$ being used to extend the hypothesis. An interlock of length k is can occur if the last k tokens of the partial translation match the first k tokens of the target side of the translation unit being used to extend the hypothesis. In this case the decoder may create an extended hypothesis with the target side of the translation unit interlocked with the target word sequence generated so far. In order to do this, the k interlocked words are not inserted a second time into the target token sequence and the word penalty (if pre-calculated) is adjusted to reflect this. In the example given in Figure 1, the translation resulting from extending the search with the interlocking translation unit will be $t_1t_2t_3t_4t_5$.

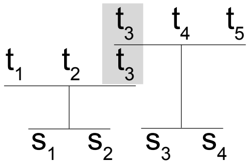

Figure 1: Interlocking target phrases.

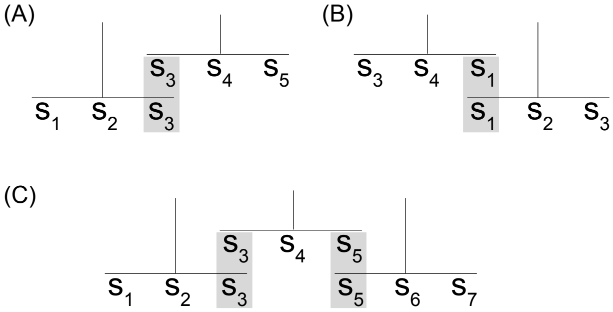

Figure 2: Interlocking source phrases.

3.2 Source Interlocking

The interlocking of source phrases can occur in three different ways as shown in Figure 2. In Figure 2 (A), a source phrase is interlocking with source words to the left; in (B) a source phrase is interlocking with source words to the right; and in (C) a source phrase is interlocking on both sides. The interlocking process is handled before the search process begins, at the time the set of translation options used in the search is created. Additional interlocking translation options are created in which the source side phrase is permitted to overlap with the surrounding source context, however, later during the search this translation unit will only be used to translate (cover) the sequence of non-interlocking words. In this way, the decoder's search algorithm can be used without modification, when dealing with interlocking source phrases.

4 Experiments

4.1 Corpora

We used twenty languages from the multilingual Basic Travel Expressions Corpus (BTEC), which is a collection of travel-related expressions (Kikui et al., 2003). The languages were Arabic (ar), Danish (da), German (de), English (en), Spenish (es), French (fr), Italian (it), Dutch (nl), Portugese (pt), Russian (ru), Tagalog (tl), Indonesian (id), Malaysian (ms), Vietnamese (vi), Thai (th), Hindi (hi), Chinese (zh), Japanese (ja), Korean (ko) and Myanmar (my). 155,121 sentences were used for training, 5,000 sentences for development and 2,000 sentences for evaluation.

In addition, we ran experiments on two language pairs from the Europarl corpus (Koehn, 2005). The language pairs were English-German, German-English, English-Spanish and Spanish-English. The corpus statistics are given in Table 2.

4.2 Experimental Methodology

We used a modified version of our in-house phrase based SMT system which operates similarly to Moses (Koehn and Haddow, 2009). GIZA++ (Och and Ney, 2000) was used for word alignment, together with the grow-diag-final-and heuristics (Koehn et al., 2003). A lexicalized reordering model was trained with the msd-bidirectional-fe option (Tillmann, 2004). We used the SRILM toolkit to create 5-gram language models with interpolated modified Kneser-Ney discounting (Stolcke, 2002; Chen and Goodman, 1996). The weights for the log-linear models were tuned using the MERT procedure (Och, 2003). The translation performance was evaluated using the BLEU score (Papineni et al., 2001).

We ran three sets of experiments; (1) target interlocking, (2) source interlocking and (3) both source and target interlocking for all possible combinations of languages (i.e. 380 language pairs). We studied two methods for accomplishing (3). In the first, interlocking as defined in Sections 3.1 and 3.2 are permitted freely. In the second, the target is allowed to interlock if and only if the source is also interlocked. This was similar to the method proposed by (Tribble and et al., 2003).

4.3 Results

In this section, we will first present the results of the experiments on the BTEC corpora and then report the results from the experiments from the Europarl corpus.

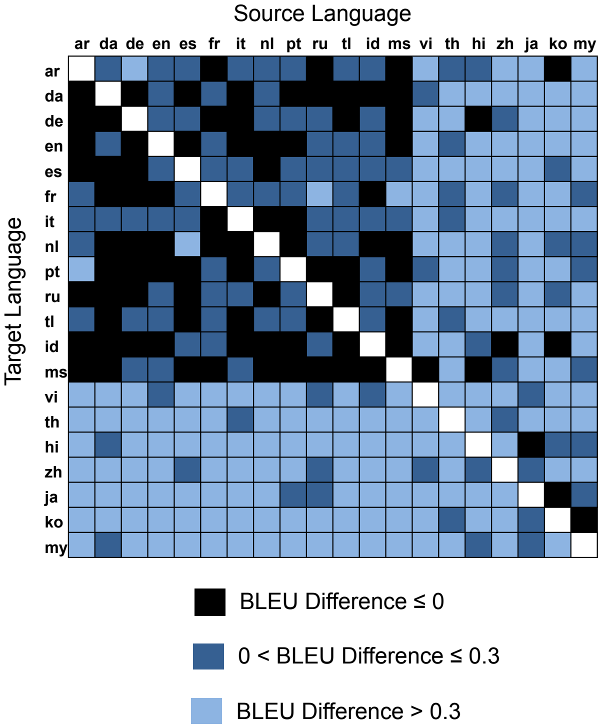

Figure 3: BLEU difference by language pair.

4.3.1 BLEU Differences

The difference in BLEU between a baseline system, a standard phrase-based SMT system without interlocking, and the proposed systems in which interlocking phrases where permitted, was calculated, and the average taken over all 380 language pairs. The results show that interlocking the phrases generally improves translation quality, and that the system gained slightly more from interlocking the target phrases, than from interlocking the source phrases. The average BLEU difference was 0.22 from interlocking target phrases, 0.14 from overlapping source phrases and 0.33 from interlocking both source and target. When the interlocking was constrained to ensure that both source and target phrases were interlocked, the average BLEU difference dropped to 0.27 BLEU. In the cases where both source and target phrases were allowed to interlock freely, 77% of the experiments showed an improvement in BLEU score.

A sequence of experiments were run on the baseline system with increasing stack size from 100, to 1000 in increments of 100. These experiments showed an increase of 0.07 BLEU points from stack

Src-Trg	Corpus Statistics (sentences)			Baseline	Interlocking		
	train	develop	test	No-interlock	Source	Target	Src & Trg
en-de	1500,000	3,000	3,000	18.70	**21.03**	18.83	18.90
de-en	1500,000	3,000	3,000	**26.08**	24.86	26.05	25.44
en-es	1500,000	3,000	3,000	33.55	**35.44**	33.68	33.89
es-en	1500,000	3,000	3,000	33.81	**36.42**	33.90	33.92

Kendall's Tau Distance	Avg BLEU Difference	% Expts Showing Gain
[0, 1.00]	0.33	77.3
[0, 0.95]	0.34	78.4
[0, 0.90]	0.38	80.5
[0, 0.85]	0.51	90.5
[0, 0.80]	0.58	93.5
[0, 0.75]	0.63	97.3
[0, 0.70]	0.68	97.3
[0, 0.65]	0.71	97.7
[0, 0.60]	0.72	97.2
[0, 0.55]	0.74	97.3
[0, 0.50]	0.75	100.0

Table 1: Filtering the Set of Language Pairs.

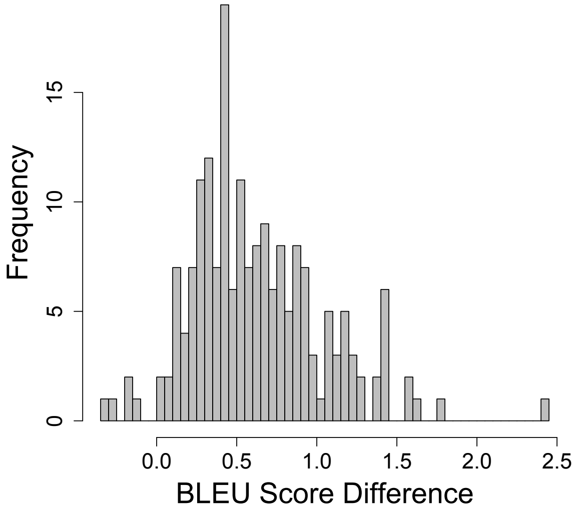

Figure 4: The Distribution of differences in BLEU score.

size 100 to stack size 200, followed by a sequence of scores that did not vary more than 0.01. Therefore, we conclude that the gains we obtained through interlocking the phrases, could not have been obtained by simply increasing the amount of searching performed by the baseline system. In other words, the interlocking method is introducing novel and useful search steps into the search space.

4.3.2 Results by Language Pair

Figure 3 shows how the gains and losses in BLEU score were distributed over the set of language pairs. Lighter cells in the figure represent gains in BLEU, the black cells represent losses. The order of the language pairs has been arranged to show the is a clear pattern. The languages on the left hand side and upper part of the figure are mostly European languages with similar word orders, whereas the remaining languages are typically Asian languages with different word orders. The language pairs that gained the most from interlocking on both source and target were: th-hi, hi-it, ko-de, ko-tl, th-ja, my-ru, my-th, my-ar, th-my, and it-ja. The languages that lost the most in BLEU score were: id-pt, ko-my, fr-id, ms-pt, id-it, da-ar, id-ko, da-es, id-ar, and de-it.

It is clear from Figure 3 that translation among the group of similar languages does not benefit from our approach, but the dissimilar languages do. This observation motivated further analysis of the data in order to develop a method for selecting language pairs

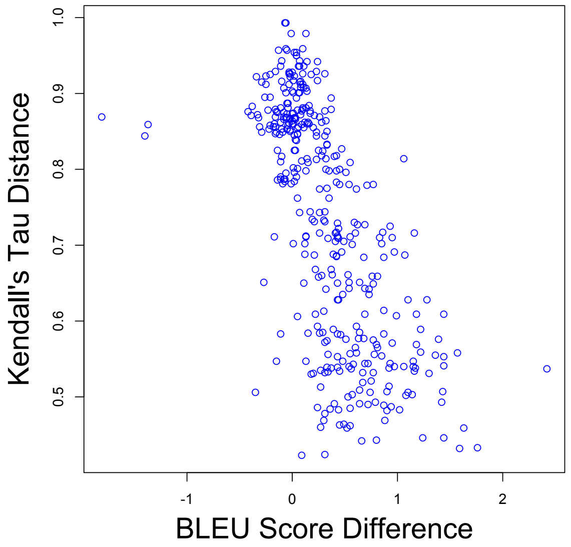

Figure 5: Plot of the Kendall's tau distance difference against BLEU difference.

suitable for our approach.

4.3.3 Kendall's Tau Distance

Kendall's tau distance is the minimum number of transpositions of adjacent symbols necessary to transform one permutation into another (Kendall, 1938; Birch, 2011), and is one method to gauge the amount of re-ordering that would be required during the translation process between two languages.

Figure 5 shows a scatter plot of all of the experiments, plotting BLEU difference against Kendall's tau. The points show a strong negative correlation (coefficient: -0.7). Therefore, we propose to use Kendall's tau as a means of selecting appropriate language pairs to be used with our method.

Table 1 shows the effect of filtering the set of language pairs by Kendall's tau. The effectiveness of the proposed method increases as languages with higher Kendall's tau distance are removed from the experimental set. When language pairs are selected according to Kendall's tau in the range $0 \leq \tau \leq 0.75$, the average BLEU gain of the set increases to 0.6 BLEU while still retaining approximately half of the language pairs in the set. Moreover, the proportion of experiments showing an in improvement in BLEU increases to over 97%. Figure 4 shows the distribution of BLEU differences for this subset of language pairs.

4.3.4 Europarl Corpus

The results of the previous sections were all based on experiments on the BTEC corpus. This corpus is unusual in that the sentences are short and the training data size is also small. In order to establish that our approach has more general application, we applied it to four language pairs from the much larger Europarl corpus. The results on the Europarl corpus are shown in Table 2. For three of the language pairs we observed increases in BLEU scores over the baseline for all interlocking methods with substantial gains of 1.9 to 2.6 BLEU points coming from the source interlocking technique. However, the German to English pair gave a negative result. The results from the Europarl corpus are generally very encouraging but the negative result motivates further study on more language pairs from different domain in the future.

5 Conclusion

In this paper we propose and evaluate a simple technique for improving the performance of phrase-based statistical machine translation decoders, that can be implemented with only minor modifications to the decoder. In the proposed method phrases are allowed to interlock freely on both the source and target side during decoding. The experimental results, based on a large-scale study involving 380 language pairs provide strong evidence that our approach is genuinely effective in improving the machine translation quality. The translation quality improved for 77% of the language pairs tested, and this was increased to over 97% when the set of language pairs was filtered according to Kendall's tau distance. The translation quality improved by an average of up to 0.75 BLEU points on this subset. This value represents a lower bound on what is possible with this technique and in future work we intend to study the introduction of additional features into the log-linear model to encourage or discourage the use of interlocking phrases during decoding, and investigate the effect of increasing the number of interlocked words.

Abstract

Poorly translated text is often disfluent and difficult to read. In contrast, well-formed translations require less time to process. In this paper, we model the differences in reading patterns of Machine Translation (MT) evaluators using novel features extracted from their gaze data, and we learn to predict the quality scores given by those evaluators. We test our predictions in a pairwise ranking scenario, measuring Kendall's tau correlation with the judgments. We show that our features provide information beyond fluency, and can be combined with BLEU for better predictions. Furthermore, our results show that reading patterns can be used to build *semi*-automatic metrics that anticipate the scores given by the evaluators.

1 Introduction

Human evaluation has been the preferred method for tracking the progress of MT systems. In the past, the prevalent criterion was to judge the quality of a translation in terms of *fluency and adequacy*, on an absolute scale (White et al., 1994). However, different evaluators focused on different aspects of the translations, which increased the subjectivity of their judgments. As a result, evaluations suffered from low inter- and intra-annotator agreements (Turian et al., 2003; Snover et al., 2006). This caused a shift towards a ranking-based approach (Callison-Burch et al., 2007). Unfortunately, the disagreement between evaluators is still a challenge that cannot be easily resolved due to the non-transparent thought-process that evaluators follow to make a judgment.

The eye-mind hypothesis (Just and Carpenter, 1980; Potter, 1983) states that when completing a task, people cognitively process objects that are in front of their eyes (i.e. where they fixate their gaze).[1] Based on this assumption, it has been possible to study reading behavior and patterns (Rayner, 1998; Garrod, 2006; Hansen and Ji, 2010).

The overall difficulty of a sentence and its syntactic complexity affects reading behavior (Coco and Keller, 2015). Ill-formed sentences take longer to process, and may cause the reader to jump back while reading. Hence, by looking into how evaluators read the translations and their accompanying references, we can learn about: (*i*) the complexity of a reference sentence, and (*ii*) the quality of a translation sentence.

Using reading patterns from evaluators could be a useful tool for MT evaluation: (*i*) to shed light into the evaluation process: e.g. the general reading behavior that evaluators follow to complete their task; (*ii*) to understand which parts of a translation are more difficult for the annotator; and (*iii*) to develop *semi*-automatic evaluation systems that use reading patterns to predict translation quality.

In this paper, we make a first step towards (*iii*): using reading patterns as a method for distinguishing between good and bad translations. Our hypothesis is that bad translations are difficult to read, which may be reflected by the reading patterns of the evaluators. Motivated by the notion of reading difficulty, we extracted novel features from the evaluator's gaze data, and used them to model and predict the quality of translations as perceived by evaluators.

[1] Except in cases of *covert* attention.

Proceedings of NAACL-HLT 2016, pages 1082–1088,
San Diego, California, June 12-17, 2016.

2 Features and Model

A perfectly *grammatical* sentence can be difficult to read for several reasons: unfamiliar vocabulary, complex syntactic structure, syntactic or semantic ambiguity, etc. (Harley, 2013). Reading automatic translations is even more challenging due to untranslated words, incorrect word order, morphological disagreements, etc. Cognitively processing difficult sentences generally results in modified reading patterns (Garrod, 2006; Coco and Keller, 2015).

In this paper, we analyze the reading patterns of human judges in terms of the word transitions (jumps), and the time spent on each word (dwell time); and use them as features to predict the quality score of a specific translation. For the sake of simplicity, as recommended by Guzmán et al. (2015), we only consider a monolingual evaluation scenario and ignore the source text . However, our features and experimental setup can be extended to include source-side features.

2.1 Features

Jump features While reading text, the gaze of a person does not visit every single word, but it advances in jumps called *saccades*. These jumps can go forwards (*progressions*) or backwards (*regressions*). The number of regressions correlates with the reading difficulty of a sentence (Garrod, 2006; Schotter et al., 2014; Metzner, 2015). In an evaluation scenario, a fluent reading would mean monotonic gaze movement. On the contrary, the reader may need to jump back multiple times while reading a poor translation. We classify the word-transitions according to the direction of the jump and distance between the start and end words. For subsequent words n, $n+1$, this would mean a forward jump of distance equal to 1. All jumps with distance greater than 4 were sorted into a 5+ bucket. Additionally, we separate the features for reference and translation jumps. We also count the total number of jumps.

Total jump distance We additionally aggregate jump distances[2] to count the total distance covered while evaluating a sentence. We have reference distance and translation distance features. Again, the idea is that for a well-formed sentence, gaze distance should be less, compared to a poorly-formed one.

Inter-region jumps While reading a translation, evaluators can jump between the translation and a reference to compare them. Intuitively, more jumps of this type could signify that the translation is harder to evaluate. Here we count the number of transitions between reference and translation.

Dwell time The amount of time a person fixates on a region is a crucial marker for processing difficulty in sentence comprehension (Clifton et al., 2007) and moderately correlates with the quality of a translation (Doherty et al., 2010). Our feature counts the time spent by the reader on each particular word. We separate reference and translation features.

Lexicalized Features The features discussed above do not associate gaze movements with the words being read. We believe that this information can be critical to judge the overall difficulty of the reference sentence, and to evaluate which translation fragments are problematic to the reader. To compute the lexicalized features, we extract streams of reference and translation lexical sequences based on the gaze jumps, and score them using a tri-gram language model. Let $R_i = r_1, r_2, \ldots, r_m$ be a sub-sequence of gaze movement over reference and there are $R_1, R_2, \ldots, R_n$ sequences, the lex feature is computed as follows:

$$lex(R) = \sum_{i}^{n} \frac{\log p(R_i)}{|R_i|}$$

$$p(R_i) = \sum_{j}^{m} p(r_j | r_{j-1}, r_{j-2})$$

The normalization factor $|R_i|$ is used to make the probabilities comparable. We also use unnormalized scores as additional feature. A similar set of features $lex(T)$ is computed for the translations. All features are normalized by the length of the sentence.

2.2 Model

For predicting the quality scores given by an evaluator, we use a linear regression model with ridge

[2] Jump count and distance features have also shown to be useful in SMT decoders (Durrani et al., 2011).

regularization. The ridge coefficient $\hat{\beta}$ is the value of β that minimizes the error:

$$\sum_i (y_i - x_i^T \beta)^2 + \lambda \sum_{j=1}^{p} \beta_j^2$$

Here the parameter λ controls the amount of shrink applied to regression coefficients. A high value of λ shrinks the coefficients close to zero (Hastie et al., 2001). We used the implementation provided in the glmnet package of R (Friedman et al., 2010), which inherits a cross-validation mechanism that finds the best value of λ on the training data.

3 Experimental Setup

We used a subset of the Spanish-English portion of the WMT'12 Evaluation task. We selected 60 medium-length sentences which have been evaluated previously by at least 2 different annotators. For each sentence we selected the *best* and *worst* translations according to a human evaluation score based on the *expected wins* (Callison-Burch et al., 2012). As a result, we had 60 references with two corresponding translations each, adding up to a total of 120 evaluation tasks. Each evaluation task was performed by 6 different evaluators, resulting in 720 evaluations.

The annotators were presented with a translation-reference pair at a time. The two evaluation tasks corresponding to the same reference were presented at two different times with at least 40 other tasks in-between. This was done to prevent any possible spurious effects that may arise from remembering the content of a first translation, when evaluating the second translation of the same sentence. During each evaluation task, the evaluators were asked to assess the quality of a translation by providing a score between 0–100 (Graham et al., 2013). The observed inter-annotator agreement (Cohen's kappa) among our annotators was 0.321. This is slightly higher than the overall inter-annotator agreement of 0.284 reported in WMT'12 for the Spanish-English.[3] For reading patterns we use the EyeTribe eye-tracker at a sampling frequency of 30Hz. Please refer to Abdelali et al. (2016) for our Eye-Tracking setup and to know about *iAppraise*, an evaluation environment that supports eye-tracking.

3.1 Evaluation

In our evaluation, we used eye-tracking features to predict the quality of a translation in a pairwise scenario in a protocol similar to the one from WMT'12. First, we obtained the predicted scores $\hat{y}_A^k$, $\hat{y}_B^k$ for translations A and B when evaluated by evaluator k. Then, we computed the agreements w.r.t. the scores y_A^k, y_B^k provided by the evaluator for the same pair of translations. That is, we considered an agreement when rankings were in order, e.g. $\hat{y}_A^k > \hat{y}_B^k \iff y_A^k > y_B^k$. Otherwise, we considered it a disagreement. Finally, we computed Kendall's tau correlation coefficient as follows: $\tau = \frac{agg-dis}{agg+dis}$. We evaluated the performance using a 10-fold cross-validation. While the folds were selected randomly, we ensured that all translations corresponding to the same sentence were included in the same fold, to prevent any overlap between train and test.

4 Results

In this section, we first analyze the results of coherent feature sets to measure their predictive power and to validate the intuitions about the information they capture. Later, we use combination of features and assess their suitability as evaluation metrics.

4.1 Gaze as a translation quality predictor

In Table 1, we show the results for the predictive models trained on different feature sets. For simplicity, we divide the feature groups in: reference only features (I), translation only features (II), translation and reference features (III); and lexicalized features (IV). In the last group, we also add a tri-gram language model scores for comparison purposes.

Reference only features In section I of the table, we observe the prediction results for the models that only used features from the references. Unsurprisingly, most of these features lack the predictive power to determine whether translation A is better than translation B (τ from 0.06 to 0.13). One would expect that important phenomena that can be

[3] For a rough comparison only. Note that these two numbers are not *exactly* comparable given that they are calculated on different subsets of the same data. Still, there is a fair agreement between the our evaluators and the *expected wins* from WMT'12 (avg. pairwise kappa of 0.381)

observed only on the reference (e.g. the overall difficulty of the sentence), are neutralized in a pairwise setting, because an evaluator would read both instances of the reference text similarly.[4]
However, some features like the dwell time ($\tau = 0.13$) yield better results than others. This could be explained by the need to go back to the reference, when reading a confusing translation, thus spending more time reading the reference.

Translation only features In section II, we observe the results for the translation features. At a first glance, we realize that the correlation results are much higher than for the reference features (τ from 0.17 to 0.23). This supports the hypothesis that reading patterns can help to distinguish good from bad translations. Furthermore, it also supports specific intuitions about these reading patterns. For example, the fluency of a sentence is important (forward jumps, $\tau = 0.17$), but the number of regressions are better predictors of the quality of a sentence ($\tau = 0.22$). Additionally, the time spent reading a translation (dwell time) is a good predictor of the quality ($\tau = 0.22$). All of the above validate the intuition that reading patterns capture information about the quality of a translation. In general, using translation eye-tracking features in a pairwise evaluation, can help to predict which translation is better.

Translation and reference features Reference and translation features are not independent. Inter-region jumps capture the number of times that evaluators go between translation and references before making judgment. In section III, we observe that these features can be useful to predict the quality of a translation ($\tau = 0.18$).

Lexicalized features In the last rows of the table, we show that reading patterns help to evaluate more than just the fluency of a translation. A simple language model score (B_{LM}), is a weaker quality predictor ($\tau = 0.17$) than most of the eye-tracking translation features. Using the lexicalized version of the jump features gives additional predictive power ($\tau = 0.22$). Furthermore, by adding the total number of jumps and backward jumps to the LM features, we would obtain a considerable gain in correlation ($\tau = 0.30$). This suggests that the reading patterns capture information about more than just fluency.

SYS	**Feature Sets (total features)**	τ
I. Eye-tracking: Reference		
EyeRef$_{fj}$	Forward jumps (5)	0.06

Table 1: Results of individual eye-tracking features based on reference region, translation region, inter-region and lexicalized information

4.2 Gaze to build an evaluation metric

So far, we've shown that the individual sets of features based on reading patterns can help to predict translation quality, and that this goes beyond simple fluency. One question that remains to be answered is whether these features could be used as a whole to evaluate the quality of a translation *semi*-automatically. That is, whether we can use the gaze information, and other lexical information to anticipate the score that an evaluator will assign to a translation. Here, we present evaluation results combining several of these gaze features, and compare them against BLEU (Papineni et al., 2002), which uses lexical information and is designed to measure not only *fluency* but also *adequacy*.

In Table 2, we present results in the following way: in (I) we present the best non-lexicalized feature

[4] Although there could be differences based on corresponding translation, which may result in different values for the reference features.

combinations that improve the predictive power of the model. In (II) we re-introduce the results of lexicalized jumps feature. In (III) we present results of BLEU and the combination of eye-tracking features with it. Finally in (IV) we present the human-to-human agreement measured in average Kendall's tau and in max human-to-human Kendall's tau.

Combinations of translation jumps In section I we present several combinations of features. All of them include the backward jumps feature. This feature provides predictive power ($\tau = 0.22$), which is orthogonal to other features. This is in line with our initial hypothesis that for a bad translation, an evaluator needs to go back and forth several times to understand it. Combining the backward jumps with the total number of jumps (CTJ$_1$) slightly increases the correlation to $\tau = 0.25$. Adding the jump distance (CTJ$_2$) also increases its τ to 0.27. While this correlation is lower than BLEU ($\tau = 0.34$), it does showcase the predictive power of the reading patterns.

Combinations with BLEU When we combined BLEU with the translation jumps, we observed an increment in the τ to 0.37. Combining BLEU with the lexicalized jumps, yields the best combination ($\tau = 0.42$). Although moderate, these increments suggest that the reading patterns could be capturing additional phenomenon besides adequacy and fluency, such as structural complexity. These phenomena remain to be explored in future work.

Human performance On average, evaluators agreements with each other are fair ($\tau = 0.33$) and below the best combination (CB$_3$), while the maximum agreement of any two evaluators is relatively higher ($\tau = 0.53$). This tells us that on average the semi-automatic approach to evaluation that we propose here is already competitive to predictions done by another (average) human. However, there is still room for improvement with respect to the most-agreeing pair of evaluators.

5 Related Work

Eye-tracking devices have been used previously in the MT research. Stymne et al. (2012) used eye-tracking to identify and classify MT errors. Doherty et al. (2010) conducted a study using eye-tracking for MT evaluation and showed correlation between fixations and BLEU scores. Doherty and O'Brien (2014) evaluated the quality of machine translation output in terms of its *usability* by an end user. Guzmán et al. (2015) used eye-tracking to show that having monolingual environment improves the consistency of the evaluation.

Table 2: Result of combining several jump and lexicalized features with BLEU. The column *Feature Sets* shows the name of the systems whose features are combined for that particular run. We also included the average and maximum observed *tau* between any two evaluators, as a reference.

Our work is different, as we: i) proposed novel eye-tracking features and ii) model gaze movements to predict human judgment.

6 Conclusion

We have shown that the reading patterns detected through eye-tracking can be used to predict human judgments of automatic translations. To this end, we extracted novel lexicalized and non-lexicalized features from the eye-tracking data motivated by notions of reading difficulty, and used them to predict the quality of a translation. We have shown that these features capture more than just the fluency of a translation, and provide complementary information to BLEU. In combination, these features can be used to produce semi-automatic metrics with improved the correlation with human judgments.

In the future, we plan to extend our experiments to a large set of users and different language pairs. Additionally we plan to improve the feature set to take into account phenomena such as *early termination*, i.e. when an evaluator makes a judgment before finishing reading a translation. We plan to deepen our analysis to determine what kind of information is being used beyond fluency and adequacy.

Abstract

This work addresses the task of dependency labeling—assigning labels to an (unlabeled) dependency tree. We employ and extend a feature representation learning approach, optimizing it for both high speed and accuracy. We apply our labeling model on top of state-of-the-art parsers and evaluate its performance on standard benchmarks including the CoNLL-2009 and the English PTB datasets. Our model processes over 1,700 English sentences per second, which is 30 times faster than the sparse-feature method. It improves labeling accuracy over the outputs of top parsers, achieving the best LAS on 5 out of 7 datasets[1].

1 Introduction

Traditionally in dependency parsing, the tasks of finding the tree structure and labeling the dependency arcs are coupled in a joint achitecture. While it has potential to eliminate errors propogated through a separated procedure, joint decoding introduces other sources of issues that can also lead to non-optimal labeling assignments. One of the issues arises from inexact algorithms adopted in order to solve the hard joint search problem. For instance, many parsers (Nivre et al., 2007; Titov and Henderson, 2007; Zhang et al., 2013; Dyer et al., 2015; Weiss et al., 2015) adopt greedy decoding such as beam search, which may prune away the correct labeling hypothesis in an early decoding stage. Another issue is caused by the absence of rich label features. Adding dependency labels to the combinatorial space significantly slows down the search procedure. As a trade-off, many parsers such as MSTParser, TurboParser and RBGParser (McDonald et al., 2005; Martins et al., 2010; Zhang et al., 2014) incorporate only single-arc label features to reduce the processing time. This restriction greatly limits the labeling accuracy.

In this work, we explore an alternative approach where the dependency labeling is applied as a separate procedure, alleviating the issues described above. The potential of this approach has been explored in early work. For instance, McDonald et al. (2006) applied a separate labeling step on top of the first-order MSTParser. The benefit of such approach is two-fold. First, finding the optimal labeling assignment (once the tree structure is produced) can be solved via an *exact* dynamic programming algorithm. Second, it becomes relatively cheap to add *rich label features* given a fixed tree, and the exact algorithm still applies when high-order label features are included. However, due to performance issues, such approach has not been adopted by the top performing parsers. In this work, we show that the labeling procedure, when optimized with recent advanced techniques in parsing, can achieve very high speed and accuracy.

Specifically, our approach employs the recent distributional representation learning technique for parsing. We apply and extend the low-rank tensor factorization method (Lei et al., 2014) to the second-order case to learn a joint scoring function over grand-head, head, modifier and their labels. Unlike the prior work which additionally requires

[1] Our code is available at `https://github.com/shentianxiao/RBGParser/tree/labeling`.

Proceedings of NAACL-HLT 2016, pages 1089–1094,
San Diego, California, June 12-17, 2016.

traditional sparse features to achieve state-of-the-art performance, our extention alone delivers the same level of accuracy, while being substantially faster. As a consequence, the labeling model can be applied either as a refinement (re-labeling) step on top of existing parsers with negligible cost of computation, or as a part of a decoupled procedure to simplify and speed up the dependency parsing decoding.

We evaluate on all datasets in the CoNLL-2009 shared task as well as the English Penn Treebank dataset, applying our labeling model on top of state-of-the-art dependency parsers. Our labeling model processes over 1,700 English sentences per second, which is 30 times faster than the sparse-feature method. As a refinement (re-labeling) model, it achieves the best LAS on 5 out of 7 datasets.

2 Method

2.1 Task Formulation

Given an unlabeled dependency parsing tree $\mathbf{y}$ of sentence $\mathbf{x}$, where $\mathbf{y}$ can be obtained using existing (non-labeling) parsers, we classify each head-modifier dependency arc $h \rightarrow m \in \mathbf{y}$ with a particular label $l_{h\rightarrow m}$. Let $\mathbf{l} = \bigcup_{h\rightarrow m \in \mathbf{y}} \{l_{h\rightarrow m}\}$, our goal is to find the assignment with the highest score:

$$\mathbf{l}^* = \arg\max_{\mathbf{l}} \ \mathrm{S}(\mathbf{x}, \mathbf{y}, \mathbf{l})$$

For simplicity, we omit $\mathbf{x}, \mathbf{y}$ in the following discussion, which remain the same during the labeling process. We assume that the score $\mathrm{S}(\mathbf{l})$ decomposes into a sum of local scores of single arcs or pairs of arcs (in the form of grand-head–head–modifier), i.e.

$$\mathrm{S}(\mathbf{l}) = \sum_{h\rightarrow m \in \mathbf{y}} \mathrm{s}_1(h \xrightarrow{q} m) + \sum_{g\rightarrow h\rightarrow m \in \mathbf{y}} \mathrm{s}_2(g \xrightarrow{p} h \xrightarrow{q} m)$$

where $p = l_{g\rightarrow h}$, $q = l_{h\rightarrow m}$.

Parameterizing the scoring function $\mathrm{s}_1(h \xrightarrow{q} m)$ and $\mathrm{s}_2(g \xrightarrow{p} h \xrightarrow{q} m)$ is a key challenge. We follow Lei et al. (2014) to learn dense representations of features, which have been shown to better generalize the scoring function.

2.2 Scoring

The representation-based approach requires little feature engineering. Concretely, let $\phi_g, \phi_h, \phi_m \in \mathbb{R}^n$ be the atomic feature vector of the grand-head, head and modifier word respectively, and $\phi_{g\rightarrow h,p}, \phi_{h\rightarrow m,q} \in \mathbb{R}^d$ be the atomic feature vector of the two dependency arcs respectively. It is easy to define and compute these vectors. For instance, ϕ_g (as well as ϕ_h and ϕ_m) can incorperate binary features which indicate the word and POS tag of the current token (and its local context), while $\phi_{g\rightarrow h,p}$ (and $\phi_{h\rightarrow m,q}$) can indicate the label, direction and length of the arc between the two words.

Unigram features:		
form	form-p	form-n
lemma	lemma-p	lemma-n
POS	POS-p	POS-n
morph	bias	
Bigram features:		
POS-p, POS	POS, POS-n	
form, POS	lemma, POS	
lemma, POS-p	lemma, POS-n	
Trigram features:		
POS-p, POS, POS-n		

Table 1: Word atomic features used by our model. *POS*, *form*, *lemma* and *morph* stand for the POS tag, word form, word lemma and morphology features respectively. The suffix *-p* refers to the previous token, and *-n* refers to the next.

The scores of the arcs are computed by (1) projecting the atomic vectors into low-dimensional spaces; and (2) summing up the element-wise products of the resulting dense vectors:

$$\mathrm{s}_1(h \xrightarrow{q} m) = \sum_{i=1}^{r_1} \ [U_1\phi_h]_i [V_1\phi_m]_i [W_1\phi_{h\rightarrow m,q}]_i$$

where r_1 is a hyper-parameter denoting the dimension after projection, and $U_1, V_1 \in \mathbb{R}^{r_1 \times n}$, $W_1 \in \mathbb{R}^{r_1 \times d}$ are projection matrices to be learned.

The above formulation can be shown equivalent to factorizing a huge score table $T_1(\cdot,\cdot,\cdot)$ into the product of three matrices U_1, V_1 and W_1, where T_1 is a 3-way array (tensor) storing feature weights of all possible features involving three components—the head, modifier and the arc between the two. Accordingly, the formula to calculate $\mathrm{s}_1(\cdot)$ is equivalent to summing up all feature weights (from T_1) over the structure $h \xrightarrow{q} m$.[2]

We depart from the prior work in the following aspects. First, we naturally extend the factorization approach to score second-order structures of grand-

[2] We refer readers to the original work (Lei et al., 2014) for the derivation and more details.

head, head and modifier,

$$\mathrm{s}_2(g \xrightarrow{p} h \xrightarrow{q} m) = \sum_{i=1}^{r_2} [U_2\phi_g]_i[V_2\phi_h]_i[W_2\phi_m]_i \\ [X_2\phi_{g\to h,p}]_i[Y_2\phi_{h\to m,q}]_i$$

Here r_2 is a hyper-parameter denoting the dimension, and $U_2, V_2, W_2 \in \mathbb{R}^{r_2\times n}$, $X_2, Y_2 \in \mathbb{R}^{r_2\times d}$ are additional parameter matrices to be learned. Second, in order to achieve state-of-the-art parsing accuracy, prior work combines the single-arc score $\mathrm{s}_1(h \xrightarrow{q} m)$ with an extensive set of sparse features which go beyond single-arc structures. However, we find this combination is a huge impediment to decoding speed. Since our extention already captures high-order structures, it readily delivers state-of-the-art accuracy without the combination. This change results in a speed-up of an order of magnitude (see section 2.4 for a further discussion).

2.3 Viterbi Labeling

We use a dynamic programming algorithm to find the labeling assignment with the highest score. Suppose h is any node apart from the root, and g is h's parent. Let $\mathrm{f}(h, p)$ denote the highest score of subtree h with $l_{g\to h}$ fixed to be p. Then we can compute $\mathrm{f}(\cdot,\cdot)$ using a bottom-up method, from leaves to the root, by transition function

$$\mathrm{f}(h,p) = \sum_{h\to m\in\mathbf{y}} \max_q \Big\{\mathrm{f}(m,q) + \mathrm{s}_1(h \xrightarrow{q} m) \\ + \mathrm{s}_2(g \xrightarrow{p} h \xrightarrow{q} m)\Big\}$$

And the highest score of the whole tree is

$$\mathrm{f}(root) = \sum_{root\to m\in\mathbf{y}} \max_q \mathrm{f}(m,q) + \mathrm{s}_1(root \xrightarrow{q} m)$$

Once we get $\mathrm{f}(\cdot,\cdot)$, we can determine the labels backward, in a top-down manner. The time complexity of our algorithm is $\mathrm{O}(NL^2 \cdot T)$, where N is the number of words in a sentence, L is the number of total labels, and T is the time of computing features and scores.

2.4 Speed-up

In this section, we discuss two simple but effective strategies to speed up the labeling procedure.

Pruning We prune unlikely labels by simply exploiting the part-of-speech (POS) tags of the head and the modifier. Specifically, let $\mathbf{1}(\mathrm{pos}_h, \mathrm{pos}_m, l)$ denote whether there is an arc $h \xrightarrow{l} m$ in the training data such that h's POS tag is pos_h and m's POS tag is pos_m. In the labeling process, we only consider the possible labels that occur with the corresponding POS tags. Let K be the average number of possible labels per arc, then the time complexity is dropped to $\mathrm{O}(NK^2 \cdot T)$ approximately. In practice, $K \approx L/4$. Hence this pruning step makes our labeler 16 times faster.

Using Representation-based Scoring Only The time to compute scores, i.e. T, consists of building the features and fetching the corresponding feature weights. For traditional methods, this requires enumerating feature templates, constructing feature ID and searching the feature weight in a look-up table. For representation-based scoring, the dense word representations (e.g. $U_1\phi_h$) can be pre-computed, and the scores are obtained by simple inner products of small vectors. We choose to use representation-based scoring only, therefore reducing the time to $\mathrm{O}(NK^2 \cdot (r_1 + r_2) + NT')$. In practice, we find the labeling process becomes about 30 times faster.

2.5 Learning

Let $\mathbf{D} = \{(\mathbf{x}_i, \mathbf{y}_i, \mathbf{l}_i)\}_{i=1}^M$ be the collection of M training samples. Our goal is to learn the values of the set of parameters $\Theta = \{U_1, V_1, W_1, U_2, V_2, W_2, X_2, Y_2\}$ based on $\mathbf{D}$. Following standard practice, we optimize the parameter values in an online maximum soft-margin framework, minimizing the structural hinge loss:

$$\mathrm{loss}(\Theta) = \max_{\hat{\mathbf{l}}} \Big\{\mathrm{S}(\hat{\mathbf{l}}) + \|\mathbf{l}_i - \hat{\mathbf{l}}\|_1\Big\} - \mathrm{S}(\mathbf{l}_i)$$

where $\|\mathbf{l}_i - \hat{\mathbf{l}}\|_1$ is the number of different labels between $\mathbf{l}_i$ and $\hat{\mathbf{l}}$. We adjust parameters Θ by $\Delta\Theta$ via passive-aggressive update:

$$\Delta\Theta = \max\left\{C, \frac{\mathrm{loss}(\Theta)}{\|\delta\Theta\|^2}\right\} \cdot \delta\Theta$$

where $\delta\Theta = \frac{\mathrm{dloss}(\Theta)}{\mathrm{d}\Theta}$ denotes the derivatives and C is a regularization hyper-parameter controlling the maximum step size of each update.

To counteract over-fitting, we follow the common practice of averaging parameters over all iterations.

3 Results

Experimental Setup We test our model on the CoNLL-2009 shared task benchmark with 7 different languages as well as the English Penn Treebank dataset. Whenever available, we use the predicted POS tags, word lemmas and morphological information provided in the datasets as atomic features. Following standard practice, we use unlabeled attachment scores (UAS) and labeled attachment scores (LAS) as evaluation measure[3]. In order to compare with previous reported numbers, we exclude punctuations for PTB in the evaluation, and include punctuations for CoNLL-2009 for consistency.

We use RBGParser[4], a state-of-the-art graph-based parser for predicting dependency trees, and then apply our labeling model to obtain the dependency label assignments. To demonstrate the effectiveness of our model on other systems, we also apply it on two additional parsers – Stanford Neural Shift-reduce Parser (Chen and Manning, 2014)[5] and TurboParser (Martins et al., 2010)[6]. In all reported experiments, we use the default suggested settings to run these parsers. The hyper-parameters of our labeling model are set as follows: $r_1 = 50$, $r_2 = 30$, $C = 0.01$.

Labeling Performance To test the performance of our labeling method, we first train our model using the gold unlabeled dependency trees and evaluate the labeling accuray on CoNLL-2009. Table 3 presents the results. For comparison, we implement a combined system which adds a rich set of traditional, sparse features into the scoring function and jointly train the feature weights. As shown in the table, using our representation-based method alone is super fast, being 30 times faster than the implementation with traditional feature computation and able to process over 1,700 English sentences per second. It does not affect the LAS accuracy except for Chinese.

	Ours + Sparse Features		Ours only	
	LAS	Speed	LAS	Speed
Catalan	96.33	30	96.42	1070
Chinese	94.16	38	93.16	1304
Czech	95.54	71	95.60	2065
English	97.00	62	96.88	1751
German	96.93	113	96.89	1042
Japanese	98.92	305	98.95	2778
Spanish	96.53	43	96.68	1142

Table 3: LAS and parsing speed (sentence per second) based on unlabeled golden trees.

UAS		Labeled	Unlabeled
	RBG	93.48	93.33
LAS		Before	After
	Stanford NN	89.37	89.55
	Turbo	90.22	90.65
	RBG	91.00	91.43
Runtime		Joint	Two-step
	Stanford NN	4.4	3.3
	Turbo	182.1	119.4
	RBG	365.4	305.7

Table 4: Joint vs. Separate analysis on PTB.

PTB Results Table 4 shows the performance on the English PTB dataset. We use RBGParser to predict both labeled and unlabeled trees, and there is no significant difference between their UAS. This finding lays the foundation for a separate procedure, as the tree structure does not vary much comparing to the joint procedure, and we can exploit rich label features and sophisticated algorithms to improve the LAS. Our re-labeling model improves over the predictions generated by the three different parsers, ranging from 0.2% to 0.4% LAS gain. Moreover, the labeling procedure runs in only 1.5 seconds on the test set. If we use the existing parsers to only predict

[6] http://www.cs.cmu.edu/~ark/TurboParser/

unlabeled trees, we also obtain speed improvement, even for the highly speed-optimzed Stanford Neural Parser.

CoNLL-2009 Results In Table 2, we compare our model with the best systems[7] of the CoNLL-2009 shared task, Bohnet (2010), Zhang and McDonald (2014) as well as the most recent neural network parser (Alberti et al., 2015). Despite the simplicity of the decoupled parsing procedure, our labeling model achieves LAS performance on par with the state-of-the-art neural network parser. Specifically, our model obtains the best LAS on 5 out of 7 languages, while the neural parser outperforms ours on Catalan and Chinese.

4 Conclusion

The most common method for dependency parsing couples the structure search and label search. We demonstrate that decoupling these two steps yields both computational gains and improvement in labeling accuracy. Specifically, we demonstrate that our labeling model can be used as a post-processing step to improve the accuracy of state-of-the-art parsers. Moreover, by employing dense feature representations and a simple pruning strategy, we can significantly speed up the labeling procedure and reduce the total decoding time of dependency parsing.

Abstract

We explore the consequences of representing token segmentations as hierarchical structures (trees) for the task of Multiword Expression (MWE) recognition, in isolation or in combination with dependency parsing. We propose a novel representation of token segmentation as trees on tokens, resembling dependency trees. Given this new representation, we present and evaluate two different architectures to combine MWE recognition and dependency parsing in the *easy-first* framework: a pipeline and a joint system, both taking advantage of lexical and syntactic dimensions. We experimentally validate that MWE recognition significantly helps syntactic parsing.

1 Introduction

Lexical segmentation is a crucial task for natural language understanding as it detects semantic units of texts. One of the main difficulties comes from the identification of multiword expressions [MWE] (Sag et al., 2002), which are sequences made of multiple words displaying multidimensional idiomaticity (Nunberg et al., 1994). Such expressions may exhibit syntactic freedom and varying degree of compositionality, and many studies show the advantages of combining MWE identification with syntactic parsing (Savary et al., 2015), for both tasks (Wehrli, 2014). Indeed, MWE detection may help parsing, as it reduces the number of lexical units, and in turn parsing may help detect MWEs with syntactic freedom (syntactic variations, discontinuity, etc.).

In the dependency parsing framework, some previous work incorporated MWE annotations within syntactic trees, in the form of complex subtrees either with flat structures (Nivre and Nilsson, 2004; Eryiğit et al., 2011; Seddah et al., 2013) or deeper ones (Vincze et al., 2013; Candito and Constant, 2014). However, these representations do not capture deep lexical analyses like nested MWEs. In this paper, we propose a two-dimensional representation that separates lexical and syntactic layers with two distinct dependency trees sharing the same nodes[1]. This representation facilitates the annotation of complex lexical phenomena like embedding of MWEs (e.g. *I will (take a (rain check))*). Given this representation, we present two easy-first dependency parsing systems: one based on a pipeline architecture and another as a joint parser.

2 Deep Segmentation and Dependencies

This section describes a lexical representation able to handle nested MWEs, extended from Constant and Le Roux (2015) which was limited to shallow MWEs. Such a lexical analysis is particularly relevant to perform deep semantic analysis.

A lexical unit [LU] is a subtree of the lexical segmentation tree composed of either a single token unit or an MWE. In case of a single token unit, the subtree is limited to a single node. In case of an MWE, the subtree is rooted by its leftmost LU, from which there are arcs to every other LU of the MWE. For instance, the MWE *in spite of* made of three single token units is a subtree rooted by *in*. It comprises two arcs: *in* → *spite* and *in* → *of*. The MWE *make*

[1] This is related to the *Prague Dependency Treebank* (Hajič et al., 2006) which encodes MWEs in tectogrammatical trees connected to syntactic trees (Bejček and Straňák, 2010).

Proceedings of NAACL-HLT 2016, pages 1095–1101,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

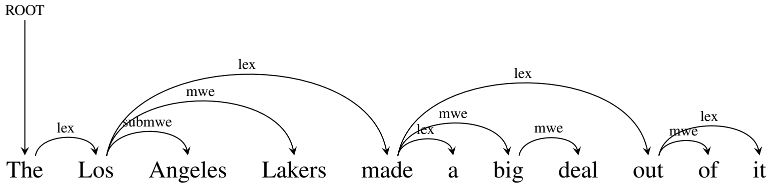

Figure 1: Deep segmentation of *Los Angeles Lakers made a big deal out of it* represented as a tree.

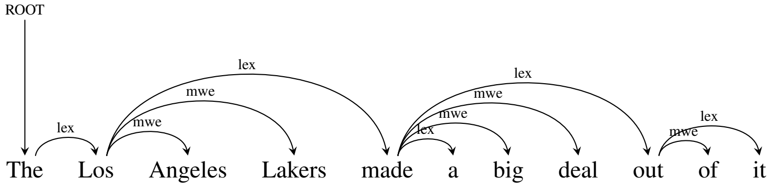

Figure 2: Shallow segmentation of *Los Angeles Lakers made a big deal out of it* represented as a tree.

big deal is more complex as it is formed of a single token unit *make* and an MWE *big deal*. It is represented as a subtree whose root is *make* connected to the root of the MWE subtree corresponding to *big deal*. The subtree associated with *big deal* is made of two single token units. It is rooted by *big* with an arc *big* → *deal*. Such structuring allows to find nested MWEs when the root is not an MWE itself, like for *make big deal*. It is different for the MWE *Los Angeles Lakers* comprising the MWE *Los Angeles* and the single token unit *Lakers*. In that case, the subtree has a flat structure, with two arcs from the node *Los*, structurally equivalent to *in spite of* that has no nested MWEs. Therefore, some extra information is needed in order to distinguish these two cases. We use arc labels.

Labeling requires to maintain a counter l in order to indicate the embedding level in the leftmost LU of the encompassing MWE. Labels have the form sub^lmwe for $l \geq 0$. Let $U = U_1...U_n$ be a LU composed of n LUs. If $n = 1$, it is a single token unit. Otherwise, $subtree(U, 0)$, the lexical subtree[2] for U is recursively constructed by adding arcs $subtree(U_1, l+1) \xrightarrow{sub^lmwe} subtree(U_i, 0)$ for $i \neq 1$. In the case of *shallow* representation, every LUs of U are single token units.

Once built the LU subtrees (the *internal dependencies*), it is necessary to create arcs to connect them and form a complete tree : that we call *external dependencies*. LUs are sequentially linked together: each pair of consecutive LUs with roots (w_i,w_j), $i < j$, gives an arc $w_i \xrightarrow{lex} w_j$. Figure 1 and Figure 2 respectively display the deep and shallow lexical segmentations of the sentence *The Los Angeles Lakers made a big deal out of it*.

For readibility, we note mwe for sub^0mwe and $submwe$ for sub^1mwe.

3 Multidimensional Easy-first Parsing

3.1 Easy-first parsing

Informally, easy-first proposed in Goldberg and Elhadad (2010) predicts easier dependencies before risky ones. It decides for each token whether it must be attached to the root of an adjacent subtree and how this attachment should be labeled[3]. The order in which these decisions are made is not decided in advance: highest-scoring decisions are made first and constrain the following decisions.

This framework looks appealing in order to test our assumption that segmentation and parsing are mutually informative, while leaving the exact flow of information to be learned by the system itself: we do not postulate any priority between the tasks nor that all attachment decisions must be taken jointly. On the contrary, we expect most decisions to be made independently except for some difficult cases that need both lexical and syntactic knowledge.

We now present two adaptations of this strategy to

[2] The second argument l corresponds to the embedding level.

[3] Labels are an extension to Goldberg and Elhadad (2010)

build both lexical and parse trees from a unique sequence of tokens[4]. The key component is to use features linking information from the two dimensions.

3.2 Pipeline Architecture

In this trivial adaptation, two parsers are run sequentially. The first one builds a structure in one dimension (i.e. for segmentation or syntax). The second one builds a structure in the other dimension, with the result of the first parser available as features.

3.3 Joint Architecture

The second adaptation is more substantial and takes the form of a joint parsing algorithm. This adaptation is provided in Algorithm 1. It uses a single classifier to predict lexical and syntactic actions. As in easy-first, each iteration predicts the most certain head attachment action given the currently predicted subtrees, but here it may belong to any dimension. This action can be mapped to an edge in the appropriate dimension via function EDGE. Function *score(a,i)* computes the dot-product of feature weights and features at position i using surrounding subtrees in both dimensions[5].

Algorithm 1 Joint Easy-first parsing

```
function JOINT EASY-FIRST PARSING($w_0 ... w_n$)
    Let $\mathcal{A}$ be the set of possible actions
    arcs$_s$,arcs$_l$ := $(\emptyset, \emptyset)$
    h$_s$,h$_l$ := $w_0 \dots w_n, w_0 \dots w_n$
    while $|h_l| > 1 \vee |h_s| > 1$ do
        $\hat{a}, \hat{i}$ := argmax$_{a \in \mathcal{A}, i \in [|h_d|]}$ score(a,i)
        $(par, lab, child, dim)$ := EDGE($(h_s, h_l), \hat{a}, \hat{i}$)
        arcs$_{dim}$ := arcs$_{dim}$ $\cup$ $(par, lab, child)$
        h$_{dim}$ := h$_{dim}$$\backslash\{child\}$
    end while
    return $(arcs_l, arcs_s)$
end function
function EDGE($(h_s, h_l), (dir, lab, dim), i$)
    if $dir = \leftarrow$ then                    ▷ we have a left edge
        return $(h_{dim}[i], lab, h_{dim}[i+1], dim)$
    else
        return $(h_{dim}[i+1], lab, h_{dim}[i], dim)$
    end if
end function
```

We can reuse the reasoning from Goldberg and Elhadad (2010) and derive a worst-case time complexity of $O(n \log n)$, provided that we restrict feature extraction at each position to a bounded vicinity.

	English	French	
Corpus	**EWT**	**FTB**	**Sequoia**
# words	55,590	564,798	33,829
# MWE labels	4,649	49,350	6,842
ratio	0.08	0.09	0.20
MWE rep.	shallow$^+$	shallow	deep

Table 1: Datasets statistics. The first part describes the number of words in training sets with MWE label ratio. shallow$^+$ refers to a shallow representation with enriched MWE labels indicating the MWE strength (collocation vs. fixed).

4 Experiments

4.1 Datasets

We used data sets derived from three different reference treebanks: English Web Treebank (Linguistic Data Consortium release LDC2012T13)[EWT], French treebank (Abeillé et al., 2003) [FTB], Sequoia Treebank (Candito and Seddah, 2012) [Sequoia]. These treebanks have MWE annotations available on at least a subpart of them. For EWT, we used the STREUSLE corpus (Schneider et al., 2014b) that contains annotations of all types of MWEs, including discontiguous ones. We used the train/test split from Schneider et al. (2014a). The FTB contains annotations of contiguous MWEs. We generated the dataset from the version described in Candito and Constant (2014) and used the shallow lexical representation, in the official train/dev/test split of the SPMRL shared task (Seddah et al., 2013). The Sequoia treebank contains some limited annotations of MWEs (usually, compounds having an irregular syntax). We manually extended the coverage to all types of MWEs including discontiguous ones. We also included deep annotation of MWEs (in particular, nested ones). We used a 90%/10% train/test split in our experiments. Some statistics about the data sets are provided in table 4.1. Tokens were enriched with their predicted part-of-speech (POS) and information from MWE lexicon[6] lookup as in Candito and Constant (2014).

[4] It is straightforward to add any number of tree structures.

[5] Let us note that the algorithm builds projective trees for each dimension, but their union may contain crossing arcs.

[6] We used the *Unitex* platform (`www-igm.univ-mlv.fr/~unitex/` for French and the STREUSLE corpus web site (`www.ark.cs.cmu.edu/LexSem/`) for English.

4.2 Parser and features

Parser. We implemented our systems by modifying the parser of Y. Goldberg[7] also used as a baseline. We trained all models for 20 iterations with dynamic oracle (Goldberg and Nivre, 2013) using the following exploration policy: always choose an oracle transition in the first 2 iterations ($k = 2$), then choose model prediction with probability $p = 0.9$.

Features. One-dimensional features were taken directly from the code supporting Goldberg and Nivre (2013). We added information on typographical cues (hyphenation, digits, capitalization, ...) and the existence of substrings in MWE dictionaries in order to help lexical analysis. Following Constant et al. (2012) and Schneider et al. (2014a), we used dictionary lookups to build a first naive segmentation and incorporate it as a set of features. Two-dimensional features were used in both pipeline and joint strategies. We first added syntactic path features to the lexical dimension, so syntax can guide segmentation. Conversely, we also added lexical path features to the syntactic dimension to provide information about lexical connectivity. For instance, two nodes being checked for attachment in the syntactic dimension can be associated with information describing whether one of the corresponding node is an ancestor of the other one in the lexical dimension (i.e. indicating whether the two syntactic nodes are linked via internal or external paths).

We also selected automatically generated features combining information from both dimensions. We chose a simple data-driven heuristics to select combined features. We ran one learning iteration over the FTB training corpus adding all possible combinations of syntactic and lexical features. We picked the templates of the 10 combined features whose scores had the greatest absolute values. Although this heuristics may not favor the most discriminant features, we found that the chosen features helped accuracy on the development set.

4.3 Results

For each dataset, we carried out four experiments. First we learned and ran independently two *distinct* baseline easy-first parsers using one-dimensional features: one producing a lexical segmentation, another one predicting a syntactic parse tree. We also trained and ran a *joint* easy-first system predicting lexical segmentations and syntactic parse trees, using two-dimensional features. We also experimented the *pipeline* system for each dimension, consisting in applying the baseline parser on one dimension and using the resulting tree as source of two-dimensional features in a standard easy first parser applied on the other dimension. Since pipeline architectures are known to be prone to error propagation, we also run an experiment where the pipeline second stage is fed with oracle first-stage trees.

Results on the test sets are provided in table 2, where LAS and UAS are computed with punctuation. Overall, we can see that the lexical information tends to help syntactic prediction while the other way around is unclear.

5 Discussion

The first striking observation is that the syntactic dimension does not help the predictions in the lexical dimension, contrary to what could be expected. In practice, we can observe that variations and discontinuity of MWEs are not frequent in our data sets. For instance, Schneider et al. (2014a) notice

[7] We started from the version available at the time of writing at `https://bitbucket.org/yoavgo/tacl2013dynamicoracles`

that only 15% of the MWEs in EWT are discontiguous and most of them have gaps of one token. This could explain why syntactic information is not useful for segmentation. On the other hand, the lexical dimension tends to help syntactic predictions. More precisely, while the pipeline and the joint approach reach comparable scores on the FTB and Sequoia, the joint system has disappointing results on EWT. The good scores for Sequoia could be explained by the larger MWE coverage.

In order to get a better intuition on the real impact of each of the three approaches, we broke down the syntax results by dependency labels. Some labels are particularly informative. First of all, the precision on the modifier label *mod*, which is the most frequent one, is greatly improved using the pipeline approach as compared with the baseline (around 1 point). This can be explained by the fact that many nominal MWEs have the form of a regular noun phrase, to which its internal adjectival or prepositional constituents are attached with the *mod* label. Recognizing a nominal MWE on the lexical dimension may therefore give a relevant clue on its corresponding syntactic structure. Then, the *dep_cpd* connects components of MWE with irregular syntax that cannot receive standard labels. We can observe that the pipeline (resp. the joint) approach clearly improves the precision (resp. recall) as compared with the baseline (+1.6 point). This means that the combination of a preliminary lexical segmentation and a possibly partial syntactic context helps improving the recognition of syntax-irregular MWEs. Coordination labels (*dep.coord* and *coord*) are particularly interesting as the joint system outperforms the other two on them. Coordination is known to be a very complex phenomenon: these scores would tend to show that the lexical and syntactic dimensions mutually help each other.

When comparing this work to state-of-the-art systems on data sets with shallow annotation of MWEs, we can see that we obtain MWE recognition scores comparable to systems of equivalent complexity and/or available information. This means that our novel representation which allows for the annotation of more complex lexical phenomena does not deteriorate scores for shallow annotations.

6 Conclusions and Future Work

In this paper we presented a novel representation of deep lexical segmentation in the form of trees, forming a dimension distinct from syntax. We experimented strategies to predict both dimensions in the easy-first dependency parsing framework. We showed empirically that joint and pipeline processing are beneficial for syntactic parsing while hardly impacting deep lexical segmentation.

The presented combination of parsing and segmenting does not enforce any structural constraint over the two trees[8]. We plan to address this issue in future work. We will explore less redundant, more compact representations of the two dimensions since some annotations can be factorized between the two dimensions (e.g. MWEs with irregular syntax) and some can easily be induced from others (e.g. sequential linking between lexical units).

Sentiment Composition of Words with Opposing Polarities

Svetlana Kiritchenko and **Saif M. Mohammad**
National Research Council Canada
{svetlana.kiritchenko,saif.mohammad}@nrc-cnrc.gc.ca

Abstract

In this paper, we explore sentiment composition in phrases that have at least one positive and at least one negative word—phrases like *happy accident* and *best winter break*. We compiled a dataset of such opposing polarity phrases and manually annotated them with real-valued scores of sentiment association. Using this dataset, we analyze the linguistic patterns present in opposing polarity phrases. Finally, we apply several unsupervised and supervised techniques of sentiment composition to determine their efficacy on this dataset. Our best system, which incorporates information from the phrase's constituents, their parts of speech, their sentiment association scores, and their embedding vectors, obtains an accuracy of over 80% on the opposing polarity phrases.

1 Introduction

The Principle of Compositionality states that the meaning of an expression is determined by the meaning of its constituents and by its grammatical structure (Montague, 1974). By extension, sentiment composition is the determining of sentiment of a multi-word linguistic unit, such as a phrase or a sentence, based on its constituents. In this work, we study sentiment composition in phrases that include at least one positive and at least one negative word—for example, phrases such as *happy accident*, *couldn't stop smiling*, and *lazy sundays*. We refer to them as *opposing polarity phrases*. Such phrases present a particular challenge for automatic sentiment analysis systems that often rely on bag-of-word features.

Word–sentiment associations are commonly captured in *sentiment lexicons*. However, most existing manually created sentiment lexicons include only single words. Lexicons that include sentiment associations for *multi-word phrases* as well as their constituent words can be very useful in studying sentiment composition. We refer to them as *sentiment composition lexicons (SCLs)*.

We created a sentiment composition lexicon for opposing polarity phrases and their constituent words (Kiritchenko and Mohammad, 2016c).[1] Both phrases and single words were manually annotated with real-valued sentiment association scores using an annotation scheme known as Best–Worst Scaling.[2] We refer to the created resource as the *Sentiment Composition Lexicon for Opposing Polarity Phrases (SCL-OPP)*. The lexicon includes entries for 265 trigrams, 311 bigrams, and 602 unigrams.

In this paper, we use SCL-OPP to analyze regularities present in different kinds of opposing polarity phrases. We calculate the extent to which different part-of-speech combinations result in phrases of positive and negative polarity. We also show that for most phrases, knowing the parts of speech and polarities of their constituents is not enough to reliably predict the sentiment of the phrase.

We apply several unsupervised and supervised techniques of sentiment composition to determine their efficacy on predicting the sentiment of opposing polarity phrases. Our experiments indicate that

[1] www.saifmohammad.com/WebPages/SCL.html#OPP

[2] Best–Worst Scaling has been shown to produce reliable real-valued sentiment association scores (Kiritchenko and Mohammad, 2016a).

Proceedings of NAACL-HLT 2016, pages 1102–1108,
San Diego, California, June 12-17, 2016.

the sentiment of the last unigram or the sentiment of the most polar unigram in the phrase are not strong predictors of the overall sentiment of the phrase. Similarly, adjectives and verbs do not always dominate the sentiment in such phrases. Finally, we show that the constituent words, their parts of speech, their sentiment association scores, and their embedding vectors are all useful features—a supervised sentiment composition system that incorporates them obtains accuracies over 80% on both bigram and trigram opposing polarity phrases.

2 Related Work

A number of approaches have been proposed to address sentiment composition, which include manually derived syntactic rules (Moilanen and Pulman, 2007; Neviarouskaya et al., 2010), combination of hand-written rules and statistical learning (Choi and Cardie, 2008), and machine learning approaches (Nakagawa et al., 2010; Yessenalina and Cardie, 2011; Dong et al., 2015). Much work has been devoted to model the impact of negators and (to a lesser degree) intensifiers, words commonly referred to as contextual valence shifters, on sentiment of words they modify (Polanyi and Zaenen, 2004; Kennedy and Inkpen, 2005; Liu and Seneff, 2009; Wiegand et al., 2010; Taboada et al., 2011; Kiritchenko et al., 2014). Kiritchenko and Mohammad (2016b) created a sentiment composition lexicon for negators, modals, and adverbs (SCL-NMA) through manual annotation and analyzed the effect of these groups of modifiers on sentiment in short phrases. Recently, recursive deep model approaches have been proposed for handling sentiment of syntactic phrases through sentiment composition over parse trees (Socher et al., 2013; Zhu et al., 2014; Irsoy and Cardie, 2014; Tai et al., 2015). In this work, we apply several unsupervised and supervised techniques of sentiment composition for a specific type of phrases—opposing polarity phrases.

3 Creating a Sentiment Lexicon for Opposing Polarity Phrases

This section summarizes how we created a sentiment composition lexicon for opposing polarity phrases using the Best–Worst Scaling annotation technique. For more details we refer the reader to (Kiritchenko and Mohammad, 2016c). Table 1 shows a few example entries from the lexicon.

Term	Sentiment score
best winter break	0.844
breaking free	0.172
isn’t long enough	-0.188
breaking	-0.500
heart breaking moment	-0.797

Table 1: Example entries in SCL-OPP.

Term selection: We polled the Twitter API (from 2013 to 2015) to collect about 11 million tweets that contain emoticons: ‘:)’ or ‘:(’. We will refer to this corpus as the *Emoticon Tweets Corpus*. From this corpus, we selected bigrams and trigrams that had at least one positive word and at least one negative word. The polarity labels (positive or negative) of the words were determined by simple look-up in existing sentiment lexicons: Hu and Liu lexicon (Hu and Liu, 2004), NRC Emotion lexicon (Mohammad and Turney, 2010; Mohammad and Turney, 2013), MPQA lexicon (Wilson et al., 2005), and NRC’s Twitter-specific lexicon (Kiritchenko et al., 2014; Mohammad et al., 2013).[3] In total, 576 opposing polarity n-grams (bigrams and trigrams) were selected. We also chose for annotation all unigrams that appeared in the selected set of bigrams and trigrams. There were 602 such unigrams. Note that even though the multi-word phrases and single-word terms were drawn from a corpus of tweets, most of the terms are used in everyday English.

Best–Worst Scaling Method of Annotation: Best–Worst Scaling (BWS), also sometimes referred to as Maximum Difference Scaling (MaxDiff), is an annotation scheme that exploits the comparative approach to annotation (Louviere and Woodworth, 1990; Louviere et al., 2015). Annotators are given four items (4-tuple) and asked which term is the Best (highest in terms of the property of interest) and which is the Worst (least in terms of the property of interest). Responses to the BWS questions can then be translated into real-valued scores through a simple counting procedure: For each term, its score is calculated as the percentage of times the term was

[3] If a word was marked with conflicting polarity in two lexicons, then that word was not considered as positive or negative.

SCP	Occ.	# phrases
▽adj. + △adj. → △phrase	0.76	17
▽adj. + △noun → ▽phrase	0.59	68
△adj. + ▽noun → ▽phrase	0.53	73
△adverb + ▽adj. → ▽phrase	0.89	18
△adverb + ▽verb → ▽phrase	0.91	11
▽noun + △noun → △phrase	0.60	10
△noun + ▽noun → ▽phrase	0.52	25
▽verb + det. + △noun → ▽phrase	0.65	17
▽verb + △noun → ▽phrase	0.82	17

Table 2: Sentiment composition patterns (SCPs) in SCL-OPP. △denotes a positive word or phrase, ▽denotes a negative word or phrase. 'Occ.' stands for occurrence rate of an SCP.

chosen as the Best minus the percentage of times the term was chosen as the Worst (Orme, 2009). The scores range from -1 to 1.

We employ Best–Worst Scaling for sentiment annotation by providing four (single-word or multi-word) terms at a time and asking which term is the most positive (or least negative) and which is the least positive (or most negative). Each question was answered by eight annotators through a crowdsourcing platform, CrowdFlower.[4] We refer to the resulting lexicon as the *Sentiment Composition Lexicon for Opposing Polarity Phrases (SCL-OPP)*.

Portions of the created lexicon have been used as development and evaluation sets in SemEval-2016 Task 7 'Determining Sentiment Intensity of English and Arabic Phrases' (Kiritchenko et al., 2016).[5] The objective of that task was to test different methods of automatically predicting sentiment association scores for multi-word phrases.

4 Sentiment Composition Patterns

SCL-OPP allows us to explore sentiment composition patterns in opposing polarity phrases. We define a *Sentiment Composition Pattern (SCP)* as a rule that includes on the left-hand side the parts of speech (POS) and the sentiment associations of the constituent unigrams (in the order they appear in the phrase), and on the right-hand side the sentiment association of the phrase. Table 2 shows examples. SCPs that have a positive phrase on the right-hand side will be called *positive SCPs*, whereas SCPs that have a negative phrase on the right-hand side will be called *negative SCPs*. Below are some questions regarding SCPs and opposing polarity phrases that we explore here:

- Which SCPs are common among opposing polarity phrases?
- With the same left-hand side of an SCP, how often is the composed phrase positive and how often is the composed phrase negative? For example, when negative adjectives combine with a positive noun, how often is the combined phrase negative?
- Are some parts of speech (of constituent words) more influential in determining the sentiment of a phrase than others?

To answer these questions, each of the entries in SCL-OPP is marked with the appropriate SCP. The part-of-speech sequence of a phrase is determined by looking up the most common part-of-speech sequence for that phrase in the Emoticon Tweets Corpus.[6] Next, for every left-hand side of an SCP, we determine the ratio of 'how often occurrences of such combinations in SCL-OPP resulted in a positive phrase' to 'how often such combinations were seen in total'. We will refer to these scores as the *occurrence rates ('Occ.') of positive SCPs*. The *occurrence rates of negative SCPs* are calculated in a similar manner.

Table 2 presents all SCPs with the left-hand side combination appearing at least ten times in SCL-OPP, and whose occurrence rate is equal to or greater than 50%. For example, the second row tells us that there are 68 bigrams in SCL-OPP such that the first word is a negative adjective and the second word is a positive noun. Out of these 68 bigrams, 59% are negative, and the remaining 41% are positive, so the occurrence rate of this pattern is 0.59.

The most common SCPs in our lexicon are "△adj. + ▽noun → ▽phrase" (73) and "▽adj. + △noun → ▽phrase" (68). Observe that the occurrence rates of the patterns are spread over the entire range from 52% to 91%. Only two patterns have very high occurrence rates (around 90%): "△adverb + ▽adj. → ▽phrase" and "△adverb + ▽verb → ▽phrase".

[4] Let *majority answer* refer to the option most chosen for a question. 81% of the responses matched the majority answer.

[5] http://alt.qcri.org/semeval2016/task7/

[6] The corpus was automatically POS tagged using the CMU Tweet NLP tool (Gimpel et al., 2011).

Thus, for most opposing polarity phrases, their sentiment cannot be accurately determined based on the POS and sentiment of the constituents alone.

Both SCPs with high occurrence rates include adverbs that serve as intensifiers—words that increase or decrease the degree of association of the following word with positive (negative) sentiment (e.g., *incredibly slow*, *dearly missed*). Only the degree of association for the next word is changed while its polarity (positive or negative) is often preserved. Some adjectives can also play the role of an intensifier when combined with another adjective (e.g., *crazy talented*) or a noun (e.g., *epic fail*). For example, the adjective *great*, often considered highly positive, becomes an intensifier when combined with some nouns (e.g., *great loss*, *great capture*). Other adjectives determine the polarity of the entire phrase (e.g., *happy tears*, *bad luck*). Therefore, the occurrence rates of patterns like "▽adj. + △noun → ▽phrase" are low. Overall, even though adjectives and verbs are frequently the primary source of sentiment in the phrase, some nouns can override their sentiment as in *new crisis* or *leave a smile*. SCL-OPP includes phrases corresponding to many different kinds of sentiment composition patterns, and therefore, it is a useful resource for studying linguistic underpinnings of sentiment composition as well as for evaluating sentiment composition algorithms for opposing polarity phrases.

5 Automatically Predicting Sentiment

We now investigate whether accurate models of sentiment composition for opposing polarity phrases can be learned. We conduct experiments with several baseline unsupervised classifiers as well supervised techniques using features, such as unigrams, POS, sentiment scores, and word embeddings.

The problem of sentiment composition can be formulated in two different ways: a binary classification task where the system has to predict if the phrase is positive or negative; and a regression task where the system has to predict the real-valued sentiment association score of the phrase. We evaluate binary classification with simple accuracy (*acc.*) and the regression task with Pearson correlation coefficient (r). Learning and evaluation are performed separately for bigrams and trigrams.

5.1 Baseline Classifiers

The oracle 'majority label' baseline assigns to all instances the most frequent polarity label in the dataset. The 'last unigram' baseline returns the sentiment score (or the polarity label) of the last unigram in the phrase. For the regression task, we use the real-valued sentiment score of the unigram whereas for the binary classification task we use the polarity label (positive or negative). The 'most polar unigram' baseline assigns to the phrase the sentiment score (or the polarity label) of the most polar word in that phrase, i.e., the word with the highest absolute sentiment score. The 'part-of-speech (POS) rule' baseline assigns sentiment as follows:

1. If the phrase has an adjective, return the sentiment score (polarity) of the last adjective;
2. Else, if the phrase has a verb, return the sentiment score (polarity) of the last verb;
3. Else, return the sentiment score (polarity) of the most polar word.

5.2 Supervised Classifiers

We train a Support Vector Machines classifier with RBF kernel for the binary classification task and a Support Vector regression model with RBF kernel for the regression task using the LibSVM package (Chang and Lin, 2011). For both tasks, the models are trained using different combinations of the following features obtained from the target phrase: all unigrams, POS tag of each unigram, sentiment label of each unigram, sentiment score of each unigram, and the word embedding vector for each unigram. The word embeddings are obtained by running word2vec software (Mikolov et al., 2013) on the Emoticon Tweets Corpus. We use the skip-gram model with the default parameters and generate 200-dimensional vectors for each unigram present in the corpus. For each task, ten-fold cross-validation is repeated ten times, and the results are averaged.

5.3 Results

The results for all baseline and supervised methods are presented in Table 3. The 'majority label', 'last unigram', 'most polar unigram', and 'POS rule' baselines are shown in rows a to d. Observe that the sentiment association of the last unigram is not very

Features	**Binary (Acc.)**		**Regression (Pearson r)**	
	2-gr	3-gr	2-gr	3-gr
Baselines				
a. majority label	56.6	60.8	-	-
b. last unigram	57.2	59.3	0.394	0.376
c. most polar unigram	66.9	69.8	0.416	0.551
d. POS rule	65.6	63.8	0.531	0.515
Supervised classifiers				
e. POS + sent. label	65.7	64.2	-	-
f. POS + sent. score	74.9	74.8	0.662	0.578
g. row f + uni	82.0	81.3	0.764	0.711
h. row f + emb(avg) + emb(max)	78.2	79.5	0.763	0.710
i. row f + emb(conc)	80.2	76.5	0.790	0.719
j. row f + emb(conc) + uni	**82.6**	**80.9**	**0.802**	**0.753**
k. POS + emb(conc) + uni	76.3	80.2	0.735	0.744

Table 3: Performance of the automatic systems on SCL-OPP. Features used: unigrams (uni), part-of-speech of a unigram (POS), sentiment binary label of a unigram (sent. label), sentiment real-valued score of a unigram (sent. score), embeddings (emb). 'emb(conc)' is the concatenation of the embedding vectors of the constituent unigrams; 'emb(avg)' is the average vector of the unigram embeddings; 'emb(max)' is maximal vector of the unigram embeddings.

predictive of the phrase's sentiment (row b).[7] Both the 'most polar unigram' and the 'POS rule' classifiers perform markedly better than the majority baseline. Interestingly, the 'most polar unigram' classifier outperforms the slightly more sophisticated 'POS rule' approach on most tasks. Also, we found that within bigram phrases that contain adjectives or verbs, the adjective or verb constituents are the most polar words in only about half of the instances (and even less so in trigrams). This indicates that adjectives and verbs do not always dominate the sentiment in a phrase.

The results obtained using supervised techniques with various feature combinations are presented in rows e to k (Table 3). Using only POS and binary sentiment labels of the constituent unigrams, the supervised learning algorithm does not perform much better than our 'POS rule' baseline (the accuracies in row e are just slightly higher than those in row d). With access to real-valued sentiment scores of unigrams much more accurate models can be learned (row f). Furthermore, the results show that the sentiment of a phrase depends on its constituent words and not only on the sentiment of the constituents (row g shows markedly better performance than row f; all the differences are statistically significant, $p < .01$). Concatenating word embeddings was found to be more effective than averaging. (Averaging is common when creating features for sentences). Having access to both unigrams and word embedding features produces the best results. (The differences between the scores in row i and row j are statistically significant, $p < .01$.) Row k shows results of the model trained without the gold sentiment scores of the unigrams. Observe that for bigrams, there is a substantial drop in performance compared to row j (6.3-point drop in accuracy on the binary task, 6.7-point drop in Pearson correlation on the regression task) whereas for trigrams the performance is not affected as much (less than 1-point change on both tasks). Thus, having access to sentiment scores of constituents is particularly useful for determining sentiment of bigram phrases.

6 Conclusions

We created a real-valued sentiment composition lexicon for opposing polarity phrases and their constituent words, through manual annotation. We analyzed patterns of sentiment composition across phrases formed with different POS combinations. Further, we applied several unsupervised and supervised techniques of sentiment composition to determine their efficacy on opposing polarity phrases. We showed that for most phrases the sentiment of the phrase cannot be reliably predicted only from the parts of speech and sentiment association of their constituent words, and that the constituent words, their parts of speech, their sentiment scores, and their embedding vectors are all useful features in supervised sentiment prediction on this dataset.

We intend to use SCL-OPP in the following applications: (1) to automatically create a large coverage sentiment lexicon of multi-word phrases and apply it in downstream applications such as sentence-level sentiment classification, and (2) to investigate how the human brain processes sentiment composition.

[7] Note that the results for the 'last unigram' baseline are still better than the results of random guessing (acc = 50, r = 0). For the majority of n-grams in SCL-OPP, the polarity of the first unigram is opposite to the polarity of the last unigram. Thus, the results for a similar 'first unigram' baseline (not shown here) are worse than those obtained by the 'last unigram' baseline.

Abstract

Previous work on Automatic Paraphrase Identification (PI) is mainly based on modeling text similarity between two sentences. In contrast, we study methods for automatically detecting whether a text fragment only appearing in a sentence of the evaluated sentence pair is important or ancillary information with respect to the paraphrase identification task. Engineering features for this new task is rather difficult, thus, we approach the problem by representing text with syntactic structures and applying tree kernels on them. The results show that the accuracy of our automatic Ancillary Text Classifier (ATC) is promising, i.e., 68.6%, and its output can be used to improve the state of the art in PI.

1 Introduction

Automatic PI is the task of detecting if two texts convey the same meaning. For example, the following two sentences from the Microsoft Research Paraphrase Corpus (MSRP) (Dolan et al., 2004):

S$_{1a}$: *Although it's unclear whether Sobig was to blame, The New York Times also asked employees at its headquarters yesterday to shut down their computers because of "system difficulties."*

S$_{1b}$: *The New York Times asked employees at its headquarters to shut down their computers yesterday because of "computing system difficulties."*

are paraphrases, while these other two are not:

S$_{2a}$: *Dr. Anthony Fauci, director of the National Institute of Allergy and Infectious Diseases, agreed.*

S$_{2b}$: *"We have been somewhat lucky," said Dr. Anthony Fauci, director of the National Institute of Allergy and Infectious Diseases.*

Most previous work on automatic PI, e.g., (Madnani et al., 2012; Socher et al., 2011), is based on a direct comparison between the two texts, exploiting different similarity scores into a machine learning framework. However, these methods consider sentences as monolithic units and can thus be misled by ancillary information that does not modify the main meaning expressed in the text.

For example, the additional text fragment (ATF), "*Although it's unclear whether Sobig was to blame*", from S_{1a} expresses ancillary information, which does not add much to the message of S_{1b}, thus the sentences are considered paraphrases. In contrast, S$_{2b}$ contains the ATF, "*We have been somewhat lucky*", whose meaning is not linked to any constituent of S$_{1b}$. Since such text expresses relevant information, the two sentences are not considered paraphrases.

In this paper, we study and design models for extracting ATFs from a sentence with respect to another one and classifying if their meaning is ancillary or important. For this purpose, we built a corpus of sentence pairs using MSRP, where at least one pair member always contains ATFs. We use SVMs with tree kernels applied to syntactic representations (Severyn and Moschitti, 2012) of ATFs for learning automatic ATCs.

The results derived on MSRP show (*i*) a promising accuracy of our ATC and (*ii*) the output of ATC

can be used as a feature for improving the state-of-the-art PI model.

2 Ancillary clauses in PI

Our main purpose in studying computational approaches to the detection of ancillary information is its practical application to PI. Thus, given a pair of sentences (in general two texts), we define ATFs as ancillary information if their semantics:

(*i*) only appears in one of the two sentences and

(*ii*) does not change the main meaning of the sentence, i.e., either the sentences are paraphrases or, if they are not, such ATFs are not the reason for their different meaning.

The definition above along with a syntactic representation of the sentences can be applied to a paraphrase corpus to build a dataset of ancillary vs. important ATFs. For example, Fig. 1 shows the shallow tree representation[1] we proposed in (Severyn and Moschitti, 2012) of the sentences, S$_{2a}$ and S$_{2b}$, reported in the introduction, where the red label ρ indicates that there is a link between the lemmas of the two sentences (also shown by the dashed edges). ρ can be propagated to the upper nodes to mark the related constituents. For example, the lemma *National* is matched by the two sentences, thus both its father node, NNP, and its grandfather constituent, NP, are marked.

Such representation makes the extraction of ATFs easier. For instance, Fig. 1 shows the text fragment of S_{2b}, "*We have been somewhat lucky*", on the right. This is an ATF since it is not aligned with any fragments of S_{2a}. Moreover, since it expresses a central information to the sentence meaning, S_{2b} cannot be in paraphrase relation with S_{2a}. Conversely, the ATF of S_{1a}, "*Although it's unclear whether Sobig was to blame*", is ancillary to the main meaning of the sentence, indeed, the annotators marked S_{1a} and S_{1b} as a valid paraphrase.

3 Building the ATC corpus

The previous section has shown an approach to extract ATFs that can be potentially ancillary. This uses an alignment approach based on lexical similarity, which may fail to align some text constituents. However, these mistakes only affect the precision in extracting ATFs rather than the recall. In other words, we can build a corpus that considers most cases of additional information.

In particular, we design the following simple heuristic: let F_i and F_j be the largest not aligned (possibly discontinuous) word sequences appearing in the sentence pair (S_i, S_j), where $F_i \in S_i$ and $F_j \in S_j$. We define ATF as the largest text between F_i and F_j subject to $d = |size(F_i) - size(F_j)| > \tau$, where $size(F)$ is the number of words[2] appearing in F. If the condition is not satisfied no ATF is extracted.

The condition over d is important because the sentence aligner may fail to match some subsequences, creating false ATFs. However, what is missed from one sentence will be missed also in the other sen-

[1] The shallow trees are constituted by four levels: (*i*) word lemmas as leaves, (*ii*) POS-tags as parent of lemmas, (*iii*) phrases grouping POS-tag nodes and (*iv*) a final root S.

[2] Only verbs, nouns, adjectives, adverbs and numbers were considered, assuming all the others as "not informative words".

	Train			Test		
τ	Ancillary	Important	Total	Ancillary	Important	Total
1	971	687	1658	387	687	1074
2	426	364	790	166	151	317
3	166	169	335	62	79	141
4	59	73	132	21	36	57

Table 1: Number of additional clauses extracted from MSRP.

tence. Thus, in general, if we set a small d then F_i and F_j misalignments may generate false ATFs. In contrast, a large d would clearly prevent this problem, although small ATFs (of size $< d$) may be discarded. More precisely, smaller values of τ may cause the selection of fragments that have corresponding fragments in the other sentence, expressed with dissimilar words (i.e., the aligner failed to match those constituents). Larger values of τ make the heuristic more precise, but less effective in retrieving smaller ATFs.

The ATF corpus. We applied the heuristic above to extract an ATF (if exists) from each sentence pair of MSRP. The number of the extracted ATFs depends on τ as reported in Table 1. A manual inspection of the retrieved fragments revealed that: (*i*) small values of τ, namely, 1 and 2, cause the extraction of many fragments from one sentence corresponding to fragments expressed with different words in the other sentence: these are not ATFs. (*ii*) With $\tau = 3$, the heuristic is very precise and captures most ATFs appearing in the sentence pairs. (*iii*) Higher values of τ cause many valid fragments to be missed.

Once ATFs are generated, we need to label them as ancillary or important for PI such that this data can be used for training and testing ATC. Interestingly, the data can be automatically labeled exploiting the MSRP annotation: given a sentence pair from MSRP, we (*i*) extract the ATF from it and (*ii*) automatically annotate it as ancillary if the pair is a paraphrase and not ancillary otherwise. In other words, an ATF is considered ancillary only if it is extracted from a paraphrase pair. To verify the correctness of this approach, two experts manually labeled the obtained data extracted with $\tau = 3$ and found that only 3.3% of the data was mislabeled with respect to one annotator. The Cohen's kappa agreement between the annotators was 85%.

4 Experiments

In these experiments, we first evaluate state-of-the-art PI models to create our baseline, then we experiment with our ATC and finally, we combine them to show that ATC can improve PI.

4.1 Deriving PI baselines

Dataset. We used MSRP, which consists of 4,076 sentence pairs in the training set and 1,725 sentence pairs in test set. About 66% of the pairs are paraphrases. The pairs were extracted from topically similar Web news articles, applying some heuristics that select potential paraphrases to be annotated by human experts. We represent the sentence pairs using shallow trees generated with the Stanford parser[3].

Models. We adopted our state-of-the-art PI approach we proposed in (Filice et al., 2015). This, given two pairs of sentences, $p_a = \langle a_1, a_2 \rangle$ and $p_b = \langle b_1, b_2 \rangle$, represents instances as shown Fig. 1, and applies tree kernels to them. In particular, we used our best kernel com derived in the work above:

$$\begin{aligned}\text{SMK}(p_a, p_b) = \quad & sf\big(\text{SPTK}(a_1, b_1) \times \text{SPTK}(a_2, b_2), \\ & \text{SPTK}(a_1, b_2) \times \text{SPTK}(a_2, b_1)\big),\end{aligned}$$

where $sf(x_1, x_2) = \frac{1}{c} log(e^{cx_1} + e^{cx_2})$, and SPTK is the Smoothed Partial Tree Kernel (Croce et al., 2011). SMK considers the inherent symmetry of the PI task and evaluates the best alignment between the sentences in the input pairs. The sf is a softmax operation used in place of the max function[4], which is not a valid kernel function. SPTK uses a similarity function between words: we generated it with the word2vec tool[5] (Mikolov et al., 2013) using the

skip-gram model applied to the UkWaC corpus (Baroni et al., 2009).

Results. As illustrated in Table 2, a binary Support Vector Machine equipped with SMK achieves a very high accuracy. Moreover, SMK combined with a linear kernel (LK) over similarity metrics[6] attains the state of the art in PI.

4.2 Experimental Evaluation on ATC

Dataset and models. We created an ATC dataset with $\tau = 3$ as described in Sec. 3. We make this dataset available[7]. We learned ATC with the C-SVM algorithm (Chang and Lin, 2011) inside KeLP[8]. The examples are represented using the shallow tree like the one on the right of Fig. 1. We used three different tree kernels: the Syntactic Tree Kernel (STK) by Collins and Duffy (2001), the Partial Tree Kernel (PTK) by Moschitti (2006) and SPTK using the word2vec similarity defined before.

Given the small size of such dataset (Only 8% of MSRP instances have additional fragments), we performed a 5-fold cross validation. Table 3 illustrates the Accuracy, Precision, Recall and F_1 of our models. ATC based on SPTK provides the best accuracy, i.e., 68.6%, which is a promising result for this research. The second most accurate classifier uses PTK, which is more flexible than STK.

4.3 Using ATC in PI

We carried out error analysis on PI and observed that the used classifier commits a systematic error: when two sentences share a very similar large part (identical in the extreme case) and one sentence has an ATF, it almost always classifies the sentences as paraphrases, even if the ATF contains important information that invalidates the paraphrase relation. This kind of mistakes can be corrected by ATC.

Kernel	Acc (%)	P	R	F_1
STK	65.1 ± 6.5	65.4 ± 8.0	58.3 ± 5.6	61.5 ± 5.8
PTK	67.4 ± 8.2	69.7 ± 8.8	56.5 ± 7.7	62.4 ± 7.8
SPTK	**68.6** ± 9.4	71.0 ± 9.0	57.9 ± 9.7	63.7 ± 9.3

Table 3: Results of Ancillary Text Classifiers

Thus, we created the following ensemble model: given a pair to be classified, we apply our heuristic for ATF extraction. If the heuristic does not find any fragment in the pair, we only rely on the prediction provided by PI. Otherwise, we combine the prediction of ATC applied to ATF with the one of the PI classifier using a stacking strategy (Wolpert, 1992), i.e., the two predictions become the input features of a third classifier that makes the final decision.

To train this meta-classifier, we need the predictions from ATC and PI computed on a validation set. Hence, we split the training set in two parts: one part is used for training ATC and PI, while the other is classified with the trained models to produce the predictions for the meta-classifier. Then, the roles of the two parts are inverted. The meta-classifier is a linear SVM (Fan et al., 2008) implemented with KeLP.

Note that: (*i*) since we use 5-fold cross-validation, for each fold, we needed to apply the process described above to each fold; and (*ii*) all the learning algorithms and kernels adopt default parameters to also facilitate the reproducibility of our results.

Results. Table 4 reports the comparison between PI and PI combined with ATC (trained with SPTK). The performance is derived only on sentence pairs with ATFs.

The first column indicates the kernel used by the PI classifier, while the second column reports '+' or '-' to indicate if PI is combined with ATC or not, respectively. We note that ATC produces a great improvement, ranging from 8 absolute percent points over LK to about 3 points over SMK+LK, i.e., the state-of-the-art model. As expected, the more accurate the baseline is, the lower the improvement is produced.

It should be noted that only a relative small subset

[6] These include *cosine similarities* of lemmas, POS-tags, and n-grams, *longest common substring* and *longest common subsequence* measures and Tree Kernel intra-pair similarities.

of MSRP contains additional fragments (about 8% when $\tau = 3$). Thus, the impact on the entire PI testset cannot be large. Tab. 5 reports the accuracy of the previous models on the entire testset. An improvement over all models, state-of-the-art included, can be still observed, although it is less visible.

5 Conclusions

In this paper, we study and design models for learning to detect ancillary information in the context of PI. We used a heuristic rule for selecting additional fragments from paraphrase pairs, which, applied to MSRP, generates our ATF dataset. We manually annotated the latter for training and testing our ATCs.

Our experiments using several kernel models show that ATC can achieve a good accuracy (about 69%) and significantly impact the PI accuracy. Our results suggest that:

(*i*) it is possible to recognize information humans believe is ancillary; and

(*ii*) to go beyond the current results and technology for high-level semantic tasks (e.g., PI), we cannot just rely on shallow similarity features, but we rather need to build components that analyze different aspects of text and then combine the output of the different modules.

In the future, it would be interesting to use methods similar to those successfully used in question answering research, e.g., matching entities in the sentence trees using linked open data (Tymoshenko et al., 2014; Tymoshenko and Moschitti, 2015) or enriching trees with semantic information automatically produced by classifiers, e.g., (Severyn et al., 2013a; Severyn et al., 2013b).

Abstract

Part-of-speech (POS) taggers trained on newswire perform much worse on domains such as subtitles, lyrics, or tweets. In addition, these domains are also heterogeneous, e.g., with respect to registers and dialects. In this paper, we consider the problem of learning a POS tagger for subtitles, lyrics, and tweets associated with African-American Vernacular English (AAVE). We learn from a mixture of randomly sampled and manually annotated Twitter data and unlabeled data, which we automatically and partially label using mined tag dictionaries. Our POS tagger obtains a tagging accuracy of 89% on subtitles, 85% on lyrics, and 83% on tweets, with up to 55% error reductions over a state-of-the-art newswire POS tagger, and 15-25% error reductions over a state-of-the-art Twitter POS tagger.

1 Introduction

Modern part-of-speech (POS) taggers perform well on what some consider canonical language, as found in domains such as newswire, for which sufficient manually-annotated data is available. For many domains, such as subtitles, lyrics, and tweets, however, labeled data is scarce, if existing, and the performance of off-the-shelf POS taggers is prohibitive of downstream applications.

Furthermore, subtitles, lyrics and tweets are very heterogeneous. Subtitles span from Shakespeare to The Wire, and the lyrics of Elvis Costello are very different from those of Tupac Shakur. Twitter can be anything from teenagers discussing where to go tonight, to researchers discussed the implications of new findings. All three sources of data exhibit a very high degree of linguistic variation, some of which is due to the dialects of the speakers or authors.

In this paper, we use a **corpus of POS-annotated tweets** recently released by CMU,[1] consisting of semi-randomly sampled US tweets. We want to use this corpus to learn a POS tagger for **subtitles, lyrics, and tweets**, which are typically associated with **African-American Vernacular English** (AAVE). We believe our POS tagger can broaden the coverage of NLP tools, and serve as an important tool for large-scale sociolinguistic analyses of language use associated with AAVE (Jørgensen et al., 2015; Stewart, 2014), which relies on the accuracy of these NLP tools.

We combine several recent trends in domain adaptation, namely word embeddings, clusters, sampling, and the use of type constraints. Word representations learned from representative unlabeled data, such as word clusters or embeddings, have been proven useful for increasing the accuracy of NLP tools for low-resource languages and domains (Owoputi et al., 2013; Aldarmaki and Diab, 2015; Gouws and Søgaard, 2015). Since similar words receive similar labels, this can give the model support for words not in the training data. In this paper, we use word clusters and word embeddings in both our baseline and system models.

Using unlabeled data to estimate a target distribution for importance sampling, or for semi-supervised

learning (Søgaard, 2013), as well as wide-coverage, crowd-sourced tag dictionaries to obtain more robust predictions for out-of-domain data have been succesfully used for domain adaptation (Das and Petrov, 2011; Hovy et al., 2015a; Li et al., 2012). In this paper, we use automatically-harvested tag dictionaries for the target variety(/-ies) in two different settings: for labeling the unlabeled data using a technique elaborating on previous work (Li et al., 2012; Wisniewski et al., 2014; Hovy et al., 2015a), and for imposing type constraints at test time in a semi-supervised setting (Garrette and Baldridge, 2013; Plank et al., 2014a). Our best models are obtained using partially labeled training data created using tag dictionaries.

Our contributions We present a POS tagger for AAVE-like language, mining tag dictionaries from various websites and using them to create partially labeled data. Our contributions include: (i) a POS tagger that performs significantly better than existing tools on three datasets containing AAVE markers, (ii) a new domain adaptation algorithm combining ambiguous and cost-sensitive learning, and (iii) an annotated corpus and trained POS tagger made publicly available at `https://bitbucket.org/soegaard/aave-pos16`.

2 Data

For historical reasons, most of the manually annotated corpora available today are newswire corpora. In contrast, very little data is available for domains such as subtitles, lyrics and tweets — especially for language varieties such as AAVE. Learning robust models for AAVE-like language and other language varieties is often further complicated by the absence of standard writing systems (Boujelbane et al., 2013; Bernhard and Ligozat, 2013; Duh and Kirchhoff, 2005).

In this paper, we use three manually annotated data sets, consisting of **subtitles** from the television series *The Wire*, **hip-hop lyrics** from black American artists and **tweets** posted within the south-eastern corner of the United States. We do *not* use this data for training, but only for evaluation, so our experiments use unsupervised (or weakly supervised) domain adaptation.

Although the language use in the three domains vary, they have several things in common: the register is very informal, and the subtitles, lyrics and tweets contain **slang terms** such as *loc'd out*, *cheesing with* and *po'*, **spoken language features** such as *uh-hum, huh* and *oh*, **phonologically-motivated spelling variations** such as *dat mouf*, *missin'* and *niggas* and **contractions** such as *we'll* and *I'd*. These features are infrequent in or absent from most commonly used training corpora for NLP.

The data was annotated by two trained linguists with experience in analyzing AAVE, using the Universal Part-of-Speech tagset (Petrov et al., 2011). They obtained an inter-annotator agreement score of 93.6%. The test sections consist of 528 sentences (subtitles), 509 sentences (lyrics), and 374 sentences (tweets). In addition, we had 546 sentences of subtitles annotated for development data. Note that we only use one domain for development to avoid overly optimistic performance estimates.

For all experiments, we use a publicly available implementation of structured perceptron[2] and train on the 1827 tweets from the CMU Twitter Corpus (Gimpel et al., 2011). Note that despite the fact that the training data also comes from an informal domain, the distribution of POS tags in this data set is different from those of the test sets. For instance, the percentage of determiners in the CMU Twitter corpus is on average 4% lower than in our test domains, and there are 7% more pronouns in the test sets than in the CMU Twitter corpus.

We also create a large **unlabeled corpus** of data that is representative of our test sets. This corpus, consisting of 4.5M sentences, is created using subtitles from the TV series *The Wire* and *The Boondocks*, English hip-hop lyrics, and tweets from the south-eastern states of the US. None of the unlabeled data overlaps with our evaluation datasets. We use this corpus for two purposes: to induce word clusters and embeddings, and to partially annotate a portion of it automatically, which we include in the training data of our ambiguous supervision model (see Section 3 below).

3 Robust learning

Word representations To learn word embeddings from our unlabeled corpus, we use the Gensim im-

[2] `https://github.com/coastalcph/rungsted`

plementation of the word2vec algorithm (Mikolov et al., 2013b; Mikolov et al., 2013a). We also learn Brown clusters from a large corpus of tweets[3] (Owoputi et al., 2013), and add both as additional features to our training and test sets. The word representations capture latent similarities between words, but more importantly enable our tagging model to generalize to unseen words.

Partially labeled data Model performance generally benefits from additional data and constraints during training (Hovy and Hovy, 2012; Täckström et al., 2013). We therefore also use the unlabeled data and tag dictionaries as additional, partially labeled training data. For this purpose, we extract a tag dictionary for AAVE-like language from various crowdsourced online lexicons.

Partial constraints from tag dictionaries have previously been used to filter out incorrect label sequences from projected labels from parallel corpora (Wisniewski et al., 2014; Das and Petrov, 2011; Täckström et al., 2013). We use a combination of a publicly available dump of *Wiktionary*[4] (Li et al., 2012), entries from *Hepster's glossary of musical terms*[5], a list of African-American names[6] and *Urban Dictionary*[7] (UD). We augment our tag dictionary by scraping UD for all words in our unlabeled corpus and extracting the part-of-speech information where available. See an example entry for the word *hooch* below, which has five possible parts of speech in our tag dictionary: VERB, NOUN, ADJ, PRON, ADV.

> *Hooch*: "Chewing tobacco commonly placed in the lower lip region. Hooch can be used as a verb, noun, adjective, pronoun, or an adverb."

We use the tag dictionary to label the unlabeled corpus. E.g., when we see the word *hooch*, we assign it the label VERB/NOUN/ADJ/PRON/ADV. We present two ways of using this data for learning better POS models: one where the tag dictionaries are used in an ambiguously supervised setting, and one where they are used as type constraints at prediction time in a self-training setup.

Ambiguous supervision Our algorithm is related to work in cross-lingual transfer (Wisniewski et al., 2014; Das and Petrov, 2011; Täckström et al., 2013) and domain adaptation (Hovy et al., 2015a; Plank et al., 2014a), where tag dictionaries are used to filter projected annotation. We use the tag dictionaries to obtain partial labeling of in-domain training data.

Our baseline sequence labeling algorithm is the structured perceptron (Collins, 2002). This algorithm performs additive updates passing over labeled data, comparing predicted sequences to gold standard sequences. If the predicted sequence is identical to the gold standard, no update is performed. We use a cost-sensitive structured perceptron (Plank et al., 2014b) to learn from the partially labeled data.

Each update for a sequence can be broken down into a series of transition and emission updates, passing over the sequence item-by-item from left to right. For a word like *hooch* labeled VERB/NOUN/ADJ/PRON/ADV, we perform an update proportional to the cost associated with the predicted label. If the predicted label is not in the mined label set, e.g., PRT, we update with a cost of 1.0 (multiplied by the learning rate α); if the predicted label is in the mined label set, we do not update our model. This means that the POS model is not penalized for predicting any of the five supplied labels. We did consider distributing a small cost between the candidates in the mined label sets, but this led to slightly worse performance on our development data.

In the experiments below, we also filter the partially labeled data by the amount of ambiguity observed in our labels. At one extreme, we require *all* words to have a single label, as in fully labeled data. Hovy et al. (2015b) also used a tag dictionary to obtain fully labeled data for domain adaptation. At the other end of the scale, we use all the partially labeled data, allowing up to 12 tags per words. Finally, we also experiment with using only sentences from our unlabeled data such that the tag dictionary assigns at most two (2) or three (3) labels to each word.

We also experimented with using different

amounts of ambiguously labeled data. The best performing system on development data uses both Wiktionary and the tag dictionaries associated with AAVE, only 100 ambiguously labeled data points for training, a cost of 0.0 for predicting labels in the mined label sets, no threshold on ambiguity levels (but leaving only sentences covered by our tag dictionaries), the CMU Brown clusters, and 20-dimensional word2vec embeddings with a sliding window of nine (9). The results of this system are shown in Table 1 as **Ambiguous**.

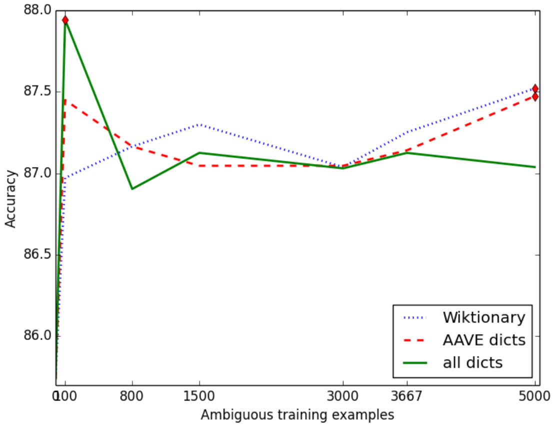

Figure 1: Learning curve ambiguous learning

Self-training with type constraints Our second system uses the harvested tag dictionary for type constraints when making predictions on the unlabeled data for self-training. The search space of possible labels for each word is simply restricted to the tags provided for that word by the tag dictionary.

For our self-training experiments, we experiment with pool size, but heuristically set the stopping criterion to be when the development set accuracy of the tagger decreases over three consecutive iterations. we obtained the best performance on development data using the tag dictionary without Wikipedia, using all entries for type constraints, the CMU Brown clusters, and 10-dimensional embeddings with a window size of five (5). The results of this model are listed in Table 1 as **Self-training**.

Pre-Normalization We also experimented with test-time pre-normalization of the input, using the normalization dictionary of Han et al. (2011), but this led to worse performance on development data.

4 Results and error analysis

Table 1 shows the baseline accuracies, with and without clusters and embeddings, as well as the performance of the two developed systems described above. All results for both ambiguous supervision and self-training with type constraints significantly outperform the simple baseline with $p < 0.01$ (Wilcoxon). The system using ambiguous supervision is also significantly better than the baseline with clusters and word embeddings on the Twitter data. The fact that we generally see worse performance on Twitter data than on the two other data set (even though the systems were trained on Twitter data) can be attributed to a higher type-token ratio.

We also provide the accuracies of three publicly available POS taggers in Table 1. The three POS systems are the bidirectional Stanford Log-linear POS Tagger[8] , the GATE Twitter POS tagger[9] , and the CMU POS Tagger.[10] We observe that our ambiguous learning system outperforms all three systems on all test sets.

Test set	Lyrics	Subtitles	Tweets	Av.
Baseline	64%	78%	48%	63%
Ambiguous	**71%**	**83%**	**78%**	**77%**
Self-train	70%	82%	61%	71%

Table 2: Accuracies on unseen words

Our improvements are primarily due to better performance on unseen words. Both systems improve the accuracy on OOV items for all three test sets, with the ambiguous learning system reducing the error by an average of 14%, and the self-training system reducing it by 7.7% on average. However, we also see an average increase in performance on known words of 1% for both systems. This increase is highest for tweets (2%) and around 0.5% for the subtitles and hip-hop lyrics test sets. The main reason for the increased overall performances of our systems is therefore the improved accuracy on OOV words. Table 2 shows that the accuracy on OOVs increases on all three test sets for both developed systems over baseline.

The OOV words learned in these two test sets are mainly verbs such as *sittin'*, *gettin'* and *feelin'* (g-dropped spellings), and words that are infrequent in canonical written language such as *'em* and *ho*.

We observe that our systems improve performance on traditionally closed word classes such as pronouns, adpositions, determiners and conjunctions. These increases can be ascribed to the systems having learned from the additional information provided on spelling variations such as *'cause*, *fo'* and *ya* and unknown entities such as *dis*, *dat*, *sum*.

Finally, we note that increasing the number of training examples for ambiguous learning seems to come with diminishing returns. The learning curve is presented in Figure 1.

5 Conclusions

We explore several techniques to learn better POS models for AAVE-like subtitles, lyrics, and tweets from a manually annotated Twitter corpus. Our systems perform significantly better than three state-of-the-art POS taggers for English, with error reductions up to 55%. The improvements were shown to be primarily due to better handling of OOV words.

PIC a Different Word: A Simple Model for Lexical Substitution in Context

Stephen Roller

Katrin Erk
Department of Linguistics
The University of Texas at Austin
katrin.erk@mail.utexas.edu

Abstract

The Lexical Substitution task involves selecting and ranking lexical paraphrases for a target word in a given sentential context. We present *PIC*, a simple measure for estimating the appropriateness of substitutes in a given context. PIC outperforms another simple, comparable model proposed in recent work, especially when selecting substitutes from the entire vocabulary. Analysis shows that PIC improves over baselines by incorporating frequency biases into predictions.

1 Introduction

Lexical substitution (McCarthy and Navigli, 2009) is a task in which word meaning in context is described not through dictionary senses but through substitutes (paraphrases) chosen by annotators. For example, consider the following usage of the adjective *bright*: "The *bright* girl was reading a book." Valid lexical substitutions for *bright* include adjectives like *smart* and *intelligent*, but not words like *luminous* or *colorful*.

Originally introduced as a SemEval task in 2007, lexical substitution has often been used to evaluate the ability of distributional models to handle polysemy (Erk and Padó, 2008; Thater et al., 2010; Dinu and Lapata, 2010; Van de Cruys et al., 2011; Melamud et al., 2015b; Melamud et al., 2015a; Kawakami and Dyer, 2015). Recent models include a simple but high-performing method by Melamud et al. (2015b), which uses the Skip-gram model of Mikolov et al. (Mikolov et al., 2013) to compute the probability of a substitute given a sentence context, and integrates it with the probability of the substitute given the target. The current state of the art is held by another model of Melamud (Melamud et al., 2015a), which uses a more complex architecture.

In this paper we build on the simple model of Melamud et al. (2015b), as simpler methods are easier to recreate and integrate into larger pipelines.[1] We explore a weak form of supervision that recently has proved beneficial on many NLP tasks: using a language modeling task on unannotated data. We find a strong improvement over Melamud's simple measure, particularly on the all-words ranking task. Interestingly, analysis of *PIC* shows it improves over baselines by incorporating frequency biases into predictions.

2 Prior Work

In the lexical substitution task, an annotator is given a target word in context and generates one or more substitutes. As multiple annotators label a target, the result is a weighted list of substitutes, where weights indicate how many annotators chose a particular substitute (McCarthy and Navigli, 2009).

There have been numerous approaches on the lexical substitution task of varying complexity and using various lexical resources (McCarthy and Navigli, 2007). Some approaches focus on explicitly modeling an in-context vector (Erk and Padó, 2008; Dinu and Lapata, 2010; Thater et al., 2010; Van de Cruys et al., 2011; Kremer et al., 2014; Kawakami and Dyer, 2015), while others approach it using more sophisticated pipelines, in both super-

[1] Code and models available at `https://github.com/stephenroller/naacl2016`.

Proceedings of NAACL-HLT 2016, pages 1121–1126,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

vised (Szarvas et al., 2013) and unsupervised (Melamud et al., 2015a) settings. The latter is the current state-of-art system, and is based around generating and pruning second-order word representations using language models.

In this work, we limit our comparisons to the model of Melamud et al. (2015b), a method which performs nearly state-of-art, is extremely easy to implement, and is a good testbed for focused hypotheses. They propose a novel measure which uses dependency-based word and context embeddings derived from Skip-gram Negative Sampling algorithm (SGNS) (Mikolov et al., 2013; Levy and Goldberg, 2014a). Their measure *addCos* for estimating the appropriateness of a substitute s as a substitute for t in the context $C = \{c_1, c_2, \ldots\}$ is defined as follows:[2]

$$\text{addCos}(s|t, C) = \cos(s, t) + \sum_{c \in C} \cos(s, c).$$

They also propose a similar measure *balAddCos*, which controls for the context size:

$$\text{balAddCos}(s|t, C) = |C|\cos(s, t) + \sum_{c \in C} \cos(s, c).$$

3 Proposed Measure

We propose a new measure, called Probability-in-Context (PIC), based on SGNS context vectors to estimate the appropriateness of a lexical substitute. Similar to *balAddCos*, the measure has two equally-weighted, independent components measuring the appropriateness of the substitute for both the target and the context, each taking the form of a softmax:[3]

$$\text{PIC}(s|t, C) = P(s|t) \times P(s|C)$$
$$P(s|t) = \frac{1}{Z_t} \exp\left\{s^T t\right\}$$
$$P(s|C) = \frac{1}{Z_C} \exp\left\{\sum_{c \in C} s^T \left[Wc + b\right]\right\}$$

The values Z_t and Z_C are normalizing constants to make sure each distribution sums to one. This measure has two free parameters, W and b, which act as a linear transformation over the context vectors. These parameters are estimated from the *original corpus*, and are trained to maximize the prediction of a *target* from only its syntactic contexts (c.f. Section 4.4). Given this formulation, a natural question is why not train the embeddings to optimize the softmax directly? We choose to parameterize the measure rather than the embeddings because (i) SGNS embeddings are already popular and readily available and (ii) it ensures the quality of embeddings remains constant across experimental settings.

To measure the importance of parameterization, we also compare to a non-parameterized PIC (*nPIC*), which only uses a softmax over the dot product:

$$\text{nPIC}(s|t, C) = P(s|t) \times P_n(s|C)$$
$$P_n(s|C) = \frac{1}{Z_n} \exp\left\{\sum_{c \in C} s^T c\right\}$$

4 Experimental Setup

We compare our proposed measures to three baselines: OOC, the Out-of-Context cosine similarity between the word and target ($\cos(s, t)$), and the *addCos* and *balAddCos* measures. It is important to note that existing papers on Lexical Substitution all contain subtle differences in experimental setup (vocabulary coverage, candidate pooling, etc.). We compare to our own re-implementation of the baselines, so our numbers differ slightly from those in the literature.

4.1 Data sets

We evaluate on three lexical substitution data sets.

SE07: The data set used in the original SemEval 2007 shared task (McCarthy and Navigli, 2007) consists of 201 words manually chosen to exhibit polysemy, with 10 sentences per target. For a given target in a particular context, five annotators were asked to propose up to 3 substitutes. As all our experiments are unsupervised, we always evaluate over the entire data set, rather than the original held-out test set.

Coinco: The Concepts-in-Context data set (Kremer et al., 2014) is a large lexical substitution corpus with proposed substitutes for nearly all content

[2] We abuse notation and allow s, t and c to refer to both the lexical items and their corresponding vectors.

[3] Note that $P(s|t)$ measures paradigmatic similarity of s and t, while $P(s|C)$ is syntagmatic fit to the context. For $P(s|t)$, Mikolov et al. (2013) show that cosine similarity of SGNS embeddings predicts paradigmatic similarity. $P(s|C)$ can be interpreted as the PMI of s and C (Levy and Goldberg, 2014b).

words in roughly 2,500 sentences from a mixture of genres (newswire, emails, and fiction). Crowdsourcing was used to obtain a minimum of 6 contextually-appropriate substitutes for over 15k tokens.

TSWI2: The Turk bootstrap Word Sense Inventory 2.0 (Biemann, 2012) is a crowdsourced lexical substitution corpus focused on about 1,000 common English nouns. The data set contains nearly 25,000 contextual uses of these nouns. Though the data set was originally constructed to induce a word-sense lexicon based on common substitution patterns, here we only use it as a lexical substitution data set.

4.2 Task Evaluation

We compare models on two variations of the lexical substitution task: candidate ranking and all-words ranking. In the *candidate ranking* task, the model is given a list of candidates and must select which are most appropriate for the given target. We follow prior work in pooling candidates from all substitutions for a given lemma and POS over all contexts, and measure performance using Generalized Average Precision (GAP). GAP is similar to Mean Average Precision, but weighted by the number of times a substitute was given by annotators. See Thater et al. (2010) for full details of the candidate ranking task.

The second task is the much more difficult task of *all-words ranking*. In this task, the model is not provided any gold list of candidates, but must select possible substitutes from the entire vocabulary.[4] We measure performance by (micro) mean Precision@1 and P@3: that is, of a system's top one/three guesses, the percentage also given by human annotators. These evaluation metrics are similar to the *best* and *oot* metrics reported in the literature, but we find P@1 and P@3 easier to interpret and analyze.

4.3 Word and Context Vectors

We use the word and context vectors released by Melamud et al. (2015b),[5] which were previously shown to perform strongly in lexical substitution tasks. These embeddings were computed from a corpus of (word, relation, context) tuples extracted from ukWaC and processed using the dependency-based word2vec model of Levy and Goldberg (2014a). These embeddings contain 600d vectors for 173k words and about 1M syntactic contexts.

4.4 Training Procedure

To train the W and b parameters, we extract tokens with syntactic contexts using the same corpus (ukWaC), parser (Chen and Manning, 2014), and extraction procedure used to generate the embeddings. See (Melamud et al., 2015b) for complete details. After extracting every token with its contexts, we randomly sample 10% of the data to reduce computation time, leaving us with 190M tokens for training W and b. We use sampled softmax to reduce training time (Jean et al., 2015), sampling 15 negative candidates uniformly from the vocabulary, optimizing cross-entropy over just these 16 words per sample. We optimize W and b in one epoch of stochastic gradient descent (SGD) with a learning rate of 0.01, momentum of 0.98, and a batch size of 2048. We found all of these hyperparameters worked well initially, and did not tune them.

5 Results

Table 1 contains results for all measures across all experimental settings.

The first observation we make is that the *PIC* measure performs best in all evaluations on all data sets by a significant margin.[6] In the GAP evaluation, all measures perform substantially better than the OOC baseline, and the *nPIC* measure performs comparably to *balAddCos*. We note that context-sensitive measures give the most improvement in SE07, reflecting its greater emphasis on polysemy.

As we turn to the all-words ranking evaluations, we observe that the absolute numbers are much lower, reflecting the increased difficulty of the task. We also see the that *nPIC* and *PIC* both improve greatly over all baselines: The *nPIC* measure is a relative 30% improvement over *balAddCos* in SE07 and Coinco, and the *PIC* measure is a relative 50% improvement over *balAddCos* in 5 evaluations.

Since both measures have a clear improvement over the baselines, especially in the more difficult

[4] All models are also hardcoded not to predict substitutes with the same stem as the target, e.g. for the *bright girl* example, models cannot predict *brighter* or *brightest*.

all-words task, we next strive to understand why.

5.1 Analysis

We first an few cherry and lemon-picked examples to give intuitions about why our model performs better. Table 2 contains the cherry example, where our model performs better than prior work. While OOC and *balAddCos* both suggest replacements with reasonable semantics, but are all misspelled. *nPIC* and *PIC* only pick words with the correct spellings, with the exception of "realy."

Table 3 shows the lemon example, where our model performs worse. We notice that the unusual "sea-change" item is prominent in the OOC and *balAddCos* models, but has dropped from the rankings in our models. From these and other examples, we hypothesize the model is simply guessing more frequent terms.

We consider a few experiments with this hypothesis that the measures do better because they capture better *unigram* statistics than the baselines. Recent literature found that the vector norm of SGNS embeddings correlates strongly with word frequency (Wilson and Schakel, 2015). We verified this for ourselves, computing the Spearman's rank correlation between the corpus unigram frequency and the vector length and found $rho = 0.90$, indicating the two correlate very strongly. Since the dot product is also the unnormalized cosine, it follows that *nPIC* and *PIC* should depend on unigram frequency.

To verify that the *nPIC* and *PIC* measures are indeed preferring more frequent substitutes, we compare the single best predictions (P@1) of the *balAddCos* and *nPIC* systems on all-words prediction on Coinco. Roughly 42% of the predictions made by the systems are identical, but of the remaining items, 74% of predictions made by *nPIC* have a higher corpus frequency than *balAddCos* (where chance is 50%). We find *balAddCos* and *PIC* make the same prediction 37% of the time, and *PIC* predicts a more frequent word in 83% of remaining items. The results for SE07 and TWSI2 are similar.

This indicates that the unigram bias is even higher for *PIC* than *nPIC*. To gain more insight, we manually inspect the learned parameters W and b. We find that the W matrix is nearly diagonal, with the values along the diagonal normally distributed around $\mu = 1.11$ ($\sigma = 0.02$) and the rest of the matrix normally distributed roughly around 0 (μ=2e-5, σ=0.02). This is to say, the *PIC* model is approximately learning to *exaggerate* the magnitude of the dot product, s^Tc. This suggests one could even replace our parameter W with a single scaling parameter, though we leave this for future work.

To inspect the bias b, we compute the inner product of the b vector with the word embedding matrix, to find each word's a priori bias, and correlate it with word frequencies. We find $rho = 0.25$, indicating that b is also capturing unigram statistics.

Is it helpful in lexical substitution to prefer more frequent substitutes? To test this, we pool all annotator responses for all contexts in Coinco, and find the number of times a substitute is given correlates strongly with frequency ($rho = 0.54$).

These results emphasize the importance of incorporating unigram frequencies when attempting the lexical substitution task (as with many other tasks in NLP). Compared to cosine, the dot product in *nPIC* stresses unigram frequency, and the parameters W and b strengthen this tendency.

OOC	*balAddCos*	*nPIC*	*PIC*
You can sort of challenge them well, did you **really** know the time when you said yes?

Table 3: Example where the *PIC* performs worse the All-Words Ranking task. The target word and correct answers are bolded.

6 Conclusion

We have presented *PIC*, a simple new measure for assessing the appropriateness of a substitute in a particular context for the Lexical Substitution task. The measure assesses the fit of the substitute both to the target word and the sentence context. It significantly outperforms comparable baselines from prior work, and does not require any additional lexical resources. An analysis indicates its performance improvements derive primarily from a tendency to lean more strongly on unigram statistics than baselines. In future work, our measure could be simplified by implementing the bias as a single scaling parameter.

Abstract

Most work on extracting parallel text from comparable corpora depends on linguistic resources such as seed parallel documents or translation dictionaries. This paper presents a simple baseline approach for bootstrapping a parallel collection. It starts by observing documents published on similar dates and the co-occurrence of a small number of identical tokens across languages. It then uses fast, online inference for a latent variable model to represent multilingual documents in a shared topic space where it can do efficient nearest-neighbor search. Starting from the Gigaword collections in English and Spanish, we train a translation system that outperforms one trained on the WMT'11 parallel training set.

1 Introduction

In statistical machine translation (SMT), the quality of the translation model is highly dependent on the amount of parallel data used to build it. Parallel data has usually been generated through the process of human translation, which imposes significant costs when building systems for new languages and domains. To alleviate this problem, researchers have considered comparable corpora—a collection of multilingual documents that are only topically aligned but not necessary translations of each other (Fung and Cheung, 2004). While most previous approaches for mining comparable corpora heavily depend on initializing the learning process with some translation dictionaries or parallel text, we use multilingual topic models to detect document translation pairs and extract parallel sentences with only minimum cross-language prior knowledge: the publication dates of articles and the tendency of some vocabulary to overlap across languages. Processing only four years of Gigaword news stories in English and Spanish, we are able to outperform the WMT'11 baseline system trained on parallel News Commentary corpus (Table 1).

2 Prior Work on Comparable Corpora

Most previous, if not all, approaches for mining comparable corpora heavily depend on bilingual resources, such as translation lexica, bitext, and/or a pretrained baseline MT system. This paper, in contrast, investigates building MT systems from comparable corpora without such resources. In a widely cited early paper, Munteanu and Marcu (2005) use a bilingual dictionary and a collection of parallel sentences to train IBM Model 1 and a maximum entropy classifier to determine whether two sentences are translations of each other. Tillmann and Xu (2009) and Smith et al. (2010) detect parallel sentences by training IBM Model 1 and maximum entropy classifiers, respectively. In later work on detecting sentence and phrase translation pairs, Cettolo et al. (2010) and Hoang et al. (2014) use SMT systems to translate candidate documents; Quirk et al. (2007) use parallel data to train a translation equivalence model; and Ture and Lin (2012) use a translation lexicon to build a scoring function for parallel documents. More recently, Ling et al. (2013) trained IBM Model 1 on bitext to detect translationally equivalent phrase pairs within single microblog posts. Abdul-Rauf and Schwenk (2009), Uszkoreit et al. (2010), and Gahbiche-Braham et al. (2011),

rather than trying to detect translated sentence pairs directly, translate the entire source language side of a comparable corpus into the target language with a baseline SMT system and then search for corresponding documents.

On the other hand, there exist approaches that mine comparable corpora without any prior translation information or parallel data. Examples of this approach are rarer, and we briefly mention two: Enright and Kondrak (2007) use singleton words (hapax legomena) to represent documents in a bilingual collection for the task of detecting document translation pairs, and Krstovski and Smith (2011) construct a vocabulary of overlapping words to represent documents in multilingual collections. The latter approach demonstrates high precision vs. recall values on various language pairs from different languages and writing systems when detecting translation pairs on a document level such as Europarl sessions. Recently proposed approaches, such as (Klementiev et al., 2012) use monolingual corpora to estimate phrase-based SMT parameters. Unlike our paper, however, they do not demonstrate an end-to-end SMT system trained without any parallel data.

Our approach differs from these and other previous approaches by not relying on any initial translation dictionary or any bitext to train a seed SMT system. Therefore, the primary experimental comparison that we perform is between no bitext at all and a system trained with some bitext.

3 Bootstrapping Approach

Our bootstrapping approach (Figure 1) is a two-stage system that used the Overlapping Cosine Distance (OCD) approach of Krstovski and Smith (2011) as its first step. OCD outputs a ranked list of candidate document pairs, which are then fed through a sentence-alignment system (Moore, 2002). A polylingual topic model (PLTM) (Mimno et al., 2009) is then trained on the aligned portions of these documents. Using the trained model, we infer topics on the whole comparable training set. Once represented as points in the topic space, documents are then compared for similarity using divergence based metrics such as Hellinger (He) distance. Results from these comparisons create a single ranked list of text translation pairs, which are on a sub document length level. From this single ranked list, using thresholding, we again extract the top n candidate translation pairs that are then fed to an aligner for further refinement.

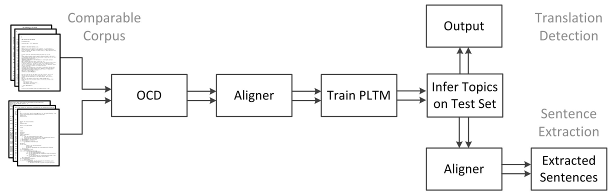

Figure 1: The bilingual collection processing pipeline.

3.1 Discovering Document Translation Pairs

For a given comparable corpus, OCD assumes that there is a set of words that exist in both languages that could be used as features in order to discriminate between documents that are translations of each other, documents that carry similar content, and documents that are not related. Firstly, for each language in the collection a vocabulary is created which consists of all word types seen in the corpora of that language. Words found in both source (s) and target (t) languages are extracted and the overlapping list of words are then used as dimensions for constructing a feature vector template. Documents in both languages are then represented using the template vector whose dimensions are the tf·idf values computed on the overlapping words which we now consider as features. While the number of overlapping words is dependent on the families of the source and target languages and their orthography, Krstovski and Smith (2011) showed that this approach yields good results across language pairs from different families and writing systems such as English-Greek, English-Bulgarian and English-Arabic where, as one would expect, most shared words are numbers and named entities.

We compare these vector representations efficiently using Cosine (Cos) distance and locality sensitive hashing (Charikar, 2002). This results in a single ranked list of all document pairs. Compared to the traditional cross-language information retrieval (CLIR) task where a set of document queries is known in advance, there is no prior information on the documents in the source language that may or may not have translation documents in the target language of the collection. Due to the length in-variance of Cos distance, the single ranked list may contain document pairs with high similarity value across all documents in the target language. This issue in OCD is resolved by applying length and diversity filtering. Length filtering removes translation pairs where the length of the target document t is not within $\pm 20\%$ of the source document s length, $lf : 0.8 \leq |s| / |t| \leq 1.2$. For a given source document, diversity filtering is done by allowing only the top five ranked target document pairs to be considered in the single ranked list. Limiting the number of target documents for a given source document may discard actual document translation pairs such as in a comparable corpus of news stories where documents in the target language originate from large number of news source. While it may restrict more document translation pairs to be discovered, the diversity filtering, on the other hand prevents from limiting the number of discovered similar and translation documents to be from the same topic and domain and thus introduces diversity on another, domain or topic based, level.

3.2 Representing Multilingual Collections with Topics

Latent topic models are statistical models of text that discover underlying hidden topics in a text collection. We use PLTM (Mimno et al., 2009), a multilingual variant of LDA, which assumes that document tuples in multilingual parallel and comparable corpora are drawn from the same tuple-specific multinomial distribution over topics θ. For each document in the tuple, PLTM assumes that words are generated from a language L specific topic distribution over words β_L. Using this generative model we represent documents in multiple languages in a common topic space which allows us to perform similarity comparisons across documents in different languages.

The original PLTM posterior inference is approximated using collapsed Gibbs sampling (Mimno et al., 2009). While more straightforward to implement, this inference approach requires iterating over the multilingual collection multiple times to achieve convergence. This incurs a computational cost that could be significant for large collections such as Gigaword. Moreover, detecting and retrieving document translation pairs requires all-pairs comparison across documents in both languages with a worst case time complexity of $O(N^2)$ which is impractical for large comparable corpora. One solution to this problem is to parallelize the brute-force approach through the MapReduce framework (Ture et al., 2011; Ture and Lin, 2012) but this approach requires special programming methods.

In order to use the PLTM on large collections and avoid the bottleneck introduced by Gibbs sampling, we use the online variational Bayes (VB) approach originally developed by (Hoffman et al., 2010) for LDA model to develop a fast, online PLTM model. As in the regular VB approach, online VB approximates the hidden parameters θ, z and β using the free variational parameters: γ, ϕ and λ. Rather than going over the whole collection of documents to bring the variational parameters to a convergence point, Krstovski and Smith (2013) perform updates of the variational parameters γ and ϕ_L on document batches and update the λ_L variational parameter as a weighted average of its stochastic gradient based approximation and its value on the previous batch. The approximation is done through Expectation-Maximization (EM).

Unlike the usual metric spaces where two vectors are compared using distance metrics such as Euclidean (Eu) or Cos distance, in the probability simplex similarity is computed using information-theoretic measurements such as Kullback-Leibler, Jensen-Shannon divergence and He distance. We alleviate the $O(N^2)$ worst case time-complexity in the probability simplex by utilizing approximate nearest-neighbor (NN) search techniques proven in the metric space. More specifically, we use the formulaic similarity between He and Eu: $He(p,q) \equiv Eu(x,y)$, when $\forall i : i = 1, n$ of x_i and y_i, $x_i = \sqrt{p_i}$ and $y_i = \sqrt{q_i}$, and compute He distance using Eu based, approximate NN computation approaches such as k-d trees[1] (Bentley, 1975).

4 Experiments and Results

We demonstrate the performance of the bootstrapping approach on the task of extracting parallel sentences to train a translation system. We evaluate MT systems trained on extracted parallel sentences and

[1] We use k-d tree implementation in the ANN library (Mount and Arya, 2010).

compare their performance against MT systems created using clean parallel collections. MT systems were evaluated with the standard BLEU metric (Papineni et al., 2002) on two official WMT test sets that cover different domains: News (WMT'11) and Europarl (WMT'08). We trained the Moses SMT system (Koehn et al., 2007) following the WMT shared task guidelines for building a baseline system with one of two parallel training collections from WMT'11: English-Spanish News Commentary (v6) and Europarl (v6). MT systems were trained using test-domain specific language models (LM) — English News Commentary for News test and English Europarl for the Europarl test. Our comparable corpus consists of news stories from the English (LDC2011T07) and Spanish (LDC2011T12) Gigaword collections.

We perform the following processing in each step of the pipeline. We run OCD on days of news originating from multiple news agencies or more specifically on news stories originating from the same day which we consider as the "minimal supervision" in initiating the bootstrapping process. Since the OCD approach generates a single list of ranked document translation pairs, for the second stage of our pipeline we consider the top n document translation pairs. We define n to be all document translation pairs whose Cos similarity is between the range of the max (i.e. the top 1 scored document translation pair in the single ranked list) and $\frac{max}{2}$. Unlike previous thresholding based on absolute values (Ture et al., 2011), this approach allows us to utilize threshold values that are automatically adjusted to the dynamic range of the Cos distance of a particular corpus. Sentences from the top n news stories are extracted and are further aligned. The output of the aligner is then used as a training set for the PLTM model. We represent each of the news stories using the per story aligned sentences. Once trained, we use the PLTM model to infer topics back on to the news stories. We then again create a single ranked list of translation news story pairs by computing divergence based similarity using He distance (§3.2). Keeping the top n ranked news story pairs, we obtain a list of what we believe are parallel documents which we then use to extract sentence pairs. Sentences are finally processed through an aligner and then used as the training corpus to our MT system.

Table 1: BLEU score values computed over the WMT'11 News test set with MT systems developed using extracted and parallel sources of training data. * denotes statistical significance level (p-value≤0.001) above NC.

The Gigaword collection contains news stories generated from various agencies in different languages. On any given day, a news story in English may or may not cover the same topic as one in a different language. To perform a fair evaluation with the WMT'11 News test, we considered stories published in non-overlapping years[2]: 2010, 2009, 2005 and 2004. Table 1 shows the performance comparison, on the News test set (WMT'11), of the MT system trained on extracted parallel sentences from four years of Gigaword data (GW) with a MT system trained on two WMT'11 baseline parallel collections: Europarl (EP) and News Commentary (NC). While over 10 times bigger than NC, EP is out of domain and thus performs only slightly better. On the News test set, parallel sentences automatically extracted from only four years of Gigaword data outperform systems trained on clean NC or EP bitext.

In order to determine statistically significant differences between the results of different MT systems we ran the randomization test (Smucker et al., 2007) on the News test set with 10k iterations. In each iteration we performed permutations across the translation sentences obtained from the two MT systems whose statistical difference in performance we evaluate.

Table 2 shows the performance comparison on the Europarl test set (WMT'08) between the MT system trained on the extracted parallel sentences and the two MT baseline systems. On this test set, unsurprisingly, EP training performed very well.

Table 3 gives a summary of ablation experiments that we performed across the two stages of our bootstrapping approach. More specifically, we ex-

[2] We did not consider news stories from 2006-2008 due to a known issue with diacritic marks in the Spanish collection.

Table 3: Summary of ablation experiments: BLEU score values of MT systems trained on extracted bitext by OCD alone and with PLTM reestimation along with the deduplication (dedup.) effect. * denotes statistical significance level (p-value≤0.001) above NC. ‡ denotes statistical significance level (p-value≤0.05) above NC. † denotes statistical significance level (p-value≤0.001) above OCD. § denotes statistical significance level (p-value≤0.03) above OCD.

plored using bitext extracted by OCD alone, without PLTM reestimation, to train a MT system. Both extracted bitext sets also contained many duplicate sentence pairs. In this set of experiments we also explored the effect of deduplicating them, i.e. going over the extracted set of English-Spanish sentence pairs and removing the duplicate ones. Bitext extracted by OCD alone without PLTM reestimation performed only slightly worse on WMT'11. The OCD-only data, however, only showed 70% overlap with OCD+PLTM (GW). Deduplicating the two bitexts (dedup.) hurts OCD somewhat more than OCD+PLTM. On the Europarl test set, however, deduplicating OCD+PLTM bitext caused a significant boost from 23.88 to 24.67, while causing slight performance drop for OCD (cf. NC-trained 25.43). These interactions of test domain, redundancy, and model settings leave room for further studies of the performance of our bootstrapping approach.

5 Conclusion

We introduced a bootstrapping approach for detecting document translations and extracting parallel sentences through latent topic models that are trained with minimal prior knowledge and no lexical resources. The proposed approach is able to extract parallel sentences from comparable corpora to train MT models that outperform a baseline model trained on a parallel collection.

Abstract

Research on grammatical error correction has received considerable attention. For dealing with all types of errors, grammatical error correction methods that employ statistical machine translation (SMT) have been proposed in recent years. An SMT system generates candidates with scores for all candidates and selects the sentence with the highest score as the correction result. However, the 1-best result of an SMT system is not always the best result. Thus, we propose a reranking approach for grammatical error correction. The reranking approach is used to re-score N-best results of the SMT and reorder the results. Our experiments show that our reranking system using parts of speech and syntactic features improves performance and achieves state-of-the-art quality, with an $F_{0.5}$ score of 40.0.

1 Introduction

Research on assisting second language learners has received considerable attention, especially regarding grammatical error correction of essays written by English as a Second Language (ESL) learners. To address all types of errors, grammatical error correction methods that use statistical machine translation (SMT) have been proposed (Brockett et al., 2006; Mizumoto et al., 2012; Buys and van der Merwe, 2013; Yuan and Felice, 2013; Felice et al., 2014; Junczys-Dowmunt and Grundkiewicz, 2014). SMT-based error correction systems have achieved rankings first and third in the CoNLL2014 Shared Task (Ng et al., 2014).

Reranking results

Figure 1: Flow of reranking.

SMT systems generate many candidates of translation. SMT systems generate scored candidates and select a sentence having the highest score as the translation result. However, the 1-best result of SMT system is not always the best result because the scoring is conducted only with local features. In other words, N-best (N > 1) results may be better than the 1-best result.

Reranking approaches have been devised to solve the scoring problem. Reranking is a method that re-scores N-best candidates of SMT and reorders the candidates by score. Figure 1 shows a flow of reranking. First, N-best results are obtained by a grammatical error correction system using SMT for a learner sentence (A in Figure 1). A reranking sys-

Proceedings of NAACL-HLT 2016, pages 1133–1138,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

tem then re-scores the N-best results and reorders them (B in Figure 1).

In this study, we apply a discriminative reranking method to the task of grammatical error correction. Syntactic information is not considered in the phrase-based SMT. We show that using syntactic features in the reranking system can improve error correction performance. Although reranking using only surface features (Shen et al., 2004) is not effective for grammatical error correction, reranking using syntactic features improves the $F_{0.5}$ score.

2 Related Work for Reranking

Reranking approaches have been proposed for common SMT tasks (Shen et al., 2004; Carter and Monz, 2011; Li and Khudanpur, 2008; Och et al., 2004). Shen et al. (2004) first used a perceptron-like algorithm for reranking of common SMT tasks. However, they used only a few features.

Li and Khudanpur (2008) proposed a reranking approach that uses a large-scale discriminative N-gram language model for common SMT tasks. They extended the reranking method for automatic speech recognition (Roark et al., 2007) to SMT tasks. The approach of Carter and Monz (2011) was similar to that of Li and Khudanpur (2008), but they used additional syntactic features (e.g. part of speech (POS), parse tree) for reranking of common SMT tasks.

The reranking approach has been used in grammatical error correction based on phrase-based SMT (Felice et al., 2014). However, their method uses only language model scores. In the reranking step, the system can consider not only surface but also syntactic features such as those in the approach of Carter and Monz (2011). We use syntactic features in our reranking system.

Heafield et al. (2009) proposed a system combination method for machine translation that is similar to that of reranking. System combination is a method that merges the outputs of multiple systems to produce an output that is better than each individual system. Susanto et al. (2014) applied this system combination to grammatical error correction. They combined pipeline systems based on classification approaches and SMT systems. Classifier-based systems use syntactic features as POS and dependency for error correction. However, syntactic information is not considered in combining systems.

Table 1: Oracle score of grammatical error correction

N-best	Precision	Recall	$F_{0.5}$
1	43.9	24.5	37.9
10	79.1	36.7	64.3
50	89.5	43.1	73.6
100	92.3	45.3	76.4

3 Why is Reranking Necessary?

Grammatical error correction using SMT has the same problem as that of common SMT task: the 1-best correction by the system is not always the best. To prove this, we conducted a grammatical error correction experiment using SMT and calculated N-best oracle scores. The oracle scores are calculated by selecting the correction candidate with the highest score from the N-best results for each sentence.

Table 1 shows oracle scores of a baseline grammatical error correction system using SMT[1]. Althogh the $F_{0.5}$ score of the 1-best output was 37.9, the $F_{0.5}$ of the 10-best oracle score was 64.3. The higher the value of N-best, the higher is the oracle score. This result reveals that the 1-best correction by a grammatical error correction system using SMT is not always the best.

Advantage of Reranking Two advantages exist for using a reranking approach for grammatical error correction. The first is that a reranking system can use POS and syntactic features unlike phrase-based SMT. With some errors, the relation between distant words must be considered (e.g., article relation between *a* and *dolls* in the phrase *a big Snoopy dolls).*

The second advantage is that POS taggers and parsers can analyze error-corrected candidates more properly than they analyze erroneous sentences, which enables more accurate features to be obtained. Thus, the fact that taggers for N-best corrected results work much better than for learner original sentences is promising.

4 Proposed Method

In this section, we explain our discriminative reranking method and features of reranking for grammati-

[1] See 5.1 for a baseline system

Table 2: Features for reranking. Examples show features for the sentence *I agree with this statement to a large extent*. The features excluding "Web dependency N-gram" are binary valued. "Web dependency N-gram" is unit interval [0,1] valued.

Feature name	Examples
Word 2,3-gram	I agree; I agree with; agree with; agree with this; this statement
POS 2,3,4,5-gram	PRP VBP; PRP VBP IN; PRP VBP IN DT; PRP VBP IN DT NN
POS-function word 2,3,4,5-gram	PRP VBP; PRP VBP with; PRP VBP with this; PRP VBP with this NN
Web dependency N-gram	prep-agree-with-statment; det-a-extent

cal error correction.

4.1 Discriminative Reranking Method

In this study, we use a discriminative reranking algorithm using perceptron which successfully exploits syntactic features for N-best reranking for common translation tasks (Carter and Monz, 2011). Figure 2 shows the standard perceptron algorithm for reranking. In this figure, T is the number of iterations for perceptron learning and N is the number of learner original sentences in the training corpus. In addition, $GEN(x)$ is the N-best list generated by a grammatical error correction system using SMT for an input sentence and $ORACLE(x^i)$ determines the best correction for each of the N-best lists according to the $F_{0.5}$ score. Moreover w is the weight vector for features and ϕ is the feature vector for candidate sentences. When selecting the sentence with the highest score from candidate sentences (line 5), if the selected sentence matches oracle sentence, then the algorithm proceeds to next sentence. Otherwise, the weight vector is updated.

The disadvantage of perceptron is instability when training data are not linearly separable. As a solution to this problem, an averaged perceptron algorithm was proposed (Freund and Schapire, 1999). In this algorithm, weight vector w_{avg} is defined as:

$$w_{avg} = \frac{1}{T}\sum_{t=1}^{T}\frac{1}{N}\sum_{i=1}^{N} w_t^i \qquad (1)$$

To select the best correction from N-best candidates, we use the following formula:

$$S(z) = \beta\phi_0(z) + w \cdot \phi(z) \qquad (2)$$

where $\phi_0(z)$ is the score calculated by the SMT system for each translation hypothesis. This score is weighted by β. Using $\phi_0(z)$ as a feature in the perceptron algorithm is possible, but this may lead to under-training (Sutton et al., 2006). We select the value for β with the highest $F_{0.5}$ score by changing β from 0 to 100 in 0.1 increments on the development data.

```
1:  $w \leftarrow 0$
2:  for $t = 1$ to $T$ do
3:      for $i = 1$ to N do
4:          $y^i \leftarrow ORACLE(x^i)$
5:          $z^i \leftarrow argmax_{x \in GEN(x^i)} \phi(z) \cdot w$
6:          if $z^i \neq y^i$ then
7:              $w \leftarrow w + \phi(y^i) - \phi(z^i)$
8:          end if
9:      end for
10: end for
11: return $w$
```

Figure 2: Perceptron algorithm for ranking.

4.2 Features of Discriminative Reranking for Grammatical Error Correction

In this study, we use the features used in Carter and Monz (2011) as well as our new features of POS and dependency. We use the features extracted from the following sequences: POS tag , shallow parse tag, and shallow parse tag plus POS tag sequences (Carter and Monz, 2011). From these sequences, features are extracted based on the following three definitions:

1. $(t_{i-2}t_{i-1}t_i)$, $(t_{i-1}t_i)$, (t_iw_i)
2. $(t_{i-2}t_{i-1}w_i)$
3. $(t_{i-2}w_{i-2}t_{i-1}w_{i-1}t_iw_i)$, $(t_{i-2}t_{i-1}w_{i-1}t_iw_i)$, $(t_{t-1}w_{i-1}t_iw_i)$, $(t_{i-1}t_iw_i)$

Here, w_i is a word at position i and t_i is a tag (POS or shallow parse tag) at position i.

Table 2 shows our new features. For the "POS-function N-gram" feature, if words are con-

Table 3: Experimental results. TP, FN, and FP denote true positive, false negative, and false positive, respectively.Asterisks indicate that the difference between the baseline and reranking results is statistically significant ($p < 0.01$, bootstrap test).

8	All features (6+7)	44.4	27.1	39.4*	679	1827	851	65.8

tained in a stop word list, we use surface form, otherwise we use POS tags. “Web dependency N-gram” is feature used in Dahlmeier et al. (2012). We collect log frequency counts for dependency N-grams from a large dependency-parsed web corpus and normalize all real-valued feature values to a unit interval [0,1].

5 Experiments of Reranking

We conducted experiments on grammatical error correction to observe the effect of discriminative reranking and our syntactic features.

5.1 Experimental Settings

We used phrase-based SMT which many previous studies used for grammatical error correction for a baseline system. We used cicada 0.3.5[2] for the machine translation tool and KenLM[3] as the language modeling tool. We used ZMERT[4] as the parameter tuning tool and implemented the averaged perceptron for reranking.

The translation model was trained on the Lang-8 Learner Corpora v2.0. We extracted English essays that were written by ESL learners and cleaned noise with the method proposed in (Mizumoto et al., 2011). From the results, we obtained 1,069,127 sentence pairs. We used a 5-gram language model built on the “Associated Press Worldstream English Service” from English Gigaword corpus and NUCLE 3.2 (Dahlmeier et al., 2013). We used these two language models as separate feature functions in the SMT system.

For training data of reranking, Lang-8 Learner Corpora was split into 10 parts and each part was corrected by a grammatical error correction system trained on the other nine parts. We selected 10 as *N* for N-best reranking. PukWaC corpus (Baroni et al., 2009) was used for constructing our “Web dependency N-gram” feature. We use Stanford Parser 3.2.0[5] as a dependency parser.

CoNLL-2013 test set were split into 700 sentences for parameter tuning of SMT and 681 sentences for tuning parameter beta. CoNLL-2014 test set, 1,312 sentences were used for evaluation. We used M2 Scorer as an evaluation tool (Dahlmeier and Ng, 2012). This scorer calculates precision, recall, and $F_{0.5}$ scores. We used $F_{0.5}$ as a tuning metric. In addition, we used GLEU (Napoles et al., 2015) as evaluation metrics.

5.2 Experimental Results and Discussion

Table 3 shows the experimental results. We used the 1-best result of the SMT correction system and reranking by probability of the large N-gram language model (Felice et al., 2014) as baseline systems. In addition, we compared the systems that are ranked first (CAMB) and second (CUUI) (Felice et al., 2014; Rozovskaya et al., 2014) in CoNLL2014

[2] http://www2.nict.go.jp/univ-com/multi_trans/cicada/

[5] http://nlp.stanford.edu/software/lex-parser.shtml

Shared Task.

The discriminative reranking system with our features achieved the best $F_{0.5}$ score. The difference between the results of baseline and reranking using our features was statistically significant ($p < 0.01$). Because a large N-gram language model was adopted for reranking, recall increased considerably but precision declined. This result is extremely similar to that of the CAMB system, which is an SMT-based error correction system that reranks by using a large N-gram language model. When we compare the reranking system using our features to CUUI, our system is better in all metrics.

When we use the discriminative reranking with our features, both precision and recall increase. In the experimental results of system combination (Susanto et al., 2014), recall increases but precision declines with respect to original SMT results. In addition, precision increases but recall declines with respect to pipeline results.

The reranking that employed all features generated a lower $F_{0.5}$ score than when only our features were used. One reason for this is that the roles of features overlap. These experiments revealed that reranking is effective in grammatical error correction tasks and that POS and syntactic features are important.

6 Conclusion

We proposed a reranking approach to grammatical error correction using phrase-based SMT. Our system achieved $F_{0.5}$ score of 40.0 (an increase of 2.1 points from that of the baseline system) on the CoNLL2014 Shared Task test set. We showed that POS and dependency features are effective for the reranking of grammatical error correction.

In future work, we will use the adaptive regularization of weight vectors (AROW) algorithm (Crammer et al., 2009) instead of the averaged perceptron. In addition, we will apply the pairwise approach to ranking (Herbrich et al., 1999) used in information retrieval to rerank of grammatical error correction.

Patterns of Wisdom: Discourse-Level Style in Multi-Sentence Quotations

Kyle Booten and **Marti A. Hearst**
UC Berkeley
Berkeley, CA 94720
kbooten@berkeley.edu, hearst@berkeley.edu

Abstract

Quotations are kernels not just of wisdom but also of beautiful and striking language. While recent studies have characterized the stylistic features of quotations, we characterize the *order* of stylistic information within quotations. Analyzing a corpus of two-sentence quotations collected from the social network Tumblr, we explore the ways that both low-level features and high-level features tend to occur in either the first or second sentence. Through analysis of examples, we interpret these tendencies as manifestations of rhetorical patterns. Results from a prediction task suggest that stylistic patterns are more prominent in quotations than in a comparison corpus.

1 Introduction

The ancient arts of rhetoric described ways of wielding language to make it particularly persuasive or memorable. Central in this endeavor—a predecessor to modern linguistics (Dolven, 2013)—was the description of rhetorical "tropes" or "figures," patterns of language from the level of the phoneme (as in the case of rhyme or alliteration) to higher-level syntactic and even logical structures (Peacham, 1954). In the figure of *epistrophe*, successive clauses end with the same words. In *pysma*, the speaker (or writer) launches a series of sharp and vehement questions; this and other rhetorical figures describe language at the level of discourse—that is, the relationship between linguistic elements across sentences.

Recent studies of quotations have described what makes certain fragments of text more memorable than others (Danescu-Niculescu-Mizil et al., 2012; Guerini et al., 2015); this ongoing project can be seen as a contemporary, empirical investigation of the rhetorical arts. Inspired by the way that classical rhetoricians described complicated and high-level linguistic patterns, the present study takes the novel step of analyzing the way linguistic elements are sequenced within quotations. After describing a minimalistic set of stylistic features designed to capture common patterns in quotations, we demonstrate that some features tend to occur in certain positions within a quotation. We investigate whether quotes are more predictable than other genres in a "Quote Ordering Task" in which the goal is to distinguish the correct version of a quotation from one whose sentences have been reversed.

2 Related Work

2.1 Style of Memorable Language

Danescu-Niculescu-Mizil et al. (2012) used a variety of features to distinguish popular movie quotations from unmemorable lines from the same movie. By modeling word and part-of-speech sequences of quotes and non-quotes, they found that quotations tended to use less common words but that these words were placed in more common syntactic patterns. The researchers evocatively hint at some "common syntactic scaffolding" that structures quotations, and we build on this finding by characterizing these patterns. They also found that quotations tend to contain linguistic features that make them more "generalizable," such as tendency toward indefinite over definite articles.

Other researchers have attempted to analyze quotations in ways that evoke the traditional figures

Proceedings of NAACL-HLT 2016, pages 1139–1144,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

of rhetoric. Exploring the same movie quotes corpus as well as other corpora, Guerini et al. (2015) found that memorable quotes were more euphonic, with more instances of rhyme and alliteration than their non-memorable counterparts. Kuznetsova et al. (2013) developed several methods for quantifying the creativity of word combinations like "disadvantageous peace," and found that quotes were more likely to contain creative combinations than non-quotes. In terms of classical rhetoric, such unexpected word combinations could embody figures such as *oxymoron*.

2.2 High-Level Style

To investigate quotations in a new way, we are inspired by researchers who have analyzed text quality using what may be called "high-level" features — i.e., moving beyond the specific lexical, syntactic, or phonemic properties of sentences to explore the overall structure of sentences or even the discursive relationships between them.

Feng et al. (2012) engineered features from sentences' CFG parse trees to describe their overall structure and classify them in terms of *a priori* rhetorical categories, such as *loose* vs. *periodic*. They found that these features were helpful for authorship classification, and a later study used similar features to predict the success of novels (Ashok et al., 2013). Wible and Tsao (2010) and Gianfortoni et al. (2011) designed n-gram based features to capture local lexico-syntactic sequences within sentences.

Looking at the level of discourse, Louis and Nenkova (2012) found that adjacent sentences "exhibit stable patterns of syntactic co-occurence" — i.e., certain types of sentences tend to follow certain other types of sentences. Furthermore, they demonstrated that sentences with similar communicative purposes are syntactically similar, so syntax can be taken as a proxy for communicative purpose. We build on both of these observations.

3 Data-sets

Quotations 1. We gathered a data-set of quotations from the social network Tumblr (Chang et al., 2014). Like other social networks, Tumblr has become a place where users frequently share quotations. In fact, users have the option of using a "quote" data-type, which provides separate text-entry fields for the quotation and its source. We gathered quotes via Tumblr's API. Users sometimes use the "quote" data-type to share messages that are not actually quotations, most often brief personal musings. To minimize such non-quotes in our corpus, we retained only those quotes that users themselves had described with the hashtag "#quote." Since we were interested primarily in discourse-level schemas of quotations, we retained only quotations that were exactly two sentences long. In the pre-processing of this and other corpora we removed repeats within and between corpora. We also removed quotations containing quotations (i.e. reported speech), as they were used in highly inconsistent ways in the Tumblr data. (n=4237)

Quotations 2. A test set. We repeated the same steps described above for Tumblr quotes gathered with the "#quotation" hashtag. (n=1846)

Non-Quotes 1. As a comparison corpus, we gathered two-sentence paragraphs from the Brown corpus (Francis and Kucera, 1979). After the same preprocessing steps, we were left with a collection of such paragraphs. (n=1846)

Non-Quotes 2. Again mining the Brown Corpus, we also gathered sequential pairs of sentences randomly chosen from paragraphs longer than two sentences. (n=1846)

4 Features

Take the following quotation from our data set, attributed to Philip Roth: "You cannot observe people through an ideology. Your ideology observes for you."[1] In simple terms, this quotation is a negative statement ("can*not*") followed by a positive one. Yet the opposite pattern can likewise appear in quotations, as in this one attributed to William Blake: "Great things are done when men and mountains meet. This is not done by jostling in the street." Some quotations begin with questions; others end with them. Some (like the one by Roth) begin with a generic "you," while others deploy this pronoun in the second sentence. We describe each sentence of each quotation in terms of the following features meant to capture general lexical and syntactic pat-

[1] This quote also exemplifies *antimetabole*, in which words in the first clause appear reversed in the second.

Feature	#S1	#S2	χ^2	NQ2?
Highest χ^2				
It	60	**175**	56.3	x
But	18	**93**	50.7	x
it	266	**436**	41.2	x
And	33	**93**	28.6	x

CC + NP + ADVP + VP + .	2	**9**	4.5	

Table 1: Features that preferentially occur in a sentence position, sorted by χ^2 value; dominant sentence position is in bold. *Highest* χ^2 represents the top five unigrams. *Other Unigrams* represents other select examples. NQ2 is whether feature is also ordered in the same way in the comparison corpus ("x" if this is the case).

terns in quotations, regardless of what other more classical rhetorical figures they may contain.

Unigrams. As a baseline feature, we note in which sentence, 1 or 2, a unigram occurs.

High-Level Syntax. Feng et al. (2012) found that the top level of syntactic parse trees (in the case of Stanford PCFG Parser's output, which we also used (Klein and Manning, 2003), two levels beneath `ROOT`) provided a useful feature for authorship identification. For instance, the sentence "Forgotten is forgiven." can be represented by the construction *NP + VP + .*, a noun phrase followed by a verb phrase followed by punctuation. This feature, they argue, provides an interpretable representation of the general syntactic structure of a sentence. We directly employ this feature.

General/Abstract Words. Through qualitative analysis of our data, we noticed that many quotation make pronouncements about nouns that might be considered as generalizations or abstractions. For instance: "Peace comes from within. Do not seek it without." In this case, the abstract noun "peace" is the subject of the first sentence. To capture such nouns, we first use the Stanford Dependency Parser (Chen and Manning, 2014) to extract all words in the head position of nominal subject dependencies (excluding stopwords). Using WordNet, we check whether the word's most common synset is both within the hyponym hierarchy of the synset "abstraction.n.06" and within a minimum distance (5) of it[2]; if so, we consider this noun Abstract.[3] The most common such nouns in the Quotations 1 corpus are not necessarily concept words like "peace". For instance, the word "men" appears in this list; many quotations use the word to evoke a generalized (male) subject.[4] We consider a nominal subject to be General if it is within a minimum distance (6) of its root hypernym. As a feature, we observe which (if either) sentence contains more such Abstract or General nouns, normalized by the number of nominal subject dependencies per sentence.

5 Differences Between Sentence Positions

5.1 Feature Comparison

Using balanced subsets of Quotations 1 and Non-Quotes 1 (n=1846), we investigated which feature was more likely to occur in either one of the two sentences' positions within a two-sentence text. For each feature we used a χ^2 test (α=.05) to compare the number of times the feature occurred in first sentences with the number of times the feature occurred in second sentences. Table 1 presents features with a statistically-significant tendency to appear in one sentence or the other, limited to those features that occur at least 5 times and are among the 300 most common features of its type for that corpus. We suggest that this type of analysis can shed light on some of the overarching stylistic strategies of quotations:

Negative-to-Positive: As shown in Table 1, "n't"

[2] We found this number by taking the whole number above the mean of distances to the "abstraction.n.06" synset of a sample of nouns from Project Gutenberg text. For General words we did the same but averaging distances to a noun's root hypernym.

[3] Kao and Jurafsky Kao and Jurafsky (2012) investigated abstractions in poetry using a dictionary of abstract terms.

[4] "The mass of men lead lives of quiet desperation." (H.D. Thoreau)

and “not” were ore likely to occur in the first sentence position than the second sentence position. This tendency suggests that quotations that begin with a negative construction (like the earlier quote by Roth) are more common than those ending with one (like the earlier quote by Blake). Quotes that contain “not” in the first sentence often use the first sentence to make a negative claim about reality, followed by a positive claim. Such quotations tend to use repetitive structures or other types of parallelism, such as *antimetabole*:

> We are not human beings having a spiritual experience. We are spiritual beings having a human experience. (P. de Chardin)

In quotations, “Never” was also more likely to occur in the first sentence than the second sentence, as was “Do”; studying examples revealed that “Do” was very often followed by “not” or “n’t.” These statistical tendencies point to the ways that Negative-to-Positive constructions also take the form of a negative commandment (e.g., “Never do *X*”) in the first sentence, followed either by a positive commandment or an explanation of the reasoning for the commandment:

> Do not worry about your difficulties in mathematics. I can assure you mine are still greater. (A. Einstein)

Cross-Sentence Conjunction: For both Quotations 1 and Non-Quotes 1, the high-level syntax feature with the highest χ^2 value was *CC* + *NP* + *VP* + .. This feature tended to occur in the second sentence for both collections; likewise, for both sentences “But” and “And” were more likely to appear in the second sentence. This is not surprising, as coordinating conjunctions mark the “conjunction” relationship of cohesion (Halliday and Hasan, 2014) (i.e. clauses that begin with conjunctions like “But” implicitly refer back to a previous clause). However, for Quotations 1, this syntax pattern was over six times as likely to occur in the second sentence, compared to nearly two times for Non-Quotes 2, a statistically-significant difference (χ^2, p<.01). In the Quotations 1 corpus, other high-level features beginning with a coordinating conjunction were also more likely to occur in sentence 1 than 2, including *CC* + *PP* + , + *NP* + *VP* + . and *CC* + *SBAR* + , + *NP* + *VP* + .. For instance:

> Where a goat can go, a man can go. And where a man can go, he can drag a gun. (William Phillips)

Similarly, the high-level syntax pattern *IN* + *NP* + *VP* + . was more likely to occur in the second sentences of quotations than the first sentence; this pattern also indicates cohesion:

> One of the most adventurous things left us is to go to bed. For no one can lay a hand on our dreams. (E.V. Lucas)

We note that either of these quotations could be rephrased as a single sentence, such as:

> One of the most adventurous things left us is to go to bed, for no one can lay a hand on our dreams.

We speculate that there is something stylistically powerful about such sentences in which the second sentence begins with a coordinating or subordinating conjunction. (Perhaps such quotations create a “dramatic” pause for the reader between the sentences.)

Questions: Table 1 shows that high-level syntax patterns that indicate questions, *WHNP* + *SQ* + . and *WHADVP* + *SQ* + . occurred more frequently in the first sentence position than the second sentence position, as did the unigram “When.” Examining data with the *WHNP* + *SQ* + . pattern revealed that many of these quotations were actually jokes that take the form of a question/answer dyad.

Sweeping Declarations: For Quotations 1, Abstract Nouns and General Nouns as nominal subjects were more prevalent in the first than in the second sentence (χ^2, p<.01). For Non-Quotes 1, General Nouns were also significantly more likely to occur in the first sentence (χ^2, p<.01); this was not the case for General Nouns. For quotations only, however, “is” was more likely to occur in the first sentence; likewise, the *NP* + *VP* + . pattern was also more likely to occur in the first sentences of quotations. Remaining open to other interpretations, we suggest that these facts point to the tendency of quotations to begin with sweeping declarations about “people,” “life,” “truth,” and other broad concepts, kernels of wisdom which the next sentence elaborates or illustrates:

> Love is a trap. When it appears, we see only its light, not its shadows. (P. Coelho)

“Simply”: Certain unigrams that tend to occur in a particular sentence can also point to a very specific rhetorical pattern. For instance, the word “simply” was more likely to appear in the second sentence of a quotation than the first. Quotations that manifest this tendency often use this word to emphasize the second sentence’s proposition with respect to the first sentence:

> I used to dream about escaping my ordinary life, but my life was never ordinary. I had simply failed to notice how extraordinary it was. (R. Riggs)

6 Quote Order Task

We have analyzed stylistic patterns in quotations. However, are these patterns *characteristic* of quotations? To explore this question and to investigate the overall robustness of our features, we define a *Quote Ordering Task*, the goal of which is to distinguish between the original and reversed versions of a quotation. This experiment is in the tradition of tasks for evaluating models of text coherence, such as the one used by Louis and Nenkova (2012). During training, the classifier is shown either the `original` or `reversed` version of a quote. At test time, the classifier must identify each quote as either `original` or `reversed`.

We conducted two experiments. First, using Naive Bayes classifiers, we performed a 5-fold cross-validation test on balanced subsets of three of the four data-sets: Quotations 1, Non-Quotes 1, and Non-Quotes 2 (n=1846 for each). Next we trained on all of Quotations 1 (n=4237) and tested on a separate test set, Quotations 2 (n=1846). In this second test, we trained on both the `original` and `reversed` version of each quote. Table 2 reports results for both tests under various conditions.

For these tests, "high-level features" refers to high-level syntax (of the first sentence, of the second sentence, and both in a sequence), which if either sentence contains more Abstract Nouns, and which if either sentence contain more General Nouns. Combined with unigrams (including stopwords), these features offered slight but not statistically-significant benefit for Non-Quotes 1 in the cross-validation test and slight but not statistically-significant benefit in the second test (testing on Quotations 2). It remains a challenge to integrate such features for classification purposes.

In both tests, however, we were able to predict the order of quotations upwards of 60% of the time. This was not the case for the non-quotes corpora. In cross-validation, the classifier achieved a high score of 62.6% on Quotations 1, 56.0% on Non-Quotes 1, and 52.9% on Non-Quotes 2. The mean top score for Quotations 1 was higher than for the other two collections (two-tailed t-test, $p<.01$). This is evidence that quotations as a genre are more "formulaic" than other textual sequences, their order more easily predicted. We suggest that adherence to latent stylistic patterns is part of what makes quotations seem quotable; as rhetoricians have observed since antiquity, there is power in a pattern.

Feature Set	Q1	NQ1	NQ2	Q2
Unigrams	**62.6**	55.6	**52.9**	63.7
All High-Level Features	57.8	54.1	52.2	58.0
All Features	**62.6**	**56.0**	52.7	**63.9**

Table 2: Performance on Quote Ordering Task for Quotations 1, Non-Quotes 1, and Non-Quotes 2 (5-fold cross-validation, baseline = 50%) and on a separate test set, Quotations 2 (baseline = 52%).

7 Conclusion

We have analyzed linguistic style not merely as the *presence* of features but also the *order* of features across sentences. In quotations, certain words as well as categories of words and syntactic patterns are more likely to appear in the first or second of two-sentence texts. While other genres may also exhibit regularities in the patterning of stylistic information, our results indicate that this stylistic patterning may be especially strong in quotations. Further research could compare a wider variety of genres. Next steps include investigating the relationship to rhetorical goals and running studies with users to determine if they are consciously aware of these stylistic elements when they post quotations. We would like to a better understanding of why people chose to share the quotations they do.

Analyzing discourse-level stylistic tendencies may prove useful for various applications. Bendersky and Smith (2012) demonstrated a method for automatically culling quotations from textual corpora, yet their method was limited to individual sentences. Taking into account the stylistic schemas of quotations could facilitate the gathering of multi-sentence quotations and assist "creative text retrieval" (Veale, 2011) more generally. In the context of social media platforms where quotes circulate, stylistic patterns could also be used to recommend users stylistically-similar quotations to read.

Abstract

This paper proposes an incremental learning strategy for neural word embedding methods, such as SkipGrams and Global Vectors. Since our method iteratively generates embedding vectors one dimension at a time, obtained vectors equip a unique property. Namely, any right-truncated vector matches the solution of the corresponding lower-dimensional embedding. Therefore, a single embedding vector can manage a wide range of dimensional requirements imposed by many different uses and applications.

1 Introduction

Word embedding vectors obtained from '*neural word embedding methods*', such as SkipGram, continuous bag-of-words (CBoW) and the family of vector log-bilinear (vLBL) models (Mnih and Kavukcuoglu, 2013; Mikolov et al., 2013a; Mikolov et al., 2013c; Mikolov et al., 2013b) have now become an important fundamental resource for tackling many natural language processing (NLP) tasks. These NLP tasks include part-of-speech tagging (Tsuboi, 2014; Ling et al., 2015), dependency parsing (Chen and Manning, 2014; Dyer et al., 2015; Alberti et al., 2015), semantic role labeling (Zhou and Xu, 2015; Woodsend and Lapata, 2015), machine translation (Sutskever et al., 2014), sentiment analysis (Kim et al., 2015), and question answering (Wang and Nyberg, 2015).

The main purpose of this paper is to further enhance the 'usability' of obtained embedding vectors in actual use. To briefly explain our motivation, we first introduce the following concept:

Definition 1 (D'-right-truncated vector[1]). *Let* $\mathbf{w}'$ *and* $\mathbf{w}''$ *be vectors, whose dimensions are* D' *and* D''*, respectively. Namely,* $\mathbf{w}' = (w'_1, \ldots, w'_{D'})$ *and* $\mathbf{w}'' = (w''_1, \ldots, w''_{D''})$*. Suppose* $\mathbf{w}$ *matches the concatenation of* $\mathbf{w}'$ *and* $\mathbf{w}''$*, that is,* $\mathbf{w} = (w'_1, \ldots, w'_{D'}, w''_1, \ldots, w''_{D''})$*. Then, we define* $\mathbf{w}'$ *as a* D'*-right-truncated vector of* $\mathbf{w}$.

This paper focuses on the fact that the appropriate dimension of embedding vectors strongly depends on applications and uses, and is basically determined based on the performance and memory space (or calculation speed) trade-off. Indeed, the actual dimensions of the previous studies listed above are diverse; often around 50, and at most 1000. It is worth noting here that each dimension of embedding vectors obtained by conventional methods has no interpretable meaning. Thus, we basically need to retrain D'-dimensional embedding vectors even if we already have a well-trained D-dimensional vector. In addition, we cannot take full advantage of freely available high-quality pre-trained embedding vectors[2] since their dimensions are already given and fixed, *i.e.*, $D = 300$.

To reduce the additional computational cost of the retraining, and to improve the 'usability' of embedding vectors, we propose a framework for incrementally determining embeddings one dimension at a time from 1 to D. As a result, our method always offers the relation that '*any* D'*-right-truncated em-*

[1] The term 'right-truncated' is originally taken from 'right-truncatable prime'

[2] *i.e.*, 'GoogleNews-vectors-negative300' obtained from https://code.google.com/archive/p/word2vec/, and 'glove.840B.300d' obtained from http://nlp.stanford.edu/projects/glove/

Proceedings of NAACL-HLT 2016, pages 1145–1151,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

bedding vector is the solution for D'-dimensional embeddings of our method'. Therefore, in actual use, we only need to construct a relatively higher-dimensional embedding vector 'just once', *i.e.*, $D = 1000$, and then truncate it to an appropriate dimension for the application.

2 Neural Word Embedding Methods

Let $\mathcal{U}$ and $\mathcal{V}$ be two sets of predefined vocabularies of possible inputs and outputs. Let $|\mathcal{U}|$ and $|\mathcal{V}|$ be the number of words in $\mathcal{U}$ and $\mathcal{V}$, respectively. Then, neural word embedding methods generally assign a D-dimensional vector to each word in $\mathcal{U}$ and $\mathcal{V}$. We denote $\mathbf{e}_i$ as representing the i-th input vector, and $\mathbf{o}_j$ for the j-th output vector. In the rest of this paper, for convenience the notation 'i' is always used as the index of input vectors, and 'j' as the index of output vectors, where $1 \leq i \leq |\mathcal{U}|$ and $1 \leq j \leq |\mathcal{V}|$.

We introduce $\mathbf{E}$ and $\mathbf{O}$ that represent lists of all input and output vectors, respectively. Namely, $\mathbf{E} = (\mathbf{e}_1, \cdots, \mathbf{e}_{|\mathcal{U}|})$ and $\mathbf{O} = (\mathbf{o}_1, \cdots, \mathbf{o}_{|\mathcal{V}|})$. $\mathcal{X}$ represents training data. Then, embedding vectors are obtained by solving the following form of a minimization problem defined in each neural word embedding method:

$$(\hat{\mathbf{E}}, \hat{\mathbf{O}}) = \underset{\mathbf{E},\mathbf{O}}{\arg\min} \left\{ \Psi(\mathbf{E}, \mathbf{O} \mid \mathcal{X}) \right\}, \tag{1}$$

where Ψ represents the objective function, and $\hat{\mathbf{E}}$ and $\hat{\mathbf{O}}$ are lists of solution embedding vectors.

Hereafter, we use Ψ as an abbreviation of $\Psi(\mathbf{E}, \mathbf{O} \mid \mathcal{X})$. For example, the objective function Ψ of 'SkipGram with negative sampling (SGNS)' can be written in the following form[3] :

$$\Psi = \sum_{(i,j)} \Big(c_{i,j} L(x_{i,j}) + c'_{i,j} L(-x_{i,j}) \Big), \tag{2}$$

where $x_{i,j} = \mathbf{e}_i \cdot \mathbf{o}_j$, and $L(x)$ represents a logistic loss function, namely, $L(x) = \log(1 + \exp(-x))$. Moreover, $c_{i,j}$ and $c'_{i,j}$ represent co-occurrences of the i-th input and j-th output words in training data and negative sampling data, respectively.

Another example, the objective function Ψ of the 'Global Vector (GloVe)' can be written in the following form (Pennington et al., 2014):

$$\Psi = \frac{1}{2} \sum_{(i,j)} \beta_{i,j} (x_{i,j} - m_{i,j})^2, \tag{3}$$

where $m_{i,j}$ and $\beta_{i,j}$ represent certain co-occurrence and weighting factors of the i-th input and the j-th output words, respectively. For example, $\beta_{i,j} = \min(1, (c_{i,j}/x_{\max})^{\gamma})$, and $m_{i,j} = \log(c_{i,j})$ are used in (Pennington et al., 2014), where $x_{\max}$ and γ are tunable hyper-parameters.

```
Input: $\mathcal{X}$: training data, $D$: maximum number of dimensions (iterations)
$\mathbf{E}^{(0)} \leftarrow \emptyset$, $\mathbf{O}^{(0)} \leftarrow \emptyset$, and $\mathbf{B}^{(0)} \leftarrow \mathbf{0}$, $d \leftarrow 0$
repeat
    $d \leftarrow d + 1$

    $\mathbf{E}^{(d)} \leftarrow$ appendVec($\mathbf{E}^{(d-1)}, \bar{\mathbf{q}}_d$)
    $\mathbf{O}^{(d)} \leftarrow$ appendVec($\mathbf{O}^{(d-1)}, \bar{\mathbf{r}}_d$)
    $\mathbf{B}^{(d)} \leftarrow$ updateBias($\mathbf{B}^{(d-1)}, \bar{\mathbf{q}}_d, \bar{\mathbf{r}}_d$) // Eq. 4
until $d = D$
Output: $(\mathbf{E}^{(D)}, \mathbf{O}^{(D)})$
```

Figure 1: An algorithm for solving an iterative additional coordinate optimization formulation for obtaining embedding vectors.

3 Incremental Construction of Embedding

This section explains our proposed method. The basic idea is very simple and clear: we convert the minimization problem shown in Eq. 1 to a series of minimization problems, each of whose individual problem determines one additional dimension of each embedding vector. We refer to this formulation of embedding problems as '*ITerative Additional Coordinate Optimization (ITACO)*' formulation. Fig. 1 shows our entire optimization algorithm for this formulation.

3.1 Bias terms and optimization variables

Suppose d represents a discrete time step, where $d \in \{1, \ldots, D\}$. Let $\mathbf{B}^{(d)}$ be a matrix representation of bias terms at the d-th time step, and $b_{i,j}^{(d)}$ denote the (i,j)-factor of $\mathbf{B}^{(d)}$. Then, we define that $b_{i,j}^{(d)}$ for all (i,j) and d have the following recursive relation:

$$b_{i,j}^{(d)} = \sum_{k=1}^{d} e_{i,k} o_{j,k} = b_{i,j}^{(d-1)} + e_{i,d} o_{j,d}, \tag{4}$$

[3] We can obtain this form by a simple reformulation from the original objective of SGNS (Mikolov et al., 2013b).

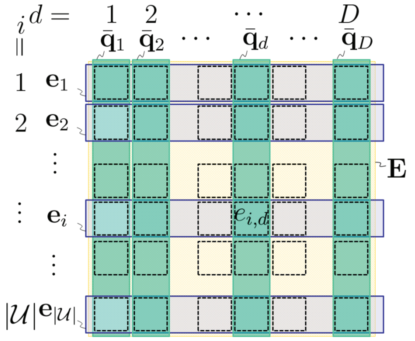

Figure 2: Relation of $\mathbf{e}_i$ and $\bar{\mathbf{q}}_d$ used to represent input vectors in this paper.

where we define $b^{(0)}_{i,j} = 0$ for all (i, j). This relation implies that the solutions of former optimizations are used as bias terms in latter optimizations.

Next, we define $\bar{\mathbf{q}}_d$ and $\bar{\mathbf{r}}_d$ as the vector representations of the concatenation of all the input and output parameters at the d-th step, respectively, that is, $\bar{\mathbf{q}}_d = (e_{1,d}, \dots, e_{|\mathcal{U}|,d})$ and $\bar{\mathbf{r}}_d = (o_{1,d}, \dots, o_{|\mathcal{V}|,d})$. Note that $\mathbf{e}_i$ used in the former part of this paper is a D-dimensional vector while $\bar{\mathbf{q}}_d$ and $\bar{\mathbf{r}}_d$ defined here are $|\mathcal{U}|$-dimensional and $|\mathcal{V}|$-dimensional vectors, respectively. Moreover, there are relations that $e_{i,d}$ is the d-th factor of $\mathbf{e}_i$, and, at the same time, the i-th factor of $\bar{\mathbf{q}}_d$.

Fig. 2 illustrates the relation of $\mathbf{e}_i$ and $\bar{\mathbf{q}}_d$ in this paper. We omit to explicitly show the relation of $\mathbf{o}_j$ and $\bar{\mathbf{r}}_d$, which are used to represent output vectors because of the space reason. However obviously, they also have the same relation as $\mathbf{e}_i$ and $\bar{\mathbf{q}}_d$.

3.2 Individual optimization problem

Then, we define the d-th optimization problem in our ITACO formulation as follows:

$$\begin{aligned} (\bar{\mathbf{q}}_d, \bar{\mathbf{r}}_d) &= \arg\min_{\bar{\mathbf{q}},\bar{\mathbf{r}}} \left\{ \bar{\Psi}\left(\bar{\mathbf{q}}, \bar{\mathbf{r}} | \mathcal{X}, \mathbf{B}^{(d-1)}\right) \right\} \\ \text{subject to:} \quad & \frac{|\mathcal{V}|}{|\mathcal{U}|} ||\bar{\mathbf{q}}||_p = ||\bar{\mathbf{r}}||_p, \end{aligned} \tag{5}$$

where $|| \cdot ||_p$ represents the L_p-norm. We generally assume that $p = \{1, 2, \infty\}$, and often select $p = 2$. Note that $\bar{\mathbf{q}}_d$ is optimization parameters in the d-th optimization problem while $\mathbf{B}^{(d-1)}$ is the constant. Fig. 3 illustrates the relation of $\mathbf{B}^{(d-1)}$ and $\bar{\mathbf{q}}_d$.

We assume that the objective function $\bar{\Psi}$ takes an identical form as used in one of the conventional methods such as SGNS and GloVe as shown by Eqs. 2 and 3. The difference appears in the variables; our ITACO formulation uses $x_{i,j} = e_i o_j + b_{i,j}$ rather than $x_{i,j} = \mathbf{e}_i \cdot \mathbf{o}_j$ as described in Sec. 2.

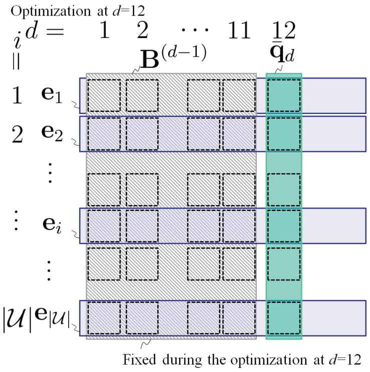

Figure 3: Relation of $\mathbf{B}^{(d-1)}$ and $\bar{\mathbf{q}}_d$, which are the constant and optimization parameters in the d-th optimization problems, respectively.

3.3 Improving stability of embeddings

The additional norm constraint in Eq. 5 is introduced to improve stability. The optimization problems of neural word embedding methods including SGNS and GloVe can be categorized as a *bi-convex optimization problem* (Gorski et al., 2007); they are convex with respect to the parameters $\mathbf{E}$ if the parameters $\mathbf{O}$ are assumed to be constants, and vice versa. One well-known drawback of unconstrained bi-convex optimization is that the optimization parameters can possibly diverge to ±∞ (See Example 4.3 in (Gorski et al., 2007)). This is because the objective function only cares about the inner product value of two vectors. Therefore, each parameter can easily have a much larger value, *i.e.*, $o_1 = 10^9$, if e_1 is smaller and approaches a zero value *i.e.*, $e_1 = 10^{-10}$. This is mainly caused by inconsistent scale problem. Thus, our norm constraint in Eq. 5 can eliminate this problem by maintaining the scale of $\bar{\mathbf{q}}$ and $\bar{\mathbf{r}}$ at the same level.

3.4 Optimization algorithm

To solve Eq. 5, we employ the idea of the '*Alternating Convex Optimization (ACO)*' algorithm (Gorski et al., 2007). ACO and its variants have been widely developed in the context of (non-negative) matrix factorization, *i.e.*, (Kim et al., 2014), and are empirically known to be an efficient method in practice. The main idea of ACO is that it iteratively and alternatively updates one parameter set, *i.e.*, $\bar{\mathbf{q}}$, while the other distinct parameter set is fixed, *i.e.*, $\bar{\mathbf{r}}$. In our case, ACO solves the following two optimization problems iteratively and alternately:

$$\bar{\mathbf{q}}_d = \arg\min_{\bar{\mathbf{q}}} \left\{ \bar{\Psi}(\bar{\mathbf{q}}, \bar{\mathbf{r}} \mid \mathcal{X}, \mathbf{B}^{(d-1)}) \right\} \quad (6)$$

$$\bar{\mathbf{r}}_d = \arg\min_{\bar{\mathbf{r}}} \left\{ \bar{\Psi}(\bar{\mathbf{q}}, \bar{\mathbf{r}} \mid \mathcal{X}, \mathbf{B}^{(d-1)}) \right\}. \quad (7)$$

There are at least two advantages of using ACO; (1) Eqs. 6 and 7 both become convex optimization problems. Therefore, the global optimum solution can be obtained when $\partial_{e_i} \bar{\Psi} = 0$ for all i and $\partial_{o_j} \bar{\Psi} = 0$ for all j, respectively. (2) ACO guarantees to converge to a stationary point (one of the local minima)[4].

For example, by a simple reformulation of $\partial_{e_i} \bar{\Psi} = 0$, we obtain the closed form solution of Eq. 6 with the GloVe objective, that is,

$$e_i = \frac{\sum_j \beta_{i,j}(m_{i,j} - b_{i,j})o_j}{\sum_j \beta_{i,j}(o_j)^2} \quad \forall i. \quad (8)$$

Similarly, the closed form solution of Eq. 7 is:

$$o_j = \frac{\sum_i \beta_{i,j}(m_{i,j} - b_{i,j})e_i}{\sum_i \beta_{i,j}(e_i)^2} \quad \forall j. \quad (9)$$

Thus, we can solve Eqs. 6 and 7 without performing iterative estimation. Next, we obtain the following equation by a simple reformulation of $\partial_{e_i} \bar{\Psi} = 0$ for the SGNS objective:

$$\sum_j c_{i,j} o_j = \sum_j (c_{i,j} + c'_{i,j}) \sigma(e_i o_j + b_{i,j}) o_j, \quad (10)$$

where $\sigma(x)$ represents a sigmoid function, that is, $\sigma(x) = \frac{1}{1+\exp(-x)}$. Similarly, we also obtain the following form of the equation for Eq. 7:

$$\sum_i c_{i,j} e_i = \sum_i (c_{i,j} + c'_{i,j}) \sigma(e_i o_j + b_{i,j}) e_i. \quad (11)$$

These equations are efficiently solvable by a simple binary search procedure since each equation only has a single parameter, that is, e_i or o_j,

During the optimization, there is no guarantee that the constraint $\frac{|\mathcal{V}|}{|\mathcal{U}|}||\bar{\mathbf{q}}||_p = ||\bar{\mathbf{r}}||_p$ always holds. Fortunately, the following transformations always satisfy this norm constraint:

```
Input: $\mathcal{X}$: training data, $\mathbf{B}$: matrix form of bias terms,
    $\epsilon$: constant for convergence check
$\bar{\mathbf{q}} \leftarrow \mathbf{1}$, and $\bar{\mathbf{r}} \leftarrow \mathbf{0}$
repeat
    $\bar{\mathbf{r}} \leftarrow$ updateIVec1D($\bar{\mathbf{r}} \mid \bar{\mathbf{q}}, \mathbf{B}$)    // Eq. 11 or 9
    $(\bar{\mathbf{q}}, \bar{\mathbf{r}}) \leftarrow$ scaleVec($\bar{\mathbf{q}}, \bar{\mathbf{r}}$)    // Eq. 12
    $\bar{\mathbf{q}} \leftarrow$ updateOVec1D($\bar{\mathbf{q}} \mid \bar{\mathbf{r}}, \mathbf{B}$)    // Eq. 10 or 8
    $(\bar{\mathbf{q}}, \bar{\mathbf{r}}) \leftarrow$ scaleVec($\bar{\mathbf{q}}, \bar{\mathbf{r}}$)    // Eq. 12
until ConvergenceCheck($\epsilon$)
Output: $(\bar{\mathbf{q}}, \bar{\mathbf{r}})$
```

Figure 4: Procedure of `updateParams1D` in Fig. 1 using the ACO-based algorithm.

$$\tilde{e}_i = \frac{|\mathcal{U}|}{|\mathcal{V}|} \frac{e_i}{||\bar{\mathbf{q}}||_p} \left(\frac{|\mathcal{V}|}{|\mathcal{U}|} ||\bar{\mathbf{q}}||_p ||\bar{\mathbf{r}}||_p \right)^{\frac{1}{2}} \quad \forall i$$
$$\tilde{o}_j = \frac{o_j}{||\bar{\mathbf{r}}||_p} \left(\frac{|\mathcal{V}|}{|\mathcal{U}|} ||\bar{\mathbf{q}}||_p ||\bar{\mathbf{r}}||_p \right)^{\frac{1}{2}} \quad \forall j, \quad (12)$$

which also maintain $\tilde{e}_i \tilde{o}_j = e_i o_j$, and the objective value. Thus, we can safely apply them at any time during the optimization.

Finally, Fig. 4 shows the optimization procedure when using the ACO framework.

4 Experiments

As in previously reported neural word embedding papers, our training data was taken from a Wikipedia dump (Aug. 2014). We used `hyperwords` tool[5] for our data preparation (Levy et al., 2015).

We compared our method, **ITACO**, with the widely used conventional methods, **SGNS** and **GloVe**. We used the `word2vec` implementation[6] to obtain word embeddings of SGNS, and `glove` implementation[7] for GloVe. Many tunable hyper-parameters were selected based on the recommended default values of each implementation, or suggestion explained in (Levy et al., 2015). For ITACO, we selected the Glove objective to solve Eqs. 6 and 7 since it requires a lower calculation cost than the SGNS objective.

We prepared three types of linguistic benchmark tasks, namely word similarity estimation (**Similarity**), word analogy estimation (**Analogy**), and sentence completion (**SentComp**) tasks. We gathered

Table 1: Results of right-truncated embedding vectors (trunc), and standard embedding vectors (retrain). '*' represents the best results in the corresponding column.

nine datasets for Similarity (Rubenstein and Goodenough, 1965; Miller and Charles, 1991; Agirre et al., 2009; Agirre et al., 2009; Bruni et al., 2014; Radinsky et al., 2011; Huang et al., 2012; Luong et al., 2013; Hill et al., 2014), three for Analogy (Mikolov et al., 2013a; Mikolov et al., 2013c) , and one for SentComp (Mikolov et al., 2013a).

Table 1 shows all the results of our experiments[8]. The rows labeled '(trunc)' show the performance of D-right-truncated embedding vectors, whose original vector of dimension is $D = 1000$. Thus, they were obtained from a single set of embedding vectors with $D = 1000$ for each corresponding method. Next, the rows labeled '(retrain)' show the performance provided by SGNS or GloVe that were independently constructed with using a standard setting and corresponding D. Note that the results of 'ITACO (retrain)' are identical to those of 'ITACO (trunc)'. Moreover, 'GloVe (trunc)' and 'GloVe (retrain)' in $D = 1000$ are equivalent, as are 'SGNS (trunc)' and 'SGNS (retrain)'. Thus, these results were omitted from the table.

First, comparing '(retrain)' and '(trunc)' in SGNS and GloVe, our experimental results first explicitly revealed that SGNS and GloVe with the simple truncation approach '(trunc)' cannot provide effective lower-dimensional embedding vectors. This observation strongly supports the significance of existence of our proposed method, ITACO.

Second, in most cases ITACO successfully provided almost the same performance level as the best SGNS and GloVe (retrain) results. We emphasize that ITACO constructed embedding vectors 'just once', while SGNS and GloVe required us to retrain embedding vectors in the corresponding times. In addition, single run of ITACO for $D = 1000$ took approximately 12,000 seconds in our machine environment, which was almost equivalent to run 4 iterations of SGNS and 8 iterations of GloVe. The results of SGNS and GloVe in Table 1 were obtained by 10 iterations and 20 iterations, respectively, which are one of the standard settings to run SGNS and GloVe[9]. This fact verified that ITACO can run efficiently as in the same level as SGNS and GloVe.

5 Conclusion

This paper proposed a method for generating interesting right-truncatable word embedding vectors. Our experiments revealed that the embedding vectors obtained with our method, ITACO, in any lower dimensions work as well as those obtained by SGNS and Glove. In addition, ITACO can also be a good alternative of SGNS and GloVe in terms of the execution speed of a single run. Now, we are free from retraining different dimensions of embedding vectors by using ITACO. Our method significantly reduces the total calculation cost and storage, which improves the 'usability' of embedding vectors[10].

Acknowledgment

We thank three anonymous reviewers for their helpful comments.

[8] Results for SGNS and GloVe are the average performance of ten runs as suggested in (Suzuki and Nagata, 2015)

[9] The performance of 4 iterations of SGNS and 8 iterations of GloVe were much lower than those of 10 iterations and 20 iterations of SGNS and GloVe shown in Table 1, respectively.

[10] The right-truncatable embedding vectors used in our experiments will be available in author's homepage

Abstract

Recent work across several AI subdisciplines has focused on automatically solving math word problems. In this paper we introduce MAWPS, an online repository of Math Word Problems, to provide a unified testbed to evaluate different algorithms. MAWPS allows for the automatic construction of datasets with particular characteristics, providing tools for tuning the lexical and template overlap of a dataset as well as for filtering ungrammatical problems from web-sourced corpora. The online nature of this repository facilitates easy community contribution. At present, we have amassed 3,320 problems, including the full datasets used in several prominent works.

1 Introduction

Automatically solving math word problems has proved a difficult and interesting challenge for the AI research community (Feigenbaum et al., 1995). Math word problems serve as a testbed for algorithms that build a precise understanding of what is being asserted in text. Consider the following:

> *Rachel bought two coloring books. One had 23 pictures and the other had 32. After one week she had colored 44 of the pictures. How many pictures does she still have to color?*

To solve such a problem, an algorithm must model implicit and explicit quantities in the text and their relationships through mathematical operations.

Many researchers have taken on this challenge to design data-driven approaches to solve different types of math word problems (Hosseini et al., 2014; Kushman et al., 2014; Roy and Roth, 2015; Zhou et al., 2015; Koncel-Kedziorski et al., 2015). Treatments of this task range from template-matching to narrative-building, and methods including integer linear programming, factorization, and more appear in the literature. As a result of the variety of approaches, several datasets have emerged. The variety of math word problems in these datasets is such that researchers have already begun specializing in the types of problems that their systems are able to successfully solve. Additionally, in some datasets one may find significant repetition of common words, a small set of equation templates used again and again, or problem texts which map to highly degraded grammatical structures. Therefore, designing general algorithms that can address different problem types while still being robust to the variations across datasets has remained a challenge.

In response to the burgeoning interest in this task, we present MAWPS (MAth Word ProblemS, pronounced *mops*), a framework for building an online repository of math word problems. Our framework includes a collection of varying types of math word problems, their answers, and equation templates, as well as interfaces which allow researchers to dynamically update and add more problem types. Additionally, in light of the problematic features of the current datasets cited above, our framework provides the possibility for customizing a dataset with regard to considerations such as lexical and template overlap or grammaticality, allowing researchers to choose how many of the difficulties of open domain web-sourced word problem texts they want

to tackle. We report the important characteristics of the current available data as well as the performance of some state-of-the-art systems on various subsets of the data. MAWPS is located at `http://lang.ee.washington.edu/MAWPS`.

2 Related Work

Recently, automatically solving math word problems has attracted several researchers. Specific topics include number word problems (Shi et al., 2015), logic puzzle problems (Mitra and Baral, 2015), arithmetic word problems (Hosseini et al., 2014; Roy and Roth, 2015), algebra word problems (Kushman et al., 2014; Zhou et al., 2015; Koncel-Kedziorski et al., 2015), and geometry word problems (Seo et al., 2015).

A few recent works, Kushman et al. (2014) and Zhou et al. (2015) focus on solving math word problems by matching quantities and variables (nouns) extracted from the problem text to templates appearing in the training data. These methods have a broad scope, but they rely heavily on overlap between templates in the training and test data. As shown in our experiments, when that overlap is reduced, the performance of the systems drops significantly.

Other work has focused on more limited domains, but aims to reduce the reliance on data overlap. Hosseini et al. (2014) solve addition and subtraction problems by learning to categorize verbs for the purpose of updating a world representation derived from the problem text. Roy and Roth (2015) treat arithmetic word problem templates as equation trees and introduce a method for learning the least governing node for two text quantities. Koncel-Kedziorski et al. (2015) focus on single equation problems and use typed semantically-rich equation trees where nodes correspond to numbers and an associated type derived from the problem text, and efficiently enumerate the space of these trees using integer linear programming.

Our work is also inspired by the recent work in introducing datasets to evaluate question answering and reading comprehension tasks that require reasoning and entailment. In contrast to Richardson et al. (2013), our work is focused on making a dataset for math word problems to evaluate robustness, scalability, and scope of algorithms in quantitative reasoning. In contrast to Weston et al. (2015), our work has more natural text and a larger vocabulary, does not use synthetic data, and is only focused on math word problems which is an extension of the counting sub-category introduced in that work.

3 Data

We compile a dataset of arithmetic and algebra word problems of varying complexity from different websites. This data extends the published word problem datasets used in Hosseini et al. (2014), Kushman et al. (2014), Koncel-Kedziorski et al. (2015), and Roy and Roth (2015). In addition to this strong foundation, the MAWPS repository provides interfaces for adding new word problems, allowing for its extension and development.

Noting that word problem datasets have varied with regard to noisiness and repetition, we define several data characteristics to capture these properties below. We then allow a user of the repository to select a subset of the data that optimizes these characteristics. The three data characteristics that can be automatically manipulated by MAWPS are:

Lexical Overlap. Lexical overlap describes the reuse of lexemes among problems in a dataset. For example, several problems may describe tickets being sold for a play, with only the number of adult and child tickets changed among them. These problems would have high lexical overlap. Previous work has shown that lexeme reuse in a dataset allows for spurious associations between the problem text and a correct solution (Koncel-Kedziorski et al., 2015). Researchers have sought to reduce this characteristic in their data so as to facilitate the development of more robust methods.

Template Overlap. By *template* we mean an equation where numerical values are replaced by a consistent, ordered set of constant variables. For example, the equations $(12*2)+7=x$ and $(6*15)+105=x$ have the same template, $(a*b)+c=x$. As shown in Roy and Roth (2015) and elsewhere, the appearance of a similar template in the training data is a requirement for some systems at test time. More general math word problem solvers have been introduced that reduce or eliminate this reliance. MAWPS provides for the automatic construction of a dataset with minimized template overlap.

Grammaticality. Many math word problems for use in AI research are drawn from user-submitted

online sources. Some problems from these sources contain grammatical errors including morphological agreement failures, misspellings, and other more complicated ungrammaticalities (for example, "Joan paid \$8.77 on a cat toy, and a cage cost her \$10.97 with a \$20 bill."). While some researchers wish to develop methods robust to these kind of errors, others would focus on the subset of the data that adheres to a high-precision, expertly developed grammar of English. To facilitate both lines of research, we allow for the selection of only those problems which meet this judgment, or the full data.

4 System Overview

The goal of the MAWPS repository is to provide an extendable collection of math word problems which allows researchers to select the portion of the data that meets their needs. To facilitate the growth of the collection, our framework allows for easily adding a single word problem or a whole dataset to the repository. We design backend tools which allow researchers to select a dataset with reduced lexical overlap, minimized template overlap, or improved grammaticality characteristics even as the repository continues to grow through community contribution. Figure 1 shows an outline of the MAWPS system.

4.1 Reduce Lexical Overlap

We consider the lexical overlap of a dataset D to be the average of the pairwise lexical overlap between each pair of problems in D. First, let $W(p)$ denote the set of unique unigrams and bigrams in a problem p. Then $\mathit{PairLex}(p,q) = \frac{|W(p) \cap W(q)|}{|W(p) \cup W(q)|}$ denotes the pairwise lexical overlap between problems p and q.

We formally define the lexical overlap of a dataset D as

$$\mathrm{Lex}(D) = \frac{1}{N} \sum_{\substack{p_i, p_j \in D \\ i<j}} \mathit{PairLex}(p_i, p_j)$$

where $N = \binom{|D|}{2}$ is the number of problem pairs in D. Given a dataset D and a target subset size k, MAWPS automatically finds a subset D' of reduced lexical overlap by solving the following optimization problem: $\min_{D' \subseteq D, |D'|=k} \mathrm{Lex}(D')$.

This is the remote clique problem[1], which is NP hard. As a result, we resort to a greedy strategy which gives an approximation ratio of 2 (Birnbaum and Goldman, 2007). We define $f_{\mathrm{lex}}(p, D') = \sum_{q \in D'} \mathit{PairLex}(p,q)$, which describes the overlap between a problem p and dataset D'. The greedy method to generate subset D' of D is as follows: we iteratively add a problem p from $D \setminus D'$ to D' which minimizes the value of $f_{\mathrm{lex}}(p, D')$. That is, at each step, we add a problem which has the least average pairwise lexical overlap with the problems already in D'. We repeat this process, starting with a randomly initialized singleton set, until a set of k problems is created.

4.2 Minimize Template Overlap

The template overlap of a dataset D is defined analogously to lexical overlap as the average of the pairwise template overlap between each pair of problems of D. Let $\mathit{PairTempl}(p,q)$ be 1 if p and q have the same template (corresponding to the gold equation), and 0 otherwise. We then define the template overlap of a dataset D as

$$\mathrm{Tmpl}(D) = \frac{1}{N} \sum_{\substack{p_i, p_j \in D \\ i<j}} \mathit{PairTempl}(p_i, p_j)$$

where $N = \binom{|D|}{2}$. Given a dataset D and a target subset size k, the template overlap reduced subset of D is generated by the following: $\min_{D' \subseteq D, |D'|=k} \mathrm{Tmpl}(D')$.

[1] Given a complete graph with nonnegative edge weights satisfying the triangle inequality and a positive integer p, the remote-clique problem is to find a subset of p vertices having a maximum-weight induced subgraph.

Dataset	# Probs$\lvert D\rvert$	# Gramm.	Lexical Overlap (Lex)			Template Overlap (Tmpl)		
			$k = \lvert D\rvert/2$	$k = \lvert D\rvert$	Reduction	$k = \lvert D\rvert/2$	$k = \lvert D\rvert$	Reduction
AddSub	395	357	6.1	7.9	22.8	33	37.2	11.3
SingleOp	562	491	6.1	7.8	21.8	24.7	25.4	2.8
MultiArith	600	526	7.8	9.4	17.0	19.7	22.1	10.9
SingleEq	508	434	5.4	6.8	20.6	11	17.9	38.5
SimulEq-S	514	437	4.7	6	21.7	2.9	12.5	76.8
SimulEq-L	1155	980	4.4	5.7	22.8	0.1	3.3	97.0

Table 1: Characteristics of datasets added to our repository. # Gramm. is no. of problems which passed our grammaticality check, the Lex column reports minimum lexical overlap for size k dataset, the Tmpl column reports minimum template overlap for size k dataset, Reduction denotes the % decrease in overlap value obtained by our system, when going from $k = |D|$ to $k = |D|/2$. We report all numbers as percentages.

Dataset	System	All $\lvert D\rvert$	Gramm.	Lex ($\lvert D\rvert/2$)	Tmpl ($\lvert D\rvert/2$)	Random ($\lvert D\rvert/2$)
SingleEq	(Koncel-Kedziorski et al., 2015)	72.2	74.2	63.6	67.0	67.2
SimulEq-S	(Kushman et al., 2014)	68.7	70.3	61.1	59.9	66.8

Table 2: Effect of lexical, template overlap and grammaticality data characteristics over various systems.

This again is an instance of remote clique problem, and we follow a similar greedy strategy. We define $f_{\mathrm{tmpl}}(p, D') = \sum_{q \in D'} \mathit{PairTempl}(p, q)$, which describes the overlap between a problem p and dataset D'. The greedy method to generate subset D' of D is as follows: we iteratively add a problem p from $D \setminus D'$ to D' which minimizes the value of $f_{\mathrm{tmpl}}(p, D')$. In other words, the algorithm iteratively chooses problem p from $D \setminus D'$ and adds it to D' such that (if possible) p adds a new template to D'. If there are no new templates to be added, then a p whose template is least frequent among those of D' is selected. This process is repeated until D' has k problems.

4.3 Template/Lexical Interaction

Given a dataset and a target subset size k, we would like a subset with the best lexical and template overlap characteristics. As an approximation, we reduce the arithmetic mean of the two overlap values. This mean can be expressed as $H(D) = \frac{1}{2}(\mathrm{Lex}(D) + \mathrm{Tmpl}(D))$. A similar greedy iterative approach as before generates the required dataset with the aforementioned approximation guarantee.

4.4 Grammaticality

Given a dataset, MAWPS can automatically remove ungrammatical word problems, resulting in a subset with improved grammaticality. Our system uses the broad-coverage, linguistically precise English Resource Grammar (ERG) (Flickinger, 2000; Flickinger, 2011) for determining grammaticality. The ERG is a continually-developed implementation of the grammatical theory of Head-Driven Phrase Structure Grammar that covers an increasingly wide variety of phenomena. Moreover, the ERG makes binary decisions for sentence acceptability: if it cannot find a valid parse among its rules, it returns no parse for that sentence. This contrasts with statistical parsers whose utility for this task is limited by the difficulties of tuning a cutoff confidence threshold for acceptability. We allow for filtering problems with ungrammatical sentences.

5 Properties of Current Data

We initialize our repository by extending the publicly available datasets. We list them below in order of increasing complexity of the final equation form.

- **AddSub**: Collection of addition, subtraction problems (Hosseini et al., 2014).
- **SingleOp**: Collection of single operation arithmetic problems (Roy et al., 2015).
- **MultiArith**: Collection of multi-step arithmetic problems (Roy and Roth, 2015).
- **SingleEq**: Single equation problems from (Koncel-Kedziorski et al., 2015).
- **SimulEq-S**: Single and two equation word problems from (Kushman et al., 2014).
- **SimulEq-L**: Collection of single and multiple equation word problems, superset of **SimulEq-S**.

Table 1 shows the characteristics of the datasets under various conditions of grammaticality, lexical and template overlap. Template overlap varies greatly across datasets, and decreases sharply with increase of complexity of target equation. Lexical overlap, on the other hand, does not show much variation, with most datasets having overlap value of around 7%. Our system effectively reduces overlap, obtaining around 20% reduction in most cases (going from $k = |D|$ to $k = |D|/2$). In the case of template overlap, this reduction varies greatly based on the complexity of target equation, ranging from 2.8% for SingleOp to 97% for SimulEq-L.

As no current system can process **SimulEq-L**, we report the performance of the two most general systems (Koncel-Kedziorski et al., 2015; Kushman et al., 2014) on **SingleEq** and **SimulEq-S** under different overlap and grammaticality properties in Table 2. We use a 5-fold cross validation setup and report average accuracy across folds. We include performance on a randomly selected dataset of the same size to analyze the effect of decreased data-size on performance.

Both systems gain from the pruning of grammatically incorrect problems from the dataset. Our results support the findings of Koncel-Kedziorski et al. (2015) regarding the diminishing performance of systems when faced with reduced lexical and template overlap. We expect, as that work showed, that further reducing these characteristics would result in even lower performance. The results on a random subset of the data show that data set size does not have as strong of an effect on algorithm performance as lexical or template overlap.

6 Conclusion

In this paper, we introduced MAWPS, a repository of math word problems. MAWPS offers a large collection of data from new and published datasets, provides interfaces for adding data, and includes data optimization tools. As current results show, designing general algorithms that can address different problem types while still being robust to the template or lexical variations has remained a challenge. We hope that our framework will help facilitate comparison between results while allowing researchers to focus on targets such as all grammatical problems or all single equation problems. We also include an official 80/20 test/train split of all problems available at the time of this publication.

Cross-genre Event Extraction with Knowledge Enrichment

Hao Li and Heng Ji
Computer Science Department
Rensselaer Polytechnic Institute
jih@rpi.edu

Abstract

The goal of Event extraction is to extract structured information of events that are of interest from unstructured documents. Existing event extractors for social media suffer from two major problems: lack of context and informal nature. In this paper, instead of conducting event extraction solely on each social media message, we incorporate cross-genre knowledge to boost the event extractor performance. Experiment results demonstrate that without any additional annotations, our proposed approach is able to provide 15% absolute F-score improvement over the state-of-the-art.

1 Introduction

The rapid development of social media and social networks since 2000s has made it an important channel of information dissemination. Because of its real-time nature, social media can be used as a sensor to gather up-to-date information about the state of the world. Effective automatic detection and extraction of events from the media will be an extremely important contribution. Recently there has been increasing interests in event extraction from social media (Yang et al., 1998; Kleinberg, 2003; He et al., 2007; Weng and Lee, 2011; Benson et al., 2011; Ritter et al., 2012).

Identifying and extracting events in social media is more challenging than traditional event extraction due to two major reasons: (1). **Lack of Context**: compared with traditional genres (e.g., new articles), social media context is usually short and incomplete (e.g., each tweet has a length limitation of 140 characters). Lacking of context, a single tweet itself usually cannot provide a complete picture of the corresponding events. For example, for the tweet *"Pray for Mali - the situation is coming to light, and it isn't pretty."*, an event extraction/discovery system (e.g. (Ji and Grishman, 2008)) fails to discover that it is about the same *war* event in *Mali* as mentioned in the news article *"State military forces on Friday retook a key town in northern Mali after intense fighting that included help from French military forces, a defense ministry spokesman said."* (2). **Informal Nature**: social media messages are written in an informal style, which causes the poor performance of event extractors designed for formal genres. For example, the tweet *"#AaronSwartz, Dead @ 26, #CarmenOrtiz "pushed him to exhaustion" don't let her get away with this! #scandal."* includes an *"Die"* event with *Aaron Swartz* as the *Victim*. However, the person name "AaronSwartz" appears in the hashtag "#AaronSwartz" and "Dead at 26" is written as "Dead @ 26". Existing supervised name taggers and event extractors fail to identify the same "Die" event mentioned in the news article *"Internet activist Aaron Swartz dead at 26"*.

Based on the intuition that news articles contain more detailed and formal information than tweet messages, we apply an unsupervised knowledge enrichment algorithm to link each tweet to its most relevant news article. By incorporating the cross-genre knowledge to tweets, we are able to formulate the task of event extraction on tweets as the task of cross-genre extraction for tweets and news articles. Thus we can alleviate the previous mentioned challenges in single-genre event extraction for tweets to

t_1: *Crowds rally in Belfast for flag protest#thetruth*
n_1: *Protesters march in Northern Ireland: Under a gray, overcast sky, more than 1,000 protesters gathered Saturday in the Northern Ireland city of Belfast carrying large Union flags, some wrapped around their shoulders.*
te_1: $\{$*EventPhrase = [rally, protest], EventArgument = Belfast, Time = 2013-01-14*$\}$
ne_1: $\{$*EventType = Conflict, EventPhrase = march, EventArgument = [protesters, Northern Ireland, Belfast]*$\}$
e_1: $\{$*EventType = Conflict, EventPhrase = [rally, protest, march], EventArgument = [protesters, Northern Ireland, Belfast], Time = 2013-01-14*$\}$.

Table 1: Cross-genre Event Extraction Example

some extent. To the best of our knowledge, it is the first work to conduct cross-genre event extraction through unsupervised knowledge enrichment.

2 Problem Definition

Given a tweet t_i, our cross-genre event extraction framework first discovers its most relevant news article n_i, then identifies event tuples (event phrases and event arguments) for the tweet (te_i) and the news article (ne_i) respectively, and finally conducts merging on the event extraction outputs from both genres to produce the cross-genre event extraction result (e_i). For example in Table 1, given the following tweet t_1, n_1 is retrieved as its most relevant news article. te_1 and ne_1 are the extracted event tuples for the tweet and the news article respectively and e_1 is the final cross-genre event extraction output after merging. To evaluate the performance of an event extractor, the precision, recall and f-measure of the extracted event phrases and event arguments will be measured using the following criteria: an event phrase is correctly labeled if it matches a reference trigger; an argument is correctly labeled if it matches a reference argument.

3 Approach

3.1 Baseline Event Extraction Systems

We use two state-of-the-art event extraction systems (Ritter et al., 2012; Li et al., 2013) to extract events from tweets and news articles respectively. The tweet event extractor TwiCal-Event (Ritter et al., 2012) is able to extract open-domain significant events from Twitter. It is a supervised system that identifies event phrases and event participants with tailored part-of-speech tagging and shallow parsing for tweets. In addition, it is also able to discover event categories and classify extracted events based on latent variable models. It takes tweets as input and outputs a four-tuple representation of events which includes event participants, event phrase, calendar date, and event type. The news event extractor (Li et al., 2013) is a joint framework based on structured prediction which extracts triggers and arguments simultaneously while incorporating diverse lexical, syntactic, semantic and global features. It takes raw documents as input, distinguish events from non-events by classifying event triggers and identifying and classifying argument roles.

3.2 Knowledge Enrichment Approach

To produce the latent vector representations for the whole dataset, we follow the same procedure in (Guo et al., 2013): represent the dataset in a matrix X, where each cell stores the TF-IDF values of words. Word vectors P and tweet vectors Q are optimized by minimizing the following objective function:

$$\sum_i \sum_j W_{ij} \left(P_{\cdot,i} \cdot Q_{\cdot,j} - X_{ij}\right)^2 + \lambda||P||_2^2 + \lambda||Q||_2^2$$
$$+\delta \cdot (\frac{Q_{\cdot,j_1} \cdot Q_{\cdot,j_2}}{|Q_{\cdot,j_1}||Q_{\cdot,j_2}|} - 1)^2$$
$$W_{i,j} = \begin{cases} 1, & \text{if } X_{ij} \neq 0 \\ w_m, & \text{if } X_{ij} = 0 \end{cases} \quad (1)$$

where λ is a regularization term, $Q_{\cdot,j_1}$ and $Q_{\cdot,j_2}$ are linked pairs connected by text-to-text relations, $|Q_{\cdot,j}|$ denotes the length of vector $Q_{\cdot,j}$ and the coefficient δ denotes the importance of the text-to-text links. we follow the same optimization procedure as (Steck, 2010) by alternating Least Square [ALS] is used for inference on P and Q.

After obtaining the vector representations for the whole dataset, for each tweet, we retrieve its cross-genre knowledge by finding the news article with the highest cosine similarity.

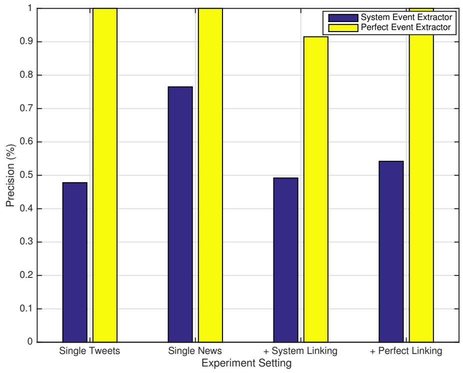

Figure 1: Event extraction precision

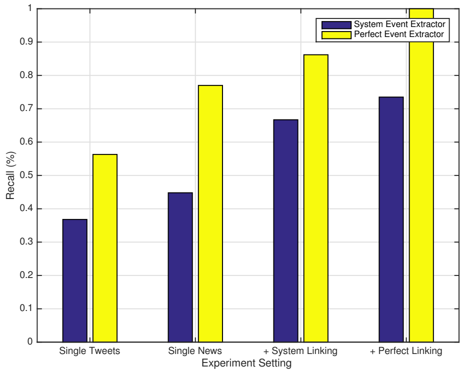

Figure 2: Event extraction recall

4 Experiments

4.1 Data Description

We use the same dataset as (Guo et al., 2013) which contains 34,888 tweets and 12,704 news articles. For each tweet, we consider the url-referred news article as its gold standard cross-genre knowledge – the most relevant news document. As the news event extractor is designed for a closed set of 33 event types (ace, 2005) while the tweet event extractor is for open domain, in this paper we only focus on the tweet-news pairs that the news event extraction output is not empty. We randomly selected 50 tweet-news pairs for the cross-genre event extraction annotation and evaluation.

4.2 Experiment Results

Figure 1, 2 and 3 present the Precision (P), Recall (R) and F-measure (F) of the overall event extraction performance for different settings respectively.

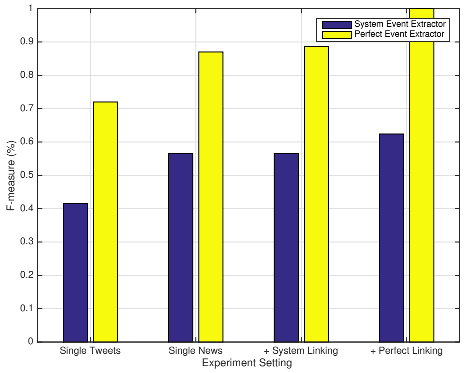

Figure 3: Event extraction f-measure

From these experiment results, we have the following four observations:

1. Event Extraction solely on tweet messages achieves the lowest precision, recall and f-measure. It exactly confirms our motivation of conducting knowledge enrichment for event extraction in tweet messages. Because of the informal nature of tweet messages, the event extractor misidentified 54.16% of the events thus the precision is low. Take the ill-formatted tweet in Section 1 as an example, the named entity "AaronSwartz" is in the hashtag "#AaronSwartz" and "Dead at 26" is written as "Dead @ 26". It makes the automatic event extractor extremely difficult to identify the "Die" event for the person "Aaron Swartz".

The low recall is mainly caused by the "lack of context" problem. Due to the length limitation of tweets, users tend to use recapitulate languages to describe an event. For Example, the following tweet *"Well. That sucks. 'Deepening Crisis for the Boeing 787'"* actually refers to an "emergency landing" event made by "All Nippon Airways" in "western Japan". The user only mentioned the summary "Deepening Crisis for the Boeing 787" to refer to the actual event. Therefore, the single-genre event extractor missed the event trigger "landing" and the event arguments "All Nippon Airways" and "western Japan".

2. Both single-genre event extractors can contribute to the cross-genre event extractor through the cross-genre linking process. Even with the automatic linking output, Figure 2 and Figure 3 show 29.9% recall and 14.0% f-measure improvement

over single-genre event extractor for tweets. It is because that in most cases, news articles cover more information than tweets as they are produced by professional news agencies while tweets are written by individuals with a 140-character length limitation. In the following example, although referring to the same events, the news article covers more event information than the tweet, thus the cross-genre event extractor can surpass the single-genre event extractor for tweets.

News: *Deepening Crisis for the Dreamliner The two largest Japanese airlines said they would ground their fleets of Boeing 787 aircraft after one operated by All Nippon Airways made an emergency landing in western Japan.*

Tweets: *Well. That sucks. "Deepening Crisis for the Boeing 787"*

For some certain cases, the cross-genre event extractor is also able to benefit from single-genre event extractor for tweets. For the following example, the event extractor for news articles missed the "Attack" event as "Halt an ... Advance" is an unusual phrase to describe an "Attack" event. However, in the related tweet, "Battling" is a strong indicator of an "Attack" event and the event extractor for tweets is able to catch it. As a result, we are able to extract the overall event tuples {EventPhrase=[Advance,Battling], EventPaticipant=[France,Islamist,Mali]}.

News: *French Troops Help Mali Halt an Islamist Advance France answered an urgent plea from the government of its former colony to help blunt an advance into the center of the country by Islamist extremist militants.*

Tweets: *France Battling Islamists in Mali #rebels tarnish W. African #Islam Western #intervention*

3. Either improving single-genre event extractors or achieving better cross-genre linking performance is able to boost the overall event extraction performance. From Figure 1, 2 and 3, we can observe that higher quality of single-genre event extractors will significantly enhance the precision while better linking performance will mainly contribute to a higher recall.

4. Compared with cross-genre linking accuracy, the quality of single-genre event extractors is more important. Figure 3 shows that "Gold Event Extractor + System Linking" achieved 26.3% higher F-measure score than "System Event Extractor + Gold Linking". It is mainly because of two reasons: on one hand, the errors of single-genre event extractors will be propagated to the final event output; on the other hand, the current linking system is able to provide reasonable linking results thus the use of perfect linking will not have too much gain.

5 Remaining Challenges

Linking Errors: mistakenly linking tweets to irrelevant news articles. For example, the tweet *"The lack of investigative movement - his return and his flippant attitude is what is insulting. Not his new placement."* is about a "Movement" event that *Assemblyman* returns to *Albany* after scandal. However, the tweets express the event so implicitly that the automatic linking system is not able to discover its corresponding news article.

Extraction Errors: single-genre event extractors failed on both the tweet side and the news article side. For the following example, both single genre event extractors missed the "Threaten" event between the *vice president Hugo Chvez* and *those questioning the legitimacy of Chavez's government.*

Tweet: *#Venezuela VP warns those questioning the legitimacy of #Chavez's government: "Watch your words and your actions."*

News: *The vice president threatened action against any who question the legality of delaying the swearing-in of President Hugo Chvez, who is still in Cuba.*

6 Conclusions and Future Work

In this paper we study the bottlenecks of event extraction for tweets. We have two observations: (1). Because of the "lack of context" and "informal nature" characteristics of tweets, conducting event extraction solely on tweet messages cannot produce satisfactory results; (2) The events embedded in tweets and news articles are often complementary. Based on these observations, we proposed to link each tweet to its most relevant news article, and further incorporated this cross-genre knowledge to conduct cross-genre event extraction. Experiment results showed that without any additional annotation, our proposed cross-genre event extractor is able to outperform state-of-the-art tweet event extraction. Our future research will focus on joint modeling of cross-genre event extraction in the training stage through cross-genre knowledge enrichment.

Emergent: a novel data-set for stance classification

William Ferreira
Department of Computer Science
University College London, UK

Andreas Vlachos
Department of Computer Science
University of Sheffield, UK

Abstract

We present Emergent, a novel data-set derived from a digital journalism project for rumour debunking. The data-set contains 300 rumoured claims and 2,595 associated news articles, collected and labelled by journalists with an estimation of their veracity (*true*, *false* or *unverified*). Each associated article is summarized into a headline and labelled to indicate whether its stance is *for*, *against*, or *observing* the claim, where *observing* indicates that the article merely repeats the claim. Thus, Emergent provides a real-world data source for a variety of natural language processing tasks in the context of fact-checking. Further to presenting the dataset, we address the task of determining the article headline stance with respect to the claim. For this purpose we use a logistic regression classifier and develop features that examine the headline and its agreement with the claim. The accuracy achieved was 73% which is 26% higher than the one achieved by the Excitement Open Platform (Magnini et al., 2014).

1 Introduction

The advent of *New Media*, such as Twitter, Facebook, etc., enables news stories and rumours to be published in real-time to a global audience, bypassing the usual verification procedures used by more traditional *Old Media* news outlets. However, the line between Old and New Media is becoming blurred as news aggregators lift stories from social media and re-publish them without fact-checking.

This issue could be helped by developing methods for automated fact-checking of news stories, part of the *reporter's black box* envisioned in Cohen et al. (2011) and one of the main objectives in computational journalism. While this task is related to a variety of natural language processing tasks such as textual entailment and machine comprehension, it poses additional challenges due to its open-domain, real-world nature. Previous work by Vlachos and Riedel (2014) proposed using data from fact-checking websites such as Politifact[1], but the labelling provided by the journalists is only the degree of truthfulness of the claims, without any machine-readable verdicts to supervise the various steps in deciding it. Thus, the task defined by the dataset proposed remains too challenging for the NLP methods currently available.

In this paper we propose to use data from the Emergent Project (Silverman, 2015), a rumour debunking project carried out in collaboration with the Tow Center for Digital Journalism at Columbia Journalism School[2]. Consisting of 300 claims and 2,595 associated news articles, the Emergent project contains a rich source of labelled data that can be used in a variety of NLP tasks, created by journalists as part of their normal workflow, thus real-world and at no annotation cost.

We leverage the Emergent dataset to investigate the task of classifying the stance of a news article headline with respect to its associated claim, i.e. for each article headline we assign a stance label which is one of *for*, *against*, or *observing*, indicating whether the article is supporting, refuting, or just reporting the claim, respectively. The large number

[1] http://www.politifact.com/

[2] http://towcenter.org/

Proceedings of NAACL-HLT 2016, pages 1163–1168,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

of claims in the dataset allows us to assess the generalization of the method evaluation to new claims more reliably than in previous work that either used a small number of claims (e. g. seven in Lukasik et al., 2015) or did not separate training claims from testing claims (Qazvinian et al., 2011).

We develop a stance classification approach based on multiclass logistic regression, using features extracted from the article headline and the claim, achieving an accuracy of 73% on our test data-set, also demonstrating that features relying on syntax, word alignment and paraphrasing contribute to the performance. Since the task bears similarities with textual entailment, we compare it against the Excitement Open Platform (Magnini et al., 2014) which achieved a substantially lower accuracy of 47%.

2 The Emergent data

The claims in Emergent are collected by journalists from a variety of sources such as rumour sites, e.g. snopes.com, and Twitter accounts such as @Hoaxalizer. Their subjects include topics such as world and national U.S. news and technology stories. Once a claim is identified, the journalist searches for articles that mention the claim and decides on the *stance* of each such article:

- *for*: The article states that the claim is true, without any kind of hedging.
- *against*: The article states that the claim is false, without any kind of hedging.
- *observing*: The claim is reported in the article, but without assessment of its veracity.

The journalist also summarises the article into a headline. In parallel to the article-level stance detection, a claim-level veracity judgement is reached as more articles associated with the claim are examined. The veracity of each claim is initially *unverified*, later becoming either *true* or *false* when the journalist decides that adequate evidence from the associated articles has been compiled. Finally, the source and the number of times each associated article is shared are recorded. An example of a claim verified on Emergent appears in Figure 1.

Claim: Robert Plant ripped up an $800 million contract offer to reunite Led Zeppelin

Source: mirror.co.uk (shares: 39,140)
Headline: Led Zeppelin's Robert Plant turns down £500MILLION to reform supergroup
Stance: *for*

Source: usnews.com (shares: 850)
Headline: No, Robert Plant Didn't Rip Up an $800 Million Contract
Stance: *against*

Source: forbes.com (shares: 3,360)
Headline: Robert Plant Reportedly Tears Up $800 Million Led Zeppelin Reunion Contract
Stance: *observing*

Veracity: *False*

Figure 1: Example verification taken from `http://www.emergent.info/led-zeppelin-contract`. The full text of the articles is omitted for brevity.

There are a number of tasks for which the Emergent data can be useful for development and evaluation. The article-level stance labels can be used to develop a stance detection system between the claim and an associated article. The claim-level veracity labels would be straightforward to use for fact-checking. Finally, the article headlines can be used for focused summarization.

In this paper we focus on stance detection of an article with respect to the claim using the headline provided by the journalist. For this purpose we obtained a database dump from the developers of Emergent and extracted all claims and associated article headlines. We made no attempt to exclude a claim or article based on grammatical errors or complex syntactic structure. Our final dataset contains 300 claims, and 2,595 associated article headlines, with an average ratio of 8.65 (7.31) articles per claim; the minimum number of articles per claim is 1 and the maximum number is 50. The class distribution of article stances is 47.7% *for*, 15.2% *against* and 37.1% *observing*. This dataset was split into training and test set parts, containing 2,071 and 524 instances respectively, ensuring that each claim appeared in only one of the parts. Both the database dump and the extracted claim-article headline dataset are available from `https://github.com/willferreira/mscproject`.

3 Stance Classification

We treat stance classification as a 3-way classification task using a logistic regression classifier with

L_1 regularization (Pedregosa et al., 2011)[3] and we explore two types of features: those extracted solely from the article headline and those extracted by combining the headline and the claim. The former are aimed at capturing the cases in which the stance of headline can be determined without consulting the claim, which is often the case with *observing* cases, as they often use hedging. The latter are aimed at determining the entailment relation between them. All feature engineering was conducted using 10-fold cross-validation on the training data. Our implementation is available from `https://github.com/willferreira/mscproject`.

Headline features The features extracted from the headline are the commonly used bag of words representation (**BoW**) and whether it ends in a question mark (**Q**). In addition, we added two features representing the minimum distance from the root of the sentence to common refuting (e. g. deny) and hedging/reporting (e.g. claim, presumably) words (**RootDist**). As an example of the **RootDist** feature, consider the dependency parse in Figure 2. The minimum number of edges from the root to a hedging/refuting word ("not" in the example) is three. The dependency parses were obtained using Stanford CoreNLP (Manning et al., 2014) and the word lists were compiled using online resources.

Claim-headline features While the article headline often provides adequate features to classify its stance, we also need to take into account its entailment relation with the claim. Therefore, based on the work by Rus and Lintean (2012) we compute an alignment using the Paraphrase Database (PPDB) (Pavlick et al., 2015) and the Kuhn-Munkres algorithm (Kuhn, 1955; Munkres, 1957) as follows. For each word pairing between the claim and the headline an edge is created and assigned a score by the following scheme:

- if the stems of the words are identical, assign *maxScore*
- else, if the words are paraphrases according to PPDB, assign their maximum paraphrase score
- else, assign *minScore*

maxScore and *minScore* were set to +10 and -10 respectively. Running the Kuhn-Munkres algorithm on this graph finds the maximum scoring 1-to-1 word alignment and the score of this alignment, normalized by the length of the claim or headline, whichever is the shorter. An additional feature is extracted to indicate if in an aligned pair of words, one of them — either in the claim or or the article headline — is negated according to the parser. Furthermore, we extracted the subject-verb-object (SVO) triples from the claim and the article headline (typically one in each) and matched them as follows. For each component of the triples we extracted from PPDB the following labels: *equivalence*, *forwardEntailment*, *backwardEntailment*, *independence* or *noRelation*. Thus the matching of an SVO triple in the claim to one in the headline is represented by a concatenation of three labels, each corresponding to the relation between the subjects, the verbs and the objects (**SVO**). Finally, we computed the cosine similarity between the vector representations for the claim and the headline (**word2vec**). The representations were calculated by multiplying the word2vec vectors (Mikolov et al., 2013a) for each word, which we found to perform better than addition. We utilised pre-trained vectors trained on part of the Google News dataset, comprising 300-dimensional vectors for 3 million words and phrases (Mikolov et al., 2013b).

4 Results

Since none of the stance labels dominates the label distribution, we evaluate the performance primarily using accuracy, also reporting per-class Precision and Recall. A majority baseline would achieve 47%, but would always predict *for*. For a better baseline we used the lexical overlap between the claim and the article headline, which we defined as the percentage of the ratio of the number of lemmas in common between them to the number of lemmas in their union. Using the training data we calculated the average overlap for each stance and found that *for* instances exhibit higher overlap, followed by *observing* and then by *against*. Following this, we defined two overlap thresholds, *minFor* and *maxAgainst*. If the overlap of a claim-headline pair is higher than *minFor* it is labeled *for*, if lower than *maxAgainst* it

[3] Specifically, we used the sklearn `LogisticRegression` classifier with the default parameters, and L_1 penalization.

method	acc.	*for*	*against*	*observing*
overlap	32%	50%/42%	18%/52%	32%/9%
EOP	47%	52%/77%	100%/1%	34%/29%
classifier	73%	71%/89%	82%/70%	74%/54%

Table 1: Test set accuracy and per stance precision and recall.

is labeled *against*, otherwise *observing*.

The comparison between the baseline and the L_1-regularized logistic regression classifier with the features described in the previous section appears in Table 1. As it can be observed, the proposed classifier performs much better in accuracy with substantial gains in all stances. Both approaches are mostly challenged by instances of the *observing* class, since the article headlines with that stance are quite similar to the claim, which is also the case for the more populous *for* class. We also compare our classifier against the Excitement Open Platform (EOP) textual entailment classifier (Magnini et al., 2014). In particular, we used the MaxEntClassificationEDA classifier with the RTE-3 pre-trained model which we found to be the best performing one among those available achieving 33% accuracy. Finally, we trained the same classifier on the Emergent training data achieving 47%, which is 26% lower than the proposed method.

In order to assess the contribution of the features developed we conducted an ablation analysis and the results appear in Table 2. The L_1 regularization used enforces sparsity which helps highlight the features relevant for each stance. The **RootDist** feature has a substantial contribution as it helps distinguish the *observing* from the *for* class. We also evaluated a model using only **BoW**, **Q** and **word2vec** features and the performance was 3% lower than using the complete feature set, thus highlighting the contribution of the features relying on alignment, syntax and the PPDB. Finally, the fact that **-word2vec** did not help, especially when compared to **PPDB**, can be partly attributed to the inability of methods relying solely on contexts to learn antonymy.

Feature	**10-fold cv**	**test**	chosen for stance
-BoW	1.66%	5.15%	ALL
-Q	1.85%	0.19%	*observing*
-RootDist	2.02%	2.48%	*for*, *observing*
-PPDB	0.47%	0.76%	*for*
-Neg	0.29%	0%	*for*, *against*
-SVO	0.20%	0.19%	*for*, *observing*
-word2vec	0.049%	-0.19%	*against*

Table 2: Ablation results: each row represents the drop in accuracy caused by removing the corresponding feature(s). The last column shows for which stance label(s) the feature(s) had non-zero weight(s).

5 Related work

The task defined by the Emergent dataset differs from recent work in stance classification (Qazvinian et al., 2011; Lukasik et al., 2015; Zhao et al., 2015) not only in the number of claims from which the article headlines are derived, but also in that correct prediction requires considering entailment relation between the claim and the headline. It also differs from work on target-specific stance prediction in debates (Walker et al., 2012; Hasan and Ng, 2013), since the targets considered there are topic labels such as abortion, instead of event claims as in this work.

Emergent, being derived from the workflow of journalists is more realistic than data-sets designed for textual entailment such as FraCas (Cooper et al., 1996) and SICK (Marelli et al., 2014) that are constructed artificially. Compared to the crowdsourced dataset of Bowman et al. (2015), it is smaller but of a different nature, since the former assumes that all sentences are visual representations, while news tend be more varied.

Stance detection in the context of Emergent is one component in the process of fact-checking claims appearing in the news which are usually more complex than the entity-relation-entity or entity-property-number triples considered in previous work (Nakashole and Mitchell, 2014; Vlachos and Riedel, 2015). The choice of claims to fact-check is a task in its own right, as shown by Hassan et al. (2015). Finally, the only other use of data from the Emergent project is by Liu et al. (2015); however their focus was not on the NLP aspects of the task but on using Twitter data to assess the veracity of the claim, ignoring the articles and their stances curated by the journalists.

6 Conclusions - Future work

In this paper we proposed Emergent, a new real-world dataset derived from the digital journalism project Emergent which can be used for a variety of NLP tasks in the context of fact-checking. We focus on stance detection, for which the large number of claims in the dataset compared to previous work allows for more reliable assessment of the generalization capabilities of the methods evaluated. We proceed to develop a model for stance classification using multiclass logistic regression and show how features beyond the typically used bag of words can be beneficial, achieving accuracy 26% better than an RTE system trained on the same data. We make both the datasets and our code available.

Despite its advantages, the dataset collected is rather small to learn all the nuances of the task. Thus in future work we will explore ways of incorporating large amounts of raw text in training stance classification models, possibly using a neural network architecture. Finally, stance detection is one of the tasks in the fact-checking process of Emergent. In future work we will develop methods for the other tasks involved, such as classifying the stance of a whole article towards a claim and truth assessment.

Acknowledgments

Many thanks to Craig Silverman and the Tow Center for Digital Journalism at Columbia University for allowing us to use the data from the Emergent Project. The research reported in this paper was conducted while the first author was at University College London.

Abstract

Word clusters are useful for many NLP tasks including training neural network language models, but current increases in datasets are outpacing the ability of word clusterers to handle them. Little attention has been paid thus far on inducing high-quality word clusters at a large scale. The predictive exchange algorithm is quite scalable, but sometimes does not provide as good perplexity as other slower clustering algorithms.

We introduce the bidirectional, interpolated, refining, and alternating (BIRA) predictive exchange algorithm. It improves upon the predictive exchange algorithm's perplexity by up to 18%, giving it perplexities comparable to the slower two-sided exchange algorithm, and better perplexities than the slower Brown clustering algorithm. Our BIRA implementation is fast, clustering a 2.5 billion token English News Crawl corpus in 3 hours. It also reduces machine translation training time while preserving translation quality. Our implementation is portable and freely available.

1 Introduction

Words can be grouped together into equivalence classes to help reduce data sparsity and better generalize data. Word clusters are useful in many NLP applications. Within machine translation word classes are used in word alignment (Brown et al., 1993; Och and Ney, 2000), translation models (Koehn and Hoang, 2007; Wuebker et al., 2013), reordering (Cherry, 2013), preordering (Stymne, 2012), target-side inflection (Chahuneau et al., 2013), SAMT (Zollmann and Vogel, 2011), and OSM (Durrani et al., 2014), among many others.

Word clusterings have also found utility in parsing (Koo et al., 2008; Candito and Seddah, 2010; Kong et al., 2014), chunking (Turian et al., 2010), NER (Miller et al., 2004; Liang, 2005; Ratinov and Roth, 2009; Ritter et al., 2011), structure transfer (Täckström et al., 2012), and discourse relation discovery (Rutherford and Xue, 2014).

Word clusters also speed up normalization in training neural network and MaxEnt language models, via class-based decomposition (Goodman, 2001a). This reduces the normalization time from $\mathcal{O}(|V|)$ (the vocabulary size) to $\approx \mathcal{O}(\sqrt{|V|})$. More improvements to $\mathcal{O}(\log(|V|))$ are found using hierarchical softmax (Morin and Bengio, 2005; Mnih and Hinton, 2009) .

2 Word Clustering

Word clustering partitions a vocabulary V, grouping together words that function similarly. This helps generalize language and alleviate data sparsity. We discuss flat clustering in this paper. Flat, or strict partitioning clustering surjectively maps word types onto a smaller set of clusters.

The **exchange algorithm** (Kneser and Ney, 1993) is an efficient technique that exhibits a general time complexity of $\mathcal{O}(|V| \times |C| \times I)$, where $|V|$ is the number of word types, $|C|$ is the number of classes, and I is the number of training iterations, typically < 20 . This omits the specific method of exchanging words, which adds further complexity. Words are exchanged from one class to another until convergence or I .

Proceedings of NAACL-HLT 2016, pages 1169–1174,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

One of the oldest and still most popular exchange algorithm implementations is `mkcls` (Och, 1995)[1], which adds various metaheuristics to escape local optima. Botros et al. (2015) introduce their implementation of three exchange-based algorithms. Martin et al. (1998) and Müller and Schütze (2015)[2] use trigrams within the exchange algorithm. Clark (2003) adds an orthotactic bias.[3]

The previous algorithms use an unlexicalized (two-sided) language model: $P(w_i|w_{i-1}) = P(w_i|c_i)\,P(c_i|c_{i-1})$, where the class c_i of the predicted word w_i is conditioned on the class c_{i-1} of the previous word w_{i-1}. Goodman (2001b) altered this model so that c_i is conditioned directly upon w_{i-1}, hence: $P(w_i|w_{i-1}) = P(w_i|c_i)\,P(c_i|w_{i-1})$. This new model fractionates the history more, but it allows for a large speedup in hypothesizing an exchange since the history doesn't change. The resulting partially lexicalized (one-sided) class model gives the accompanying **predictive exchange algorithm** (Goodman, 2001b; Uszkoreit and Brants, 2008) a time complexity of $\mathcal{O}((B+|V|)\times|C|\times I)$ where B is the number of unique bigrams in the training set.[4] We introduce a set of improvements to this algorithm to enable high-quality large-scale word clusters.

3 BIRA Predictive Exchange

We developed a *bidirectional, interpolated, refining, and alternating* (BIRA) predictive exchange algorithm. The goal of BIRA is to produce better clusters by using multiple, changing models to escape local optima. This uses both forward and reversed bigram class models to improve cluster quality by evaluating log-likelihood on two different models. Unlike using trigrams, bidirectional bigram models only linearly increase time and memory requirements, and in fact some data structures can be shared. The two directions are interpolated to allow softer integration of these two models:

$$\begin{aligned} P(w_i|w_{i-1},w_{i+1}) \triangleq\ & P(w_i|c_i) \\ & \cdot(\lambda P(c_i|w_{i-1}) \\ & \quad + (1-\lambda)P(c_i|w_{i+1})) \end{aligned} \tag{1}$$

The interpolation weight λ for the forward direction alternates to $1-\lambda$ every a iterations (i):

$$\lambda_i := \begin{cases} 1-\lambda_0 & \text{if } \ i \bmod a = 0 \\ \lambda_0 & \text{otherwise} \end{cases} \tag{2}$$

Figure 1 illustrates the benefit of this λ-inversion to help escape local minima, with lower training set perplexity by inverting λ every four iterations:

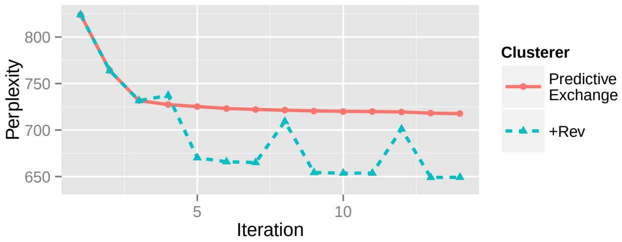

Figure 1: Training set perplexity using lambda inversion (`+Rev`), using 100M tokens of the Russian News Crawl (cf. §4.1). Here $a=4$, $\lambda_0=1$, and $|C|=800$.

The time complexity is $\mathcal{O}(2\times(B+|V|)\times|C|\times I)$. The original predictive exchange algorithm can be obtained by setting $\lambda=1$ and $a=0$.[5]

Another innovation, both in terms of cluster quality *and* speed, is *cluster refinement*. The vocabulary is initially clustered into $|G|$ sets, where $|G| \ll |C|$, typically 2–10. After a few iterations (i) of this, the full partitioning C_f is explored. Clustering G converges very quickly, typically requiring no more than 3 iterations.[6]

$$|C|_i := \begin{cases} |G| & \text{if } \ i \le 3 \\ |C|_f & \text{otherwise} \end{cases} \tag{3}$$

The intuition behind this is to group words first into broad classes, like nouns, verbs, adjectives, etc. In contrast to divisive hierarchical clustering and coarse-to-fine methods (Petrov, 2009), after the initial iterations, the algorithm is still able to exchange

[3] `http://bit.ly/1VJwZ7n`

[4] Green et al. (2014) provide a Free implementation of the original predictive exchange algorithm within the Phrasal MT system, at `http://nlp.stanford.edu/phrasal`. Another implementation is in the Cicada semiring MT system.

[5] The time complexity is $\mathcal{O}((B+|V|)\times|C|\times I)$ if $\lambda=1$.

[6] The piecewise definition could alternatively be conditioned upon a percentage threshold of moved words.

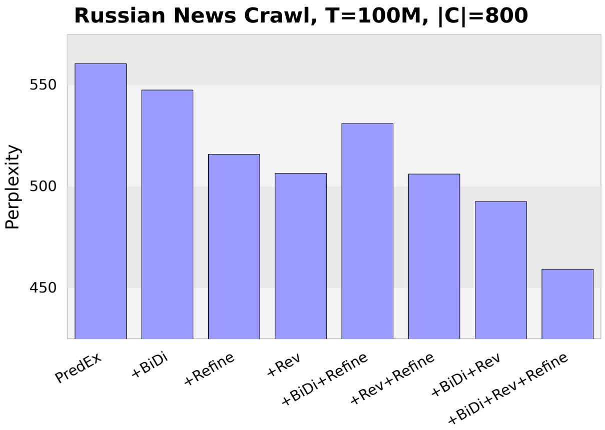

Figure 2: Development set PP of combinations of improvements to predictive exchange (cf. §3), using 100M tokens of the Russian News Crawl, with 800 word classes.

any word to any cluster—there is no hard constraint that the more refined partitions be subsets of the initial coarser partitions. This gives more flexibility in optimizing on log-likelihood, especially given the noise that naturally arises from coarser clusterings. We explored cluster refinement over more stages than just two, successively increasing the number of clusters. We observed no improvement over the two-stage method described above.

Each BIRA component can be applied to any exchange-based clusterer. The contributions of each of these are shown in Figure 2, which reports the development set perplexities (PP) of all combinations of BIRA components over the original predictive exchange algorithm. The data and configurations are discussed in more detail in Section 4. The greatest PP reduction is due to using lambda inversion (`+Rev`), followed by cluster refinement (`+Refine`), then interpolating the bidirectional models (`+BiDi`), with robust improvements by using all three of these—an 18% reduction in perplexity over the predictive exchange algorithm. We have found that both lambda inversion and cluster refinement prevent early convergence at local optima, while bidirectional models give immediate and consistent training set PP improvements, but this is attenuated in a unidirectional evaluation.

We observed that most of the computation for the predictive exchange algorithm is spent on the logarithm function, calculating $\delta \leftarrow \delta - N(w,c) \cdot \log N(w,c)$.[7] Since the codomain of $N(w,c)$ is $\mathbb{N}_0$, and due to the power law distribution of the algorithm's access to these entropy terms, we can precompute $N \cdot \log N$ up to, say 10e+7, with minimal memory requirements.[8] This results in a considerable speedup of around 40%.

4 Experiments

Our experiments consist of both intrinsic and extrinsic evaluations. The intrinsic evaluation measures the perplexity (PP) of two-sided class-based models for English and Russian, and the extrinsic evaluation measures BLEU scores of phrase-based MT of Russian↔English and Japanese↔English texts.

4.1 Class-based Language Model Evaluation

In this task we used 400, 800, and 1200 classes for English, and 800 classes for Russian. The data comes from the 2011–2013 News Crawl monolingual data of the WMT task.[9] For these experiments the data was deduplicated, shuffled, tokenized, digit-conflated, and lowercased. In order to have a large test set, one line per 100 of the resulting (shuffled) corpus was separated into the test set.[10] The minimum count threshold was set to 3 occurrences in the training set. Table 1 shows information on the resulting corpus.

Corpus	Tokens	Types	Lines
English Train	1B	2M	42M
English Test	12M	197K	489K
Russian Train	550M	2.7M	31M
Russian Test	6M	284K	313K

Table 1: Monolingual training & test set sizes.

The clusterings are evaluated on the PP of an external 5-gram *unidirectional two-sided* class-based language model (LM). The *n*-gram-order interpolation weights are tuned using a distinct development set of comparable size and quality as the test set.

Table 2 and Figure 3 show perplexity results using a varying number of classes. Two-sided exchange gives the lowest perplexity across the board, although this is within a two-sided LM evaluation.

[7] δ is the change in log-likelihood, and $N(w,c)$ is the count of a given word followed by a given class.

[8] This was independently discovered in Botros et al. (2015).

[9] http://www.statmt.org/wmt15/translation-task.html

[10] The data setup script is at http://www.dfki.de/~jode03/naacl2016.sh.

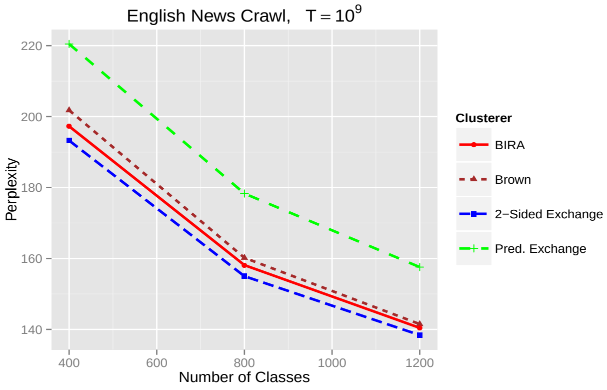

Figure 3: 5-gram two-sided class-based LM perplexities for various clusterers on English News Crawl varying the number of classes.

We also evaluated clusters derived from word2vec (Mikolov et al., 2013) using various configurations[11], and all gave poor perplexities. BIRA gives better perplexities than both the original predictive exchange algorithm and Brown clusters.[12] The Russian experiments yielded higher perplexities for all clusterings, but otherwise the same comparative results.

Training Set	2-Side Ex.	BIRA	Brown	Pred. Ex.
EN, $\lvert C\rvert = 400$	193.3	197.3	201.8	220.5
EN, $\lvert C\rvert = 800$	155.0	158.1	160.2	178.3
EN, $\lvert C\rvert = 1200$	138.4	140.4	141.5	157.6
RU, $\lvert C\rvert = 800$	322.4	340.7	350.4	389.3

Table 2: 5-gram two-sided class-based LM perplexities.

In general Brown clusters give slightly worse results relative to exchange-based clusters, since Brown clustering requires an early, permanent placement of frequent words, with further restrictions imposed on the $|C|$-most frequent words (Liang, 2005).[13] Liang-style Brown clustering is only efficient on a small number of clusters, since there is a $|C|^2$ term in its time complexity.

Training Set	mkcls	BIRA	Brown	Phrasal
EN, $\lvert C\rvert = 400$	39.0	1.0	2.3	3.1
EN, $\lvert C\rvert = 800$	48.8	1.4	12.5	5.1
EN, $\lvert C\rvert = 1200$	68.8	1.7	25.5	6.2
RU, $\lvert C\rvert = 800$	75.0	1.5	14.6	5.5

Table 3: Clustering times (hours) of full training sets. Mkcls implements two-sided exchange, and Phrasal implements one-sided predictive exchange.

The original predictive exchange algorithm has a more fractionated history than the two-sided exchange algorithm. Interestingly, increasing the number of clusters causes a convergence in the word clusterings themselves, while also causing a divergence in the time complexities of these two varieties of the exchange algorithm. The metaheuristic techniques employed by the two-sided clusterer `mkcls` can be applied to other exchange-based clusterers—including ours—for further improvements.

Table 3 presents wall clock times using the full training set, varying the number of word classes $|C|$ (for English).[14] The predictive exchange-based clusterers (BIRA and Phrasal) exhibit slow increases in time as the number of classes increases, while the others (Brown and `mkcls`) are much more sensitive to $|C|$. Our BIRA-based clusterer is three times faster than Phrasal for all these sets.

We performed an additional experiment, adding more English News Crawl training data.[15] *Our implementation took 3.0 hours to cluster 2.5 billion training tokens*, with $|C| = 800$ using modest hardware.[14]

4.2 Machine Translation Evaluation

We also evaluated the BIRA predictive exchange algorithm extrinsically in machine translation. As discussed in Section 1, word clusters are employed in a variety of ways within machine translation systems, the most common of which is in word alignment where `mkcls` is widely used. As training sets get larger every year, `mkcls` struggles to keep pace, and

[11] Negative sampling & hierarchical softmax; CBOW & skip-gram; various window sizes; various dimensionalities.

[12] For the two-sided exchange we used `mkcls`; for the original pred. exchange we used Phrasal's clusterer; for Brown clustering we used Percy Liang's brown-cluster (329dc). All had min-count=3, and all but `mkcls` (which is not multithreaded) had threads=12, iterations=15.

[13] Recent work by Derczynski and Chester (2016) loosens some restrictions on Brown clustering.

[14] All time experiments used a 2.4 GHz Opteron 8378 featuring 16 threads.

[15] Adding years 2008–2010 and 2014 to the existing training data. This training set was too large for the external class-based LM to fit into memory, so no perplexity evaluation of this clustering was possible.

is a substantial time bottleneck in MT pipelines with large datasets.

We used data from the Workshop on Machine Translation 2015 (WMT15) Russian↔English dataset and the Workshop on Asian Translation 2014 (WAT14) Japanese↔English dataset (Nakazawa et al., 2014). Both pairs used standard configurations, like truecasing, MeCab segmentation for Japanese, MGIZA alignment, grow-diag-final-and phrase extraction, phrase-based Moses, quantized KenLM 5-gram modified Kneser-Ney LMs, and MERT tuning.

$\lvert C \rvert$	**EN-RU**	**RU-EN**	**EN-JA**	**JA-EN**
10	20.8→20.9*	26.2→26.0	23.5→23.4	16.9→16.8
50	21.0→21.2*	25.9→25.7	24.0→23.7*	16.9→16.9
100	20.4→21.1	25.9→25.8	23.8→23.5	16.9→17.0
200	21.0→20.8	25.8→25.9	23.8→23.4	17.0→16.8
500	20.9→20.9	25.8→25.9*	24.0→23.8	16.8→17.1*
1000	20.9→21.1	25.9→26.0**	23.6→23.5	16.9→17.1

Table 4: BLEU scores (mkcls→BIRA) and significance across cluster sizes ($\lvert C \rvert$).

The BLEU score differences between using mkcls and our BIRA implementation are small but there are a few statistically significant changes, using bootstrap resampling (Koehn, 2004). Table 4 presents the BLEU score changes across varying cluster sizes (*: p-value < 0.05, **: p-value < 0.01). MERT tuning is quite erratic, and some of the BLEU differences could be affected by noise in the tuning process in obtaining quality weight values. Using our BIRA implementation reduces the translation model training time with 500 clusters from 20 hours using mkcls (of which 60% of the time is spent on clustering) to just 8 hours (of which 5% is spent on clustering).

5 Conclusion

We have presented improvements to the predictive exchange algorithm that address longstanding drawbacks of the original algorithm compared to other clustering algorithms, enabling new directions in using large scale, high cluster-size word classes in NLP.

Botros et al. (2015) found that the one-sided model of the predictive exchange algorithm produces better results for training LSTM-based language models compared to two-sided models, while two-sided models generally give better perplexity in class-based LM experiments. Our paper shows that BIRA-based predictive exchange clusters are competitive with two-sided clusters even in a two-sided evaluation. They also give better perplexity than the original predictive exchange algorithm and Brown clustering.

Abstract

When translating into a morphologically complex language, segmenting the target language can reduce data sparsity, while introducing the complication of desegmenting the system output. We present a method for decoder-integrated desegmentation, allowing features that consider the desegmented target, such as a word-level language model, to be considered throughout the entire search space. Our results on a large-scale, English to Arabic translation task show significant improvement over the 1-best desegmentation baseline.

1 Introduction

State-of-the-art systems for translating into morphologically complex languages, such as Arabic, employ morphological segmentation of the target language in order to reduce data sparsity and improve translation quality. For example, the Arabic word لدولتهم *ldwlthm* "for their country" is segmented into the prefix +ل *l+* "for", the stem دولة *dwlp* "country" and the suffix هم+ *+hm* "their." The segmentation sometimes involves performing orthographic normalizations, such as transforming the stem-final *t* to *p*. The result is not only a reduction in the number of word types, but also better token-to-token correspondence with the source language.

Morphological segmentation is typically performed as a pre-processing step before the training phase, which results in a model that translates the source language into segmented target language. *Desegmentation* is the process of transforming the segmented output into a readable word sequence, which can be performed using a table lookup combined with a small set of rules. Desegmentation is usually applied to the 1-best output of the decoder. However, this pipeline suffers from error propagation: errors made during decoding cannot be corrected, even when desegmentation results in an illegal or extremely unlikely word. Two principal types of solutions have been proposed for this problem: *rescoring* and *phrase-table desegmentation*.

The rescoring approach desegments either an n-best list (Oflazer and Durgar El-Kahlout, 2007) or lattice (Salameh et al., 2014), and then re-ranks with features that consider the desegmented word sequence of each hypothesis. Rescoring features include the score from an unsegmented target language model and contiguity indicators that flag target words that were translated from contiguous source tokens. Rescoring widens the desegmentation pipeline, allowing desegmentation features to reduce the number of translation errors. However, these features are calculated for only a subset of the search space, and the extra rescoring step complicates the training and translation processes.

Phrase-table desegmentation (Luong et al., 2010) also translates into a segmented target language, but alters training to perform word-boundary-aware phrase extraction. The extracted phrases are constrained to contain only complete target words, without any *dangling affixes*. With this restriction in place, the phrase table can be desegmented before decoding begins, allowing the decoder to track features over both the segmented and desegmented target. This ensures that desegmentation features are integrated into the complete search space, and

Proceedings of NAACL-HLT 2016, pages 1175–1180,
San Diego, California, June 12-17, 2016.

side-steps the complications of rescoring. However, Salameh et al. (2015) show experimentally that these benefits are not worth giving up phrase-pairs with dangling affixes, which are eliminated by word-boundary-aware phrase extraction.

We present a method for decoder-integrated desegmentation that combines the strengths of these two approaches. Like a rescoring approach, it places no restrictions on what morpheme sequences can appear in the target side of a phrase pair. Like phrase-table desegmentation, its desegmentation features are integrated directly into decoding and considered throughout the entire search space. We achieve this by augmenting the decoder to desegment hypotheses on the fly, allowing the inclusion of an unsegmented language model and other features. Our results on a large-scale, NIST-data English to Arabic translation task show significant improvements over the 1-best desegmentation baseline, and match the performance of the state-of-the-art lattice desegmentation approach of Salameh et al. (2014), while eliminating the complication and cost of its rescoring step. Our approach is implemented as a single stateful feature function in Moses (Koehn et al., 2007), which we will submit back to the community.

2 Method

Our approach extends the multi-stack phrase-based decoding paradigm to enable the extraction of word-level features inside morpheme-segmented models.[1] We assume that the target side of the parallel corpus has been segmented into morphemes with prefixes and suffixes marked.[2] This allows us to define a *complete word* as a maximal morpheme sequence consisting of 0 or more prefixes, followed by at most one stem, and then 0 or more suffixes.

We also assume access to a desegmentation function that takes as input a morpheme sequence matching the above definition, and returns the corresponding word as output. Depending on the complexity of the segmentation, desegmentation can be achieved through simple concatenation, a small set of rules, a statistical table (Badr et al., 2008), or a statistical transducer (Salameh et al., 2013). El Kholy and Habash (2012) provide an extensive study on the influence of segmentation and desegmentation on English-to-Arabic SMT. In this work, we adopt the Table+Rules technique of El Kholy and Habash (2012) for English-Arabic SMT. The technique relies on a look-up table that stores mappings of segmented-unsegmented forms, and falls back on manually crafted rules for segmented sequences not found in the table. When a segmented form has multiple desegmentation options available in the table, we select the most frequent option.

The output of a phrase-based decoder is built from left to right, and at each step, a hypothesis is expanded with a phrasal translation of a previously uncovered source segment. We augment this process with *in-decoder desegmentation*, which monitors the target sequence of each translation hypothesis as it grows, detecting morpheme sequences that correspond to complete words and desegmenting them on the fly to generate new features. This is described in detail in Section 2.1.

The task of determining whether a word is complete is non-trivial. We are never sure if we will see another suffix as we expand the hypothesis, so we can only recognize a complete word as we begin the next word. For example, take hyp1 in Figure 1. This hypothesis ends with a stem *nšr*, which may end a complete word, as is the case when we expand to hyp2, or may represent a word that is still in progress, which occurs as we extend to hyp3. This means that the word-based scoring of the morpheme sequence *l+ nšr* must be delayed or approximated until we know what follows. A related challenge involves scoring phrase-pairs out of context, as is required for future-cost estimates. Take, for example, the target phrase *+h AfkAr* added by hyp3 in Figure 1. Without the context, we have insufficient information at the left boundary to score *+h* with word-based models, while *AfkAr* at the right boundary may or may not form a complete word. Here, there is no choice but to approximate. The quality of these approximations and the length of our delays will determine how effective our new features will be when incorporated into beam search.

[1] The ideas presented here could also be applied to hierarchical decoding, which would require generalizing them to account for right context as well as left.

[2] Throughout this paper, we use a token-final "+" to denote a prefix, and a token-initial "+" for a suffix.

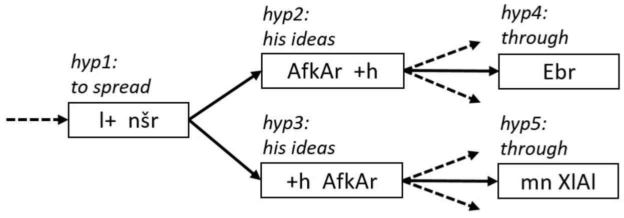

Figure 1: Decoding the Arabic translation of the phrase *"to spread his ideas through"*.

2.1 Decoder Integration

A typical phrase-based decoder represents a hypothesis with a state that contains the information to guide search and calculate features, such as the source coverage vector and the target context for the language model. Hypotheses with identical states can be recombined to improve search efficiency. We augment the state with two structures: (1) a buffer Q containing all of the morphemes that contribute to the current word in progress, represented as a queue of tokens; and (2) n-gram context C for the word-level target language model. The search's initial state begins with an empty Q and with *n-1* beginning-of-sentence tokens in *C*.

When a state is extended with a target phrase *P*, we update the in-decoder desegmentation structures Q and *C* with Algorithm 1. Tokens are appended to Q until a token t would begin a new word, at which point the tokens from Q are desegmented and the resulting word is used to calculate features and update the target context. Following the lower decoding path in Figure 1, Q would be emptied and desegmented first during hyp3 when $t =$ *AfkAr*, calculating features for $W =$ *lnšrh*.

The main cost of in-decoder desegmentation comes from maintaining the context necessary to evaluate the n-gram, word-level language model. As each desegmented word in C will correspond to at least one segmented token, the system's effective language-model order in terms of segmented tokens will frequently be much larger than n. Storing larger language-model contexts make it less likely that states will be equal to one another, which reduces the amount of recombination the system can do, and increases the number of states that must be expanded during search.

Algorithm 1 Desegmentation State Update

```
Input: State variables $Q$, $C$
Input: Extending phrase $P$
for each token $t$ in $P$ do
    if $t$ cannot continue the word in Q then
        $W$ = Desegmentation of tokens in $Q$
        Extract word-level features for $W$
         (Word-level LM score is $p(W|C)$)
        Update current feature vector
        Update $C$ with $W$
        Empty $Q$
    Append token $t$ to $Q$
```

2.2 Delayed and Optimistic Scoring

In the above approach, desegmentation and feature scoring are applied only when a complete word is formed. We refer to this as **delayed scoring** because the features for a token are not applied until other tokens have been added to the hypothesis. For example, in Figure 1, the tokens *l+ nšr* added in hyp1 are not evaluated with word-level features until hyp2 or hyp3 completes the word. This delay results in inaccurate scoring of hypotheses, as the cost from these tokens is hidden until Q is emptied. These inaccuracies can lead to poor pruning choices and search errors during beam search.

Alternatively, we can perform **optimistic scoring**, which tries to score the contents of Q as early as possible. In this case, we assume that the contents of Q form a complete word, without waiting for the next token to confirm it. With each hypothesis extension, when the last token in P is processed and added to the queue, we desegment the contents of Q and extract features, but without emptying Q. The scores of these features are cached in a variable S that does not affect recombination, as the scores are deterministic given Q, C and the model. When a later token confirms the end of the word, we subtract S from the scores derived from the actual desegmented word, to account for our earlier approximation. Note that for a Q containing only a prefix, we must still delay scoring.

2.3 Features

Three features are extracted from each desegmented form: an unsegmented language model, contiguity indicators, and a desegmented word penalty.

The unsegmented n-gram language model scores W in the context of C, as shown in Algorithm 1. This language model will heavily penalize malformed Arabic words, as they will appear as out-of-vocabulary items. Furthermore, it will evaluate well-formed Arabic words in a larger, word-level context, complementing the morpheme-level n-gram language model that is naturally included in SMT systems built over a segmented target.

We also implement the contiguity features proposed by Salameh et al. (2014). These indicators check if the desegmented form is generated from a contiguous block of source tokens, a block with 1 discontiguity, or a block with multiple discontiguities. These features enable the decoder to prefer desegmented words whose component segments were translated from contiguous or nearly contiguous source sequences. This encourages the system to select a more local, and hopefully safer, translation path when possible.

Finally, most phrase-based decoders incorporate a "word penalty" feature that counts the number of target tokens in a hypothesis. When the target language has been segmented into morphemes, this actually corresponds to a morpheme penalty. However, with in-decoder desegmentation, we now have the option to count either words or morphemes. There is reason to believe that by counting words, instead of morphemes, we will give the system greater control over the length of its output word sequence, which is particularly relevant because of BLEU's brevity penalty. We try both options in our experiments. Unfortunately, the obvious solution of including two features, a word count and a morpheme count, did not perform well during development.

2.4 Future costs

For future cost estimates, we must also provide out-of-context feature scores for each phrase-pair in our system. To do so, we ignore suffixes appearing at the beginning of a target phrase and prefixes appearing at the end. We assume that the remaining tokens form complete words, and desegment and score them to provide out-of-context scores. We also consider dangling affixes as half words, with a count of 0.5, for out-of-context scoring of the word penalty feature.

3 Experiments

We use the NIST 2012 dataset (1.49 million sentence pairs excluding UN pairs) to train an English-to-Arabic system. The system is tuned with the NIST 2004 (1353 pairs) evaluation set and tested using NIST 2005 (1056 sentences) and the newswire portion of NIST 2008 (813 pairs) and NIST 2009 (586 pairs). As there are multiple English reference translations provided for these evaluation sets, we use the first reference as our source text.

The Arabic part of the training set is morphologically segmented and tokenized by MADA 3.2 (Habash et al., 2009) using the Penn Arabic Treebank (PATB) segmentation scheme. Variants of Alif and Ya characters are uniformly normalized. We generate a desegmentation table from the Arabic side of the training data by collecting mappings of segmented forms to surface forms.

We align the parallel data with GIZA++ (Och et al., 2003), and decode with Moses (Koehn et al., 2007). The decoder's log-linear model uses a standard feature set, including four phrase table scores, six features from a lexicalized distortion model, along with a phrase penalty and a distance-based distortion penalty. KN-smoothed 5-gram language models are trained on both the segmented and unsegmented views of the target side of the parallel data. We experiment with word penalties based on either morphemes or desegmented words. The decoder uses Moses' default search parameters, except for the maximum phrase length, which is set to 8, and the translation table limit, which is set to 40. The decoder's log-linear model is tuned with MERT (Och, 2003) using unsegmented Arabic reference translations. When necessary, we desegment our 100-best-lists before MERT evaluates each hypothesis. We evaluate with BLEU (Papineni et al., 2002) measured on unsegmented Arabic, and test statistical significance with multeval (Clark et al., 2011) over 3 tuning replications.

We test four systems that differ in their desegmentation approach. The **NoSegm.** baseline involves no segmentation. The **One-best** baseline translates into segmented Arabic and desegments the decoder's 1-best output. The **Lattice** system is the lattice-desegmentation approach of Salameh et al. (2014). We implement our **in-Decoder** desegmenta-

System	WP	mt05	mt08	mt09
NoSegm.	word	33.2	18.6	25.6
One-best	morph.	33.8	19.1	26.8
Lattice	morph.	34.4	**19.7**	**27.4**
Delayed	morph.	34.1	19.4	27.0
	word	34.1	19.5	26.8
Optimistic	morph.	34.2	19.6	27.2
	word	**34.5**	**19.7**	27.2

Table 1: Evaluation of the desegmentation methods using BLEU score. Both Delayed and Optimistic refer to in-Decoder Desegmentation method used. WP shows whether Word Penalty feature is based on a complete desegmented word or a morpheme.

tion approach as a feature functions in Moses, testing scoring variants (delayed vs. optimistic), and word penalty variants (morpheme vs. word).

Table 1 shows the results on three NIST test sets, each averaged over 3 tuning replications. The lattice approach is significantly better than the 1-best system, which in turn is significantly better than the unsegmented baseline. Our **Optimistic** in-decoder approach with word penalty calculated on word tokens is significantly ($p < 0.05$) better than the 1-best approach, and effectively matches the quality of the more complex lattice approach.

All of the systems with word-level features improve over 1-best desegmentation, as their features penalize desegmentations resulting in illegal words or unlikely word sequences. We see a small, consistent benefit from optimistic scoring. Error analysis reveals that translations with many consecutive stems benefit the most from this variant, which makes sense, as our approximations would be exact in these cases. Using a word penalty calculated on word tokens appears to work slightly better on average than one calculated on morphemes.

Typically, one would hope to surpass a rescoring approach with decoder integration; however, our lattice implementation fully searches its lattice, even if composition with the word-level language model would cause the lattice to explode in size. That is, lattice desegmentation has an advantage, as it trades time-efficiency for a perfect search that ignores the complexity introduced by expanded n-gram context. A lattice beam search that dynamically calculates word-level language model scores while pruning away unlikely paths would provide a more fair, and more efficient, comparison point.

Lattice rescoring also involves many steps, requiring one to train and tune a complete segmented system with segmented references, then desegment lattices and compose them with a word LM, and then tune a lattice rescorer on unsegmented references. In contrast, our system is implemented as a single decoder feature function in Moses.[3] This one function replaces the lattice desegmentation, LM composition, and lattice rescoring steps, greatly simplifying the translation pipeline.

4 Conclusions and Future Work

We have presented a method for in-decoder desegmentation, which allows a phrase-based decoder to simultaneously consider both segmented and desegmented views of the target language. We have shown that this approach outperforms 1-best desegmentation, and matches the performance of lattice desegmentation, while eliminating the complication of its lattice transformation and rescoring steps.

We are interested in building an unsegmented, word-level language model that can provide meaningful estimates for morphological segments, which would improve scoring for out-of-context phrases and incomplete words. Also, our system currently considers only the most likely desegmentation of each segmented word. Inspired by the disambiguating desegmentation system of El Kholy and Habash (2012), we would like to extend our system to propose multiple desegmentation candidates for each word, and allow the decoder to select the correct form using its other features.

Acknowledgments

This research was supported by the Natural Sciences and Engineering Research Council of Canada (NSERC).

[3] This function references a desegmentation table and an unsegmented language model, which are needed to carry out Algorithm 1. Even though it is conceptually one function, it produces a vector of feature scores, producing the various features described in Section 2.3.

The Instantiation Discourse Relation: A Corpus Analysis of Its Properties and Improved Detection

Junyi Jessy Li and **Ani Nenkova**
University of Pennsylvania
{ljunyi,nenkova}@seas.upenn.edu

Abstract

INSTANTIATION is a fairly common discourse relation and past work has suggested that it plays special roles in local coherence, in sentiment expression and in content selection in summarization. In this paper we provide the first systematic corpus analysis of the relation and show that relation-specific features can improve considerably the detection of the relation. We show that sentences involved in INSTANTIATION are set apart from other sentences by the use of gradable (subjective) adjectives, the occurrence of rare words and by different patterns in part-of-speech usage. Words across arguments of INSTANTIATION are connected through hypernym and meronym relations significantly more often than in other sentences and that they stand out in context by being significantly less similar to each other than other adjacent sentence pairs. These factors provide substantial predictive power that improves the identification of implicit INSTANTIATION relation by more than 5% F-measure.

1 Introduction

In an INSTANTIATION relation, one text span explains in further detail the events, reasons, behaviors and attitudes mentioned in the other (Miltsakaki et al., 2008), as illustrated by the segments below:

[a] Other fundamental "reforms" of the 1986 act have been threatened as well.

[b] The House seriously considered raising the top tax rate paid by individuals with the highest incomes.

Sentence **[a]** mentions "other reforms" and a threat to them, but leaves unspecified what are the reforms or how they are threatened. Sentence **[b]** provides sufficient detail for the reader to infer more concretely what has happened.

The INSTANTIATION relation has some special properties. A study of discourse relations as indicators for content selection in single document summarization revealed that the first sentences from INSTANTIATION pairs are included in human summaries significantly more often than other sentences (Louis et al., 2010) and that being a first sentence in an INSTANTIATION relation is *the* most powerful indicator for content selection related to discourse relation sense. The sentences between which the relation holds also contain more sentiment expressions than other sentences (Trnavac and Taboada, 2013), making it a special target for sentiment analysis applications. Moreover, INSTANTIATION relations appear to play a special role in local coherence (Louis and Nenkova, 2010), as the flow between INSTANTIATION sentences is not explained by the major coherence theories (Kehler, 2004; Grosz et al., 1995). Many of the sentences in INSTANTIATION relation contain entity instantiations (complex examples of set-instance anaphora), such as "several EU countries"—"the UK", "footballers"—"Wayne Rooney" and "most cosmetic purchase"—"lipstick" (McKinlay and Markert, 2011), raising further questions about the relationship between INSTANTIATIONS and key discourse phenomena.

Detecting an INSTANTIATION, however, is hard. In the Penn Discourse Treebank (PDTB) (Prasad et al., 2008), INSTANTIATION is one of the few relations that are more often *implicit*, i.e., expressed without a discourse marker such as "for exam-

Proceedings of NAACL-HLT 2016, pages 1181–1186,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

ple". Identifying implicit discourse relation is an acknowledged difficult task (Braud and Denis, 2015; Ji and Eisenstein, 2015; Rutherford and Xue, 2014; Biran and McKeown, 2013; Park and Cardie, 2012; Lin et al., 2009; Pitler et al., 2009), but the challenge is exacerbated due to the lack of *explicit* INSTANTIATIONs: explicit relations are shown to improve their implicit counterparts using data source expansion (Rutherford and Xue, 2015). Moreover, detecting INSTANTIATION also involves the skewed class distribution problem (Li and Nenkova, 2014a) because although it is one of the largest class of implicit relations, it constitutes less than 10% of all the implicit relations annotated in the PDTB.

In this work, we identify a rich set of factors that sets apart each sentence in an implicit INSTANTIATION and the pair as a whole. We show that these factors improve the identification of implicit INSTANTIATION by at least 5% in F-measure and 8% in balanced accuracy compared to prior systems.

2 Presence of INSTANTIATION

We use the Penn Discourse Tree Bank (PDTB) (Prasad et al., 2008) for the analysis and experiments presented in this paper. There are a total of 1,747 INSTANTIATION relations in the PDTB, of which 83% are implicit. INSTANTIATIONs make up 8.7% of all implicit relations and is the 5th largest among the 16 second-level relations in the PDTB.

3 Characteristics of INSTANTIATION

We identify significant factors[1] that characterize: *(i)* s_1 and s_2: the first and second sentence in an INSTANTIATION pair vs. all other sentences; *(ii)* s_1 vs. s_2: adjacent sentence pairs in INSTANTIATION relation vs. all other adjacent sentence pairs.

Our analysis is conducted on the PDTB except section 23, which is reserved for testing as in prior work (Lin et al., 2014; Biran and McKeown, 2015). In total, there are 1,337 INSTANTIATION sentence pairs and 43,934 non-INSTANTIATION sentences for the corpus analysis.

	s_1	s_2	$\neg$ Inst.
#words/sent	18.4*	26.8*	23.9

Table 1: Average # words. [$*$]: significant ($p < 0.05$) compared to non-instantiation sentences.

	s_1	s_2	$\neg$ Inst.
%oov/sent	0.68*	1.54	1.46

Table 2: Average % of rare words per sentence. [$*$]: significant ($p < 0.05$) compared to non-instantiation sentences.

Sentence length. Intuitively, longer sentences are more likely to involve details. Table 1 demonstrates that there is an average of 8.4-word difference in length between the two sentences in an INSTANTIATION relation; moreover, s_1s are significantly shorter (more than 5 words on average) than other sentences, and s_2s are significantly longer.

Rare words. For each sentence, we compute the percentage of words that are not present in the 400K vocabulary of the Glove vector representations (Pennington et al., 2014). Table 2 shows that s_1 of INSTANTIATIONs contain significantly *fewer* out-of-vocabulary words compared to either s_2 and non-INSTANTIATIONs. We also compare the difference in unigram probability[2] of content word pairs across sentence pairs, i.e., $(w_i, w_j), w_i \in s_1, w_j \in s_2$. Compared to non-INSTANTIATION, words across INSTANTIATION arguments show significantly larger average unigram log probability difference (1.24 vs. 1.22). These numbers show that the first sentences of INSTANTIATION do not involve many unfamiliar words — an indication of higher readability (Pitler and Nenkova, 2008).

Gradable adjectives. The use of gradable adjectives (Frazier et al., 2008; de Marneffe et al., 2010)—*popular, high, likely*— may require further explanation to justify the appropriateness of their use. Here we compute the average percentage of gradable adjectives in a sentence. The list of adjectives is from Hatzivassiloglou and Wiebe (2000) and the respective percentages are shown in Table 3. Compared to other sentences, s_1 of INSTANTIATION involves significantly more gradable adjectives.

[1] $p < 0.05$ according to paired Wilcoxon signed rank test for real valued comparison between the two sentences in a relation, non-paired Wilcoxon rank sum for real valued factors in different types of sentences, and Kruskal-Wallis for binary valued features across different types of sentences.

[2] We use a unigram language model on year 2006 of the New York Times Annotated Corpus (Sandhaus, 2008).

	s_1	s_2	Δsim
Inst.	0.282*	0.275*	0.007
$\neg$ Inst.	0.390	0.358	0.042*

Table 6: Average Jaccard similarity of an adjacent sentence pair s_1, s_2 with immediate context. [$*$]: significant ($p < 0.05$) compared to non-instantiation sentence pairs.

Parts of speech. We study word categories that are heavily or rarely used with INSTANTIATION by inspecting the percentage of part-of-speech tags found in each sentence. In Table 4, we show POS tags whose presence is significantly different across arguments in INSTANTIATION but not so across non-INSTANTIATION, with significance in non-INSTANTIATION in the reverse direction denoted in †. Four cases of POS occurrences are inspected:

- more often in s_1 compared to s_2,
- more often in s_2 compared to s_1,
- more (+) or less (-) in s_1 compared to non-INSTANTIATION,
- more (+) or less (-) in s_2 compared to non-INSTANTIATION.

We see that s_1 of INSTANTIATION contains more characteristic POS usage than s_2. There are more comparative adjectives and adverbs as well as fewer nouns in s_1 compared to s_2 in INSTANTIATION pairs. The usage of verbs is also different between two arguments and s_1 contains more conjunctions and existential there. On the other hand, s_2 contains more nouns, numbers, determiners, personal pronouns and proper nouns, intuitively associated with the presence of detailed information.

Wordnet relations. Here we consider word-level relationships across arguments using Wordnet (Fellbaum, 1998). For each noun, verb, adjective and adverb content word pairs across arguments, we calculate the percentage of sentences with each type of Wordnet relation. Shown in Table 5, among INSTANTIATION sentence pairs there are significantly more noun-noun pairs with hypernym or meronym relationships and verbs with indirect hypernym relationship. We also observe significantly more semantically similar verbs (*group (v)*).

Lexical similarity. Finally, we inspect the similarity between sentences in each pair as well as between each sentence in a pair and their immediate prior context; specifically:

- Between s_1 and s_2;
- Between s_1 and C and between s_2 and C, where C denotes up to two sentences immediately before s_1.

We compute the Jaccard similarity between sentences using their nouns, verbs, adjectives and adverbs. INSTANTIATION arguments are significantly less similar than other adjacent sentence pairs (0.335 vs. 0.505), indicating higher difference in content.

System	P	R	F	BA
Inst. specific	0.3072	0.6986	**0.4268**	**0.7862**
Vote (L&N)	0.3052	0.6438	0.4141	0.7632
L&N	0.3028	0.4521	0.3626	0.6843
B&M	0.2542	0.2055	0.2273	0.5786
Lin et al.	0.5500	0.1507	0.2366	0.5704
Brown-concat	0.1333	0.3836	0.1979	0.5919

Table 7: Precision, recall, F-measure and balanced accuracy of identifying INSTANTIATION.

Shown in Table 6, both arguments of INSTANTIATION are less similar to the immediate context. While other sentence pairs follow the pattern that s_2 is much less similar to s_1's immediate context, this phenomenon is not significant for INSTANTIATION.

4 Experiments

In this section, we demonstrate the benefit of exploiting INSTANTIATION characteristics in the identification of the relation.

Settings. Following prior work that identifies the more detailed (second-level) relations in the PDTB (Biran and McKeown, 2015; Lin et al., 2014), we use sections 2-21 as training, section 23 as testing. The rest of the corpus is used for development. The task is to predict if an implicit INSTANTIATION relation holds between pairs of adjacent sentences in the same paragraph. Sentence pairs with INSTANTIATION relation constitute the positive class; all other non-explicit relations[3] constitute the negative class. We use Logistic Regression with class weights inversely proportional to the size of each class.

Features. The factors discussed in § 3 are adopted as the *only* features in the classifier. We use the average values of s_1 and s_2 and their difference for: the number of words, difference in number of words compared to the sentence before s_1, the percentage of OOVs, gradable adjectives, POS tags and Jaccard similarity to immediate context. We use the minimum, maximum and average differences in word-pair unigram log probability, and average Jaccard similarity across sentence pairs. For Wordnet relations, we use binary features indicating the presence of a relation.

Results. To compare with our INSTANTIATION-specific classifier (*Inst. specific*), we show results from two state-of-the-art PDTB discourse parsers that identify second-level relations: Biran and McKeown (2015) (*B&M*) and Lin et al. (2014). We also compare the results with the classifier from our prior work (Li and Nenkova, 2014b) (*L&N*). In that work we introduce syntactic production-stick features, which minimize the occurrence of zero values in instance representation. Furthermore, we reimplemented Brown-cluster features (concatenation of clusters in each sentence) that have been shown to perform well in identifying INSTANTIATION's parent class EXPANSION (Braud and Denis, 2015).[4]

Table 7 shows the precision, recall, F-measure and balanced accuracy (average of the accuracies for the positive and negative class respectively) for each system. We show balanced accuracy rather than overall accuracy due to the highly skewed class distribution. For *Inst. specific*, we use a threshold of 0.65 for positive labels[5]. We also use it along with L&N for a *soft voting* classifier where the label is assigned to the class with larger weighted posterior probability sum from each classifier[6]. Both classifiers achieved at least 5% improvement of F-measure and 8%-10% improvement of balanced accuracy compared to other systems. These improvements mostly come from a dramatic improvement in recall. The improvement achieved by the voting classifier also indicate that *Inst. specific* provide complementary signals to syntactic production rules. Note that compared to Lin et al., *Inst. specific* behaves very differently in precision and recall, indicating potential for further system combination.

Finally, we analyze the confusion matrix induced by false positives and false negatives across Lin et al., B&M, *Inst. specific* and soft vote[7]. In Table 8, we list relations contributing at least 10% to false positives for at least one system. Remarkably, INSTANTIATION is consistently confused with

[3] including AltLex, EntRel and NoRel

[4] The dimension of clusters are tuned on the development set. As in prior work, we use clusters in Turian et al. (2010).

[5] Tuned on development set.

[6] The weights are: 0.9 for L&N and 1.0 for *Inst. specific*, tuned on development set. We also tried voting with Brown-concat but it did not outperform combining with L&N.

[7] For other systems, we did not perform full implicit discourse parsing.

Relation	Lin et al.	B&M	Inst.	Vote
Restatement	33.3	34.1	28.7	30.8
Cause	22.2	25.0	33.9	33.6
Contrast	22.2	6.8	9.6	10.3
Conjunction	11.1	4.5	6.1	2.8
EntRel	11.1	18.2	17.4	19.6

Table 8: Relations involved in false positives, $\geq 10\%$ for least one system.

a constant set of relations: RESTATEMENT, CAUSE and EntRel. Different from other systems, the *Inst. specific* classifier demonstrates more confusion towards CAUSE than RESTATEMENT. On the false negative side, all 62 mistakes are not annotated (i.e., NoRel/EntRel) in Lin et al. For the 58 false negatives in B&M, we observe above 10%: NoRel/EntRel (56.9%), CAUSE (19.0%), RESTATEMENT (13.8%), consistent with relations relations involved in false positives.

5 Conclusion

We have characterized the implicit INSTANTIATION relation by studying significant factors that discriminate individual arguments and the sentence pairs connected by the relation. We show distinctive patterns in sentence length, word usage, semantic relationships between words as well as cross-argument and contextual similarity associated with INSTANTIATION. Using these factors as features we demonstrate significant improvement on the detection of implicit INSTANTIATION relation.

Sparse Bilingual Word Representations for Cross-lingual Lexical Entailment

Abstract

We introduce the task of *cross-lingual lexical entailment*, which aims to detect whether the meaning of a word in one language can be inferred from the meaning of a word in another language. We construct a gold standard for this task, and propose an unsupervised solution based on distributional word representations. As commonly done in the monolingual setting, we assume a word e entails a word f if the prominent context features of e are a subset of those of f. To address the challenge of comparing contexts across languages, we propose a novel method for inducing sparse bilingual word representations from monolingual and parallel texts. Our approach yields an F-score of 70%, and significantly outperforms strong baselines based on translation and on existing word representations.

1 Introduction

Multilingual Natural Language Processing lacks techniques to automatically compare and contrast the meaning of words across languages. Machine translation (Koehn, 2010) lets us discover translation correspondences in bilingual texts, but a word and its translation often do not cover the exact same semantic space: distinct word senses might translate differently (Gale et al., 1992; Diab and Resnik, 2002, among others); semantic relations and associations do not always translate, an important issue when constructing multilingual ontologies (Fellbaum and Vossen, 2012); and words in parallel text might be translated non-literally due to lexical gaps (Santos, 1990; Bentivogli and Pianta, 2000) or decisions of the translator, as becomes clear when comparing multiple translations of the same source text (Bhagat and Hovy, 2013).

As a result, correct word translations found in parallel corpora exhibit a variety of relations including equivalence, hypernymy, and meronymy. For instance, even after removing noisy examples (Johnson et al., 2007) from a Machine Translation bilexicon induced from parallel corpora (Koehn et al., 2007), we find that the French word "appartement" (apartment) is linked to related but not strictly equivalent English words, such as "home" or "condo".

house	|||	*foyer* (foyer)
house	|||	*maison* (house)
house	|||	*chambre* (chamber)
home	|||	*appartement*
condo	|||	*appartement*
apartment	|||	*appartement*

Table 1: Examples of translations drawn from an English-French bilexicon automatically learned on parallel text.

We aim to design models that capture these differences and similarities in word meaning across languages, beyond translation correspondences. As a first step, we introduce *cross-lingual lexical entailment*, the task of detecting whether the meaning of a word in one language can be inferred from the meaning of a word in another language. In monolingual settings, lexical entailment has received significant attention as a representation-agnostic way of modeling lexical semantics, and as a step toward textual inference (Zhitomirsky-Geffet and Dagan, 2009; Turney and Mohammad, 2015; Levy et

Proceedings of NAACL-HLT 2016, pages 1187–1197,
San Diego, California, June 12-17, 2016.

al., 2015; Pavlick et al., 2015). We hypothesize that the cross-lingual task can help do the same with multilingual texts.

Building on prior work on the monolingual task, we take an unsupervised approach, and use a directional semantic similarity metric motivated by the distributional inclusion hypothesis (Geffet and Dagan, 2005a; Kotlerman et al., 2010): we assume a word e entails a word f if the prominent context features of e are a subset of those of f. However, we face a new challenge in the cross-lingual case: how can we represent and compare word contexts across languages? Our solution leverages recent work on sparse representations for natural language processing. We develop sparse bilingual word representations that represent contexts based on interpretable dimensions that are aligned across languages.

As we will see, this approach successfully detects cross-lingual lexical entailment (with an F-score of 70%), and significantly outperforms strong baselines based (1) on machine translation, and (2) on existing dense bilingual word representations. Along the way, we construct a new dataset to evaluate cross-lingual lexical entailment, and also show the benefits of our approach in the monolingual setting.

2 A Cross-Lingual View of Lexical Entailment

Zhitomirsky-Geffet and Dagan (2009) formalize lexical entailment as a substitutional relationship. Under their definition, given a word pair (w, v), w entails v if the following two conditions are fulfilled

1. The meaning of a possible sense of w implies a possible sense of v, and

2. w can substitute for v in a sentence, such that the meaning of the modified sentence entails the meaning of the original sentence.

As a result, monolingual lexical entailment includes various semantic relations, such as synonymy, hypernymy, some meronymy relations, but also cause-effect relations (*murder* entails *death*), and other associations (*ocean* entails *water*) (Kotlerman et al., 2010).

We extend this definition to the cross-lingual case by modifying the second condition. Given a word pair (w', v'), where w' is a word in language $\boldsymbol{e}$ and v' is a word in language $\boldsymbol{f}$, w' entails v' if

1. The meaning of a possible sense of w' implies a possible sense of v', and

2. Given a sentence T in $\boldsymbol{f}$ containing v', w' can substitute for v' in the translation of T in $\boldsymbol{e}$, such that the meaning of the modified sentence entails the meaning of the original sentence.

Cross-lingual lexical entailment helps us refine our understanding of semantic mappings across languages: while the French word *ouvrier* can be translated as *worker* in English, knowing that *worker* does not entail *ouvrier* could be useful in many multilingual applications, including machine translation and its evaluation, question answering or entity linking in multilingual texts.

As can be seen in Table 2, lexical entailment is not always preserved by translation: while *aspirin* entails the English word *drug*, it does not entail the French *drogue*, which only refers to the narcotic sense of *drug* and not to its medicinal sense.

English-English	**English-French**
affection → feeling	affection → sentiment
aspirin → drug	aspirin ↛ drogue
water → wet	water → humide
feeling ↛ nostalgia	feeling ↛ nostalgie

Table 2: Examples of monolingual and cross-lingual lexical entailment: → can be read as “entails”, ↛ as “does not entail”.

When evaluating lexical entailment, we use the same approach as in monolingual tasks (Baroni et al., 2012; Baroni and Lenci, 2011; Kotlerman et al., 2010; Turney and Mohammad, 2015): given a bilingual word pair, systems are asked to make a binary true/false decision on whether the first word entails the second. We describe the collection of gold standard annotations in Section 5.2.

3 Unsupervised Detection of Lexical Entailment

We choose to detect lexical entailment without supervision. As in the monolingual case, detection can be done using a scoring function which quantifies the *directional* semantic similarity of an input word pair. On monolingual tasks, despite reaching better performance, supervised systems do not really learn entailment relations for word pairs, but instead learn when a particular word in the pair is a "prototypical hypernym" (Levy et al., 2015). [1] Thus, we limit our investigation to unsupervised models. As a result, our approach only requires a small number of annotated examples to tune the scoring threshold.

We use the *balAPinc* score (Kotlerman et al., 2009), which is based on the distributional inclusion hypothesis (Geffet and Dagan, 2005b): given feature representations of the contexts of two words u and v, u is assumed to entail v if all features of u tend to appear within the features of v.

Formally, *balAPinc* is the geometric mean of a symmetric similarity score, *LIN* (Lin, 1998), and an asymmetric score, *APinc*. Given a directional entailment pair $(u \rightarrow v)$,

$$\mathit{balAPinc}(u \rightarrow v) = \sqrt{\mathit{LIN}(u,v) \cdot \mathit{APinc}(u \rightarrow v)}$$

Assume we are given ranked feature lists FV_u and FV_v for words u and v respectively. Let $w_u(f)$ denote the weight of a particular feature f in FV_u. *LIN* is defined by

$$\mathit{LIN}(u,v) = \frac{\sum\limits_{f \in FV_u \cap FV_v} [w_u(f) + w_v(f)]}{\sum\limits_{f \in FV_u} w_u(f) + \sum\limits_{f \in FV_v} w_v(f)} \quad (1)$$

APinc is a modified asymmetric version of the Average Precision metric used in Information Retrieval:

$$\mathit{APinc}(u \rightarrow v) = \frac{\sum\limits_{r=1}^{|FV_u|} [P(r, FV_u, FV_v) \cdot rel'(f_r)]}{|FV_u|} \quad (2)$$

where,

$$P(r, FV_u, FV_v) = \frac{|\text{\# features of } v \text{ in top } r \text{ features of } u\,|}{r}$$

$$rel'(f) = \begin{cases} 1 & \text{if} f \in FV_u \\ 0 & \text{otherwise} \end{cases}$$

Thus, to use *balAPinc* for cross-lingual lexical entailment, we need a ranked list of features that capture information about the context of words in two languages. In the monolingual case, features are dimensions in a distributional semantic space. For the cross-lingual task, we need to represent words in two languages in the same space, or in spaces where a one-to-one mapping between dimensions exists.

4 Learning Sparse Bilingual Word Representations

As we will see in Section 9, there is a wealth of existing methods for learning representations that capture context of words in two different languages in the literature. However, they have been evaluated on tasks that do not require much semantic analysis, such as translation lexicon induction or document categorization. In contrast, detecting lexical entailment requires the ability to capture more subtle semantic distinctions. This requires bilingual representations to capture both the full range of word contexts observed in original language texts, as well as cross-lingual correspondences from translated texts.

We propose a new model that uses *sparse nonnegative embeddings* to represent word contexts as interpretable dimensions, and facilitate context comparisons across languages. This is an instance of sparse coding, which consists of modeling data vectors as sparse linear combinations of basis elements. In contrast with dimensionality reduction techniques such as PCA, the learned basis vectors need not be orthogonal, which gives more flexibility to represent the data (Mairal et al., 2009). These models have been introduced as word representations in monolingual settings (Murphy et al., 2012) with the goal of obtaining interpretable, cognitively-plausible representations. We review the monolingual models, before introducing our novel bilingual formulation.

4.1 Review: Learning Monolingual Sparse Representations

Previous work (Murphy et al., 2012; Faruqui et al., 2015) on obtaining sparse monolingual representations is based on a variant of the Nonnegative Matrix Factorization problem. Given a matrix $\mathbf{X}$ containing v dense word representations arranged row-wise, sparse representations for the v words can be ob-

[1] Given a word pair such as (dog,animal), supervised methods tend to learn that animal is very likely to be a category word i.e. one that is likely to be a hypernym, and do not take into account the relationship of animal with dog.

tained by solving the following optimization problem

$$\begin{aligned} \underset{\mathbf{A},\mathbf{D}}{\text{argmin}} \quad & \sum_{i=1}^{v} ||\mathbf{A}_i\mathbf{D}^T - \mathbf{X}_i||_2^2 + \lambda||\mathbf{A}_i||_1 \\ \text{subject to} \quad & \mathbf{A}_{ij} >= 0, \forall i, j \qquad (3) \\ & \mathbf{D}_i^T\mathbf{D}_i <= 1, \forall i \end{aligned}$$

The first term in the objective 3 aims to factorize the dense representation matrix $\mathbf{X}$ into two matrices, $\mathbf{A}$ and $\mathbf{D}$ such that the l_2 reconstruction error is minimized. The second term is an l_1 regularizer on $\mathbf{A}$ which encourages sparsity, where the level of sparsity is controlled by the λ hyperparameter. This, together with the non-negativity constraint, helps in obtaining sparsified and interpretable representations in $\mathbf{A}$ since non-negativity has been shown to correlate with interpretability. Note that the objective function on its own is degenerate since it can be trivially optimized by making the entries of $\mathbf{D}$ arbitrarily large and choosing corresponding small values as entries of $\mathbf{A}$. To avoid this, an additional constraint is imposed on $\mathbf{D}$.

4.2 Proposed Bilingual Model

Learning bilingual word representations for entailment requires two sources of information:

- Monolingual distributional representations independently learned from large amounts of text in each language. We denote them as two input matrices, $\mathbf{X_e}$ and $\mathbf{X_f}$, of respective sizes $v_e \times n_e$ and $v_f \times n_f$. Each row in $\mathbf{X_e}$ represents the representation of a particular word in the first language, ***e***, while $\mathbf{X_f}$ represents word representations for the other language ***f***.

- Cross-lingual correspondences that enable comparison across languages. We define a "score" matrix $\mathbf{S}$ of size $v_e \times v_f$, which captures high-confidence correspondences between the vocabularies of the two languages. There are many ways of defining $\mathbf{S}$. As a starting point, we define each row of $\mathbf{S}$ as a one-hot vector that identifies the word in ***f*** that is most frequently aligned with the ***e*** word for that row in a large parallel corpus. This reduction leads to a many-to-one mapping from ***e*** to ***f***, which captures translation ambiguity by allowing multiple words in ***e*** to be aligned to the same word in ***f***.

We formulate the following optimization problem to obtain sparse bilingual representations:

$$\begin{aligned} \underset{\mathbf{A_e},\mathbf{D_e},\mathbf{A_f},\mathbf{D_f}}{\text{argmin}} & \sum_{i=i}^{v_e} \frac{1}{2}||\mathbf{A_e}_i\mathbf{D_e}^{\mathrm{T}} - \mathbf{X_e}_i||_2^2 \ + \lambda_e||\mathbf{A_e}_i||_1 \\ & + \sum_{j=i}^{v_f} \frac{1}{2}||\mathbf{A_f}_j\mathbf{D_f}^{\mathrm{T}} - \mathbf{X_f}_j||_2^2 \ + \lambda_f||\mathbf{A_f}_j||_1 \\ & + \sum_{i=1}^{v_e}\sum_{j=1}^{v_f} \frac{1}{2}\lambda_x\mathbf{S}_{ij}||\mathbf{A_e}_i - \mathbf{A_f}_j||_2^2 \qquad (4) \\ \text{subject to} \ & \mathbf{A_e} > 0 \ ; \mathbf{D_e}_i{}^{\mathrm{T}}.\mathbf{D_e}_i \leq 1, 1 \leq i \leq v_e; \\ & \mathbf{A_f} > 0 \ ; \mathbf{D_f}_j{}^{\mathrm{T}}.\mathbf{D_f}_j \leq 1, 1 \leq j \leq v_f; \end{aligned}$$

The first two rows and the constraints in Equation 4 can be understood as in Equation 3 - they encourage sparsity in word representations for each language. The third row imposes bilingual correspondence constraints, weighted by the regularizer λ_x: it encourages words in ***e*** and ***f*** that are strongly aligned according to $\mathbf{S}$ to have similar representations.

4.3 Optimization

Equations 3 and 4 define non-differentiable, nonconvex optimization problems and finding the globally optimally solution is not feasible. However, various methods used to solve convex problems work well in practice. We use *Forward Backward Splitting*, a proximal gradient method for which an efficient generic solver, FASTA, is available (Goldstein et al., 2015; Goldstein et al., 2014). FASTA (Fast Adaptive Shrinkage / Thresholding Algorithm) is designed to minimize functions of the form $f(Ax)+g(x)$, where f is a differentiable function, g is a function (possibly non-differentiable) for which we can calculate the proximal operator, and A is a linear operator. For the objective function in our model, the l_1 terms form g and the l_2 terms form f.

We have now described all components of the model required to detect bilingual lexical entailment: solving objective 4 as described yields sparse representations for words in the two languages that can be compared directly using the *balAPinc* metric.

5 Constructing a Gold Standard

5.1 Existing Monolingual Test Suites

A comprehensive suite of lexical entailment test beds is available for English (Levy et al., 2015). They were constructed either by asking humans to annotate entailment relations directly (Kotlerman et al., 2010), or by deriving entailment labels from semantic relation annotations (Baroni et al., 2012; Baroni and Lenci, 2011; Turney and Mohammad, 2015). Each test set has 900 to 1300 positive examples of lexical entailment - word pairs (w, v) such that $w \rightarrow v$. All but one are balanced.

5.2 Creating a Cross-Lingual Test Set

We select French as the second language: it is a good starting point for studying cross-lingual entailment, as it is a resource-rich language with many available bilingual annotators. We will construct data sets for more distant language pairs in future work.

We aim to construct a balanced test set of positive and negative bilingual entailment examples in the spirit of the existing English test beds. While it is attractive to leverage existing English examples, we cannot translate them directly as entailment relations might be affected by translation ambiguity (as illustrated in Table 2).

We therefore obtain annotated bilingual examples using a two step process: (1) automatic translation of monolingual examples, and (2) manual annotation through crowdsourcing. For a sample of positive examples of entailment $w_e \rightarrow v_e$ in the monolingual datasets, we generate up to two French translations for v_e, v_{f1} and v_{f2}, using the top translations from BabelNet (Navigli and Ponzetto, 2012) and Google Translate. v_{f1} and v_{f2} are then paired back with w_e, thus generating two unannotated crosslingual examples. Annotation is crowdsourced on Crowdflower [2]: for each example pair (w_e, v_f), workers are asked to label it as true $(w_e \rightarrow v_f)$ or false $(w_e \not\rightarrow v_f)$. We select the positive examples annotated with high-agreement, and obtain the same number of negative examples by applying the same translation process to negative examples[3].

5.3 Crowdsourcing Cross-lingual Entailment Judgments

Detecting lexical entailment for bilingual word pairs is a non-trivial annotation task, and requires a good command of both French and English. For quality control, we first ask a bilingual speaker in our group to conduct a pilot annotation task, which we use to evaluate workers' ability to perform the task. In addition, Crowdflower allows us to present this task to only workers who have a proven knowledge of French, and to georestrict the task to countries most likely to have French-English bilinguals.

N	Examples
0	(*animal*,*couleur*), (*animal*,*reptile*), (*art*, *serpent*)
1	(*asp*, *vertébré*), (*chancellor*, *guide*), (*psychotherapy*,*capacité*)
2	(*bookmark*, *marque*), (*postman*, *ouvrier*), (*endurance*, *force*)
3	(*cricket*,*insecte*), (*muse*,*divinité*), (*parapet*, *paroi*)
4	(*ape*, *animal*), (*reimbursement*,*paiement*), (*lady*,*adulte*)
5	(*epistle*,*lettre*), (*gin*,*boisson*), (*potato*,*nourriture*)

Table 3: Randomly selected examples for each level of annotator agreement: N is the number of annotators who labeled pair as true (out of five)

This approach yielded a large number of high-quality annotations quickly. 1680 cross-lingual pairs were presented to five annotators each. 24 pairs did not receive enough judgments. For the remaining 1656 pairs, four or more annotators agreed for 75% of examples (Figure 1).

This result first shows that we can indeed generate a gold standard for the challenging task of cross-lingual lexical entailment using such crowdsourcing techniques. We ensure high-quality annotations by selecting all 945 (w, v) where four or more annotators agree that $w \rightarrow v$.

In addition, the degree of agreement sheds light on how the notion of lexical entailment is interpreted by non-expert annotators. In Table 3, we present randomly selected examples for each agree-

[2] http://crowdflower.com

[3] Manual annotation is unnecessary for negative examples: it is unlikely that a negative example $w \not\rightarrow v$ will become positive by translating v automatically. We verified this by asking a bilingual speaker to manually check a random sample of 100 such translated pairs, which were all found to remain negative.

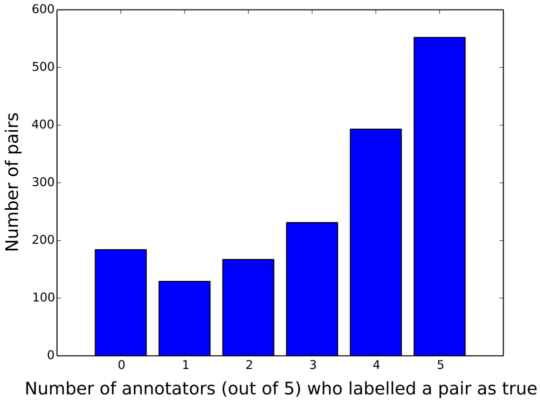

Figure 1: Agreement statistics for dataset creation. X-axis indicates number of annotators who labeled pair as true (out of five)

ment level. The bottom two rows represent clear positive examples, that are cross-lingual equivalents of hypernymy or synonymy relations: e.g., *gin* is a kind of drink (*boisson* in French). The top row represent clear negative examples, where the two words are unrelated (e.g., *art* and *serpent*, which means *snake* in English) or the directionality is wrong (e.g., *animal* ← *reptile*). The middle rows where one to three annotators chose to annotate the word pair as negative contain less clear-cut cases, including association relations (e.g., *endurance* → *force*), and examples where entailment judgments requires taking into account more subtle word sense or translation distinctions (e.g., *bookmark* can be translated as *marque* for a positive example, but the most frequent sense of *marque* translates into English as *brand*, for which the entailment relation does not hold.)

6 Experimental Conditions

We estimate the following models for evaluation on the test sets described in the previous section.

6.1 Sparse Bilingual Model

Estimating sparse, bilingual representations as described in Section 4.2 first requires learning dense monolingual representations in two languages ($\mathbf{X_e}$ and $\mathbf{X_f}$). We can in principle use any type of dense representations. We choose to train GloVe (Pennington et al., 2014) vectors on a corpus comprised of Gigaword and Wikipedia to learn dense representations of 2000 dimensions for English and French. English vectors are trained on a corpus of 4.9B words, while French vectors are trained on 1.2B words.

Second, we construct $\mathbf{S}$ by word-aligning large amounts of parallel corpora using a fast implementation of IBM model 2 (Dyer et al., 2013). We combine Europarl (Koehn, 2005), News Commentary [4], and Wikipedia [5] to create a large parallel corpus of 72M English tokens and 78M French tokens. All corpora are tokenized and lowercased.

We learn 100-dimensional sparse representations with hyperparameters $\lambda_e = \lambda_f = 0.5, \lambda_x = 10$.

6.2 Contrastive Models

We also learn two other sets of 100-dimensional word representations, as a basis for comparison.

First, we learn sparse monolingual English word representations, which will be used in monolingual lexical entailment experiments (Section 7.1). These are trained using the non-negative sparse method described in Section 4.1, on the same 4.9B word English corpus that was used for learning bilingual representations.

Second, we learn dense bilingual word representations using BiCVM (Hermann and Blunsom, 2014), to use as a baseline for our cross-lingual lexical entailment experiments (Section 7.2). BiCVM uses sentence aligned parallel corpora to learn representations for words in two languages, with the objective that when these representations are composed into representations for parallel sentences, the Euclidean distance between the parallel sentences should be minimized. We learn English-French vectors on the parallel corpora described in Section 6.1.

7 Results

7.1 Monolingual Tasks

We first evaluate the monolingual version of our sparse model on English test sets. While our focus is on the cross-lingual setting, the monolingual evaluation lets us compare a version of our newly proposed approach with existing lexical entailment results (Levy et al., 2015), obtained using dense word representations compared with cosine similarity. This is not a controlled comparison, as training conditions are not comparable. Nevertheless it

Turney and Mohammad (2015)	.642	.576	.587

Table 4: Evaluating sparse representations on monolingual lexical entailment (F-score): we compare previously published unsupervised results (Levy et al.) to our sparse word representations. While this is not a controlled comparison, we can see that our word representations yield roughly comparable performance to prior work.

is reassuring to see that sparse word representations are roughly on par with previously published results. This suggests that they indeed provide good features for discovering entailment relations, using both cosine and *balAPinc* as metrics[6].

Results (Table 4) show that sparse representations lead to performance comparable to previous approaches, thus providing a strong motivation for using the same for the crosslingual task.

7.2 Cross-lingual Task

Word Representations	Cosine	*balAPinc*
bilingual + dense	.528	.548
monolingual + sparse	.663	.675
bilingual + sparse	.687	**.703**

Table 5: F-Score on Cross-lingual Lexical Entailment Task. All results are obtained by 10-fold cross-validation. Using *balAPinc* with features from the sparse bilingual representations outperforms all other approaches.

We evaluate our proposed approach on the new English-French lexical entailment test set. We evaluate the impact of choosing a sparse representation by comparing our approach to the dense bilingual word representations obtained with the BiCVM model (Section 6.2). We also evaluate the usefulness of bilingual vs. monolingual word representations: given a bilingual example (w_e, v_f), we translate v_f into English using Google Translate, and then detect lexical entailment using English sparse representations for the English pair (w_e, v_e) as described in Section 6.2.

Results are summarized in Table 5. First, we observe that *balAPinc* outperforms cosine for all word representations, confirming that the directional metric is better suited to discovering lexical entailment. Second, all sparse models significantly outperform the model based on dense representation, which suggests that sparsity helps discover useful context features. Finally, our proposed approach (*balAPinc* with features from sparse bilingual representations) yields the best result overall, perofrming better than the second best model (cosine with features from sparse bilingual representations) by approximately 1.6 points. This difference is highly statistically significant (at $p < 0.01$) according to the McNemar's Test (Dietterich, 1998). Our model also outperforms translation followed by monolingual entailment, confirming the need for models that directly compare the meaning of words across languages, instead of using translation as a proxy.

8 Discussion

8.1 Examining bilingual dimensions learned

One motivation for using sparse representations is that they yield interpretable dimensions: one can summarize a dimension using the top scoring words in its column. Interpreting five randomly selected dimensions learned in our bilingual model (Table 6) shows that we indeed learn English and French dimensions that align well, but that are not identical - reflecting the difference in contexts observed in monolingual English vs. French corpora, as needed to detect lexical entailment.

8.2 Sparse Vectors Help Capture Distributional Inclusion

One advantage of our sparse representations over dense bilingual representations is that they can better leverage an asymmetric scoring function like

[6] While cosine and *balAPinc* yield comparable F-scores here, *balAPinc* is still a better metric as it captures directionality. If the test sets included examples of both entailment direction for every pair, cosine would yield incorrect predictions for as many as half of the examples, since its predictions would be the same regardless of the direction.

French Dimensions	English Dimensions
logiciel, fichiers, web, microsoft	files, web, microsoft, www
université, collège, lycée, conseil de administration	university, college, graduate, faculty
virus informatique, virus, infection, cellules	virus, viruses, infection, cells
doigts, genoux, jambes, muscles	bruises, fingers, toes, knees
budapest, stockholm, copenhague, buenos	lahore, dhaka, harare, karachi

Table 6: Top scoring words in 5 randomly selected French and English dimensions learned by our bilingual model.

balAPinc . Consider the following two pairs from our dataset - *(mesothelioma,tumeur)* and *(tumor,mésothéliome)*. The former is a positive example since *mesothelioma → tumeur*, but the latter is negative (since not all tumors are mesotheliomas.)

Cosine similarity is unable to differentiate between these two cases, assigning a high score to both these pairs, causing both of them to be labeled positive. However, *balAPinc* with sparse representations teases them apart by giving a high score to the first pair and a low score to the second.

In the bilingual sparse model, *mesothelioma* and *mésothéliome* have only one non-zero entry (in the dimension corresponding to [‘virus’, ‘viruses’, ‘infection’, ‘cells’, ‘cancer’]) whereas *tumeur* and *tumor* have five non-zero entries in their representations. Based on the distributional inclusion hypothesis, this difference in the number of non-zero entries is a strong basis for *mesothelioma → tumor*.

8.3 Benefits of Bilingual Modeling

Examining the results of the approach based on translation followed by monolingual entailment confirms the problems raised by sense ambiguities.

Consider the English word *drug*, which can be translated into the French *drogue* when used in the narcotics sense, and *médicament* when used in the medicinal sense. Thus the pair *(antibiotic,drogue)* that is correctly labeled as negative in the crosslingual case, gets converted to *(antibiotic,drug)* by translation and is then incorrectly labeled as positive. Similarly, the pair (*coriander, herbe*), which is positive in the crosslingual case, gets translated to (*coriander, grass*) because the French *herbe* is primarily aligned to the English *grass* (rather than *herb*). The translated pair is labeled negative.

9 Related Work

Bilingual Word Representations Much recent work targets the problem of learning low-dimensional multilingual word representations, using matrix decomposition techniques such as Principal Component Analysis and Canonical Correlation Analysis (Gaussier et al., 2004; Jagarlamudi and Daumé III, 2012; Gardner et al., 2015), Latent Dirichlet Allocation (Mimno et al., 2009; Jagarlamudi and Daumé III, 2010), and neural distributional representations (Klementiev et al., 2012; Gouws et al., 2015; Lu et al., 2015, among others). However, these models have typically been evaluated on translation induction or document categorization, which, unlike lexical entailment, focus on capturing coarse cross-lingual correspondences.

Sparse Word Representations While cooccurrence matrices and their PPMI transformed variants are early examples of sparse representations, recent work has leveraged Nonnegative Sparse Embedding (NNSE) (Murphy et al., 2012). These models have been augmented to incorporate different types of linguistically motivated constraints, such as compositionality of words into phrases (Fyshe et al., 2015), or a hierarchical regularizer that captures knowledge of word relations (Yogatama et al., 2015).

Sparse representations have also been used for monolingual lexical entailment in the Boolean Distributional Semantic Model (Kruszewski et al., 2015), which shares our hypothesis on the usefulness of sparsity in meaning representations. However, they are meant to be used in different settings: while the boolean features can interestingly capture formal semantics, they are not as useful in our unsupervised setting, since they do not provide the feature rankings required to use the *balAPinc* metric.

Cross-Lingual Semantic Analysis To the best of our knowledge, lexical entailment has not been previously addressed in a cross-lingual setting. The long tradition of lexical semantic analysis in cross-lingual settings has mostly focused on using translations to characterize word meaning (Diab and Resnik, 2002; Carpuat and Wu, 2007; Lefever and Hoste, 2010; McCarthy et al., 2013, among others). An exception is Cross-lingual *Textual* Entailment (Mehdad et al., 2010), which aims to detect whether an English hypothesis H entails a text T written in another language. We plan to use our lexical models to address this task in the future.

10 Conclusion

In this work, we introduced the task of cross-lingual lexical entailment, which aims to detect whether the meaning of a word in one language can be inferred from the meaning of a word in another language. We constructed a dataset with gold annotations through crowdsourcing, and presented a top-performing solution based on novel sparse bilingual word representations that leverages both word co-occurrence patterns in monolingual corpora and bilingual correspondences learned in parallel text[7].

A key limitation of this work is that we address lexical entailment out of context, based on word representations that collapse multiple word senses into a single vector . These could be addressed in future work by adapting existing methods for learning sense-specific representations for dense vectors (Jauhar et al., 2015; Ettinger et al., 2016; Reisinger and Mooney, 2010; Guo et al., 2014; Huang et al., 2012; Neelakantan et al., 2015) to our sparse representations, and target cross-lingual textual entailment tasks, which focus on full sentences rather than isolated words. We also plan to study lexical entailment on more languages and example types, as well as investigate the usefulness of our bilingual representations in higher level multilingual applications such as machine translation.

Abstract

Given the limited success of medication in reversing the effects of Alzheimer's and other dementias, a lot of the neuroscience research has been focused on early detection, in order to slow the progress of the disease through different interventions. We propose a Natural Language Processing approach applied to descriptive writing to attempt to discriminate decline due to normal aging from decline due to pre-dementia conditions. Within the context of a longitudinal study on Alzheimer's disease, we created a unique corpus of 201 descriptions of a control image written by subjects of the study. Our classifier, computing linguistic features, was able to discriminate normal from cognitively impaired patients to an accuracy of 86.1% using lexical and semantic irregularities found in their writing. This is a promising result towards elucidating the existence of a general pattern in linguistic deterioration caused by dementia that might be detectable from a subject's written descriptive language.

1 Introduction

Alzheimer's disease is prevalent and becoming more so as the world's population ages (Prince et al., 2014). Since no cure is known, it is hoped that early detection and intervention might slow the onset of symptomatic cognitive decline and dementia. Clinical methods to detect Alzheimer's disease are typically applied well after symptoms have progressed to a troubling degree, and may be costly. Families, however, often report earlier signs of the disease through their language interactions with their elders. This has led clinical researchers to study linguistic differences to detect the disease in conversational speech (Asp and de Villiers, 2010). One approach is to search for non-informative phrases or semantic incoherences, which was confirmed to distinguish patients with Alzheimer's disease from controls (Nicholas et al., 1985). A strong limitation for its automatic application is the need of a trained expert to annotate the incoherences and scoring by hand.

We propose in this study to use Natural Language Processing (NLP) to evaluate samples of a patient's descriptive writing in order to attempt to

Proceedings of NAACL-HLT 2016, pages 1198–1207,
San Diego, California, June 12-17, 2016.

discriminate decline due to normal aging from decline due to pre-demented conditions. The Arizona Alzheimer's Disease Center (ADC) is a longitudinal study of patients with Alzheimer's disease and normal control subjects, who receive an annual battery of clinical and neuropsychological exams, to which we added the following brief and a simple task. Participants are asked to describe, in writing, a picture typically used within the speech-based Boston battery (Nicholas and Brookshire, 1993). We collected 201 descriptions written by ADC participants by hand, which were scanned, transcribed, and later analyzed. We describe here a statistical machine learning method relying on lexical, syntactical and semantical features to discriminate evidence of abnormal deterioration in the writings of the patients. Our results confirm a correlation between linguistic decline on this writing task and the cognitive decline revealed by the more time consuming neuropsychological test battery.

2 Background

Alzheimer's disease (AD) is a highly prevalent neurodegenerative dementia that increases exponentially with age. It is the most common form of dementia in the United States. AD is characterized by a severe memory deficit and at least one of the following: aphasia (an impairment of language, affecting the production or comprehension of speech and the ability to read or write), apraxia (loss of the ability to execute or carry out skilled movements and gestures), agnosia (inability to recognize and identify objects or persons), and a disturbance in the internal control of cognitive processes (such as reflection, planning, working memory, etc.) (American Psychiatric Association, 1994). While clinical testing often leads to an accurate diagnosis during its middle and late stages, several signs may alert a patient's family to much earlier stages of the disease even in the absence of frank aphasia (Obler and de Santi, 2000).

Given the repeated failures of experimental therapies targeting dementia stage AD, current strategies are targeting early intervention at preclinical and early symptomatic stages thereby necessitating more accurate methods for earlier detection of AD. Mild Cognitive Impairment (MCI), is defined as abnormal cognitive decline relative to age-matched peers that does not impair normal activities of daily living (Gauthier et al., 2006). AD is a frequent but not invariant cause. Some MCI patients may even recover, but all AD patients transition through the MCI stage before developing frank dementia (Petersen et al., 2001). As a result, an increasing number of clinical studies are trying to define and predict each stage in the life of an AD patient: normal, MCI and Alzheimer (Drummond et al., 2015).

2.1 Predicting Cognitive Decline with Language

Test batteries commonly used to measure cognitive decline include tests to evaluate the language production of patients, but they are criticized for their simplicity. For example, the Mini-Mental State Examination (MMSE), a widely used screening tool, asks to name 2 objects, to repeat a phrase, write a sentence and obey a 3-step instruction. Bucks et al., 2000, citing Sabat, 1994, assert that these structured tests break down language into artificial components that fail to represent the psychological and sociological context involved in daily conversations. As a consequence, such tests may be insensitive to early linguistic decline, when anomalies are already detectable by patients' families (Key-DeLyria, 2013).

More sophisticated exercises have been proposed to complement the existing linguistic test batteries (Asp and de Villiers, 2010). These exercises are centered around conversation and narration abilities of patients. Conversation and narration abilities are developed in the early age of children (around 2-3 years for conversation and around 4 years for narration). Since they play a fundamental role in cognitive and social development, they are intensively studied. Cognitive tests addressing narration capabilities can probe memory, spontaneity and the quality of interactions with the interlocutor. Tests can be complex, like narrating through informal conversation a habitual task, a memorable day of their life, or an event they participated in during the last week or month. Typically, the exact utterances are not captured, but rather the examiner notes if the narrative was coherent, or if the expected events were mentioned. Simpler tests ask patients to comment on an image, or a sequence of related images or to narrate a movie previously displayed. The patients participating in our study are receiving an extensive battery of tests annually to which we added a linguistic task. We therefore opted for a simple exercise of image description to avoid exhausting our participants. While the majority of the exercises testing the narration abilities are spoken, with the exception of (Hayashi et al., 2015) and (Hirst and Feng, 2012), all studies work with a corpus of transcribed oral narratives. We opted for a written version for a direct analysis of written language, a form that remains relatively unexplored (Hayashi et al., 2015).

2.2 Clinical Studies for Linguistic Decline Prediction

A seminal longitudinal study (Snowdon et al., 1996) demonstrated that writing performance in young women correlated with development of AD in old age. Since then, clinical studies of cognitive decline have been scrutinizing all linguistic levels (Reilly et al., 2011), lexical, syntactical, semantical and pragmatic (Bolshakov and Gelbukh, 2004), in order to detect elements deteriorating with normal aging, those commonly observed degraded in the MCI stage, and finally their disintegration during the continuous phases of dementia. Various properties of language are studied, *e.g.* number of words, size of sentences, number and correctness of anaphoric references, number of propositions per sentence, number of relevant facts and the structure of the narration (Hier et al., 1985; Drummond et al., 2015). These properties are most often computed manually on samples of small size (usually around 50 patients) and appropriate statistical tests are used to determine the properties which can discriminate controls, MCI and AD patients.

From these studies has emerged a general pattern of pathological language decline observed during the MCI and the early stage of dementia (Obler and de Santi, 2000). Phonology and morphology are conserved. Syntax is also mostly spared even if it tends to be simplified. Degradations are mainly found at the lexical and semantical levels (Hier et al., 1985). At the lexical level, the vocabulary is reduced with fewer words and fewer occurrences. It becomes more abstract and vague with multiple phrasal repetitions (Xuan et al., 2011). At the semantic level, complex questions are reduced and, early in the dementia phase, patients have difficulty making exact and pertinent remarks (Nicholas and Brookshire, 1993). Empty words and incomplete sentences are often observed in oral exercises.

These alterations of the language seem to allow caregivers and researchers to distinguish decline due to normal aging from pathological decline but, further studies with larger patient numbers are needed to confirm these initial results. A significant limitation in clinical environment has been the need for a trained language pathologist to annotate and evaluate all linguistic productions of each patient examined. More recently, however, some efforts have been made to automate the annotation process using NLP techniques. The next section reviews the progress made.

2.3 Automatic prediction of Linguistic Decline

A first hypothesis to detect the cognitive decline in an older person is to compare his/her writing at a young age with his/her writing at an old age. In (Hirst and Feng, 2012) sophisticated stylometric measures were tested to identify the differences caused by the disease in the style of three well-known authors (2 probable ADs and 1 healthy). However, not only were results not decisive given the small number of subjects, but this approach required a large amount of writings from the same person in order to establish the shift in the style of that person, conditions rarely met with common subjects. A variant of this approach is to compute two distinct profiles by modeling separately normal subjects and aphasic subjects from their writings. The results reported in (Holmes and Singh, 1996) report 88% of subjects correctly predicted from a corpus of 100 conversations. Few features were used and the computation of some of them still required a human intervention.

Bigger set of features can be explored with the use of NLP and machine learning. A first attempt in (Thomas et al., 2005) was to combine stylometric features (Stamatatos, 2009) and language model within a classifier. Their classifier obtained reasonable performances with 70% accuracy when distinguishing cognitively impaired from normal subjects in 95 oral interviews. In (Jarrold et al., 2010), the authors evaluated 80 features from various categories computed using dictionaries and predefined rules: positive sentiments words, socially related words, use of the first person, among others. The performance reported an accuracy of 82.6% in the prediction task in 45 interviews.

The most efficient features for discrimination are semantic features which capture the abilities of a subject to understand and convey a set of pertinent information (Nicholas and Brookshire, 1993). Automatic computation of such features are still challenging for automatic systems. Therefore, several publications integrated heuristics for computing such features. A prototype to approximate the density of idea has been released by (Brown et al., 2008). Idea density can be thought of as the total number of assertions or claims whether true or false, in a proposition. The number of claims is estimated from the number of verbs, adjectives/adverbs and conjunctions given certain conditions. The integration of the idea density proved to be significant to separate AD subjects from controls in (Jarrold et al., 2010).

3 Methods

3.1 Corpus Description and Preprocessing

In the context of the ADC study we created a corpus for our experiments. At the day of writing, the total number of subjects participating in the ADC study was roughly 500 corresponding to about 200 normal controls, 100 with MCI and 200 with AD or other form of degenerative dementia. In the beginning of the year 2015, in collaboration with the five institutes participating on the ADC study, a cognitive test was added to the protocol of the study. Subjects were asked to describe an image at the end of their annual visit. This control image is the same for all subjects (Nicholas and Brookshire, 1993). The image (Figure 1) represents a family having a picnic near a lake. Subjects were asked to write (by hand) a detailed description of the scene in the picture. No time limit is imposed, and the time it takes them to write their description is noted. The test giver is asked to read the description when the subject completes it, asking the subjects to clarify any unreadable words and to write them in the descriptions. We collected 201 descriptions for this study, 154 from healthy subjects and 47 from subjects in decline. The collection process is ongoing[1].

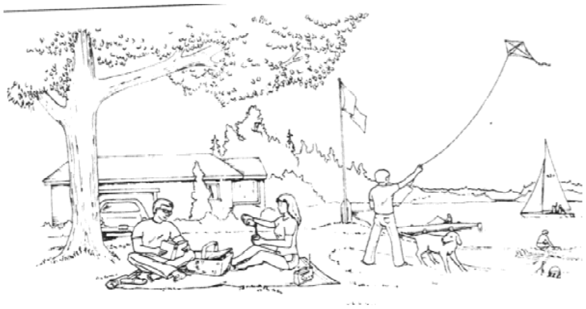

Figure 1: The picnic scene described by the ADC cohort of patients.

We developed a web site to centralize the collection of the scans of the descriptions from the different institutions. The web site offers a basic interface to display the scans and to transcribe their contents. We trained a student (native English speaker) to transcribe the scans, preserving, as much as possible, the original presentation of the description (*i.e.* punctuations, uppercase, indents and new lines) as well as misspellings and crossed words.

Alzheimer Patient
Jane and Joe went out to blow But the weather was windy in the Oposit Direction, so they decided To blow the joint rather place and go home and have a bond fire in Their backyard and enjoy all the cooked things they could
Normal Patient
A family outing at a lake shore showed people doing several things. Mom and Dad sat on a blanket while dad read a book. Dad was over comfortable without his shoes, while mom listened to the radio and poured herself a cup of coffee. Junior was having fun flying his kite, and the family dog was interested in what all was going on. Another of the family was spending quiet time and fisherman, and another was playing in the shallow water. Other friends waved to them as they sailed by. It was a perfect day with just enough wind to move the flag and provide lift for the kite. It must have been comfortable sitting under the shade tree.

Table 1: Example of writings AD vs Normal Patient.

The descriptions are processed through an NLP pipeline composed of several off-the-shelf NLP modules. First, a homemade tokenizer and the Stanford Lemmatizer[2] are applied. Part of Speech as well as chunks are computed thanks to Genia

[1] The corpus is fully de-identified and will be publicly released at the end of the study.

[2] Available at http://stanfordnlp.github.io/CoreNLP/

tagger[3]. The descriptions are split into phrases by the sentence splitter found in the ANNIE tools suites of the Gate pipeline[4]. To compute the language models we have integrated the character Ngrams module provided by LingPipe[5] as well as a specific Perl module Text::NGrams (Keselj et al., 2003) for computing character Ngram frequencies. Finally, for computing the semantic features describe below (section 3.2.3), we compute vectors of words which are semantically close to a selected set of words that correspond to a model description. To generate these vectors we have selected the tool Word2Vec[6]. We used the vectors trained on part of Google News dataset (about 100 billion words).

For each sample writing, we have access to all information acquired during the ADCC study about the subjects enrolled. This includes personal information (*e.g.* gender, sex or education), social and medical information (*e.g.* social status, smoking habit, depression) as well as the subjects' tests administered during the visits. For our experiments, we used the primary diagnostic made during the last visit of a subject. If the subject was diagnosed with any form of dementia, including possible or probable Alzheimer's, or with MCI, the subject was labeled as *Declined*. If the subject was not diagnosed with dementia we checked the score measuring the cognitive status. This score is assigned by a neuropsychologist and it summarizes the performance of the subject during the cognitive exams. If the neuropsychologist diagnosed the subject as cognitively impaired or as demented, the subject is labeled as *Declined*. Finally, we checked the Clinical Dementia Rating (CDR) global score (Morris et al., 1997). The CDR is assigned using a semi-structured standardized interview completed with the subject's caregiver and the subject independently. The CDR score is used to help diagnose dementia, indicating: Normal, MCI, Early Dementia, Moderate Dementia, and Severe Dementia, depending on its value. Administrators of the CDR are trained in a standardized fashion. If the score of the CDR indicated the subject as MCI or Dementia, then we labeled the subject as *Declined*, otherwise the subject was *NotInDecline*. These labels were used as gold standard during our experiments.

3.2 A Classifier for Detecting Linguistic Decline

In order to automate the analysis of the descriptions of our 201 subjects we created a classifier to discriminate subjects in abnormal decline from subjects with normal aging decline. Our classifier incorporates various features proposed by us or found in the literature. The following sections details the features and the motivations for their use.

3.2.1 Lexical Features

Adjective/Noun/verb/Pronoun ratios (Thomas et al., 2005). Given an abnormal decline we expected an important impoverishment of the vocabulary. Our initial hypothesis was a sensitive diminution of the number of adjective and pronouns since they are indicative of a precise description and complex syntactic structures. These ratios were computed by taking the number of adjectives/nouns/verbs/pronouns divided by the total number of tokens contains in a description. We relied on the POS tags to determine if a word was a noun, adjective or verb. To find the pronouns we matched a list of 73 pronouns.

Type Token Ratio (Thomas et al., 2005). The use of this ratio was supported by the idea that a subject presenting an abnormal decline will see his/her vocabulary reduced and would tend to repeat general words. This ratio was computed by taking the size of the vocabulary of a description over the total number of tokens. The vocabulary was found by adding up the lemmas occurring in the description.

Documents, Sentences and Tokens length (Hirst and Feng, 2012). The length of the different components of a document are often a good indicator of the quality of the writing and the ability to produce long and complex descriptions. We expressed several statistics which describe the description. The description length is expressed in number of tokens and punctuations. The size of the longest and shortest sentences, *min-max sentence length*, were used as features as well as the average of the length of all sentences occurring in the description.

[3] Available at http://www.nactem.ac.uk/GENIA/tagger/

[4] Available at https://gate.ac.uk/

[5] Available at http://alias-i.com/lingpipe/

[6] The tool and its documentation are available at https://code.google.com/p/word2vec/

The average length of the tokens occurring in the description was also added as feature.

Misspelling Ratio (Proposed). For this ratio we considered only orthographic errors present in a description. Since longer descriptions are more likely to have more misspellings we normalized the metric by dividing the number of errors with the total number of tokens in the description. To discover automatically the misspellings we used the rule-based spell checker languagetool-3.0[7]. As for the previous ratios we assumed that a higher percentage of misspellings would reflect an underlying lexical problems.

3.2.2 Stylometric Features

Functional Words Ratio (Hirst and Feng, 2012). Functional words are known to be good indicators of a personal style (Stamatatos, 2009). We matched an extended dictionary of 337 entries to retrieve the functional words in our descriptions. The ratio was given by the number of functional words over the total number of tokens in a description.

Brunét's Index and Honoré's Statistic (Thomas et al., 2005). Both metrics are length insensitive versions of the *type token ratio* and often reported as useful features for discriminating abnormal decline in the literature. They were computed by the following equations:

Brunét's Index = $N^{V-0.165}$ and Honoré's Statistic = $100logN/1 - \frac{V_1}{V}$ where V is the total vocabulary, N the total number of tokens and V_1 the total number of hapax.

Character NGrams and Character NGram Frequencies (Thomas et al., 2005). Ngrams of words capture lexical regularities hidden in the writing style of an author as well as its syntactic complexity. They also help to highlight syntactic errors. Since sparsity problems raise quickly when Ngrams of words are created from a small size corpus, we preferred to use Ngrams of characters. By taking the most frequent Ngrams for both profiles Normal subjects and subjects in decline, we expected to capture the set of words which are the most indicative of each profile. We set the size of the Ngrams to 5 for the character NGrams and to 10 for the Character NGram Frequencies. We limited to the 2000 most frequent Ngrams. Those parameters were set manually and can be optimized in future experiments.

3.2.3 Semantic Features

Idea Density (Brown et al., 2008) To compute the idea density detailed in section 2.3, a heuristic to estimate the quantity of information convey in the description, we integrated the software CPIDR 3.2[8]. No change has been made in the set of rules used by the software.

Word2Vec Distance (Proposed). A characteristic of subjects in abnormal decline is their inability to convey pertinent information and to digress from the initial subject. To model this characteristic we propose a new feature which takes advantage of the specificity of our corpus: all subjects, normal and subjects in decline, are describing the same image. By taking only descriptions written by normal subjects we obtained a set of words describing correctly the image. We named this set *generative words*. All functional words were removed from this set. Our hypothesis was that subjects in decline would use less words from *generative words* and add more inappropriate words (given the context of the image). Since the size of our corpus is small, not all relevant words were present in *generative words*. We extended *generative words* into a set called *Word2Vec clusters* by adding for each word of *generative words*, the corresponding vector returned by Word2Vec. These vectors are composed by words semantically close to the generative words. This includes synonyms, meronyms, hyperonyms but also correlated words. At run time, when an unknown description was submitted to the system, we created a subset of *Word2Vec clusters*, called *Filtered Word2Vec clusters*, by taking all vectors V_i in *Word2Vec clusters* related to the words W_i occurring in the unknown description. We added V_i in *Filtered Word2Vec clusters* if W_i was the generating word of V_i or if W_i was a word occurring in V_i with W_i belonging to the set *generative words*. If W_i was found in a vector V_j ∈ *Word2Vec clusters* but V_j was generated by a word w_j not occurring in the unknown description,

[7] Available at http://wiki.languagetool.org/java-api

[8] The software and its documentation are freely available at http://ai1.ai.uga.edu/caspr/

V_j was not added in *Filtered Word2Vec clusters*. This filtering step is crucial to guarantee good performances when using this feature. Additional tests were performed without filtering *Word2Vec clusters* and a significant drop of performances was observed due to noise or ambiguity in the vector generated by Word2Vec, for example vectors generated by *go*, *be* etc. The filtering step insures that the vectors of *Filtered Word2Vec clusters* contain only words semantically related with the content of the unknown description. Given the set of words in *Filtered Word2Vec clusters* the distance is the ratio of words W_i in *Filtered Word2Vec clusters* and total number of words in W_i.

3.2.4 Subject Features

All clinical information about the subjects participating in the ADC study were available during our experiments. We retained only criteria known to affect linguistic competences or known to contribute to the development of the disease. *Age* and *gender* are important factors for the Alzheimer's disease as well as the version of the *APOE* gene of a subject. The presence of an e4 allele increases significantly the risk of the disease. *Education* and *primary language* (native English speaker or not) are obvious attributes to consider to measure the linguistic abilities as well as the *social status* of the subject. A subject living alone, with relatives or spouse will not have the same opportunities to speak.

4 Results

We evaluated our classifier on the data mining platform *Weka*. This platform implements state-of-the art machine learning algorithms (Witten et al., 2011). The size of our corpus being small we opted for a leave-one-out cross validation. We chose the framework of a Bayesian Network (BN) (Koller and Friedman, 2009) to perform the evaluation of our classifier. For all following experiments we learned the structure of the network and its conditional probabilities automatically from our data. No Naive Bayes structure were *a priori* imposed during the training and the number of possible parents for a node were manually set to 20. We selected this machine learning algorithm because it learns complex decision functions, its decisions are interpretable by medical experts, it has very few global parameters to set up and it was fast to train on our problem.

Our first experiment evaluated the performances of our classifier when all features were used (Table 2). We confirmed the quality of our classifier by comparing its performances with a baseline classifier. The baseline classifier predicted the majority class label *NotInDecline* for all instances. The baseline system obtained 76.6% of accuracy (Acc). With this setting, our classifier obtained a better score with 80.6% Acc. and thus demonstrated its abilities to learn the difference between normal subjects from subjects in abnormal decline using linguistic features.

Classifier	Accuracy (%)	FN	FP
Baseline	76.6	47	0
Bayesian Network			
- All Features	83.1	25	9
- Selected Features	86.1	21	7

Table 2: Performances of the classifiers for decline detection. Considering Decline as the targeted class, False Positive are Normal patients labeled as patients in decline and False Negative are patients in decline labeled as Normal patients.

We proceeded to an ablation study to assess the benefits of each feature. We removed one at a time each feature, or complementary features such as *min-max length of sentence*, and rerun the training/testing of our classifier. The results are detailed in Table 3. For brevity we did not report in the table the features which did not change the score of our classifier once removed.

Feature removed	Accuracy (%)
None	83.1
Misspelling Ratio	85.1
Word2Vec Distance	81.9
Brunét's Index	82.1
Average Sentence Length + Min-Max Sentence Length	83.6
Ngram Frequencies	85.1
Ngrams	81.6
Patient APOE	84.1
Patient Age	82.6

Table 3: Performances of the Bayesian Network during the ablation study.

In the light of the ablation study we performed a second experiment to determine the optimal performances of our classifier. We run several feature selection/reduction algorithms implemented in the *Weka* platform. The Correlation-based Feature Selection algorithm (CFS) (Hall, 1999) found a set of features which maximized the performances of the classifier. Under this setting our classifier outperformed the baseline system with a score of 86.1 Acc. against 76.6 Acc (Table 2). Inspection of the confusion matrix shown that the classifier correctly recognized 24 patients in abnormal decline and 149 normal patients. Considering *Decline* as the targeted class, our classifier mistakenly predicted 7 False Positives (FP) and 21 False Negatives (FN). We reproduced comparable performances with other machine learning algorithms using this set of features. A multilayer perceptron got a score of 84.6% Acc., a random forest 81.1% Acc. and a bagging algorithm 83.6% Acc. Five features only were selected by the CFS algorithm: Ngrams, Honoré's Statistic, Misspelling Ratio, Age and the Word2Vec Distance. This set of features differs from the set indicated by the ablation study but obtained better performances on our task. When trained and tested using only the four features which improved the classification during the ablation study, the score of the classifier reached 85.6 Acc. with 4 FP and 25 FN.

From these experiments we can conclude that our system showed promising performances when learning to discriminate subjects in abnormal cognitive decline from their writings. The ablation study and the set of optimal features found by the CFS algorithm seem to confirm the existence of the general pattern postulated in the clinical literature where lexical and semantical capacities are damaged during the cognitive decline. The most important features were the semantic features, Ngrams and Word2Vec, with a total drop of 2.7 points when they were removed. Both features capture the tendency of the subjects in decline to describe few topics of the image, resulting in a low Word2Vec distance, and to digress from the description task by mentioning several facts or statements that could not be inferred from the image or were not plausible with its content. These digressions caused the system to compute a higher probability for the description written by a subject in decline to be generated by the profile of the abnormal subjects and a low probability for being generated by the profile of the normal subjects. The profile of abnormal subjects contained more words than the profile of normal subjects, this latter containing only words related to the image.

The decline of the lexical capacities are suggested by the higher number of misspellings made by subjects in decline as well as the positive role of the Brunét's Index or Honoré's Statistic Brunet during the classification.

4.1 Analysis of Errors

The prediction of abnormal decline is a hard learning problem. Since it is still difficult to clinically diagnose the cognitive decline and potentially the following dementia, the labels of the target class in our corpus remains uncertain. Patients labeled normal can quickly show sign of decline and MCIs can recover over time. Therefore, for our analysis, we focused more on the capacity of our classifier to detect good descriptions rather than to strictly predict the target class. Additional analysis of our errors will be carried out by pathologists specialized in aphasia.

The 7 FPs where all primary diagnosed normal during their last visit. Their ages varied from 69 to 86 year old. Our manual inspection of their writings revealed that 4 descriptions presented strong irregularities which may explain the decision of our classifier. In the first case we found short descriptions containing misspellings, repeated phrases, ungrammatical sentences and descriptions focused on small details of the image. In the second case, descriptions were longer but they all contained digressions such as *"The turtle is shuffling back to be with the water."* (no turtle is drawn in the image), or *"Mom is torn between the playtime there and being being with her friends back home"* (the woman seems perfectly relaxed). Additional analysis of such digressions on our corpus are needed to know how strongly they are correlated with the decline. The reasons the classifier tagged the last 3 descriptions as *Decline* remained unclear. The Bayesian Networks learned for these instances are currently analyzed to understand which features deceived the classifier. The BN classifiers learned are probabilistic directed acyclic graphs which represent causal relations between variables. They can be displayed in a dedicated Graphical User Interface where values for different variables observed can be manually imposed to see the changes on the likelihood of the others unseen variables.

The 21 FNs can be separated in 3 groups: 2 patients whose primary diagnosis were AD, 11 whose primary diagnosis were MCIs and 8 normal patients but whose cognitive exams results (3 patients) or global CDR (5 patients) showed signs of decline.

Our corpus contains in total 7 cases of patients diagnosed with AD, 5 cases were correctly classified by the system and 2 incorrectly, making it fairly sensitives to strong signs of decline. The majority of the classifier's errors were made on light and mild impairments. In order to understand these errors we randomly selected 10 descriptions written by these patients and proceeded to a manual examination. A clear difference with the descriptions of the FPs is the absence of digressions. Only one description mentioned some implausible facts, others strictly described the image with most of its topics commented. 6 descriptions presented anomalies like misspellings, phrases repeated, verbs/auxiliaries missing, incomplete sentences or wrong choices of pronouns and, for 2 of them, a simplified syntax with unnatural constructions (*e.g. "A coulle having a picnic, the man with a book the girl pouring a soda."*). The 4 remaining descriptions exhibit a good quality and would be difficult to discriminate with linguistic features only.

5 Conclusion and Perspectives

With the general aging of the population more attention has been given to Alzheimer's disease. In this study we presented a NLP system to predict early signs of cognitive decline, which precedes the disease, based on the analysis of written descriptions of an image. To perform our experiments we created a corpus which is, to the best of our knowledge, unique by its nature and its size. With a final score of 86.1% Accuracy our system outperformed our baseline system and showed state-of-the-art performances with existing classifiers working on oral interviews. Our results suggest a correlation between abnormal cognitive decline and the dislocation of the language ability. Our ablation study revealed that our system discriminates patients with abnormal decline using lexical and semantical irregularities found in their writings, consolidating the hypothesis of a general pattern in the linguistic impairment already postulated in the literature. The analysis of its classification errors showed the limitation of our approach: the presence of linguistic irregularities are not always sufficient to diagnose abnormal decline and may not always be observed in writings of patients already diagnosed in abnormal decline. To overcome this limitation we are currently designing a classifier based on Conditional Random Fields. This classifier will integrate all information available about our patients (i.e. medical, cognitive, linguistic, and imaging information) and will allow the representation of the performances of the patients over the time.

Consensus Maximization Fusion of Probabilistic Information Extractors

Miguel Rodríguez and **Sean Goldberg** and **Daisy Zhe Wang**
University of Florida, Dept of Computer Science, Gainesville, FL, USA
{mer,sean,daisyw}@cise.ufl.edu

Abstract

Current approaches to Information Extraction (IE) are capable of extracting large amounts of facts with associated probabilities. Because no current IE system is perfect, complementary and conflicting facts are obtained when different systems are run over the same data. Knowledge Fusion (KF) is the problem of aggregating facts from different extractors. Existing methods approach KF using supervised learning or deep linguistic knowledge, which either lack sufficient data or are not robust enough. We propose a semi-supervised application of Consensus Maximization to the KF problem, using a combination of supervised and unsupervised models. Consensus Maximization Fusion (CM Fusion) is able to promote high quality facts and eliminate incorrect ones. We demonstrate the effectiveness of our system on the NIST Slot Filler Validation contest, which seeks to evaluate and aggregate multiple independent information extractors. Our system achieved the highest F1 score relative to other system submissions.

1 Introduction

The abundance of unstructured text on the web such as news, discussion forums, wiki pages, etc. has increased the interest of the research community in the automatic extraction of information at scale. Information extractors can be used to construct or expand Knowledge Bases (KBs) through a process known as Knowledge Base Population (KBP) or Construction. Facts in a KB are typically modeled as (`subject`, `relation`, `object`) triples such as (*Facebook*, *org:city_of_headquarters*, *Menlo Park*).

No current information extractor is perfectly accurate and different models exhibit different strengths and weaknesses. As a result, many state-of-the-art KBs in academia and industry employ multiple complementary information extractors for KBP. NELL(Mitchell and Fredkin, 2014) employs rules, statistically-learned pattern extractors, and context extractors among others. YAGO (Suchanek et al., 2007) uses heuristic extractors at text and ontological levels and Google has multiple extractors crawling text, tables, and HTML.

Different extraction systems may also agree or disagree on the information they extract. Consider three systems that extract the facts (*Facebook*, *org:city_of_headquarters*, *Menlo Park*), (*Facebook*, *org:city_of_headquarters*, *Palo Alto*), and (*Facebook*, *org:city_of_headquarters*, *Menlo Park*) with probabilities 0.6, 0.3, and 0.5 respectively. The *Palo Alto* extraction is erroneous and should be removed. The two *Menlo Park* extractions should be promoted by agreement and have their confidences increased.

The aggregation of facts from multiple extractors into a single probabilistic triple is known as Knowledge Fusion (KF) (Dong et al., 2014) and can be modeled as an ensemble learning problem. Previous ensemble approaches at the output layer divide into unsupervised and supervised methods (Gao et al., 2010). Unsupervised methods establish a consensus or *majority vote* among extractors without distinguishing the merit of each, but perform poorly if all the extractors are weak. Supervised methods such as *stacking* achieve better performance by learning weights for each extractor and combining them as a weighted sum. The difficulty in obtaining training

Proceedings of NAACL-HLT 2016, pages 1208–1216,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

data usually results in high precision, but low recall among all facts.

As a solution to the low recall problem we present a probabilistic ensemble fusion model based on Consensus Maximization (CM) (Gao et al., 2009), which is a semi-supervised learning method able to combine the strengths of both supervised and unsupervised approaches. In the knowledge fusion domain, where the number of unsupervised systems can be rather large compared to those with manually labeled data, Consensus Maximization Fusion is able to leverage both for improved performance.

We apply our CM Fusion approach to the NIST Slot Filling Validation (SFV) task, an ensemble learning problem that aims to combine multiple information extractors participating in the NIST English Slot Filling (ESF) task. Our experiments show an improved F1 score relative to the current state-of-the-art SFV systems.

We make the following overall contributions in this paper:

- Present a novel probabilistic fusion system that incorporates Consensus Maximization to solve the Knowledge Fusion problem.
- Develop an application of our system to the NIST Slot Filling Validation task.
- Outline an evaluation of our system that improves upon the previous state-of-the-art F1 score by 28%.

Though we choose to focus on the SFV task in this paper, there are clear applications beyond this and to the Knowledge Fusion problem in general. The remainder of this paper is organized as follows. In Section 2, we discuss background material on the ESF and SFV tasks as well as the Consensus Maximization algorithm. Section 3 outlines our CM Fusion system and how it maps into the knowledge fusion problem. Our experiments are detailed in Section 4 and we conclude in Section 5.

2 Background

Here we present the appropriate background knowledge on the English Slot Filling (ESF) and Slot Filling Validation (SFV) tasks that are part of the NIST Text Analysis Conference (TAC). We also introduce the Consensus Maximization framework that forms the foundation of CM Fusion.

2.1 Knowledge Base Construction: Slot Filling

A knowledge base is a repository of information about people, places, and things. The usual representation is as (`subject`, `relation`, `object`) triple. The subject and object are entities such as *Facebook* or *Menlo Park*. The relation is some property that holds between the subject and object and usually adheres to a fixed ontology such as *headquarters_in*. Knowledge Base population involves the generation of triples from unstructured text sources.

To facilitate and encourage further research into KBP, NIST has organized a series of workshops known as the Text Analysis Conference (TAC). The English Slot Filler (ESF) task involves connecting a (`subject`, `relation`, `*`) pair with a set of corresponding `object` attributes. Teams compete with each other to develop the best system for the job (Surdeanu and Ji, 2014).

Each team receives as input a set of queries in XML format and a text corpus. The queries are empty slots such (*Facebook*, *org:city_of_headquarters*, *) and the corpus is a formatted set of web pages, newswire, and discussion forums. For each query slot, the systems extract the appropriate attribute as either a single value or list of values or `NIL`. Overall evaluation is determined by final F1 score across all queries. Query evaluation occurs after submission by a team of human judges. Teams do not know their final accuracy at submission time.

2.2 Ensembling ESF: Slot Filling Validation

The massive quantity of data makes manual labeling impossible and thus system evaluation very difficult. A parallel TAC task is Slot Filling Validation (SFV), which aims to develop a meta-classifier for the purpose of validating individual systems. SFV systems receive as input the set of query results from each ESF system. Without any truth information, they must evaluate the evidence from each query and return a final slot value. The process of sorting conflicting and complementary information from different systems and aggregating into a unified KB is equivalent to the Knowledge Fusion problem.

Sys.	Slot Filler	Provenance	Prob
03_1	Menlo Park	D1:683-692	0.087
03_2	Menlo Park	D1:683-692	0.197
12_4	Menlo Park	D2:655-665	0.987
10_3	Menlo Park	D3:683-692	1.000
13_3	San Francisco	D4:974-986	1.000
07_4	San Francisco	D5:3534-3544	0.210
09_1	Chinatown	D6:3520-3529	0.200
16_1	California	D6:7250-7258	1.000
10_2	California	D7:263-267	1.000

Table 1: Slot fillers extracted by multiple systems for the query (*Facebook*, *org:city_of_headquarters*). The columns represent each system, their response, document provenance, and extracted probabilities.

Table 1 shows an example set of query results from different systems for the (*Facebook*, *org:city_of_headquarters*, *) slot. Included with the slot filler are provenance information about where the filler was mentioned in the corpus and the system's confidence probability.

As stated in the introduction, previous work in SFV has used majority voting (Sammons et al., 2014) or stacking (Viswanathan et al., 2015) to combine the output of multiple ESF systems. The lack of ground truth motivated the majority voting approach of (Sammons et al., 2014), which performs decently in precision and recall. Because of the annual nature of the TAC-KBP competition, some systems repeat submissions in successive years. While current truth data is not available, for a small number of systems there is data available from previous years on a different set of queries. (Viswanathan et al., 2015) uses those systems as training data in a stacking ensemble. Viewing each triple as a binary classification problem into true or false, they extract features based on the probabilities each ESF system gave to each fact (or 0.0 if they did not extract the fact) and train an L1-regularized SVM with a linear kernel. While this gives high precision, the lack of systems participating in multiple years leads to very low recall among all extracted facts.

2.3 Consensus Maximization

Consensus Maximization (Gao et al., 2009) is an ensemble learning method that merges both supervised and unsupervised learning models into a single cohesive framework. While unsupervised models don't provide class labels, they do provide constraints that reduce the hypothesis space of the overall learning problem. Examples in the same cluster are likely to receive the same class label and may improve prediction accuracy through increased model diversity.

Like majority voting and stacking, CM operates at the output level of each individual model and aims to predict the conditional probabilities of each example belonging to each class. By providing class labels, supervised models naturally partition the example space into groups and give those groups labels. Unsupervised models do the same partitioning, but cannot label the groups. Using the supervised methods and their examples as a starting point, CM propagates labels to other unsupervised clusters containing the same examples and to other examples within those clusters.

Formally, the framework of Consensus Maximization is a constrained optimization problem over a bipartite graph. The two sets of nodes are object nodes and group nodes. Each Object node represents a single example given to each system for classification/clustering. Group nodes represent within-system partitions. There are as many partitions as there are classes. For c classes and m systems, there will be $v = cm$ total groups.

The conditional probabilities are expressed in the form of matrices $U_{n\times c}$ for objects and $Q_{v\times c}$ for groups, where rows are object or group nodes from the graph and columns are classes. Rows or columns of the matrix are denoted with the vector $\vec{u_i}$ or $\vec{q_i}$. Each element $u_{iz} \in U_{n\times c}$ represents the conditional probability of object i belonging to class z. Similarly, each element $q_{jz} \in Q_{n\times v}$ represents the conditional probability of group j belong class z as shown in the following equations:

$$u_{iz} = P(y = z|x_i) \tag{1}$$

$$q_{jz} = P(y = z|g_i) \tag{2}$$

The adjacency matrix of the bipartite graph is represented by $A_{n\times v}$ where $a_{ij} = 1$ when x_i has been assigned to group g_j by its respective model, or 0 otherwise. Initial group label assignments are provided by supervised models and encoded in the matrix $Y_{v \times c}$, where $y_{jz} = 1$ if the group g_j comes from supervised learning and belongs to class z, or 0 otherwise. The sum of the rows of Y determines if a group node belongs to a supervised or unsupervised model. Let $k_j = \sum_{z=1}^{c} y_{jz}$ binarily represent such scenario. Note that $k_j = 0$ when there is no supervised evidence for group j. The consensus among models is formulated as the following optimization problem:

$$\begin{aligned} \min_{Q,U} (& \sum_{i=1}^{n} \sum_{j=1}^{v} a_{ij} \parallel \vec{u_i} - \vec{q_j} \parallel^2 \\ & + \alpha \sum_{j=1}^{v} k_j \parallel \vec{q_j} - \vec{y_j} \parallel^2 \\ & + \beta \sum_{i=1}^{n} h_i \parallel \vec{u_i} - \vec{f_i} \parallel^2) \\ s.t & \\ & \vec{u_i} \geq \vec{0}, \mid \vec{u_i} \mid = 1, i = 1, \ldots, n \\ & \vec{q_j} \geq \vec{0}, \mid \vec{q_j} \mid = 1, j = 1, \ldots, v \end{aligned} \tag{3}$$

The first term finds consensus across models by minimizing the deviation between the conditional probability of object i in the vector $\vec{u_i}$, and the conditional probability of the groups, $\vec{u_j}$, where it has been originally assigned by the input models. The second term penalizes deviations of the group probability $\vec{q_j}$ from its initial assignment $\vec{y_j}$, with α being the penalization factor that has to be paid for violating supervised predictions. Consensus Maximization does not require labeled objects to estimate the probability matrices Q and U. Nevertheless, a small amount known labels can help bias the optimization and improve the model. If l objects have known labels, the matrix $F_{n \times c}$ encodes this information such that $f_{iz} = 1$ when x_i's true label is z and 0 otherwise. In this matrix, i is the index of an object node, and z a class label. The sum of rows in F determine if an object has a label assigned, $h_i = \sum_{z=1}^{c} f_{iz}$. For instance, $\vec{f_i} = \vec{0}$ represents an objects without labeled data. The third term in the objective function penalizes deviations of the conditional probability of an object $\vec{u_i}$ from its known label $\vec{f_i}$; when $h_i = 0$ this term is dismissed. Labeled variables incorporated in CM are not final. The value of β is the penalization factor for violating label constraints. For a fuller treatment of the methodology, see (Gao et al., 2009).

3 Consensus Maximization Fusion

In this section we describe the ensemble CM Fusion system we built for combining multiple information extractors. Similar to (Viswanathan et al., 2015), we view the slot filling problem in terms of a binary classification task. The set of all extractions across all systems produce an initial knowledge base of facts. This KB is noisy and redundant and contains a lot of conflicting and complementary evidence. For each fact in the KB, we fuse decisions coming from each system into a true class and a false class.

Figure 1 shows the architecture of the system. Offline all individual extractors operate over the same corpus and produce their extractions. A preprocessing step canonicalizes strings and clusters systems producing the same extraction. The feature extraction step converts set of probabilities about each system's fact into the unsupervised feature vector. For the systems for which previous years evaluation data is available we train 6 different meta-classifiers. Their decisions on the same corpus comprise the supervised feature vector. The supervised and unsupervised data are passed into the consensus maximization component that produces a final aggregated probability for each value. As part of a final cleaning process, constraints are applied that remove certain mutually exclusive conflicting facts.

For the remainder of this section we describe each component of our Consensus Maximization Fusion system in more detail.

3.1 Preprocessing

Our system takes as input extractions produced using a number of information extractors that differ in their methodology and application. Their output is uniform and their "filled slots" correspond to a set of extracted facts. Each fact is processed by transforming all text into lower case and deleting trailing spaces. Using exact string match we map each fact onto a cluster of the multiple systems that extracted it.

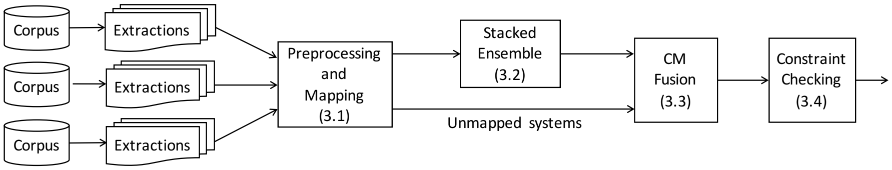

Figure 1: Consensus Maximization Fusion system components and pipeline.

3.2 Stacked Ensemble

Consensus Maximization Fusion is able to take into account supervised and unsupervised systems for knowledge fusion. The supervised portion is able to weight certain systems using previously labeled data and combine their decisions into a meta-classifier. The unsupervised portion operating over unlabeled data treats every system equally and is closer in spirit to a majority vote.

Of the extractors submitting results to ESF, about 10% had participated in previous years where labeled data was available. This idea was used in (Viswanathan et al., 2015) to generate a series meta-classifiers using stacking. A meta-classifier combines the outputs of multiple systems using learned weights. (Viswanathan et al., 2015) generate a total of 6 meta-classifiers for comparison that differ in classifier type and feature vector. The basic feature vector includes one entry for each system and with the value being that system's extraction probability. Two additional feature vectors were generated by adding relational information for each system and both relational information and provenance information. These three feature vectors were independently trained using logistic regression (LR) and SVM for a total of 6 meta-classifiers. CM Fusion runs each trained meta-classifier over the same ESF corpus and uses their output as an additional 6 systems in the ensemble combination. Though we use only 6 our method generalizes to any number of meta-classifiers.

3.3 Fusing Systems

In total there are S systems submitting runs to be ensemble by CM Fusion. N of these systems have evaluation data for the training a total of M meta-classifiers. The top half of Figure 2 shows the collection of supervised meta-classifiers and remaining unsupervised systems.

Symbol	Definition
$o_1, ..., o_k$	Unique facts extracted
$g_1, ..., g_{2m}$	Group nodes from meta-classifiers
$g_{2m+1}, ..., g_t$	Group nodes from unmapped runs
$A = [a_{ij}]$	Indicator of fact i in group j
$U = \vec{u_i}$	Conditional prob of $o_i = true$
$Q = \vec{q_i}$	Indicator of unmapped run $g_i = yes$
$Y = \vec{y_j}$	Indicator of meta-classifier $g_j = yes$
$F = \vec{f_i}$	o_i label if known a priori

Table 2: CM Fusion notations mapped to the SFV task.

Consensus Maximization operates as a bipartite graph between object nodes representing examples to classify and group nodes representing classes within each system. In the knowledge fusion domain, each object node pertains to a specific fact triple under consideration. The two classes for each system (*Yes*/*No*) all combined represent the set of group nodes. The translation component of CM Fusion generates the bipartite graph in Figure 2 as input to the consensus maximization component.

The overall goal of consensus maximization is to combine labeled predictions from the M supervised meta-classifiers and consensus predictions from the unsupervised systems using a constrained optimization framework. As recalled in Section 2, CM optimizes U and Q, which are conditional probabilities between object nodes (facts) and classes (*Yes*/*No*) and between group nodes (output classes for each system) and classes (*Yes*/*No*) respectively. Because we are only interested in the *Yes* class probabilities, the matrices collapse into vectors $\vec{u}$ and $\vec{q}$ as per equation 3. $\vec{u_i}$ is initialized as an uninformed prior with value 0.5 for each object node. Since unsupervised output labels are known a priori, $\vec{q_j}$ remains unchanged in the optimization process and encodes the pertinence of each group node j to a *Yes*/*No* class. Finally $\vec{y_j}$ includes the supervised meta-classifier output for each group. Running the

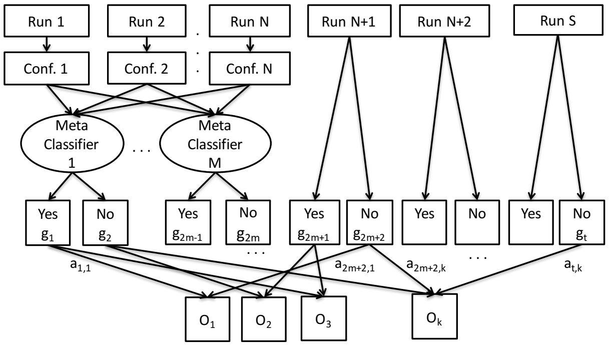

Figure 2: CM Bipartite graph for SFV. Object nodes correspond to facts. Each of S systems partition facts into *Yes* or *No* classes, which act as groups in CM translation.

optimization program generates a final $\vec{u_i}$ that gives a posterior probability for each fact. Table 2 maps all CM symbols in equation 3 to their corresponding elements in the SFV problem definition.

3.4 Enforced Constraints

After applying consensus maximization, there may be some facts that can be eliminated using functionality constraints. A slot is functional when it has only one possible value for its filler. Functional slots with different fillers may have certain facts eliminated based on mutual exclusion. As an example, consider the various slot filler responses in Table 1. An organization can only have its headquarters in one city at any given time. In this case *Menlo Park* should be chosen based on it having the maximum probability and all other facts eliminated. When the extraction probability is the same for multiple systems, one of the extractions is chosen at random. Nevertheless, this is hardly ever the case.

4 Experiments

We evaluate our system using a collection of queries supplied by TAC-KBP SFV. In this section we more fully describe the dataset and our experiment methodology. We compare to the current state-of-the-art ESF and SFV systems and show an improvement in F1 score. Finally, we provide an analysis of our results.

4.1 Datasets

Three datasets were used for training and testing spread across the three years that the English Slot Filling task has been run. Each team in the competition submits multiple models vying for the highest score on unseen training data. Each submission is viewed as a different system in our ensemble. 2013 contains 52 systems. 2014 contains 65 and 2015 contains 69. In 2013 and 2014 we use only ESF data, but 2015 adds Cold Start Knowledge Base (CSKB) data. The total number of labeled queries in both 2013 and 2014 were 100 each. 2015 had 9340 unlabeled queries. In addition, 2015 had 164 labeled queries supplied for initial system assessment that was incorporated into the training data for 2015 submissions.

We performed two distinct experiments and compared multiple baselines for each. Table 3 shows results where we trained on 2013 only and tested on 2014 data only. Table 4 results are for training on 2013 and 2014 data and testing on 2015 data.

4.2 0-Hop and 1-Hop Queries

The 2015 ESF task introduced more complex queries into the fold. 1-hop queries use the result of a previous query to answer a new query. For example, consider a query asking for all companies headquartered in the same city as Facebook. The equivalent 1-hop query is (*Facebook*, *org:city_of_headquarters*, *?x*), (*?x*, *gpe:headquarters_in_city*, *). The second part of the query can be seen as a join to the first part using a common answer in both. The terminology exploits the idea of "hopping" from one query to another. By contrast, a regular slot filling task is a 0-hop query.

4.3 Evaluation

All systems were evaluated using the standard metrics of precision, recall, and F1 which is the harmonic mean of precision and recall. Precision is the amount of correctly extracted facts compared to the total facts extracted by the system. Recall is the amount of correct facts compared all facts in the ground truth. In review:

$$Recall(R) = \frac{\text{Correct}}{\text{Total}} \tag{4}$$

$$Precision(P) = \frac{\text{Correct}}{\text{Extracted}} \tag{5}$$

$$F1 = 2\frac{PR}{P+R} \tag{6}$$

Method	P	R	F1
LR	0.648	0.335	0.441
LR + REL	0.662	0.343	0.452
LR + PROV + REL	0.634	0.374	0.470
SVM	0.639	0.319	0.425
SVM + REL	0.720	0.299	0.422
SVM + PROV + REL	**0.729**	0.298	0.423
MV	0.467	0.447	0.457
Stanford	0.585	0.298	0.395
CM Fusion	0.549	**0.538**	**0.544**

Table 3: Result comparisons for the testing on the 2014 SFV task with training done on 2013 ESF data. The first 6 methods correspond to stacking while the others correspond to majority vote, the best performing 2014 ESF system, and CM Fusion. By increasing recall, CM Fusion has the highest F1 among all baselines.

The 0-hop queries are scored trivially on the correctness of the slot filler. The 1-hop queries require two verifications to undergo scoring. The 0-hop query from which it was derived must both exist and be correct. Any slot fillers that don't meet this criteria are omitted even if their 1-hop slot was ultimately correct. For example, the 1-hop extraction (*Palo Alto*, *gpe:headquarters_in_city*, *Hewlett-Packard*) will be ignored even though it is correct because the 0-hop query (*Facebook*, *gpe:city_of_headquarters*, *Palo Alto*) that derives it is incorrect (Facebook is headquarted in Menlo Park).

4.4 Results

Table 3 shows results using 2013 ESF systems as training data for the meta-classifiers and 2014 ESF systems as testing data. The first 6 rows are a combination of classifiers and feature vectors using stacking as described in (Viswanathan et al., 2015). MV refers to the majority voting described (Sammons et al., 2014). Majority voting accepts a fact if a certain number of systems above some learned threshold have extracted it. Both of these systems showcased results on the 2014 SFV task. The Stanford system (Angeli et al., 2014) was the best performing ESF system during the 2014 competition. The final row is our CM Fusion algorithm. Only 0-hop queries are used for these results.

Table 4 showcases two of the three runs we officially submitted as part of the recent 2015 SFV task for different query types. For each query, the first two rows refer to our CM Fusion system with different training data and the final row the best performing 2015 ESF system for that particular query type. 2015 results are not officially published yet for either ESF or SFV. Nevertheless, at 2015 workshop announcing the results, CM Fusion was awarded as the top ranked SFV system by F1 score.

	P	R	F1	Queries
2013 & 2014	**0.528**	0.481	0.504	0-Hop
2014 only	0.477	**0.539**	**0.506**	
BBN	0.493	0.391	0.436	
2013 & 2014	**0.393**	0.097	0.155	1-Hop
2014 only	0.314	0.141	0.194	
Stanford	0.184	**0.304**	**0.229**	
2013 & 2014	**0.503**	0.307	0.381	ALL
2014 only	0.436	**0.358**	**0.393**	
BBN	0.378	0.261	0.309	

Table 4: Summary of submissions to the SFV 2015 task for different query types. We trained the meta-classifiers on 2014 ESF data or 2013 and 2014 ESF data. Comparison is made to the highest scoring individual ESF system by F1.

4.5 Analysis

The main drawback between previous ensemble systems that utilize only supervised systems is high precision, but very low recall. This is evidenced in the disproportion between precision and recall in the first 6 systems of Table 3. Majority voting, while learning a threshold using supervision, does include some unsupervised consensus.

The main idea behind CM Fusion is to take into account the answers from potentially well-ranked extractors that stacking meta-classifiers omit due lack of training data. CM Fusion outperforms both approaches in terms of F1 by greatly increasing the recall while maintaining high precision. It also produces better results than the best performing 2014 ESF system. On 2015 data in Table 4, both systems outperform the best performing 2015 ESF system.

The benefit of using CM Fusion over other supervised ensemble models is the ability to use unsupervised systems that lack sufficient training data. When these systems agree on extractions, their consensus can be a source of discriminative power which CM Fusion is able to harness. For our submis-

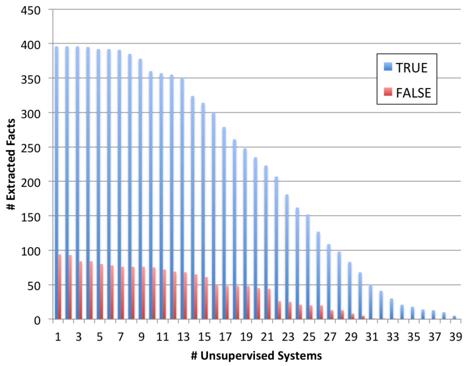

Figure 3: Extracted facts among unsupervised systems that agree with at least one supervised system using 2015 queries. The x-axis shows the minimum number of systems used for consensus.

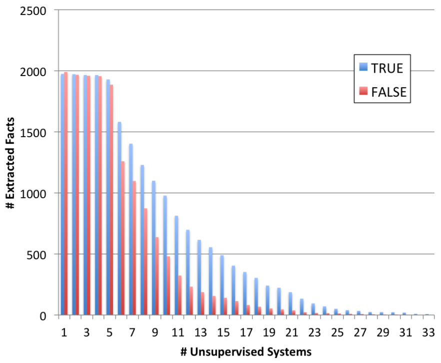

Figure 4: Extracted facts among unsupervised systems using 2015 queries using only unsupervised consensus. The x-axis shows the minimum number of systems used for consensus. The scale is larger than Figure 3 because agreement with a supervised system is not needed.

sion trained only on 2014 ESF data, Figures 3 and 4 break down the difference between extracted facts derivable only from supervised systems and those able to be attained from unsupervised systems.

Specifically, Figure 3 measures the number of extracted facts supported by a consensus of the number of systems on the x-axis that also agree with the output of a supervised system. Blue bars represent the amount of correct extractions and red bars incorrect extractions. When only supervision is used there is good precision across the board. Figure 4 shows the number of extracted facts supported only by a consensus of systems on the x-axis without any supervision. The disparity in the scale of facts extracted supports the recall of supervised systems. When only a few systems agree on an extraction, about as many good facts are extracted as bad ones. As consensus increases, precision greatly improves. This idea of unsupervised consensus is exactly what improves CM Fusion over supervised ensemble approaches.

To understand the impact of the number of unsupervised systems fused and the quality of the fused runs in the ensemble, we applied CM Fusion in an incremental fashion by adding one unsupervised system at a time and scored the produced ensemble at each step. Techniques for ranking unsupervised systems are outside the scope of this work, for simplicity we examine the best- and worst-cases for adding systems incrementally. Ranking each unsupervised system by its final individual F1 score on the SFV 2015 data, we ran CM Fusion adding the best performing run (CMF-BEST) and worst performing run (CMF-WORST) at each step. The results are displayed in Figure 5. For comparison, we also included the results of the best performing ESF system (BBN-F1) and the score of a supervised-only ensemble (SUP-ONLY). Fusing unsupervised systems with lower accuracy negatively affects the quality of the ensemble compared to supervised-only. When ensembleing very similar runs, such as runs submitted by the same team, the diversity of the systems is compromised and may lower the ensemble quality. On the other hand, unsupervised systems with higher accuracy can rapidly increase the quality of the ensemble above the best individual results and reach the highest ensemble score. Nevertheless, more does not necessarily mean better, as shown in the plateau of the best-case plot in Figure 5, when noisy systems are added to the ensemble the F1 score is maintained. The average case would lie somewhere in between the extremes of the best- and worst-case. As is shown, a large number of systems are extremely error-prone, but the combination using CM Fusion produces a result ultimately superior.

5 Conclusions

This paper presented our Consensus Maximization Fusion of multiple probabilistic information extractors. This approach combines supervised stacking

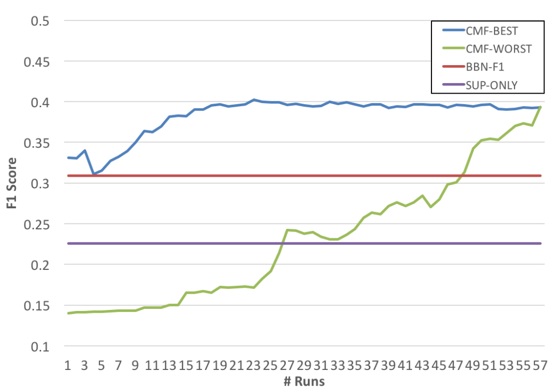

Figure 5: Incremental CM Fusion in terms of adding best-performing (blue) and worst-performing (green) systems one-by-one. Performance is ranked by F1 scores from the 2015 SFV dataset. F1 scores are in the range $[0.03 - 0.309]$ with an average F1 of 0.140

meta-classifiers with unsupervised extraction outputs in an ensemble classifier. Our system outperformed the current state-of-the-art ensemble models submitted to the TAC-KBP Slot Filler Validation task in 2014. CM Fusion was also chosen as the leading system at the 2015 TAC-KBP Workshop. This is the first cross-model ensemble approach that fuses multiple knowledge graphs obtained from both supervised and unsupervised information extractors. Optimal performance is attained when the extractors represent different systems running over the same corpus and the shared extraction density is high.

The canonicalization of facts in CM Fusion represents a new state-of-the-art contribution to entity-centric information extraction compared to traditional document-centric approaches. While our approach has been experimentally verified using TAC-KBP data, it generalizes to overlapping ensemble of knowledge bases. Some such as NELL (Mitchell and Fredkin, 2014) have a small supervised human feedback component and others such as OpenIE (Banko et al., 2007) are entirely unsupervised. Future work concerns using CM Fusion to to align and canonicalize multiple such knowledge bases to solve the knowledge fusion problem.

Abstract

We present a simple algorithm to efficiently train language models with noise-contrastive estimation (NCE) on graphics processing units (GPUs). Our NCE-trained language models achieve significantly lower perplexity on the One Billion Word Benchmark language modeling challenge, and contain one sixth of the parameters in the best single model in Chelba et al. (2013). When incorporated into a strong Arabic-English machine translation system they give a strong boost in translation quality. We release a toolkit so that others may also train large-scale, large vocabulary LSTM language models with NCE, parallelizing computation across multiple GPUs.

1 Introduction

Language models are used to compute probabilities of sequences of words. They are crucial for good performance in tasks like machine translation, speech recognition, and spelling correction. They can be classified into two categories: count-based and continuous-space language models. The language modeling literature abounds with successful approaches for learning-count based language models: modified Kneser-Ney smoothing, Jelinek-Mercer smoothing, etc. In recent years, continuous-space language models such as feed-forward neural probabilistic language models (NPLMs) and recurrent neural network language models (RNNs)[1] have outperformed their count-based counterparts (Chelba et al., 2013; Zaremba et al., 2014; Mikolov, 2012). RNNs are more powerful than n-gram language models, as they can exploit longer word contexts to predict words. Long short-term memory language models (LSTMs) are a class of RNNs that have been designed to model long histories and are easier to train than standard RNNs. LSTMs are currently the best performing language models on the Penn Treebank (PTB) dataset (Zaremba et al., 2014).

The most common method for training LSTMs, maximum likelihood estimation (MLE), is prohibitively expensive for large vocabularies, as it involves time-intensive matrix-matrix multiplications. Noise-contrastive estimation (NCE) has been a successful alternative to train continuous space language models with large vocabularies (Mnih and Teh, 2012; Vaswani et al., 2013). However, NCE in its standard form is not suitable for GPUs, as the computations are not amenable to dense matrix operations. In this paper, we present a natural modification to the NCE objective function for language modeling that allows a very efficient GPU implementation. Using our new objective, we train large multi-layer LSTMs on the One Billion Word benchmark (Chelba et al., 2013), with its full 780k word vocabulary. We achieve significantly lower perplexities with a single model, while using only a sixth of the parameters of a very strong baseline model (Chelba et al., 2013). We release our toolkit[2] to allow researchers to train large-scale, large-vocabulary LSTMs with NCE. The contributions in this paper are the following:

*Equal contribution.

[1] Henceforth we will use terms like "RNN" and "LSTM" with the understanding that we are referring to language models that use these formalisms

- A fast and simple approach for handling large vocabularies effectively on the GPU.
- Significantly improved perplexities (43.2) on the One Billion Word benchmark over Chelba et al. (2013)
- Extrinsic machine translation improvement over a strong baseline.
- Fast decoding times because in practice there is no need to normalize.

2 Long Short Term Memory Language Models

In recent years, LSTMs (Hochreiter and Schmidhuber, 1997) have achieved state-of-the-art performance in many natural language tasks such as language modeling (Zaremba et al., 2014) and statistical machine translation (Sutskever et al., 2014; Luong et al., 2015). LSTMs were designed to have longer memories than standard RNNs, allowing them to exploit more context to make predictions. To compute word probabilities, the LSTM reads words left-to-right, updating its memory after each word and producing a hidden state h, which summarizes all of the history. For details on the architecture and computations of the LSTM, the reader can refer to (Zaremba et al., 2014). In this model the probability of word w given history $\mathbf{u}$ is

$$P(w \mid \mathbf{u}) = \frac{p(w \mid \mathbf{u})}{\mathbf{Z}(\mathbf{u})}, \qquad (1)$$

where $p(w \mid \mathbf{u}) = \exp D_w h^T + b_w$ is an unnormalized probability. D_w and b_w are the output word embedding and biases respectively, which are learned during training. The normalization constant is $\mathbf{Z}(u) = \sum_{w \in V} p(w \mid \mathbf{u})$, and V is the vocabulary.

3 Noise Contrastive Estimation For Training Neural Language Models

The standard approach for estimating neural language models is maximum liklelihood estimation (MLE), where we learn the parameters θ^* that maximize the likelihood of the training data,

$$\theta^* = arg\ max_\theta \sum_{w,\mathbf{u}} \log P(w \mid \mathbf{u}; \theta) \qquad (2)$$

However, for each training instance, gradient-based approaches for MLE require a summation over all units in the output layer, one for each word in V. This makes MLE training infeasible for large vocabularies.

Noise-contrastive estimation (NCE) (Gutmann and Hyvärinen, 2010) has been successfully adopted for training neural language models with large vocabularies (Mnih and Teh, 2012; Vaswani et al., 2013; Baltescu and Blunsom, 2014; Williams et al., 2015). NCE avoids repeated summations by training the model to correctly classify between generated noise samples and words observed in the training data. For each training pair $\mathbf{u}_i, w_i$, we generate k noise samples, $\bar{w}_{i1} \ldots, \bar{w}_{ik}$ from a noise distribution $q(w)$, which is known. We label $\mathbf{u}_i, w_i$ as true ($C = 1$), and all $\mathbf{u}_i, \bar{w}_{ik}$ as false ($C = 0$). We then train the parameters to maximize the binary classification log likelihood,

$$\begin{aligned}\mathbf{L} = \sum_i \Big(&\log P(C = 1 \mid \mathbf{u}_i, w_i) + \\ &\sum_k \log P(C = 0 \mid \mathbf{u}, \bar{w}_{ik}) \Big),\end{aligned} \qquad (3)$$

where

$$P(C = 1 \mid w, \mathbf{u}) = \frac{\frac{p(w|\mathbf{u})}{\mathbf{Z}(\mathbf{u})}}{\frac{p(w|\mathbf{u})}{\mathbf{Z}(\mathbf{u})} + k \cdot q(w)}, \qquad (4)$$

and $P(C = 0 \mid w, \mathbf{u}) = 1 - P(C = 1 \mid w, \mathbf{u})$.

We learn parameters to maximize this objective with gradient ascent. In NCE, we treat $\mathbf{Z}(\mathbf{u})$ as another parameter and learn its estimate along with the rest of the parameters. Following Mnih and Teh (2012) and Vaswani et al. (2013), we freeze $\mathbf{Z}(\mathbf{u})$ to 1 and the model learns to approximately satisfy the constraint. In practice, we find that our mean for $\mathbf{Z}(\mathbf{u})$ is very close to 1 and the variance is quite small (Section 6). For each training instance, we compute gradients for the observed word and each noise word, reducing the time complexity from $\mathcal{O}(|V|)$ for MLE to $\mathcal{O}(k)$. However, unlike MLE, since we typically sample different noise samples for each training instance, our gradient computations for the NCE objective are not amenable to dense matrix operations, making it difficult to benefit from fast dense matrix arithmetic on GPUs. In this paper, we present a simple solution to this problem: sharing the noise samples across all the training instances in a minibatch. Sharing noise samples allows us to describe NCE gradients with dense matrix operations, and implement them easily on the GPU. In the next section, we describe our NCE implementation on the GPU with shared noise samples.

4 Our NCE Modification

In typical Noise-Contrastive Estimation, the objective function requires noise samples coming from some distribution (in our case, the uniform distribution). The objective function for NCE is shown above in Equation 3, where we must calculate $P(C = 1 \mid w, \mathbf{u})$ for the true word and the noise samples generated. There are three components to this calculation: $p(w \mid \mathbf{u})$, $\mathbf{Z}(\mathbf{u})$, and $k \cdot q(w)$. In NCE we fix $\mathbf{Z}(\mathbf{u})$ to be one, so we only need to calculate $p(w \mid \mathbf{u})$ and $k \cdot q(w)$. The term $k \cdot q(w)$ is simply an $O(1)$ lookup, so the only costly operation is computing $p(w \mid \mathbf{u})$ for all k noise samples and the true word. The operation to compute $p(w \mid \mathbf{u})$ for a single word w is $\exp D_w h^T + b_w$ where D_w and b_w represent the word embedding and bias corresponding to the word we are computing it for.

The main cost in calculating the NCE objective function is computing $\exp D_w h^T + b_w$, where in normal NCE a dense matrix multiplication cannot be done. The reason is that the noise samples generated per training example will be different. Therefore, when we parallelize our algorithm by running multiple training examples in parallel (a minibatch), the D_w we need are different per h^T that we are running in parallel. If a constraint is set such that the noise samples must be the same across all training examples in the minibatch, then a matrix multiplication can be done to compute $\exp D_w h^T + b_w$ for all words across that minibatch. This matrix multiplication is $D h_M^T$, where h_M^T is now a matrix of all the hidden states being used in parallel, whereas before h_T was just a vector. Additionally, D is the matrix of word embedding for the samples that are being shared across a minibatch. Before, this was not possible as the D matrix would have to be much larger, being (minibatch size) $\cdot$ (k + 1) in size, making the algorithm run much slower. An alternative is to not restrict the noise samples to be the same, but then we must use a sparse matrix multiplication as in Williams et al. (2015), which is neither as fast nor as easy to implement. A comparison between these two approaches is shown in Figure 1. We find that sharing noise samples across the minibatch gives us significant speedups over a baseline of using different noise samples for each word in the minibatch. These timings were calculated for a single layer LSTM with 1000 hidden units, a vocabulary of $350k$, and a minibatch of 128. Not surprisingly, MLE is quite expensive, limiting it's use for large vocabularies. Additionally, the memory requirements for NCE are much lower than MLE, since we do not need to store the gradient which has the same size as the output embedding matrix. For this MLE run, we had to distribute the computation across two GPUs because of memory limitations.

5 Experiments

We conducted two series of experiments to validate the efficiency of our approach and the quality of the models we learned using it: An *intrinsic* study of language model perplexity using the standard One Billion Word benchmark (Chelba et al., 2013) and an *extrinsic* end-to-end statistical machine translation task that uses an LSTM as one of several feature functions in re-ranking. Both experiments achieve excellent results.

5.1 Language Modeling

For our language modeling experiment we use the One Billion Word benchmark proposed by Chelba et al. (2013). In this task there are roughly 0.8 billion words of training data. We use perplexity to evaluate the quality of language models we train on this data. We train an LSTM with 4 layers, where each layer has 2048 hidden units, with a target vocabulary size of 793,471. For training, we also use dropout to prevent overfitting. We follow Zaremba et al. (2014) for dropout locations, and we use a dropout rate of 0.2. The training is parallelized across 4 GPUs, such that each layer lies on its own GPU and communicates its activations to the next layer once it finishes its computation.

5.2 Statistical Machine Translation

We incorporate our LSTM as a rescoring feature on top of the output of a strong Arabic-English syntax-based string-to-tree statistical machine translation system (Galley et al., 2006; Galley et al., 2004). That system is trained on 208 million words of parallel Arabic-English data from a variety of sources, much of which is Egyptian discussion forum content. The Arabic side is morphologically segmented with MADA-ARZ (Habash et al., 2013). We use a standard set of features, including two conventional count-based language models, as well as thousands of sparsely-occurring, lexicalized syntactic features (Chiang et al., 2009). The system additionally uses a source-to-target feed-forward neural network translation model during decoding, analogous to the model of (Devlin et al., 2014). These features are tuned with MIRA (Chiang et al., 2009) on approximately 63,000 words of Arabic discussion forum text, along with three references. We evaluate this baseline on two test sets, each with approximately 34,000 words from the same genre used in tuning.

We generate n-best lists ($n = 1000$) of unique translations for each sentence in the tuning set and re-rank the translations using an approach based on MERT (Och, 2003). We collapse all features other than language models, text length, and derivation size into a single feature, formed by taking the dot product of the previously learned feature and weight vectors. We then run a single iteration of MERT on the n-best lists to determine optimal weights for the collapsed feature, the uncollapsed features, and an LSTM feature formed by taking the score of the hypothesis according to the LSTM described in Section 5.1. We use the weights to rerank hypotheses from the n-best lists of the two test sets. We repeated this experiment, substituting instead a two-layer LSTM trained on the English side of the training data.

6 Results

Our two experiments with LSTMs trained with our modification of NCE show strong results in their corresponding tasks.

Our perplexity results are shown in Table 1, where we get significantly lower perplexities than the best single model from Chelba et al. (2013), while having almost 6 times fewer parameters. We also compute the partition function values, $\log\big(Z(\mathbf{u})\big)$, for our development set and we find that the mean is 0.058 and the variance is 0.139, indicating that training has encouraged self-normalization.

Model	Parameters	Perplexity
Chelba et al. (2013)	20m	51.3
NCE (ours)	3.4m	43.2

Table 1: For the One Billion Word Benchmark, our NCE method performs significantly better than the best single model in the baseline, Chelba et al. (2013), while using many fewer parameters.

Recently, (Józefowicz et al., 2016) achieved state-of-the-art language modeling perplexities (30.0) on the billion word dataset with a single model, using importance sampling to approximate the normalization constant, $\mathbf{Z}(\mathbf{u})$.

Independent of our work, they also share noise samples across the minibatch. However, they use 8192 noise samples, while we achieve strong perplexities with 100 noise samples. We also show significant improvements in machine translation, exploiting self-normalization for fast decoding, in addition to releasing a efficient toolkit that practitioners can use.

Table 2 shows our re-scoring experiments. When we incorporate only the LSTM trained on the BOLT dataset we get a +1.1 BLEU improvement on Tune, +1.4 on Test 1, and +1.1 on Test 2. When we also incorporate the LSTM trained on the One Billion Word dataset as a feature, we see another +0.2 BLEU increase on Tune and Test 2. In these re-scoring experiments we simply use the un-normalized numerator $p(w \mid \mathbf{u})$ as our word score, which means we never have to compute the costly partition function, $\mathbf{Z}(u)$. This is because the partition function is so close to 1 that the un-normalized

System	Tune	Test 1	Test 2
Baseline SMT	38.7	38.9	39.7
LSTM (BOLT)	39.8	40.3	40.8
LSTM (1b+BOLT)	40.0	40.3	41.0

Table 2: Our NCE-based language model successfully re-ranks Arabic-to-English n-best lists. The baseline is a state-of-the-art, statistical string-to-tree system. BOLT is a 208m-word, in-domain English corpus; “1b” refers to the One Billion Word benchmark corpus.

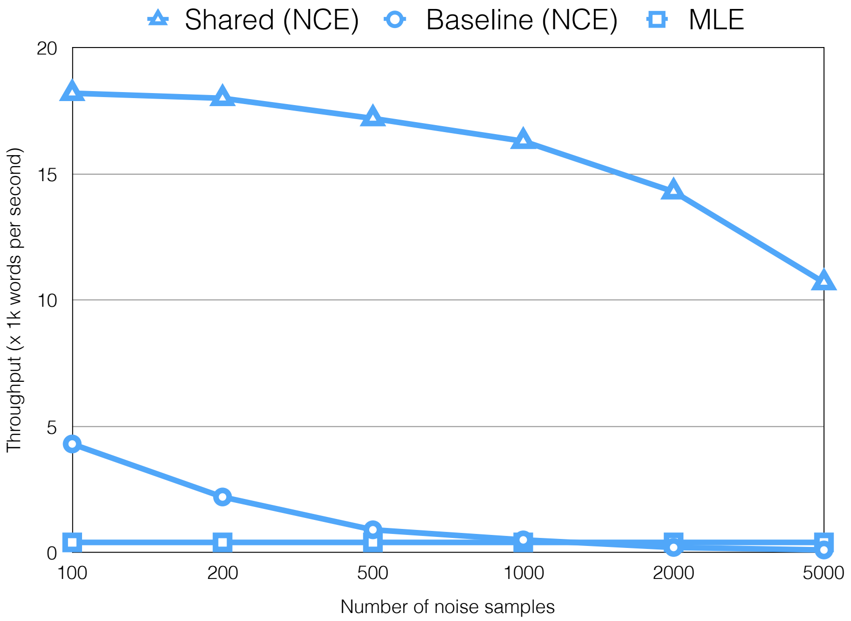

Figure 1: Sharing noise samples across the minibatch is at least 4 times faster than a baseline of not sharing them.

scores are very close to the normalized ones.

7 Conclusion

We describe a natural extension to NCE that achieves a large speedup on the GPU while also achieving good empirical results. LSTM models trained with our NCE modification achieve strong results on the One Billion Word dataset. Additionally, we get good BLEU gains when re-ranking n-best lists from a strong string-to-tree machine translation system. We also release an efficient toolkit for training LSTM language models with NCE.

Abstract

A simile is a figure of speech comparing two fundamentally different things. Sometimes, a simile will explain the basis of a comparison by explicitly mentioning a shared property. For example, *"my room is as cold as Antarctica"* gives "cold" as the property shared by the room and Antarctica. But most similes do not give an explicit property (e.g., *"my room feels like Antarctica"*) leaving the reader to infer that the room is cold. We tackle the problem of automatically inferring implicit properties evoked by similes. Our approach involves three steps: (1) generating candidate properties from different sources, (2) evaluating properties based on the influence of multiple simile components, and (3) aggregated ranking of the properties. We also present an analysis showing that the difficulty of inferring an implicit property for a simile correlates with its *interpretive diversity*.

1 Introduction

A simile is a figure of speech comparing two essentially unlike things, typically using "like" or "as" (Paul, 1970). Comparing fundamentally different types of entities is what makes a simile figurative (Israel et al., 2004). Similes may be *closed* or *open* (Beardsley, 1981). A *closed* simile explains the basis for a comparison by explicitly mentioning a shared property. For example, the simile *"my room is as cold as Antarctica"* gives "cold" as the property shared by both the room and Antarctica. But most similes do not explicitly mention the basis for comparison, leaving people to infer what the entities have in common. An *open* simile expressing the same comparison is *"my room feels like Antarctica"*, where the shared property of being cold is left implicit. In our study of similes in tweets, we found that 92% of similes are open similes so the property must be inferred. Our research tackles this problem of inferring the implicit property evoked by an open simile.

Inferring the basis of comparison in a simile is central to natural language understanding and metaphor interpretation. For example, *"John was like a lion in battle"* is probably a statement about John's bravery or courage, not a description of John's physical appearance. Methods to understand figurative similes could also be valuable to understand metaphor in other linguistic constructions, such as predicate nominals (e.g., *"he is a lion"*). Furthermore, identifying the implicit property of a simile could be useful for sentiment analysis, because similes are often used to express positive and negative feelings (Li et al., 2012). For example, *"John was like a lion in battle"* contains only neutral words, but inferring "bravery" as the implicit property suggests that the simile has positive polarity.

We designed a three step process to infer the implicit properties of open similes. First, we generate candidate properties for a simile by harvesting words that are associated with its verb ("event") or object of comparison ("vehicle") using a variety of methods, including syntactic patterns, dictionary definitions, and word embeddings. Each candidate property is generated from just one component of the simile. The second step of the process then evaluates each property's compatibility with the complementary component of the simile (event or vehi-

Proceedings of NAACL-HLT 2016, pages 1223–1232,
San Diego, California, June 12-17, 2016.

cle). Finally, the third step of the process aggregates all of the candidates generated by different methods and ranks them based on collective evidence from the different sources. We evaluate the performance of our approach using gold standard properties provided by seven human annotators. We also present an analysis of the similes in our data set with respect to their *interpretive diversity* (intuitively, a measure of how many plausible interpretations a simile has). We show that our method performs best on similes with low diversity, as one would expect since their implicit properties are most clear to humans.

2 Problem Description and Data

A simile typically consists of four key components: the **topic** or **tenor** (subject of the comparison), the **vehicle** (object of the comparison), the **event** (act or state), and a **comparator** (usually "as", "like", or "than") (Niculae and Danescu-Niculescu-Mizil, 2014). For the simile *"the room feels like Antarctica"*, "room" is the tenor, "feels" is the event, and "Antarctica" is the vehicle. A **property** (shared attribute) can optionally be included to explicitly state how the tenor is being compared with the vehicle, (e.g., *"the room is as **cold** as Antarctica"*).

Table 1 shows examples of open similes from our Twitter data set, along with several properties inferred by our human annotators (our data set will be described in Section 2.1). We represent each simile using just the head noun of the tenor and vehicle, and the lemma of the event. Veale and Hao (2007) observed that when a property is explicitly given, it is usually a salient property of the vehicle. Table 1 illustrates some examples of inferred properties that are strongly associated with the vehicle (e.g., "melodic" and "dulcet" are musical attributes).

We observed that implicit properties can be strongly evoked from the event as well. For example, most inferred properties for *"person buzz like fridge"* emanate from the word "buzz", such as "humming", "vibrating", "distracting", and "annoying". Similarly, the tenor can also evoke properties, as we see with the inferred property "squinty" for the simile *"eye feel like clam"* although our observation is that this is less common. The event and the tenor need to be semantically rich to evoke implicit properties. The event in many similes is a form of "to be" or a perception verb (e.g., "feels"), which are semantically weak and contribute little. A tenor provides limited information when it is a pronoun or unknown entity (e.g., *"John drives like a snail"* is understandable without knowing who John is).

Simile	**Properties Inferred by Humans**
laugh be like music	melodic, pleasing, dulcet, tinkly
person sound like prophet	wise, insightful, prescient, enlightened
eye feel like clam	slimy, squinty, weary, gummy, heavy
person look like carrot	orange, thin, scrawny, slim, tall
person buzz like fridge	humming, vibrating, distracting, annoying, motorized
person fight like animal	ferociously, scratches, tenaciously
person be like shark	sneaky, primordial, dangerous, cold
time be like river	flowing, fast, winding, unending, moving
praise be like sunlight	warm, rejuvenating, energizing, cheerful

Table 1: Similes with sample properties inferred by humans.

Ultimately, an implicit property must be compatible with the vehicle, event, and the tenor in order for a simile to make sense. For example, Antarctica is strongly associated with the color "white", but it would not make sense to infer the property "white" for the simile *"my room feels like Antarctica"* because of the verb "feel". Although in this example the tenor "room" is still compatible with "white" and will not help to eliminate "white" as a property, in other similes it may (e.g., rivers can be "wide", but time can not be, so "wide" can be eliminated as an implicit property in the simile "time be like river").

A novel aspect of our work is that our architecture is designed to consider a property's compatibility with multiple components. In this research, for generating candidate properties and utilizing their influence for compatibility, we particularly focus on the vehicle and event terms. Initially, we generate candidate properties from the vehicle and the event separately. But the second step then evaluates each candidate property's compatibility with the *complementary* simile component. If a property was initially generated from the vehicle, then we evaluate its compatibility with the event; if a property was initially generated from the event, then we evaluate its compatibility with the vehicle. This approach emphasizes the need to consider multiple components of a simile when inferring implicit properties.

2.1 Collecting Similes with Implicit Properties

For our research, we created a new data set of open similes, where the property is implicit. Similes are common on Twitter, so we extracted similes from roughly 140 million English tweets collected during the time period 2/13/2013 – 4/15/2014. To identify similes, we applied a part-of-speech tagger designed for Twitter (Owoputi et al., 2013) to tweets containing the word "like" and applied rules to recognize simple noun phrases and verb phrases. We then selected tweets matching the syntactic pattern: $NP_1\ VERB\ like\ NP_2$, where NP_2 can contain only a noun and an optional indefinite article. We required similes to have a vehicle term with no premodifiers to avoid problems associated with coreference (e.g., "the man" or "that man") and to focus on vehicles that represent general concepts. We leave for future work the challenge of tackling multi-word vehicle phrases (e.g., *"my room is like stepping into a hurricane"* or *"my room is like a boots store"*).

This selection process extracted many similes, but it also extracted literal comparisons with no apparent property (e.g., *"this flower smells like a rose"*) and statements that are not comparisons (e.g., *"I called like five times"*). To focus on figurative similes with an implicit property, we further filtered the collection to only retain similes with vehicle terms that had occurred in comparisons with an explicit property. Using the same Twitter data, we extracted nouns that appeared in the following syntactic patterns, which represent comparison constructions with an adjectival property: $ADJ\ like\ [a, an]\ NOUN$ (e.g., *"red like a tomato"*) and $ADJ\ as\ [a, an]\ NOUN$ (e.g., *"red as a tomato"*). We only kept similes whose vehicle occurred in these patterns. Finally, we filtered similes that contain a pronoun (except personal pronouns in the tenor, which we generalized to a *"person"* token), common person first names[1], profanity,[2] or words not in a dictionary[3] to avoid issues with Twitter language such as misspellings, elongated words, etc.

2.2 Gold Standard Implicit Properties

We developed a gold standard set of implicit properties for each simile using Mechanical Turk. We prequalified 7 workers, who each annotated 700 similes with frequency ≥ 3 randomly selected from our collection. Each annotator was asked to provide up to 2 properties that best captured the most likely basis for comparison between the tenor and vehicle. We also provided the annotators with the option to label a simile as Invalid if it was not a simile at all (most commonly due to parse errors, such as *"he looks like ran"*) or label a simile as having No Property (often due to literal or underspecified comparisons, such as *"she looks like my aunt"*). The annotators were asked to give adjectives, adverbs, or verbs but occasionally they provided a noun. Table 1 presents sample annotated simile properties.

Among the 700 similes, a majority of the annotators labeled 59 of them as either Invalid or No Property, so we did not use these. We set aside 183 similes (29%) as a development set and the remaining 458 similes (71%) as a test set.

3 Inferring Implicit Properties

Our research tackles the problem of inferring properties in open similes by decomposing the problem into three subtasks: (1) generating candidate properties, (2) evaluating the candidate properties with respect to multiple simile components, and (3) aggregated ranking of the properties. Figure 1 illustrates our approach.

[3] Using Wordnik: https://www.wordnik.com/

from syntactic structures and dictionary definitions, identifying relevant properties using statistical co-occurrence, and assessing similarity between word embedding vectors.

Second, the candidates generated by each method are evaluated based on their strength of association with the complementary component of the simile. For candidates generated from the vehicle term, we evaluate them based on their association with the event term, and vice versa. We explore three association measures: point-wise mutual information to measure statistical co-occurrence, and vector similarity using single and composite word embeddings.

Third, we produce an aggregate ranking over the entire set of properties hypothesized by *all* of the candidate generation methods. Intuitively, we view each candidate generation method as an independent source, and look at the aggregate evidence across the set of different candidate generation methods (similar to an ensemble). Each property is scored based on its average rank across the different methods, so that properties highly ranked by multiple methods are preferred.

3.1 Candidate Property Generation

We generate candidate properties from the vehicle and event words of a simile. However when the event is a form of "to be" or a perception verb (taste, smell, feel, sound, look), we do not generate candidate properties from the event because the verb is too general. Only 73 (16%) of the similes in our evaluation data have a verb other than "to be" or a perception verb. We restrict properties to be adjectives, adverbs, or verb forms that can function as nominal premodifiers (e.g., "crying baby", "wilted lettuce"). We explore a total of seven methods for generating candidate properties and generate candidates using our entire Twitter corpus.

Modifying ADJ: Given a vehicle term, we extract pre-modifying adjectives. For example, "ripe" is extracted for the vehicle "tomato" from the phrase "ripe tomato".

Predicate ADJ: Given a vehicle term, we extract adjectives in predicate adjective constructions with the vehicle. For example, "red" is extracted for the vehicle "tomato" from the phrase "tomato is red".

Modifying ADV: Given an event term (verb), we extract adverbs that precede or follow the verb. For example, "immaturely" is extracted for the event "act" due to the phrase "acts immaturely".

Explicit Property: We extract properties mentioned explicitly in comparison phrases. For vehicle terms, we extract properties from phrases of the form: "ADJ/ADV like NP" (e.g., *"cold like Antarctica"*) and "ADJ/ADV as NP" (e.g., *"cold as Antarctica"*). For event terms, we extract properties from phrases of the form: "VERB ADJ/ADV like" and "VERB as ADJ/ADV as" (e.g., *"feels as cold as"*).

Dictionary Definition: Dictionary definitions often mention salient properties associated with a word. We harvest adjectives, adverbs and verbs (functioning as premodifiers) as candidate properties from the dictionary definitions of the vehicle and event terms. For the definitions, we use Wordnik[4], which contains 5 source dictionaries: Heritage Dictionary of the English Language, Wiktionary, the Collaborative International Dictionary of English, The Century Dictionary and Cyclopedia, and WordNet 3.0 (Miller, 1995).

PMI: Given a vehicle or event term, we compute point-wise mutual information (PMI) between that term and candidate properties (appearing in $\geq$ 100 tweets) in our Twitter corpus.

Word Embedding: We train a word embedding model using our tweet collection, limiting the vocabulary to nouns, verbs, adjectives and adverbs that occurred in $\geq$ 100 tweets. For training, we use word2vecf[5] (Levy and Goldberg, 2014) which allows training for arbitrary context using the skip-gram model. We use 300 dimensions for the output word and context vectors. Candidate properties are generated by selecting the words whose context vector[6] is most similar to the vehicle or event's word vector using cosine similarity. To control for noisy candidates, we require that the property occurred with the vehicle (or event) as a bigram with frequency $\geq$ 10 in the Twitter corpus.

For each generation method, we rank the candidates and select the top 20 properties. For the four methods that use syntactic patterns, we calculate

[4] https://www.wordnik.com/

[5] https://bitbucket.org/yoavgo/word2vecf

[6] properties are expected in the context of a component word.

P(property | vehicle) based on the number of times the property and the vehicle appear together in that syntactic construction among all times the vehicle appear in that syntactic construction. We use this probability to rank the candidates. For the dictionary definition method, we sort the properties based on how many of the 5 dictionaries mention the property in the word's definition. We break ties based on the frequency of the property in the definitions. For the word embedding-based method, we use cosine similarity scores.

3.2 Productivity of the Candidate Generation Methods

First we investigate how many candidates each method is able to generate. If a method generates too few candidates, it will not be very useful. Conversely, if a method generates a large number of candidates, then our ranking framework needs to be robust to rank the plausible properties higher than the properties that do not fit.

	Average	Min	Max
# of Candidates Generated from Vehicle			
Modifying ADJ	423.62	1	3177
Predicate ADJ	104.21	0	1070
Explicit Property	8.28	0	116
Dictionary Def.	20.5	0	71
# of Candidates Generated from Event			
Modifying ADV	68.67	2	223
Explicit Property	19.85	0	61
Dictionary Def.*	18.59	3	55

Figure 2: Statistics about candidates generated by different methods. Similes with a "to be" or perception verb were excluded for the methods that use the event as the source.

Figure 2 presents statistics about the candidate properties generated by different methods. The PMI and Word Embedding-based methods were excluded here as these methods evaluate all words in the corpus. The methods that used the explicit property extraction patterns and dictionary definitions generate fewer candidates than the methods that used general syntactic structures. The trend lines in Figure 2 show that these methods do not generate more than 20 candidate properties for most similes.

3.3 Coverage of the Generated Candidates

Next, we investigate the effectiveness of our candidate generation methods. The last column of Table 2 shows candidate ranking results based on Mean Reciprocal Rank (MRR) for the top 20 properties produced by each candidate generation method. MRR is calculated by:

$$MRR = \frac{1}{|S|} \sum_{s \in S} \frac{1}{(rank\ of\ 1^{st}\ acceptable\ property)}$$

where S is the set of similes. We observe that the *PMI* method (for both vehicles and events) and the *Dictionary Definition* method (for events) produced low MRR scores < 0.10. Therefore we decided not to use these candidate generation methods.[7]

One of our primary concerns is assessing the ability of our candidate generation methods to generate at least some acceptable properties. We expect them to over-generate, but they need to produce at least one acceptable property or the downstream components will be helpless. To assess this, we evaluated the coverage of each candidate generation method based on the Top 10, Top 20, and Top 30 properties that it produced. Coverage is the percentage of similes for which the method generates at least one gold standard property (from the human annotators). Table 2 shows that the *Dictionary Definitions* for vehicles was the best performing method for the Top 10 candidates, generating at least one acceptable property for 40% of the similes. The *Modifying ADJ* method performed best for the Top 30 candidates, generating an acceptable property for 63% of similes. Note that the *Explicit Property* method performs reasonably well (40% coverage for Top 30 properties generated from vehicles and 6% coverage for properties generated from events), but clearly is

[7] We made this decision based on similar results observed on our development data.

not sufficient on its own, showing the limitation of harvesting explicitly stated properties.

	Top10	Top20	Top30	MRR
Coverage of Candidates Generated from Vehicle				
PMI*	18%	31%	37%	.06
Modifying ADJ	39%	55%	63%	.16
Predicate ADJ	28%	39%	43%	.11
Explicit Property	37%	39%	40%	.23
Dictionary Def.	40%	47%	49%	.22
Word Embedding	35%	48%	58%	.15
ALL	76%	84%	86%	n/a
Coverage of Candidates Generated from Event				
PMI*	2%	3%	4%	.09
Modifying ADV	4%	5%	5%	.13
Explicit Property	4%	5%	6%	.16
Dictionary Def.*	3%	4%	4%	.09
Word Embedding	5%	6%	6%	.16
ALL	9%	10%	10%	n/a
All Candidates				
TOTAL	78%	86%	88%	n/a

Table 2: Coverage and MRR for the candidate generation methods. Top10, Top20, Top30 = percent of similes with a plausible property within top 10, 20, 30 ranked properties. Methods excluded in "ALL" and "TOTAL" rows are marked with (*). In the MRR calculation when the event component is source, similes with a "to be" or a perception verb were excluded.

The ALL rows show the coverage obtained by combining the property lists from all generation methods listed above in the table. The combined set of properties (Top 30) generated from vehicles yields 86% coverage, while the combined set of properties generated from events yields only 10% coverage (partly because these methods apply to only 16% of the similes), showing that vehicles are more effective for candidate generation. However, the TOTAL row shows that combining properties generated from both vehicles and events yields 88% coverage using the Top 30 candidates. The Top 20 candidates provide coverage that is nearly as good (86%) with substantially fewer properties to process downstream, so we use the Top 20 candidates for all of our experiments.[8]

3.4 Ranking the Candidate Properties Using Influence from the Second Component

Next, we investigate whether the initial ranking results in the previous step can be improved by considering the second component of the simile. Intuitively, suppose that "green", "slow", and "endangered" are generated as candidate properties from the vehicle "turtle" (e.g., for *"dad drives like a turtle"*). Taking the event verb "drive" into account can help to rank "slow" more highly than the other candidates. We explore three criteria to rank candidates generated from one simile component based on its association with the second component (unless the event is "to be" in which case we retain the original candidate ranking because the verb is too general).

PMI with second component (PMI): We calculate Pointwise Mutual Information between a candidate property and the second component of a simile.

Embedding word vector similarity with the second component (EMB$_1$): We use our trained word embeddings model to calculate cosine similarity between a candidate property and the second component of the simile. As before, for properties we use the context vectors.

Embedding word vector similarity with composite simile vector (EMB$_2$): For a given event and vehicle, we create a composite simile vector by performing element-wise addition of the vectors for the event and the vehicle, and calculate cosine similarity with the candidate properties. For example, for *"person talks like robot"*, the vectors for "talk" and "robot" are used to create a composite vector, and the similarity of the resulting vector with a candidate property's context vector is used as the ranking criteria. The intuition here is to capture what is common in the context distribution (Mikolov et al., 2013) of "robot" and "talk", and the context vector of a suitable property should have strong similarity with the resulting vector.

3.5 Results for Candidate Re-ranking

Table 3 presents MRR results after the initially generated candidates are re-ranked using the influence of the second simile component. For comparison, the MRR results from Table 2 are also presented in the first column (**Orig**).

Influence from the second simile component assessed with PMI and EMB$_1$ improved the MRR scores for some candidate generation methods (e.g., Predicate ADJ), but did not for others (e.g., Modifying ADV). However using the composite word embedding vector (EMB$_2$) to capture the common

[8] The decision to use the Top 20 candidates was based on similar results on our development data.

Ranking Method	Orig	PMI	EMB$_1$	EMB$_2$
Candidates Generated from Vehicle				
Modifying ADJ	.16	.22	.19	**.24**
Predicate ADJ	.11	.16	.14	**.22**
Explicit Property	.23	.25	.23	**.28**
Dictionary Def.	.22	.21	.20	**.25**
Word Embedding	.15	.19	.20	**.21**
Candidates Generated from Event				
Modifying ADV	.13	.10	.13	**.19**
Explicit Property	.16	**.18**	**.18**	**.18**
Word Embedding	.16	.11	.14	**.18**

Table 3: MRR scores for candidate ranking methods.

aspects in the context distributions of the event and vehicle consistently improved MRR for all candidate generation methods. Consequently, we use the composite word embedding vector as the ranking method for each set of candidate properties.

3.6 Aggregated Ranking

Finally, we need to consider all of the properties produced by the various candidate generation methods. As we saw in Table 2, they produce complementary sets of properties and coverage is highest when we use all of them together. To produce an aggregated ranking of all candidate properties, we calculate the harmonic mean of the rank for each individual candidate generation method. This approach rewards properties that have a consistently high ranking across different methods.

For comparison, we also show results for a voting method where a candidate property is ranked based on how many different methods generated it. To break ties, we used the frequency of the candidate in our Twitter corpus.

3.7 Results for Aggregated Ranking

Our final results use two gold standard property sets: (1) Gd (Gold): uses the set of properties from the human annotators, and (2) Gd+WN expands Gold with WordNet synsets (words in the same synset of a gold property are added) and WordNet's "similar to" relation (words that are connected to a gold property by the relation are added). The reason for using *Gd+WN* is to include synonyms of a gold property that would otherwise be considered wrong (e.g., if a human annotator said "beautiful" and our system said "pretty").

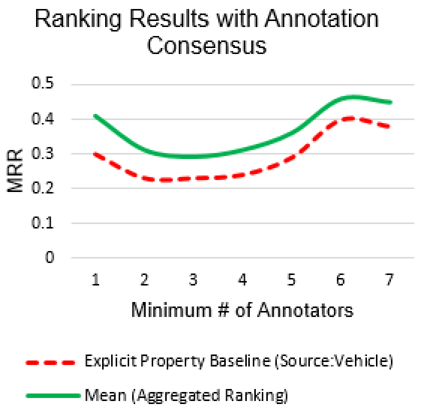
The first two columns in Table 4 present MRR results for our final ranking. The results show that with both *Gd* and *Gd+WN*, our aggregated ranking using harmonic mean yields much better MRR results than the individual methods and better than the Voted method, yielding our highest MRR: .33 and .41.

	MRR		**Top 1**		**Top 5**	
	Gd	Gd + WN	Gd	Gd + WN	Gd	Gd + WN
Voted	.25	.35	14%	21%	36%	52%
Mean	**.33**	**.41**	**21%**	**27%**	**46%**	**58%**

Table 4: Aggregate ranking results.

The last 4 columns of Table 4 present the percentage of similes for which an acceptable property was ranked #1 (Top 1) or within the Top 5. Our aggregate ranking scheme ranks an acceptable property in the Top 1 position for 27% of similes based on *Gd+WN*, and inferred an acceptable property within the Top 5 positions for 58% of all similes.

For the above evaluations, any property given by the annotators is deemed correct, and any consensus that the annotators may have had is not accounted for. To address this, we retained properties with different degrees of consensus, and subdivided the evaluation data set. Each subset of the data kept similes that have properties from a minimum number of annotators, and only those properties are used as the gold standard. WordNet synsets and "similar to" relations are also used in determining consensus.



Min # of Annotators	1	2	3	4	5	6	7
# of Similes in Data Set	641	588	418	252	136	67	27

Figure 3: Ranking results tracked by annotation consensus with Gd+WN gold standard, and corresponding data set sizes.

Figure 3 shows that for all degrees of consensus, the aggregated ranking is consistently better than the method that uses the explicit property extraction patterns, which was the best individual candidate generation method. When properties given by at least 2 annotators are considered as the gold standard, MRR is lower than when properties given by any annotator are used. With higher consensus, MRR gradually increases, which is probably because the properties with high consensus have stronger association with the simile components, so are easier to infer.

4 Analysis and Discussion

Our gold standard property collection confirmed our intuition that some similes have many plausible interpretations while others do not. We hypothesized that this should contribute to the difficulty of implicit property inference. Utsumi and Kuwabara (2005) introduced "interpretive diversity" with the hypothesis that similes with more diversity in the inferred property tend to be more metaphorical, and the values of salience of the properties are more uniform. They used Shannon's entropy to measure the interpretive diversity of a simile.

To explore our hypothesis regarding difficulties associated with property inference, we first cluster our gold-standard annotated properties. When a property appears in the WordNet synset of another property, or if two properties are connected by the WordNet "similar to" relation, we group the properties to form property clusters. So each property cluster represents a set of words that are synonyms of each other. We aggregate frequency statistics of individual words in a cluster and measure interpretive diversity of a simile using Shannon's entropy (here, X is the random variable representing property clusters of a simile):

$$H(X) = -\sum_{x \in X} P(x) \log_2 P(x)$$

Figure 4 shows the entropy curve after the 641 similes are sorted by the entropy values of their property clusters. Based on changes in the slope of the curve, we then divided the data into 3 subsets, similes with high (1–100 similes), medium (101–500 similes), and low (501–641 similes) interpretive diversity. Table 5 presents examples of similes in each category. High interpretive diversity is clearly demonstrated by *"person act like mom"*, showing properties with many different characteristics attributed to mom. Note that the properties contain both positive (e.g., friendly, loving) and negative (scolding, annoying) attributes. On the other side of the spectrum are similes with low interpretive diversity, as exemplified by *"throat feel like sandpaper"* where the vocabulary of the property set is more limited.

Table 6 shows that it is much harder to infer the implicit property in similes with high interpretive diversity, demonstrated by a .19 difference in MRR score from high to low. This trend is also consistent when we see the percentage of similes for which the system ranks a plausible property at the topmost

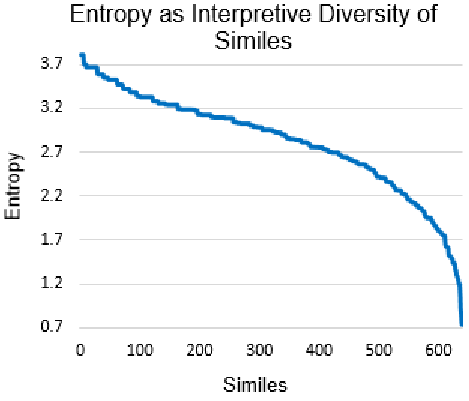


Figure 4: Entropy as interpretive diversity of similes.

High Interpretive Diversity
person act like mom : bossy (2), friendly, nuturing, overbearing, loving, scolding, caring, hovers, strict protective, cleans, nurturing, annoying
person act like baby : {childish,immature,young} (4), crying (2), whine, silly, cry, dependent, needy, pouting, whiny, weak
Medium Interpretive Diversity
person look like robot : stiff (5), jointed, stoic, blank, expressionless, mechanical, inhuman, dull, uneasy
girl be like butterfly : {beautiful,pretty} (4), free (2), delicate (2), graceful (2), fluttering, floating, happy, flowy
Low Interpretive Diversity
person act like clown : {goofy,ridiculous,silly} (5), {amusing,comical,funny} (5), stupid, degrading, disruptive, childish
throat feel like sandpaper : {rough,scratchy} (9), coarse (2), raspy, sore, dry

Table 5: Similes with different levels of interpretive diversity. Aggregated frequencies are presented within parenthesis.

Diversity	High	Medium	Low
MRR	.31	.40	.50
Top 1	15%	26%	37%
Top 5	47%	57%	66%

Table 6: Results for different subsets of similes divided by interpretive diversity, using Gold+WN properties.

position (Top 1) or within the Top 5. It is possible that with low interpretive diversity, when the property distribution is unimodal or bimodal, statistical associations between a property and simile components are stronger, and so more easily discovered by our candidate generation and ranking methods.

5 Related Work

Similes have been studied in linguistics and psycholinguistics to understand how humans process similes, comparisons, and metaphors, and the interplay among different components of these linguistic forms. Glucksberg et al. (1997) presented a property attribution model of metaphor comprehension where the candidate properties are selected from a vehicle and applied to a topic. Chiappe and Kennedy (2000) investigated if the number of properties varies between a metaphor and its simile form. The impacts of semantic dimensions of tenor and property salience have been compared by Gagné (2002). Fishelov (2007) experimented with affective connotation and degrees of difficulty associated with understanding a simile when a simile property is conventional or unconventional, or no property is given. Hanks (2005) manually categorized vehicle nouns of similes into semantic categories.

Automatic approaches that use computational models for similes are relatively rare. Veale and Hao (2007) extracted salient properties of vehicles from the web using “as ADJ as a/an NOUN” extraction pattern to acquire knowledge for concept categories. Veale (2012) built a knowledge-base of affective stereotypes by characterizing simile vehicles with salient properties. Li et al. (2012) used explicit property extraction patterns to determine the sentiment that properties convey toward simile vehicles. Niculae and Yaneva (2013) and Niculae (2013) used constituency and dependency parsing-based techniques to identify similes in text. Qadir et al. (2015) classified similes into positive and negative affective polarities using supervised classification, with features derived from simile components. Niculae and Danescu-Niculescu-Mizil (2014) designed a classifier with domain specific, domain agnostic, and metaphor inspired features to determine when comparisons are figurative.

Computational approaches to work on figurative language also include figurative language identification using word sense disambiguation (Rentoumi et al., 2009), harvesting metaphors by using noun and verb clustering-based techniques (Shutova et al., 2010), interpreting metaphors by generating literal paraphrases (Shutova, 2010), etc.

Although previous research has extensively used explicit property extraction patterns for various tasks, none has explored the impact of multiple simile components for inferring properties. To our knowledge, we are the first to introduce the task of automatically inferring the implicit properties in open similes, which is fundamental to automatic understanding of similes.

6 Conclusion

In this work, we addressed the problem of inferring implicit properties in open similes. We showed that acceptable properties for most similes can be identified by harvesting properties using syntactic structures, dictionary definitions, statistical co-occurrence, and word embedding vectors. We then demonstrated that capturing the combined influence of a simile’s event and vehicle terms using a composite word embedding vector improved our ability to rank candidate properties. Finally, we showed that properties harvested by different methods can be aggregated and effectively ranked using the harmonic mean of rankings from the individual methods. Our method for inferring implicit properties performed best on similes with low interpretive diversity. In future work, we plan to use the inferred properties to improve affective polarity recognition in similes.

Abstract

We introduce the first dataset for **sequential vision-to-language**, and explore how this data may be used for the task of *visual storytelling*. The first release of this dataset, SIND[1] v.1, includes 81,743 unique photos in 20,211 sequences, aligned to both descriptive (caption) and story language. We establish several strong baselines for the storytelling task, and motivate an automatic metric to benchmark progress. Modelling concrete description as well as figurative and social language, as provided in this dataset and the storytelling task, has the potential to move artificial intelligence from basic understandings of typical visual scenes towards more and more human-like understanding of grounded event structure and subjective expression.

1 Introduction

Beyond understanding simple objects and concrete scenes lies interpreting causal structure; making sense of visual input to tie disparate moments together as they give rise to a cohesive narrative of events through time. This requires moving from reasoning about single images – static moments, devoid of context – to sequences of images that depict events as they occur and change. On the vision side, progressing from single images to images in context allows us to begin to create an artificial intelligence (AI) that can reason about a visual moment given what it has already seen. On the language side, progressing from literal description to narrative helps to learn more evaluative, conversational, and abstract language. This is the difference between, for example, "sitting next to each other" versus "having a good time", or "sun is setting" versus "sky illuminated with a brilliance..." (see Figure 1). The first descriptions capture image content that is literal and concrete; the second requires further inference about what a *good time* may look like, or what is special and worth sharing about a particular sunset.

DII	A group of people that are sitting next to each other.	Adult male wearing sunglasses lying down on black pavement.	The sun is setting over the ocean and mountains.
SIS	Having a good time bonding and talking.	[M] got exhausted by the heat.	Sky illuminated with a brilliance of gold and orange hues.

Figure 1: Example language difference between descriptions for images in isolation (DII) vs. stories for images in sequence (SIS).

We introduce the first dataset of sequential images with corresponding descriptions, which captures some of these subtle but important differences, and advance the task of visual storytelling. We release the data in three tiers of language for the same images: **(1) Descriptions of images-in-isolation (DII)**; **(2) Descriptions of images-in-sequence (DIS)**; and **(3) Stories for images-in-sequence (SIS)**. This tiered approach reveals the effect of temporal context and the effect of narrative language. As all the tiers are aligned to the same images, the dataset facilitates directly modeling the relationship between literal and more abstract visual concepts, including the relationship between visual

imagery and typical event patterns. We additionally propose an automatic evaluation metric which is best correlated with human judgments, and establish several strong baselines for the visual storytelling task.

2 Motivation and Related Work

Work in vision to language has exploded, with researchers examining image captioning (Lin et al., 2014; Karpathy and Fei-Fei, 2015; Vinyals et al., 2015; Xu et al., 2015; Chen et al., 2015; Young et al., 2014; Elliott and Keller, 2013), question answering (Antol et al., 2015; Ren et al., 2015; Gao et al., 2015; Malinowski and Fritz, 2014), visual phrases (Sadeghi and Farhadi, 2011), video understanding (Ramanathan et al., 2013), and visual concepts (Krishna et al., 2016; Fang et al., 2015).

Such work focuses on direct, literal description of image content. While this is an encouraging first step in connecting vision and language, it is far from the capabilities needed by intelligent agents for naturalistic interactions. There is a significant difference, yet unexplored, between remarking that a visual scene shows "sitting in a room" – typical of most image captioning work – and that the same visual scene shows "bonding". The latter description is grounded in the visual signal, yet it brings to bear information about social relations and emotions that can be additionally inferred in context (Figure 1). Visually-grounded stories facilitate more evaluative and figurative language than has previously been seen in vision-to-language research: If a system can recognize that colleagues look *bored*, it can remark and act on this information directly.

Storytelling itself is one of the oldest known human activities (Wiessner, 2014), providing a way to educate, preserve culture, instill morals, and share advice; focusing AI research towards this task therefore has the potential to bring about more human-like intelligence and understanding.

Figure 3: Interface for the *Storytelling* task, which contains: 1) the photo album, and 2) the storyboard.

3 Dataset Construction

Extracting Photos We begin by generating a list of "storyable" event types. We leverage the idea that "storyable" events tend to involve some form of possession, e.g., "John*'s* birthday party," or "Shabnam*'s* visit." Using the Flickr data release (Thomee et al., 2015), we aggregate 5-grams of photo titles and descriptions, using Stanford CoreNLP (Manning et al., 2014) to extract possessive dependency patterns. We keep the heads of possessive phrases if they can be classified as an EVENT in WordNet3.0, relying on manual winnowing to target our collection efforts.[2] These terms are then used to collect albums using the Flickr API.[3] We only include albums with 10 to 50 photos where all album photos are taken within a 48-hour span and CC-licensed. See Table 1 for the query terms with the most albums returned.

The photos returned from this stage are then presented to crowd workers using Amazon's Mechanical Turk to collect the corresponding stories and descriptions. The crowdsourcing workflow of developing the complete dataset is shown in Figure 2.

Crowdsourcing Stories In Sequence We develop a 2-stage crowdsourcing workflow to collect naturalistic stories with text aligned to images. The first stage is *storytelling*, where the crowd worker selects a subset of photos from a given album to form a

photo sequence and writes a story about it (see Figure 3). The second stage is *re-telling*, in which the worker writes a story based on one photo sequence generated by workers in the first stage.

In both stages, all album photos are displayed in the order of the time that the photos were taken, with a "storyboard" underneath. In *storytelling*, by clicking a photo in the album, a "story card" of the photo appears on the storyboard. The worker is instructed to pick at least five photos, arrange the order of selected photos, and then write a sentence or a phrase on each card to form a story; this appears as a full story underneath the text aligned to each image. Additionally, this interface captures the alignments between text and photos. Workers may skip an album if it does not seem storyable (e.g., a collection of coins). Albums skipped by two workers are discarded. The interface of *re-telling* is similar, but it displays the two photo sequences already created in the first stage, which the worker chooses from to write the story. For each album, 2 workers perform *storytelling* (at \$0.3/HIT), and 3 workers perform *re-telling* (at \$0.25/HIT), yielding a total of 1,907 workers. All HITs use quality controls to ensure varied text at least 15 words long.

Crowdsourcing Descriptions of Images In Isolation & Images In Sequence We also use crowdsourcing to collect descriptions of images-in-isolation (DII) and descriptions of images-in-sequence (DIS), for the photo sequences with stories from a majority of workers in the first task (as Figure 2). In both DII and DIS tasks, workers are asked to follow the instructions for image captioning proposed in MS COCO (Lin et al., 2014) such as *describe all the important parts*. In DII, we use the MS COCO image captioning interface.[4] In DIS, we use the storyboard and story cards of our *storytelling* interface to display a photo sequence, with MS COCO instructions adapted for sequences. We recruit 3 workers for DII (at \$0.05/HIT) and 3 workers for DIS (at \$0.07/HIT).

Data Post-processing We tokenize all storylets and descriptions with the CoreNLP tokenizer, and replace all people names with generic MALE/FEMALE tokens,[5] and all identified named entities with their entity type (e.g., `location`). The data is released as *training*, *validation*, and *test* following an 80%/10%/10% split on the stories-in-sequence albums. Example language from each tier is shown in Figure 4.

4 Data Analysis

Our dataset includes 10,117 Flickr albums with 210,819 unique photos. Each album on average has 20.8 photos ($\sigma = 9.0$). The average time span of each album is 7.9 hours ($\sigma = 11.4$). Further details of each tier of the dataset are shown in Table 2.[7]

[4] https://github.com/tylin/coco-ui

[5] We use those names occurring at least 10,000 times. `https://ssa.gov/oact/babynames/names.zip`

[6] The DIS columns VocabSize-Ppl estimated based on 17,425 Txt,Img pairs. Full set will be updated shortly.

[7] We exclude words seen only once.

We use normalized pointwise mutual information to identify the words most closely associated with each tier (Table 3). Top words for descriptions-in-isolation reflect an impoverished disambiguating context: References to people often lack social specificity, as people are referred to as simply "man" or "woman". Single images often do not convey much information about underlying events or actions, which leads to the abundant use of posture verbs ("standing", "sitting", etc.). As we turn to descriptions-in-sequence, these relatively uninformative words are much less represented. Finally, top story-in-sequence words include more storytelling elements, such as names ([*male*]), temporal references (*today*) and words that are more dynamic and abstract (*went*, *decided*).

5 Automatic Evaluation Metric

Given the nature of the complex storytelling task, the best and most reliable evaluation for assessing the quality of generated stories is human judgment. However, automatic evaluation metrics are useful to quickly benchmark progress. To better understand which metric could serve as a proxy for human evaluation, we compute pairwise correlation coefficients between automatic metrics and human judgments on 3,000 stories sampled from the SIS training set.

For the human judgements, we again use crowdsourcing on MTurk, asking five judges per story to rate how strongly they agreed with the statement "If these were my photos, I would like using a story like this to share my experience with my friends".[8] We take the average of the five judgments as the final score for the story. For the automatic metrics, we use METEOR,[9] smoothed-BLEU (Lin and Och, 2004), and Skip-Thoughts (Kiros et al., 2015) to compute similarity between each story for a given sequence. Skip-thoughts provide a Sentence2Vec embedding which models the semantic space of novels.

As Table 4 shows, METEOR correlates best with human judgment according to all the correlation coefficients. This signals that a metric such as METEOR which incorporates paraphrasing correlates best with human judgement on this task. A more detailed study of automatic evaluation of stories is an area of interest for a future work.

	METEOR	BLEU	Skip-Thoughts
r	0.22 (2.8e-28)	0.08 (1.0e-06)	0.18 (5.0e-27)
ρ	0.20 (3.0e-31)	0.08 (8.9e-06)	0.16 (6.4e-22)
τ	0.14 (1.0e-33)	0.06 (8.7e-08)	0.11 (7.7e-24)

Table 6: Captions generated per-image with METEOR scores.

6 Baseline Experiments

We report baseline experiments on the storytelling task in Table 7, training on the SIS tier and testing on half the SIS validation set (valtest). Example output from each system is presented in Table 5. To highlight some differences between story and caption generation, we also train on the DII tier in isolation, and produce captions per-image, rather than in sequence. These results are shown in Table 7.

To train the story generation model, we use a sequence-to-sequence recurrent neural net (RNN) approach, which naturally extends the single-image captioning technique of Devlin et al. (2015) and Vinyals et al. (2014) to multiple images. Here, we encode an image *sequence* by running an RNN over the `fc7` vectors of each image, in reverse order. This is used as the initial hidden state to the story decoder model, which learns to produce the story one word at a time using softmax loss over the training data vocabulary. We use Gated Recurrent Units (GRUs) (Cho et al., 2014) for both the image encoder and story decoder.

In the baseline system, we generate the story using a simple beam search (size=10), which has been successful in image captioning previously (Devlin et al., 2015). However, for story generation, the results of this model subjectively appear to be very poor – the system produces generic, repetitive, high-level descriptions (e.g., "This is a picture of a dog").

Beam=10	**Greedy**	**-Dups**	**+Grounded**
23.13	27.76	30.11	31.42

Table 7: Stories baselines with METEOR scores.

[8] Scale presented ranged from "Strongly disagree" to "Strongly agree", which we convert to a scale of 1 to 5.

[9] We use METEOR version 1.5 with `hter` weights.

+Viterbi	This is a picture of a family. This is a picture of a cake. This is a picture of a dog. This is a picture of a beach. This is a picture of a beach.
+Greedy	The family gathered together for a meal. The food was delicious. The dog was excited to be there. The dog was enjoying the water. The dog was happy to be in the water.
-Dups	The family gathered together for a meal. The food was delicious. The dog was excited to be there. The kids were playing in the water. The boat was a little too much to drink.
+Grounded	The family got together for a cookout. They had a lot of delicious food. The dog was happy to be there. They had a great time on the beach. They even had a swim in the water.

Table 5: Example stories generated by baselines.

This is a predictable result given the label bias problem inherent in maximum likelihood training; recent work has looked at ways to address this issue directly (Li et al., 2016).

To establish a stronger baseline, we explore several decode-time heuristics to improve the quality of the generated story. The first heuristic is to lower the decoder beam size substantially. We find that using a beam size of 1 (greedy search) significantly increases the story quality, resulting in a 4.6 gain in METEOR score. However, the same effect is not seen for caption generation, with the greedy caption model obtaining worse quality than the beam search model. This highlights a key difference in generating stories versus generating captions.

Although the stories produced using a greedy search result in significant gains, they include many repeated words and phrases, e.g., “The kids had a great time. And the kids had a great time.” We introduce a very simple heuristic to avoid this, where the same content word cannot be produced more than once within a given story. This improves METEOR by another 2.3 points.

An advantage of comparing captioning to storytelling side-by-side is that the captioning output may be used to help inform the storytelling output. To this end, we include an additional baseline where “visually grounded” words may only be produced if they are licensed by the caption model. We define the set of visually grounded words to be those which occurred at higher frequency in the caption training than the story training:

$$\frac{P(w|T_{caption})}{P(w|T_{story})} > 1.0 \qquad (1)$$

We train a separate model using the caption annotations, and produce an n-best list of captions for each image in the valtest set. Words seen in at least 10 sentences in the 100-best list are marked as ‘licensed’ by the caption model. Greedy decoding without duplication proceeds with the additional constraint that if a word is visually grounded, it can only be generated by the story model if it is licensed by the caption model for the same photo set. This results in a further 1.3 METEOR improvement.

It is interesting to note what a strong effect relatively simple heuristics have on the generated stories. We do not intend to suggest that these heuristics are the *right* way to approach story generation. Instead, the main purpose is to provide clear baselines that demonstrate that story generation has fundamentally different challenges from caption generation; and the space is wide open to explore for training and decoding methods to generate fluent stories.

7 Conclusion and Future Work

We have introduced the first dataset for **sequential vision-to-language**, which incrementally moves from images-in-isolation to stories-in-sequence. We argue that modelling the more figurative and social language captured in this dataset is essential for evolving AI towards more human-like understanding. We have established several strong baselines for the task of visual storytelling, and have motivated METEOR as an automatic metric to evaluate progress on this task moving forward.

PRIMT: A Pick-Revise Framework for Interactive Machine Translation

Shanbo Cheng, Shujian Huang, Huadong Chen, Xinyu Dai and **Jiajun Chen**
State Key Laboratory for Novel Software Technology
Nanjing University

{chengsb, huangsj, chenhd, daixy, chenjj}@nlp.nju.edu.cn

Abstract

Interactive machine translation (IMT) is a method which uses human-computer interactions to improve the quality of MT. Traditional IMT methods employ a left-to-right order for the interactions, which is difficult to directly modify critical errors at the end of the sentence. In this paper, we propose an IMT framework in which the interaction is decomposed into two simple human actions: picking a critical translation error (Pick) and revising the translation (Revise). The picked phrase could be at any position of the sentence, which improves the efficiency of human computer interaction. We also propose automatic suggestion models for the two actions to further reduce the cost of human interaction. Experiment results demonstrate that by interactions through either one of the actions, the translation quality could be significantly improved. Greater gains could be achieved by iteratively performing both actions.

1 Introduction

To obtain high quality translations, human translators usually have to modify the results generated by a machine translation (MT) system (called post editing, PE). In many cases, PE needs a lot of modifications, which is time-consuming (Plitt and Masselot, 2010). To speed up the process, interactive machine translation (IMT) is proposed which instantly update the translation result after every human action (Langlais et al., 2000; Foster et al., 2002; Barrachina et al., 2009; Koehn, 2009; González-Rubio et al., 2013; Alabau et al., 2014). Because the translation quality could be improved after every update, IMT is expected to generate high quality translations with less human actions (Sanchis-Trilles et al., 2014).

Typical IMT systems usually use a left-to-right sentence completing framework pioneered by Langlais et al (2000), in which the users process the translation from the beginning of the sentence and interact with the system at the left-most error. By assuming the translation from the beginning to the modified part (called "prefix") to be correct, the system generates new translations after the given prefix (Koehn, 2009; Barrachina et al., 2009; Ortiz, 2011; Alabau et al., 2014).

Despite the success of this left-to-right framework, one potential weakness is that it is difficult to modify critical translation errors at the end of a sentence. Critical translation errors are those errors that has large impact on the translation of other words or phrases. When a translation ambiguity occurs at the end of a sentence while it causes translation errors at the beginning, modifying this critical errors first may bring great positive effects on previous parts of the translation, which may reduce human efforts in an IMT process. Modifying from left to right will delay the modification of the ambiguity point and lowers the interaction efficiency.

Critical errors are often caused by the inherent difficulty of translating source phrases. Mohit et al. (2007) proposed a classifier to identify the difficult-to-translate phrases (DTPs), which were extracted from syntactic trees. They demonstrated that asking human to translate these DTPs can bring a significant gain to the overall translation quality compared to translating other phrases. However, to our

Table 1: Examples of applying the Left-to-right (L2R) framework and the Pick-Revise framework (PR) in modifying a Chinese-English translation. Both the PR and left-to-right actions are performed only once. The first row shows the Chinese words and their translations. The following rows are the reference translations, the translation of the baseline system, the translation after a L2R interaction cycle and the translation after a PR interaction cycle, respectively. The dashed underline phrase is picked as the error to be modified by L2R. The underline phrase is picked as the error to be modified. The bold parts show the positive effects of revising the selected translation error on the translation of their contexts in a constrained decoding.

best knowledge, there is no practice in integrating these DTPs into an IMT framework.

In this paper, we propose a Pick-Revise IMT framework (PRIMT) to explicitly split the modification of a translation result into two very simple actions. Firstly, a wrongly-translated phrase is selected from the whole sentence (**Pick**); secondly, the correct translation is selected from the translation table (or manually added) to replace the original one (**Revise**). Our system then re-translates the sentence and searches for the best translation using previous modifications as constraints (Section 2). Furthermore, we propose two automatic suggestion models that could predict the wrongly-translated phrases and select the revised translation, respectively (Section 3). With the suggestion models, users only perform one of the actions (picking or revising) and let the suggestion models complete the other one. In this case, the interactions could be further simplified to be only one of the actions, which is as simple as one mouse click.

Experiment results show that by performing only one mouse click, the translation quality could be significantly improved (around +2 BLEU points in one PR cycle). Performing both two actions multiple times will bring greater gain in translation quality (+17 BLEU) with a relatively low Keystroke and Mouse-action Ratio (KSMR) (Barrachina et al., 2009) (3.3% KSMR).

2 The Pick-Revise IMT Framework

2.1 PRIMT System

We first explain the difference between Pick-Revise (PR) framework and left-to-right framework (Foster et al., 2002) with an example (in Table 1). For the given input source sentence, the MT system firstly generates a baseline translation. In the left-to-right framework human translator modifies the left-most error from "to discuss" to "discuss". But this modification may not bring any positive effects on the other part of the translation. So more interactions are needed to further improve the translation quality.

In our pick-revise framework, the human translator picks the phrase " 反 恐" which was considered the most critical translation error, and revise the translation from "the" to "anti-terrorism" according to phrase table. After a PR cycle, our constrained decoder re-translates the sentence. It not only generates the correct translation for the pick-revise pair (PRP), but also improves the translation around the PRP (bold parts).

Compared to left-to-right framework, our framework can modify the most critical error at first, which brings larger improvements on translation quality and improves the efficiency of human interactions.

Figure 1 shows an overview of our framework. For a source sentence $s_1 ... s_n$, our framework iteratively generates the translation using a constrained decoder. The constraints come from previous picking and revising processes. The picking and revising results can also be collected for model adaptation. The whole process continues until the translation is considered acceptable by the users. We explain the key components of our framework below.

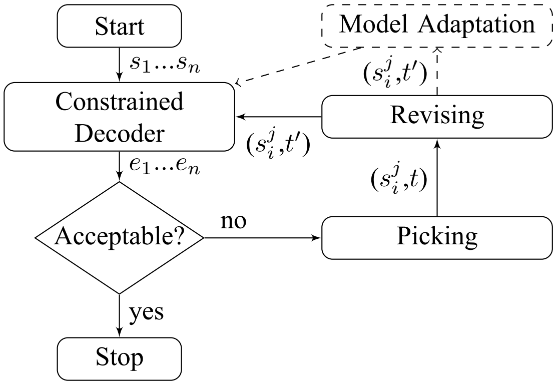

Figure 1: An overview of PRIMT framework.

2.2 Picking

In the picking step, the users pick the wrongly-translated phrase, (s_i^j, t)[1], to be revised. The picking process aims at finding critical errors in the translation, caused by errors in the translation table or inherent translation ambiguities. The more critical the error is, the larger translation quality improvement can be achieved by correcting the error (Mohit and Hwa, 2007). Critical errors might have a large influence to the translation of their context.

To make the picking step easier to be integrated into MT system, we limit the selection of translation errors to be those phrases in the previous PR-cycle output. If it's the first PR-cycle, then those errors come from phrases used to generate the baseline translation. For more convenient user interactions, in our PRIMT system, critical errors can be picked from both the source and target side by simply a mouse click on it. The correspondence/alignment between source and target phrases are visualized for easier human observation.

Green et al. (2014) demonstrated that performing post-editing, i.e. directly editing the translation errors, could get acceptable translations faster than performing left-to-right IMT. Such result also indicates that identifying critical translation errors is not a difficult task for human to perform.

2.3 Revising

In the revising step, the users revise the translation of s_i^j by selecting the correct translation t' from the translation table, or manually add one if there is no correct translation in the translation table. Whether to perform selection or adding depends on the quality of the translation table. When the translation system is trained with large enough parallel data, the quality of the translation table is usually high enough to offer the correct translation.

For a picked phrase, the translation options in the phrase table could be presented to the users as a list. The users just need to click on the correct translation to complete the revising step. The users could also type a new translation through a separated input area.

2.4 Decoder and Model Adaptation

A pick-revise pair (PRP), $(s_i^j,\ t')$, is obtained after a PR cycle for a source sentence. We use a constrained decoder to search for the best translation with the previous PRPs as constraints. The constrained search algorithm is similar to the algorithm in a typical phrase-based machine translation (Koehn et al., 2003). The only exception is that it makes an extra comparison between each translation option and previous PR pairs, which ignores all the phrases that overlap with the source side of a PRP. As a result, a lot of translation options are ignored, which makes the search space much smaller than standard decoding. In this way, we could guarantee that all the PRPs are correctly translated and the whole process can be carried out in real-time.

The system could collect all PRPs and adapt the models using methods described in Germann (2014) or Marie (2015). In our current implementation, we mainly focus on the picking and revising step and leave model adaptation as future work.

3 Automatic Suggestion Models

To further reduce the human actions, we propose to use automatic suggestion models for the picking and revising step, respectively. Such models can offer suggestions to users in both picking and revising steps. Because both picking and revising actions are performing selections from multiple candidates, we use classifier-based approaches to model these two steps. In the following subsections, we will introduce how we define the picking and revising tasks as classification tasks and how we choose features to model the tasks. Note that these automatic suggestion models could be interpreted as simplified confidence measurements.

[1] s_i^j is the phrase that covers the source words from index i to j, and translated into t.

3.1 The Picking Suggestion Model (PSM)

3.1.1 PSM Training

The picking process aims at selecting critical errors which has huge impact on the translation quality of their context. The goal of PSM is to automatically recognize those phrases that might be wrongly-translated, and suggest users to pick these phrases. In real world systems, the users can either accept or refuse the suggestion.

Within all the phrases of a source sentence, we need to separate the wrongly-translated phrases and correctly-translated phrases. Because translation errors often cause low translation quality, we use the translation quality gain after the revising action as a measurement. We treat those phrases that achieve translation quality improvement after revising as wrongly-translated phrases; those lead to translation quality deterioration as correctly-translated phrases.

We select phrases that lead to a BLEU improvement/deterioration greater than a threshold as positive/negative instances. In this paper, the threshold is set as 10% of the BLEU score of the baseline sentence.

3.1.2 PSM Features

Modeling the picking process needs two aspects of information. One of them is to determine whether the phrase is difficult-to-translate; the other is to determine whether the current translation option is correct. We use features from translation models (TMs), language models (LMs), lexical reordering models (LRMs), as well as counting and lexical features in Table 2. These features cover information of the source side, target side, translation ambiguity, and context, etc.

Category	Description
TM	TM scores of baseline translation
	Normalized TM scores of baseline translation
	TM entropy of all translation options
LM	LM score of baseline translation
	LM score of previous/next phrase translation
	LM score of each target word
	LM score of the bigram at the border of current and previous/next phrase
LRM	LRM scores of baseline translation
	LRM scores of previous/next phrase translation
Count	Source/target word count
	Number of translation options for current source phrase
POS	POS-tags of source words
	POS-tags of previous/next word of source phrase
Lexical	Source words
	Target words

Table 2: Features for the PSM.

3.2 The Revising Suggestion Model (RSM)

3.2.1 RSM Training

The revising process aims at selecting a correct translation for a given phrase under the given context. The goal of RSM is to predict the correct translation and suggest users to replace the wrong translation with the predicted one. The users can either accept it or use another translation.

Translation table has multiple translation options for one phrase. Within the translation option set of a source phrase, we need to separate the correct and wrong translation options. Instead of asking human translators to label these translations, we use two criteria to distinguish correct translation options from wrong translation options.

Firstly, the correct translation option should be a substring of the references, which ensures the correctness of the options itself. Secondly, the correct translation option should be consistent with pre-trained word alignment on the translated sentence pair[2]. This is to ensure that the translation option does not get credit for words that are not translations of the source side phrase. The remaining options are considered wrong translations.

With the above criteria, we select all correct translation options as positive instances for the revising step, and randomly sample the same number of wrong translation options to be negative instances. Specifically, translation options that are used by the baseline system are included as negative instances.

3.2.2 RSM Features

The features used for RSM are showed in Table 3. For translations of a given source phrase, there is no need to compare their source-side information because these translation options share the same source phrase and context. So these features mainly focus

[2] We trained word alignments with Giza++(Och and Ney, 2003)

on estimating the translation quality of a given translation option. As a result, features for RSM only including the scores for TM, LM and LRM, etc, which are simpler compared to PSM.

Category	Description
TM	TM scores of current translation option
LM	LM score of current translation option
	LM score of each target word
LRM	LRM scores of current translation option
count	Target word count
Lexical	Target words

Table 3: Features for the RSM

4 Experiments

4.1 Experiment Settings

4.1.1 Translation Settings

Through out the experiments, we use an in-house implementation of the phrase-based machine translation system (Koehn et al., 2003) and incorporate our PRIMT framework into the translation system. The parallel data for training the translation model includes 8.2 million sentences pairs from LDC2002E18, LDC2003E14, LDC2004E12, LDC2004T08, LDC2005T10, LDC2007T09. A 5-gram language model is trained with MKN smoothing (Chen and Goodman, 1999) on Xinhua portion of Gigaword which contains 14.6 million sentences. We use a combination of NIST02 and NIST03 to tune the MT system parameters and train the suggestion models. We test the system on NIST04 and NIST05 data. The translation results are evaluated with case insensitive 4-gram BLEU (Papineni et al., 2002). Our baseline phrase-based MT system has comparable performance with the open source toolkit Moses (Koehn et al., 2003).

4.1.2 Classification Settings

We use three classification models to model the automatic suggestion models: the maximum entropy model, the SVM model and the neural network model. We use a maximum entropy model (Zhang, 2004) with 30 iterations of L-BFGS. We use the LibSVM implementation (Chang and Lin, 2011) with RBF kernel and L2 regularization ($c = 128$, $\gamma = 0.5$). We use a feedforward neural network with the CNTK implementation (Agarwal et al., 2014). The neural network has one hidden layer of 80 nodes, with sigmoid function as the activation function.

We use one-hot representation for the source and target word features when using the maximum entropy and SVM model, and use pre-trained word embeddings (Mikolov et al., 2013) for the neural model.

4.2 Methodology

4.2.1 Simulated Human Interaction

Because real-world human interactions are expensive and time-consuming to obtain, we use simulated human interactions for picking and revising in the experiment.

Directly identifying critical errors in the translation is not an easy task without human annotation. Instead, we find critical errors by judging the influence of a given error to the translation of their context. We try picking every phrase in a baseline translation result and revising it using the simulated revising strategy (described below). The influence of the phrase is measured by the translation quality improvement after re-translation with the current phrase be revised. The phrase with the highest translation quality improvement is picked to be the simulated human picking result.

Given the phrase to be revised, the simulated revising action is straightforward. Among all the translation options that are considered correct (Sec. 3.2.1), we choose the longest one to be the simulated human revising result.

With the above simulated actions, one PR cycle takes exactly two mouse clicks and none keystroke. For fair comparison, we use the same simulated revising action for the left-to-right framework. Each cycle of left-to-right framework also takes two mouse clicks. We also compare the post editing method which selects the most critical error and edits it to be the simulated revising translation. The key-stroke count for each editing is the number of characters of the correct phrase translation.

4.3 Translation Quality Improvement in Ideal Environment

Our first experiment is to test the PRIMT performance in an ideal environment. We conduct experiments on sentences for which the reference could be generated by our current MT system using forced decoding. Forced decoding forces the decoder to gen-

Data	NIST04(forced)		NIST05(forced)	
	BLEU	KSMR	BLEU	KSMR
Baseline	44.59	0	41.48	0
PR*1	**63.21 (+18.62)**	2.2	**55.10 (+13.62)**	2.2
PR*2	**70.82 (+26.23)**	4.3	**63.03 (+21.55)**	4.4
PR*3	**73.99 (+29.50)**	6.5	**68.56 (+27.08)**	6.7
PR*4	**75.48 (+30.89)**	8.6	**72.20 (+30.72)**	8.9
PR*5	**76.59 (+32.00)**	10.8	**73.90 (+32.42)**	11.1
PR*6	**78.07 (+33.48)**	12.9	**75.22 (+33.74)**	13.3
PR*7	**79.27 (+34.68)**	15.1	**75.57 (+34.09)**	15.5
PR*8	**79.54 (+34.93)**	17.2	**76.02 (+34.54)**	17.8
L2R*1	49.32 (+4.73)	2.2	46.34 (+4.86)	2.2
PE*1	49.77 (+5.18)	8.3	46.81 (+5.33)	8.2

Table 4: Experiments on sentences that can be forced-decoded for both NIST04 and NIST05 data, with 186 and 92 sentence counts, respectively. (PR*n denotes system that repeat picking and revising for n cycles; the PE system post edits the most critical error; the L2R system modifies the left most error).

erate translations exactly the same as the references. A reference translation could be generated by forced decoding means that it won't be necessary to input new words to generate a correct translation. Because we only simulate human revising actions as selecting the best translation option from phrase table (without adding new options), such a setting guarantees that the phrase table contains the correct translation for every phrase.

Table 4 shows that picking and revising the most critical error (PR*1) can bring +18 and +13 BLEU improvements in the two data sets, respectively. Revising the left-most error (L2R*1) only achieves an improvement around +5 BLEU. This result demonstrates that picking the critical error to be revised is critical in our PR framework. Compared to the left-to-right method, our framework has the advantage of correcting the critical errors in a high priority. By correcting such errors, the BLEU gain is much larger than left-to-right correction.

Post-editing the most critical error (PE*1) uses 8% KSMR, but only brings +5 BLEU improvement. Compared to post-editing, which just edits the critical error without affecting other parts of the translation, our PRIMT framework can re-decode for better translations with less human interactions.

In 8 PR-cycles (PR*8) (around 17% KSMR), the PRIMT achieves very high quality translation results with a BLEU score higher than 75 (around +35 BLEU to baseline). These results demonstrate the efficiency of PRIMT in multiple interactions.

Data	NIST04		NIST05	
	BLEU	KSMR	BLEU	KSMR

	Feedforward	0.71/0.73/0.72	0.68/0.70/0.69
RSM	MaxEnt	0.71/0.58/0.63	0.70/0.57/0.63
	SVM	0.70/0.61/0.0.65	0.68/0.62/0.65
	Feedforward	0.66/0.67/0.66	0.65/0.65/0.65

Table 6: Classification performance of automatic suggestion models. The three values of each cell denotes the precision, recall and F-score, respectively, calculated on positive instances of corresponding classifier.

4.4 Translation Quality Improvement in General Environment

We also validate the improvements of translation quality in a general environment. We perform similar experiments on all NIST04 and NIST05 data. In some of the sentences, the translation table might not contain the correct translation for source phrase, due to the limitation of the training of our current MT system.

The results are listed in Table 5. Although the BLEU score in general environment are lower than those in ideal environment, the results show basically the same trends as in the previous experiment. The third row (PR*1) in Table 5 shows that picking and revising the most critical error can bring around +11 BLEU improvements in both data sets. The improvements in L2R*1 (+3.2) and PE*1 (+2.5) are much less. Three PR-cycles (around 3.3 KSMR) can achieve +17 BLEU improvements (PR*3). Compared to left-to-right and PE methods, our framework still has a significant advantage in the general environment.

4.5 Using Automatic Suggestion Models

We validate the effectiveness of our automatic suggestion models by both classification performance and translation performance.

Table 6 shows the classification performances of the PSM and the RSM, with different models. The precision and recall are calculated on positive instances in the test set, because only those instances that are predicted as positive will be used in the IMT system. Because it is harder to automatically identify the correct translation, we keep the translation unchanged when the RSM classifies all translation options to be negative.

The performance of the three classifiers are similar. Feedforward neural network has a moderate advantage. In general, the PSM could recognize the critical translation errors with an F-score around 0.67. The RSM achieves about 0.65 F-score for recognizing the correct translation. The F-scores are all in the range between 60 and 70, which is reasonable considering the difficulty of the tasks themselves.

We also evaluate the translation improvements when automatic suggestion models are used in the PR framework (Table 7). If the picking action performs a random pick of phrase (RandomPicking), there is barely no improvement in the translation quality, even with the simulated revising action. For comparison, using PSM could achieve a significant BLEU improvement of around 2 BLEU, on both test sets. It suggests that the BLEU gain does not come from the long reference translation match in the revising step. Picking critical errors is crucial in our framework.

Choosing the most critical error and performing a random revising action (RandomRevising) brings no improvement in BLEU either. Using our RSM could still improve the translation quality by 1.5 BLEU.

In general, using one of our PSM and RSM could still achieve significant improvement in translation quality. But the uses only need to perform one type of actions, which might be more suitable to be performed by a single human translator. However, the improvement is relatively small compared to fully simulated results, suggesting that human involvement is still critical for improve the translation quality. Better modeling or training with larger data may also improvement the performance of automatic suggestions.

		NIST04	NIST05
	Baseline	31.83	30.64
	RandomPicking	31.92 (+0.09)	30.69 (+0.05)
PSM	MaxEnt	33.89 (+2.06)	32.57 (+1.93)
	SVM	34.01 (+2.18)	32.66 (+2.02)
	FeedForward	34.23 (+2.40)	32.81 (+2.17)
	RandomRevising	31.90 (+0.07)	30.71 (+0.08)
RSM	MaxEnt	33.62 (+1.79)	32.38 (+1.74)
	SVM	33.73 (+1.90)	32.42 (+1.78)
	FeedForward	33.77 (+1.94)	32.44 (+1.80)

Table 7: Improvements of translation quality using random selection and automatic suggestion models.

5 Example Analysis

We further analyze the performance of our PRIMT system by examples. Table 8 shows the PRIMT procedure of improving translation quality for three different sentences.

In the first sentence, two PR cycles (4.7% KSMR) lead to a perfect translation. In the first PR cycle (PR*1), revising the translation of " 第六" from "the" to "the 6th" improves the neighboring translation. The translation of " 证实" change from "confirms" to "confirm", which is a positive effect. In PR*2, revising the translation of " 病例" from "cases" to "case" also changes the neighborhood translation (the translation of " 禽流感 死亡 病例" changes to "death case from the bird flu"). After two PR cycles, the reference translation is obtained.

In our current settings, the reference translation could not always be obtained. The maximum achievable BLEU is around 60-70 in general environment. The next two examples shows some possible explanations.

In the second sentence in Table 8, " 需要 一定" is picked in the first PR cycle. Revising the translation from "a" to "need a certain" makes the translation of " 通常" changing from "is" to "usually". In the next PR cycle, revising the translation of " 过程" from "process" to "course" makes the neighboring translation changing from "," to ", and". Meanwhile, the position of "course" moves to the right place (in front of ","). In the last PR cycle, the translation of " 很难" is revised from "it" to "it cannot be". After three PR cycles, the translation quality improves significantly. However, the translation is still different from the

Table 8: Examples of applying PR actions multiple times in the Chinese-English translation. The superscript i of the underline phrases, P_i in source sentence denotes the underline phrase is picked in the i-th PR cycle as the critical error. The original translation of P_i is the underline phrase without superscript in PR*$(i-1)$ (Baseline is PR*0). The correct translation is the underline parts with superscript in PR*i. The bold parts shows the positive effects on other parts near the PRPs.

reference. This is because " 一蹴而就" should be translated into "accomplished in one action" instead of "accomplished". But there is no suitable translation options for it in the current phrase table. So the system cannot generate a perfect translation. The problems will be less significant when real-world human translators are involved. Human translator inputs the correct translation "accomplished in one action", the system will generate the reference translation after constrained decoding (Human).

In the last sentence in Table 8, " 无法" is picked as the critical error. Revising the translation from "to the" to "failed to", leads to an improvement on neighboring phrase (the translation of " 充分扫除" to "fully clear"). In the second PR cycle, " 以色列的" is picked. Revising the translation from "the israeli" to "israel 's", makes the translation of " 回答" change from "response" to "reply", which is also a positive effect. However, after two PR cycles, all phrase translations are correct, but the translation is still different from the reference. This is because the language model and lexical reordering model prefer the wrong phrase ordering, which put "the us" at the end of the whole sentence. This problem raises from the MT system itself, which may not be solved directly in our current framework.

If more interactions are allowed, for example, performing reordering operations, the above problems could be solved. But the interactions become more complex, and may not be acceptable to human translators. Other solutions includes using better statistical models such as neural language models (Bengio et al., 2003). This is an interesting issue we will look into.

6 Conclusion

We introduced a pick-revise IMT framework, PRIMT, where the users could pick critical translation errors anywhere in the sentence and revise the translation. By correcting the critical error instead of the left most one, our framework could improve the translation quality in a quicker and more efficient way. By using automatic suggestion models, we could reduce human interaction to a single type, either picking or revising. It is also possible to let different human translators to perform different action-

s. In this case every translator will focus on a single action, which might be easier to train and may have higher efficiency.

On the other hand, the performance of current framework is still related to the underlying MT system. Further improvement could be achieved by supporting other type of interactions, such as reordering operations, or building the system with stronger statistical models. We will also conduct real-world experiments to see how this new IMT framework works when human translators are actually involved.

Abstract

Recurrent neural network language models (RNNLM) have recently demonstrated vast potential in modelling long-term dependencies for NLP problems, ranging from speech recognition to machine translation. In this work, we propose methods for conditioning RNNLMs on external side information, e.g., metadata such as keywords, description, document title or topic headline. Our experiments show consistent improvements of RNNLMs using side information over the baselines for two different datasets and genres in two languages. Interestingly, we found that side information in a foreign language can be highly beneficial in modelling texts in another language, serving as a form of cross-lingual language modelling.

1 Introduction

Neural network approaches to language modelling (LM) have made remarkable performance gains over traditional count-based $n$gram LMs (Bengio et al., 2003; Mnih and Hinton, 2007; Mikolov et al., 2011). They offer several desirable characteristics, including the capacity to generalise over large vocabularies through the use of vector space representation, and – for recurrent models (Mikolov et al., 2011) – the ability to encode long distance dependencies that are impossible to include with a limited context windows used in conventional $n$gram LMs. These early papers have spawned a cottage industry in neural LM based applications, where text generation is a key component, including conditional language models for image captioning (Kiros et al., 2014; Vinyals et al., 2015) and neural machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015).

Inspired by these works for conditioning LMs on complex side information, such as images and foreign text, in this paper we investigate the possibility of improving LMs in a more traditional setting, that is when applied directly to text documents. Typically corpora include rich side information, such as document titles, authorship, time stamp, keywords and so on, although this information is usually discarded when applying statistical models. However, this information can be highly informative, for instance, keywords, titles or descriptions, often include central topics which will be helpful in modelling or understanding the document text. We propose mechanisms for encoding this side information into a vector space representation, and means of incorporating it into the generating process in a RNNLM framework. Evaluating on two corpora and two different languages, we show consistently significant perplexity reductions over the state-of-the-art RNNLM models.

The contributions of this paper are as follows:

1. We propose a framework for encoding structured and unstructured side information, and its incorporation into a RNNLM.
2. We introduce a new corpus, the RIE corpus, based on the Europarl web archive, with rich annotations of several types of meta-data.
3. We provide empirical analysis showing consistent improvements from using side information across two datasets in two languages.

2 Problem Formulation & Model

We first review RNNLM architecture (Mikolov et al., 2011) before describing our extension in §2.2.

2.1 RNNLM Architecture

The standard RNNLM consists of 3 main layers: an input layer where each input word has its embedding via one-hot vector coding; a hidden layer consisting of recurrent units where a state is conditioned recursively on past states; and an output layer where a target word will be predicted. RNNLM has an advantage over conventional n-gram language model in modelling long distance dependencies effectively.

In general, an RNN operates from left-to-right over the input word sequence; i.e.,

$$\begin{aligned} \boldsymbol{h}_t &= \mathrm{RU}\left(\boldsymbol{x}_t, \boldsymbol{h}_{t-1}\right) \\ &= \mathrm{f}\left(\boldsymbol{W}^{(hh)}\boldsymbol{h}_{t-1} + \boldsymbol{W}^{(ih)}\boldsymbol{x}_t + \boldsymbol{b}^{(h)}\right) \\ \boldsymbol{x}_{t+1} &\sim \mathrm{softmax}\left(\boldsymbol{W}^{(ho)}\boldsymbol{h}_t + \boldsymbol{b}^{(o)}\right); \end{aligned}$$

where $f(.)$ is a non-linear function, e.g., $\tanh$, applied element-wise to its vector input; $\boldsymbol{h}_t$ is the current RNN hidden state at time-step t; and matrices $\boldsymbol{W}$ and vectors $\boldsymbol{b}$ are model parameters. The model is trained using gradient-based methods to optimise a (regularised) training objective, e.g. the likelihood function. In principle, a recurrent unit (RU) can be employed using different variants of recurrent structures such as: Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997), Gated Recurrent Unit (GRU) (Cho et al., 2014), or recently deeper structures, e.g. Depth Gated Long Short Term Memory (DGLSTM) – a stack of LSTMs with extra connections between memory cells in deep layers (Yao et al., 2015). It can be regarded as being a generalisation of LSTM recurrence to both time and depth. Such deep recurrent structure may capture long distance patterns at their most general. Empirically, we found that RNNLM with DGLSTM structure appears to be best performer across our datasets, and therefore is used predominantly in our experiments.

2.2 Incorporating Side Information

Nowadays, many corpora are archived with side information or contextual meta-data. In this work, we argue that such information can be useful for language modelling (and presumably other NLP tasks). By providing this auxiliary information directly to the RNNLM, we stand to boost language modelling performance.

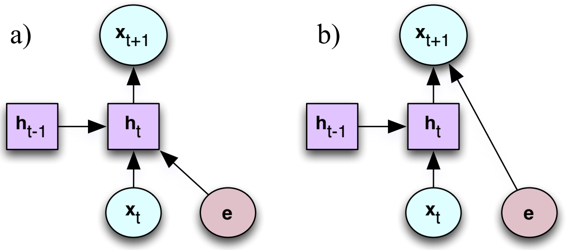

Figure 1: Integration methods for auxiliary information, $\boldsymbol{e}$: a) as input to the RNN, or b) as part of the output $\mathrm{softmax}$ layer.

The first question in using side information is how to encode these unstructured inputs, $\boldsymbol{y}$, into a vector representation, denoted $\boldsymbol{e}$. We discuss several methods for encoding the auxiliary vector:

BOW additive bag of words, $\boldsymbol{e} = \sum_t \boldsymbol{y}_t$, and

average the average embedding vector, $\boldsymbol{e} = \frac{1}{T}\sum_t \boldsymbol{y}_t$, both inspired by (Hermann and Blunsom, 2014a);

bigram convolution with sum-pooling, $\boldsymbol{e} = \sum_t \tanh\left(\boldsymbol{y}_{t-1} + \boldsymbol{y}_t\right)$ (Hermann and Blunsom, 2014b); and

RNN a recurrent neural network over the word sequence (Sutskever et al., 2014), using the final hidden state(s) as $\boldsymbol{e}$.

From the above methods, we found that BOW worked consistently well, outperforming the other approaches, and moreover lead to a simpler model with faster training. For this reason we report only results for the BOW encoding. Note that when using multiple auxiliary inputs, we use a weighted combination, $\boldsymbol{e} = \sum_i \boldsymbol{W}^{(ai)}\boldsymbol{e}^{(i)}$.

The next step is the integration of $\boldsymbol{e}$ into the RNNLM. We consider two integration methods: as input to the hidden state (denoted **input**), and connected to the output $\mathrm{softmax}$ layer (**output**), as shown in Figure 1 a and b, respectively. In both cases, we compare experimentally the following integration strategies:

add adding the vectors together, e.g., using $\boldsymbol{x}_t + \boldsymbol{e}$ as the input to the RNN, such that

$\boldsymbol{h}_t = \mathrm{RU}\left(\boldsymbol{x}_t + \boldsymbol{e}, \boldsymbol{h}_{t-1}\right)$;

stack concatenating the vectors, e.g., using $\left[\boldsymbol{x}_t^\top \boldsymbol{e}^\top\right]^\top$ for generating the RNN hidden state, such that $\boldsymbol{h}_t = \mathrm{RU}\left(\begin{bmatrix} \boldsymbol{x}_t \\ \boldsymbol{e} \end{bmatrix}, \boldsymbol{h}_{t-1}\right)$; and

mlp feeding both vectors into an extra perceptron with single hidden layer, using a tanh nonlinearity and projecting the output to the required dimensionality; i.e.,

$$\boldsymbol{h}'_t = \tanh\left(\boldsymbol{W}^{(hh')}\boldsymbol{h}_t + \boldsymbol{W}^{(he)}\boldsymbol{e} + \boldsymbol{b}^{(h')}\right)$$
$$\boldsymbol{x}_{t+1} \sim \mathrm{softmax}\left(\boldsymbol{W}^{(ho)}\boldsymbol{h}'_t + \boldsymbol{b}^{(o)}\right).$$

Note that *add* requires the vectors to be the same dimensionality, while the other two methods do not. The *stack* method can be quite costly, given that it increases the size of several matrices, either in the recurrent unit (for *input*) or the *output* mapping for word generation. This is a problem in the latter case: given the large size of the vocabulary, the matrix $\boldsymbol{W}^{(ho)}$ is already very large and making it larger (doubling the size, to become $\boldsymbol{W}^{(h'o)}$) has a sizeable effect on training time (and presumably also propensity to over-fit). The *output+stack* method does however have a compelling interpretation as a jointly trained product model between a RNNLM and a unigram model conditioned on the side information, where both models are formulated as softmax classifiers. Considered as a product model (Hinton, 2002; Pascanu et al., 2013), the two components can concentrate on different aspects of the problem where the other model is not confident, and allowed each model the ability to 'veto' certain outputs, by assigning them a low probability.

3 Experiments

Datasets. We conducted our experiments on two datasets with different genres in two languages. As the first dataset, we use the IWSLT2014 MT track on TED Talks[1] due to its self-contained rich auxiliary information, including: title, description, keywords, and author related information. We chose the English-French pair for our experiments[2] . The statistics of the training set is shown in Table 1. We used dev2010 (7 talks/817 sentences) for early stopping of training neural network models. For evaluation, we used different testing sets over years, including tst2010 (10/1587), tst2011 (7/768), tst2012 (10/1083).

	tokens (M)	types (K)	docs	sents (K)
TED-en	4.0	18.3	1414	179
TED-fr	4.3	22.6	1414	179
RIE-en	13.7	15.0	200	460
RIE-fr	14.9	19.4	200	460

Table 1: Statistics of the training sets, showing in each cell the number of word tokens, types, documents (talks or plenaries), and sentences. Note that "types" here refers to word frequency thresholded at 5 and 15 for TED Talks and RIE datasets, respectively.

As the second dataset, we crawled the entire European Parliament[3] website, focusing on plenary sessions. Such sessions contain useful structural information, namely multilingual texts divided into speaker sessions and topics. We believe that those texts are interesting and challenging for language modelling tasks. Our dataset contains 724 plenary sessions over 12.5 years until June 2011 with multilingual texts in 22 languages[4]. We refer to this dataset by RIE[5] (**R**ich **I**nformation **E**uroparl). We randomly select 200/5/30 plenary sessions as the training/development/test sets, respectively. We believe that the new data including side information pose another challenge for language modelling. Furthermore, the sizes of our working datasets are an order of magnitude larger than the standard Penn Treebank set which is often used for evaluating neural language models.

Set-up and Baselines. We have used cnn[6] to implement our models. We use the same configurations for all neural models: 512 input embedding and hidden layer dimensions, 2 hidden layers, and vocabulary sizes as given in Table 1. We used the same vocabulary for the auxiliary and modelled text. We trained a conventional 5−gram language model using modified Kneser-Ney smoothing, with the KenLM toolkit (Heafield, 2011). We used the

Wilcoxon signed-rank test (Wilcoxon, 1945) to measure the statistical significance ($p < 0.05$) on differences between sentence-level perplexity scores of improved models compared to the best baseline. Throughout our experiments, punctuation, stop words and sentence markers ($\langle$s$\rangle$, $\langle$/s$\rangle$, $\langle$unk$\rangle$) are filtered out in all auxiliary inputs. We observed that this filtering was required for BOW to work reasonably well. For each model, the best perplexity score on development set is used for early stopping of training models, which was obtained after 2-5 and 2-3 epochs on TED Talks and RIE datasets, respectively.

Results & Analysis. The perplexity results on TED Talks dataset are presented in Table 2 and 3. RNNLM variants consistently achieve substantially better perplexities compared to the conventional 5−gram language model baseline.[7] Of the basic RNNLM models (middle), the DGLSTM works consistently better than both the standard RNN and the LSTM. This may be due to better interactions of memory cells in hidden layers. Since the DGLSTM outperformed others[8], we used it for all subsequent experiments. For TED Talks dataset, there are three kinds of side information, including keywords, title, description. We attempted to inject those into different RNNLM layers, resulting in model variants as shown in Table 2. First, we chose “keywords” (+k) information as an anchor to figure out which incorporation method works well. Comparing *input*+add+k, *input*+mlp+k and *input*+stack+k, the largest decrease is obtained by *output*+mlp+k consistently across all test sets (and development sets, not shown here). We further evaluated the addition of other side information (e.g., “description” (+d), “title” (+t)), finding that +d has similar effect as +k whereas +t has a mixed effect, being detrimental for one test set (test2011). We suspect that it is due to often-times short sentences of titles in that test, after our filtering step, leading to a shortage of useful information fed into neural network learning. Interestingly, the best performance is obtained when incorporating both +k and +d, showing that there is complementary information in the two auxiliary inputs. Further, we also achieved the similar results in the counterpart of English part (in French) using *output*+mlp with both +t and +d as shown in Table 3. In French data, no “keywords” information is available. For this reason, we run additional experiments by injecting English keywords as side information into neural models of French. Interestingly, we found that “keywords” side information in English effectively improves the modelling of French texts as shown in Table 3, serving as a new form of cross-lingual language modelling.

We further achieved similar results by incorporating the topic headline in the RIE dataset. The consistently-improved results (in Table 4) demonstrate the robustness of the *output*+mlp approach.

[7] For fair comparison, when computing the perplexity with the 5-gram LM, we exclude all test words marked as $\langle$unk$\rangle$ (i.e., with low counts or OOVs) from consideration.

[8] This concurs with the finding in (Yao et al., 2015), who showed that DGLSTM produced the state-of-the-art results over Penn Treebank dataset.

DGLSTM	36.4	25.4
output+mlp+h	**33.3**	**24.0**

Table 4: Perplexity scores based on the sampled RIE dataset. +h: topic headline.

4 Conclusion

We have proposed an effective approach to boost the performance of RNNLM using auxiliary side information (e.g. keywords, title, description, topic headline) of a textual utterance. We provided an empirical analysis of various ways of injecting such information into a distributed representation, which is then incorporated into either the input, hidden, or output layer of RNNLM architecture. Our experimental results reveal consistent improvements are achieved over strong baselines for different datasets and genres in two languages. Our future work will investigate the model performance on a closely-related task, i.e., neural machine translation (Sutskever et al., 2014; Bahdanau et al., 2015). Furthermore, we will explore learning methods to combine utterances with and without the auxiliary side information.

Capturing Semantic Similarity for Entity Linking with Convolutional Neural Networks

Matthew Francis-Landau, Greg Durrett and **Dan Klein**
Computer Science Division
University of California, Berkeley
{mfl,gdurrett,klein}@cs.berkeley.edu

Abstract

A key challenge in entity linking is making effective use of contextual information to disambiguate mentions that might refer to different entities in different contexts. We present a model that uses convolutional neural networks to capture semantic correspondence between a mention's context and a proposed target entity. These convolutional networks operate at multiple granularities to exploit various kinds of topic information, and their rich parameterization gives them the capacity to learn which n-grams characterize different topics. We combine these networks with a sparse linear model to achieve state-of-the-art performance on multiple entity linking datasets, outperforming the prior systems of Durrett and Klein (2014) and Nguyen et al. (2014).[1]

1 Introduction

One of the major challenges of entity linking is resolving contextually polysemous mentions. For example, *Germany* may refer to a nation, to that nation's government, or even to a soccer team. Past approaches to such cases have often focused on collective entity linking: nearby mentions in a document might be expected to link to topically-similar entities, which can give us clues about the identity of the mention currently being resolved (Ratinov et al., 2011; Hoffart et al., 2011; He et al., 2013; Cheng and Roth, 2013; Durrett and Klein, 2014). But an even simpler approach is to use context information from just the words in the source document itself to make sure the entity is being resolved sensibly in context. In past work, these approaches have typically relied on heuristics such as tf-idf (Ratinov et al., 2011), but such heuristics are hard to calibrate and they capture structure in a coarser way than learning-based methods.

In this work, we model semantic similarity between a mention's source document context and its potential entity targets using convolutional neural networks (CNNs). CNNs have been shown to be effective for sentence classification tasks (Kalchbrenner et al., 2014; Kim, 2014; Iyyer et al., 2015) and for capturing similarity in models for entity linking (Sun et al., 2015) and other related tasks (Dong et al., 2015; Shen et al., 2014), so we expect them to be effective at isolating the relevant topic semantics for entity linking. We show that convolutions over multiple granularities of the input document are useful for providing different notions of semantic context. Finally, we show how to integrate these networks with a preexisting entity linking system (Durrett and Klein, 2014). Through a combination of these two distinct methods into a single system that leverages their complementary strengths, we achieve state-of-the-art performance across several datasets.

2 Model

Our model focuses on two core ideas: first, that topic semantics at different granularities in a document are helpful in determining the genres of entities for entity linking, and second, that CNNs can distill a block of text into a meaningful topic vector.

Our entity linking model is a log-linear model that places distributions over target entities t given a mention x and its containing source document. For now, we take $P(t|x) \propto \exp w^\top f_C(x, t; \theta)$, where f_C produces a vector of features based on CNNs with parameters θ as discussed in Section 2.1. Section 2.2 describes how we combine this simple model with a full-fledged entity linking system. As shown in the middle of Figure 1, each feature in f_C

Figure 1: Extraction of convolutional vector space features $f_C(x, t_e)$. Three types of information from the input document and two types of information from the proposed title are fed through convolutional networks to produce vectors, which are systematically compared with cosine similarity to derive real-valued semantic similarity features.

is a cosine similarity between a topic vector associated with the source document and a topic vector associated with the target entity. These vectors are computed by distinct CNNs operating over different subsets of relevant text.

Figure 1 shows an example of why different kinds of context are important for entity linking. In this case, we are considering whether *Pink Floyd* might link to the article `Gavin_Floyd` on Wikipedia (imagine that *Pink Floyd* might be a person's nickname). If we look at the source document, we see that the immediate source document context around the mention *Pink Floyd* is referring to rock groups (*Led Zeppelin*, *Van Halen*) and the target entity's Wikipedia page is primarily about sports (*baseball starting pitcher*). Distilling these texts into succinct topic descriptors and then comparing those helps tell us that this is an improbable entity link pair. In this case, the broader source document context actually does not help very much, since it contains other generic last names like *Campbell* and *Savage* that might not necessarily indicate the document to be in the music genre. However, in general, the whole document might provide a more robust topic estimate than a small context window does.

2.1 Convolutional Semantic Similarity

Figure 1 shows our method for computing topic vectors and using those to extract features for a potential Wikipedia link. For each of three text granularities in the source document (the mention, that mention's immediate context, and the entire document) and two text granularities on the target entity side (title and Wikipedia article text), we produce vector representations with CNNs as follows. We first embed each word into a d-dimensional vector space using standard embedding techniques (discussed in Section 3.2), yielding a sequence of vectors $w_1, \ldots, w_n$. We then map those words into a fixed-size vector using a convolutional network parameterized with a filter bank $M \in \mathbb{R}^{k \times d\ell}$. We put the result through a rectified linear unit (ReLU) and combine the results with sum pooling, giving the following formulation:

$$\mathrm{conv}_g(w_{1:n}) = \sum_{j=1}^{n-\ell} \max\{0, M_g w_{j:j+\ell}\} \qquad (1)$$

where $w_{j:j+\ell}$ is a concatenation of the given word vectors and the max is element-wise.[2] Each convolution granularity (mention, context, etc.) has a distinct set of filter parameters M_g.

This process produces multiple representative topic vectors s_{ment}, $s_{context}$, and s_{doc} for the source document and t_{title} and t_{doc} for the target entity, as shown in Figure 1. All pairs of these vectors between the source and the target are then compared using cosine similarity, as shown in the middle of Figure 1. This yields the vector of features $f_C(s, t_e)$ which indicate the different types of similarity; this

[2] For all experiments, we set $\ell = 5$ and $k = 150$.

vector can then be combined with other sparse features and fed into a final logistic regression layer (maintaining end-to-end inference and learning of the filters). When trained with backpropagation, the convolutional networks should learn to map text into vector spaces that are informative about whether the document and entity are related or not.

2.2 Integrating with a Sparse Model

The dense model presented in Section 2.1 is effective at capturing semantic topic similarity, but it is most effective when combined with other signals for entity linking. An important cue for resolving a mention is the use of link counts from hyperlinks in Wikipedia (Cucerzan, 2007; Milne and Witten, 2008; Ji and Grishman, 2011), which tell us how often a given mention was linked to each article on Wikipedia. This information can serve as a useful prior, but only if we can leverage it effectively by targeting the most salient part of a mention. For example, we may have never observed *President Barack Obama* as a linked string on Wikipedia, even though we have seen the substring *Barack Obama* and it unambiguously indicates the correct answer.

Following Durrett and Klein (2014), we introduce a latent variable q to capture which subset of a mention (known as a *query*) we resolve. Query generation includes potentially removing stop words, plural suffixes, punctuation, and leading or tailing words. This processes generates on average 9 queries for each mention. Conveniently, this set of queries also defines the set of candidate entities that we consider linking a mention to: each query generates a set of potential entities based on link counts, whose unions are then taken to give on the possible entity targets for each mention (including the null link). In the example shown in Figure 1, the query phrases are *Pink Floyd* and *Floyd*, which generate `Pink_Floyd` and `Gavin_Floyd` as potential link targets (among other options that might be derived from the *Floyd* query).

Our final model has the form $P(t|x) = \sum_q P(t, q|x)$. We parameterize $P(t, q|x)$ in a log-linear way with three separate components:

$$P(t, q|x) \propto \exp\left(w^\top(f_Q(x, q) + f_E(x, q, t) + f_C(x, t; \theta))\right)$$

f_Q and f_E are both sparse features vectors and are taken from previous work (Durrett and Klein, 2014). f_C is as discussed in Section 2.1. Note that f_C has its own internal parameters θ because it relies on CNNs with learned filters; however, we can compute gradients for these parameters with standard backpropagation. The whole model is trained to maximize the log likelihood of a labeled training corpus using Adadelta (Zeiler, 2012).

The indicator features f_Q and f_E are described in more detail in Durrett and Klein (2014). f_Q only impacts which query is selected and not the disambiguation to a title. It is designed to roughly capture the basic shape of a query to measure its desirability, indicating whether suffixes were removed and whether the query captures the capitalized subsequence of a mention, as well as standard lexical, POS, and named entity type features. f_E mostly captures how likely the selected query is to correspond to a given entity based on factors like anchor text counts from Wikipedia, string match with proposed Wikipedia titles, and discretized cosine similarities of tf-idf vectors (Ratinov et al., 2011). Adding tf-idf indicators is the only modification we made to the features of Durrett and Klein (2014).

3 Experimental Results

We performed experiments on 4 different entity linking datasets.

- ACE (NIST, 2005; Bentivogli et al., 2010): This corpus was used in Fahrni and Strube (2014) and Durrett and Klein (2014).
- CoNLL-YAGO (Hoffart et al., 2011): This corpus is based on the CoNLL 2003 dataset; the test set consists of 231 news articles and contains a number of rarer entities.
- WP (Heath and Bizer, 2011): This dataset consists of short snippets from Wikipedia.
- Wikipedia (Ratinov et al., 2011): This dataset consists of 10,000 randomly sampled Wikipedia articles, with the task being to resolve the links in each article.[3]

[3] We do not compare to Ratinov et al. (2011) on this dataset because we do not have access to the original Wikipedia dump they used for their work and as a result could not duplicate their results or conduct comparable experiments, a problem which was also noted by Nguyen et al. (2014).

Table 1: Performance of the system in this work (Full) compared to two baselines from prior work and two ablations. Our results outperform those of Durrett and Klein (2014) and Nguyen et al. (2014). In general, we also see that the convolutional networks by themselves can outperform the system using only sparse features, and in all cases these stack to give substantial benefit.

We use standard train-test splits for all datasets except for WP, where no standard split is available. In this case, we randomly sample a test set. For all experiments, we use word vectors computed by running word2vec (Mikolov et al., 2013) on all Wikipedia, as described in Section 3.2.

Table 1 shows results for two baselines and three variants of our system. Our main contribution is the combination of indicator features and CNN features (Full). We see that this system outperforms the results of Durrett and Klein (2014) and the AIDA-LIGHT system of Nguyen et al. (2014). We can also compare to two ablations: using just the sparse features (a system which is a direct extension of Durrett and Klein (2014)) or using just the CNN-derived features.[5] Our CNN features generally outperform the sparse features and improve even further when stacked with them. This reflects that they capture orthogonal sources of information: for example, the sparse features can capture how frequently the target document was linked to, whereas the CNNs can capture document context in a more nuanced way. These CNN features also clearly supersede the sparse features based on tf-idf (taken from (Ratinov et al., 2011)), showing that indeed that CNNs are better at learning semantic topic similarity than heuristics like tf-idf.

$cosim(s_{ment}, t_{title})$	80.19	80.86	70.25
All CNN pairs	84.85	86.91	82.02

Table 2: Comparison of using only topic information derived from the document and target article, only information derived from the mention itself and the target entity title, and the full set of information (six features, as shown in Figure 1). Neither the finest nor coarsest convolutional context can give the performance of the complete set. Numbers are reported on a development set.

In the sparse feature system, the highest weighted features are typically those indicating the frequency that a page was linked to and those indicating specific lexical items in the choice of the latent query variable q. This suggests that the system of Durrett and Klein (2014) has the power to pick the right span of a mention to resolve, but then is left to generally pick the most common link target in Wikipedia, which is not always correct. By contrast, the full system has a greater ability to pick less common link targets if the topic indicators distilled from the CNNs indicate that it should do so.

3.1 Multiple Granularities of Convolution

One question we might ask is how much we gain by having multiple convolutions on the source and target side. Table 2 compares our full suite of CNN features, i.e. the six features specified in Figure 1, with two specific convolutional features in isolation. Using convolutions over just the source document (s_{doc}) and target article text (t_{doc}) gives a system[6] that performs, in aggregate, comparably to using convolutions over just the mention (s_{ment}) and the entity title (t_{title}). These represent two extremes of the system: consuming the maximum amount of context, which might give the most robust representation of topic semantics, and consuming the minimum amount of context, which gives the most focused representation of topics semantics (and which more generally might allow the system to directly memorize train-test pairs observed in training). However, neither performs as well as the combination of all CNN features, showing that the different granularities capture complementary aspects of the entity linking task.

[4] The test set for this dataset is only 40 out of 10,000 documents and subject to wide variation in performance.

[5] In this model, the set of possible link targets for each mention is still populated using anchor text information from Wikipedia (Section 2.2), but note that link counts are not used as a feature here.

[6] This model is roughly comparable to Model 2 as presented in Sun et al. (2015).

Table 3: Five-grams representing the maximal activations from different filters in the convolution over the source document (M_{doc}, producing s_{doc} in Figure 1). Some filters tend towards singular topics as shown in the first and second columns, which focus on weapons and trials, respectively. Others may have a mix of seemingly unrelated topics, as shown in the third column, which does not have a coherent theme. However, such filters might represent a superposition of filters for various topics which never cooccur and thus never need to be disambiguated between.

Wikipedia	89.5	90.6	85.5

Table 4: Results of the full model (sparse and convolutional features) comparing word vectors derived from Google News vs. Wikipedia on development sets for each corpus.

3.2 Embedding Vectors

We also explored two different sources of embedding vectors for the convolutions. Table 4 shows that word vectors trained on Wikipedia outperformed Google News word vectors trained on a larger corpus. Further investigation revealed that the Google News vectors had much higher out-of-vocabulary rates. For learning the vectors, we use the standard word2vec toolkit (Mikolov et al., 2013) with vector length set to 300, window set to 21 (larger windows produce more semantically-focused vectors (Levy and Goldberg, 2014)), 10 negative samples and 10 iterations through Wikipedia. We do not fine-tune word vectors during training of our model, as that was not found to improve performance.

3.3 Analysis of Learned Convolutions

One downside of our system compared to its purely indicator-based variant is that its operation is less interpretable. However, one way we can inspect the learned system is by examining what causes high activations of the various convolutional filters (rows of the matrices M_g from Equation 1). Table 3 shows the n-grams in the ACE dataset leading to maximal activations of three of the filters from M_{doc}. Some filters tend to learn to pick up on n-grams characteristic of a particular topic. In other cases, a single filter might be somewhat inscrutable, as with the third column of Table 3. There are a few possible explanations for this. First, the filter may generally have low activations and therefore have little impact in the final feature computation. Second, the extreme points of the filter may not be characteristic of its overall behavior, since the bulk of n-grams will lead to more moderate activations. Finally, such a filter may represent the superposition of a few topics that we are unlikely to ever need to disambiguate between; in a particular context, this filter will then play a clear role, but one which is hard to determine from the overall shape of the parameters.

4 Conclusion

In this work, we investigated using convolutional networks to capture semantic similarity between source documents and potential entity link targets. Using multiple granularities of convolutions to evaluate the compatibility of a mention in context and several potential link targets gives strong performance on its own; moreover, such features also improve a pre-existing entity linking system based on sparse indicator features, showing that these sources of information are complementary.

K-Embeddings: Learning Conceptual Embeddings for Words using Context

Thuy Vu and **D. Stott Parker**
Department of Computer Science

{thuy;stott}@cs.ucla.edu

Abstract

We describe a technique for adding contextual distinctions to word embeddings by extending the usual embedding process — into two phases. The first phase resembles existing methods, but also constructs K classifications of concepts. The second phase uses these classifications in developing refined K embeddings for words, namely word K-embeddings. The technique is iterative, scalable, and can be combined with other methods (including Word2Vec) in achieving still more expressive representations.

Experimental results show consistently large performance gains on a Semantic-Syntactic Word Relationship test set for different K settings. For example, an overall gain of 20% is recorded at $K = 5$. In addition, we demonstrate that an iterative process can further tune the embeddings and gain an extra 1% ($K = 10$ in 3 iterations) on the same benchmark. The examples also show that polysemous concepts are meaningfully embedded in our K different conceptual embeddings for words.

1 Introduction

Neural-based word embeddings are vectorial representations of words in high dimensional real valued space. Success with these representations have resulted in their being considered for an increasing range of natural language processing (NLP) tasks. Recent advances in word embeddings have shown great effects that are pushing forward state-of-the-art results in NLP (Koo et al., 2008; Turian et al., 2010; Collobert et al., 2011; Yu et al., 2013; Mikolov et al., 2013a; Mikolov et al., 2013b; Mikolov et al., 2013c). Embedding learning models for words are also being adapted for tasks in other research fields (Reinanda et al., 2015; Vu and Parker, 2015). The Continuous bag of words (CBOW) and Skip-gram (Mikolov et al., 2013a) are currently considered as state-of-the-art in learning algorithms for word embeddings.

The ability of words to assume different roles (syntax) or meanings (semantics) presents a basic challenge to the notion of word embedding (Erk and Padó, 2008; Reisinger and Mooney, 2010; Huang et al., 2012; Tian et al., 2014; Neelakantan et al., 2014; Chen et al., 2015). External resources and features are introduced to address this challenge. In general, individuals with no linguistic background can generally resolve these differences without difficulty. For example, they can distinguish "bank" as referring to a riverside or a financial establishment without semantic or syntactic analysis.

Distinctions of role and meaning often follow from context. The idea of exploiting context in linguistics was introduced with a distributional hypothesis: "linguistic items with similar distributions have similar meanings" (Harris, 1954). Firth soon afterwards emphasized this in a famous quote: "a word is characterized by the company it keeps" (1957).

We propose to exploit only context information to distinguish different concepts behind words in this paper. The contribution of this paper is to note that a *two-phase word embedding* training can be helpful in adding contextual information to existing embedding methods:

- we use learned context embeddings to effi-

Proceedings of NAACL-HLT 2016, pages 1262–1267,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

ciently cluster word contexts into K classifications of concepts, independent of the word embeddings.

- this approach can complement existing sophisticated, linguistically-based features, and can be used with word embeddings to achieve gains in performance by considering contextual distinctions for words.

- two-phase word embedding may have other applications as well, conceivably permitting some 'non-linear' refinements of linear embeddings.

In the next section we present our learning strategy for word K-embeddings, outlining how the value of K affects its power in increasing syntactic and semantic distinctions. Following this, a large-scale experiment serves to validate the idea — from several different perspectives. Finally, we offer conclusions about how adding contextual distinctions to word embeddings (with our second phase of embedding) can gain power in distinguishing among different aspects of words.

2 Learning Word K-Embeddings

The use of multiple semantic representations for a word in resolving polysemy has a significant literature (Erk and Padó, 2008; Reisinger and Mooney, 2010; Huang et al., 2012; Tian et al., 2014; Neelakantan et al., 2014; Chen et al., 2015). Strategies often focus on discrimination using syntactic and semantic information.

We investigate another direction — the extension of the word embedding process into a second phase — which allows context information to be consolidated with the embedding. Rather than annotating words with features, our technique treats context as second-order in nature, suggesting an additional representation step.

Our learning strategy for word K-embeddings is therefore done, possibly iteratively, in two phases:

1. Annotating words with concepts (defined by their contextual clusters)

2. Training embeddings using the resulting annotated text.

2.1 Concept Annotation using Context Embeddings

We propose to annotate words with concepts given by learned context embeddings, which are an underutilized output of word embedding training. Our strategy is based on the assumption that the context of a word is useful for discriminating its conceptual alternatives in polysemy. In general, our concept annotation for words is performed in two steps — clustering of context embeddings followed by annotation.

Specifically, we first employ a clustering algorithm to cluster the context embeddings. K-means is our algorithm of choice. The clustering algorithm will assign each context word to a distinct cluster. This result is then used to re-assign words in training data to their contextual cluster.

Second, we annotate words in the training data with their most common contextual cluster (of their context words). We define *context words* to mean the surrounding words of a given word. Formally, a word is annotated with a concept given by the following function:

$$\max_{c \in \mathcal{C}} \sum_{(w_i, c_i) \in W} f(c_i, c)$$

Here W is the set of context words of the current word, and $f(c_i, c_j)$ is a boolean function whose output is 1 if the input parameters are equal:

$$f(c_i, c_j) = \begin{cases} 1, & \text{if } c_i = c_j \\ 0, & \text{otherwise.} \end{cases}$$

The cluster-annotated dataset is then passed into the next training phase.

2.2 Training Word K-Embeddings

The second phase is similar to existing word embedding training systems. The number of clusters K defines the maximum number of different representations for words. Table 1 presents the statistics for different selections of K using the dataset mentioned in the **Experiments** section.

Each value K in Table 1 is shown with the total number of embeddings and vocabulary size. Words in the vocabulary can have up to K different embeddings for different annotated concepts. As K increases, the size of the vocabulary decreases —

K	total embeddings	vocabulary size	ratio
1	1,965,139	1,965,139	1.00
5	2,807,016	1,443,061	1.95
10	2,740,351	1,474,704	1.86
15	3,229,945	1,374,055	2.35
20	3,236,882	1,410,521	2.29
25	3,382,722	1,383,162	2.45
30	3,404,150	1,418,027	2.40

Table 1: Total embeddings and vocabulary size for different K for Wikipedia dataset. Words with frequency lower than 5 are filtered during pre-processing.

yet remains largely stable for different values of K greater than 1. This is explained by the count of words being scattered to different concepts, resulting in a lower word count per concept. In our setting, concept-annotated words with fewer than 5 occurrences will be discarded during training of word embeddings.

It is interesting to note that the total number of embeddings is broadly stable and less affected by K. For example, as we allow up to 10 different concepts for a word ($K = 10$), the total number of embeddings grows only slightly compared to the result for $K = 1$. The average number of embeddings for a word is 1.86 for $K = 10$. In other words, concept annotations do converge as we increase K.

2.3 Word K-Embedding Training Workflow

Figure 1 presents our proposed workflow to train context-based conceptual word K-embeddings. Our system allows each word to have at most K different embeddings, where each is a representation for a certain concept.

The input to the workflow is a large-scale text dataset. Initially, we compute context embeddings for words as presented previously. We can derive context embeddings directly from the training of almost any context-based word embeddings, where word embeddings are computed via their context words.

Subsequently, we cluster context embeddings into groups which reflect varied concepts on some semantic vector space. Each context embedding is assigned to a cluster denoting its conceptual role as a context word. Any clustering algorithm for vectors can be applied for this task.

Embeddings of annotated context words are used to compute concepts of words in a sentence. We hypothesize that the concept of a word is defined by the concept of its surrounding words. We annotate concepts for all words in the training data.

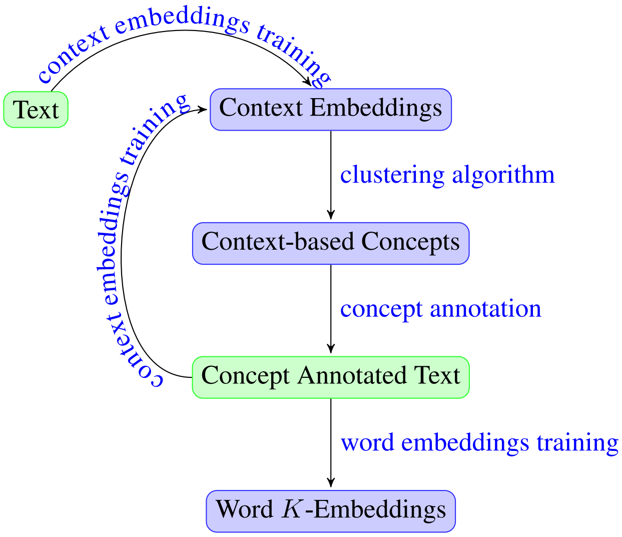

Figure 1: Training Word K-Embeddings

Finally, the concept-annotated training data is passed into any standard algorithm for training word embeddings for the conceptual word K-embeddings.

3 Experiments

3.1 Settings

Our training data for word embeddings is Wikipedia for English, downloaded on November 29, 2014. It consists of 4,591,457 articles, with a total of 2,015,823,886 words. The dataset is pre-processed with sentence and word tokenization. We convert text to lower-case prior to training. We consider $|W| = 5$ for the size of the context window W presented in Section 2.1.

We used the Semantic-Syntactic Word Relationship test set (Mikolov et al., 2013a) for our experimental studies. This dataset consists of 8,869 semantic and 10,675 syntactic queries. Each query is a tuple of four words (A, B, C, D) for the question "A is to B as C to what?". These queries can be either semantic or syntactic. D, to be predicted from the learned embeddings, is defined as the closest word to the vector $(A - B + C)$. We used Word2Vec for training and `scikit-learn` for clustering tasks.

We evaluate the accuracy of the prediction of D in these queries. A query is considered hit if there exists at least one correct match and all the words are in the same concept group. This is based on the assumption that if "A is to B as C is to D", either (A, B) and (C, D) OR (A, C) and (B, D) have to be in the same concept group.

3.2 Results

The embeddings learned in phases 1 and 2 can be compared, using different values for K in the K-means clustering. Word relationship performance results are shown in Table 2.

Our proposed technique in phase 2 achieves consistently high performance. For example, when $K = 5$, our absolute performance is 89% and 81% in semantic and syntactic relationship evaluations, gaining 24% and 16% from the standard CBOW model (phase 1). When $K = 25$, the performance yields the best combined result. As shown in Table 1, the total number of embeddings and vocabulary size differ by a small multiplicative factor as K increases.

In another comparison, Figure 2 plots our K-Embeddings results versus the results of a *relaxed* evaluation for CBOW, which considers the top K embeddings instead of the best. Even though our evaluation is restricted to one-best for each of the K embeddings, the overall (combined) performance for different K settings is still consistently better than the top K embeddings of CBOW. Moreover, for a specific K setting, the total number of different embeddings considered in K-Embeddings is always less than that of the top K. For example, in our peak result ($K = 25$), the total number of embeddings considered in the evaluation set is only about 76.17% of the total embeddings with the top 25 of CBOW.

In addition, we also compare the performances of K-embeddings in multiple iterations under the same K setting in Table 3. It shows that the K-embeddings are improved after certain number of iterations. Particularly, for $K = 10$, we can achieve best performance after 3 to 4 iterations, gaining roughly 1%.

Finally, it is also worth noting that the performance does not always increase linearly with the number of embeddings or vocabulary size. This suggests that as we achieve better performance in K-embeddings, we should also gain more compact conceptual embeddings.

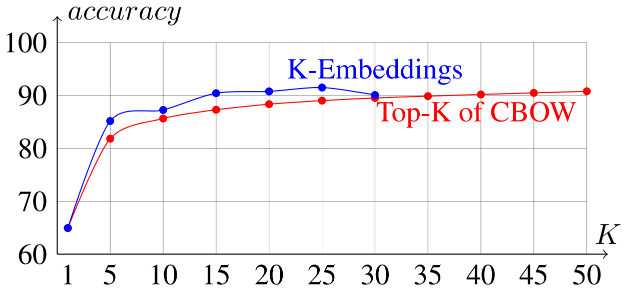

Figure 2: Word K-Embeddings and Top-K of CBOW accuracy comparison

3.3 Word Expressivity Analysis

Expressivity of word groups for "mercury" and "fan" are studied in Table 4. The first two rows shows most related words of "mercury" and "fan" without concepts annotation (baseline). The following rows present our K-embeddings result. This table illustrates the differences that arise in multiple representations of a word, and shows semantic distinctions among these representations.

For example, different representations for the word "mercury" indeed represent a spectrum of aspects for the word, ranging from related-cosmos, related chemical element, automobile, or even to music. The same can be seen for "fan" — where we find concepts related to fan as a follower/supporter, fan as in machinery, or Fan as a common Chinese surname. Indeed, we can find many different conceptual readings of these words. These not only reflect different polysemous meanings, but also their conceptual aspects in the real world. Observe that most related words are grouped into distinct concept groups, and thus yield strong semantic distinctions. The result firmly suggests that context embeddings, like word embeddings, can capture linguistic regularities efficiently.

Table 4: Word Expressivity Analysis

4 Conclusion

In this paper, we have presented a technique for adding contextual distinctions to word embeddings with a second phase of embedding. This contextual information gains power in distinguishing among different aspects of words. Experimental results with embedding of the English variant of Wikipedia (over 2 billion words) shows significant improvements in both semantic- and syntactic- based word embedding performance. The result also presents a wide range of interesting concepts of words in expressivity analysis.

These results strongly support the idea of using context embeddings to exploit context information for problems in NLP. As we highlighted earlier, context embeddings are underutilized, even though word embeddings have been extensively exploited in multiple applications.

Furthermore, the contextual approach can complement existing sophisticated, linguistically-based features, and can be combined with other learning methods for embedding. These results are encouraging; they suggest that useful extensions of current methods are possible with two-phase embeddings.

Abstract

In this paper, we study, compare and combine two state-of-the-art approaches to automatic feature engineering: Convolution Tree Kernels (CTKs) and Convolutional Neural Networks (CNNs) for learning to rank answer sentences in a Question Answering (QA) setting. When dealing with QA, the key aspect is to encode relational information between the constituents of question and answer in learning algorithms. For this purpose, we propose novel CNNs using relational information and combined them with relational CTKs. The results show that (i) both approaches achieve the state of the art on a question answering task, where CTKs produce higher accuracy and (ii) combining such methods leads to unprecedented high results.

1 Introduction

The increasing use of machine learning for the design of NLP applications pushes for fast methods for feature engineering. In contrast, the latter typically requires considerable effort especially when dealing with highly semantic tasks such as QA. For example, for an effective design of automated QA systems, the question text needs to be put in relation with the text passages retrieved from a document collection to enable an accurate extraction of the correct answers from passages. From a machine learning perspective, encoding the information above consists in manually defining expressive rules and features based on syntactic and semantic patterns.

Therefore, methods for automatizing feature engineering are remarkably important also in the light of fast prototyping of commercial applications. To the best of our knowledge, two of the most effective methods for engineering features are: (i) kernel methods, which naturally map feature vectors or directly objects in richer feature spaces; and more recently (ii) approaches based on deep learning, which have been shown to be very effective.

Regarding the former, in (Moschitti et al., 2007), we firstly used CTKs in Support Vector Machines (SVMs) to generate features from a question (Q) and their candidate answer passages (AP). CTKs enable SVMs to learn in the space of convolutional subtrees of syntactic and semantic trees used for representing Q and AP. This automatically engineers syntactic/semantic features. One important characteristic we added in (Severyn and Moschitti, 2012) is the use of relational links between Q and AP, which basically merged the two syntactic trees in a relational graph (containing relational features).

Although based on different principles, also CNNs can generate powerful features, e.g., see (Kalchbrenner et al., 2014; Kim, 2014). CNNs can effectively capture the compositional process of mapping the meaning of individual words in a sentence to a continuous representation of the sentence. This way CNNs can efficiently learn to embed input sentences into low-dimensional vector space, preserving important syntactic and semantic aspects of the input sentence. However, engineering features spanning two pieces of text such as in QA is a more complex task than classifying single sentences. Indeed, only very recently, CNNs were proposed for QA by Yu et al. (2014). Although, such network achieved high accuracy, its design is still not enough to model relational features.

Proceedings of NAACL-HLT 2016, pages 1268–1278,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

In this paper, we aim at comparing the ability of CTKs and CNNs of generating features for QA. For this purpose, we first explore CTKs applied to shallow linguistic structures for automatically learning classification and ranking functions with SVMs.

At the same time, we assess a novel deep learning architecture for effectively modeling Q and AP pairs generating relational features we initially modeled in (Severyn and Moschitti, 2015; Severyn and Moschitti, 2016). The main building blocks of our approach are two sentence models based on CNNs. These work in parallel, mapping questions and answer sentences to fixed size vectors, which are then used to learn the semantic similarity between them. To compute question-answer similarity score we adopt the approach used by Yu et al. (2014). Our main novelty is the way we model relational information: we inject overlapping words directly into the word embeddings as additional dimensions. The augmented word representation is then passed through the layers of the convolutional feature extractors, which encode the relatedness between Q and AP pairs in a more structured manner. Moreover, the embedding dimensions encoding overlapping words are parameters of the network and are tuned during training.

We experiment with two different QA benchmarks for sentence reranking TREC13 (Wang et al., 2007) and WikiQA (Yang et al., 2015). We compare CTKs and CNNs and then we also combine them. For this purpose, we design a new kernel that sum together CTKs and different embeddings extracted from different CNN layers. Our CTK-based models achieve the state of the art on TREC 13, obtaining an MRR of 85.53 and an MAP of 75.18 largely outperforming all the previous best results. On WikiQA, our CNNs perform almost on par with tree kernels, i.e., an MRR of 71.07 vs. 72.51 of CTK, which again is the current state of the art on such data. The combination between CTK and CNNs produces a further boost, achieving an MRR of 75.52 and an MAP of 73.99, confirming that the research line of combining these two interesting machine learning methods is very promising.

2 Related Work

Relational learning from entire pieces of text concerns several natural language processing tasks, e.g., QA (Moschitti, 2008), Textual Entailment (Zanzotto and Moschitti, 2006) and Paraphrase Identification (Filice et al., 2015). Regarding QA, a referring work for our research is the IBM Watson system (Ferrucci et al., 2010). This is an advanced QA pipeline based on deep linguistic processing and semantic resources.

Wang et al. (2007) used quasi-synchronous grammar to model relations between a question and a candidate answer with syntactic transformations. (Heilman and Smith, 2010) applied Tree Edit Distance (TED) for learning tree transformations in a Q/AP pair. (Wang and Manning, 2010) designed a probabilistic model to learn tree-edit operations on dependency parse trees. (Yao et al., 2013) applied linear chain CRFs with features derived from TED to automatically learn associations between questions and candidate answers. Yih et al. (2013a) applied enhanced lexical semantics to build a word-alignment model, exploiting a number of large-scale external semantic resources.

Although the above approaches are very valuable, they required considerable effort to study, define and implement features that could capture relational representations. In contrast, we are interested in techniques that try to automatize the feature engineering step. In this respect, our work (Moschitti et al., 2007) is the first using CTKs applied to syntactic and semantic structural representations of the Q/AP pairs in a learning to rank algorithm based on SVMs. After this, we proposed several important improvement exploiting different type of relational links between Q and AP, i.e., (Severyn and Moschitti, 2012; Severyn et al., 2013; Severyn and Moschitti, 2013; Tymoshenko et al., 2014; Tymoshenko and Moschitti, 2015). The main difference with our previous approaches is usage of better-preprocessing algorithms and new structural representations, which highly outperform them.

Recently, deep learning approaches have been successfully applied to various sentence classification tasks, e.g., (Kalchbrenner et al., 2014; Kim, 2014), and for automatically modeling text pairs, e.g., (Lu and Li, 2013; Hu et al., 2014). Additionally, a number of deep learning models have been recently applied to question answering, e.g., Yih et al. (2014) applied CNNs to open-domain QA; Bordes et al. (2014b) propose a neural embedding model

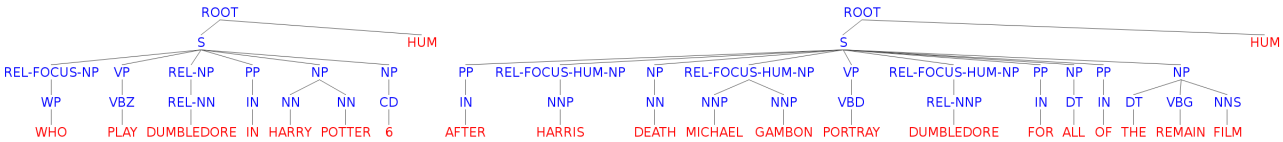

Figure 1: Shallow chunk-based tree for the Q/AP pair in the running example.

combined with the knowledge base for open-domain QA; Iyyer et al. (2014) applied recursive neural networks to factoid QA over paragraphs. (Miao et al., 2015) proposed a neural variational inference model and a Long-short Term Memory network for the same task. Recently (Yin et al., 2015) proposed a siamese convolutional network for matching sentences that employ an attentive average pooling mechanism, obtaining state-of-the-art results in various tasks and datasets. The work closest to this paper is (Yu et al., 2014) and (Severyn and Moschitti, 2015). The former presented a CNN architecture for answer sentence selection that uses a bigram convolution and average pooling, whereas in the latter we used convolution with k-max pooling. However, these models only partially captures relational information. In contrast, in this paper, we encode relational information about words that are matched betweem Q and AP.

3 Feature Engineering for QA with CTKs

Our approach to learning relations between two texts is to first convert them into a richer structural representation based on their syntactic and semantic structures, and then apply CTKs. To make our approach more effective, we further enriched structures with relational semantics by linking the related constituents with lexical and other semantic links.

3.1 Shallow Representation of Short Text Pairs

In our study, we employ a modified version of the shallow structural representation of question and answer pairs, **CH**, described in (Severyn et al., 2013; Tymoshenko and Moschitti, 2015). We represent a pair of short texts as two trees with lemmas at leaf level and their part-of-speech (POS) tags at the preterminal level. Preterminal POS-tags are grouped into chunk nodes and the chunks are further grouped into sentences. Figure 1 provides an example of this structure.

We enrich the above representation with the information about question class and question focus. Questions are classified in terms of their expected answer type. (Severyn et al., 2013) employed coarse-grained classes from (Li and Roth, 2002), namely HUM (person), ENTY (an entity), DESC (description), LOC (location), and NUM (number). In this work, we split the NUM class into three subcategories, DATE, QUANTITY, CURRENCY and train question classifiers as described in (Severyn et al., 2013). Differently from before, we add the question class node as the rightmost child of the root node both to the question and the answer structures.

We detect question focus using a focus classifier, FCLASS, trained as in (Severyn et al., 2013). However, in our previous model, we classified all words over the chunks in the question and picked the one with the highest FCLASS prediction score as a focus even if it is negative. In this work, if FCLASS assigns negative scores to all the question chunks, we consider the first question chunk, which is typically a question word, to be a focus. We mark the focus chunk by prepending the REL-FOCUS tag to its label.

In previous work, we have shown the importance of encoding information about the relatedness between Q and AP into their structural representations. Thus, we employ lexical and question class match, described hereafter.

Lexical match. Lemmas that occur both in Q and AP are marked by prepending the **REL** tag to the labels of the corresponding preterminal nodes and their parents.

Question class match. We detect named entities (NEs) in AP and mark the NEs of type compatible[1] with the question class by prepending the REL-FOCUS-QC label to the corresponding prepreterminals in the trees. The QC suffix in the labels

[1] Compatibility is checked using a predefined table, namely Person, Organization→HUM, ENTY; Misc→ENTY; Location→LOC; Date, Time, Number→DATE; Money, Number→CURRENCY; Percentage, Number→QUANTITY

is replaced by the question class in the given pair.

For example, in Figure 1, the *Dumbledore* lemma occurs in both Q and AP, therefore the respective POS and chunk nodes are marked with **REL**. The named entities, *Harris*, *Michael Gambon* and *Dumbledore* have the type Person compatible with the question class HUM, thus their respective chunk nodes are marked as REL-FOCUS-HUM (overriding the previously inserted REL tag for the *Dumbledore* chunk).

3.2 Reranking with Tree Kernels

We aim at learning reranker that can decide which Q/AP pair is more probably correct than others, where correct Q/AP pairs are formed by an AP containing a correct answer to Q along with a supporting justification. We adopt the following kernel for reranking: $P_K(\langle o_1, o_2\rangle, \langle o'_1, o'_2\rangle) = K(o_1, o'_1) + K(o_2, o'_2) - K(o_1, o'_2) - K(o_2, o'_1)$. In our case, $o_i = \langle Q_i, AP_i\rangle$ and $o'_j = \langle Q'_j, AP'_j\rangle$, where Q and AP are the trees defined in the previous section, $K(o_i, o'_j) = TK(Q_i, Q'_j) + TK(AP_i, AP'_j)$ and TK is a tree kernel function. Finally, we also add $(\vec{V}(o_1) - \vec{V}(o_2)) \cdot (\vec{V}(o'_1) - \vec{V}(o'_2))$ to P_K, where $\vec{V}(o_i)$ is a feature vector representing Q/AP pairs.

4 Feature Engineering for QA with CNNs

The architecture of our convolutional neural network for matching Q and AP pairs is presented in Fig. 2. Its main components are: (i) sentence matrices $\mathbf{s}_i \in \mathbb{R}^{d\times|\mathbf{i}|}$ obtained by the concatenation of the word vectors $\mathbf{w}_j \in \mathbb{R}^d$ (with d being the size of the embeddings) of the corresponding words w_j from the input sentences (Q and AP) $\mathbf{s}_i$; (ii) a convolutional sentence model $f : \mathbb{R}^{d\times|\mathbf{i}|} \to \mathbb{R}^m$ that maps the sentence matrix of an input sentence $\mathbf{s}_i$ to a fixed-size vector representations $\mathbf{x}_{s_i}$ of size m; (iii) a layer for computing the similarity between the obtained intermediate vector representations of the input sentences, using a similarity matrix $\mathbf{M} \in \mathbb{R}^{m\times m}$ – an intermediate vector representation $\mathbf{x}_{s_1}$ of a sentence $\mathbf{s}_1$ is projected to a $\tilde{\mathbf{x}}_{s_1} = \mathbf{x}_{s_1}\mathbf{M}$, which is then matched with $\mathbf{x}_{s_2}$ (Bordes et al., 2014a), i.e., by computing a dot-product $\tilde{\mathbf{x}}_{s_1}\mathbf{x}_{s_2}$, thus resulting in a single similarity score x_{sim}; (iv) a set of fully-connected hidden layers that model the similarity between sentences using their vector representations produced by the sentence model (also integrating the single similarity score from the previous layer); and (v) a *sigmoid* layer that outputs probability scores reflecting how well the Q-AP pairs match with each other.

The choice of the sentence model plays a crucial role as the resulting intermediate representations of the input sentences will affect the successive step of computing their similarity. Recently, convolutional sentence models, where $f(\mathbf{s})$ is represented by a sequence of convolutional-pooling feature maps, have shown state-of-the-art results on many NLP tasks, e.g., (Kalchbrenner et al., 2014; Kim, 2014). In this paper, we opt for a convolutional operation followed by a k-max pooling layer with $k = 1$ as proposed in (Severyn and Moschitti, 2015).

Considering recent applications of deep learning models to the problem of matching sentences, our network is most similar to the models in (Hu et al., 2014) applied for computing sentence similarity and in (Yu et al., 2014) (answer sentence selection in QA) with the following difference. To compute the similarity between the vector representation of the input sentences, our network uses two methods: (i) computing the similarity score obtained using a similarity matrix $\mathbf{M}$ (explored in (Yu et al., 2014)), and (ii) directly modelling interactions between intermediate vector representations of the input sentences via fully-connected hidden layers (used by (Hu et al., 2014)). This approach, as proposed in (Severyn and Moschitti, 2015), results in a significant improvement in the task of question answer selection over the two methods used separately. Differently from the above models we do not add additional features in the join layer.

4.1 Representation Layers

It should be noted that NNs non-linearly transform the input at each layer. For instance, the output of the convolutional and pooling operation $f(s_i)$ is a fixed-size representation of the input sentence s_i. In the reminder of the paper, we will refer to these vector representations for the question and the answer passage as the question embedding (QE) and the answer embedding (AE), respectively. Similarly, the output of the penultimate layer of the network (the hidden layer whose output is fed to the final classification layer) is a compact representation of the input Question and Answer pair, which we call Joint

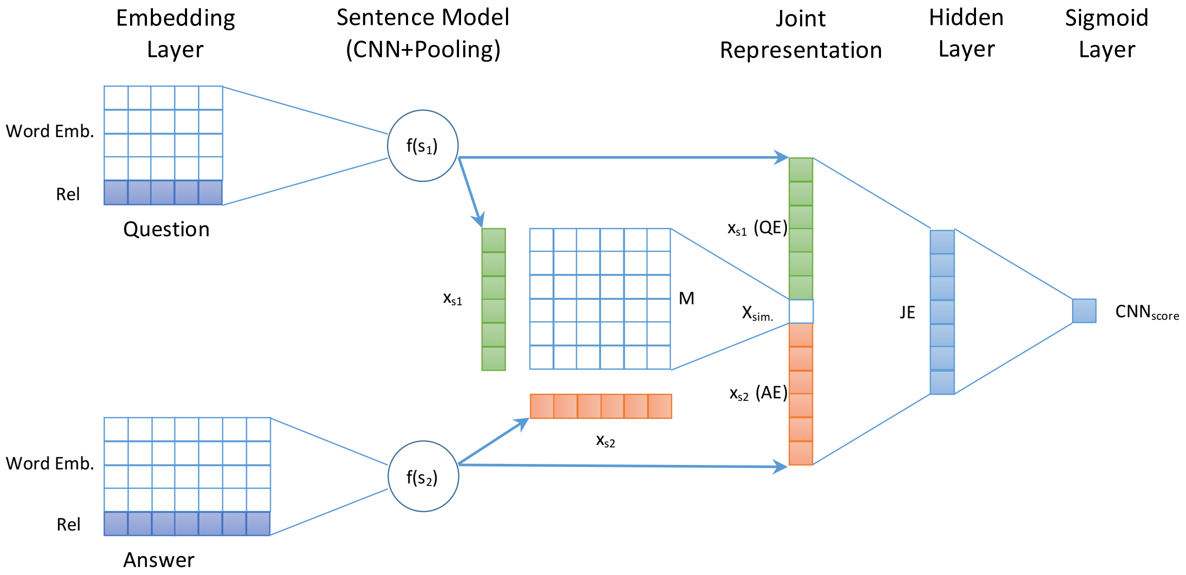

Figure 2: CNN for computing the similarity between question and answer.

Embedding (JE).

4.2 Injecting Relational Information in CNNs

Sec. 3 has shown that establishing relational links (REL nodes) between Q and A pairs is very important for solving the QA task. Yih et al. (2013b) also use latent word-alignment structure in their semantic similarity model to compute similarity between question and answer sentences. Yu et al. (2014) achieve large improvement by combining the output of their deep learning model with word count features in a logistic regression model. Differently from (Yu et al., 2014; Severyn and Moschitti, 2015) we do not add additional features such as the word count in the join layer. We allow our convolutional neural network to capture the connections between related words in a pair and we feed it with an additional binary-like input about overlapping words (Severyn and Moschitti, 2016).

In particular, in the input sentence, we associate an additional *word overlap* indicator feature $o \in \{0, 1\}$ with each word w, where 1 corresponds to words that overlap in a given pair and 0 otherwise. To decide if the words overlap, we perform string matching. Basically this small feature vector plays the role of REL tag added to the CTK structures.

Hence, we require an additional lookup table layer for the word overlap features $LT_{\mathbf{W}_o}(\cdot)$ with parameters $\mathbf{W}_o \in \mathbb{R}^{d_o \times 2}$, where $d_o \in \mathbb{N}$ is a hyper-parameter of the model, which indicates the number of dimensions used for encoding the word overlap features. Thus, we augment word embeddings with additional dimensions that encode the fact that a given word in a pair is overlapping or semantically similar and let the network learn its optimal representation. Given a word w_i, its final word embedding $\mathbf{w}_i \in \mathbb{R}^d$ (where $d = d_w + d_o$) is obtained by concatenating the output of two lookup table operations $LT_{\mathbf{W}}(w_i)$ and $LT_{\mathbf{W_o}}(w_i)$.

5 Experiments

In these experiments, we compare the impact in accuracy of two main methods for automatic feature engineering, i.e., CTKs and CNNs, for relational learning, using two different answer sentence selection datasets, WikiQA and TREC13. We propose several strategies to combine CNNs with CTKs and we show that the two approaches are complementary as their joint use significantly boosts both models.

5.1 Experimental Setup

We utilized two datasets for testing our models:

TREC13. This is the factoid open-domain TREC QA corpus prepared by (Wang et al., 2007). The training data was assembled from the 1,229 TREC8-12 questions. The answers for the training questions were automatically marked in sentences by applying regular expressions, therefore the dataset can be noisy. The test data contains 68 questions, whose answers were manually annotated. We used 10 answer passages for each question for training our classifiers and all the answer passages available for each question for testing.

WikiQA. TREC13 is a small dataset with an even smaller test set, which makes the system evaluation rather unstable, i.e., a small difference in parameters and models can produce very different results. Moreover, as pointed by (Yih et al., 2013b), it has significant lexical overlap between questions and answer candidates, therefore simple lexical match models may likely outperform more elaborate methods if trained and tested on it. WikiQA dataset (Yang et al., 2015) is a larger dataset, created for open domain QA, which overcomes these problems. Its questions were sampled from the Bing query logs and candidate answers were extracted from the summary paragraphs of the associated Wikipedia pages. The train, test, and development sets contain 2,118, 633 and 296 questions, respectively. There is no correct answer sentence for 1,245 training, 170 development and 390 test questions. Consistently with (Yin et al., 2015), we remove the questions without answers for our evaluations.

Preprocessing. We used the Illinois chunker (Punyakanok and Roth, 2001), question class and focus classifiers trained as in (Severyn and Moschitti, 2013) and the Stanford CoreNLP (Manning et al., 2014) toolkit for the needed preprocessing.

CTKs. We used SVM-light-TK[2] to train our models. The toolkit enables the use of structural kernels (Moschitti, 2006) in SVM-light (Joachims, 2002). We applied (i) the partial tree kernel (PTK) with its default parameters to all our structures and (ii) the polynomial kernel of degree 3 on all feature vectors we generate.

Metaclassifier. We used the *scikit*[3] logistic regression classifier implementation to train the metaclassifier on the outputs of CTKs and CNNs.

CNNs. We pre-initialize the word embeddings by running the `word2vec` tool (Mikolov et al., 2013) on the English Wikipedia dump and the jacana corpus as in (Severyn and Moschitti, 2015). We opt for a skipgram model with window size 5 and filtering words with frequency less than 5. The dimensionality of the embeddings is set to 50. The input sentences are mapped to fixed-sized vectors by computing the average of their word embeddings. We use a single non-linear hidden layer (with hyperbolic tangent activation, Tanh), whose size is equal to the size of the previous layer. The network is trained using SGD with shuffled mini-batches using the Adam update rule (Kingma and Ba, 2014). The batch size is set to 100 examples. The network is trained for a fixed number of epochs (i.e., 3) for all the experiments. We decided to avoid using early stopping, in order to do not overfit the development set and have a fair comparison with the CTKs models.

Table 3: Performance on the WikiQA on the development set

ABCNN is the Attention-Based CNN,
LSTM$_{a,c}$ is the long short-term memory network with attention and word count, and
NASM$_c$ is the neural answer selection model with word count.
CNN$_R$ is the relational CNN described in Section 4.
CH[4] is a tree kernel-based SVM reranker trained on the shallow pos-chunk tree representations of question and answer sentences (Sec. 3.1), where the subscript $_{\text{coarse}}$ refers to the model with the coarse-grained question classes as in (Tymoshenko and Moschitti, 2015).
V is a polynomial SVM reranker, where the subscripts AE, QE, JE indicate the use of the answer, question or joint embeddings (see Sec. 4.1) as the feature vector of SVM and + means that two embeddings were concatenated into a single vector.

The results show that our CNN$_R$ model performs comparably to ABCNN (Yin et al., 2015), which is the most recent and accurate NN model and to CH$_{\text{coarse}}$. The performance drops when the embeddings AE, QE and JE are used in a polynomial SVM reranker. In contrast, CH (using our tree structure enriched with fine-grained categories) outperforms all the models, showing the importance of syntactic relational information for the answer sentence selection task.

5.2.1 Combining CNN with CTK on WikiQA

We experiment with two ways of combining CTK with CNN$_R$: (i) at the kernel level, i.e., summing tree kernels with the polynomial kernel over different embeddings, i.e., CH+V, and (ii) using the predictions of SVM and CNN$_R$ models (computed on the development set) as features to train logistic regression meta-classifiers (again only on the development set). These are reported in the last three lines of Table 1, where the name of the classifiers participating with their outputs are illustrated as a comma-separated list. The results are very interesting as all kinds of combinations largely outperform the state of the art, e.g., by around 3 points in terms of MRR, 2 points in terms of MAP and 5 points in terms of P@1 with respect to the strongest standalone system, CH. Directly using the predictions of the CNN$_R$ as features in the meta-classifier does not impact the overall performance. It should be noted that the meta-classifier could only be trained on the

[4] Models marked by * use an improved version of the preference ranking framework we described in Section 3.2. It is important to show such results as they provide a referring baseline for future research in this field.

development data to avoid predictions biased by the training data.

5.2.2 Using less training data

Since we train the weights of CNN$_R$ on the training set of WikiQA, to obtain the embeddings minimizing the loss function, we risk to have overfitted, i.e., "biased", JE, AE and QE on the questions and answers of the training set. Therefore, we conducted another set of experiments to study this case. We randomly split the training set into two equal subsets. We train CNN$_R$ on one of them and in the other subset, (referred to as **TRAIN50**) we produce the embeddings of questions and answers.

Table 2 reports the results on the WikiQA test set which we obtained when training SVM on TRAIN50 and on the development set, **DEV**. We trained the meta-classifier on the predictions of the standalone models on DEV. Consistently with the previous results, we obtain the best performance combining the CNN$_R$ embeddings with CTK. Even when we train on the 50% of the training data only, we still outperform the state of the art, and our best model CH+V_{JE} performs only around 2 points lower in terms of MRR, MAP and P@1 than when training on the full training set.

Finally, Table 3 reports the performance of our models when tested on the development set and demonstrates that the improvement obtained when combining CTK and CNN$_R$ embeddings also holds on it. Note, that we did not use the development set for any parameter tuning and we train all the models with the default parameters.

5.3 Experiments on TREC13 dataset

TREC13 corpus has been used for evaluation in a number of works starting from 2007. Table 4 reports our as well as some state-of-the-art system results on TREC13. It should be noted that, to be consistent with the previous work, we evaluated our models in the same setting as (Wang et al., 2007; Yih et al., 2013a), i.e., we (i) remove the questions having only correct or only incorrect answer sentence candidates and (ii) used the same evaluation script and the gold judgment file as they used. As pointed out by Footnote 7 in (Yih et al., 2014), the evaluation script always considers 4 questions to be answered incorrectly thus penalizing the overall system score.

Models	**MRR**	**MAP**
State of the art		
Wang et al. (2007)	68.52	60.29
Heilman and Smith (2010)	69.17	60.91
Wang and Manning (2010)	69.51	59.51
Yao et al. (2013)	74.77	63.07
Severyn and Moschitti (2013)	73.58	67.81
Yih et al. (2013a)	77.00	70.92
Yu et al. (2014)	78.64	71.13
Wang and Ittycheriah (2015)	77.40	70.63
Tymoshenko and Moschitti (2015)	82.29	73.34
Yang et al. (2015)	76.33	69.51
Miao et al. (2015)	81.17	73.39
Individual Models		
CNN$_R$	77.93	71.09
V_{AE+QE}	79.32	73.37
V_{JE}	77.24	71.34
CH	**85.53**	**75.18**
Model Combinations		
CH+V_{JE}	79.75	74.29
CH+V_{AE+QE}	79.74	75.06
Meta: CH, V_{AE+QE}, CNN$_R$	81.67	75.77
Model Combinations using simpler CH		
CH$_{smpl}$	78.66	71.18
CH$_{smpl}$+V_{AE+QE}	80.19	75.01
CH$_{smpl}$+V_{JE}	80.42	74.16

Table 4: Results on the TREC13, answer selection task.

We note that our models, i.e., CNN$_R$, V_{JE}, V_{AE+QE}, again align with the state of the art. In contrast, our CTK using CH largely outperforms all previous work, e.g., 7.6 points more than CNN$_R$ in terms of MRR. Considering that the evaluation of CH with a script that does not penalize systems would show real MRR and MAP of 90.56 and 80.08, respectively, there is little room for improvement with combinations. Indeed, the table shows no improvement of model combinations over CH.

Therefore, we trained a simplified version of CH, CH$_{smpl}$, which employs shallow chunk-based representations without the question focus or question class information, i.e., only using the basic relational information represented by the lexical match **REL** tags. CH$_{smpl}$ performs comparably to CNN$_R$, and the combination with embeddings produced by CNN$_R$, i.e., CH$_{smpl}$+V_{AE+QE}, outperforms both CH$_{smpl}$ and CNN$_R$.

6 Discussion

The main focus and novelty of this paper is comparing and combining CTKs and CNETs. We showed that the features they generate are complementary as their combination improve both models. For the combinations, we used voting and our new method of combining network layers embedded in a polynomial kernels added to tree kernels.

We would like to stress that to the best of our knowledge we are the first to merge CNNs and CTK together. We showed that kernels based on different embedding layers learned with our CNNs, when used in SVMs, deliver the same accuracy of CNNs. This enables an effective combination between TK and CNNs at kernel level. Indeed, we experimented with different kernel combinations built on top of different CNN layers, improving the state of the art, largely outperforming all previous systems exactly using the same testing conditions. These results are important for developing future research as they provide indications on features/methods and referring baselines to compare with.

Finally, we generated modified structures and used better parsers outperforming our initial result in (Severyn and Moschitti, 2013) by more than 10 points.

6.1 Efficiency

An interesting question is the practical use of our models, which require the discussion of their efficiency. In this respect, our framework combines CTKs and CNNs by generating a global kernel. Thus, the time complexity during training is basically given by (i) training CNNs, (ii) extracting their embeddings and (iii) use these embeddings during the CTK training. The time for computing steps (i) and (ii) is linear with respect to the number of examples as the architecture and the number of optimization steps are fixed. In practice, the bottleneck of training our CNN architecture is in the number of weights.

Regarding Step (iii), since the embeddings just feed a polynomial kernel, which is slightly more efficient than CTKs, the overall complexity is dominated by the one of the CTK framework, i.e., $O(n^2)$. In practice, this is rather efficient, e.g., see the discussion in (Tymoshenko and Moschitti, 2015). The testing complexity is reduced to the number of kernel operations between the support vectors and the test examples (the worst case is $O(n^2)$), which are also parallelizable.

7 Conclusions

This paper compares two state-of-the-art feature engineering approaches, namely CTKs and CNNs, on the very complex task of answer reranking in a QA setting. In order to have a meaningful comparison, we have set the best configuration for CTK by defining and implementing innovative linguistic structures enriched with semantic information from statistical classifiers (i.e., question and focus classifiers). At the same time, we have developed powerful CNNs, which can embed relational information in their representations.

We tested our models for answer passage reranking in QA on two benchmarks, WikiQA and TREC13. Thus, they are directly comparable with many systems from previous work. The results show that our models outperform the state of the art achieved by more complex networks.

In particular, CTKs outperform our CNNs but use more information, e.g., on TREC 13, CTKs obtain an MRR and MAP of 85.53 and 75.18 vs. 77.93 and 71.09 of CNNs. On WikiQA, CNNs combined with tree kernels achieves an MRR of 75.88 and an MAP of 74.17 largely outperforming the current state of the art, i.e., MRR of 71.27 and MAP 69.14 of ABCNN by Yin et al. (2015).

It should be noted that CTK models use syntactic parsing, two statistical classifiers for focus and question classification and a named entity recognizer whereas CNNs only use words and two additional unsupervised corpora.

In the future, we would like to embed CNN similarity in CTKs. A straightforward methods for achieving this is to use the Smoothed Partial Tree Kernel by Croce et al. (2011). Our preliminary experiments using word2vec were not successful. However, CNNs may provide a more effective similarity. Finally, it would be also very interesting to exploit structural kernels in the network layers.

Abstract

Question answering forums are rapidly growing in size with no effective automated ability to refer to and reuse answers already available for previous posted questions. In this paper, we develop a methodology for finding semantically related questions. The task is difficult since 1) key pieces of information are often buried in extraneous details in the question body and 2) available annotations on similar questions are scarce and fragmented. We design a recurrent and convolutional model (gated convolution) to effectively map questions to their semantic representations. The models are pre-trained within an encoder-decoder framework (from body to title) on the basis of the entire raw corpus, and fine-tuned discriminatively from limited annotations. Our evaluation demonstrates that our model yields substantial gains over a standard IR baseline and various neural network architectures (including CNNs, LSTMs and GRUs).[1]

1 Introduction

Question answering (QA) forums such as Stack Exchange[2] are rapidly expanding and already contain millions of questions. The expanding scope and coverage of these forums often leads to many duplicate and interrelated questions, resulting in the same questions being answered multiple times. By identifying similar questions, we can potentially reuse existing answers, reducing response times and unnecessary repeated work. Unfortunately in most forums, the process of identifying and referring to existing similar questions is done manually by forum participants with limited, scattered success.

Title: How can I boot Ubuntu from a USB?
Body: I bought a Compaq pc with Windows 8 a few months ago and now I want to install Ubuntu but still keep Windows 8. I tried Webi but when my pc restarts it read ERROR 0x000007b. I know that Windows 8 has a thing about not letting you have Ubuntu but I still want to have both OS without actually losing all my data ...

Title: When I want to install Ubuntu on my laptop I'll have to erase all my data. "Alonge side windows" doesnt appear
Body: I want to install Ubuntu from a Usb drive. It says I have to erase all my data but I want to install it along side Windows 8. The "Install alongside windows" option doesn't appear. What appear is, ...

Figure 1: A pair of similar questions.

The task of automatically retrieving similar questions to a given user's question has recently attracted significant attention and has become a testbed for various representation learning approaches (Zhou et al., 2015; dos Santos et al., 2015). However, the task has proven to be quite challenging – for instance, dos Santos et al. (2015) report a 22.3% classification accuracy, yielding a 4 percent gain over a simple word matching baseline.

Several factors make the problem difficult. First, submitted questions are often long and contain extraneous information irrelevant to the main question being asked. For instance, the first question in Figure 1 pertains to booting Ubuntu using a USB stick. A large portion of the body contains tangential de-

tails that are idiosyncratic to this user, such as references to *Compaq pc*, *Webi* and the error message. Not surprisingly, these features are not repeated in the second question in Figure 1 about a closely related topic. The extraneous detail can easily confuse simple word-matching algorithms. Indeed, for this reason, some existing methods for question retrieval restrict attention to the question title only. While titles (when available) can succinctly summarize the intent, they also sometimes lack crucial detail available in the question body. For example, the title of the second question does not refer to installation from a USB drive. The second challenge arises from the noisy annotations. Indeed, the pairs of questions marked as similar by forum participants are largely incomplete. Our manual inspection of a sample set of questions from AskUbuntu[3] shows that only 5% of similar pairs have been annotated by the users, with a precision of around 79%.

In this paper, we design a neural network model and an associated training paradigm to address these challenges. On a high level, our model is used as an encoder to map the title, body, or the combination to a vector representation. The resulting "question vector" representation is then compared to other questions via cosine similarity. We introduce several departures from typical architectures on a finer level. In particular, we incorporate adaptive gating in non-consecutive CNNs (Lei et al., 2015) in order to focus temporal averaging in these models on key pieces of the questions. Gating plays a similar role in LSTMs (Hochreiter and Schmidhuber, 1997), though LSTMs do not reach the same level of performance in our setting. Moreover, we counter the scattered annotations available from user-driven associations by training the model largely based on the entire unannotated corpus. The encoder is coupled with a decoder and trained to reproduce the title from the noisy question body. The methodology is reminiscent of recent encoder-decoder networks in machine translation and document summarization (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014b; Rush et al., 2015). The resulting encoder is subsequently fine-tuned discriminatively on the basis of limited annotations yielding an additional performance boost.

We evaluate our model on the AskUbuntu corpus from Stack Exchange used in prior work (dos Santos et al., 2015). During training, we directly utilize noisy pairs readily available in the forum, but to have a realistic evaluation of the system performance, we manually annotate 8K pairs of questions. This clean data is used in two splits, one for development and hyper parameter tuning and another for testing. We evaluate our model and the baselines using standard information retrieval (IR) measures such as Mean Average Precision (MAP), Mean Reciprocal Rank (MRR) and Precision at n (P@n). Our full model achieves a MRR of 75.6% and P@1 of 62.0%, yielding 8% absolute improvement over a standard IR baseline, and 4% over standard neural network architectures (including CNNs, LSTMs and GRUs).

2 Related Work

Given the growing popularity of community QA forums, question retrieval has emerged as an important area of research (Nakov et al., 2015; Nakov et al., 2016). Previous work on question retrieval has modeled this task using machine translation, topic modeling and knowledge graph-based approaches (Jeon et al., 2005; Li and Manandhar, 2011; Duan et al., 2008; Zhou et al., 2013). More recent work relies on representation learning to go beyond word-based methods. For instance, Zhou et al. (2015) learn word embeddings using category-based metadata information for questions. They define each question as a distribution which generates each word (embedding) independently, and subsequently use a Fisher kernel to assess question similarities. Dos Santos et al. (2015) propose an approach which combines a convolutional neural network (CNN) and a bag-of-words representation for comparing questions. In contrast to (Zhou et al., 2015), our model treats each question as a word sequence as opposed to a bag of words, and we apply a recurrent convolutional model as opposed to the traditional CNN model used by dos Santos et al. (2015) to map questions into meaning representations. Further, we propose a training paradigm that utilizes the entire corpus of unannotated questions in a semi-supervised manner.

Recent work on answer selection on community QA forums, similar to our task of question retrieval,

[3] `http://askubuntu.com/`

has also involved the use of neural network architectures (Severyn and Moschitti, 2015; Wang and Nyberg, 2015; Shen et al., 2015; Feng et al., 2015; Tan et al., 2015). Compared to our work, these approaches focus on improving various other aspects of the model. For instance, Feng et al. (2015) explore different similarity measures beyond cosine similarity, and Tan et al. (2015) adopt the neural attention mechanism over RNNs to generate better answer representations given the questions as context.

3 Question Retrieval Setup

We begin by introducing the basic discriminative setting for retrieving similar questions. Let q be a query question which generally consists of both a title sentence and a body section. For efficiency reasons, we do not compare q against all the other queries in the data base. Instead, we retrieve first a smaller candidate set of related questions $Q(q)$ using a standard IR engine, and then we apply the more sophisticated models only to this reduced set. Our goal is to rank the candidate questions in $Q(q)$ so that all the similar questions to q are ranked above the dissimilar ones. To do so, we define a similarity score $s(q, p; \theta)$ with parameters θ, where the similarity measures how closely candidate $p \in Q(q)$ is related to question q. The method of comparison can make use of the title and body of each question.

The scoring function $s(\cdot, \cdot; \theta)$ can be optimized on the basis of annotated data $D = \{(q_i, p_i^+, Q_i^-)\}$, where p_i^+ is a question similar to question q_i and Q_i^- is a negative set of questions deemed not similar to q_i. During training, the correct pairs of similar questions are obtained from available user-marked pairs, while the negative set Q_i^- is drawn randomly from the entire corpus with the idea that the likelihood of a positive match is small given the size of the corpus. The candidate set during training is just $Q(q_i) = \{p_i^+\} \cup Q_i^-$. During testing, the candidate sets are retrieved by an IR engine and we evaluate against explicit manual annotations.

In the purely discriminative setting, we use a max-margin framework for learning (or fine-tuning) parameters θ. Specifically, in a context of a particular training example where q_i is paired with p_i^+, we minimize the max-margin loss $L(\theta)$ defined as

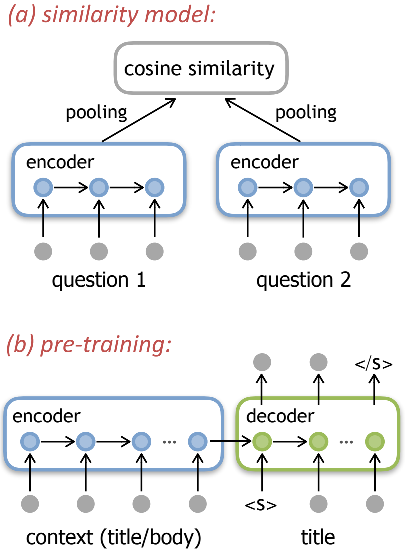

Figure 2: Illustration of our model.

$$\max_{p \in Q(q_i)} \left\{ s(q_i, p; \theta) - s(q_i, p_i^+; \theta) + \delta(p, p_i^+) \right\},$$

where $\delta(\cdot, \cdot)$ denotes a non-negative margin. We set $\delta(p, p_i^+)$ to be a small constant when $p \neq p_i^+$ and 0 otherwise. The parameters θ can be optimized through sub-gradients $\partial L / \partial \theta$ aggregated over small batches of the training instances.

There are two key problems that remain. First, we have to define and parameterize the scoring function $s(q, p; \theta)$. We design a recurrent neural network model for this purpose and use it as an *encoder* to map each question into its meaning representation. The resulting similarity function $s(q, p; \theta)$ is just the cosine similarity between the corresponding representations, as shown in Figure 2 (a). The parameters θ pertain to the neural network only. Second, in order to offset the scarcity and limited coverage of the training annotations, we pre-train the parameters θ on the basis of the much larger unannotated corpus. The resulting parameters are subsequently fine-tuned using the discriminative setup described above.

4 Model

4.1 Non-consecutive Convolution

We describe here our encoder model, i.e., the method for mapping the question title and body to a vector representation. Our approach is inspired by temporal convolutional neural networks (LeCun et al., 1998) and, in particular, its recent refinement (Lei et al., 2015), tailored to capture longer-range, non-consecutive patterns in a weighted manner. Such models can be used to effectively summarize occurrences of patterns in text and aggregate them into a vector representation. However, the summary produced is not selective since all pattern occurrences are counted, weighted by how cohesive (non-consecutive) they are. In our problem, the question body tends to be very long and full of irrelevant words and fragments. Thus, we believe that interpreting the question body requires a more selective approach to pattern extraction.

Our model successively reads tokens in the question title or body, denoted as $\{\mathbf{x}_i\}_{i=1}^l$, and transforms this sequence into a sequence of states $\{\mathbf{h}_i\}_{i=1}^l$. The resulting state sequence is subsequently aggregated into a single final vector representation for each text as discussed below. Our approach builds on (Lei et al., 2015), thus we begin by briefly outlining it. Let W_1 and W_2 denote filter matrices (as parameters) for pattern size $n = 2$. Lei et al. (2015) generate a sequence of states in response to tokens according to

$$\begin{aligned}\mathbf{c}_{t',t} &= \mathbf{W}_1\mathbf{x}_{t'} + \mathbf{W}_2\mathbf{x}_t \\ \mathbf{c}_t &= \sum_{t'<t} \lambda^{t-t'-1}\mathbf{c}_{t',t} \\ \mathbf{h}_t &= \tanh(\mathbf{c}_t + \mathbf{b})\end{aligned}$$

where $\mathbf{c}_{t',t}$ represents a bigram pattern, $\mathbf{c}_t$ accumulates a range of patterns and $\lambda \in [0, 1)$ is a constant decay factor used to down-weight patterns with longer spans. The operations can be cast in a "recurrent" manner and evaluated with dynamic programming. The problem with the approach for our purposes is, however, that the weighting factor λ is the same (constant) for all, not triggered by the state $\mathbf{h}_{t-1}$ or the observed token $\mathbf{x}_t$.

Adaptive Gated Decay We refine this model by learning context dependent weights. For example, if the current input token provides no relevant information (e.g., symbols, functional words), the model should ignore it by incorporating the token with a vanishing weight. In contrast, strong semantic content words such as "ubuntu" or "windows" should be included with much larger weights. To achieve this effect we introduce *neural gates* similar to LSTMs to specify when and how to average the observed signals. The resulting architecture integrates recurrent networks with non-consecutive convolutional models:

$$\begin{aligned}\lambda_t &= \sigma(\mathbf{W}^\lambda\mathbf{x}_t + \mathbf{U}^\lambda\mathbf{h}_{t-1} + \mathbf{b}^\lambda) \\ \mathbf{c}_t^{(1)} &= \lambda_t \odot \mathbf{c}_{t-1}^{(1)} + (1-\lambda_t) \odot (\mathbf{W}_1\mathbf{x}_t) \\ \mathbf{c}_t^{(2)} &= \lambda_t \odot \mathbf{c}_{t-1}^{(2)} + (1-\lambda_t) \odot (\mathbf{c}_{t-1}^{(1)} + \mathbf{W}_2\mathbf{x}_t) \\ &\cdots \\ \mathbf{c}_t^{(n)} &= \lambda_t \odot \mathbf{c}_{t-1}^{(n)} + (1-\lambda_t) \odot (\mathbf{c}_{t-1}^{(n-1)} + \mathbf{W}_n\mathbf{x}_t) \\ \mathbf{h}_t &= \tanh(\mathbf{c}_t^{(n)} + \mathbf{b})\end{aligned}$$

where $\sigma(\cdot)$ is the sigmoid function and $\odot$ represents the element-wise product. Here $\mathbf{c}_t^{(1)}, \cdots, \mathbf{c}_t^{(n)}$ are accumulator vectors that store weighted averages of 1-gram to n-gram features. When the gate $\lambda_t = 0$ (vector) for all t, the model represents a traditional CNN with filter width n. As $\lambda_t > 0$, however, $\mathbf{c}_t^{(n)}$ becomes the sum of an exponential number of terms, enumerating all possible n-grams within $\mathbf{x}_1, \cdots, \mathbf{x}_t$ (seen by expanding the formulas). Note that the gate $\lambda_t(\cdot)$ is parametrized and responds directly to the previous state and the token in question. We refer to this model as RCNN from here on.

Pooling In order to use the model as part of the discriminative question retrieval framework outlined earlier, we must condense the state sequence to a single vector. There are two simple alternative *pooling* strategies that we have explored – either averaging over the states[4] or simply taking the last one as the meaning representation. In addition, we apply the encoder to both the question title and body, and the final representation is computed as the average of the two resulting vectors.

Once the aggregation is specified, the parameters of the gate and the filter matrices can be learned in a purely discriminative fashion. Given that the available annotations are limited and user-guided, we instead use the discriminative training only for fine tuning an already trained model. The method of pretraining the model on the basis of the entire corpus of questions is discussed next.

[4] We also normalize state vectors before averaging, which empirically gets better performance.

4.2 Pre-training Using the Entire Corpus

The number of questions in the AskUbuntu corpus far exceeds user annotations of pairs of similar questions. We can make use of this larger raw corpus in two different ways. First, since models take word embeddings as input we can tailor the embeddings to the specific vocabulary and expressions in this corpus. To this end, we run word2vec (Mikolov et al., 2013) on the raw corpus in addition to the Wikipedia dump. Second, and more importantly, we use individual questions as training examples for an auto-encoder constructed by pairing the encoder model (RCNN) with an corresponding decoder (of the same type). As illustrated in Figure 2 (b), the resulting encoder-decoder architecture is akin to those used in machine translation (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Cho et al., 2014b) and summarization (Rush et al., 2015).

Our encoder-decoder pair represents a conditional language model $P(\text{title}|\text{context})$, where the context can be any of (a) the original title itself, (b) the question body and (c) the title/body of a similar question. All possible (title, context) pairs are used during training to optimize the likelihood of the words (and their order) in the titles. We use the question title as the target for two reasons. The question body contains more information than the title but also has many irrelevant details. As a result, we can view the title as a distilled summary of the noisy body, and the encoder-decoder model is trained to act as a denoising auto-encoder. Moreover, training a decoder for the title (rather than the body) is also much faster since titles tend to be short (around 10 words).

The encoders pre-trained in this manner are subsequently fine-tuned according to the discriminative criterion described already in Section 3.

5 Alternative models

For comparison, we also train three alternative benchmark encoders (LSTMs, GRUs and CNNs) for mapping questions to vector representations. LSTM and GRU-based encoders can be pre-trained analogously to RCNNs, and fine-tuned discriminatively. CNN encoders, on the other hand, are only trained discriminatively. While plausible, neither alternative reaches quite the same level of performance as our pre-trained RCNN.

LSTMs LSTM cells (Hochreiter and Schmidhuber, 1997) have been used to capture semantic information across a wide range of applications, including machine translation and entailment recognition (Bahdanau et al., 2015; Bowman et al., 2015; Rocktäschel et al., 2016). Their success can be attributed to neural gates that adaptively read or discard information to/from internal memory states.

Specifically, a LSTM network successively reads the input token $\mathbf{x}_t$, internal state $\mathbf{c}_{t-1}$, as well as the visible state $\mathbf{h}_{t-1}$, and generates the new states $\mathbf{c}_t, \mathbf{h}_t$:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}^i\mathbf{x}_t + \mathbf{U}^i\mathbf{h}_{t-1} + \mathbf{b}^i) \\
\mathbf{f}_t &= \sigma(\mathbf{W}^f\mathbf{x}_t + \mathbf{U}^f\mathbf{h}_{t-1} + \mathbf{b}^f) \\
\mathbf{o}_t &= \sigma(\mathbf{W}^o\mathbf{x}_t + \mathbf{U}^o\mathbf{h}_{t-1} + \mathbf{b}^o) \\
\mathbf{z}_t &= \tanh(\mathbf{W}^z\mathbf{x}_t + \mathbf{U}^z\mathbf{h}_{t-1} + \mathbf{b}^z) \\
\mathbf{c}_t &= \mathbf{i}_t \odot \mathbf{z}_t + \mathbf{f}_t \odot \mathbf{c}_{t-1} \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned}$$

where $\mathbf{i}$, $\mathbf{f}$ and $\mathbf{o}$ are *input*, *forget* and *output* gates, respectively. Given the visible state sequence $\{\mathbf{h}_i\}_{i=1}^l$, we can aggregate it to a single vector exactly as with RCNNs. The LSTM encoder can be pre-trained (and fine-tuned) in the similar way as our RCNN model. For instance, Dai and Le (2015) recently adopted pre-training for text classification task.

GRUs A GRU is another comparable unit for sequence modeling (Cho et al., 2014a; Chung et al., 2014). Similar to the LSTM unit, the GRU has two neural gates that control the flow of information:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(\mathbf{W}^i\mathbf{x}_t + \mathbf{U}^i\mathbf{h}_{t-1} + \mathbf{b}^i) \\
\mathbf{r}_t &= \sigma(\mathbf{W}^r\mathbf{x}_t + \mathbf{U}^r\mathbf{h}_{t-1} + \mathbf{b}^r) \\
\mathbf{c}_t &= \tanh(\mathbf{W}\mathbf{x}_t + \mathbf{U}(\mathbf{r}_t \odot \mathbf{h}_{t-1}) + \mathbf{b}) \\
\mathbf{h}_t &= \mathbf{i}_t \odot \mathbf{c}_t + (1 - \mathbf{i}_t) \odot \mathbf{h}_{t-1}
\end{aligned}$$

where i and r are *input* and *reset* gate respectively. Again, the GRUs can be trained in the same way.

CNNs Convolutional neural networks (LeCun et al., 1998) have also been successfully applied to various NLP tasks (Kalchbrenner et al., 2014; Kim, 2014; Kim et al., 2015; Zhang et al., 2015; Gao et al., 2014). As models, they are different from LSTMs since the temporal convolution operation

Corpus	# of unique questions	167,765

	# of annotated pairs	200×20
	Avg # of positive pairs per query	5.8
Test	# of query questions	200
	# of annotated pairs	200×20
	Avg # of positive pairs per query	5.5

Table 1: Various statistics from our Training, Dev, and Test sets derived from the Sept. 2014 Stack Exchange AskUbuntu dataset.

and associated filters map *local chunks* (windows) of the input into a feature representation. Concretely, if we let n denote the filter width, and $\mathbf{W}_1, \cdots, \mathbf{W}_n$ the corresponding filter matrices, then the convolution operation is applied to each window of n consecutive words as follows:

$$\mathbf{c}_t = \mathbf{W}_1\mathbf{x}_{t-n+1} + \mathbf{W}_2\mathbf{x}_{t-n+2} + \cdots + \mathbf{W}_n\mathbf{x}_t$$
$$\mathbf{h}_t = \tanh(\mathbf{c}_t + \mathbf{b})$$

The sets of output state vectors $\{\mathbf{h}_t\}$ produced in this case are typically referred to as feature maps. Since each vector in the feature map only pertains to local information, the last vector is not sufficient to capture the meaning of the entire sequence. Instead, we consider *max-pooling* or *average-pooling* to obtain the aggregate representation for the entire sequence.

6 Experimental Setup

Dataset We use the Stack Exchange AskUbuntu dataset used in prior work (dos Santos et al., 2015). This dataset contains 167,765 unique questions, each consisting of a title and a body[5], and a set of user-marked similar question pairs. We provide various statistics from this dataset in Table 1.

Gold Standard for Evaluation User-marked similar question pairs on QA sites are often known to be incomplete. In order to evaluate this in our dataset, we took a sample set of questions paired with 20 candidate questions retrieved by a search engine trained on the AskUbuntu data. The search engine used is the well-known BM25 model (Robertson and Zaragoza, 2009). Our manual evaluation of the candidates showed that only 5% of the similar questions were marked by users, with a precision of 79%. Clearly, this low recall would not lead to a realistic evaluation if we used user marks as our gold standard. Instead, we make use of expert annotations carried out on a subset of questions.

Training Set We use user-marked similar pairs as positive pairs in training since the annotations have high precision and do not require additional manual annotations. This allows us to use a much larger training set. We use random questions from the corpus paired with each query question p_i as negative pairs in training. We randomly sample 20 questions as negative examples for each p_i during each epoch.

Development and Test Sets We re-constructed the new dev and test sets consisting of the first 200 questions from the dev and test sets provided by dos Santos et al. (2015). For each of the above questions, we retrieved the top 20 similar candidates using BM25 and manually annotated the resulting 8K pairs as similar or non-similar.[6]

Baselines and Evaluation Metrics We evaluated neural network models—including **CNNs**, **LSTMs**, **GRUs** and **RCNNs**—by comparing them with the following baselines:

- **BM25**, we used the BM25 similarity measure provided by Apache Lucene.
- **TF-IDF**, we ranked questions using cosine similarity based on a vector-based word representation for each question.
- **SVM**, we trained a re-ranker using SVM-Light (Joachims, 2002) with a linear kernel incorporating several similarity measures from the DKPro similarity package (Bär et al., 2013).

We evaluated the models based on the following IR metrics: Mean Average Precision (MAP), Mean Reciprocal Rank (MRR), Precision at 1 (P@1), and Precision at 5 (P@5).

[5] We truncate the body section at a maximum of 100 words.

[6] The annotation task was initially carried out by two expert annotators, independently. The initial set was refined by comparing the annotations and asking a third judge to make a final decision on disagreements. After a consensus on the annotation guidelines was reached (producing a Cohen's kappa of 0.73), the overall annotation was carried out by only one expert.

Table 2: Comparative results of all methods on the question similarity task. Higher numbers are better. For neural network models, we show the best average performance across 5 independent runs and the corresponding pooling strategy. Statistical significance with $p < 0.05$ against other types of model is marked with $*$.

	d	$\|\theta\|$	n
LSTMs	240	423K	-
GRUs	280	404K	-
CNNs	667	401K	3
RCNNs	400	401K	2

Table 3: Configuration of neural models. d is the hidden dimension, $|\theta|$ is the number of parameters and n is the filter width.

Hyper-parameters We performed an extensive hyper-parameter search to identify the best model for the baselines and neural network models. For the **TF-IDF** baseline, we tried n-gram feature order $n \in \{1, 2, 3\}$ with and without stop words pruning. For the **SVM** baseline, we used the default SVM-Light parameters whereas the dev data is only used to increase the training set size when testing on the test set. We also tried to give higher weight to dev instances but this did not result in any improvement.

For all the neural network models, we used Adam (Kingma and Ba, 2015) as the optimization method with the default setting suggested by the authors. We optimized other hyper-parameters with the following range of values: learning rate $\in \{1e - 3, 3e - 4\}$, dropout (Hinton et al., 2012) probability $\in \{0.1, 0.2, 0.3\}$, CNN feature width $\in \{2, 3, 4\}$. We also tuned the pooling strategies and ensured each model has a comparable number of parameters. The default configurations of LSTMs, GRUs, CNNs and RCNNs are shown in Table 3. We used MRR to identify the best training epoch and the model configuration. For the same model configuration, we report average performance across 5 independent runs.[7]

Word Vectors We ran word2vec (Mikolov et al., 2013) to obtain 200-dimensional word embeddings using all Stack Exchange data (excluding StackOverflow) and a large Wikipedia corpus. The word vectors are fixed to avoid over-fitting across all experiments.

7 Results

Overall Performance Table 2 shows the performance of the baselines and the neural encoder models on the question retrieval task. The results show that our full model, RCNNs with pre-training, achieves the best performance across all metrics on both the dev and test sets. For instance, the full model gets a P@1 of 62.0% on the test set, outperforming the word matching-based method BM25 by over 8 percent points. Further, our RCNN model also outperforms the other neural encoder models and the baselines across all metrics. This superior performance indicates that the use of non-consecutive filters and a varying decay is effective in improving traditional neural network models.

Table 2 also demonstrates the performance gain from pre-training the RCNN encoder. The RCNN model when pre-trained on the entire corpus consistently gets better results across all the metrics.

[7] For a fair comparison, we also pre-train 5 independent models for each configuration and then fine tune these models. We use the same learning rate and dropout rate during pre-training and fine-tuning.

title only	54.3	66.8	52.7
title + body	53.2	67.1	53.8
RCNNs, mean-pooling	MAP	MRR	P@1
title only	56.0	68.9	55.7
title + body	58.5	71.7	56.7
RCNNs, last state	MAP	MRR	P@1
title only	58.2	70.7	56.6
title + body	60.7	72.9	59.1

Table 5: Comparision between model variants on the test set when question bodies are used or not used.

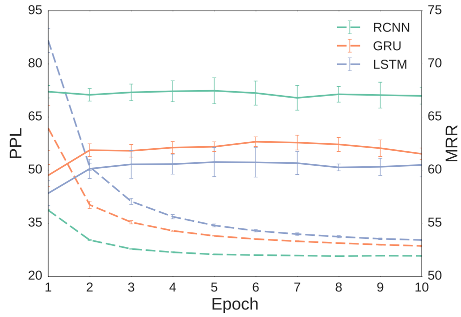

Figure 3: Perplexity (dotted lines) on a heldout portion of the corpus versus MRR on the dev set (solid lines) during pre-training. Variances across 5 runs are shown as vertical bars.

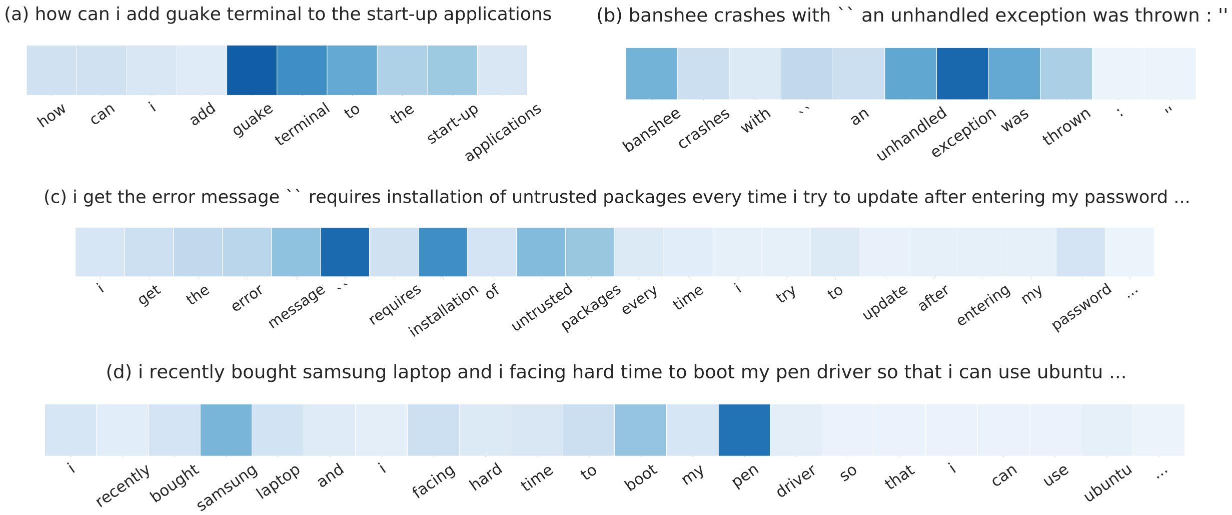
Pooling Strategy We analyze the effect of various pooling strategies for the neural network encoders. As shown in Table 4, our RCNN model outperforms other neural models regardless of the two pooling strategies explored. We also observe that simply using the last hidden state as the final representation achieves better results for the RCNN model.

Using Question Body Table 5 compares the performance of the TF-IDF baseline and the RCNN model when using question titles only or when using question titles along with question bodies. TF-IDF's performance changes very little when the question bodies are included (MRR and P@1 are slightly better but MAP is slightly worse). However, we find that the inclusion of the question bodies improves the performance of the RCNN model, achieving a 1% to 3% improvement with both model variations. The RCNN model's greater improvement illustrates the ability of the model to pick out components that pertain most directly to the question being asked from the long, descriptive question bodies.

Pre-training Note that, during pre-training, the last hidden states generated by the neural encoder are used by the decoder to reproduce the question titles. It would be interesting to see how such states capture the meaning of questions. To this end, we evaluate MRR on the dev set using the last hidden states of the question titles. We also test how the encoder captures information from the question bodies to produce the distilled summary, i.e. titles. To do so, we evaluate the perplexity of the trained encoder-decoder model on a heldout set of the corpus, which contains about 2000 questions.

As shown in Figure 3, the representations generated by the RCNN encoder perform quite well, resulting in a perplexity of 25 and over 68% MRR without the subsequent fine-tuning. Interestingly, the LSTM and GRU networks obtain similar perplexity on the heldout set, but achieve much worse MRR for similar question retrieval. For instance, the GRU encoder obtains only 63% MRR, 5% worse than the RCNN model's MRR performance. As a result, the LSTM and GRU encoder do not benefit clearly from pre-training, as suggested in Table 2.

The inconsistent performance difference may be explained by two hypotheses. One is that the perplexity is not suitable for measuring the similarity of the encoded text, thus the power of the encoder is not illustrated in terms of perplexity. Another hy-



(a) how can i add guake terminal to the start-up applications

(b) banshee crashes with `` an unhandled exception was thrown : ''

(c) i get the error message `` requires installation of untrusted packages every time i try to update after entering my password ...

(d) i recently bought samsung laptop and i facing hard time to boot my pen driver so that i can use ubuntu ...

Figure 4: Visualizations of $1 - \lambda_t$ of our model on several question pieces from the data set. λ_t is set to a *scalar value* (instead of 400-dimension vector) to make the visualization simple. The corresponding model is a simplified variant, which is about 4% worse than our full model.

pothesis is that the LSTM and GRU encoder may learn non-linear representations therefore their semantic relatedness can not be directly accessed by cosine similarity.

Adaptive Decay Finally, we analyze the gated convolution of our model. Figure 5 demonstrates at each word position t how much input information is taken into the model by the adaptive weights $1 - \lambda_t$. The average of weights in the vector decreases as t increments, suggesting that the information encoded into the state vector saturates when more input are processed. On the other hand, the largest value in the weight vector remains high throughout the input, indicating that at least some information has been stored in $\mathbf{h}_t$ and $\mathbf{c}_t$.

We also conduct a case study on analyzing the neural gate. Since directly inspecting the 400-dimensional decay vector is difficult, we train a model that uses a *scalar decay* instead. As shown in Figure 4, the model learns to assign higher weights to application names and quoted error messages, which intuitively are important pieces of a question in the AskUbuntu domain.

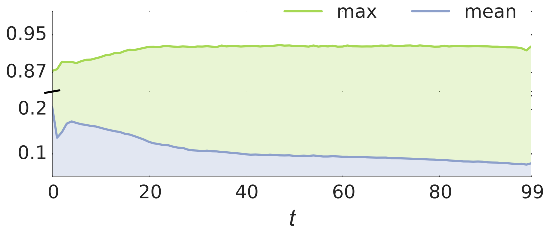


Figure 5: The maximum and mean value of the 400-dimentional weight vector $1 - \lambda_t$ at each step (word position) t. Values are averaged across all questions in the dev and test set.

8 Conclusion

In this paper, we employ gated (non-consecutive) convolutions to map questions to their semantic representations, and demonstrate their effectiveness on the task of question retrieval in community QA forums. This architecture enables the model to glean key pieces of information from lengthy, detail-riddled user questions. Pre-training within an encoder-decoder framework (from body to title) on the basis of the entire raw corpus is integral to the model's success.

This is how we do it: Answer Reranking for Open-domain How Questions with Paragraph Vectors and Minimal Feature Engineering

Dasha Bogdanova and Jennifer Foster

Abstract

We present a simple yet powerful approach to non-factoid answer reranking whereby question-answer pairs are represented by concatenated distributed representation vectors and a multilayer perceptron is used to compute the score for an answer. Despite its simplicity, our approach achieves state-of-the-art performance on a public dataset of *How* questions, outperforming systems which employ sophisticated feature sets. We attribute this good performance to the use of paragraph instead of word vector representations and to the use of suitable data for training these representations.

1 Introduction

In contrast to factoid question answering (QA), non-factoid QA is concerned with questions whose answer is not easily expressed as an entity or list of entities and can instead be quite complex – compare, for example, the factoid question *Who is the secretary general of the UN?* with the non-factoid manner question *How is the secretary general of the UN chosen?* A significant amount of research has been carried out on factoid QA, with non-factoid questions receiving less attention. This is changing, however, with the popularity of community-based question answering (CQA) sites such as Yahoo! Answers[1], Quora[2] and the StackExchange[3] family of forums. The ability of users to vote for their favourite answer makes these sites a valuable source of training data for open-domain non-factoid QA systems.

In this paper, we present a neural approach to open-domain non-factoid QA, focusing on the subtask of answer reranking, i.e. given a list of candidate answers to a question, order the answers according to their relevance to the question. We test our approach on the Yahoo! Answers dataset of manner or *How* questions introduced by Jansen et al. (2014), who describe answer reranking experiments on this dataset using a diverse range of features incorporating syntax, lexical semantics and discourse. In particular, they show how discourse information (obtained either via a discourse parser or using shallow techniques based on discourse markers) can complement distributed lexical semantic information. Sharp et al. (2015) show how discourse structure can be used to generate artificial question-answer training pairs from documents, and test their approach on the same dataset. The best performance on this dataset – 33.01 P@1 and 53.96 MRR – is reported by Fried et al. (2015) who improve on the lexical semantic models of Jansen et al. (2014) by exploiting indirect associations between words using higher-order models.

In contrast, our approach is very simple and requires no feature engineering. Question-answer pairs are represented by concatenated distributed representation vectors and a multilayer perceptron is used to compute the score for an answer (the probability of an answer being the best answer to the question). Despite its simplicity, we achieve state-of-the-art performance on this dataset – 37.17 P@1 and 56.82 MRR. We attribute this improved performance to the use of paragraph vector representations (Le and Mikolov, 2014) instead of averaging over word

vectors, and to the use of suitable data for training these representations.

2 Approach

2.1 Learning Algorithm

We use a simple feedforward neural network, i.e. a multilayer perceptron, to predict the best answer. As shown in Figure 1, the first layer of the network is a projection layer that transforms question-answer pairs into their vector representations. The vector representation for a question-answer pair (q, a) is a concatenation of the distributed representations q and a for the question and the answer respectively. Each representation is a real-valued vector of a fixed dimensionality d, which is a parameter to be tuned. The projection layer is followed by one or more hidden layers, the number of layers and units in each of these layers are also parameters to be experimentally tuned. We use the rectified linear (ReLU) activation function. Finally, a softmax layer is used to compute the output probability p, i.e. the probabilities p_1 and p_2 of the negative (i.e. not best answer) and positive (i.e. best answer) classes respectively. For each question, all its user-generated answers are ranked according to their probability of being the best answer, as predicted by the network.

Given a question-answer pair (q, a), the possible values for the ground-truth label are 1 (best answer) and 0 (not a best answer). The network is trained by minimizing the L2-regularized cross-entropy loss function between the ground-truth labels and the network predictions on the training set. We use stochastic gradient descent to minimize the loss over the training set. The development set is used for early stopping.

2.2 Document Representations

Our approach requires question-answer pairs to be represented as a fixed-size vector. We experimentally evaluate the Paragraph Vector model (PV) proposed by Le and Mikolov (2014). The PV is an extension of the widely used continuous bag-of-words (CBOW) and skip-gram word embedding models, known as *word2vec*. However, in contrast to CBOW and skip-gram models that only learn word embeddings, the PV is able to learn representations for pieces of text of arbitrary length, e.g. sentences, paragraphs or documents. The PV includes (1) the distributed memory (DM) model, that predicts the next word using the concatenation of the previous words and the paragraph vector, that is shared among all words in the same paragraph (or sentence); (2) the distributed bag-of-words (DBOW) model, that – similar to the skip-gram model – predicts words randomly sampled from the paragraph, given the paragraph vector. We experiment with both DM and DBOW models, as well as their combination. For comparison with recent work in answer reranking (Jansen et al., 2014; Sharp et al., 2015), we also evaluate the averaged word embedding vectors obtained with the skip-gram model (Mikolov et al., 2013) (henceforth referred to as the *SkipAvg* model).

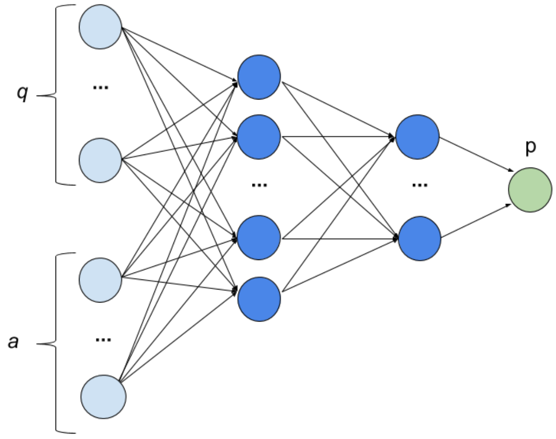

Figure 1: Neural network architecture used to predict answer ranking.

3 Experiments

3.1 Data

In order to be able to compare our work with previous research, we use the Yahoo! Answers dataset that was first introduced by Jansen et al. (2014) and was later used by Sharp et al. (2015) and Fried et al. (2015). This dataset contains 10K *How* questions from Yahoo! Answers. Each question has at least four user-generated answers, and the average number of answers per question is nine. 50% of the dataset is used for training, 25% for development and 25% for testing. Further information about the dataset can be found in Jansen et al. (2014).

Our approach requires unlabelled data for unsupervised pre-training of the word and paragraph vectors. For these purposes we use the *L6 Yahoo! Answers Comprehensive Questions and Answers* corpus obtained via Webscope.[4] This dataset contains about 4.5M questions from Yahoo! Answers along with their user-generated answers, and was provided as training data at the recent TREC LiveQA competition (Agichtein et al., 2015), the goal of which was to answer open-domain questions coming from real users in real time.[5] The Yahoo! Answers manner question dataset prepared by Jansen et al. (2014) and described in the previous paragraph, was initially sampled from this larger dataset. We want to emphasize that the L6 dataset is only used for unsupervised pretraining – no meta-information is used in our experiments.

We also experiment with the English Gigaword corpus,[6] which contains data from several English newswire sources. Jansen et al. (2014) used this corpus to train word embeddings, which were then included as features in their answer reranker.

3.2 Experimental Setup

Following Jansen et al. (2014) and Fried et al. (2015), we implement two baselines: the baseline that selects an answer randomly and the candidate retrieval (CR) baseline. The CR baseline uses the same scoring as in Jansen et al. (2014): the questions and the candidate answers are represented using `tf-idf` (Salton, 1991) over lemmas; the candidate answers are ranked according to their cosine similarity to the respective question.

We use the *gensim*[7] implementation of the DBOW and DM paragraph vector models. The word embeddings for the SkipAvg model are obtained with *word2vec*.[8] The data was tokenized with the Stanford tokenizer[9] and then lowercased.

Model	dim	P@1	MRR
Random Baseline	-	15.06	37.13
CR Baseline	-	24.83	48.82
SkipAvg Baseline	200	31.25	52.56
DBOW	100	38.95*	58.18*
DBOW	200	**39.91***	**58.68***
DBOW	300	39.47*	58.35*
DM	100	38.19*	57.01*
DM	200	38.35*	57.28*
DM	300	37.55*	56.67*
DBOW+DM	200	**40.55**$^{*\#}$	**59.12**$^{*\#}$
DBOW+SkipAvg	200	**40.39**$^{*\#}$	**58.91**$^{*\#}$
DBOW+DM+SkipAvg	200	**40.63**$^{*\#}$	**59.14**$^{*\#}$

Table 1: Development P@1 and MRR for different vectors representations. * indicates that improvements over the baselines are statistically significant with $p < 0.05$. # indicates that the improvement over the DBOW model with 200-dimensional vectors is not statistically significant. All significance tests are performed with one-tailed bootstrap resampling with 10,000 iterations.

To evaluate our models, we use standard implementations of the P@1 and mean reciprocal rank (MRR) evaluation metrics. To evaluate whether the difference between two models is statistically significant, statistical significance testing is performed using one-tailed bootstrap resampling with 10,000 iterations. Improvements are considered to be statistically significant at the 5% confidence level (p < 0.05).

3.3 Results

In Table 1, we report best development P@1 and MRR of the multilayer perceptron trained on Yahoo! Answers (Jansen et al., 2014) data. Early stopping is used to maximize P@1 on the development set. The distributed representations, including the SkipAvg model, beat both random and candidate retrieval baselines by a large and statistically significant margin. Likewise, the multilayer perceptron with DBOW and DM representations significantly outperform the SkipAvg representations. Both paragraph vector representations initially proposed by Le and Mikolov (2014) – DBOW and DM – provide similarly high performance, however the DBOW model performs slightly better, with the improvement over the DM model being statistically significant. Different dimensionalities of the pretrained vectors provide similar results, with

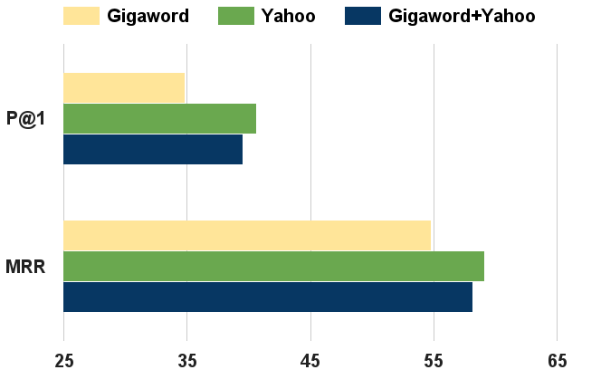

Figure 2: Development P@1 and MRR of a DBOW model pretrained on Yahoo! Answers and Gigaword corpora.

200 outperforming the rest by a small margin. The multilayer perceptron with combinations of different distributed representations reach slightly higher P@1 and MRR on the development set. However, these improvements over the 200-dimension DBOW model are not statistically significant.

Table 2 presents the results on the test set. We only evaluate the 200-dimension DBOW model and its combinations with other models, comparing these to the baselines and the previous results on the same dataset (we use the same train/dev/test split as Jansen et al. (2014)). The DBOW outperforms the baselines by a statistically significant margin. The combination of the DBOW, DM and SkipAvg models provides slightly better results, but the improvement over the DBOW is not statistically significant.

3.4 Analysis

Jansen et al. (2014) report that answer reranking benefits from lexical semantic models, and describe experiments using SkipAvg embeddings pretrained using the English Gigaword corpus. Here we compare the performance of the reranker with distributed representations pretrained on a large "out-of-domain" newswire corpus (Gigaword), versus a smaller "in-domain" non-factoid QA one (L6 Yahoo). Figure 2 shows the development P@1 and MRR of the multilayer perceptron with DBOW model on the Yahoo! Answers dataset pretrained on 30M random paragraphs from the English Gigaword corpus versus the multilayer perceptron with DBOW model pretrained on the Yahoo L6 corpus containing about 8.5M paragraphs. We also evaluate the combination of the two models. The results highlight the importance of finding a suitable source of unlabelled training data since vectors pretrained on reasonably large amounts of Yahoo! Answers data are more beneficial than using a much larger Gigaword dataset.

Even our best model is still, however, far from being perfect, i.e. for about 60% of questions, the answer selected as best by the author of the question is not assigned the highest rank by our system. We believe that one of the reasons for that is that the choice of the best answer purely relies on the question's author and may be subjective (see Table 3). A possible useful direction for future research is to incorporate the user-level information into the neural reranking model. This approach has been recently found beneficial in the task of sentiment analysis (Tang et al., 2015).

Another potential source of error lies in the user-generated nature of the data. Yahoo! Answers contains a large number of spelling and grammar mistakes (e.g. *how do i thaw fozen [sic] chicken?*), non-standard spelling and punctuation (e.g. *Booorrrriinng!!!!!*). A common way to deal with this problem is normalization (Baldwin et al., 2015). To determine whether this might be helpful, we normalized the data following the strategy described by Le Roux et al. (2012). We trained the DBOW model with 200 dimensions and applied the MLP, as described in Section 2. The best development P@1 was only 33.95, with MRR 54.23 (versus 39.91 P@1 and 58.68 MRR without normalization). Even

Question	*How should I wear my hair tomorrow?*
Best answer	*Very good question...Lets see, I think you should wear it in pigtails.....*
Other answers	*Losen it.* *Close your eyes, grab some scissors, and GO CRAZY!* *I think you should scrunch it! It looks awesome. Just tip ur head over and put jell in ur hands and like scrunch!* *just brush it and go, it always works for me when i can't figure out what to do with it.* *pull it up in a high pony tail & small curls falling down!* *make it into braids*

Table 3: Example question from the Yahoo! Answers dataset

though our preliminary experiments show that applying lexical normalization results in significantly lower performance, further study is needed. One direction is in using character-level embeddings that have been proven promising for user-generated content because of their ability to better handle spelling variation (Kim et al., 2015).

4 Conclusions

We have conducted answer reranking experiments for open-domain non-factoid QA and achieved state-of-the-art performance on the Yahoo! Answers manner question corpus using a very straightforward neural approach which involves representing question-answer pairs as paragraph vectors and training a multilayer perceptron to order candidate answers. Our experiments show that representing the question-answer pair as a paragraph vector is clearly superior to the use of averaged word vectors. We have also shown that a smaller amount of unlabelled data taken from a CQA site is more useful for training representations than a larger newswire set.

In this paper, we use general purpose distributed document representations provided by Paragraph Vector models to represent question-answer pairs. Then a machine learning algorithm is used to rank the pairs. One possible direction for future research is in learning distributed document representations and the ranking simultaneously and applying more sophisticated recurrent models such as long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) neural networks, that have been shown to be effective in similar tasks (Wang and Nyberg, 2015; Zhou et al., 2015).

Multilingual Language Processing From Bytes

Abstract

We describe an LSTM-based model which we call Byte-to-Span (BTS) that reads text as bytes and outputs span annotations of the form [start, length, label] where start positions, lengths, and labels are separate entries in our vocabulary. Because we operate directly on unicode bytes rather than language-specific words or characters, we can analyze text in many languages with a single model. Due to the small vocabulary size, these multilingual models are very compact, but produce results similar to or better than the state-of-the-art in Part-of-Speech tagging and Named Entity Recognition that use only the provided training datasets (no external data sources). Our models are learning "from scratch" in that they do not rely on any elements of the standard pipeline in Natural Language Processing (including tokenization), and thus can run in standalone fashion on raw text.

1 Introduction

The long-term trajectory of research in Natural Language Processing has seen the replacement of rules and specific linguistic knowledge with machine learned components. Perhaps the most standardized way that knowledge is still injected into largely statistical systems is through the processing pipeline: Some set of basic language-specific tokens are identified in a first step. Sequences of tokens are segmented into sentences in a second step. The resulting sentences are fed one at a time for syntactic analysis: Part-of-Speech (POS) tagging and parsing. Next, the predicted syntactic structure is typically used as features in semantic analysis, Named Entity Recognition (NER), Semantic Role Labeling, etc. While each step of the pipeline now relies more on data and models than on hand-curated rules, the pipeline structure itself encodes one particular understanding of how meaning attaches to raw strings.

One motivation for our work is to try removing this structural dependence. Rather than rely on the intermediate representations invented for specific subtasks (for example, Penn Treebank tokenization), we are allowing the model to learn whatever internal structure is most conducive to producing the annotations of interest. To this end, we describe a Recurrent Neural Network (RNN) model that reads raw input string *segments*, one byte at a time, and produces output *span annotations* corresponding to specific byte regions in the input[1]. This is truly language annotation from scratch (see Collobert et al. (2011) and Zhang and LeCun (2015)).

Two key innovations facilitate this approach. First, Long Short Term Memory (LSTM) models (Hochreiter and Schmidhuber, 1997) allow us to replace the traditional independence assumptions in text processing with structural constraints on memory. While we have long known that long-term dependencies are important in language, we had no mechanism other than conditional independence to keep sparsity in check. The memory in an LSTM, however, is not constrained by any explicit assumptions of independence. Rather, its ability to learn patterns is limited only by the structure of the network and the size of the memory (and of course the

[1] Our span annotation model can be applied to any sequence labeling task; it is not immediately applicable to predicting more complex structures like trees.

Figure 1: A diagram showing the way the Byte-to-Span (BTS) model converts an input text segment to a sequence of span annotations. The model reads the input segment one byte at a time (this can involve multibyte unicode characters), then a special Generate Output (GO) symbol, then produces the argmax output of a softmax over all possible start positions, lengths, and labels (as well as STOP, signifying no additional outputs). The prediction from the previous time step is fed as an input to the next time step.

amount of training data).

Second, sequence-to-sequence models (Sutskever et al., 2014), allow for flexible input/output dynamics. Traditional models, including feedforward neural networks, read fixed-length inputs and generate fixed-length outputs by following a fixed set of computational steps. Instead, we can now read an entire segment of text before producing an arbitrary number of outputs, allowing the model to learn a function best suited to the task.

We leverage these two ideas with a basic strategy: Decompose inputs and outputs into their component pieces, then read and predict them as sequences. Rather than read words, we are reading a sequence of unicode bytes[2]; rather than producing a label for each word, we are producing triples [start, length, label], that correspond to the spans of interest, as a sequence of three separate predictions (see Figure 1). This forces the model to learn how the components of words and labels interact so all the structure typically imposed by the NLP pipeline (as well as the rules of unicode) are left to the LSTM to model.

Decomposed inputs and outputs have a few important benefits. First, they reduce the size of the vocabulary relative to word-level inputs, so the resulting models are extremely compact (on the order of a million parameters). Second, because unicode is essentially a universal language, we can train models to analyze many languages at once. In fact, by stacking LSTMs, we are able to learn representations that appear to generalize across languages, improving performance significantly (without using any additional parameters) over models trained on a single language. This is the first account, to our knowledge, of a multilingual model that achieves good results across many languages, thus bypassing all the language-specific engineering usually required to build models in different languages[3]. We describe results similar to or better than the state-of-the-art in Part-of-Speech tagging and Named Entity Recognition that use only the provided training datasets (no external data sources).

The rest of this paper is organized as follows. Section 2 discusses related work; Section 3 describes our model; Section 4 gives training details including a new variety of dropout (Hinton et al., 2012);

[2] We use the variable length UTF-8 encodings to keep the vocabulary as small as possible.

[3] These multilingual models are able to handle code-mixed text, an important practical problem that's received relatively little attention. However, we do not have any annotated data that contains code switching, so we cannot report any results.

Section 5 gives inference details; Section 6 presents results on POS tagging and NER across many languages; Finally, we summarize our contributions in section 7.

2 Related Work

One important feature of our work is the use of byte inputs. Character-level inputs have been used with some success for tasks like NER (Klein et al., 2003), parallel text alignment (Church, 1993), and authorship attribution (Peng et al., 2003) as an effective way to deal with n-gram sparsity while still capturing some aspects of word choice and morphology. Such approaches often combine character and word features and have been especially useful for handling languages with large character sets (Nakagawa, 2004). However, there is almost no work that explicitly uses bytes – one exception uses byte n-grams to identify source code authorship (Frantzeskou et al., 2006) – but there is nothing, to the best of our knowledge, that exploits bytes as a cross-lingual representation of language. Work on multilingual parsing using Neural Networks that share some subset of the parameters across languages (Duong et al., 2015) seems to benefit the low-resource languages; however, we are sharing all the parameters among all languages.

Recent work has shown that modeling the sequence of characters in each token with an LSTM can more effectively handle rare and unknown words than independent word embeddings (Ling et al., 2015; Ballesteros et al., 2015). Similarly, language modeling, especially for morphologically complex languages, benefits from a Convolutional Neural Network (CNN) over characters to generate word embeddings (Kim et al., 2015). Rather than decompose words into characters, Rohan and Denero (2015) encode rare words with Huffman codes, allowing a neural translation model to learn something about word subcomponents. In contrast to this line of research, our work has no explicit notion of tokens and operates on bytes rather than characters.

Our work is philosophically similar to Collobert et al.'s (2011) experiments with "almost from scratch" language processing. They avoid task-specific feature engineering, instead relying on a multilayer feedforward (or convolutional) Neural Network to combine word embeddings to produce features useful for each task. In the Results section, below, we compare NER performance on the same dataset they used. The "almost" in the title actually refers to the use of preprocessed (lowercased) tokens as input instead of raw sequences of letters. Our byte-level models can be seen as a realization of their comment: "A completely from scratch approach would presumably not know anything about words at all and would work from letters only." Recent work with convolutional neural networks that read character-level inputs (Zhang et al., 2015) shows some interesting results on a variety of classification tasks, but because their models need very large training sets, they do not present comparisons to established baselines on standard tasks.

Finally, recent work on Automatic Speech Recognition (ASR) uses a similar sequence-to-sequence LSTM framework to produce letter sequences directly from acoustic frame sequences (Chan et al., 2015; Bahdanau et al., 2015). Just as we are discarding the usual intermediate representations used for text processing, their models make no use of phonetic alignments, clustered triphones, or pronunciation dictionaries. This line of work – discarding intermediate representations in speech – was pioneered by Graves and Jaitly (2014) and earlier, by Eyben et al. (2009).

3 Model

Our model is based on the sequence-to-sequence model used for machine translation (Sutskever et al., 2014), an adaptation of an LSTM that encodes a variable length input as a fixed-length vector, then decodes it into a variable number of outputs[4].

Generally, the sequence-to-sequence LSTM is trained to estimate the conditional probability $P(y_1, ..., y_{T'}|x_1, ..., x_T)$ where $(x_1, ..., x_T)$ is an input sequence and $(y_1, ..., y_{T'})$ is the corresponding output sequence whose length T' may differ from T. The encoding step computes a fixed-dimensional representation v of the input $(x_1, ..., x_T)$ given by the hidden state of the LSTM

[4] Related translation work adds an attention mechanism (Bahdanau et al., 2014), allowing the decoder to attend directly to particularly relevant inputs. We tried adding the same mechanism to our model but saw no improvement in performance on the NER task, though training converged in fewer steps.

after reading the last input x_T. The decoding step computes the output probability $P(y_1, ..., y_{T'})$ with the standard LSTM formulation for language modeling, except that the initial hidden state is set to v:

$$P(y_1, ..., y_{T'}|x_1, ..., x_T) = \prod_{t=1}^{T'} P(y_t|v, y_1, ..., y_{t-1}) \quad (1)$$

Sutskever et al. used a separate LSTM for the encoding and decoding tasks. While this separation permits training the encoder and decoder LSTMs separately, say for multitask learning or pre-training, we found our results were no worse if we used a single set of LSTM parameters for both encoder and decoder.

3.1 Vocabulary

The primary difference between our model and the translation model is our novel choice of vocabulary. The set of inputs include all 256 possible bytes, a special Generate Output (GO) symbol, and a special DROP symbol used for regularization, which we will discuss below. The set of outputs include all possible span start positions (byte $0..k$), all possible span lengths ($0..k$), all span labels (PER, LOC, ORG, MISC for the NER task), as well as a special STOP symbol. A complete span annotation includes a start, a length, and a label, but as shown in Figure 1, the model is trained to produce this triple as three separate outputs. This keeps the vocabulary size small and in practice, gives better performance (and faster convergence) than if we use the cross-product space of the triples.

More precisely, the prediction at time t is conditioned on the full input and all previous predictions (via the chain rule). By splitting each span annotation into a sequence [start, length, label], we are making no independence assumption; instead we are relying on the model to maintain a memory state that captures the important dependencies.

Each output distribution $P(y_t|v, y_1, ..., y_{t-1})$ is given by a softmax over all possible items in the output vocabulary, so at a given time step, the model is free to predict any start, any length, or any label (including STOP). In practice, because the training data always has these complete triples in a fixed order, we seldom see malformed or incomplete spans (the decoder simply ignores such spans). During training, the true label y_{t-1} is fed as input to the model at step t (see Figure 1), and during inference, the argmax prediction is used instead. Note also that the training procedure tries to maximize the probability in Equation 1 (summed over all the training examples). While this does not quite match our task objectives (F1 over labels, for example), it is a reasonable proxy.

3.2 Independent segments

Ideally, we would like our input segments to cover full documents so that our predictions are conditioned on as much relevant information as possible. However, this is impractical for a few reasons. From a training perspective, a Recurrent Neural Network is unrolled to resemble a deep feedforward network, with each layer corresponding to a time step. It is well-known that running backpropagation over a very deep network is hard because it becomes increasingly difficult to estimate the contribution of each layer to the gradient, and further, RNNs have trouble generalizing to different length inputs (Erhan et al., 2009).

So instead of document-sized input segments, we make a segment-independence assumption: We choose some fixed length k and train the model on segments of length k (any span annotation not completely contained in a segment is ignored). This has the added benefit of limiting the range of the start and length label components. It can also allow for more efficient batched inference since each segment is decoded independently. Finally, we can generate a large number of training segments by sliding a window of size k one byte at a time through a document. Note that the resulting training segments can begin and end mid-word, and indeed, mid-character. For both tasks described below, we set the segment size $k = 60$.

3.3 Sequence ordering

Our model differs from the translation model in one more important way. Sutskever et al. found that feeding the input words in reverse order and generating the output words in forward order gave significantly better translations, especially for long sentences. In theory, the predictions are conditioned on the entire input, but as a practical matter, the learning problem is easier when relevant information is ordered appropriately since long dependencies are harder to learn than short ones.

Because the byte order is more meaningful in the forward direction (the first byte of a multibyte character specifies the length, for example), we found somewhat better performance with forward order than reverse order (less than 1% absolute). But unlike translation, where the outputs have a complex order determined by the syntax of the language, our span annotations are more like an unordered set. We tried sorting them by end position in both forward and backward order, and found a small improvement (again, less than 1% absolute) using the backward ordering (assuming the input is given in the forward order). This result validates the translation ordering experiments: the modeling problem is easier when the sequence-to-sequence LSTM is used more like a stack than a queue.

3.4 Model shape

We experimented with a few different architectures and found no significant improvements in using more than 320 units for the embedding dimension and LSTM memory and 4 stacked LSTMs (see Table 4). This observation holds for both models trained on a single language and models trained on many languages. Because the vocabulary is so small, the total number of parameters is dominated by the size of the recurrent matrices. All the results reported below use the same architecture (unless otherwise noted) and thus have roughly 900k parameters.

4 Training

We trained our models with Stochastic Gradient Descent (SGD) on mini-batches of size 128, using an initial learning rate of 0.3. For all other hyperparameter choices, including random initialization, learning rate decay, and gradient clipping, we follow Sutskever et al. (2014). Each model is trained on a single CPU over a period of a few days, at which point, development set results have stabilized. Distributed training on GPUs would likely speed up training to just a few hours.

4.1 Dropout and byte-dropout

Neural Network models are often trained using *dropout* (Hinton et al., 2012), which tends to improve generalization by limiting correlations among hidden units. During training, dropout randomly zeroes some fraction of the elements in the embedding layer and the model state just before the softmax layer (Zaremba et al., 2014).

We were able to further improve generalization with a technique we are calling *byte-dropout*: We randomly replace some fraction of the input bytes in each segment with a special DROP symbol (without changing the corresponding span annotations). Intuitively, this results in a more robust model, perhaps by forcing it to use longer-range dependencies rather than memorizing particular local sequences.

It is worth noting that noise is often added at training time to images in image classification and speech in speech recognition where the added noise does not fundamentally alter the input, but rather blurs it. By using a byte representation of language, we are now capable of achieving something like blurring with text. Indeed, if we removed 20% of the characters in a sentence, humans would be able to infer words and meaning reasonably well.

5 Inference

We perform inference on a segment by (greedily) computing the most likely output at each time step and feeding it to the next time step. Experiments with beam search show no meaningful improvements (less than 0.2% absolute). Because we assume that each segment is independent, we need to choose how to break up the input into segments and how to stitch together the results.

The simplest approach is to divide up the input into segments with no overlapping bytes. Because the model is trained to ignore incomplete spans, this approach misses all spans that cross segment boundaries, which, depending on the choice of k, can be a significant number. We avoid the missed-span problem by choosing segments that overlap such that each span is likely to be fully contained by at least one segment.

For our experiments, we create segments with a fixed overlap ($k/2 = 30$). This means that with the exception of the first segment in a document, the model reads 60 bytes of input, but we only keep predictions about the last 30 bytes.

6 Results

Here we describe experiments on two datasets that include annotations across a variety of languages. The multilingual datasets allow us to highlight the advantages of using byte-level inputs: First, we can train a single compact model that can handle many languages at once. Second, we demonstrate some cross-lingual abstraction that improves performance of a single multilingual model over each single-language model. In the experiments, we refer to the LSTM setup described above as Byte-to-Span or BTS.

Most state-of-the-art results in POS tagging and NER leverage unlabeled data to improve a supervised baseline. For example, word clusters or word embeddings estimated from a large corpus are often used to help deal with sparsity. Because our LSTM models are reading bytes, it is not obvious how to insert information like a word cluster identity. Recent results with sequence-to-sequence auto-encoding (Dai and Le, 2015) seem promising in this regard, but here we limit our experiments to use just annotated data.

Each task specifies separate data for training, development, and testing. We used the development data for tuning the dropout and byte-dropout parameters (since these likely depend on the amount of available training data), but did not tune the remaining hyperparameters. In total, our training set for POS Tagging across 13 languages included 2.87 million tokens and our training set for NER across 4 languages included 0.88 million tokens. Recall, though, that our training examples are 60-byte segments obtained by sliding a window through the training data, shifting by 1 byte each time. This results in 25.3 million and 6.0 million training segments for the two tasks.

6.1 Part-of-Speech Tagging

Our part-of-speech tagging experiments use Version 1.1 of the Universal Dependency data[5], a collection of treebanks across many languages annotated with a universal tagset (Petrov et al., 2011). The most relevant recent work (Ling et al., 2015) uses different datasets, with different finer-grained tagsets in each language. Because we are primary interested in multilingual models that can share language-independent parameters, the universal tagset is important, and thus our results are not immediately comparable. However, we provide baseline results (for each language separately) using a Conditional Random Field (Lafferty et al., 2001) with an extensive collection of features with performance comparable to the Stanford POS tagger (Manning, 2011). For our experiments, we chose the 13 languages that had at least 50k tokens of training data. We did not subsample the training data, though the amount of data varies widely across languages, but rather shuffled all training examples together. These languages represent a broad range of linguistic phenomena and character sets so it was not obvious at the outset that a single multilingual model would work.

Table 1 compares the baselines with (CRF+) and without (CRF) externally trained cluster features with our model trained on all languages (BTS) as well as each language separately (BTS*). The single BTS model improves on average over the CRF models trained using the same data, though clearly there is some benefit in using external resources. Note that BTS is particularly strong in Finnish, surpassing even CRF+ by nearly 1.5% (absolute), probably because the byte representation generalizes better to agglutinative languages than word-based models, a finding validated by Ling et al. (2015). In addition, the baseline CRF models, including the (compressed) cluster tables, require about 50 MB per language, while BTS is under 10 MB. BTS improves on average over BTS*, suggesting that it is learning some language-independent representation.

6.2 Named Entity Recognition

Our main motivation for showing POS tagging results was to demonstrate how effective a single BTS model can be across a wide range of languages. The NER task is a more interesting test case because, as discussed in the introduction, it usually relies on a pipeline of processing. We use the 2002 and 2003 ConLL shared task datasets[6] for multilingual NER because they contain data in 4 languages (English, German, Spanish, and Dutch) with consistent annotations of named entities (PER, LOC, ORG, and MISC). In addition, the shared task competition

Table 1: Part-of-speech tagging accuracy for two CRF baselines and 2 versions of BTS. CRF+ uses resources external to the training data (word clusters) and CRF uses only the training data. BTS (unlike CRF+ and CRF) is a single model trained on all the languages together, while BTS* is a separate Byte-to-Span model for each language.

produced strong baseline numbers for comparison. However, most published results use extra information beyond the provided training data which makes fair comparison with our model more difficult.

The best competition results for English and German (Florian et al., 2003) used a large gazetteer and the output of two additional NER classifiers trained on richer datasets. Since 2003, better results have been reported using additional semi-supervised techniques (Ando and Zhang, 2005) and more recently, Passos et al. (2014) claimed the best English results (90.90% F1) using features derived from word-embeddings. The 1st place submission in 2002 (Carreras et al., 2002) comment that without extra resources for Spanish, their results drop by about 2% (absolute).

Perhaps the most relevant comparison is the overall 2nd place submission in 2003 (Klein et al., 2003). They use only the provided data and report results with character-based models which provide a useful comparison point to our byte-based LSTM. The performance of a character HMM alone is much worse than their best result (83.2% vs 92.3% on the English development data), which includes a variety of word and POS-tag features that describe the context (as well as some post-processing rules). For English (assuming just ASCII strings), the character HMM uses the same inputs as BTS, but is hindered by some combination of the independence assumption and smaller capacity.

Collobert et al.'s (2011) convolutional model (discussed above) gives 81.47% F1 on the English test set when trained on only the gold data. However, by using carefully selected word-embeddings trained on external data, they are able to increase F1 to 88.67%. Huang et al. (2015) improve on Collobert's results by using a bidirectional LSTM with a CRF layer where the inputs are features describing the words in each sentence. Either by virtue of the more powerful model, or because of more expressive features, they report 84.26% F1 on the same test set and 90.10% when they add pretrained word embedding features. Dos Santos et al. (2015) represent each word by concatenating a pretrained word embedding with a character-level embedding produced by a convolutional neural network.

There is relatively little work on multilingual NER, and most research is focused on building systems that are unsupervised in the sense that they use resources like Wikipedia and Freebase rather than manually annotated data. Nothman et al. (2013) use Wikipedia anchor links and disambiguation pages joined with Freebase types to create a huge amount of somewhat noisy training data and are able to achieve good results on many languages (with some extra heuristics). These results are also included in Table 2.

While BTS does not improve on the state-of-the-art in English, its performance is better than the best previous results that use only the provided training data. BTS improves significantly on the best known results in German, Spanish, and Dutch even though these leverage external data. In addition, the BTS* models, trained separately on each language, are worse than the single BTS model (with the same number of parameters as each single-language model) trained on all languages combined, again suggesting that the model is learning some language-independent representation of the task.

One interesting shortcoming of the BTS model is that it is not obvious how to tune it to increase recall. In a standard classifier framework, we could simply increase the prediction threshold to increase

Table 2: A comparison of NER systems. The results are F1 scores, where a correct span annotation exactly matches a gold span annotation (start, length, and entity type must all be correct). Results of the systems described in the text are shown for English, German, Spanish, and Dutch. BTS* shows the results of the BTS model trained separately on each language while BTS is a single model trained on all 4 languages together. The top set of results leverage resources beyond the training data; the middle set do not, and thus are most comparable to our results (bottom set).

precision and decrease the prediction threshold to increase recall. However, because we only produce annotations for spans (non-spans are not annotated), we can adjust a threshold on total span probability (the product of the start, length, and label probabilities) to increase precision, but there is no clear way to increase recall. The untuned model tends to prefer precision over recall already, so some heuristic for increasing recall might improve our overall F1 results.

6.3 Dropout and Stacked LSTMs

There are many modeling options and hyperparameters that significantly impact the performance of Neural Networks. Here we show the results of a few experiments that were particularly relevant to the performance obtained above.

First, Table 3 shows how dropout and byte-dropout improve performance for both tasks. Without any kind of dropout, the training process starts to overfit (development data perplexity starts increasing) relatively quickly. For POS tagging, we set dropout and byte-dropout to 0.2, while for NER, we set both to 0.3. This significantly reduces the overfitting problem.

BTS Training	POS Accuracy	NER F1
Vanilla	94.78	74.75
+ Dropout	95.35	78.76
+ Byte-dropout	95.85	82.13

Table 3: BTS Part-of-speech tagging average accuracy across all 13 evaluated languages and Named Entity Recognition average F1 across all 4 evaluated languages with various modifications to the vanilla training setup. Dropout is standard in Neural Network model training because it often improves generalization; Byte-dropout randomly replaces input bytes with a special DROP marker.

Depth	Width=320	Width=640
1	76.15	77.59
2	79.40	79.73
3	81.44	81.93
4	82.13	82.18

Table 4: Macro-averaged (across 4 languages) F1 for the NER task using different model architectures.

Second, Table 4 shows how performance improves as we increase the size of the model in two ways: the number of units in the model's state (width) and the number of stacked LSTMs (depth). Increasing the width of the model improves performance less than increasing the depth, and once we use 4 stacked LSTMs, the added benefit of a much wider model has disappeared. This result suggests that rather than learning to partition the space of inputs according to the source language, the model is learning some lanugage-independent representation at the deeper levels.

To validate our claim about language-independent representation, Figure 2 shows the results of a tSNE plot of the LSTM's memory state when the output is one of PER, LOC, ORG, MISC across the four languages. While the label clusters are neatly separated, the examples of each individual label do not appear to be clustered by language. Thus rather than partitioning each (label, language) combination, the model is learning unified label representations that are independent of the language.

7 Conclusions

We have described a model that uses a sequence-to-sequence LSTM framework that reads a segment of

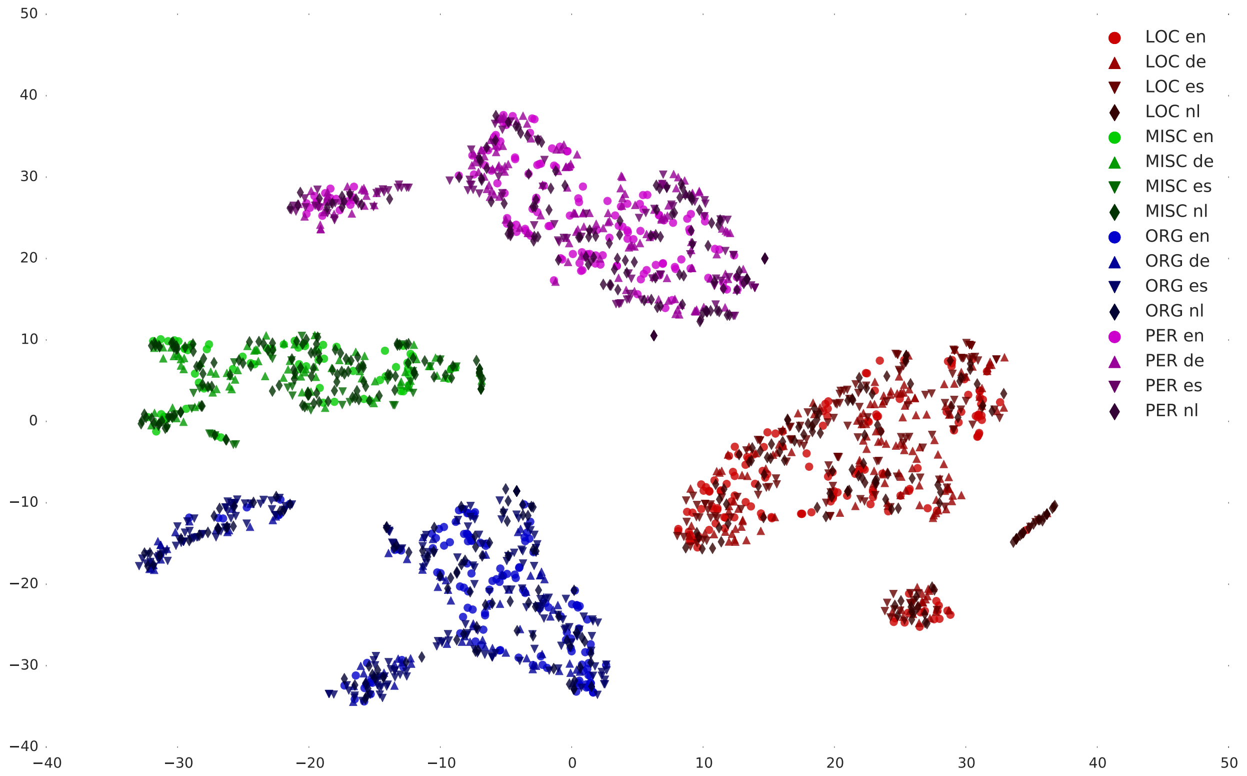

Figure 2: A tSNE plot of the BTS model's memory state just before the softmax layer produces one of the NER labels.

text one byte at a time and then produces span annotations over the inputs. This work makes a number of novel contributions:

First, we use the bytes in variable length unicode encodings as inputs. This makes the model vocabulary very small and also allows us to train a multilingual model that improves over single-language models without using additional parameters. We introduce byte-dropout, an analog to added noise in speech or blurring in images, which significantly improves generalization.

Second, the model produces span annotations, where each is a sequence of three outputs: a start position, a length, and a label. This decomposition keeps the output vocabulary small and marks a significant departure from the typical Begin-Inside-Outside (BIO) scheme used for labeling sequences.

Finally, the models are much more compact than traditional word-based systems and they are standalone – no processing pipeline is needed. In particular, we do not need a tokenizer to segment text in each of the input languages.

Ten Pairs to Tag – Multilingual POS Tagging via Coarse Mapping between Embeddings

Abstract

In the absence of annotations in the target language, multilingual models typically draw on extensive parallel resources. In this paper, we demonstrate that accurate multilingual part-of-speech (POS) tagging can be done with just a few (e.g., ten) word translation pairs. We use the translation pairs to establish a coarse linear isometric (orthonormal) mapping between monolingual embeddings. This enables the supervised source model expressed in terms of embeddings to be used directly on the target language. We further refine the model in an unsupervised manner by initializing and regularizing it to be close to the direct transfer model. Averaged across six languages, our model yields a 37.5% absolute improvement over the monolingual prototype-driven method (Haghighi and Klein, 2006) when using a comparable amount of supervision. Moreover, to highlight key linguistic characteristics of the generated tags, we use them to predict typological properties of languages, obtaining a 50% error reduction relative to the prototype model.[1]

1 Introduction

After two decades of study, the best performing multilingual methods can in some cases approach their supervised monolingual analogues. To reach this level of performance, however, multilingual methods typically make use of significant parallel resources such as parallel translations or bilingual dictionaries. These resources act as substitutes for explicit annotations available in the target language for supervised methods. It is less clear what can be done without extensive parallel resources. Indeed, the motivation for our paper comes from trying to understand how little parallel data is necessary for effective multilingual transfer.

In this paper, we demonstrate that only ten word translation pairs suffice for effective multilingual transfer of part-of-speech (POS) tagging. To achieve this we make use of and integrate two sources of statistical signal. First, we enable transfer of information from the source to target languages by establishing a coarse mapping between word embeddings in two languages on the basis of the few available translation pairs. The mapping is useful because of significant structural similarity of embedding spaces across languages. Second, we leverage the potential of unsupervised monolingual models to capture language-specific syntactic properties. The two sources of signals are largely complementary. Embeddings provide a coarse alignment between languages while unsupervised methods fine tune the correspondences in service of the task at hand. While unsupervised methods are fragile and challenging to estimate in general, they can be helpful if initialized and regularized properly, which is our focus.

In order to transfer annotations, we align monolingual embeddings between languages. However, a full fine-grained alignment is not possible with only ten translation pairs due to differences between the languages and variations across raw corpora from which the embeddings are derived. Instead, we re-

[1] Our code and data are available at https://github.com/yuanzh/transfer_pos.

San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

strict the initial coarse mapping to be linear and isometric (orthonormal) so as to leave lengths and angles between the word vectors invariant. One advantage is that this preserves cosine similarity between vectors, which is viewed as a proxy for syntactic/semantic similarity (Mikolov et al., 2013a; Pennington et al., 2014; Herbelot and Vecchi, 2015). The resulting coarse alignment is then used to initialize and guide an unsupervised model over the target language.

Our unsupervised model is a feature-based hidden Markov model (HMM) expressed in terms of word embeddings. By establishing a common multilingual embedding space, we can map the source HMM estimated from supervised annotations directly to the target. The resulting "direct transfer" model should be further adjusted as languages differ, and the initial alignment obtained based on embeddings is imperfect. For this reason we cast the direct transfer model as a regularizer for the target HMM, and permit the HMM to further adjust the embedding transformations and relations of embeddings to the tags both globally (overall rotation and scaling) and locally (introducing small corrections).

Our two phase approach is simple to implement, performs well, and can be adapted to other NLP tasks. We evaluate our approach on POS tagging using the multilingual universal dependency treebanks (Nivre et al., 2016). Specifically, we use English as the source language and test on three Indo-European languages (Danish, German and Spanish) and three non-Indo-European-languages (Finnish, Hungarian and Indonesian). Experimental results show that our method consistently outperforms various baselines across languages. On average, our full model achieves 8% absolute improvement over the direct transfer counterpart. We also compare against a prototype-driven tagger (Haghighi and Klein, 2006) using 14 prototypes as supervision. Our model significantly outperforms Haghighi and Klein (2006)'s model by 37.5% (67.5% vs 30%).

We also introduce a novel task-based evaluation of automatic POS taggers, where tagger predictions are used to determine typological properties of the target language. This evaluation highlights key linguistic features of the generated tags. On this task, our model achieves 80% accuracy, yielding 50% error reduction relative to the prototype model.

2 Related Work

Multilingual POS Tagging Prior work on multilingual POS tagging has mainly focused on the *tag projection* method (Yarowsky et al., 2001; Wisniewski et al., 2014; Duong et al., 2013; Duong et al., 2014; Täckström et al., 2013; Das and Petrov, 2011; Snyder et al., 2008; Naseem et al., 2009; Chen et al., 2011). All these approaches assume access to a large amount of parallel sentences to facilitate multilingual transfer. In our work, we focus on a more challenging scenario, in which we do not assume access to parallel sentences. Instead of projecting tag information via word alignment, the transfer in our model is driven by mapping multilingual embedding spaces. Kim et al. (2015) also use latent word representations for multilingual transfer. However, similarly to prior work, this representation is learned using parallel data.

The feasibility of POS tagging transfer without parallel data has been shown by Hana et al. (2004). The transfer is performed between typologically similar languages, which enables the model to directly transfer the transition probabilities from source to the target. Moreover, emission probabilities are hand-engineered to capture language-specific morphological properties. In contrast, our method does not require any language-specific knowledge on the target side.

Multilingual Word Embeddings There is an expansive body of research on learning multilingual word embeddings (Gouws et al., 2014; Faruqui and Dyer, 2014; Lu et al., 2015; Lauly et al., 2014; Luong et al., 2015). Previous work has shown its effectiveness across a wide range of multilingual transfer tasks including tagging (Kim et al., 2015), syntactic parsing (Xiao and Guo, 2014; Guo et al., 2015; Durrett et al., 2012), and machine translation (Zou et al., 2013; Mikolov et al., 2013b). However, these approaches commonly require parallel sentences or bilingual lexicon to learn multilingual embeddings. Vulic and Moens (2015) have alleviated the requirements by inducing multilingual word embeddings directly from a document-aligned corpus such as a set of Wikipedia pages on the same theme but in different languages. However, they still used about ten thousands aligned documents as parallel supervision. Our work demonstrates that useful multilingual embeddings can be learned with a minimal amount of parallel supervision.

3 Multilingual POS Tagger

Our method is designed to operate in the regime where there are no parallel sentences or target annotations. We assume only a few, in our case ten, word translation pairs. This small number of translation pairs together with the tags that they carry from the source to the target do not provide sufficient information to train a reasonable supervised tagger, even for very close languages where word translations would be mostly one-to-one and tags fully preserved in translation. Other cues are necessary.

The few translation pairs provide just enough information to obtain a coarse global alignment between the source and target language embeddings. We limit the initial linear transformation between embeddings to isometric (orthonormal) mappings so as to preserve norms and angles (e.g., cosine similarities) between words. Once the embeddings are aligned, any source language model expressed in terms of embeddings can be mapped to a target language model. The approach is akin to direct transfer commonly applied in parsing (McDonald et al., 2011; Zeman and Resnik, 2008) though often with more information. We use the term "direct transfer" to mean the process where no further adjustment is performed beyond the immediate mapping via (coarsely) aligned embeddings.

Direct transfer is insufficient between languages that are syntactically (even moderately) divergent. Instead, we use the directly transferred model to initialize and regularize an unsupervised tagger. Specifically, we employ a feature-based HMM (Berg-Kirkpatrick et al., 2010) tagger for both the source and target languages with two important modifications. The emission probabilities in the source language HMM are expressed solely in terms of word embeddings (cf. skip-gram models). Such distributions can be directly transferred to the target domain. Our target language HMM is, however, equipped with additional adjustable parameters that can be learned in an unsupervised manner. These include parameters for modifying the initial global linear transformation between embeddings. Beyond this linear transformation, we also add "correction terms" to each tag-word pair that are in principle sufficient to specify any HMM. Both of these additional sets of parameters are regularized towards keeping the initial direct transfer model. As a result, our strongly governed unsupervised tagger can succeed where an unguided unsupervised tagger would typically fail.

In the remainder of this section, we describe the approach more formally, starting with the coarse alignment between embeddings, followed by the supervised feature-based HMM, and the unsupervised target language HMM.

3.1 Isometric Alignment of Word Embeddings

Here we find a linear transformation from the target language embeddings to the source language embeddings using the translation pairs. The resulting transformation permits us to directly apply any source language model on the target language, i.e., it enables direct transfer. To this end, let $\boldsymbol{V}_s \in \mathbb{R}^{n_s \times d}$ and $\boldsymbol{V}_t \in \mathbb{R}^{n_t \times d}$ be the word embeddings estimated for the source and target languages, respectively, with vocabulary sizes n_s and n_t. All the embeddings are of dimension d. The submatrices of embeddings pertaining to k anchor words (from translation pairs) are denoted as $\boldsymbol{\Sigma}_s$ and $\boldsymbol{\Sigma}_t$, where $\boldsymbol{\Sigma}_s, \boldsymbol{\Sigma}_t \in \mathbb{R}^{k \times d}$.

We find a linear transformation $\boldsymbol{P} \in \mathbb{R}^{d \times d}$ that best aligns the embeddings of the translation pairs in the sense of minimizing

$$||\boldsymbol{\Sigma}_t \boldsymbol{P} - \boldsymbol{\Sigma}_s||^2 \tag{1}$$

subject to the **isometric** (orthonormal) constraint $\boldsymbol{P}^T \boldsymbol{P} = \boldsymbol{I}$. We use the steepest descent algorithm (Abrudan et al., 2008) to solve this optimization problem.[2] Once $\boldsymbol{P}$ is available, we can map all the target language embeddings $\boldsymbol{V}_t$ to the source language space with $\boldsymbol{V}_t \boldsymbol{P}$. Note that since typically in our setting $k < d$ (e.g. $k = 10$) additional constraints such as isometry are required.

Motivation behind the Isometric Constraint We impose isometry on the linear transformation so as to preserve angles and lengths of the word vectors after the transformation. A number of recent studies have explored the use of cosine similarity of word

[2] Our implementation is based on the toolkit available at `http://legacy.spa.aalto.fi/sig-legacy/unitary_optimization/`.

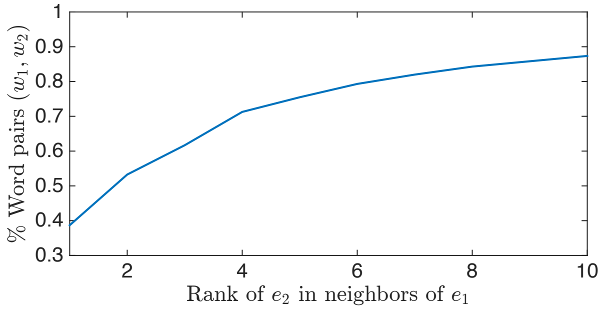

Figure 1: Cumulative fraction of word translation pairs among top 1,000 most frequent words where the nearest neighbor of a German word (vector) appears as the r^{th} nearest neighbor after translation, measured in terms of their monolingual word embeddings.

vectors as a measure of semantic relations between words. Thus, for example, if two words have high cosine similarity in German (target), the corresponding words in English (source) should also be similar. To validate our isometric constraint further, we verify whether nearest neighbors are preserved in monolingual embeddings after translation. To this end, we take the top 1,000 most frequent words in German and their translations into English and ask whether nearest neighbors are preserved if measured in terms of their monolingual embeddings. For each word vector w_1 and its nearest neighbor w_2 in German, let e_1 and e_2 be the corresponding English vectors. We compute the rank of e_2 in the ordered list of nearest neighbors of e_1. As Figure 1 shows, in more than 50% of word pairs, e_2 is among the top-2 neighbors of e_1. In over 90% of the word pairs e_2 is among e_1's top-10 closest neighbors.

For the purposes of comparison (see Section 5), we introduce also a linear transformation without isometry. In other words, we find $\boldsymbol{P}$ that minimizes $||\boldsymbol{\Sigma}_t\boldsymbol{P} - \boldsymbol{\Sigma}_s||^2$ via the **Moore–Penrose pseudoinverse** (Moore, 1920; Penrose, 1955). Specifically, let $\boldsymbol{\Sigma}_t^+$ be the pseudoinverse of $\boldsymbol{\Sigma}_t$. Then the solution takes the form $\boldsymbol{P} = \boldsymbol{\Sigma}_t^+\boldsymbol{\Sigma}_s$, and has the minimum Frobenius norm among all possible solutions.

3.2 Supervised Source Language HMM

Here we briefly describe how we train a supervised tagger on the source language. The resulting model, together with aligned embeddings, specifies the direct transfer model. It will also be used to initialize and guide the unsupervised tagger on the target language.

Our model has the same structure as the standard HMM but we replace the transition and emission probabilities with log-linear models (cf. feature-based HMM by Berg-Kirkpatrick et al. (2010)). The transition probabilities include all indicator features and therefore impose no additional constraints. The emission probabilities, in contrast, are expressed entirely in terms of word embeddings $\boldsymbol{v}_x$ as features. More formally, the emission probability of word x given tag y is given by

$$p_\theta(x|y) \propto \exp\{\, \boldsymbol{v}_x^T \boldsymbol{\mu}_y \,\} \qquad (2)$$

Note that the parameters $\boldsymbol{\mu}_y$ (one vector per tag) can be viewed as tag embeddings. This supervised tagging model is trained to maximize the joint log-likelihood with l_2-regularization over parameters. We use the L-BFGS (Liu and Nocedal, 1989) algorithm to optimize the parameters.

Once the HMM has been trained, we can specify the direct transfer model. It has the same transition probabilities but the emission probabilities are modified according to $p_\theta^{dt}(x|y) \propto \exp\{\, \boldsymbol{v}_x^T \boldsymbol{P} \boldsymbol{\mu}_y \,\}$ where $\boldsymbol{v}_x$ is now the monolingual target embedding, transformed into the source space via $\boldsymbol{v}_x^T\boldsymbol{P}$. We apply the Viterbi algorithm to predict the most likely POS tag sequence.

3.3 Unsupervised Target Language HMM

Our unsupervised HMM for the target language is strictly more expressive than the direct transfer model so as to better tailor it to the target language. Let $\boldsymbol{v}_x$ again be the monolingual target embeddings estimated separately, prior to the HMMs. We map these vectors to the source language embedding space via $\boldsymbol{v}_x^T\boldsymbol{P}$ as discussed earlier, where $\boldsymbol{P}$ is already set and no longer considered a parameter. The form of the emission probabilities

$$p_\theta^t(x|y) \propto \exp\{\boldsymbol{v}_x^T \boldsymbol{P} \boldsymbol{M} \boldsymbol{\mu}_y + \theta_{x,y}\} \qquad (3)$$

includes two modifications to the direct transfer model. First, we have introduced an additional global linear transformation $\boldsymbol{M}$ to correct the initial alignment represented by $\boldsymbol{P}$. Second, we include per-symbol parameters $\theta_{x,y}$ which, in principle, are capable of specifying any emission distribution on their own. The adjustable parameters in this model (denoted collectively θ) are $\boldsymbol{M}$, $\{\boldsymbol{\mu}_y\}$, $\{\theta_{x,y}\}$, and the parameters pertaining to the transition probabilities. If we set $\boldsymbol{M} = \boldsymbol{I}$, $\theta_{x,y} = 0$ for all x and y, and borrow $\boldsymbol{\mu}_y$ and the transition parameters from the supervised HMM, then we recover the direct transfer model. Let θ_0 denote this setting of the parameters. In other words, the unsupervised HMM with initial parameters θ_0 is the direct transfer model.

Our approach include initializing $\theta = \theta_0$ and later regularizing θ to remain close to θ_0. The motivation behind this approach is two-fold. First, the initial alignment between embeddings was obtained only on the basis of the few available anchor words and may therefore need to be adjusted. Note that the linear transformation of embeddings now involves scaling and is no longer necessarily isometric. Second, the source and target languages differ and the embeddings are not strictly related to each other via any global linear transformation. We can interpret parameters $\theta_{x,y}$ as local (per word) non-linear deformations of the embedding vectors that specify the emission probabilities. We allow only small non-linear corrections by regularizing $\theta_{x,y}$ to remain close to zero, i.e., the values they have in θ_0.

Our unsupervised HMM is estimated by maximizing the regularized log-likelihood

$$L(\theta) = \sum_{i=1}^{n} \log P_\theta(\mathbf{x}_i) - \frac{\beta}{2}||\theta - \theta_0||_2^2 \qquad (4)$$

where $\mathbf{x}_i$ is the i^{th} target language sentence, $P_\theta(\mathbf{x}_i)$ is the HMM with parameters θ, and n is the number of sentences in the target text to be annotated. Since all the parameters in the model are in a log-linear form, we simply use the regularization parameter β. Once estimated, we use the Viterbi algorithm to predict the most likely POS tag sequence.

Estimation Details We maximize $L(\theta)$ using the Expectation-maximization (EM) algorithm. In the E-step, we evaluate expected counts $e_{y',y}$ for tag-tag and $e_{x,y}$ for word-tag pairs, using the forward-backward algorithm. The M-step searches for θ that maximizes

$$\begin{aligned} l(\theta) = &\sum_{y',y} e_{y',y} \log p_\theta^t(y'|y) + \sum_{x,y} e_{x,y} \log p_\theta^t(x|y) \\ &- \frac{\beta}{2}||\theta - \theta_0||_2^2 \end{aligned} \qquad (5)$$

The maximization can be be done via L-BFGS which involves computing the gradients of $\log p_\theta^t(y'|y)$ and $\log p_\theta^t(x|y)$ with respect to θ at every iteration. Because the conditional probabilities are expressed in a log-linear form, the gradients take on typical forms such as

$$\begin{aligned} \frac{dl(\theta)}{d\boldsymbol{\mu}_y} &= \sum_x e_{x,y}(\boldsymbol{v}_x^T \boldsymbol{P}\boldsymbol{M} - \sum_{x'} p_\theta^t(x'|y)\boldsymbol{v}_{x'}^T \boldsymbol{P}\boldsymbol{M}) \\ &\quad - \beta(\boldsymbol{\mu}_y - \boldsymbol{\mu}_{0y}) \\ \frac{dl(\theta)}{d\boldsymbol{M}} &= \sum_{x,y} e_{x,y}(\boldsymbol{P}^T \boldsymbol{v}_x \boldsymbol{\mu}_y^T - \sum_{x'} p_\theta^t(x'|y)\boldsymbol{P}^T \boldsymbol{v}_{x'} \boldsymbol{\mu}_y^T) \\ &\quad - \beta(\boldsymbol{M} - \boldsymbol{I}) \end{aligned} \qquad (6)$$

where $\boldsymbol{\mu}_{0y}$ are initial values for $\boldsymbol{\mu}_y$.

4 Experimental Setup

Dataset We evaluate our method on the latest Version 1.2 of the Universal Dependencies Treebanks (Nivre et al., 2016; McDonald et al., 2013). We use English as the source language and six other languages as targets. Specifically, we choose three Indo-European languages: Danish (da), German (de), Spanish (es), and three non-Indo-European languages: Finnish (fi), Hungarian (hu), Indonesian (id). All treebanks are annotated with the same universal POS tagset. In our work, we map proper nouns to nouns and map symbol marks[3] and interjections to a catch-all tag X because it is hard and unnecessary to disambiguate them in a low-resource learning scenario. After mapping, our tagset includes the following 14 tags: noun, verb, auxiliary verb, adjective, adverb, pronoun, determiner, adposition, numeral, conjunction, sentence conjunction, particle, punctuation mark, and a catch-all tag X. Note that this universal tagset contains two more tags than the traditional universal tagset proposed by Petrov et al. (2011): auxiliary verb and sentence conjunction. We follow the standard split of the treebanks for every language. For each target language, we use the sentences in the training set as unlabeled data, and evaluate on the testing set.

Word Embeddings To induce monolingual word embeddings, we use the processed Wikipedia text dumps (Al-Rfou et al., 2013) for each language.

[3] Examples of symbol mark include "-", "/" etc.

Language	English	Danish	German	Spanish	Finnish	Hungarian	Indonesian
Tokens (10^6)	1,888	44	687	399	66	89	41

Table 1: Number of tokens of the Wikipedia dumps used for inducing word embeddings.

While Wikipedia texts may contain parallel articles, we show in Table 1 that the amount of text varies significantly across languages. Smith et al. (2010) also demonstrated that parallel information in Wikipedia is very noisy. Therefore, direct translations are difficult to get from these texts. We use the `word2vec` tool with the skip-gram learning scheme (Mikolov et al., 2013a). In our experiments we use $d = 20$ for the dimension of word embeddings and $w = 1$ for the context window size of the skip-gram, which yields the best overall performance for our model. In our analysis, we also explore the impact of embedding dimension and window size.

Word Translation Pairs For each target language, we collect English translations for the top ten most frequent words in the training corpus. Our preliminary experiments show that this selection method performs the best. The selected words are typically from closed classes, such as punctuation marks, determiners and prepositions. We find translations using Wiktionary.[4]

Model Variants Our model varies along two dimensions. On one dimension, we use two different methods for inducing multilingual word embeddings: **Pseudoinverse** and **Isometric** alignment as described in Section 3.1. On the other dimension, we experiment with two different multilingual transfer models. We use **Direct Transfer** to denote our direct transfer model, and **Transfer+EM** for our unsupervised model trained in the target language.

Baselines We also compare against the prototype-driven method of Haghighi and Klein (2006). Specifically, we use the publicly available implementation provided by the authors.[5] Note that their model requires at least one prototype for each POS category. Therefore, we select 14 prototypes (the most frequent word from each category) for the baseline, while our method only uses ten translation pairs.

Evaluation Unlike other unsupervised methods, all models in our experiments can identify the label for each POS tag because of knowledge from either the source languages or prototypes. Therefore, we directly report the token-level POS accuracy for all experiments.

Other Details For all experiments, we use the following regularization weights: $\gamma = 0.001$ for supervised models learned on the source language and $\beta = 0.01$ for unsupervised models learned on the target language. During training, we also normalize the log-likelihood of labeled or unlabeled data by the total number of tokens. As a result, the magnitude of the objective value is independent of the corpus size, hence we do not need to tune the regularization weight for each target language. We run ten iterations of the EM algorithm.

5 Results

In this section, we first show the main comparison between the tagging performance of our model and the baselines. In addition, we include an experiment on typology prediction. In Section 5.2, we provide a more detailed analysis of model properties.

5.1 Main Results

Table 2 summarizes the results of the prototype baseline and different variations of our transfer model. Averaged across languages, our model significantly outperforms the prototype baseline by about 37.5% (67.5% vs 30%), demonstrating the effectiveness of multilingual transfer. Moreover, Table 2 shows that our full model (Transfer+EM with the isometric alignment mapping) consistently achieves the best performance compared to other model variations. Our model performs better on Indo-European languages than on other languages (72.9% vs. 62.1% on average), because Indo-European languages are linguistically more similar to the source language (English).

Impact of Training in the Target Language We observe that training on unlabeled data in the tar-

Method	Indo-European				Non-Indo-European			
	da	de	es	Avg.	fi	hu	id	Avg.
Prototype Model	41.3	25.5	28.7	31.8	8.2	44.5	30.1	27.6
Pseudoinverse								
Direct Transfer	56.7	49.4	68.4	58.2	54.3	60.1	57.7	57.4
Transfer+EM	64.4	65.8	74.9	68.4	57.5	**65.3**	62.7	61.8
Isometric Alignment								
Direct Transfer	59.8	55.4	67.4	60.9	54.4	61.4	57.2	57.7
Transfer+EM	**72.5**	**68.7**	**77.5**	**72.9**	**58.2**	63.4	**64.8**	**62.1**

Table 2: Token-level POS tagging accuracy (%) for different variants of our transfer model. We always use English as the source language. Target languages include Danish (da), German (de), Spanish (es), Finnish (fi), Hungarian (hu) and Indonesian (id). We average the results separately for Indo-European and non-Indo-European languages. The first row shows performance of the prototype-driven baseline (Haghighi and Klein, 2006). The rest shows results of our model when multilingual embeddings are induced with the pseudoinverse or isometric alignment method. "Direct Transfer" and "Transfer+EM" indicates our direct transfer model and our transfer model trained in the target language respectively.

get language (Transfer+EM model) consistently improves over the direct transfer counterpart. As the bottom part of Table 2 shows, running EM on unlabeled data yields an average of 12% absolute gain on Indo-European languages, while on non-Indo-European languages the gain is only 4.4%.

Impact of the Isometric Alignment Constraint As Table 2 shows, when we use Transfer+EM models, the isometric alignment method yields a 4.5% improvement over the pseudoinverse method (72.9% vs. 68.4%) on Indo-European languages. However, the improvement margin drops to 0.3% on non-Indo-European languages (62.1% vs. 61.8%). We hypothesis that this discrepancy is due to the difference in the degree of ambiguities of the anchor words across languages. For example, the anchor words of Spanish have an average of 1.5 possible translations to English, while for Indonesian the average ambiguity is 2.7. Therefore, the isometric assumption holds better and the EM algorithm finds a better local optimum for Indo-European languages than for non-Indo-European languages. We also observe a similar pattern in the direct transfer scenario.

Tagging Method	Typology Accuracy
Prototype	60.0
Direct Transfer	66.7
Transfer + EM	80.0
Gold	93.3

Table 3: The accuracy (%) of typological properties prediction using the outputs from different taggers. "Gold" indicates the result using gold POS annotations.

Prediction of Linguistic Typology To assess the quality of automatically generated tags, we use them to determine typological properties of the target language. We predict values of the following five typological properties for each language: subject-verb, verb-object, adjective-noun, adposition-noun and demonstrative-noun. More specifically, the goal is to predict word ordering preferences such as whether an adjective comes before a noun (as in English) or after a noun (as in Spanish). We collect the true ordering preferences from "The World Atlas of Language Structure (WALS)" (Dryer et al., 2005). To make predictions, we train a multiclass support vector machine (SVM) classifier (Tsochantaridis et al., 2004) on a multilingual corpus using bigrams and trigrams of POS tags as features. The training data for SVM comes from a combination of the Universal Dependencies Treebanks, CoNLL-X, and CoNLL-07 datasets (Buchholz and Marsi, 2006; Nilsson et al., 2007), excluding all sentences in the target language. We train one classifier for each typological property, and make predictions for each of the six target languages. For evaluation, we directly report the overall accuracy on all 30 test cases (six languages combined with five typological prop-

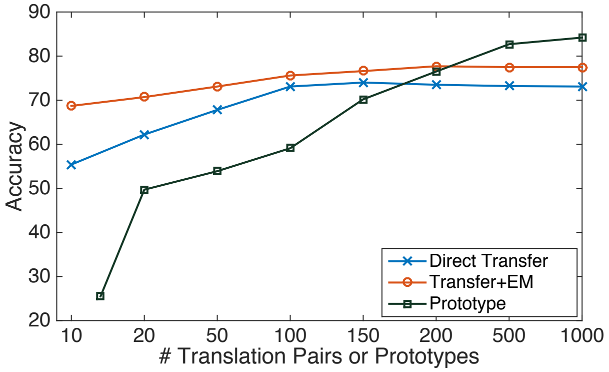

Figure 2: Accuracy of our models and the prototype baseline as a function of the amount of supervision, in German. x-axis is the number of translation pairs or prototypes used as supervision. Our models use multilingual embeddings induced with the isometric alignment method. The minimum number of prototypes used by the prototype baseline is 14.

erties).

Table 3 shows the accuracy of predicting typological properties with different tagging models. "Gold" corresponds to the result with gold POS annotations and is an upper bound of the prediction accuracy. We observe that the typology prediction accuracy correlates with the tagging quality. With the output of our best model, we predict the correct values for 80% of the typological properties. This corresponds to a 50% error reduction relative to the prototype model.

5.2 Analyses

Impact of the Amount of Supervision Figure 2 shows the accuracy of the Direct Transfer, Transfer+EM models, and prototype baseline with different amounts of supervision in German. Specifically, the x-axis is the number of translation pairs or prototypes used as supervision. The numbers with ten pairs or prototypes are the same as that in Table 2. We automatically extract more translation pairs using the Europarl parallel corpus (Koehn, 2005) and select pairs based on the word frequency in the target language. For the prototype model, we select the most frequent words as prototypes based on annotations in the training data, and guarantee that each POS category has at least one prototype. Note that the minimum number of prototypes used by the prototype model is 14.

One particularly interesting observation is that our model with ten pairs achieves an equivalent performance as that of the prototype-driven method with 150 prototypes. Multilingual transfer compensates for 15 times the amount of supervision. We also observe that the prototype-driven model outperforms our model when large amount of annotations are available. This can be explained by noise in the translation and the limitation from the linear embedding mapping process, which makes POS tags not preserve well across languages.

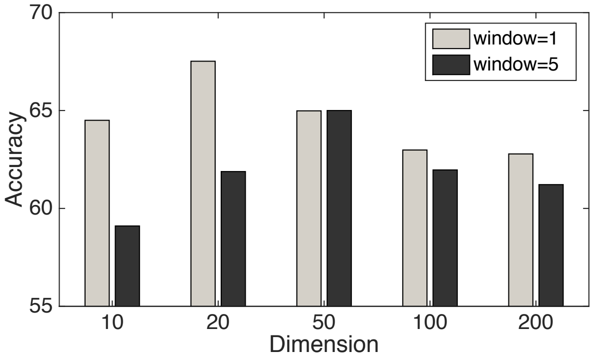

Figure 3: The average tagging accuracy (%) with different embedding dimensions and context window sizes. The model is Transfer+EM with the isometric alignment projection method.

When comparing between our models, Figure 2 shows that Transfer+EM consistently improves over the Direct Transfer, while the gains are more profound in the low-supervision scenario. This is not surprising because with more translation pairs, we are able to induce higher quality multilingual embeddings, which is more beneficial to the direct transfer model.

Impact of Embedding Dimensions and Window Size Figure 3 shows the average accuracy across six target languages with different embedding dimensions and context window sizes. First, we observe that a small window size $w = 1$ consistently outperforms window size $w = 5$, demonstrating that smaller window sizes appear to produce word embeddings better for POS tagging. This observation is in line with the finding by Lin et al. (2015). Moreover, we obtain the best performance with dimension $d = 20$ when $w = 1$. On one hand, embeddings with smaller dimension (e.g. $d = 10$) have too little syntactic information for good POS tagging. On the other hand, if the embedding space has larger dimen-

Model	da	de	es	fi	hu	id	Average
All features	72.5	68.7	77.5	58.2	63.4	64.8	67.5
- Indicator features	70.8	64.8	73.9	53.7	62.9	56.8	63.8
- Transformation matrix M	60.2	65.6	73.2	58.6	59.6	70.8	64.7

Table 4: The accuracy (%) of our best Transfer+EM model with different feature sets, removing either indicator features or transformation matrix M at a time.

sion, the space will be more complex and mapping embedding spaces will be more difficult given only ten translation pairs. Therefore, we observe a performance drop with either smaller or larger dimensions.

Ablation Analysis on Features In our Transfer+EM model, we add indicator features and transformation matrix M to enhance the emission distribution (see Section 3.3). To analyze their contribution, we remove these features in turn and report the results in Table 4. Averaged over all languages, adding indicator features improves the accuracy by 3.7%, and adding a transformation matrix increases the accuracy by 2.8%.

6 Conclusions

In this paper, we demonstrate that ten translation pairs suffice for an effective multilingual transfer of POS tagging. Experimental results show that our model significantly outperforms the direct transfer method and the prototype baseline. The effectiveness of our approach suggests its potential application to a broader range of NLP tasks that require word-level multilingual transfer, such as multilingual parsing and machine translation.

Part-of-Speech Tagging for Historical English

Yi Yang and **Jacob Eisenstein**
School of Interactive Computing
Georgia Institute of Technology
Atlanta, GA 30308
{yiyang+jacobe}@gatech.edu

Abstract

As more historical texts are digitized, there is interest in applying natural language processing tools to these archives. However, the performance of these tools is often unsatisfactory, due to language change and genre differences. Spelling normalization heuristics are the dominant solution for dealing with historical texts, but this approach fails to account for changes in usage and vocabulary. In this empirical paper, we assess the capability of domain adaptation techniques to cope with historical texts, focusing on the classic benchmark task of part-of-speech tagging. We evaluate several domain adaptation methods on the task of tagging Early Modern English and Modern British English texts in the Penn Corpora of Historical English. We demonstrate that the Feature Embedding method for unsupervised domain adaptation outperforms word embeddings and Brown clusters, showing the importance of embedding the entire feature space, rather than just individual words. Feature Embeddings also give better performance than spelling normalization, but the combination of the two methods is better still, yielding a 5% raw improvement in tagging accuracy on Early Modern English texts.

1 Introduction

There is growing interest in applying natural language processing (NLP) techniques to historical texts (Piotrowski, 2012), with applications in information retrieval (Dougherty, 2010; Jurish, 2011), linguistics (Baron et al., 2009; Rayson et al., 2007), and the digital humanities (Hendrickx et al., 2011; Muralidharan and Hearst, 2013; Pettersson and Nivre, 2011). However, these texts differ from contemporary training corpora in a number of linguistic respects, including the lexicon (Giusti et al., 2007), morphology (Borin and Forsberg, 2008), and syntax (Eumeridou et al., 2004). This imposes significant challenges for modern NLP tools: for example, the accuracy of the CLAWS part-of-speech Tagger (Garside and Smith, 1997) drops from 97% on the British National Corpus to 82% on Early Modern English texts (Rayson et al., 2007). There are two main approaches that could improve the accuracy of NLP systems on historical texts: normalization and domain adaptation.

Original: and drewe vnto hym all ryottours & wylde dysposed persones
Normalization: and drew unto him all ryottours & wild disposed persons

Figure 1: An example sentence from Early Modern English and its VARD normalization.

Normalization Spelling normalization (also called canonicalization) involves mapping historical spellings to their canonical forms in modern languages, thus bridging the gap between contemporary training corpora and target historical texts. Figure 1 shows one historical sentence and its normalization by VARD (Baron and Rayson, 2008). Rayson et al. (2007) report an increase of about 3% accuracy on adaptation of POS tagging from Modern English texts to Early Modern English texts if the target texts were automatically normalized by the VARD system. However, normalization is not always a well-defined problem (Eisenstein,

Proceedings of NAACL-HLT 2016, pages 1318–1328,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

2013), and it does not address the full range of linguistic changes over time, such as unknown words, morphological differences, and changes in the meanings of words (Kulkarni et al., 2015). In the example above, the word 'ryottours' is not successfully normalized to 'rioters'; the syntax is comprehensible to contemporary English speakers, but usages such as 'wild disposed' and 'drew unto' are sufficiently unusual as to pose problems for NLP systems trained on contemporary texts.

Domain adaptation A more generic machine learning approach is to apply unsupervised domain adaptation techniques, which transform the representations of the training and target texts to be more similar, typically using feature co-occurrence statistics (Blitzer et al., 2006; Ben-David et al., 2010). It is natural to think of historical texts as a distinct domain from contemporary training corpora, and Yang and Eisenstein (2014, 2015) show that the accuracy of historical Portuguese POS tagging can be significantly improved by domain adaption. However, we are unaware of prior work that empirically evaluates the efficacy of this approach on Early Modern English texts. Furthermore, historical texts are often associated with multiple metadata attributes (e.g., author, genre, and epoch), each of which may influence the text's linguistic properties. *Multi-domain adaptation* (Mansour et al., 2009) and *multi-attribute domain adaptation* (Joshi et al., 2013; Yang and Eisenstein, 2015) can potentially exploit these metadata attributes to obtain further improvements.

This paper presents the first comprehensive empirical comparison of effectiveness of these approaches for part-of-speech tagging on historical texts. We focus on the two historical treebanks of the Penn Corpora of Historical English — the Penn Parsed Corpus of Modern British English (Kroch et al., 2010, PPCMBE) and the Penn-Helsinki Parsed Corpus of Early Modern English (Kroch et al., 2004, PPCEME). These datasets enable a range of analyses, which isolate the key issues in dealing with historical corpora:

- In one set of analyses, we focus on the PPCMBE and the PPCEME corpora, training on more recent texts and testing on earlier texts. This isolates the impact of language change on tagging performance.
- In another set of analyses, we train on the Penn Treebank (Marcus et al., 1993, PTB), and test on the historical corpora, using the tag mappings from Moon and Baldridge (2007). We apply the well-known Stanford CoreNLP tagger to this task (Manning et al., 2014), thus replicating the most typical situation for users of existing language technology.
- We show that FEMA, a domain adaptation algorithm that is specifically designed for sequence labeling problems (Yang and Eisenstein, 2015), achieves an increase of nearly 4% in tagging accuracy when adapting from the PTB to the PPCEME.
- We compare the impact of normalization with domain adaptation, and demonstrate that they are largely complementary.
- Error analysis shows that the improvements obtained by domain adaptation are largely due to better handling of out-of-vocabulary (OOV) tokens. Many of the most frequent errors on in-vocabulary (IV) tokens are caused by mismatches in the tagsets or annotation guidelines, and may be difficult to address without labeled data in the target domain.

2 Data

The Penn Corpora of Historical English consist of the Penn-Helsinki Parsed Corpus of Middle English, second edition (Kroch et al., 2010, PPCME2), the Penn-Helsinki Parsed Corpus of Early Modern English (Kroch et al., 2004, PPCEME), and the Penn Parsed Corpus of Modern British English (Kroch and Taylor, 2000, PPCMBE). The corpora are annotated with part-of-speech tags and syntactic parsing trees in an annotation style similar to that of the Penn Treebank. In this work, we focus on POS tagging the PPCMBE and the PPCEME.[1]

[1] Middle English is outside the scope of this paper, because it is sufficiently unintelligible to modern English speakers that texts such as Canterbury Tales are published in translation. In tagging Middle English texts, Moon and Baldridge (2007) apply bitext projection techniques from multilingual learning, rather than domain adaptation.

Period	# Sentence	# Token
1840-1914	17,770	322,255
1770-1839	23,462	427,424
1700-1769	16,083	343,024
Total	57,315	1,092,703

Table 1: Statistics of the Penn Parsed Corpus of Modern British English (PPCMBE), by time period.

Period	# Sentence	# Token
1640-1710	29,181	614,315
1570-1639	39,799	706,587
1500-1569	31,416	640,255
Total	100,396	1,961,157

Table 2: Statistics of the Penn Parsed Corpus of Early Modern English (PPCEME), by time period.

The Penn Parsed Corpus of Modern British English The PPCMBE is a syntactically annotated corpus of text, containing roughly one million word tokens from documents written in the period 1700-1914. It is divided into three 70-year time periods according to the composition date of the works. Table 1 shows the statistics of the corpus by time period.[2] In contrast to the PTB, the PPCMBE contains text from a variety of genres, such as Bible, Drama, Fiction, and Letters.

The Penn-Helsinki Parsed Corpus of Early Modern English The PPCEME is a collection of text samples from the Helsinki Corpus (Rissanen et al., 1993), as well as two supplements mainly consisting of text material by the same authors and from the same editions as the material in the Helsinki Corpus. The corpus contains nearly two million words from texts in the period from 1500 until 1710, and it is divided into three 70-year time periods similar to the PPCMBE corpus. The statistics of the corpus by time period is summarized in Table 2. The PPCEME consists of text from the same eighteen genres as the PPCMBE.

Penn Treebank Release 3 The Penn Treebank (Marcus et al., 1993) is the de facto standard syntactically annotated corpus for English, which is used to train software such as Stanford CoreNLP (Manning et al., 2014). When using this dataset for supervised training, we follow Toutanova et al. (2003) and use WSJ sections 0-18 for training, and sections 19-21 for tuning. When applying unsupervised domain adaptation, we use all WSJ sections, together with texts from the PPCMBE and the PPCEME.

Tagsets The Penn Corpora of Historical English (PCHE) use a tagset that differs from the Penn Treebank, mainly in the direction of greater specificity. Auxiliary verbs 'do', 'have', and 'be' all have their own tags, as do words like 'one' and 'else', due to their changing syntactic function over time. Overall, there are 83 tags in the PPCEME, and 81 in the PPCMBE, as compared with 45 in the PTB. Furthermore, the tags in the PCHE tagset are allowed to join constituent morphemes in compounds, yielding complex tags such as `PRO+N` (e.g., 'himself') and `ADJ+NS` (e.g., 'gentlemen').

To measure the tagging accuracy of PTB-trained taggers on the historical texts, we follow Moon and Baldridge (2007), who define a set of deterministic mappings from the PCHE tags to the PTB tagset. For simplicity, we first convert each complex tag to the simple form by only considering the first simple tag component (e.g., `PRO+N` to `PRO` and `ADJ+NS` to `ADJ`). This has little effect on the tagging performance, as the complex tags cover only slightly more than 1% of the tokens in the PCHE treebanks. Among the 83 tags, 74 mappings to the corresponding PTB tags are obtained from Moon and Baldridge (2007). We did our best to convert the other tags according to the tag description. The complete list of mappings is published in Appendix A.

3 Unsupervised Domain Adaptation

In typical usage scenarios, the user wants to tag some historical text but has no labeled data in the target domain (e.g., Muralidharan and Hearst, 2013). This best fits the paradigm of unsupervised domain adaptation, when labeled data from the source domain (e.g., the PTB) is combined with unlabeled data from the target domain. Representational differences between source and target domains can be a major source of errors in domain adaptation (Ben-

[2] All the statistics in this section include punctuation, but exclude extra-linguistic material such as page numbers or token ID numbers.

David et al., 2010), and so several representation learning approaches have been proposed.

The most straightforward approach is to replace lexical features with **word representations**, such as Brown clusters (Brown et al., 1992; Lin et al., 2012) or word embeddings (Turian et al., 2010), such as word2vec (Mikolov et al., 2013). Lexical features can then be replaced or augmented with the resulting word representations. This can assist in domain adaptation by linking out-of-vocabulary words to in-vocabulary words with similar distributional properties.

Word representations are suitable for adapting lexical features, but a more general solution is to adapt the entire feature representation. One such method is **Structural Correspondence Learning** (Blitzer et al., 2006, **SCL**). In SCL, we create artificial binary classification problems for thousands of cross-domain "pivot" features, and then use the weights from the resulting classifiers to project the instances into a new dense representation. We also consider a recently-published approach called **Feature Embedding** (**FEMA**), which achieves the state-of-the-art results on several POS tagging adaptation tasks (Yang and Eisenstein, 2015). The intuition of FEMA is similar to SCL and other prior work: it relies on co-occurrence statistics to link features across domains. Specifically, FEMA exploits the tendency of many NLP tasks to divide features into templates, and induces feature embeddings by using the features in each template to predict the active features in all other templates — just as the skipgram model learns word embeddings to predict neighboring words. The resulting embeddings can be substituted for the "one-hot" representation of each feature template, resulting in a dense, low-dimensional representation of each instance.

A further advantage of FEMA is that it can perform multi-attribute domain adaptation, enabling it to exploit the many metadata attributes (e.g., year, genre, and author) that are often associated with historical texts. This is done by accounting for the specific impact of each domain attribute on the feature predictors, and then building a domain-neutral representation from the common substructure that is shared across all domain attributes. In the experiments that follow, we use genre and epoch as domain attributes.

4 Experiments

We evaluate these unsupervised domain adaptation approaches on part-of-speech tagging for historical English (the PPCMBE and the PPCEME), in two settings: (1) temporal adaptation within each individual corpus, where we train POS taggers on the most modern data in the corpus and test on increasingly distant datasets; (2) adaptation of English POS tagging from modern news text to historical texts. The first setting focuses on temporal differences, and eliminates other factors that may impair tagging performance, such as different annotation schemes and text genres. The second setting is the standard and well-studied evaluation scenario for POS tagging, where we train on the Wall Street Journal (WSJ) text from the PTB and test on historical texts. In addition, we evaluate the effectiveness of the VARD normalization tool (Baron and Rayson, 2008) for improving POS tagging performance on the PPCEME corpus.

4.1 Experimental Settings

The datasets used in the experiments are described in § 2. All the hyperparameters are tuned on development data in the source domain. In the case where there is no specific development dataset (adaptation within the historical corpora), we randomly sample 10% sentences from the training datasets for hyperparameter tuning.

4.1.1 Baseline systems

We include two baseline systems for POS tagging: a classification-based support vector machine (SVM) tagger and a bidirectional maximum entropy Markov model (MEMM) tagger. Specifically, we use the L_2-regularized L_2-loss SVM implementation in the scikit-learn package (Pedregosa et al., 2011) and L_2-regularized bidirectional MEMM implementation provided by Stanford CoreNLP (Toutanova et al., 2003; Manning et al., 2014).

Following Yang and Eisenstein (2015), we apply the feature templates defined by Ratnaparkhi (1996) to extract the basic features for all taggers. There are three broad types of templates: five lexical feature templates, eight affix feature templates, and three orthographic feature templates.

Task	baseline		SCL	Brown	word2vec	FEMA	
	SVM	MEMM (Stanford)				single embedding	attribute embeddings (error reduction)
Modern British English (training from 1840-1914)							
→ 1770-1839	96.30	96.57	96.42	96.45	96.44	96.80	**96.84** (15%)
→ 1700-1769	94.57	94.83	95.07	95.15	94.85	95.65	**95.75** (22%)
AVERAGE	95.43	95.70	95.74	95.80	95.64	96.23	**96.30** (19%)
Early Modern English (training from 1640-1710)							
→ 1570-1639	93.62	93.98	94.23	94.36	94.18	95.01	**95.20** (25%)
→ 1500-1569	87.59	87.47	89.39	89.73	89.30	91.40	**91.63** (33%)
AVERAGE	90.61	90.73	91.81	92.05	91.74	93.20	**93.41** (30%)

Table 3: Accuracy results for temporal adaptation in the PPCMBE and the PPCEME of historical English. Percentage error reduction is shown for the best-performing method, FEMA-attribute.

4.1.2 Domain adaptation systems

We consider the unsupervised domain adaptation methods described in § 3: structural correspondence learning (SCL), Brown clustering, word2vec,[3] and FEMA, which we train in both the single embedding mode (FEMA-single), where metadata attributes are ignored, and in multi-attribute mode (FEMA-attribute), where metadata attributes are used. The domain adaptation models are trained on the union of the (unlabeled) source and target datasets. This ensures that there are no out-of-vocabulary items for the word or feature embeddings.

Following Yang and Eisenstein (2015), we do not learn feature embeddings for the three orthographic feature templates: as each orthographic feature template represents only a binary value, it is unnecessary to replace it with a much longer numerical vector. The learned representations are then concatenated with the basic surface features to form the augmented representations. For computational reasons, the domain adaptation systems are all based on the SVM tagger, as pilot studies showed that Viterbi tagging offers minimal improvements.

4.1.3 Parameter tuning

We choose the SVM regularization parameter by sweeping the range $\{0.1, 0.3, 0.5, 0.8, 1.0\}$. Following Blitzer et al. (2006), we consider pivot features that appear more than 50 times in all the domains for SCL. We empirically fix the number of singular vectors of the projection matrix K to 25, and also employ feature normalization and rescaling, as these settings yield best performance in prior work. The number of Brown clusters is chosen from the range $\{50, 100, 200, 400\}$. For FEMA and word2vec, we choose embedding sizes from the range $\{50, 100, 200, 300\}$ and fix the numbers of negative samples to 15. The window size for training word embeddings is set as 5. Finally, we adopt the same regularization penalty for all the attribute-specific embeddings of FEMA, which is selected from the range $\{0.01, 0.1, 1.0, 10.0\}$. All parameters were tuned on development data in the source domain. We train the Stanford MEMM tagger using the default configuration file.

4.2 Temporal Adaptation

In the temporal adaptation setting, we work within each corpus, training on the most recent section, and evaluating on the two earlier sections. For PPCMBE, the source domain is the period from 1840 to 1914; for PPCEME, the source domain is the period from 1640 to 1710. All earlier texts are treated as target domains. We transform the tags to the PTB tagset for evaluation, so that results can be compared with the next experiment, in which the PTB is used for supervision.

Settings We randomly sample 10% sentences from the training data as the development data for optimizing hyperparameters, and then retrain the models on the full training data using the best parameters. For FEMA, we consider domain attributes

[3] https://code.google.com/p/word2vec/

for 70-year temporal periods and genres, resulting in a total of 21 attributes for each corpus. The numbers of pivot features used in SCL are 4400 and 5048 for the PPCMBE and the PPCEME respectively. The best number of Brown clusters is 200, and the best embedding sizes are 200 and 100 for word2vec and FEMA.

Results As shown in Table 3, accuracies are significantly improved by domain adaptation, especially for the PPCEME. English spelling had become mostly uniform and stable since around 1700 (Baron et al., 2009), which may explain why improvements on the PPCMBE are relatively modest, especially in the 1770-1839 epoch. Among the two baseline systems, MEMM performs slightly better than SVM, showing a small benefit to structured prediction. Among the domain adaptation algorithms, FEMA clearly outperforms SCL, Brown clustering and word2vec, with an averaged increase of about 0.5% and 1.5% accuracies on the PPCMBE and the PPCEME test sets respectively. The metadata attribute information boosts performance by a small but consistent margin, 0.1-0.2% on average.

4.3 Adaptation from the Penn Treebank

Newspaper text is the primary data source for training modern NLP systems. For example, most "off-the-shelf" English POS taggers (e.g., the Stanford Tagger (Toutanova et al., 2003), SVMTool (Giménez and Marquez, 2004), and CRFTagger (Phan, 2006)) are trained on the WSJ portion of the Penn Treebank, which is composed of professionally-written news text from 1989. This motivates this evaluation scenario, in which we train the tagger on the Penn Treebank WSJ data and apply it to historical English texts, using all sentences of the PPCMBE and PPCEME for testing.

Settings The feature representations are trained on the union of the PTB and the PPCEME. The domain attributes for FEMA are set to include the three corpora themselves (PTB, PPCMBE, and PPCEME), and the genre attributes in the historical corpora. Note that all sentences in the Penn Treebank WSJ data belong to the same genre (news). For SCL, we use the same threshold of 50 occurrences for pivot features, and include 8089 features that pass this threshold. PTB WSJ sections 19-21 are used for parameter tuning: we find that the best number of Brown clusters is 200, and the optimum embedding sizes are 200 and 100 for word2vec and FEMA.

Spelling normalization Spelling variants lead to a high percentage of out-of-vocabulary (OOV) tokens in historical texts, which poses problems for POS tagging. We normalize the PPCEME sentences using VARD (Baron and Rayson, 2008), a widely used spelling normalization tool that has been proven to improve performance on POS tagging (Rayson et al., 2007) and syntactic parsing (Schneider et al., 2014). VARD is designed specifically for Early Modern English spelling variation, and additional labeled data and training are required for other forms of spelling variation, which we do not consider here. Following Schneider et al. (2014), we utilize VARD's auto-normalization function with a 50% normalization threshold, achieving a balance between precision and recall. At this threshold, a total of 12% $(236298/1961157)$ of the tokens in the PPCEME are normalized.[4]

Results As shown in Table 4, this task is considerably more difficult, with even the best systems achieving accuracies that are nearly 15% worse than in-domain training. Nonetheless, domain adaptation can help: FEMA improves performance by 1.3% on the PPCMBE data, and by 3.8% on the unnormalized PPCEME data. Spelling normalization also helps, improving the baseline systems by more than 2.5%. The combination of spelling normalization and domain adaptation gives an overall improvement in accuracy from 74.2% to 79.1%. The relative error reduction is lower than in the temporal adaptation setting: only 19% at best, versus 30% error reduction in temporal adaptation. This is because there are now at least two sources of error — language change and tagset mismatch — and unsupervised domain adaptation cannot address mismatches in the tag set.

5 Analysis

As expected, the Early Modern English dataset (PPCEME) is considerably more challenging than the Modern British English dataset (PPCMBE): the

[4] We only consider $1:1$ mappings, and ignore 328 normalizations corresponding to $1:n$ mappings.

Target	Normalized	baseline		SCL	Brown	word2vec	FEMA	
		SVM	MEMM (Stanford)				single embedding	attribute embeddings (error reduction)
PPCMBE	No	81.12	81.35	81.66	81.65	81.75	82.34	**82.46** (7%)
PPCEME	No	74.15	74.34	75.89	76.04	75.85	77.77	**77.92** (15%)
PPCEME	Yes	76.73	76.87	77.61	77.65	77.76	78.85	**79.05** (19%*)

Table 4: Accuracy results for adapting from the PTB to the PPCMBE and the PPCEME of historical English. *Error reduction for the normalized PPCEME is computed against the unnormalized SVM accuracy, showing total error reduction.

baseline accuracy is 7% worse on the PPCEME than the PPCMBE. However, the PPCEME is also more amenable to domain adaptation, with FEMA offering considerably larger improvements. One reason is that the PPCEME has many more out-of-vocabulary (OOV) tokens: 23%, versus 9.2% in the PPCMBE. Both domain adaptation and normalization help to address this specific issue, and they yield further improvements when used in combination. This section offers further insights on the sources of errors and possibilities for improvement on the PPCEME data.

5.1 Feature Ablation

Table 5 presents the results of feature ablation experiments for the non-adapted SVM tagger. Word context features are important for obtaining good accuracies on both IV and OOV tokens. Affix features, particularly suffix features, are crucial for the OOV tokens. The orthographic features are shown to be nearly irrelevant, as long as affix features are present. Overall, the high percentage of OOV tokens can be a major source of errors, as the tagging accuracy on OOV tokens is below 50% in our best baseline system. Note that these results are for a classification-based tagger; while the Viterbi-based MEMM tagger performs only marginally better overall ($\sim 0.2\%$ improvement), it is possible that its error distribution might be different due to the advantages of structured prediction.

5.2 Error Analysis

The accuracy on out-of-vocabulary (OOV) tokens is generally low, and spelling variation is a major source of OOV tokens. For instance, 'ye' and 'thy', the older forms of 'the' and 'your', are often incorrectly tagged as NN and JJ in the PPCEME. In general, the per-tag accuracies are roughly correlated with the percentages of OOV tokens. Some exceptions including VB, NNP and NNS, where the affix features can be very useful for tagging OOV tokens.

Feature set	IV	OOV	All
All features	81.68	48.96	74.15
– word context	79.69	38.62	70.23
– prefix	81.61	46.11	73.43
– suffix	81.36	38.13	71.40
– affix	81.22	34.40	70.44
– orthographic	81.68	48.92	74.14

Table 5: Tagging accuracies of adaptation of our baseline SVM tagger from the PTB to the PPCEME in ablation experiments.

That said, the cross-domain accuracy on in-vocabulary (IV) tokens is also low, at roughly 80% when adapting from the PTB to the PPCEME. A major source of error here is the mismatch in annotation schemes between the two datasets, which is only partially addressed by a deterministic tag mapping. Table 6 presents the SVM accuracy per tag, and the most common error correspondingly. Most of the errors shown in the table are owing to different annotations of the same token in the two corpora.

One major cause of errors is in misalignments of punctuations and their POS tags. For example, in the PPCEME, 16.6% of commas are labeled as . (sentence-final punctuation), and 12.3% periods are labeled as , (sentence-internal punctuation); these punctuations are less ambiguous in the PTB. The historical corpora lack special tags for colons and ellipses, which are present in the PTB. In contrast to the PTB, there is no distinction between opening quotation mark and closing quotation mark in the PPCEME. Moon and Baldridge (2007) avoid these difficulties by mapping all the punctuation tokens

Tag	% of OOV	Accuracy	Most common error
IN	6.93	82.79	to/TO
NN	48.39	64.74	Lord/NNP
DT	3.45	94.62	that/IN
PRP	13.57	78.80	other/JJ
,	0.41	87.86	./.
JJ	32.20	48.60	all/DT
CC	1.98	91.29	for/IN
RB	26.22	65.74	such/JJ
.	0.56	54.43	,/,
VB	34.69	75.06	have/VBP
NNP	58.91	88.31	god/NN
NNS	59.12	73.88	Lords/NNPS
VBD	25.87	81.93	quoth/NN
VBN	37.75	63.09	said/VBD
PRP$	13.57	85.49	thy/JJ

Table 6: Accuracy (recall) rates per tag with the SVM model, for the 15 most common tags. For each gold category, the most common error word and predicted tag are shown.

to a single tag. We did not follow their setting because it would lead to a significant change of test data. However, it should be noted that these "errors" are not particularly meaningful for linguistic analysis, and could easily be addressed by heuristic post-processing.

The tagging performance is also impaired by the different annotations of many common words. For example, in the PTB, more than 99.9% of token 'to' are labeled as `TO`, but in the PCHE this word can also be labeled as `IN`, distinguishing the infinitive marker from the preposition. The words 'all', 'any' and 'every' are annotated as quantifiers in the PCHE; this tag is mapped to `JJ`, but these specific words are all labeled as `DT` in the PTB. A simple remapping from `Q` to `DT` leads to an increase of 0.78% baseline accuracy; it is possible that other changes to the tag mappings of Moon and Baldridge (2007) might yield further improvements, but a more systematic approach would be outside the bounds of *unsupervised* domain adaptation.

5.3 Improvements from Normalization

As shown above, the tagging accuracy decreases from 81.7% on IV tokens to 49.0% on OOV tokens. Spelling normalization helps to increase the accuracy by transforming OOV tokens to IV tokens. After normalization, the OOV rate for the PPCEME falls from 23.0% to 13.5%, corresponding to a reduction of 41.5% OOV tokens. Normalization is not perfectly accurate, and the tagging performance for IV tokens drops slightly to 81.2% on IV tokens. But due to the dramatic decrease in the number of OOV tokens, normalization improves the overall accuracy by more than 2.5%. We also observe performance drops on tagging OOV tokens after normalization (49.0% to 48.1%), which suggests that the remaining unnormalized OOV tokens are the tough cases for both normalization and POS tagging.

System	IV	OOV	All
SVM	81.68	48.96	74.15
SCL	82.01	55.45	75.89
Brown	81.81	56.76	76.04
word2vec	81.79	56.00	75.85
FEMA-single	82.30	62.63	77.77
FEMA-attribute	82.34	63.16	77.92

Table 7: Tagging accuracies of domain adaptation models from the PTB to the PPCEME.

5.4 Improvements from Domain Adaptation

As presented in Table 7, the tagging accuracies are increased on both IV and OOV tokens with the domain adaptation methods. Compared against the baseline tagger, FEMA-attribute achieves an absolute improvement of 14% in accuracy on OOV tokens. SCL performs slightly better than Brown clustering and word2vec on IV tokens, but worse on OOV tokens. By incorporating metadata attributes, FEMA-attribute performs better than FEMA-single on OOV tokens, though the accuracies on IV tokens are similar. Interestingly, the venerable method of Brown clustering (slightly) outperforms both word2vec and SCL.

We further study the relationship between domain adaptation and spelling normalization by looking into the errors corrected by both approaches. Domain adaptation yields larger improvements than spelling normalization on both IV and OOV tokens, although as noted above, the approaches are somewhat complementary. The results show that among the 60,928 error tokens corrected by VARD, 60% are also corrected by FEMA-attribute, while the remaining 40% would be left uncorrected by the domain adaptation technique. Conversely, among the errors corrected by FEMA-attribute, 38% are also corrected by VARD, while the remaining 62% would be left uncorrected. The overlap of reduced errors is because both approaches exploit similar sources of information, including affixes and local word contexts.

6 Related Work

Domain adaptation Early work on domain adaptation focuses on supervised setting, in which some amount of labeled instances are available in the target domain (Jiang and Zhai, 2007; Daumé III, 2007; Finkel and Manning, 2009). Unsupervised domain adaptation is more challenging but attractive in many applications, and several representation learning methods have been proposed for addressing this problem. Structural Correspondence Learning (Blitzer et al., 2006, SCL) and marginalized denoising autoencoders (Chen et al., 2012, mDA) seek cross-domain representations that are useful to predict a subset of features in the original instances, called pivot features. Schnabel and Schütze (2014) directly induce distributional representations for POS tagging based on local left and right neighbors of the token. More recent work trains cross-domain representations with neural networks, with additional objectives such as minimizing errors in the source domain and maximizing domain confusion loss (Ganin and Lempitsky, 2015; Tzeng et al., 2015). We show the Feature Embedding model, which is specifically designed for NLP problems with feature templates (Yang and Eisenstein, 2015), achieves strong performance on historical adaptation tasks.

Historical texts Historical texts differ from modern texts in spellings, syntax and semantics, posing significant challenges for standard NLP systems, which are usually trained with modern news text. Numerous resources have been created for overcoming the difficulties, including syntactically annotated corpora (Kroch et al., 2004; Kroch et al., 2010; Galves and Faria, 2010) and spelling normalization tools (Giusti et al., 2007; Baron and Rayson, 2008). Most previous work focuses on normalization, which can significantly increase tagging accuracy on historical English (Rayson et al., 2007) and German (Scheible et al., 2011). Similar improvements have been obtained for syntactic parsing (Schneider et al., 2014). Domain adaptation offers an alternative approach which is more generic — for example, it can be applied to any corpus without requiring the design of a set of normalization rules. As shown above, when normalization is possible, it can be combined with domain adaptation to yield better performance than that obtained by either approach alone.

7 Conclusion

Syntactic analysis is a key first step towards processing historical texts, but it is confounded by changes in spelling and usage over time. We empirically evaluate several unsupervised domain adaptation approaches for POS tagging of historical English texts. We find that domain adaptation methods significantly improve the tagger performance on two historical English treebanks, with relative error reductions of 30% in the temporal adaptation setting. FEMA outperforms other domain adaptation approaches, showing the importance of adapting the entire feature vector, rather than simply using word embeddings. Normalization and domain adaptation combine to yield even better performance, with a total of 5% raw accuracy improvement over a baseline classifier in the most difficult setting. Error analysis reveals that tagset mismatch is the most common source of errors for in-vocabulary words. We hope that our work encourages further research on domain adaptation for historical texts and provides useful baselines in these efforts.

Statistical Modeling of Creole Genesis

Yugo Murawaki

Abstract

Creole languages do not fit into the traditional tree model of evolutionary history because multiple languages are involved in their formation. In this paper, we present several statistical models to explore the nature of creole genesis. After reviewing quantitative studies on creole genesis, we first tackle the question of whether creoles are typologically distinct from non-creoles. By formalizing this question as a binary classification problem, we demonstrate that a linear classifier fails to separate creoles from non-creoles although the two groups have substantially different distributions in the feature space. We then model a creole language as a mixture of source languages plus a special *restructurer*. We find a pervasive influence of the restructurer in creole genesis and some statistical universals in it, paving the way for more elaborate statistical models.

1 Introduction

While most linguistic applications of computational phylogeny rely on lexical data (Gray and Atkinson, 2003; Bouckaert et al., 2012), there is a growing trend to make use of typological data (Tsunoda et al., 1995; Dunn et al., 2005; Teh et al., 2008; Longobardi and Guardiano, 2009; Murawaki, 2015). One advantage of typological features over lexical traits (cognates) is that they allow us to compare an arbitrary pair of languages even if they do not share enough cognates. For this reason, they have the potential of uncovering external relations involving language isolates and tiny language families such as Ainu, Basque, and Japanese.

However, our understanding of typological changes is far from satisfactory in at least two respects. First, typological changes are less intuitive than the birth and death of a lexical trait. Modeling word-order change with a single transition matrix (Maurits and Griffiths, 2014), for example, appears to be an oversimplification because some complex mechanisms must be hidden behind the changes (Murawaki, 2015).

The second point, the main focus of this paper, is that it is not clear whether typological data fit into the traditional tree model for a group of languages, which has long been used as the default choice to summarize evolutionary history (Schleicher, 1853). To be precise, regardless of whether typological features are involved, linguists have viewed the tree model with suspicion. A central problem of the tree model is its assumption that after a branching event, two resultant languages evolve completely independently. However, linguists have noted that horizontal contact is a constitutive part of evolutionary history. Various models for contact phenomena have been proposed to address this problem, including the wave theory (Schmidt, 1872) and the gravity model (Trudgill, 1974). As for linguistic typology, areal linguistics has worked on the diffusion of typological features across languages within a geographical area (Campbell, 2006).

In this paper, we study creole languages as an extreme case of non-tree-like evolution (Wardhaugh and Fuller, 2015). A creole is developed as a result of intense contact between multiple languages: typically one socioculturally dominant language (superstrate) and several low-prestige languages (*sub-*

San Diego, California, June 12-17, 2016.

strates). Superstrates are also known as *lexifiers* because the lexicon of a creole is largely derived from its superstrate. In spite of this, the grammar of a creole is drastically different from that of its lexifier. It is often said that creole grammars are simpler than non-creole ones although it is not easy to measure grammatical simplicity.

Creoles are not irrelevant to historical linguistics because some have speculated about the plausibility of creole status for Middle English (Bailey and Maroldt, 1977) and (pre-)Old Japanese (Kawamoto, 1974; Akiba-Reynolds, 1984; Kawamoto, 1990) while they have been criticized harshly by others.

This controversy can only be settled by fully understanding creole genesis, or the question of how creoles emerge, which also remains unresolved (Wardhaugh and Fuller, 2015). One theory called the gradualist hypothesis suggests their staged development from pidgin languages. A pidgin arises when speakers of different languages with no common language try to have a makeshift conversation, which results in a drastic simplification of grammar called *pidgin formation*. A pidgin is then acquired by children as their first language and is transformed into a fully functional language. This process of grammatical elaboration is known as *creole formation*.

We follow Bakker, Daval-Markussen and colleagues in taking data-driven approaches to this problem (Bakker et al., 2011; Daval-Markussen and Bakker, 2012; Daval-Markussen, 2013). They argue that creoles are typologically distinct from non-creoles. They compare four theories of creole genesis:

1. *Superstratist*. The lexifier plays a major role in creole genesis.

2. *Substratist*. Substrates do, instead of the lexifier.

3. *Feature pool*. Both the lexifier and substrates, but nothing else, provide a feature pool from which each feature value of a creole is selected.

4. *Universalist*. Innate ability of humans to create language is emphasized. The hypothetical linguistic universals for creole formation are called *restructuring universals*.

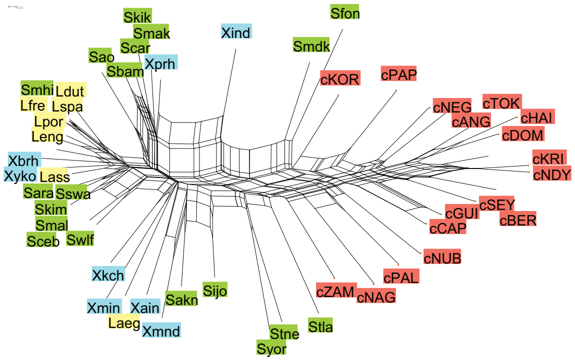

Figure 1: NeighborNet graph of creoles (c), lexifiers (L), substrates (S) and other non-creole languages (X). A language type (c/L/S/X) is followed by a three-letter language code. The bottom-up clustering (i.e., basically tree-building) method produced a cluster of creoles on the right. We reproduced Figure 5 of Daval-Markussen and Bakker (2012) using their online supplementary materials.

To test these explanations, they apply NeighborNet (Bryant and Moulton, 2004), a bottom-up, distance-based clustering method developed in the field of computational biology. By demonstrating that, as in Figure 1, creoles form a cluster distinguishable from lexifiers, substrates and other non-creole languages, they argue for the universalist position and for creole distinctiveness.

However, we find both theoretical and methodological problems in their discussion. Theoretically, the synchronic question of creole distinctiveness is confused with the diachronic question of creole genesis. If creoles are distinct from non-creoles, then something specific to creoles (e.g., restructuring universals) would play a role, but not vice versa. It is logically possible that even with restructuring universals, creoles are indistinguishable from (a subgroup of) non-creoles. Methodologically speaking, NeighborNet does not straightforwardly explain fundamentally non-tree-like evolution because it does assume tree-like evolution even though it represents conflicting signals with reticulations.

We begin by addressing the question of creole (non-)distinctiveness. Whether one is distinct from another is straightforwardly formalized as a binary classification problem. We show that an SVM classifier fails to separate creoles from non-creoles. Fol-

Figure 2: Schematic comparison of two approaches to creole genesis.

lowing a practice in population genetics, we visualize the data using principal component analysis (PCA). The result suggests that although creoles have a substantially different distribution from non-creoles, they nevertheless overlap.

Next, we propose to model creole genesis with mixture models. In this approach, a creole is stochastically generated by mixing its lexifier, substrate(s) plus a special *restructurer*. Conceptually, this is the opposite of the tree model, as illustrated in Figure 2. Specifically, we present two Bayesian models. The first one considers one mixing proportion per creole, and the other decomposes the proportions into per-feature and per-creole factors. Our experimental results suggest that the restructurer dominates creole genesis, dismissing the superstratist, substratist and feature pool theories. We also find some statistical universals in the restructurer although we refrain from identifying them as *restructuring* universals. In this way, we represent a first step toward understanding the complex process of creole genesis through statistical models.

2 Related Work

2.1 Population Genetics

Like Bakker, Daval-Markussen and colleagues (Bakker et al., 2011; Daval-Markussen and Bakker, 2012; Daval-Markussen, 2013), we borrow ideas from computational biology. For reasons unknown to us, they chose clustering models that basically assume tree-like evolution (Saitou and Nei, 1987; Bryant and Moulton, 2004). However, creole genesis is more comparable to models that explicitly take into account genetic admixture (i.e., contact phenomena). See Jones et al. (2015), for example, to take a look at standard practices in population genetics.

Population genetic analysis of genotype data (binary sequences comparable to sets of linguistic features) can be grouped into two types: population-level and individual-level analysis. Populations, such as Sardinian, Yoruba and Japanese, are predefined sets of individuals. Population-level analysis utilizes genetic variation within a population (Patterson et al., 2012). From a modeling point of view, languages are more comparable to individuals. Although a language is spoken by a population, no linguistic data available are comparable to *a set of* individuals.

Individual-level analysis, where population labels are used only for the purpose of visualization, is often done using PCA and admixture analysis. PCA is used for dimensionality reduction: by selecting the first two principal components, high-dimensional sequences are projected onto an informative two-dimensional diagram (Patterson et al., 2006).

Admixture analysis (Pritchard et al., 2000; Alexander et al., 2009) closely resembles topic models, most notably Latent Dirichlet Allocation (LDA) (Blei et al., 2003), in NLP. It assumes that each individual is a mixture of K ancestral components (i.e., topics). One difference is that while each LDA topic is associated with a single word distribution (K distributions in total), each SNP (i.e., feature type) has its own distribution ($K \times J$ distributions in total for sequences with length J).

2.2 Linguistic Typology and Non-tree-like Evolution

Like lexical data, typological features are usually analyzed with a tree model, but Reesink et al. (2009) are a notable exception. They applied admixture analysis to Australian and Papuan languages, for which tree-building techniques had not been successful. They related inferred ancestral components to putative prehistoric dispersals and contacts.

Independently of biologically-inspired studies, Daumé III (2009) incorporated linguistic areas into a phylogenetic tree. In his Bayesian generative model, each feature of a language has a latent variable which determines whether it is derived from an areal cluster or the tree. Thus his model can be seen as a mixture model.

3 Data and Preprocessing

We used the online edition[1] of the Atlas of Pidgin and Creole Language Structures (APiCS) (Michaelis et al., 2013), a database of pidgin and creole languages. It was larger than the datasets of Bakker et al. (2011). As of 2015, it contained 76 languages (104 varieties). It was essentially a pidgin-and-creole version of the online edition[2] of the World Atlas of Language Structures (WALS) (Haspelmath et al., 2005), but it contained sociolinguistic features, phonological inventories and example texts in addition to typological features.

As APiCS did not mark creoles, we used the sociolinguistic feature “Ongoing creolization of pidgins” as a criterion to select creoles. Specifically, we filtered out languages whose feature value was neither “Not applicable (because the language is not a pidgin)” nor “Widespread.”

In APiCS, 48 out of 130 typological features were mapped to WALS features. We used these features to combine creoles from APiCS with non-creoles from WALS. Since the WALS database was sparse, we selected languages for which at least 30% of the features were present. As a result, we obtained 64 creoles and 541 non-creoles.

We imputed missing data using the `R` package *missMDA* (Josse et al., 2012). It handled missing values using multiple correspondence analysis (MCA). Specifically, we used the `imputeMCA` function to predict missing feature values.

When investigating creole distinctiveness, we used binary representations of features. Using a one-of-K encoding scheme, we transformed 48 categorical features into 220 binary features.

Our mixture models require each creole to be associated with a lexifier and substrate(s). Unfortunately, APiCS described these languages in an obscure way (and many of them are indeed not fully resolved). We had no choice but to manually select several modern languages as *proxies* for them. For simplicity, we chose only one substrate per creole, but it is not difficult to extend our model for multiple substrates. We are aware that these are oversimplification, but we believe they would be adequate for a proof-of-concept demonstration.

4 Creole Non-distinctiveness

4.1 Binary Classification

To determine whether creoles are distinct from non-creoles, we apply a linear SVM classifier to the typological data. Here, linearity is assumed for two reasons. First, since the supposed distinctiveness is explained by restructuring universals, there is no way for creoles to have an XOR-like distribution. Second, Daval-Markussen (2013) claims that as few as three features are sufficient to distinguish creoles from non-creoles. If this is correct, it is expected that given 48 categorical features, even a simple lin-

Table 1: Confusion matrix of binary classification. C stands for creoles and NC for non-creoles.

ear classifier can work nearly perfectly.

The classifier is trained to classify whether a given language, represented by binarized features, is a creole ($+1$) or non-creole (-1). We use 5-fold cross validation with grid search to tune hyperparameters.

In our experiments, the accuracy, recall, precision and F1-measure were 97.2%, 88.5%, 84.4% and 86.4%, respectively. Table 1 shows the confusion matrix. We can see that the classifier failed to separate creoles from non-creoles. Although the classifier worked well, borderline cases remained.

4.2 PCA

For exploratory analysis and visualization, we applied PCA to creoles and non-creoles, again represented by binarized features. Figure 3 depicts the scatterplot of the first two principal components. We can see that creoles were characterized by quite a different distribution from that of non-creoles. The creoles were concentrated on the lower center while most non-creoles belonged to one of two clusters in the middle. However, the distribution of creoles did overlap with that of non-creoles.

Having a closer look at the diagram, we found that Negerhollands (Dutch), Cape Verdean Creole of Brava (Portuguese) and Vincentian Creole (English) were among the most "typical" creoles (lexifiers in parentheses). Tok Pisin (English) and Bislama (English) were at the periphery of the cluster. The outliers on the upper left included Korlai (Portuguese) while Kikongo-Kituba (Bantu) lay on the upper right.

On the other hand, "creole-like" non-creoles included Chontal Maya (a Mayan language of Mexico), Mussau (an Oceanic language of Papua New Guinea),[3] Catalan and other European languages. The non-creole cluster on the middle left consisted of Japanese, Kannada, Maltese and others. Another non-creole cluster on the middle right included Swahili, Hawaiian and Khmer. The creoleless upper central area was occupied by Lalo (Sino-Tibetan), Maninka (Western) (Mande in West Africa), Salt-Yui (Trans-New Guinea) among others.

5 Mixture Models for Creole Genesis

5.1 Basic Idea

Forsaking the quest for synchronic distinctiveness, we take a more direct approach to the diachronic question of creole genesis. Since multiple languages are involved in creole genesis, it is reasonable to apply a mixture model. We assume that a creole is stochastically generated by mixing three sources: (1) a lexifier, (2) a substrate and (3) a global *restructurer*. Under this assumption, the main question is with what proportions these sources are mixed.

An unusual property of our model as a mixture model is that not only outcomes (creoles) but most sources (lexifiers and substrates) are observed. We only need to infer the restructurer. Thus another question is what the restructurer looks like.

Note that our model is constructed such that it does not commit to a particular theory of creole genesis. If the superstratist theory is correct, then lexifiers would dominate the inferred mixing proportions. The same is true of the substratist theory. Similarly, the feature pool theory entails that the restructurer only occupies negligible portions. Also note that even if the restructurer plays a significant role, it does not necessarily imply the universalist position. The restructurer is a set of catch-all feature distributions for those which are explained neither by the lexifier nor by the substrate (that is why we avoid calling it restructuring universals). In order for it to be linguistic universals, it must show some consistent patterns in its distributions.

5.2 Mono Model

Our idea is materialized in two Bayesian generative models. The first one, called Mono, is similar to the Structure algorithm of admixture analysis (Pritchard et al., 2000).[4]

[3] Interestingly, Mussau is noted for contact-induced changes (Brownie, 2012).

[4] As seen in Section 2.1, Mono is more similar to Structure than to LDA in that each feature type has its own distributions. The difference is that while Structure infers all K global components, Mono always has one global component

Every language in the model is represented by a sequence of categorical features. The number of possible values varies among feature types. For feature j of creole i, the latent assignment variable $z_{i,j}$ determines from which source the feature is derived, a lexifier (L), a substrate (S) or the restructurer (R). Each creole i is associated a priori with a lexifier and a substrate. Let $y_{i,j,\mathrm{L}}$ and $y_{i,j,\mathrm{S}}$ be the values of feature j of creole i's lexifier and substrate, respectively. If the source is the lexifier (or substrate), the creole simply copies $y_{i,j,\mathrm{L}}$ (or $y_{i,j,\mathrm{S}}$). For the sake of uniformity, we can think of a lexifier (or substrate) as a set of feature distributions each of which concentrates all probability mass on its observed value (i.e., the δ function). The remaining source, the restructurer, is a set of categorical feature distributions each of which is drawn from a Dirichlet prior.

The assignment variable $z_{i,j}$ is generated from θ_i, which in turn is generated from a Dirichlet prior. $\theta_i = (\theta_{i,\mathrm{L}}, \theta_{i,\mathrm{S}}, \theta_{i,\mathrm{R}})$ is the parameter of a categorical distribution which specifies the mixing proportion of the three sources for creole i.[5]

More concretely, the generative story of MONO is as follows:

1. For each feature type $j \in \{1, \cdots, J\}$ of the restructurer:
   (a) draw a distribution from a symmetric Dirichlet distribution $\phi_j \sim \mathrm{Dir}(\beta_j)$
2. For each creole $i \in \{1, \cdots, N\}$:
   (a) draw a mixing proportion from a symmetric Dirichlet distribution $\theta_i \sim \mathrm{Dir}(\alpha_i)$
   (b) then for each feature type $j \in \{1, \cdots, J\}$:
      i. draw a topic assignment $z_{i,j} \sim \mathrm{Categorical}(\theta_i)$
      ii. draw a feature value

$$x_{i,j} \sim \begin{cases} \delta(y_{i,j,\mathrm{L}}) & \text{if } z_{i,j} = \mathrm{L} \\ \delta(y_{i,j,\mathrm{S}}) & \text{if } z_{i,j} = \mathrm{S} \\ \mathrm{Categorical}(\phi_j) & \text{if } z_{i,j} = \mathrm{R} \end{cases}$$

As usual, we marginalize out ϕ_j and θ_i using conjugacy of Dirichlet and categorical distributions (Griffiths and Steyvers, 2004). We use Gibbs sampling to infer $z_{i,j}$, whose probability conditioned on the rest is proportional to

$$\begin{cases} \left(\alpha_i + c_{i,\mathrm{L}}^{-(i,j)}\right) \mathrm{I}(x_{i,j} = y_{i,j,\mathrm{L}}) & \text{if } z_{i,j} = \mathrm{L} \\ \left(\alpha_i + c_{i,\mathrm{S}}^{-(i,j)}\right) \mathrm{I}(x_{i,j} = y_{i,j,\mathrm{S}}) & \text{if } z_{i,j} = \mathrm{S} \\ \left(\alpha_i + c_{i,\mathrm{R}}^{-(i,j)}\right) \frac{\beta_j + c_{\mathrm{R},j,x_{i,j}}^{-(i,j)}}{B_j + c_{\mathrm{R},j,*}^{-(i,j)}} & \text{if } z_{i,j} = \mathrm{R} \end{cases} \tag{1}$$

where I is an indicator function, $B_j = \sum \beta_j$, $c_{i,k}^{-(i,j)}$ is the number of assignments for creole i, except $z_{i,j}$, whose values are k, and $c_{\mathrm{R},j,l}^{-(i,j)}$ is the number of observed features for feature type j, except $x_{i,j}$, that is derived from the restructurer and has l as its value. Intuitively, the first term gives priority to the source from which many other features of creole i are derived. The second term concerns how likely the source generates the feature value. For the lexifier or the substrate, it is 1 only if the source shares the same feature value with the creole; otherwise 0. To tune hyperparameters α_i and β_j, we set a vague gamma prior $\mathrm{Gamma}(1, 1)$ and sample these parameters using slice sampling (Neal, 2003).

5.3 FACT Model

It is said that some features are more easily borrowed than others (Matras, 2011). For creoles, some seems to reflect substrate influence on phonology while reduced inflections might be attributed to the restructurer. Inspired by these observations, we extend the MONO model such that some feature types can have strong connections to particular sources. We call this extended model FACT.

To do this, we decomposes the mixing proportions into per-feature and per-creole factors. We apply additive operations to these factors in log-space in a way similar to the Sparse Additive Generative model (Eisenstein et al., 2011). As a result of this extension, every feature j of creole i has its own mixing proportion, $\theta_{i,j} = (\theta_{i,j,\mathrm{L}}, \theta_{i,j,\mathrm{S}}, \theta_{i,j,\mathrm{R}})$:

$$\theta_{i,j,k} = \frac{\exp(m_{j,k} + n_{i,k})}{\sum_k \exp(m_{j,k} + n_{i,k})}, \tag{2}$$

where $m_{j,k}$ is a factor specific to feature type j and $n_{i,k}$ is the one specific to creole i. To penalize extreme values, we put Laplacian priors on $m_{j,k}$ and $n_{i,k}$, with mean 0 and scale γ.

To sum up, the generative story of FACT is as follows:

and two local, observed components.

[5] By letting another categorical distribution subdivide $\theta_{i,\mathrm{S}}$, we can incorporate multiple substrates into the model.

Model		Sources		
		L	S	R
MONO		16.6%	9.3%	74.1%
FACT	Combined	17.6%	6.0%	76.4%
	Per-feature	22.5%	6.8%	70.8%
	Per-creole	25.0%	20.4%	54.6%

Table 2: Summary of mixing proportions. The arithmetic mean of 50 samples after 5,000 iterations, with an interval of 100 iterations.

```
1. For each feature type $j \in \{1, \cdots, J\}$:
   (a) draw $\phi_j \sim \mathrm{Dir}(\beta_j)$
   (b) for each source $k \in \{\mathrm{L}, \mathrm{S}, \mathrm{R}\}$:
       i. draw $m_{j,k} \sim \mathrm{Laplace}(0, \gamma)$
2. For each creole $i \in \{1, \cdots, N\}$:
   (a) for each source $k \in \{\mathrm{L}, \mathrm{S}, \mathrm{R}\}$:
       i. draw $n_{i,k} \sim \mathrm{Laplace}(0, \gamma)$
   (b) then for each feature $j \in \{1, \cdots, J\}$:
       i. normalize $m_{j,k}$ and $n_{i,k}$ to obtain $\theta_{i,j}$ (Equation (2))
       ii. draw a topic assignment $z_{i,j} \sim \mathrm{Categorical}(\theta_{i,j})$
       iii. draw $x_{i,j}$ as in MONO
```

ϕ_j is integrated out as before, but the conjugacy no longer holds for $\theta_{i,j}$.

For inference, a modification is needed to infer $z_{i,j}$: the first term $\alpha_i + c_{i,k}^{-(i,j)}$ of Equation (1) is replaced with $\theta_{i,j,k}$. $m_{j,k}$ and $n_{i,k}$ are sampled using the Metropolis algorithm, with a Gaussian proposal distribution centered at the previous value. Hyperparameter γ is set to 10.

5.4 Results

Table 2 summarizes mixing proportions. For MONO and FACT (combined), we use a fraction of assignment variables pointing to a particular souce. Per-feature and per-creole factors are converted into probabilities as follows: per-feature proportions $\tilde{\phi}_j = (\tilde{\phi}_{j,\mathrm{L}}, \tilde{\phi}_{j,\mathrm{S}}, \tilde{\phi}_{j,\mathrm{R}})$, where $\tilde{\phi}_{j,k} = \frac{\exp(m_{j,k})}{\sum_k \exp(m_{j,k})}$. Similarly, per-creole proportions $\tilde{\theta}_i = (\tilde{\theta}_{j,\mathrm{L}}, \tilde{\theta}_{j,\mathrm{S}}, \tilde{\theta}_{j,\mathrm{R}})$, where $\tilde{\theta}_{i,k} = \frac{\exp(n_{i,k})}{\sum_k \exp(n_{i,k})}$.

We can see that the overwhelming majority of features were derived from the restructurer both in MONO and FACT (combined). The restructurer was followed by lexifiers, and substrates were the least influential.[6] These results can be interpreted as counter-evidence to the superstratist, substratist and feature pool theories.

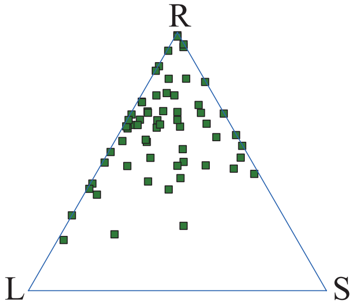

Figure 4: Mixing proportions of MONO projected onto a simplex. Each point denotes a creole. It is the parameter of the posterior predictive distribution of an assignment variable: $\tilde{\theta}_i = (\frac{\alpha_i + c_{i,\mathrm{L}}}{Z}, \frac{\alpha_i + c_{i,\mathrm{S}}}{Z}, \frac{\alpha_i + c_{i,\mathrm{R}}}{Z})$, where the normalizer $Z = \sum_k \alpha_i + c_{i,k}$. One sample after 10,000 iterations.

MONO and FACT (combined) exhibited similar patterns. When the mixing proportions are decomposed into per-feature and per-creole factors, per-creole factors exhibited less uneven distributions than per-feature factors. This implies heterogeneous behavior of features in creole genesis. Table 3 lists top-5 feature types for each source.

Figure 4 plots creoles on a simplex of mixing proportions in MONO. Creoles scattered across the simplex but leaned toward the restructurer. This implies that a lexifier cannot be mixed with substrates without interference from the restructurer.

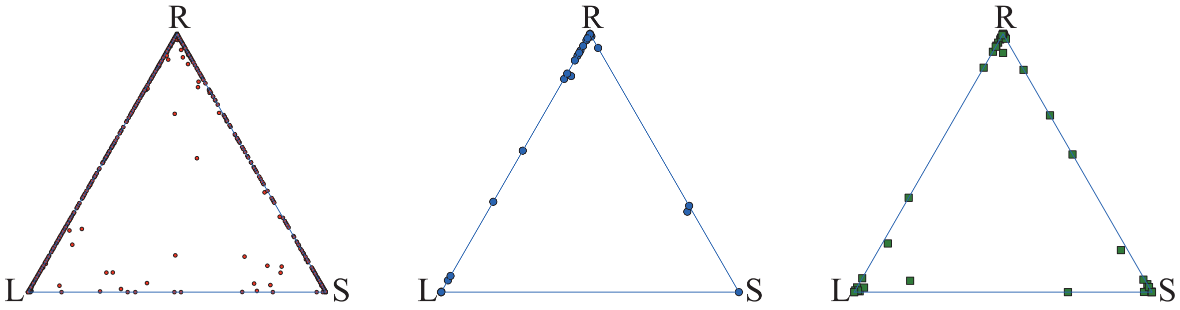
Compared with MONO, FACT tended to push points to the edges of the simplex. This can be confirmed in Figure 5. In particular, Figure 5(c) is directly comparable to Figure 4. It is possible that halfway points in MONO were artifacts of its limited expressive power.

Table 4 lists the top-10 feature type-value pairs that were derived from the restructurer. In other words, we stochastically removed the influence of the lexifiers and substrates from creole data. These features can be regarded as (statistical) universals

[6] The substrates would probably occupy a larger portion if multiple substrates are incorporated in future work.

Source	Ratio	Feature type
Lexifier	100.0%	Order of Adposition and Noun Phrase
	100.0%	Order of Relative Clause and Noun
	99.9%	Applicative Constructions
	99.5%	The Prohibitive
	98.2%	Alignment of Case Marking of Full Noun Phrases
Substrate	84.9%	Order of Genitive and Noun
	56.6%	Tone
	54.9%	Order of Subject, Object and Verb
	26.5%	Pronominal and Adnominal Demonstratives
	24.0%	Relativization on Subjects
Restructurer	100.0%	Intensifiers and Reflexive Pronouns
	100.0%	Numeral Classifiers
	100.0%	Suppletion According to Tense and Aspect
	100.0%	Expression of Pronominal Subjects
	100.0%	Polar Questions

Table 3: Top-5 feature types for each source according to per-feature factors of FACT. The arithmetic mean of 50 samples after 5,000 iterations, with an interval of 100 iterations.



(a) Combined.

(b) Per-feature factors.

(c) Per-creole factors.

Figure 5: Mixing proportions of FACT projected onto a simplex. One sample after 10,000 iterations. (a) $J \times N$ points for combined mixing proportions $\theta_{i,j}$. (b) J points for per-feature factors $\tilde{\phi}_j$ as in Table 2. (c) N points for per-creole factors $\tilde{\theta}_i$.

although our model leaves the possibility that they were not *restructuring* universals. To answer this question, we need to break down the restructurer by types of linguistic universals.

Among the 10 feature type-value pairs, only four apply to Japanese (Negative Indefinite Pronouns and Predicate Negation, Intensifiers and Reflexive Pronouns, Alignment of Case Marking of Pronouns, and Order of Numeral and Noun). For reference, English has seven. Combined with the PCA analysis in Section 4.2, this suggests that Japanese is a very non-creole-like language. However, we are unsure if the possibility of creole status for (pre-)Old Japanese is completely rejected. This question might be answered if we figure out how long it takes to make creole-like traits disappeared.

It is often said that creoles have SVO word order. According to APiCS, the number of creoles with SVO order was 61 (exclusive) and 71 (exclusive plus shared) in the 76 language dataset. However, this feature value only gained the ratio of 67.3%. This is mainly because SVO is the word order of most lexifiers, but it can also be attributed to data representation: since WALS did not allow multi-valued features (e.g., SVO *and* SOV), some creoles with multiple word orders were mapped to a separate category "No dominant order," underestimating the influence of SVO.

Ratio	Feature type	Feature value
91.2%	Numeral Classifiers	Absent
74.3%	Gender Distinctions in Independent Personal Pronouns	No gender distinctions
72.3%	Negative Indefinite Pronouns and Predicate Negation	Predicate negation also present
70.5%	Occurrence of Nominal Plurality	All nouns, always optional
69.7%	Intensifiers and Reflexive Pronouns	Identical
68.4%	Distributive Numerals	No distributive numerals
67.2%	Expression of Pronominal Subjects	Obligatory pronouns in subject position
66.9%	Politeness Distinctions in Pronouns	No politeness distinction
66.6%	Alignment of Case Marking of Pronouns	Nominative - accusative (standard)
66.3%	Order of Numeral and Noun	Numeral-Noun

Table 4: Top-10 features derived from the restructurer in FACT. The ratio of the feature type-value pair (j, l) is defined as $|\{(i \,|\, x_{i,j} = l, z_{i,j} = \mathrm{R}\}| \,/\, N$. The arithmetic mean of 50 samples after 5,000 iterations, with an interval of 100 iterations.

5.5 Discussion

The main contribution of our work is the introduction of mixture models to creole studies. This is, however, only the first step toward understanding the complex process of creole genesis by means of statistical modeling. Better data are needed with respect to proxies for substrates, missing values, multi-valued features among others.

With better data, more elaborate models could uncover the detailed process of creole genesis. Our models mix several sources in one step, but we may want to model the staged development of pidgin formation and creole formation. As a result of continued influence from its superstrate, a creole might undergo *decreolization*. It is argued that pidgins themselves have several development stages, from each of which creoles can emerge (Mühlhäusler, 1997). Hopefully, these hypotheses could be tested with statistical models.

Our finding that the restructurer plays a dominant role in creole genesis has a negative implication for tree-based inference of language relationships. If most features of a language come from nowhere, we are unable to trace its origin back into the deep past. In the meanwhile, it has been argued that creole genesis only occurred in modern and early-modern, exceptional circumstances and cannot be responsible for most historical changes. Thus identifying the social conditions under which creoles arise (Tria et al., 2015) is another research direction to be explored.

6 Conclusion

In this paper, we present several statistical models of linguistic typology to answer questions concerning creole genesis. First, we formalized creole (non-)distinctiveness as a binary classification problem. Second, we propose to model creole genesis with mixture models, which makes more sense than tree-building techniques.

Recent studies on linguistic applications of computational phylogeny have been heavily influenced from computational biology. They often depend on ready-to-use software packages developed in that field. We observe that, as a result, linguistic phenomena that lack exact counterparts in biology tend to be left untouched. In this paper, we have hopefully demonstrated that computational linguists could fill the gap.

Abstract

In this study, the problem of shallow parsing of Hindi-English code-mixed social media text (CSMT) has been addressed. We have annotated the data, developed a language identifier, a normalizer, a part-of-speech tagger and a shallow parser. To the best of our knowledge, we are the first to attempt shallow parsing on CSMT. The pipeline developed has been made available to the research community with the goal of enabling better text analysis of Hindi English CSMT. The pipeline is accessible at [1].

1 Introduction

Multilingual speakers tend to exhibit code-mixing and code-switching in their use of language on social media platforms. Code-Mixing is the embedding of linguistic units such as phrases, words or morphemes of one language into an utterance of another language whereas code-switching refers to the co-occurrence of speech extracts belonging to two different grammatical systems (Gumperz., 1982). Here we use code-mixing to refer to both the scenarios.

Hindi-English bilingual speakers produce huge amounts of CSMT. Vyas et al. (2014) noted that the complexity in analyzing CSMT stems from non-adherence to a formal grammar, spelling variations, lack of annotated data, inherent conversational nature of the text and of course, code-mixing. Therefore, there is a need to create datasets and Natural Language Processing (NLP) tools for CSMT as traditional tools are ill-equipped for it. Taking a step in this direction, we describe the shallow parsing pipeline built during this study.

2 Background

Bali et al. (2014) gathered data from Facebook generated by English-Hindi bilingual users which on analysis, showed a significant amount of code-mixing. Barman et al. (2014) investigated language identification at word level on Bengali-Hindi-English CSMT. They annotated a corpus with more than 180,000 tokens and achieved an accuracy of 95.76% using statistical models with monolingual dictionaries.

Solorio and Liu (2008) experimented with POS tagging for English-Spanish Code-Switched discourse by using pre-existing taggers for both languages and achieved an accuracy of 93.48%. However, the data used was manually transcribed and thus lacked the problems added by CSMT. Vyas et al. (2014) formalized the problem, reported challenges in processing Hindi-English CSMT and performed initial experiments on POS tagging. Their POS tagger accuracy fell by 14% to 65% without using gold language labels and normalization. Thus, language identification and normalization are critical for POS tagging (Vyas et al., 2014), which in turn is critical further down the pipeline for shallow parsing as evident in Table 5.

Jamatia et al. (2015) also built a POS tagger for Hindi-English CSMT using Random Forests on 2,583 utterances with gold language labels and achieved an accuracy of 79.8%. In the monolin-

Lang.	Sentences
English	141 (16.43%)
Hindi	111 (12.94%)
Code-mixed	606 (70.63%)
Total	858

Table 1: Data distribution at sentence level.

Lang.	All Sentences	Only CM Sentences
Hindi	6318 (57.05%)	5352 (63.34%)
English	3015 (27.22%)	1886 (22.32%)
Rest	1742 (15.73%)	1212 (14.34%)
Total	11075	8450

Table 2: Data distribution at token level.

gual social media text context, Gimpel et al. (2011) built a POS tagger for English tweets and achieved an accuracy of 89.95% on 1,827 annotated tweets. Owoputi et al. (2013) further improved this POS tagger, increasing the accuracy to 93%.

3 Data Preparation

CSMT was obtained from social media posts from the data shared for Subtask 1 of FIRE-2014 Shared Task on Transliterated Search. The existing annotation on the FIRE dataset was removed, posts were broken down into sentences and 858 of those sentences were randomly selected for manual annotation.

Table 1 and Table 2 show the distribution of the dataset at sentence and token level respectively. The language of 63.33% of the tokens in code-mixed sentences is Hindi. Based on the distribution, it is reasonable to assume that Hindi is the matrix language (Azuma, 1993; Myers-Scotton, 1997) in most of the code-mixed sentences.

3.1 Dataset examples

1. hy... try fr sm gov job jiske forms niklte h...
   Gloss: Hey... try for some government job which forms give out...
   Translation: Hey... try for some government job which gives out forms...

2. To tum divya bharti mandir marriage kendra ko donate karna
   Gloss: So you divya bharti temple marriage center to donate do
   Translation: So you donate to divya bharti temple marriage center

The dataset is comprised of sentences similar to example 1 and 2. Example 1 shows code-switching as the language switches from English to Hindi whereas example 2 shows code-mixing as some English words are embedded in a Hindi utterance. Spelling variations (`sm - some`, `gov - government`), ambiguous words (`To - So` in Hindi or `To` in English) and non-adherence to a formal grammar (out of place ellipsis - `...`, no or misplaced punctuation) are some of the challenges evident in analyzing the examples above.

3.2 Annotation

Annotation was done on the following four layers:

1. **Language Identification**: Every word was given a tag out of three 'en', 'hi' and 'rest' to mark its language. Words that a bilingual speaker could identify as belonging to either Hindi or English were marked as 'hi' or 'en'. The label 'rest' was given to symbols, emoticons, punctuation, named entities, acronyms, foreign words and words with sub-lexical code-mixing like `chapattis` (Gloss: chapatti - bread) which is a Hindi word (*chapatti*) following English morphology (plural marker *-s*).

2. **Normalization**: Words with language tag 'hi' in Roman script were labeled with their standard form in the native script of Hindi, Devanagari. Similarly, words with language tag 'en' were labeled with their standard spelling. Words with language tag 'rest' were kept as they are. This acted as testing data for our Normalization module.

3. **Parts-of-Speech (POS)**: Universal POS tagset (Petrov et al., 2011) was used to label the POS of each word as this tagset is applicable to both English and Hindi words. Sub-lexical code-mixed words were annotated based on their context, since POS is a function of a word in a given context. For example, an English verb used as a noun in Hindi context is labeled as a noun.

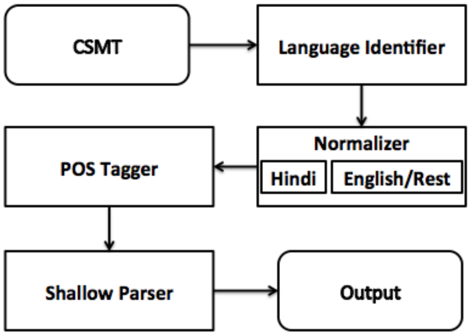

Figure 1: Schematic Diagram of the Pipeline

4. **Chunking**: A chunk tag comprises of chunk label and chunk boundary. The chunk label tagset is a coarser version of AnnCorra tagset (Bharati et al., 2006). Unlike AnnCorra, only one tag is used for all verb chunks in our tagset. Chunk boundary is marked using BI notation where 'B-' prefix indicates beginning of a chunk and 'I-' prefix indicates that the word is inside a chunk.

This whole dataset was annotated by eight Hindi-English bilingual speakers. Two other annotators reviewed and cleaned it. To measure inter-annotator agreement, another annotator read the guidelines and annotated 25 sentences (334 tokens) from scratch. The inter-annotator agreement calculated using Cohen's κ (Cohen, 1960) came out to be 0.97, 0.83 and 0.89 for language identification, POS tagging and shallow parsing respectively.

4 Shallow Parsing Pipeline

Shallow parsing is the task of identifying and segmenting text into syntactically correlated word groups (Abney, 1992; Harris, 1957). Shallow parsing is a viable alternative to full parsing as shown by (Li and Roth, 2001). Our shallow parsing pipeline is composed of four main modules, as shown in Figure 1. These modules, in the order of their usage, are *Language Identification*, *Normalization*, *POS Tagger* and *Shallow Parser*.

Our pipeline takes a raw utterance in Roman script as input on which each module runs sequentially. Twokenizer[2] (Owoputi et al., 2013) which performs well on Hindi-English CSMT (Jamatia et al., 2015) was used to tokenize the utterance into words. The *Language Identification* module assigns each token a language label. Based on the language label assigned, the *Normalizer* runs the Hindi normalizer or the English/Rest normalizer. The *POS tagger* uses the output of the normalizer to assign each word a POS tag. Finally, the *Shallow Parser* assigns a chunk label with boundary.

Features	**Accuracy**
BNC	61.26
+LEXNORM	71.43
+HINDI_DICT	77.50
+NGRAM	93.18
+AFFIXES	93.98

Table 3: Feature Ablation for Language Identifier

The functionality and performance of each module is described in greater detail in the following subsections.

4.1 Language Identification

While language identification at the document level is a well-established task (McNamee, 2005), identifying language in social media posts has certain challenges associated to it. Spelling errors, phonetic typing, use of transliterated alphabets and abbreviations combined with code-mixing make this problem interesting. Similar to (Barman et al., 2014), we performed two experiments treating language identification as a three class ('hi', 'en', 'rest') classification problem. The feature set comprised of - **BNC**: normalized frequency of the word in British National Corpus (BNC)[3]. **LEXNORM**: binary feature indicating presence of the word in the lexical normalization dataset released by Han et al. (2011). **HINDI_DICT**: binary feature indicating presence of the word in a dictionary of 30,823 transliterated Hindi words as released by Gupta (2012). **NGRAM**: word n-grams. **AFFIXES**: prefixes and suffixes of the word.

Using these features and introducing a context-window of n-words, we trained a linear SVM. In another experiment we modeled language identification as a sequence labeling task, where we employed CRF into usage. The idea behind this was that

[2] http://www.ark.cs.cmu.edu/TweetNLP/

[3] http://www.natcorp.ox.ac.uk/

code-mixed text has some inherent structure which is largely dictated by the matrix language of the text. The latter approach using CRF had a greater accuracy, which validated our hypothesis. The results of this module are shown in Table 3.

4.2 Normalization

Once the language identification task was complete, there was a need to convert the noisy non-standard tokens (such as Hindi words inconsistently written in many ways using the Roman script) in the text into standard words. To fix this, a normalization module that performs language-specific transformations, yielding the correct spelling for a given word was built. Two language specific normalizers, one for Hindi and other for English/Rest, had two subnormalizers each, as described below. Both subnormalizers generated normalized candidates which were then ranked, as explained later in this subsection.

1. **Noisy Channel Framework**: A generative model was trained to produce noisy (unnormalized) tokens from a given normalized word. Using the model's confidence score and the probability of the normalized word in the background corpus, *n*-best normalizations were chosen. First, we obtained character alignments between noisy Hindi words in Roman script ($\mathrm{H_r}$) to normalized Hindi words-format($\mathrm{H_w}$) using GIZA++ (Och and Ney, 2003) on 30,823 Hindi word pairs of the form ($\mathrm{H_w}$ - $\mathrm{H_r}$) (Gupta et al., 2012). Next, a CRF classifier was trained over these alignments, enabling it to convert a character sequence from Roman to Devanagari using learnt letter transformations. Using this model, noisy $\mathrm{H_r}$ words were created for $\mathrm{H_w}$ words obtained from a dictionary of 1,17,789 Hindi words (Biemann et al., 2007). Finally, using the formula below, we computed the most probable H_w for a given H_r.

$$\begin{aligned} H_w &= argmax_{H_{w_i}} p(H_{w_i}|H_r) \\ &= argmax_{H_{w_i}} p(H_r|H_{w_i})p(H_{w_i}) \end{aligned}$$

where $p(H_{w_i})$ is the probability of word H_{w_i} in the background corpus.

Features	Accuracy
Baseline	69.27
+LANG	70.44
+NORM	72.61
+TPOS	73.18
+HPOS, -TPOS	73.55
+COMBINED	75.07

Table 4: Feature Ablation for POS Tagger

2. **SILPA Spell Checker**: This subnormalizer uses SILPA libindic spell-checker[4] to compute the top 10 normalized words for a given input word.

The candidates obtained from these two systems are ranked on the basis of the observed precision of the systems. The top-k candidates from each system are selected if they have a confidence score greater than an empirically observed Λ. A similar approach was used for English text normalization, using the English normalization pairs from (Han et al., 2012) and (Liu et al., 2012) for the noisy channel framework, and Aspell[5] as the spell-checker. Words with language tag 'rest' were left unprocessed. The accuracy for the Hindi Normalizer was 78.25%, and for the English Normalizer was 69.98%. The overall accuracy of this module is 74.48%; P@n (Precision@n) for n=3 is 77.51% and for n=5 is 81.76%.

4.3 Part-Of-Speech Tagging

Part-of-Speech (POS) tagging provides basic level of syntactic analysis for a given word or sentence. It was modeled as a sequence labeling task using CRF. The feature set comprised of - **Baseline**: Word based features - affixes, context and the word itself. **LANG**: Language label of the token. **NORM**: Normalized lexical features. **TPOS**: Output of Twitter POS tagger (Owoputi et al., 2013). **HPOS**: Output of IIIT's Hindi POS tagger[6]. **COMBINED**: HPOS for Hindi words and TPOS for English and Rest. The results of POS Tagger are shown in Table 4.

4.4 Shallow Parsing

A chunk comprises of two aspects - the chunk boundary and the chunk label. Shallow Parsing was modeled as three separate sequence labeling problems: **Label**, **Boundary** and **Combined**, for each of which a CRF model was trained. The feature set comprised of - **POS**: POS tag of the word. **POS Context**: POS tags in the context window of length 5, i.e., the two previous tags, current tag and next two tags. **POS_LEX**: A special feature made up of concatenation of POS and LEX. **NORMLEX**: The word in its normalized form. The results of this module are shown in Table 5.

5 Pipeline Results

The best performing model was selected from each module and was used in the pipeline. Table 6 tabulates the step by step accuracy of the pipeline calculated using 10 fold cross-validation.

6 Conclusion and Future Work

In this study, we have developed a system for Hindi-English CSMT data that can identify the language of the words, normalize them to their standard forms, assign them their POS tag and segment them into chunks. We have released the system.

In the future, we intend to continue creating more annotated code-mixed social media data. We would also like to improve upon the challenging problem of normalization of monolingual social Hindi sentences. Also, we would further extend our pipeline and build a full parser which has aplenty applications in NLP.

Abstract

We present an approach to learning multi-sense word embeddings relying both on monolingual and bilingual information. Our model consists of an encoder, which uses monolingual and bilingual context (i.e. a parallel sentence) to choose a sense for a given word, and a decoder which predicts context words based on the chosen sense. The two components are estimated jointly. We observe that the word representations induced from bilingual data outperform the monolingual counterparts across a range of evaluation tasks, even though crosslingual information is not available at test time.

1 Introduction

Approaches to learning word embeddings (i.e. real-valued vectors) relying on word context have received much attention in recent years, and the induced representations have been shown to capture syntactic and semantic properties of words. They have been evaluated intrinsically (Mikolov et al., 2013a; Baroni et al., 2014; Levy and Goldberg, 2014) and have also been used in concrete NLP applications to deal with word sparsity and improve generalization (Turian et al., 2010; Collobert et al., 2011; Bansal et al., 2014; Passos et al., 2014). While most work to date has focused on developing embedding models which represent a word with a single vector, some researchers have attempted to capture *polysemy* explicitly and have encoded properties of each word with multiple vectors (Huang et al., 2012; Tian et al., 2014; Neelakantan et al., 2014; Chen et al., 2014; Li and Jurafsky, 2015).

In parallel to this work on multi-sense word embeddings, another line of research has investigated integrating *multilingual* data, with largely two distinct goals in mind. The first goal has been to obtain representations for several languages in the same semantic space, which then enables the transfer of a model (e.g., a syntactic parser) trained on annotated training data in one language to another language lacking this annotation (Klementiev et al., 2012; Hermann and Blunsom, 2014; Gouws et al., 2014; Chandar A P et al., 2014). Secondly, information from another language can also be leveraged to yield better first-language embeddings (Guo et al., 2014). Our paper falls in the latter, much less explored category. We adhere to the view of multilingual learning as a means of language grounding (Faruqui and Dyer, 2014b; Zou et al., 2013; Titov and Klementiev, 2012; Snyder and Barzilay, 2010; Naseem et al., 2009). Intuitively, polysemy in one language can be at least partially resolved by looking at the translation of the word and its context in another language (Kaji, 2003; Ng et al., 2003; Diab and Resnik, 2002; Ide, 2000; Dagan and Itai, 1994; Brown et al., 1991). Better sense assignment can then lead to better sense-specific word embeddings.

We propose a model that uses second-language embeddings as a supervisory signal in learning multi-sense representations in the first language. This supervision is easy to obtain for many language pairs as numerous parallel corpora exist nowadays. Our model, which can be seen as an autoencoder with a discrete hidden layer encoding word senses, leverages bilingual data in its encoding part, while the decoder predicts the surrounding words relying on the

predicted senses. We strive to remain flexible as to the form of parallel data used in training and support both the use of word- and sentence-level alignments.

Our findings are:

- The second-language signal effectively improves the quality of multi-sense embeddings as seen on a variety of intrinsic tasks for English, with the results superior to that of the baseline Skip-Gram model, even though the crosslingual information is not available at test time.
- This finding is robust across several settings, such as varying dimensionality, vocabulary size and amount of data.
- In the extrinsic POS-tagging task, the second-language signal also offers improvements over monolingually-trained multi-sense embeddings, however, the standard Skip-Gram embeddings turn out to be the most robust in this task.

We make the implementation of all the models as well as the evaluation scripts available at `http://github.com/rug-compling/bimu`.

2 Word Embeddings with Discrete Autoencoders

Our method borrows its general structure from neural autoencoders (Rumelhart et al., 1986; Bengio et al., 2013). Autoencoders are trained to reproduce their input by first mapping their input to a (lower dimensional) hidden layer and then predicting an approximation of the input relying on this hidden layer. In our case, the hidden layer is not a real-valued vector, but is a categorical variable encoding the sense of a word. Discrete-state autoencoders have been successful in several natural language processing applications, including POS tagging and word alignment (Ammar et al., 2014), semantic role induction (Titov and Khoddam, 2015) and relation discovery (Marcheggiani and Titov, 2016).

More formally, our model consists of two components: an *encoding* part which assigns a sense to a pivot word, and a *reconstruction* (decoding) part recovering context words based on the pivot word and its sense. As predictions are probabilistic ('soft'), the reconstruction step involves summation over all potential word senses. The goal is to find embedding parameters which minimize the error in recovering context words based on the pivot word and the sense assignment. Parameters of both encoding and reconstruction are jointly optimized. Intuitively, a good sense assignment should make the reconstruction step as easy as possible. The encoder uses not only words in the first-language sentence to choose the sense but also, at training time, is conditioning its decisions on the words in the second-language sentence. We hypothesize that the injection of crosslingual information will guide learning towards inducing more informative sense-specific word representations. Consequently, using this information at training time would benefit the model even though crosslingual information is not available to the encoder at test time.

We specify the encoding part as a log-linear model:

$$p(s|x_i, C_i, C'_i, \theta) \propto \exp\big(\varphi_{i,s}^{\top}(\frac{1-\lambda}{|C_i|}\sum_{j \in C_i} \gamma_j + \frac{\lambda}{|C'_i|}\sum_{k \in C'_i} \gamma'_k)\big). \quad (1)$$

To choose the sense $s \in \mathcal{S}$ for a word x_i, we use the bag of context words C_i from the first language l, as well as the bag of context words C'_i from the second language l'.[1] The context C_i is defined as a

[1] We have also considered a formulation which included a sense-specific bias $b_{x_i,s} \in \mathbb{R}$ to capture relative frequency of latent senses but it did not seem to affect performance.

multiset $C_i = \{x_{i-n}, \ldots, x_{i-1}, x_{i+1}, \ldots, x_{i+n}\}$, including words around the pivot word in the window of size n to each side. We set n to 5 in all our experiments. The crosslingual context C'_i is discussed in § 3, where we either rely on word alignments or use the entire second-language sentence as the context. We distinguish between sense-specific embeddings, denoted by $\varphi \in \mathbb{R}^d$, and generic sense-agnostic ones, denoted $\{\gamma, \gamma'\} \in \mathbb{R}^d$ for first and second language, respectively. The number of sense-specific embeddings is the same for all words. We use θ to denote all these embedding parameters. They are learned jointly, with the exception of the pre-trained second-language embeddings.

The hyperparameter $\lambda \in \mathbb{R}, 0 \leq \lambda \leq 1$ weights the contribution of each language. Setting $\lambda = 0$ would drop the second-language component and use only the first language. Our formulation allows the addition of new languages easily, provided that the second-language embeddings live in the same semantic space.

The reconstruction part predicts a context word x_j given the pivot x_i and the current estimate of its s:

$$p(x_j|x_i, s, \theta) = \frac{\exp(\varphi_{i,s}^\top \gamma_j)}{\sum_{k \in |\mathcal{V}|} \exp(\varphi_{i,s}^\top \gamma_k)}, \qquad (2)$$

where $|\mathcal{V}|$ is the vocabulary size. This is effectively a Skip-Gram model (Mikolov et al., 2013a) extended to rely on senses.

2.1 Learning and regularization

As sense assignments are not observed during training, the learning objective includes marginalization over word senses and thus can be written as:

$$\sum_i \sum_{j \in C_{x_i}} \log \sum_{s \in \mathcal{S}} p(x_j|x_i, s, \theta) p(s|x_i, C_i, C'_i, \theta),$$

in which index i goes over all pivot words in the first language, j over all context words to predict at each i, and s marginalizes over all possible senses of the word x_i. In practice, we avoid the costly computation of the normalization factor in the softmax computation of Eq. (2) and use negative sampling (Mikolov et al., 2013b) instead of $\log p(x_j|x_i, s, \theta)$:

$$\log \sigma(\varphi_{i,s}^\top \gamma_j) + \sum_{x \in N} \log \sigma(-\varphi_{i,s}^\top \gamma_x), \qquad (3)$$

where σ is the sigmoid non-linearity function and γ_x is a word embedding from the sample of negative (noisy) words N. Optimizing the autoencoding objective is broadly similar to the learning algorithm defined for multi-sense embedding induction in some of the previous work (Neelakantan et al., 2014; Li and Jurafsky, 2015). Note though that this previous work has considered only monolingual context.

We use a minibatch training regime and seek to optimize the objective function $L(\mathcal{B}, \theta)$ for each minibatch $\mathcal{B}$. We found that optimizing this objective directly often resulted in inducing very flat posterior distributions. We therefore use a form of posterior regularization (Ganchev et al., 2010) where we can encode our prior expectations that the posteriors should be sharp. The regularized objective for a minibatch is defined as

$$L(\mathcal{B}, \theta) + \lambda_H \sum_{i \in \mathcal{B}} H(q_i), \qquad (4)$$

where H is the entropy function and q_i are the posterior distributions from the encoder ($p(s|x_i, C_i, C'_i, \theta)$). This modified objective can also be motivated from a variational approximation perspective, see Marcheggiani and Titov (2016) for details. By varying the parameter $\lambda_H \in \mathbb{R}$, it is easy to control the amount of entropy regularization. For $\lambda_H > 0$, the objective is optimized with flatter posteriors, while $\lambda_H < 0$ infers more peaky posteriors. When $\lambda_H \to -\infty$, the probability mass needs to be concentrated on a single sense, resulting in an algorithm similar to hard EM. In practice, we found that using hard-update training[2], which is closely related to the $\lambda_H \to -\infty$ setting, led to best performance.

2.2 Obtaining word representations

At test time, we construct the word representations by averaging all sense embeddings for a word x_i and weighting them with the sense expectations (Li and Jurafsky, 2015)[3]:

$$\omega_i = \sum_{s \in \mathcal{S}} p(s|x_i, C_i) \varphi_{i,s}. \qquad (5)$$

[2] I.e. updating only that embedding φ_{i,s^*} for which $s^* = \arg\max_s p(s|x_i, C_i, C'_i, \theta)$.

[3] Although our training objective has sparsity-inducing properties, the posteriors at test time are not entirely peaked, which makes weighting beneficial.

Unlike in training, the sense prediction step here does not use the crosslingual context C'_i since it is not available in the evaluation tasks. In this work, instead of marginalizing out the unobservable crosslingual context, we simply ignore it in computation.

Sometimes, even the first-language context is missing, as is the situation in many word similarity tasks. In that case, we just use the uniform average, $1/|\mathcal{S}| \sum_{s \in \mathcal{S}} \varphi_{i,s}$.

3 Word affiliation from alignments

In defining the crosslingual signal we draw on a heuristic inspired by Devlin et al. (2014). The second-language context words are taken to be the multiset of words around and including the pivot affiliated to x_i:

$$C'_i = \{x'_{a_i - m}, ..., x'_{a_i}, ..., x'_{a_i + m}\}, \qquad (6)$$

where x'_{a_i} is the word affiliated to x_i and the parameter m regulates the context window size. By choosing $m = 0$, only the affiliated word is used as l' context, and by choosing $m = \infty$, the l' context is the entire sentence (≈uniform alignment). To obtain the index a_i, we use the following:

1) If x_i aligns to exactly one second-language word, a_i is the index of the word it aligns to.
2) If x_i aligns to multiple words, a_i is the index of the aligned word in the middle (and rounding down when necessary).
3) If x_i is unaligned, C'_i is empty, therefore no l' context is used.

We use the cdec aligner (Dyer et al., 2010) to word-align the parallel corpora.

4 Parameters and Set-up

4.1 Learning parameters

We use the AdaGrad optimizer (Duchi et al., 2011) with initial learning rate set to 0.1. We set the mini-batch size to 1000, the number of negative samples to 1, the sampling factor to 0.001 and the window size parameter m to 5. All the embeddings are 50-dimensional (unless specified otherwise) and initialized by sampling from the uniform distribution between $[-0.05, 0.05]$. We include in the vocabulary all words occurring in the corpus at least 20 times. We set the number of senses per word to 3 (see further discussion in § 6.4 and § 7). All other parameters with their default values can be examined in the source code available online.

4.2 Bilingual data

In a large body of work on multilingual word representations, Europarl (Koehn, 2005) is the preferred source of parallel data. However, the domain of Europarl is rather constrained, whereas we would like to obtain word representations of more general language, also to carry out an effective evaluation on semantic similarity datasets where domains are usually broader. We therefore use the following parallel corpora: News Commentary (Bojar et al., 2013) (NC), Yandex-1M[4] (RU-EN), CzEng 1.0 (Bojar et al., 2012) (CZ-EN) from which we exclude the EU legislation texts, and GigaFrEn (Callison-Burch et al., 2009) (FR-EN). The sizes of the corpora are reported in Table 1. The word representations trained on the NC corpora are evaluated only intrinsically due to the small sizes.

Corpus	Language	Words	Sent.
NC	Fr, Ru, Cz, De, Es	3-4 M	.1-.2 M
RU-EN	Ru	24 M	1 M
CZ-EN	Cz	126 M	10 M
FR-EN	Fr	670 M	23 M

Table 1: Parallel corpora used in this paper. The word sizes reported are based on the English part of the corpus. Each language pair in NC has a different English part, hence the varying number of sentences per target language.

5 Evaluation Tasks

We evaluate the quality of our word representations on a number of tasks, both intrinsic and extrinsic.

5.1 Word similarity

We are interested here in how well the semantic similarity ratings obtained from embedding comparisons correlate to human ratings. For this purpose, we use a variety of similarity benchmarks for English and report the Spearman ρ correlation scores between the human ratings and the cosine ratings obtained from our word representations. The **SCWS** benchmark (Huang et al., 2012) is probably the most suitable

[4] `https://translate.yandex.ru/corpus`

similarity dataset for evaluating multi-sense embeddings, since it allows us to perform the sense prediction step based on the sentential context provided for each word in the pair.

The other benchmarks we use provide the ratings for the word pairs without context. WS-353 contains 353 human-rated word pairs (Finkelstein et al., 2001), while Agirre et al. (2009) separate this benchmark for similarity (WS-SIM) and relatedness (WS-REL). The RG-65 (Rubenstein and Goodenough, 1965) and the MC-30 (Miller and Charles, 1991) benchmarks contain nouns only. The MTurk-287 (Radinsky et al., 2011) and MTurk-771 (Halawi et al., 2012) include word pairs whose similarity was crowdsourced from AMT. Similarly, MEN (Bruni et al., 2012) is an AMT-annotated dataset of 3000 word pairs. The YP-130 (Yang and Powers, 2006) and Verb-143 (Baker et al., 2014) measure verb similarity. Rare-Word (Luong et al., 2013) contains 2034 rare-word pairs. Finally, SimLex-999 (Hill et al., 2014b) is intended to measure pure similarity as opposed to relatedness. For these benchmarks, we prepare the word representations by taking a uniform average of all sense embeddings per word. The evaluation is carried out using the tool described in Faruqui and Dyer (2014a). Due to space constraints, we report the results by averaging over all benchmarks (**Similarity**), and include the individual results in the online repository.

5.2 Supersense similarity

We also evaluate on a task measuring the similarity between the embeddings—in our case uniformly averaged in the case of multi-sense embeddings—and a matrix of supersense features extracted from the English SemCor, using the **Qvec** tool (Tsvetkov et al., 2015). We choose this method because it has been shown to output scores that correlate well with extrinsic tasks, e.g. text classification and sentiment analysis. We believe that this, in combination with word similarity tasks from the previous section, can give a reliable picture of the generic quality of word embeddings studied in this work.

5.3 POS tagging

As our downstream evaluation task, we use the learned word representations to initialize the embedding layer of a neural network tagging model. We use the same convolutional architecture as Li and Jurafsky (2015): an input layer taking a concatenation of neighboring embeddings as input, three hidden layers with a rectified linear unit activation function and a softmax output layer. We train for 10 epochs using one sentence as a batch. Other hyperparameters can be examined in the source code. The multi-sense word embeddings are inferred from the sentential context (weighted average), as for the evaluation on the SCWS dataset. We use the standard splits of the Wall Street Journal portion of the Penn Treebank: 0–18 for training, 19–21 for development and 22–24 for testing.

6 Results

We compare three embeddings models, Skip-Gram (SG), Multi-sense (MU) and Bilingual Multi-sense (BIMU), using our own implementation for each of them. The first two can be seen as simpler variants of the BIMU model: in SG we omit the encoder entirely, and in MU we omit the second-language (l') part of the encoder in Eq. (1). We train the SG and the MU models on the English part of the parallel corpora. Those parameters common to all methods are kept fixed during experiments. The values λ and m for controlling the second-language signal in BIMU are set on the POS-tagging development set (cf. § 6.3).

The results on the **SCWS** benchmark (Table 2) show consistent improvements of the BIMU model over SG and MU across all parallel corpora, except on the small CZ-EN (NC) corpus. We have also measured the 95% confidence intervals of the difference between the correlation coefficients of BIMU and SG, following the method described in Zou (2007). According to these values, BIMU significantly outperforms SG on RU-EN, and on French, Russian and Spanish NC corpora.[5]

Next, ignoring any language-specific factors, we would expect to observe a trend according to which the larger the corpus, the higher the correlation score. However, this is not what we find. Among the largest corpora, i.e. RU-EN, CZ-EN and FR-EN, the models trained on RU-EN perform surprisingly well, practically on par with the 23-times larger FR-EN corpus. Similarly, the quality of the embeddings trained on CZ-EN is generally lower than when trained on the

[5] I.e. counting those results in which the CI of the difference does not include 0.

Task	Corpus	SG	MU	BIMU	BIMU-SG

	CZ-EN	**56.6**	56.5	55.9	
	FR-EN	57.5	57.1	**57.6**	
POS	RU-EN	**93.5**	93.2	93.3	
	CZ-EN	**94.0**	93.7	**94.0**	
	FR-EN	**94.1**	93.8	94.0	

Table 2: Results, per-row best in bold. SG and MU are trained on the English part of the parallel corpora. In BIMU-SG, we report the difference between BIMU and SG, together with the 95% CI of that difference. The **Similarity** scores are averaged over 12 benchmarks described in § 5.1. For POS tagging, we report the accuracy.

10 times smaller RU-EN corpus. One explanation for this might be different text composition of the corpora, with RU-EN matching the domain of the evaluation task better than the larger two corpora. Also, FR-EN is known to be noisy, containing web-crawled sentences that are not parallel or not natural language (Denkowski et al., 2012). Furthermore, language-dependent effects might be playing a role: for example, there are signs of Czech being the least helpful language among those studied. But while there is evidence for that in all intrinsic tasks, the situation in POS tagging does not confirm this speculation.

We relate our models to previously reported SCWS scores from the literature using 300-dimensional models in Table 3. Even though we train on a much smaller corpus than the previous works,[6] the BIMU model achieves a very competitive correlation score.

Model (300-dim.)	SCWS
SG	65.0
MU	66.7
BIMU	69.0
Chen et al. (2014)	68.4
Neelakantan et al. (2014)	69.3
Li and Jurafsky (2015)	69.7

Table 3: Comparison to other works (reprinted), for the vocabulary of top-6000 words. Our models are trained on RU-EN, a much smaller corpus than those used in previous work.

The results on **similarity** benchmarks and **qvec** largely confirm those on SCWS, despite the lack of sentential context which would allow to weight the contribution of different senses more accurately for the multi-sense models. Why, then, does simply averaging the MU and BIMU embeddings lead to better results than when using the SG embeddings? We hypothesize that the single-sense model tends to over-represent the dominant sense with its generic, one-vector-per-word representation, whereas the uniformly averaged embeddings yielded by the multi-sense models better encode the range of potential senses. Similar observations have been made in the context of selectional preference modeling of polysemous verbs (Greenberg et al., 2015).

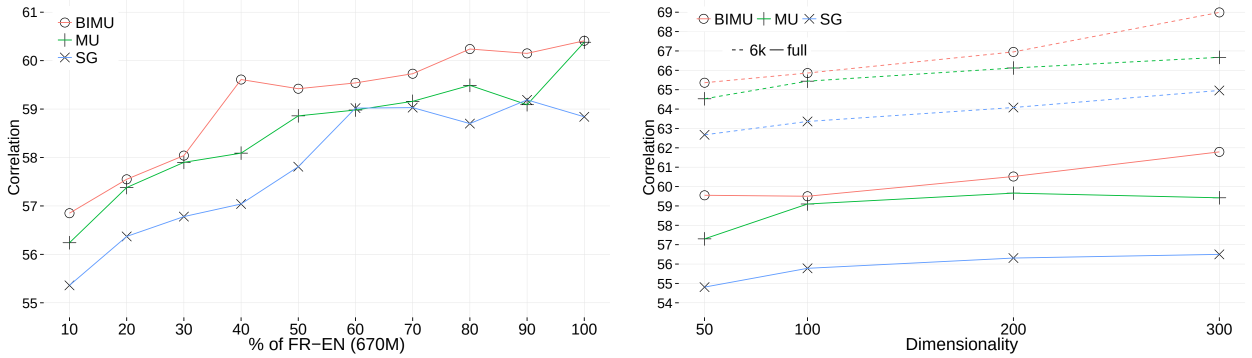
In **POS** tagging, the relationship between MU and BIMU models is similar as discussed above. Overall, however, neither of the multi-sense models outperforms the SG embeddings. The neural network tagger may be able to implicitly perform disambiguation on top of single-sense SG embeddings, similarly to what has been argued in Li and Jurafsky (2015). The tagging accuracies obtained with MU on CZ-EN and FR-EN are similar to the one obtained by Li and Jurafsky with their multi-sense model (93.8), while the accuracy of SG is more competitive in our case (around 94.0 compared to 92.5), although they use a larger corpus for training the word representations.

In all tasks, the addition of the bilingual component during training increases the accuracy of the encoder for most corpora, even though the bilingual information is not available during evaluation.

6.1 The amount of (parallel) data

Fig. 2a displays how the semantic similarity as measured on SCWS evolves as a function of increasingly

[6] For example, Li and Jurafsky (2015) use the concatenation of Gigaword and Wikipedia with more than 5B words.



(a)

(b)

Figure 2: (a) Effect of amount of data used in learning on the SCWS correlation scores. (b) Effect of embedding dimensionality on the models trained on RU-EN and evaluated on SCWS with either full vocabulary or the top-6000 words.

larger sub-samples from FR-EN, our largest parallel corpus. The BiMu embeddings show relatively stable improvements over Mu and especially over Sg embeddings. The same performance as that of Sg at 100% is achieved by Mu and BiMu sooner, using only around 40/50% of the corpus.

6.2 The dimensionality and frequent words

It is argued in Li and Jurafsky (2015) that often just increasing the dimensionality of the Sg model suffices to obtain better results than that of their multi-sense model. We look at the effect of dimensionality on semantic similarity in fig. 2b, and see that simply increasing the dimensionality of the Sg model (to any of 100, 200 or 300 dimensions) is not sufficient to outperform the Mu or BiMu models. When constraining the vocabulary to 6,000 most frequent words, the representations obtain higher quality. We can see that the models, especially Sg, benefit slightly more from the increased dimensionality when looking at these most frequent words. This is according to expectations—frequent words need more representational capacity due to their complex semantic and syntactic behavior (Atkins and Rundell, 2008).

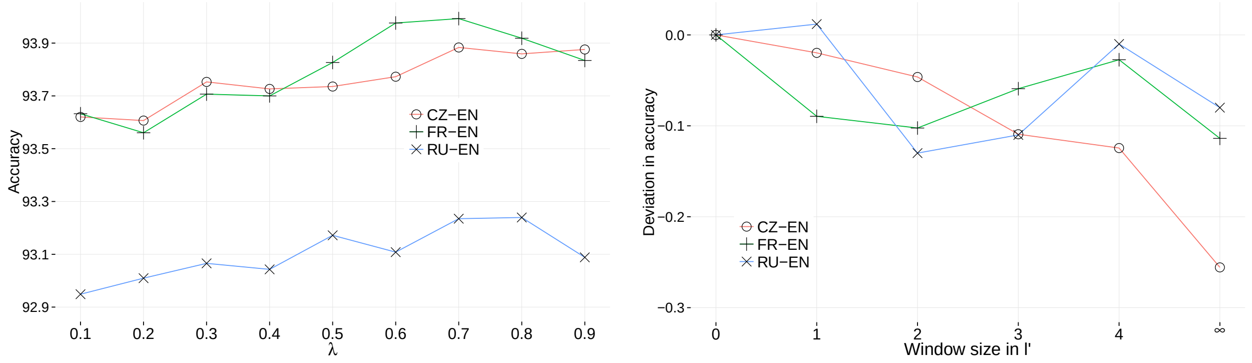
6.3 The role of bilingual signal

The degree of contribution of the second language l' during learning is affected by two parameters, λ for the trade-off between the importance of first and second language in the sense prediction part (encoder) and the value of m for the size of the window around the second-language word affiliated to the pivot. Fig. 3a suggests that the context from the second language is useful in sense prediction, and that it should be weighted relatively heavily (around 0.7 and 0.8, depending on the language).

Regarding the role of the context-window size in sense disambiguation, the WSD literature has reported both smaller (more local) and larger (more topical) monolingual contexts to be useful, see e.g. Ide and Véronis (1998) for an overview. In fig. 3b we find that considering a very narrow context in the second language—the affiliated word only or a $m = 1$ window around it—performs the best, and that there is little gain in using a broader window. This is understandable since the l' representation participating in the sense selection is simply an average over all generic embeddings in the window, which means that the averaged representation probably becomes noisy for large m, i.e. more irrelevant words are included in the window. However, the negative effect on the accuracy is still relatively small, up to around -0.1 for the models using French and Russian as the second languages, and -0.25 for Czech when setting $m = \infty$. The infinite window size setting, corresponding to the sentence-only alignment, performs well also on SCWS, improving on the monolingual multi-sense baseline on all corpora (Table 4).

Model	RU-EN	CZ-EN	FR-EN
Mu	63.29	59.12	64.19
BiMu, $m = \infty$	**65.61**	**62.07**	**64.36**

Table 4: Comparison of SCWS correlation scores of BiMu trained with infinite l' window to the Mu baseline (vocabulary of top-6000 words).



(a) (b)

Figure 3: Controlling the bilingual signal. (a) Effect of varying the parameter λ for controlling the importance of second-language context (0.1-least important, 0.9-most important). (b) Effect of second-language window size m on the accuracy. In both (a) and (b) the reported accuracies are measured on the POS-tagging development set.

6.4 The number of senses

In our work, the number of senses k is a model parameter, which we keep fixed to 3 throughout the empirical study. We comment here briefly on other choices of $k \in \{2, 4, 5\}$. We have found $k = 2$ to be a good choice on the RU-EN and FR-EN corpora (but not on CZ-EN), with an around 0.2-point improvement over $k = 3$ on SCWS and in POS tagging. With the larger values of k, the performance tends to degrade. For example, on RU-EN, the $k = 5$ score on SCWS is about 0.6 point below our default setting.

7 Additional Related Work

Multi-sense models. One line of research has dealt with sense induction as a separate, clustering problem that is followed by an embedding learning component (Huang et al., 2012; Reisinger and Mooney, 2010). In another, the sense assignment and the embeddings are trained jointly (Neelakantan et al., 2014; Tian et al., 2014; Li and Jurafsky, 2015; Bartunov et al., 2015). Neelakantan et al. (2014) propose an extension of Skip-Gram (Mikolov et al., 2013a) by introducing sense-specific parameters together with the k-means-inspired 'centroid' vectors that keep track of the contexts in which word senses have occurred. They explore two model variants, one in which the number of senses is the same for all words, and another in which a threshold value determines the number of senses for each word. The results comparing the two variants are inconclusive, with the advantage of the dynamic variant being virtually nonexistent. In our work, we use the static approach. Whenever there is evidence for less senses than the number of available sense vectors, this is unlikely to be a serious issue as the learning would concentrate on some of the senses, and these would then be the preferred predictions also at test time. Li and Jurafsky (2015) build upon the work of Neelakantan et al. with a more principled method for introducing new senses using the Chinese Restaurant Processes (CRP). Our experiments confirm the findings of Neelakantan et al. that multi-sense embeddings improve Skip-gram embeddings on intrinsic tasks, as well as those of Li and Jurafsky, who find that multi-sense embeddings offer little benefit to the neural network learner on extrinsic tasks. Our discrete-autoencoding method when viewed without the bilingual part in the encoder has a lot in common with their methods.

Multilingual models. The research on using multilingual information in the learning of *multi-sense* embedding models is scarce. Guo et al. (2014) perform a sense induction step based on clustering translations prior to learning word embeddings. Once the translations are clustered, they are mapped to a source corpus using WSD heuristics, after which a recurrent neural network is trained to obtain sense-specific representations. Unlike in our work, the sense induction and embedding learning components are entirely separated, without a possibility for one to influence another. In a similar vein, Bansal et al. (2012) use bilingual corpora to perform soft word clustering, extending the previous work on the monolingual case of

Lin and Wu (2009). *Single-sense* representations in the multilingual context have been studied more extensively (Lu et al., 2015; Faruqui and Dyer, 2014b; Hill et al., 2014a; Zhang et al., 2014; Faruqui and Dyer, 2013; Zou et al., 2013), with a goal of bringing the representations in the same semantic space. A related line of work concerns the crosslingual setting, where one tries to leverage training data in one language to build models for typically lower-resource languages (Hermann and Blunsom, 2014; Gouws et al., 2014; Chandar A P et al., 2014; Soyer et al., 2014; Klementiev et al., 2012; Täckström et al., 2012).

The recent works of Kawakami and Dyer (2015) and Nalisnick and Ravi (2015) are also of interest. The latter work on the infinite Skip-Gram model in which the embedding dimensionality is stochastic is relevant since it demonstrates that their embeddings exploit different dimensions to encode different word meanings. Just like us, Kawakami and Dyer (2015) use bilingual supervision, but in a more complex LSTM network that is trained to predict word translations. Although they do not represent different word senses separately, their method produces representations that depend on the context. In our work, the second-language signal is introduced only in the sense prediction component and is flexible—it can be defined in various ways and can be obtained from sentence-only alignments as a special case.

8 Conclusion

We have presented a method for learning multi-sense embeddings that performs sense estimation and context prediction jointly. Both mono- and bilingual information is used in the sense prediction during training. We have explored the model performance on a variety of tasks, showing that the bilingual signal improves the sense predictor, even though the crosslingual information is not available at test time. In this way, we are able to obtain word representations that are of better quality than the monolingually-trained multi-sense representations, and that outperform the Skip-Gram embeddings on intrinsic tasks. We have analyzed the model performance under several conditions, namely varying dimensionality, vocabulary size, amount of data, and size of the second-language context. For the latter parameter, we find that bilingual information is useful even when using the entire sentence as context, suggesting that sentence-only alignment might be sufficient in certain situations.

Acknowledgments

We would like to thank Jiwei Li for providing his tagger implementation, and Robert Grimm, Diego Marcheggiani and the anonymous reviewers for useful comments. Polyglot Neural Language Models:
A Case Study in Cross-Lingual Phonetic Representation Learning

Abstract

We introduce polyglot language models, recurrent neural network models trained to predict symbol sequences in many different languages using shared representations of symbols and conditioning on typological information about the language to be predicted. We apply these to the problem of modeling phone sequences—a domain in which universal symbol inventories and cross-linguistically shared feature representations are a natural fit. Intrinsic evaluation on held-out perplexity, qualitative analysis of the learned representations, and extrinsic evaluation in two downstream applications that make use of phonetic features show (i) that polyglot models better generalize to held-out data than comparable monolingual models and (ii) that polyglot phonetic feature representations are of higher quality than those learned monolingually.

1 Introduction

Nearly all existing language model (LM) architectures are designed to model one language at a time. This is unsurprising considering the historical importance of count-based models in which every surface form of a word is a separately modeled entity (English *cat* and Spanish *gato* would not likely benefit from sharing counts). However, recent models that use distributed representations—in particular models that share representations across languages (Hermann and Blunsom, 2014; Faruqui and Dyer, 2014; Huang et al., 2015; Lu et al., 2015, *inter alia*)—suggest universal models applicable to multiple languages are a possibility. This paper takes a step in this direction.

We introduce **polyglot language models**: neural network language models that are trained on and applied to any number of languages. Our goals with these models are the following. First, to facilitate data and parameter sharing, providing more training resources to languages, which is especially valuable in low-resource settings. Second, models trained on diverse languages with diverse linguistic properties will better be able to learn naturalistic representations that are less likely to "overfit" to a single linguistic outlier. Finally, polyglot models offer convenience in a multilingual world: a single model replaces dozens of different models.

Exploration of polyglot language models at the sentence level—the traditional domain of language modeling—requires dealing with a massive event space (i.e., the union of words across many languages). To work in a more tractable domain, we evaluate our model on phone-based language modeling, the modeling sequences of *sounds*, rather than words. We choose this domain since a common assumption of many theories of phonology is that all spoken languages construct words from a finite inventory of phonetic symbols (represented conveniently as the elements of the the International Phonetic Alphabet; IPA) which are distinguished by language-universal features (e.g., place and manner of articulation, voicing status, etc.). Although our focus is on sound sequences, our solution can be ported to the semantic/syntactic problem as resulting from adaptation to constraints on semantic/syntactic structure.

This paper makes two primary contributions: in

Proceedings of NAACL-HLT 2016, pages 1357–1366,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

modeling and in applications. In §2, we introduce a novel polyglot neural language model (NLM) architecture. Despite being trained on multiple languages, the multilingual model is more effective (9.5% lower perplexity) than individual models, and substantially more effective than naive baselines (over 25% lower perplexity). Our most effective polyglot architecture conditions not only on the identity of the language being predicted in each sequence, but also on a vector representation of its phono-typological properties. In addition to learning representations of phones as part of the polyglot language modeling objective, the model incorporates features about linguistic typology to improve generalization performance (§3). Our second primary contribution is to show that downstream applications are improved by using polyglot-learned phone representations. We focus on two tasks: predicting adapted word forms in models of cross-lingual lexical borrowing and speech synthesis (§4). Our experimental results (§5) show that in borrowing, we improve over the current state-of-the-art, and in speech synthesis, our features are more effective than manually-designed phonetic features. Finally, we analyze the phonological content of learned representations, finding that our polyglot models discover standard phonological categories such as length and nasalization, and that these are grouped correctly across languages with different phonetic inventories and contrastive features.

2 Model

In this section, we first describe in §2.1 the underlying framework of our model—RNNLM—a standard recurrent neural network based language model (Mikolov et al., 2010; Sundermeyer et al., 2012). Then, in §2.2, we define a Polyglot LM—a modification of RNNLM to incorporate language information, both learned and hand-crafted.

Problem definition. In the phonological LM, *phones* (sounds) are the basic units. Mapping from words to phones is defined in pronunciation dictionaries. For example, “cats” [kæts] is a sequence of four phones. Given a prefix of phones $\phi_1, \phi_2, \ldots, \phi_{t-1}$, the task of the LM is to estimate the conditional probability of the next phone $p(\phi_t \mid \phi_1, \phi_2, \ldots, \phi_{t-1})$.

2.1 RNNLM

In NLMs, a vocabulary V (here, a set of phones composing all word types in the language) is represented as a matrix of parameters $\mathbf{X} \in \mathbb{R}^{d \times |V|}$, with $|V|$ phone types represented as d-dimensional vectors. $\mathbf{X}$ is often denoted as lookup table. Phones in the input sequence are first converted to phone vectors, where ϕ_i is represented by $\mathbf{x}_i$ by multiplying the phone indicator (one-hot vector of length $|V|$) and the lookup table.

At each time step t, most recent phone prefix vector[1] $\mathbf{x}_t$ and hidden state $\mathbf{h}_{t-1}$ are transformed to compute a new hidden representation:

$$\mathbf{h}_t = f(\mathbf{x}_t, \mathbf{h}_{t-1}),$$

where f is a non-linear transformation. In the original RNNLMs (Mikolov et al., 2010), the transformation is such that:

$$\mathbf{h}_t = \tanh(\mathbf{W}_{h_x}\mathbf{x}_t + \mathbf{W}_{h_h}\mathbf{h}_{t-1} + \mathbf{b}_h).$$

To overcome the notorious problem in recurrent neural networks of vanishing gradients (Bengio et al., 1994), following Sundermeyer et al. (2012), in recurrent layer we use long short-term memory (LSTM) units (Hochreiter and Schmidhuber, 1997):[2]

$$\mathbf{h}_t = \mathrm{LSTM}(\mathbf{x}_t, \mathbf{h}_{t-1}).$$

Given the hidden sequence $\mathbf{h}_t$, the output sequence is then computed as follows:

$$p(\phi_t = i \mid \phi_1, \ldots, \phi_{t-1}) = \\ \mathrm{softmax}(\mathbf{W}_{out}\mathbf{h}_t + \mathbf{b}_{out})_i,$$

where $\mathrm{softmax}(x_i) = \frac{e^{x_i}}{\sum_j e^{x_j}}$ ensures a valid probability distribution over output phones.

[1] We are reading at each time step the most recent n-gram context rather than—as is more common in RNNLMs—a single phone context. Empirically, this works better for phone sequences, and we hypothesize that this lets the learner rely on direct connections for local phenomena (which are abundant in phonology) and minimally use the recurrent state to model longer-range effects.

[2] For brevity, we omit the equations describing the LSTM cells; they can be found in (Graves, 2013, eq. 7–11).

2.2 Polyglot LM

We now describe our modifications to RNNLM to account for multilinguality. The architecture is depicted in figure 1. Our task is to estimate the conditional probability of the next phone given the preceding phones and the language (ℓ): $p(\phi_t \mid \phi_1, \ldots, \phi_{t-1}, \ell)$.

In a multilingual NLM, we define a vocabulary V^* to be the union of vocabularies of all training languages, assuming that all language vocabularies are mapped to a shared representation (here, IPA). In addition, we maintain V_ℓ with a special symbol for each language (e.g., $\phi_{english}$, ϕ_{arabic}). Language symbol vectors are parameters in the new lookup table $\mathbf{X}_\ell \in \mathbb{R}^{d \times |\#langs|}$ (e.g., $\mathbf{x}_{english}$, $\mathbf{x}_{arabic}$). The inputs to the Polyglot LM are the phone vectors $\mathbf{x}_t$, the language character vector $\mathbf{x}_\ell$, and the typological feature vector constructed externally $\mathbf{t}_\ell$. The typological feature vector will be discussed in the following section.

The input layer is passed to the hidden local-context layer:

$$\mathbf{c}_t = \mathbf{W}_{c_x}\mathbf{x}_t + \mathbf{W}_{c_{lang}}\mathbf{x}_{lang} + \mathbf{b}_c.$$

The local-context vector is then passed to the hidden LSTM global-context layer, similarly to the previously described RNNLM:

$$\mathbf{g}_t = \mathrm{LSTM}(\mathbf{c}_t, \mathbf{g}_{t-1}).$$

In the next step, the global-context vector $\mathbf{g}_t$ is "factored" by the typology of the training language, to integrate manually-defined language features. To obtain this, we first project the (potentially high-dimensional) $\mathbf{t}_\ell$ into a low-dimensional vector, and apply non-linearity. Then, we multiply the $\mathbf{g}_t$ and the projected language layer, to obtain a global-context-language matrix:

$$\mathbf{f}_\ell = \tanh(\mathbf{W}_\ell \mathbf{t}_\ell + \mathbf{b}_\ell),$$
$$\mathbf{G}_t^\ell = \mathbf{g}_t \otimes \mathbf{f}_\ell^\top.$$

Finally, we vectorize the resulting matrix into a column vector and compute the output sequence as follows:

$$p(\phi_t = i \mid \phi_1, \ldots, \phi_{t-1}, \ell) = \mathrm{softmax}(\mathbf{W}_{out}\mathrm{vec}(\mathbf{G}_t^\ell) + \mathbf{b}_{out})_i.$$

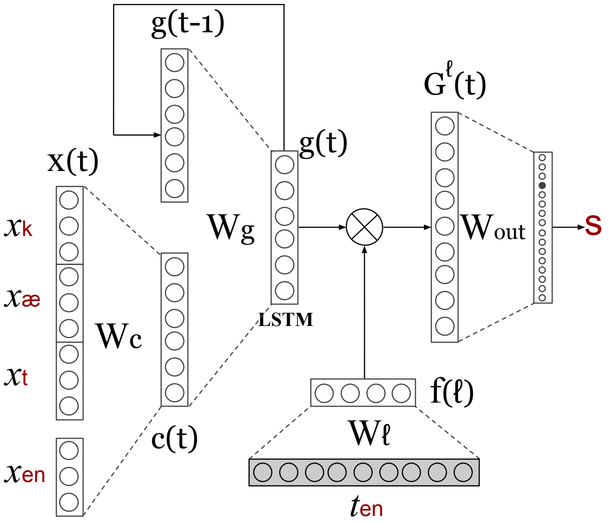

Figure 1: Architecture of the Polyglot LM.

Model training. Parameters of the models are the lookup tables $\mathbf{X}$ and $\mathbf{X}_\ell$, weight matrices $\mathbf{W}_i$, and bias vectors $\mathbf{b}_i$. Parameter optimization is performed using stochastic updates to minimize the categorical cross-entropy loss (which is equivalent to minimizing perplexity and maximizing likelihood): $H(\phi, \hat{\phi}) = -\Sigma_i \hat{\phi}_i \log \phi_i$, where ϕ is predicted and $\hat{\phi}$ is the gold label.

3 Typological features

Typological information is fed to the model via vectors of 190 binary typological features, all of which are phonological (related to sound structure) in their nature. These feature vectors are derived from data from the WALS (Dryer and Haspelmath, 2013), PHOIBLE (Moran et al., 2014), and Ethnologue (Lewis et al., 2015) typological databases via extensive post-processing and analysis.[3] The features primarily concern properties of sound inventories (i.e., the set of phones or phonemes occurring in a language) and are mostly of one of four types:

1. **Single segment represented in an inventory**;

[3] This data resource, which provides standardized phono-typological information for 2,273 languages, is available at `https://github.com/dmort27/uriel-phonology/tarball/0.1`. It is a subset of the URIEL database, a comprehensive database of typological features encoding syntactic and morphological (as well as phonological) properties of languages. It is available at `http://cs.cmu.edu/~dmortens/uriel.html`.

e.g., does language ℓ's sound inventory include /g/, a voiced velar stop?

2. **Class of segments represented in an inventory**; e.g., does language ℓ's sound inventory include voiced fricatives like /z/ and /v/?
3. **Minimal contrast represented in an inventory**; e.g., does language ℓ's sound inventory include two sounds that differ only in voicing, such as /t/ and /d/?
4. **Number of sounds representative of a class that are present in an inventory**; e.g., does language ℓ's sound inventory include exactly five vowels?

The motivation and criteria for coding each individual feature required extensive linguistic knowledge and analysis. Consider the case of tense vowels like /i/ and /u/ in "beet" and "boot" in contrast with lax vowels like /ɪ/ and /ʊ/ in "bit" and "book." Only through linguistic analysis does it become evident that (1) all languages have tense vowels—a feature based on the presence of tense vowels is uninformative and that (2) a significant minority of languages make a distinction between tense and lax vowels—a feature based on whether languages display a minimal difference of this kind would be more useful.

4 Applications of Phonetic Vectors

Learned continuous word representations—word vectors—are an important by-product of neural LMs, and these are used as features in numerous NLP applications, including chunking (Turian et al., 2010), part-of-speech tagging (Ling et al., 2015), dependency parsing (Lazaridou et al., 2013; Bansal et al., 2014; Dyer et al., 2015; Watanabe and Sumita, 2015), named entity recognition (Guo et al., 2014), and sentiment analysis (Socher et al., 2013; Wang et al., 2015). We evaluate phone vectors learned by Polyglot LMs in two downstream applications that rely on phonology: modeling lexical borrowing (§4.1) and speech synthesis (§4.2).

4.1 Lexical borrowing

Lexical borrowing is the adoption of words from another language, that inevitably happens when speakers of different languages communicate for a long period of time (Thomason and Kaufman, 2001). Borrowed words—also called *loanwords*—constitute 10–70% of most language lexicons (Haspelmath, 2009); these are content words of foreign origin that are adapted in the language and are not perceived as foreign by language speakers. Computational modeling of cross-lingual transformations of loanwords is effective for inferring lexical correspondences across languages with limited parallel data, benefiting applications such as machine translation (Tsvetkov and Dyer, 2015; Tsvetkov and Dyer, 2016).

In the process of their nativization in a foreign language, loanwords undergo primarily **phonological adaptation**, namely insertion/deletion/substitution of phones to adapt to the phonotactic constraints of the recipient language. If a foreign phone is not present in the recipient language, it is usually replaced with its closest native equivalent—we thus hypothesize that cross-lingual phonological features learned by the Polyglot LM can be useful in models of borrowing to quantify cross-lingual similarities of sounds.

To test this hypothesis, we augment the hand-engineered models proposed by Tsvetkov and Dyer (2016) with features from phone vectors learned by our model. Inputs to the borrowing framework are loanwords (in Swahili, Romanian, Maltese), and outputs are their corresponding "donor" words in the donor language (Arabic, French, Italian, resp.). The framework is implemented as a cascade of finite-state transducers with insertion/deletion/substitution operations on sounds, weighted by high-level conceptual linguistic constraints that are learned in a supervised manner. Given a loanword, the system produces a candidate donor word with lower ranked violations than other candidates, using the shortest path algorithm. In the original borrowing model, insertion/deletion/substitution operations are unweighted. In this work, we integrate transition weights in the phone substitution transducers, which are cosine distances between phone vectors learned by our model. Our intuition is that similar sounds appear in similar contexts, even if they are not present in the same language (e.g., /$s^{ʕ}$/ in Arabic is adapted to /s/ in Swahili). Thus, if our model effectively captures cross-lingual signals, similar sounds should have smaller distances in the vector space, which can improve the shortest path results. Figure 2 illustrates our modifications to the original framework.

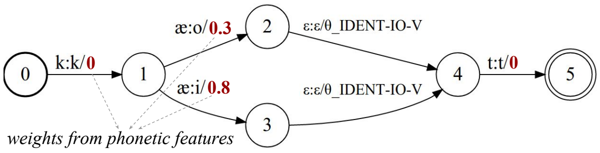

Figure 2: Distances between phone vectors learned by the Polyglot LM are integrated as substitution weights in the lexical borrowing transducers. An English word *cat* [kæt] is adapted to its Russian counterpart КОТ [kot]. The transducer has also an erroneous path to КИТ [kit] 'whale'. In the original system, both paths are weighted with the same feature IDENT-IO-V, firing on vowel substitution. Our modification allows the borrowing model to identify more plausible paths by weighting substitution operations.

4.2 Speech synthesis

Speech synthesis is the process of converting text into speech. It has various applications, such as screen readers for the visually impaired and hands-free voice based systems. Text-to-speech (TTS) systems are also used as part of speech-to-speech translation systems and spoken dialog systems, such as personal digital assistants. Natural and intelligible TTS systems exist for a number of languages in the world today. However, building TTS systems remains prohibitive for many languages due to the lack of linguistic resources and data.

The language-specific resources that are traditionally used for building TTS systems in a new language are: (1) audio recordings with transcripts; (2) pronunciation lexicon or letter to sound rules; and (3) a phone set definition. Standard TTS systems today use phone sets designed by experts. Typically, these phone sets also contain phonetic features for each phoneme, which are used as features in models of the spectrum and prosody. The phonetic features available in standard TTS systems are multidimensional vectors indicating various properties of each phoneme, such as whether it is a vowel or consonant, vowel length and height, place of articulation of a consonant, etc. Constructing these features by hand can be labor intensive, and coming up with such features automatically may be useful in low-resource scenarios.

In this work, we replace manually engineered phonetic features with phone vectors, which are then used by classification and regression trees for modeling the spectrum. Each phoneme in our phone set is assigned an automatically constructed phone vector, and each member of the phone vector is treated as a phoneme-level feature which is used in place of the manually engineered phonetic features. While prior work has explored TTS augmented with acoustic features (Watts et al., 2015), to the best of our knowledge, we are the first to replace manually engineered phonetic features in TTS systems with automatically constructed phone vectors.

5 Experiments

Our experimental evaluation of our proposed polyglot models consists of two parts: (i) an intrinsic evaluation where phone sequences are modeled with independent models and (ii) an extrinsic evaluation of the learned phonetic representations. Before discussing these results, we provide details of the data resources we used.

5.1 Resources and experimental setup

Resources. We experiment with the following languages: Arabic (AR), French (FR), Hindi (HI), Italian (IT), Maltese (MT), Romanian (RO), Swahili (SW), Tamil (TA), and Telugu (TE). In our language modeling experiments, two main sources of data are pronunciation dictionaries and typological features described in §3. The dictionaries for AR, FR, HI, TA, and TE are taken from in-house speech recognition/synthesis systems. For remaining languages, the dictionaries are automatically constructed using the Omniglot grapheme-to-IPA conversion rules.[4]

We use two types of pronunciation dictionaries: (1) AR, FR, HI, IT, MT, RO, and SW dictionaries used in experiments with lexical borrowing; and (2) EN, HI, TA, and TE dictionaries used in experiments with speech synthesis. The former are mapped to IPA, with the resulting phone vocabulary size—the number of distinct phones across IPA dictionaries—of 127 phones. The latter are encoded using the UniTran universal transliteration resource (Qian et al., 2010), with a vocabulary of 79 phone types.

From the (word-type) pronunciation dictionaries, we remove 15% of the words for development, and a further 10% for testing; the rest of the data is

	EN	HI	TA	TE
train	101/867	191/1,523	74/780	71/690
dev	20/169	37/300	14/152	14/135
test	11/97	21/171	8/87	8/77

Table 2: Train/dev/test statistics for UniTran pronunciation dictionaries for words (phone sequences) and phone tokens, in thousands: #thousands of sequences/# thousands of tokens.

used to train the models. In tables 1 and 2 we list—for both types of pronunciation dictionaries—train/dev/test data statistics for words (phone sequences) and phone tokens. We concatenate each phone sequence with beginning and end symbols (<*s*>, </*s*>).

Hyperparameters. We used the following network architecture: 100-dimensional phone vectors, with hidden local-context and LSTM layers of size 100, and hidden language layer of size 20. All language models were trained using the left context of 3 phones (4-gram LMs). Across all language modeling experiments, parameter optimization was performed on the dev set using the Adam algorithm (Kingma and Ba, 2014) with mini-batches of size 100 to train the models for 5 epochs.

5.2 Intrinsic perplexity evaluation

Perplexity is the standard evaluation measure for language models, which has been shown to correlate strongly with error rates in downstream applications (Klakow and Peters, 2002). We evaluated perplexities across several architectures, and several monolingual and multilingual setups. We kept the same hyper-parameters across all setups, as detailed in §5. Perplexities of LMs trained on the two types of pronunciation dictionaries were evaluated separately; table 3 summarizes perplexities of the models trained on IPA dictionaries, and table 4 summarizes perplexities of the UniTran LMs.

In columns, we compare three model architectures: *baseline* denotes the standard RNNLM architecture described in §2.1; *+lang* denotes the Polyglot LM architecture described in §2.2 with input language vector but without typological features and language layer; finally, *+typology* denotes the full Polyglot LM architecture. This setup lets us separately evaluate the contribution of modified architecture and the contribution of auxiliary set of features introduced via the language layer.

Test languages are IT in table 3, and HI in table 4. The rows correspond to different sets of training languages for the models: *monolingual* is for training and testing on the same language; *+similar* denotes training on three typologically similar languages: IT, FR, RO in table 3, and HI, TA, TE in table 4; *+dissimilar* denotes training on four languages, three similar and one typologically dissimilar language, to evaluate robustness of multilingual systems to diverse types of data. The final sets of training languages are IT, FR, RO, HI in table 3, and HI, TA, TE, EN in table 4.

	Perplexity (↓)			
training set	baseline	+lang	+typology	
monolingual	4.36	–	–	
+similar	5.73	4.93	**4.24**	(↓ 26.0%)
+dissimilar	5.88	4.98	**4.41**	(↓ 25.0%)

Table 3: Perplexity experiments with IT as test language. Training languages: monolingual: IT; +similar: IT, FR, RO; +dissimilar: IT, FR, RO, HI.

	Perplexity (↓)			
training set	baseline	+lang	+typology	
monolingual	3.70	–	–	
+similar	4.14	3.78	**3.35**	(↓ 19.1%)
+dissimilar	4.29	3.82	**3.42**	(↓ 20.3%)

Table 4: Perplexity experiments with HI as test language. Training languages: monolingual: HI; +similar: HI, TA, TE; +dissimilar: HI, TA, TE, EN.

We see several patterns of results. First, polyglot models require, unsurprisingly, information about what language they are predicting to obtain good modeling performance. Second, typological information is more valuable than letting the model learn representations of the language along with the characters. Finally, typology-augmented polyglot models outperform their monolingual baseline, providing evidence in support of the hypothesis that cross-lingual evidence is useful not only for learning cross-lingual representations and models, but monolingual ones as well.

5.3 Lexical borrowing experiments

We fully reproduced lexical borrowing models described in (Tsvetkov and Dyer, 2016) for three language pairs: AR–SW, FR–RO, and IT–MT. Train and test corpora are donor–loanword pairs in the language pairs. Corpora statistics are given in table 5 (note that these are extremely small data sets; thus small numbers of highly informative features a necessary for good generalization). We use the reproduced systems as the baselines, and compare these to the corresponding systems augmented with phone vectors, as described in §4.1.

	AR–SW	FR–RO	IT–MT
train	417	282	425
test	73	50	75

Table 5: Number of training and test pairs the the borrowing datasets.

Integrated vectors were obtained from a single polyglot model with typology, trained on all languages with IPA dictionaries. For comparison with the results in table 3, perplexity of the model on the IT dataset (used for evaluation is §5.2) is 4.16, even lower than in the model trained on four languages. To retrain the high-level conceptual linguistic features learned by the borrowing models, we initialized the augmented systems with feature weights learned by the baselines, and retrained. Final weights were established using cross-validation. Then, we evaluated the accuracy of the augmented borrowing systems on the held-out test data.

Accuracies are shown in table 6. We observe improvements of up to 5% in accuracies of FR–RO and IT–MT pairs. Effectiveness of the same polyglot model trained on multiple languages and integrated in different downstream systems supports our assumption that the model remains stable and effective with addition of languages. Our model is less effective for the AR–SW language pair. We speculate that the results are worse, because this is a pair of (typologically) more distant languages; consequently, the phonological adaptation processes that happen in loanword assimilation are more complex than mere substitutions of similar phones that we are targeting via the integration of phone vectors.

	Accuracy (↑)		
	AR–SW	FR–RO	IT–MT
baseline	**48.4**	75.6	83.3
+multilingual	46.9	**80.6**	**87.1**

Table 6: Accuracies of the baseline models of lexical borrowing and the models augmented with phone vectors. In all the experiments, we use vectors from a single Polyglot LM model trained on AR, SW, FR, RO, IT, MT.

5.4 Speech synthesis experiments

A popular objective metric for measuring the quality of synthetic speech is the Mel Cepstral Distortion (MCD) (Hu and Loizou, 2008). The MCD metric calculates an L2 norm of the Mel Frequency Cepstral Coefficients (MFCCs) of natural speech from a held out test set, and synthetic speech generated from the same test set. Since this is a distance metric, a lower value of MCD suggests better synthesis. The MCD is a database-specific metric, but experiments by Kominek et al. (Kominek et al., 2008) have shown that a decrease in MCD of 0.08 is perceptually significant, and a decrease of 0.12 is equivalent to doubling the size of the TTS database. In our experiments, we use MCD to measure the relative improvement obtained by our techniques.

We conducted experiments on the IIIT-H Hindi voice database (Prahallad et al., 2012), a 2 hour single speaker database recorded by a professional male speaker. We used the same front end (UniTran) to build all the Hindi TTS systems, with the only difference between the systems being the presence or absence of phonetic features and our vectors. For all our voice-based experiments, we built CLUSTERGEN Statistical Parametric Synthesis voices (Black, 2006) using the Festvox voice building tools (Black and Lenzo, 2003) and the Festival speech synthesis engine (Black and Taylor, 1997).

The baseline TTS system was built using no phonetic features. We also built a TTS system with standard hand-crafted phonetic features. Table 7 shows the MCD for the HI baseline, the standard TTS with hand-crafted features, and augmented TTS systems built using monolingual and multilingual phone vectors constructed with Polyglot LMs.

	MCD (↓)
baseline	4.58
+monolingual	4.40
+multilingual	**4.39**
+hand-crafted	4.41

Table 7: MCD for the HI TTS systems. Polyglot LM training languages: monolingual: HI; +multilingual: HI, TA, TE, EN.

Our multilingual vectors outperform the baseline, with a significant decrease of 0.19 in MCD. Crucially, TTS systems augmented with the Polyglot LM phone vectors outperform also the standard TTS with hand-crafted features. We found that using both feature sets added no value, suggesting that learned phone vectors are capturing information that is equivalent to the hand-engineered vectors.

5.5 Qualitative analysis of vectors

Phone vectors learned by Polyglot LMs are mere sequences of real numbers. An interesting question is whether these vectors capture linguistic (phonological) qualities of phones they are encoding. To analyze to what extent our vectors capture linguistic properties of phones, we use the QVEC—a tool to quantify and interpret linguistic content of vector space models (Tsvetkov et al., 2015). The tool aligns dimensions in a matrix of learned distributed representations with dimensions of a hand-crafted linguistic matrix. Alignments are induced via correlating columns in the distributed and the linguistic matrices. To analyze the content of the distributed matrix, annotations from the linguistic matrix are projected via the maximally-correlated alignments.

We constructed a phonological matrix in which 5,059 rows are IPA phones and 21 columns are boolean indicators of universal phonological properties, e.g. *consonant*, *voiced*, *labial*.[5] We the projected annotations from the linguistic matrix and manually examined aligned dimensions in the phone vectors from §5.3 (trained on six languages). In the maximally-correlated columns—corresponding to linguistic features *long*, *consonant*, *nasalized*—we examined phones with highest coefficients. These were: [ɐː, ʊː, iː, ɔː, ɛː] for *long*; [v, ɲ, d͡ʒ, d, f, j, t͡s, ŋ] for *consonant*; and [ɔ̃, ɛ̃, ɑ̃, œ̃] for *nasalized*. Clearly, the learned representation discover standard phonological features. Moreover, these top-ranked sounds are not grouped by a single language, e.g., /d͡ʒ/ is present in Arabic but not in French, and /ɲ, ŋ/ are present in French but not in Arabic. From this analysis, we conclude that (1) the model discovers linguistically meaningful phonetic features; (2) the model induces meaningful related groupings across languages.

6 Related Work

Multilingual language models. Interpolation of monolingual LMs is an alternative to obtain a multilingual model (Harbeck et al., 1997; Weng et al., 1997). However, interpolated models still require a trained model per language, and do not allow parameter sharing at training time. Bilingual language models trained on concatenated corpora were explored mainly in speech recognition (Ward et al., 1998; Wang et al., 2002; Fügen et al., 2003). Adaptations have been proposed to apply language models in bilingual settings in machine translation (Niehues et al., 2011) and code switching (Adel et al., 2013). These approaches, however, require adaptation to every pair of languages, and an adapted model cannot be applied to more than two languages.

Independently, Ammar et al. (2016) used a different polyglot architecture for multilingual dependency parsing. This work has also confirmed the utility of polyglot architectures in leveraging multilinguality.

Multimodal neural language models. Multimodal language modeling is integrating image/video modalities in text LMs. Our work is inspired by the neural multimodal LMs (Kiros and Salakhutdinov, 2013; Kiros et al., 2015), which defined language models conditional on visual contexts, although we use a different language model architecture (recurrent vs. log-bilinear) and a different approach to gat-

[5] This matrix is described in Littell et al. (2016) and is available at `https://github.com/dmort27/panphon/`.

ing modality.

7 Conclusion

We presented a novel *multilingual* language model architecture. The model obtains substantial gains in perplexity, and improves downstream text and speech applications. Although we focus on phonology, our approach is general, and can be applied in problems that integrate divergent modalities, e.g., topic modeling, and multilingual tagging and parsing.

Abstract

Unsupervised methods for learning distributed representations of words are ubiquitous in today's NLP research, but far less is known about the best ways to learn distributed phrase or sentence representations from unlabelled data. This paper is a systematic comparison of models that learn such representations. We find that the optimal approach depends critically on the intended application. Deeper, more complex models are preferable for representations to be used in supervised systems, but shallow log-bilinear models work best for building representation spaces that can be decoded with simple spatial distance metrics. We also propose two new unsupervised representation-learning objectives designed to optimise the trade-off between training time, domain portability and performance.

1 Introduction

Distributed representations - dense real-valued vectors that encode the semantics of linguistic units - are ubiquitous in today's NLP research. For single-words or word-like entities, there are established ways to acquire such representations from naturally occurring (unlabelled) training data based on comparatively task-agnostic objectives (such as predicting adjacent words). These methods are well understood empirically (Baroni et al., 2014b) and theoretically (Levy and Goldberg, 2014). The best word representation spaces reflect consistently-observed aspects of human conceptual organisation (Hill et al., 2015b), and can be added as features to improve the performance of numerous language processing systems (Collobert et al., 2011).

By contrast, there is comparatively little consensus on the best ways to learn distributed representations of phrases or sentences.[1] With the advent of deeper language processing techniques, it is relatively common for models to represent phrases or sentences as continuous-valued vectors. Examples include machine translation (Sutskever et al., 2014), image captioning (Mao et al., 2015) and dialogue systems (Serban et al., 2015). While it has been observed informally that the internal sentence representations of such models can reflect semantic intuitions (Cho et al., 2014), it is not known which architectures or objectives yield the 'best' or most useful representations. Resolving this question could ultimately have a significant impact on language processing systems. Indeed, it is phrases and sentences, rather than individual words, that encode the human-like general world knowledge (or 'common sense') (Norman, 1972) that is a critical missing part of most current language understanding systems.

We address this issue with a systematic comparison of cutting-edge methods for learning distributed representations of sentences. We focus on methods that do not require labelled data gathered for the purpose of training models, since such methods are more cost-effective and applicable across languages and domains. We also propose two new phrase or sentence representation learning objectives - *Sequential Denoising Autoencoders* (SDAEs)

[1] See the contrasting conclusions in (Mitchell and Lapata, 2008; Clark and Pulman, 2007; Baroni et al., 2014a; Milajevs et al., 2014) among others.

and *FastSent*, a sentence-level log-bilinear bag-of-words model. We compare all methods on two types of task - *supervised* and *unsupervised evaluations* - reflecting different ways in which representations are ultimately to be used. In the former setting, a classifier or regression model is applied to representations and trained with task-specific labelled data, while in the latter, representation spaces are directly queried using cosine distance.

We observe notable differences in approaches depending on the nature of the evaluation metric. In particular, deeper or more complex models (which require greater time and resources to train) generally perform best in the supervised setting, whereas shallow log-bilinear models work best on unsupervised benchmarks. Specifically, SkipThought Vectors (Kiros et al., 2015) perform best on the majority of supervised evaluations, but SDAEs are the top performer on paraphrase identification. In contrast, on the (unsupervised) SICK sentence relatedness benchmark, FastSent, a simple, log-bilinear variant of the SkipThought objective, performs better than all other models. Interestingly, the method that exhibits strongest performance across both supervised and unsupervised benchmarks is a bag-of-words model trained to compose word embeddings using dictionary definitions (Hill et al., 2015a). Taken together, these findings constitute valuable guidelines for the application of phrasal or sentential representation-learning to language understanding systems.

2 Distributed Sentence Representations

To constrain the analysis, we compare neural language models that compute sentence representations from unlabelled, naturally-ocurring data, as with the predominant methods for word representations.[2] Likewise, we do not focus on 'bottom up' models where phrase or sentence representations are built from fixed mathe proposed bymatical operations on word vectors (although we do consider a canonical case - see CBOW below); these were already compared by Milajevs et al. (2014). Most space is devoted to our novel approaches, and we refer the reader to the original papers for more details of existing models.

2.1 Existing Models Trained on Text

SkipThought Vectors For consecutive sentences S_{i-1}, S_i, S_{i+1} in some document, the **SkipThought** model (Kiros et al., 2015) is trained to predict target sentences S_{i-1} and S_{i+1} given source sentence S_i. As with all *sequence-to-sequence* models, in training the source sentence is 'encoded' by a Recurrent Neural Network (RNN) (with Gated Recurrent uUnits (Cho et al., 2014)) and then 'decoded' into the two target sentences in turn. Importantly, because RNNs employ a single set of update weights at each time-step, both the encoder and decoder are sensitive to the order of words in the source sentence.

For each position in a target sentence S_t, the decoder computes a softmax distribution over the model's vocabulary. The cost of a training example is the sum of the negative log-likelihood of each correct word in the target sentences S_{i-1} and S_{i+1}. This cost is backpropagated to train the encoder (and decoder), which, when trained, can map sequences of words to a single vector.

ParagraphVector Le and Mikolov (2014) proposed two log-bilinear models of sentence representation. The **DBOW** model learns a vector $\mathbf{s}$ for every sentence S in the training corpus which, together with word embeddings v_w, define a softmax distribution optimised to predict words $w \in S$ given S. The v_w are shared across all sentences in the corpus. In the **DM** model, k-grams of consecutive words $\{w_i \dots w_{i+k} \in S\}$ are selected and $\mathbf{s}$ is combined with $\{v_{w_i} \dots v_{w_{i+k}}\}$ to make a softmax prediction (parameterised by additional weights) of w_{i+k+1}.

We used the Gensim implementation,[3] treating each sentence in the training data as a 'paragraph' as suggested by the authors. During training, both DM and DBOW models store representations for every sentence (as well as word) in the training corpus. Even on large servers it was therefore only possible to train models with representation size 200, and DM models whose combination operation was averaging (rather than concatenation). Unlike other models considered in this section, for both ParagraphVector architectures an inference step is re-

[2] This excludes innovative supervised sentence-level architectures including (Socher et al., 2011; Kalchbrenner et al., 2014) and many others.

[3] `https://radimrehurek.com/gensim/`

quired after training to estimate sentence representations s for arbitrary sentences based on the v_w. This additional computation is reflected in the higher encoding time in Table 1 (TE).

Bottom-Up Methods We train **CBOW** and **Skip-Gram** word embeddings (Mikolov et al., 2013b) on the same text corpus as the SkipThought and ParagraphVector models, and compose by elementwise addition as per Mitchell and Lapata (2010).[4]

We also compare to **C-PHRASE** (Pham et al., 2015), an approach that exploits a (supervised) parser to infer distributed semantic representations based on a syntactic parse of sentences. C-PHRASE achieves state-of-the-art results for distributed representations on several evaluations used in this study.[5]

Non-Distributed Baseline We implement a **TFIDF BOW** model in which the representation of sentence S encodes the count in S of a set of feature-words weighted by their *tfidf* in C, the corpus. The feature-words are the 200,000 most common words in C.

2.2 Models Trained on Structured Resources

The following models rely on (freely-available) data that has more structure than raw text.

DictRep Hill et al. (2015a) trained neural language models to map dictionary definitions to pre-trained word embeddings of the words defined by those definitions. They experimented with **BOW** and **RNN** (with LSTM) encoding architectures and variants in which the input word embeddings were either learned or pre-trained (**+embs.**) to match the target word embeddings. We implement their models using the available code and training data.[6]

CaptionRep Using the same overall architecture, we trained (**BOW** and **RNN**) models to map captions in the COCO dataset (Chen et al., 2015) to pre-trained vector representations of images. The image representations were encoded by a deep convolutional network (Szegedy et al., 2014) trained on the ILSVRC 2014 object recognition task (Russakovsky et al., 2014). Multi-modal distributed representations can be encoded by feeding test sentences forward through the trained model.

NMT We consider the sentence representations learned by neural MT models. These models have identical architecture to SkipThought, but are trained on sentence-aligned translated texts. We used a standard architecture (Cho et al., 2014) on all available **En-Fr** and **En-De** data from the 2015 Workshop on Statistical MT (WMT).[7]

2.3 Novel Text-Based Models

We introduce two new approaches designed to address certain limitations with the existing models.

Sequential (Denoising) Autoencoders The SkipThought objective requires training text with a coherent inter-sentence narrative, making it problematic to port to domains such as social media or artificial language generated from symbolic knowledge. To avoid this restriction, we experiment with a representation-learning objective based on *denoising autoencoders* (DAEs). In a DAE, high-dimensional input data is corrupted according to some noise function, and the model is trained to recover the original data from the corrupted version. As a result of this process, DAEs learn to represent the data in terms of features that explain its important factors of variation (Vincent et al., 2008). Transforming data into DAE representations (as a 'pre-training' or initialisation step) gives more robust (supervised) classification performance in deep feedforward networks (Vincent et al., 2010).

The original DAEs were feedforward nets applied to (image) data of fixed size. Here, we adapt the approach to variable-length sentences by means of a noise function $N(S|p_o, p_x)$, determined by free parameters $p_o, p_x \in [0, 1]$. First, for each word w in S, N deletes w with (independent) probability p_o. Then, for each non-overlapping bigram $w_i w_{i+1}$ in S, N swaps w_i and w_{i+1} with probability p_x. We then train the same LSTM-based encoder-decoder architecture as NMT, but with the denoising objective to predict (as target) the original source sentence S given a corrupted version $N(S|p_o, p_x)$ (as source).

[4] We also tried multiplication but this gave very poor results.

[5] Since code for C-PHRASE is not publicly-available we use the available pre-trained model (`http://clic.cimec.unitn.it/composes/cphrase-vectors.html`). Note this model is trained on 3× more text than others in this study.

[6] `https://www.cl.cam.ac.uk/~fh295/`. Definitions from the training data matching those in the WordNet STS 2014 evaluation (used in this study) were excluded.

[7] `www.statmt.org/wmt15/translation-task.html`

The trained model can then encode novel word sequences into distributed representations. We call this model the *Sequential Denoising Autoencoder* (**SDAE**). Note that, unlike SkipThought, SDAEs can be trained on sets of sentences in arbitrary order.

We label the case with no noise (i.e. $p_o = p_x = 0$ and $N \equiv id$) **SAE**. This setting matches the method applied to text classification tasks by Dai and Le (2015). The 'word dropout' effect when $p_o \geq 0$ has also been used as a regulariser for deep nets in supervised language tasks (Iyyer et al., 2015), and for large p_x the objective is similar to word-level 'debagging' (Sutskever et al., 2011). For the SDAE, we tuned p_o, p_x on the validation set (see Section 3.2).[8] We also tried a variant (**+embs**) in which words are represented by (fixed) pre-trained embeddings.

FastSent The performance of SkipThought vectors shows that rich sentence semantics can be inferred from the content of adjacent sentences. The model could be said to exploit a type of *sentence-level Distributional Hypothesis* (Harris, 1954; Polajnar et al., 2015). Nevertheless, like many deep neural language models, SkipThought is very slow to train (see Table 1). FastSent is a simple additive (log-bilinear) sentence model designed to exploit the same signal, but at much lower computational expense. Given a BOW representation of some sentence in context, the model simply predicts adjacent sentences (also represented as BOW) .

More formally, FastSent learns a source u_w and target v_w embedding for each word in the model vocabulary. For a training example S_{i-1}, S_i, S_{i+1} of consecutive sentences, S_i is represented as the sum of its source embeddings $\mathbf{s_i} = \sum_{w \in S_i} u_w$. The cost of the example is then simply:

$$\sum_{w \in S_{i-1} \cup S_{i+1}} \phi(\mathbf{s_i}, v_w) \qquad (1)$$

where $\phi(v_1, v_2)$ is the softmax function.

We also experiment with a variant (**+AE**) in which the encoded (source) representation must predict its own words as target in addition to those of adjacent sentences. Thus in FastSent+AE, (1) becomes

$$\sum_{w \in S_{i-1} \cup S_i \cup S_{i+1}} \phi(\mathbf{s_i}, v_w). \qquad (2)$$

At test time the trained model (very quickly) encodes unseen word sequences into distributed representations with $\mathbf{s} = \sum_{w \in S} u_w$.

	OS	R	WO	SD	WD	TR	TE

Table 1: Properties of models compared in this study **OS:** requires training corpus of sentences in order. **R:** requires structured resource for training. **WO:** encoder sensitive to word order. **SD:** dimension of sentence representation. **WD:** dimension of word representation. **TR:** approximate training time (hours) on the dataset in this paper. * indicates trained on GPU. **TE:** approximate time (s) taken to encode 0.5m sentences.

2.4 Training and Model Selection

Unless stated above, all models were trained on the Toronto Books Corpus,[9] which has the inter-sentential coherence required for SkipThought and FastSent. The corpus consists of 70m ordered sentences from over 7,000 books.

Specifications of the models are shown in Table 1. The log-bilinear models (SkipGram, CBOW, ParagraphVec and FastSent) were trained for one epoch on one CPU core. The representation dimension d for these models was found after tuning $d \in \{100, 200, 300, 400, 500\}$ on the validation set.[10] All other models were trained on one GPU. The S(D)AE models were trained for one epoch ($\approx$ 8 days). The SkipThought model was trained for two weeks, covering just under one epoch.[11] For CaptionRep and DictRep, performance was monitored on held-out training data and training was stopped after 24 hours after a plateau in cost. The NMT models were trained for 72 hours.

[8] We searched $p_o, p_x \in \{0.1, 0.2, 0.3\}$ and observed best results with $p_o = p_x = 0.1$.

[9] `http://www.cs.toronto.edu/~mbweb/`

[10] For ParagraphVec only $d \in \{100, 200\}$ was possible due to the high memory footprint.

Table 2: Example sentence pairs and 'similarity' ratings from the unsupervised evaluations used in this study.

3 Evaluating Sentence Representations

In previous work, distributed representations of language were evaluated either by measuring the effect of adding representations as features in some classification task - *supervised evaluation* (Collobert et al., 2011; Mikolov et al., 2013a; Kiros et al., 2015) - or by comparing with human relatedness judgements - *unspervised evaluation* (Hill et al., 2015a; Baroni et al., 2014b; Levy et al., 2015). The former setting reflects a scenario in which representations are used to inject general knowledge (sometimes considered as *pre-training*) into a supervised model. The latter pertains to applications in which the sentence representation space is used for direct comparisons, lookup or retrieval. Here, we apply and compare both evaluation paradigms.

3.1 Supervised Evaluations

Representations are applied to 6 sentence classification tasks: paraphrase identification (MSRP) (Dolan et al., 2004), movie review sentiment (MR) (Pang and Lee, 2005), product reviews (CR) (Hu and Liu, 2004), subjectivity classification (SUBJ) (Pang and Lee, 2004), opinion polarity (MPQA) (Wiebe et al., 2005) and question type classification (TREC) (Voorhees, 2002). We follow the procedure (and code) of Kiros et al. (2015): a logistic regression classifier is trained on top of sentence representations, with 10-fold cross-validation used when a train-test split is not pre-defined.

3.2 Unsupervised Evaluations

We also measure how well representation spaces reflect human intuitions of the semantic sentence relatedness, by computing the cosine distance between vectors for the two sentences in each test pair, and correlating these distances with gold-standard human judgements. The SICK dataset (Marelli et al., 2014) consists of 10,000 pairs of sentences and relatedness judgements. The STS 2014 dataset (Agirre et al., 2014) consists of 3,750 pairs and ratings from six linguistic domains. Example ratings are shown in Table 2. All available pairs are used for testing apart from the 500 SICK 'trial' pairs, which are held-out for tuning hyperparameters (representation size of log-bilinear models, and noise parameters in SDAE). The optimal settings on this task are then applied to both supervised and unsupervised evaluations.

4 Results

Performance of the models on the supervised evaluations (grouped according to the data required by their objective) is shown in Table 3. Overall, SkipThought vectors perform best on three of the six evaluations, the BOW DictRep model with pre-trained word embeddings performs best on two, and the SDAE on one. SDAEs perform notably well on the paraphrasing task, going beyond SkipThought by three percentage points and approaching state-of-the-art performance of models designed specifically for the task (Ji and Eisenstein, 2013). SDAE is also consistently better than SAE, which aligns with other findings that adding noise to AEs produces richer representations (Vincent et al., 2008).

Results on the unsupervised evaluations are shown in Table 4. The same DictRep model performs best on four of the six STS categories (and overall) and is joint-top performer on SICK. Of the models trained on raw text, simply adding CBOW word vectors works best on STS. The best performing raw text model on SICK is FastSent, which achieves almost identical performance to C-PHRASE's state-of-the-art performance for a distributed model (Pham et al., 2015). Further, it uses less than a third of the training text and does not

require access to (supervised) syntactic representations for training. Together, the results of FastSent on the unsupervised evaluations and SkipThought on the supervised benchmarks provide strong support for the sentence-level distributional hypothesis: the context in which a sentence occurs provides valuable information about its semantics.

Across both unsupervised and supervised evaluations, the BOW DictRep with pre-trained word embeddings exhibits by some margin the most consistent performance. Ths robust performance suggests that DictRep representations may be particularly valuable when the ultimate application is non-specific or unknown, and confirms that dictionary definitions (where available) can be a powerful resource for representation learning.

5 Discussion

Many additional conclusions can be drawn from the results in Tables 3 and 4.

Different objectives yield different representations It may seem obvious, but the results confirm that different learning methods are preferable for different intended applications (and this variation appears greater than for word representations). For instance, it is perhaps unsurprising that SkipThought performs best on TREC because the labels in this dataset are determined by the language immediately following the represented question (i.e. the answer) (Voorhees, 2002). Paraphrase detection, on the other hand, may be better served by a model that focused entirely on the content *within* a sentence, such as SDAEs. Similar variation can be observed in the unsupervised evaluations. For instance, the (multimodal) representations produced by the CaptionRep model do not perform particularly well apart from on the Image category of STS where they beat all other models, demonstrating a clear effect of the well-studied modality differences in representation learning (Bruni et al., 2014).

The nearest neighbours in Table 5 give a more concrete sense of the representation spaces. One notable difference is between (AE-style) models whose semantics come from within-sentence relationships (CBOW, SDAE, DictRep, ParagraphVec) and SkipThought/FastSent, which exploit the context around sentences. In the former case, nearby sentences often have a high proportion of words in common, whereas for the latter it is the general con-

Table 4: Performance of sentence representation models (Spearman/Pearson correlations) on **unsupervised** (relatedness) evaluations (Section 3.2). Models are grouped according to training data as indicated in Table 3.

cepts and/or function of the sentence that is similar, and word overlap is often minimal. Indeed, this may be a more important trait of FastSent than the marginal improvement on the SICK task. Readers can compare the CBOW and FastSent spaces at http://45.55.60.98/.

Differences between supervised and unsupervised performance Many of the best performing models on the supervised evaluations do not perform well in the unsupervised setting. In the SkipThought, S(D)AE and NMT models, the cost is computed based on a non-linear decoding of the internal sentence representations, so, as also observed by (Almahairi et al., 2015), the informative geometry of the representation space may not be reflected in a simple cosine distance. The log-bilinear models generally perform better in this unsupervised setting.

Knowledge transfer shows some promise It is notable that, with a few exceptions, the models with pre-trained word embeddings (+embs) outperform those with learned embeddings on both supervised and unsupervised evaluations. In the case of the DictRep models, whose training data is otherwise limited to dictionary definitions, this effect can be considered as a rudimentary form of knowledge transfer. The DictRep+embs model benefits both from the dictionary data and the enhanced lexical semantics acquired from a massive text corpus to build overall higher-quality sentence representations.

Differences in resource requirements As shown in Table 1, different models require different resources to train and use. This can limit their possible applications. For instance, while it was easy to make an online demo for fast querying of near neighbours in the CBOW and FastSent spaces, it was not practical for other models owing to memory footprint, encoding time and representation dimension.

The role of word order is unclear The average scores of models that are sensitive to word order (76.3) and of those that are not (76.6) are approximately the same across supervised evalua-

Query	***If he had a weapon, he could maybe take out their last imp, and then beat up Errol and Vanessa.***	***An annoying buzz started to ring in my ears, becoming louder and louder as my vision began to swim.***
CBOW	*Then Rob and I would duke it out, and every once in a while, he would actually beat me.*	*Louder.*
Skip Thought	*If he could ram them from behind, send them saling over the far side of the levee, he had a chance of stopping them.*	*A weighty pressure landed on my lungs and my vision blurred at the edges, threatening my consciousness altogether.*
FastSent	*Isak's close enough to pick off any one of them, maybe all of them, if he had his rifle and a mind to.*	*The noise grew louder, the quaking increased as the sidewalk beneath my feet began to tremble even more.*
SDAE	*He'd even killed some of the most dangerous criminals in the galaxy, but none of those men had gotten to him like Vitktis.*	*I smile because I'm familiar with the knock, pausing to take a deep breath before dashing down the stairs.*
DictRep (FF+embs.)	*Kevin put a gun to the man's head, but even though he cried, he couldn't tell Kevin anything more.*	*Then gradually I began to hear a ringing in my ears.*
Paragraph Vector (DM)	*I take a deep breath and open the doors.*	*They listened as the motorcycle-like roar of an engine got louder and louder then stopped.*

0.94 (6)	0.85 (1)	0.86 (4)	0.85 (1)	0.86 (3)	0.89 (5)	0.92 (4)	0.92 (3)	0.92 (4)	0.93 (6)	0.95 (8)	0.92 (2)	0.91 (1)	0.93 (7)

Table 6: Internal consistency (Chronbach's α) among evaluations when individual benchmarks are left out of the (supervised or unsupervised) cohorts. Consistency rank within cohort is in parentheses (1 = most consistent with other evaluations).

tions. Across the unsupervised evaluations, however, BOW models score 0.55 on average compared with 0.42 for RNN-based (order sensitive) models. This seems at odds with the widely held view that word order plays an important role in determining the meaning of English sentences. One possibility is that order-critical sentences that cannot be disambiguated by a robust conceptual semantics (that could be encoded in distributed lexical representations) are in fact relatively rare. However, it is also plausible that current available evaluations do not adequately reflect order-dependent aspects of meaning (see below). This latter conjecture is supported by the comparatively strong performance of TFIDF BOW vectors, in which the effective lexical semantics are limited to simple relative frequencies.

The evaluations have limitations The internal consistency (Chronbach's α) of all evaluations considered together is 0.81 (just above 'acceptable').[12] Table 6 shows that consistency is far higher ('excellent') when considering the supervised or unsupervised tasks as independent cohorts. This indicates that, with respect to common characteristics of sentence representations, the supervised and unsupervised benchmarks do indeed prioritise different properties. It is also interesting that, by this metric, the properties measured by MSRP and image-caption relatedness are the furthest removed from other evaluations in their respective cohorts.

While these consistency scores are a promising sign, they could also be symptomatic of a set of evaluations that are all limited in the same way. The inter-rater agreement is only reported for one of the 8 evaluations considered (MPQA, 0.72 (Wiebe et al., 2005)), and for MR, SUBJ and TREC, each item is only rated by one or two annotators to maximise coverage. Table 2 illustrates why this may be an issue for the unsupervised evaluations; the notion of sentential 'relatedness' seems very subjective. It should be emphasised, however, that the tasks considered in this study are all frequently used for evaluation, and, to our knowledge, there are no existing benchmarks that overcome these limitations.

6 Conclusion

Advances in deep learning algorithms, software and hardware mean that many architectures and objectives for learning distributed sentence representations from unlabelled data are now available to NLP researchers. We have presented the first (to our knowledge) systematic comparison of these methods. We showed notable variation in the performance of approaches across a range of evaluations. Among other conclusions, we found that the op-

[12] `wikipedia.org/wiki/Cronbach's_alpha`

timal approach depends critically on whether representations will be applied in supervised or unsupervised settings - in the latter case, fast, shallow BOW models can still achieve the best performance. Further, we proposed two new objectives, FastSent and Sequential Denoising Autoencoders, which perform particularly well on specific tasks (MSRP and SICK sentence relatedness respectively).[13] If the application is unknown, however, the best all round choice may be DictRep: learning a mapping of pre-trained word embeddings from the word-phrase signal in dictionary definitions. While we have focused on models using naturally-occurring training data, in future work we will also consider supervised architectures (including convolutional, recursive and character-level models), potentially training them on multiple supervised tasks as an alternative way to induce the 'general knowledge' needed to give language technology the elusive human touch.

Retrofitting Sense-Specific Word Vectors Using Parallel Text

Abstract

Jauhar et al. (2015) recently proposed to learn sense-specific word representations by "retrofitting" standard distributional word representations to an existing ontology. We observe that this approach does not require an ontology, and can be generalized to any graph defining word senses and relations between them. We create such a graph using translations learned from parallel corpora. On a set of lexical semantic tasks, representations learned using parallel text perform roughly as well as those derived from WordNet, and combining the two representation types significantly improves performance.

1 Introduction

Vector space models (VSMs) provide a powerful tool for representing word meanings and modeling the relations between them. While these models have demonstrated impressive success in capturing some aspects of word meaning (Landauer and Dumais, 1997; Turney et al., 2010; Mikolov et al., 2013; Baroni et al., 2014; Levy et al., 2014), they generally fail to capture the fact that single word forms often have multiple meanings. This can lead to counterintuitive results—for example, it should be possible for the nearest word to *rock* to be *stone* in everyday usage, *punk* in discussions of music, and *crack* (cocaine) in discussions about drugs.

In a recent paper, Jauhar et al. (2015) introduce a method for "retrofitting" generic word vectors to create *sense-specific* vectors using the WordNet semantic lexicon (Miller, 1995). From WordNet, they create a graph structure comprising two classes of relations: form-based relations between each word form and its respective senses, and meaning-based relations between word senses with similar meanings. This graph structure is then used to transform a traditional VSM into an enriched VSM, where each point in the space represents a word sense, rather than a word form. This approach is appealing as, unlike with prior sense-aware representations, senses are defined categories in a semantic lexicon, rather than clusters induced from raw text (Reisinger and Mooney, 2010; Huang et al., 2012; Neelakantan et al., 2015; Tian et al., 2014), and the method does not require performing word sense disambiguation (Guo et al., 2014).

In this paper, we observe that the crucial meaning relationships in the Jauhar et al. retrofitting process—the word sense graph—can be inferred based on another widely available resource: bilingual parallel text. This observation is grounded in a well-established tradition of using cross-language correspondences as a form of sense annotation (Gale et al., 1992; Diab and Resnik, 2002; Ng et al., 2003; Carpuat and Wu, 2007; Lefever and Hoste, 2010, and others). Using parallel text to define sense distinctions sidesteps the persistent difficulty of identifying a single correct sense partitioning based on human intuition, and avoids large investments in manual curation or annotation.

We use parallel text and word alignment to infer both word sense identities and inter-sense relations required for the sense graph, and apply the approach of Jauhar et al. to retrofit existing word vector representations and create a sense-based vec-

Proceedings of NAACL-HLT 2016, pages 1378–1383,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

tor space, using bilingual correspondences to define word senses. When evaluated on semantic judgment tasks, the vector spaces derived from this graph perform comparably to and sometimes better than the WordNet-based space of Jauhar et al., indicating that parallel text is a viable alternative to WordNet for defining graph structure. Combining the output of parallel-data-based and WordNet-based retrofitted VSMs consistently improves performance, suggesting that the different sense graph methods make complementary contributions to this sense-specific retrofitting process.

2 Model

Retrofitting. The technique introduced by Jauhar et al. (2015) is based on what we will call a *sense graph*, which we formulate as follows. Nodes in the sense graph comprise the words w_i in a vocabulary W together with the senses s_{ij} for those words. Labeled, undirected edges include word-sense edges $\langle w_i, s_{i,j} \rangle$, which connect each word to all of its possible senses, and sense-sense edges $\langle s_{ij}, s_{i'j'} \rangle$ labeled with a meaning relationship r that holds between the two senses.

Jauhar et al. use WordNet to define their sense graph. Synsets in the WordNet ontology define the sense nodes, a word-sense edge exists between any word and every synset to which it belongs, and WordNet's synset-to-synset relations of synonymy, hypernymy, and hyponymy define the sense-sense edges. Figure 1 illustrates a fragment of a WordNet-based sense graph, suppressing edge labels.

Adopting Jauhar et al.'s notation, the original vector space to be retrofitted is defined by the original word-form vectors $\hat{u}_i$ for each $w_i \in W$, and the goal is to infer a set V of sense-specific vectors v_{ij} corresponding to each sense s_{ij}. Jauhar et al. use the sense graph to define a Markov network with variables for all word vectors and sense vectors, within which each word's vector $\hat{u}_i$ is connected to all of its sense vectors v_{ij}, and the variables for sense vectors v_{ij} and $v_{i'j'}$ are connected iff the corresponding senses are connected in the sense graph.

Retrofitting then consists in optimizing the following objective, where α is a sense-agnostic weight, and β_r are relation-specific weights for types of relations between senses:

$$C(V) = \arg\min_V \sum_{i-ij} \alpha \|\hat{u}_i - v_{ij}\|^2 + \sum_{ij-i'j'} \beta_r \|v_{ij} - v_{i'j'}\|^2 \quad (1)$$

The objective encourages similarity between a word's vector and its senses' vectors (first term), as well as similarity between the vectors for senses that are related in the sense graph (second term).

Defining a sense graph from parallel text. Our key observation is that, although Jauhar et al. (2015) assume their sense graph to be an ontology, this graph can be based on *any* inventory of word-sense and sense-sense relationships. In particular, given a parallel corpus, we can follow the tradition of translation-as-sense-annotation: the senses of an English word type can be defined by different possible translations of that word in another language.

Operationalizing this observation is straightforward, given a word-aligned parallel corpus. If English word form e_i is aligned with Chinese word form c_j, then $e_i(c_j)$ is a sense of e_i in the sense graph, and there is a word-sense edge $\langle e_i, e_i(c_j) \rangle$. Edges signifying a meaning relation are drawn between sense nodes if those senses are defined by the same translation word. For instance, English senses *swear*(发誓) and *vow*(发誓) both arise via alignment to 发誓 (*fashi*), so a sense-sense edge will be drawn between these two sense nodes. See Figure 2 for illustration.

3 Evaluation

Tasks. We evaluate on both the synonym selection and word similarity rating tasks used by Jauhar et al. Synonym selection nicely demonstrates the advantages afforded by sense partitioning: if we believe that *spin* means "make up a story", then we are not likely to perform well on a question in which the correct synonym is *twirl*. Word similarity rating, on the other hand, is a classic test of the extent to which vector representations simulate human intuitions of word relations in general.

For synonym selection, we follow Jauhar et al. in testing with ESL-50 (Turney, 2001), RD-300 (Jarmasz and Szpakowicz, 2004), and TOEFL-80 (Landauer and Dumais, 1997), using maxSim for multi-

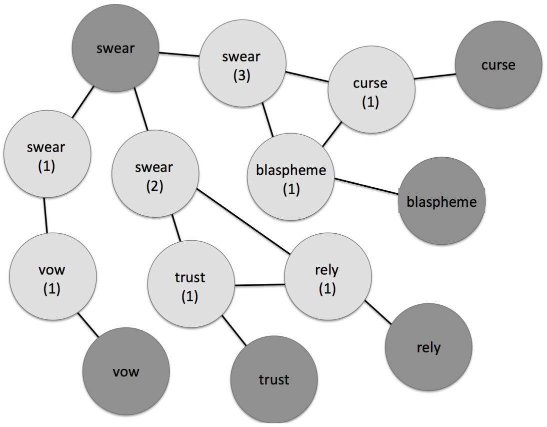

Figure 1: Illustration of WordNet-based sense graph.

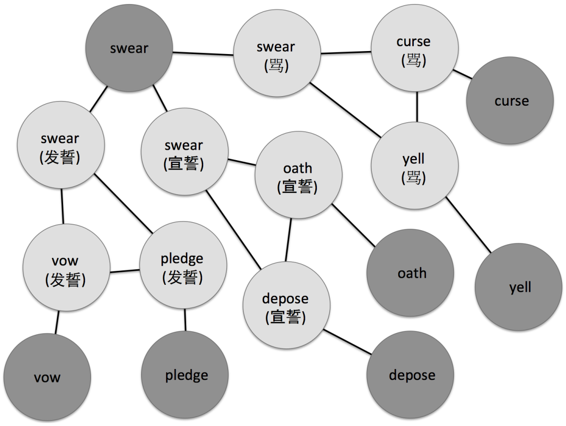

Figure 2: Illustration of parallel-text-based sense graph.

sense models (Jauhar et al., 2015, eq. 9) to select the most similar word.[1] For similarity rating, we again mirror Jauhar et al., testing with WS-353 (Finkelstein et al., 2001), RG-65 (Rubenstein and Goodenough, 1965), MC-30 (Miller and Charles, 1991), and the designated test subset (1000 items) of MEN-3k (Bruni et al., 2014), using avgSim (Jauhar et al., 2015, eq. 8) as the similarity rating, and evaluating model ratings against human similarity ratings via Spearman's rank correlation coefficient (ρ).[2]

Initial word representations. We use the word2vec (Mikolov et al., 2013) skip-gram architecture to train 80-dimensional word vectors (in keeping with Jauhar et al.), based on evidence that this model shows consistently strong performance on a wide array of tasks (Baroni et al., 2014; Levy et al., 2015). Training is on ukWaC (Ferraresi et al., 2008), a diverse 2B-word web corpus.[3]

Sense-graph construction from parallel text. To construct the sense graph per Section 2, we use $\sim$5.8M lines of segmented Chinese-English parallel text from the DARPA BOLT project and the Broadcast Conversation subset of the segmented Chinese-English parallel data in the OntoNotes corpus (Weischedel et al., 2013).[4] We perform word alignment with the Berkeley aligner (Liang et al., 2006). We filter out noisy alignments using the G-test statistic (Dunning, 1993), with a threshold selected during tuning on a development set.

We set α (see Equation 1) to 1.0. Each sense-sense edge $\langle e_i(c_j), e_{i'}(c_j)\rangle$ has individual weight $0 < \beta_r \leq 1$, computed by obtaining the G-test statistic for the alignment of e_i with c_j and for the alignment of $e_{i'}$ with c_j, running these values through a logistic function, and averaging. Parameters for these computations, as well as the G-test statistic threshold below which we filtered out noisy alignments, were selected during tuning on the development set.

Note that we have not currently incorporated special treatment for alignments of a single word to a multi-word phrase. This does create the possibility of noisy or uninformative sense annotations (e.g., sense annotations corresponding to parts of aligned Chinese phrases) when such alignments are not filtered out by the G-test thresholding.

Experimental conditions. We evaluate the following experimental conditions: Skip-gram (SG) uses the un-retrofitted word2vec vectors, Word-

[1] Because it is not clear how multi-word phrases should best be treated (and this is not a question being investigated here), we filter out any questions containing multi-word phrases for any of the relevant items (probe or possible response), and any questions for which any of the relevant items is completely out of vocabulary (no vectors available) for any of the evaluated models. This leaves 48 items in ESL, 87 items in RD, and 77 items in TOEFL.

[2] The designated development set of MEN-3k (2000 items) was used for tuning.

[3] To alleviate sparsity we lemmatized the ukWaC corpus. Runs without lemmatization produced weaker results.

[4] English was lemmatized post-alignment via lookup in the XTAG morphological database (XTAG Research Group, 2001).

Net (WN) retrofits using the WordNet-based sense graph, and Parallel Data (PD) retrofits using the sense graph built from parallel text. We also combine the two retrofitting approaches (PD-WN). For synonym selection, we compute maxSim over all sense pairs for WN and PD separately, and select the sense pair with the overall maximum cosine similarity across the two. For similarity rating, we explore two PD-WN combination approaches: for each word pair, we take the avgSim from each separate model, and then we (a) take the average of the values given by the two models (avg), or (b) take the maximum value between the two models (max).

	Synonym Selection SYMM (%)		
	ESL-48	RD-87	TOEFL-77
SG	58.3	58.6	71.4
WN	66.7	74.7	81.8
PD	68.8	62.1	80.5
PD-WN	**70.8**	**79.3**	**84.4**

Table 1: Synonym selection task results: accuracy

	Word similarity: avgSim SYMM (ρ)			
	WS-353	RG-65	MC-30	MEN-1k
SG	**.708**	.729	.722	.763
WN	.610	.725	.750	.739
PD	.636	**.777**	.715	.769
PD-WN (avg)	.666	**.777**	.742	**.773**
PD-WN (max)	.630	.731	**.758**	.756

Table 2: Similarity rating task results

4 Results

Table 1 shows that combining our new method with Jauhar et al.'s WN retrofitting performs best on synonym selection across all datasets, and both retrofitted models consistently outperform the no-retrofitting model (SG). Error analysis on RD-87, the only set on which WN substantially outperforms PD, suggests that PD's errors are driven by the large number of lower frequency items that characterize this dataset. Given that WordNet is a hand-curated lexicon while the parallel data mirrors actual usage, it is not surprising that the latter suffers when it comes to low frequency items.

Error analysis also indicates that PD performs particularly well on the synonym task precisely when one would expect: when the probe and the correct answer have an alignment to the same Chinese word form, so that the corresponding sense vectors are extremely close in vector space. Occasionally, PD yields "the wrong answer for the right reason", choosing an option for which there is indeed a correct alignment that matches an alignment of the probe word. For instance, though the probe *passage* is intended to have the answer *hallway*, PD chooses *ticket* because both *passage* and *ticket* have a sense defined by alignment to the Chinese word 机票 (*jipiao*), meaning "air ticket". Though this is a less frequent sense of *passage*, it is a reasonable one.

Results on the similarity rating task (presented in Table 2) are less clearly interpretable, top performance being divided between the PD model and the combined models—with the exception of WS-353. We note that WS-353 is a test set for which human raters were explicitly told to rate relatedness, rather than similarity, while the retrofitting process is intended to encourage similarity *per se*. If we exclude this set from consideration, we can observe that SG is outperformed by at least one sense-specific model in all cases.[5]

Note that as expected, the amount of training data has an impact on the quality of the alignments and of the sense graph. Retrofitting sense-specific embeddings using only 300k sentence pairs, which represent about 5% of the total training data, does not give clear benefit over word-form embeddings.

5 Conclusions and future work

Building on Jauhar et al. (2015), we have presented an alternative means of deriving information about senses and sense relations to build sense-specific vector space representations of words, making use of parallel text rather than a manually constructed ontology. We show that this is a viable alternative, producing representations that perform on par with those retrofitted to sense graphs based on WordNet.[6]

[5] We also explored using maxSim for similarity ratings, on the intuition that when human annotators give similarity judgments, they are likely to judge based on senses of the given words that are biased toward the words with which they are paired. However, top performance is similarly scattered when using maxSim for similarity scores and fails to improve over the SG baseline for two of the datasets.

[6] Sample sense-specific vectors and code for generating a sense graph from parallel data can be accessed at http://ling.umd.edu/~aetting/retropd.html.

Based on these results, it would be interesting to evaluate further refinements of the sense graph: alignment-based senses could be clustered, or further filtered to reduce the impact of alignment noise; new edges could be added using other multilingual resources. Finally, it will be important to evaluate the effectiveness of the retrofitted word embeddings on extrinsic tasks that require disambiguating word meaning in context.

End-to-End Argumentation Mining in Student Essays

Abstract

Understanding the argumentative structure of a persuasive essay involves addressing two challenging tasks: identifying the components of the essay's argument and identifying the relations that occur between them. We examine the under-investigated task of *end-to-end* argument mining in persuasive student essays, where we (1) present the first results on end-to-end argument mining in student essays using a *pipeline* approach; (2) address error propagation inherent in the pipeline approach by performing *joint inference* over the outputs of the tasks in an Integer Linear Programming (ILP) framework; and (3) propose a novel objective function that enables F-score to be maximized directly by an ILP solver. We evaluate our joint-inference approach with our novel objective function on a publicly-available corpus of 90 essays, where it yields an 18.5% relative error reduction in F-score over the pipeline system.

1 Introduction

There has been a surge of interest in argumentation mining in recent years. Argumentation mining typically involves addressing two subtasks: (1) *argument component identification* (ACI), which consists of identifying the locations and types of the components that make up the arguments (i.e., Major Claims, Claims, and Premises), and (2) *relation identification* (RI), which involves identifying the type of relation that holds between two argument components (i.e., Support, Attack, None). As a first step towards mining arguments in persuasive essays, Stab and Gurevych (S&G) annotated a corpus of 90 student essays with argument components and their relations (Stab and Gurevych, 2014a). To illustrate, consider the following excerpt from one essay:

> From this point of view, I firmly believe that (1) we should attach more importance to cooperation during primary education. First of all, (2) through cooperation, children can learn about interpersonal skills which are significant in the future life of all students. (3) What we acquired from team work is not only how to achieve the same goal with others but more importantly, how to get along with others.

In this example, premise (3) supports claim (2), which in turn supports major claim (1).

Using their annotated corpus, S&G presented initial results on *simplified* versions of the ACI and RI tasks (Stab and Gurevych, 2014b). Specifically, they applied their learned ACI classifier to classify only *gold* argument components (i.e., text spans corresponding to a Major Claim, Claim, or Premise in the gold standard) or sentences that contain no gold argument components (as *non-argumentative*). Similarly, they applied their learned RI classifier to classify only the relation between two *gold* argument components. In other words, they simplified both tasks by avoiding the challenging task of identifying the locations of argument components. Consequently, their approach cannot be applied in a realistic setting where the input is an *unannotated* essay.

Motivated by this weakness, we examine in this paper argument mining in persuasive student essays in a considerably more challenging setting than that of S&G: the *end-to-end* setting. In other words, we

San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

perform argument mining on raw, unannotated essays. Our work makes three contributions. First, we present the first results on end-to-end argument mining in student essays using a *pipeline* approach, where the ACI task is performed prior to the RI task. Second, to avoid the error propagation problem inherent in the pipeline approach, we perform *joint inference* over the outputs of the ACI and RI classifiers in an Integer Linear Programming (ILP) framework (Roth and Yih, 2004), where we design constraints to enforce global consistency. Finally, we argue that the typical objective function used extensively in ILP programs for NLP tasks is not ideal for tasks whose primary evaluation metric is F-score, and subsequently propose a novel objective function that enables F-score to be maximized directly in an ILP framework. We believe that the impact of our work goes beyond argument mining, as our F-score optimizing objective function is general enough to be applied to any ILP-based joint inference tasks.

2 Related Work

Recall that identifying argumentative discourse structures consists of (1) identifying the locations and types of the argument components, and (2) identifying how they are related to each other. Below we divide related works into five broad categories based on which of these subtasks they addressed.

Argument location identification. Works in this category aimed to classify whether a sentence contains an argument or not (Florou et al., 2013; Moens et al., 2007; Song et al., 2014; Swanson et al., 2015). The usefulness of existing works is somewhat limited by the task's coarseness: it won't tell us which portion of a potentially long sentence contains the argument, for instance, but it can serve as a potentially useful first step in argument mining.

Argument component typing. Works in this category focused on determining the *type* of an argument. The vast majority of previous works perform argument component typing at the *sentence* level. For instance, Rooney et al. (2012) classified sentences into premises, conclusions, premise-conclusions, and non-argumentative components; Teufel (1999) classified each sentence into one of seven rhetorical classes (e.g., claim, result, purpose); Burstein et al. (2003), Ong et al. (2014), and Falakmasir et al. (2014) assigned argumentative labels (e.g., claim, thesis, conclusion) to an essay's sentences; Levy et al. (2014) detected sentences that support or attack an article's topic; Lippi and Torroni (2015; 2016) detected sentences containing claims; and Rinott et al. (2015) detected sentences containing evidence for a given claim. Sentence-level argument component typing has limitations, however. For example, it can identify sentences containing claims, but it cannot tell how many claims a sentence has or where in the sentence they are.

Argument location identification and typing. Some works focused on the more difficult task of *clause-level* argument component typing (Park and Cardie, 2014; Goudas et al., 2015; Sardianos et al., 2015), training a Conditional Random Field to jointly identify and type argument components.

Argument component typing and relation identification. Given the difficulty of clause-level argument component location identification, recent argument mining works that attempted argument component typing and relation identification are not end-to-end. Specifically, they simplified the task by assuming as input *gold* argument components (Stab and Gurevych, 2014b; Peldszus and Stede, 2015).

End-to-end argument mining. To our knowledge, only Palau and Moens (2009) addressed all the argument mining subtasks. They employed a hand-crafted context-free grammar (CFG) to generate (i.e., extract and type) argument components at the clause level and identify the relations between them. A CFG approach is less appealing in the essay domain because (1) constructing a CFG is a time- and labor-intensive task, (2) which would be more difficult in the less-rigidly structured essay domain, which contains fewer rhetorical markers indicating component types (e.g. words like "reject", or "dismiss" which indicate a legal document's conclusion); and (3) about 20% of essay arguments' structures are non-projective (i.e., when mapped to the ordered text, their argument trees have edges that cross), and thus cannot be captured by CFGs.

3 Corpus

Our corpus consists of 90 persuasive essays collected and annotated by S&G. Some relevant statistics are shown in Table 1. Each essay is an average

Essays: 90	Paragraphs: 417	Sentences: 1,673
Major Claims: 90	Claims: 429	Premises: 1,033
Support Relations: 1,312		Attack Relations: 161

Table 1: Corpus statistics.

of 4.6 paragraphs (18.6 sentences) in length and is written in response to a topic such as "should high school make music lessons compulsory?" or "competition or co-operation-which is better?".

The corpus annotations describe the essays' argument structure, including the locations and types of the components that make up the arguments, and the types of relations that hold between them. The three annotated argument component types include: **Major Claims**, which express the author's stance with respect to the essay's topic, **Claims**, which are controversial statements that should not be accepted by readers without additional support, and **Premises**, which are reasons authors give to persuade readers about the truth of another argument component statement. The two relation types include: **Support**, which indicates that one argument component supports another, and **Attack**, which indicates that one argument component attacks another.

4 Pipeline-Based Argument Mining

Next, we describe our end-to-end *pipeline* argument mining system, which will serve as our baseline. In this system, ACI is performed prior to RI.

4.1 Argument Component Identification

We employ a two-step approach to the ACI task, where we first heuristically extract *argument component candidates* (ACCs) from an essay, and then classify each ACC as either a premise, claim, major claim, or non-argumentative, as described below.

4.1.1 Extracting ACCs

We extract ACCs by constructing a set of low precision, high recall heuristics for identifying the locations in each sentence where an argument component's boundaries might occur. The majority of these rules depend primarily on a syntactic parse tree we automatically generated for all sentences in the corpus using the Stanford CoreNLP (Manning et al., 2014) system. Since argument components are a clause-level annotation and therefore a large majority of annotated argument components are substrings of a simple declarative clause (an S node in the parse tree), we begin by identifying each S node in a sentence's tree.

(a) Potential left boundary locations

#	Rule
1	Exactly where the S node begins.
2	After an initial explicit connective, or if the connective is immediately followed by a comma, after the comma.
3	After nth comma that is an immediate child of the S node.
4	After nth comma.

(b) Potential right boundary locations

#	Rule
5	Exactly where the S node ends, or if S ends in a punctuation, immediately before the punctuation.
6	If the S node ends in a (possibly nested) SBAR node, immediately before the nth shallowest SBAR.[1]
7	If the S node ends in a (possibly nested) PP node, immediately before the nth shallowest PP.

Table 2: Rules for extracting ACC boundary locations.

Given an S clause, we collect a list of left and right boundaries where an argument component may begin or end. The rules we used to find these boundaries are summarized in Table 2. We then construct ACCs by combining each left boundary with each right boundary that occurs after it. As a result, we are able to find exact (boundaries exactly match) and approximate (over half of tokens shared) matches for 92.1% and 98.4% respectively of all ACs.

4.1.2 Training the ACI Classifier

We train a classifier for ACI using MALLET's (McCallum, 2002) implementation of maximum entropy classification. We create a training instance from each ACC extracted above. If the ACC's left and right endpoints exactly match an annotated argument component's, the corresponding training instance's class label is the same as that of the component. Otherwise, its class label is "non-

[1] An additional point that requires explanation is that the last two right boundary rules mention "possibly nested" nodes. In boundary rule 7, for example, this means that the S node might end in a PP node, which itself has a PP node as its last child, and so on. We generate a separate right boundary immediately before each of these PP nodes.

argumentative". Each training instance is represented using S&G's structural, lexical, syntactic, indicator, and contextual features for solving the same problem. Briefly, the structural features describe an ACC and its covering sentence's length, punctuations, and location in the essay. Lexical features describe the $1-3$ grams of the ACC and its covering sentence. Syntactic features are extracted from the ACC's covering sentence's parse tree and include things such as production rules. Indicator features describe any explicit connectives that immediately precede the ACC. Contextual features describe the contents of the sentences preceding and following the ACC primarily in ways similar to how the structural features describe the covering sentence.

4.2 Relation Identification

We consider RI between pairs of argument components to be a five class classification problem. Given a pair of ACCs A_1 and A_2 where A_1 occurs before A_2 in the essay, either they are unrelated, A_1 supports A_2, A_2 supports A_1, A_1 attacks A_2, or A_2 attacks A_1. Below we describe how we train and apply our classifier for RI.

We learn our RI classifier using MALLET's implementation of maximum entropy classification. Each training instance, which we call a training *relation candidate* (RC), consists of a pair of ACCs and one of the above five labels. By default, the instance's label is "no relation" unless each ACC has the exact boundaries of a gold standard argument component and one of the remaining four relations holds between the two gold argument components.

We create training RCs as follows. We construct RCs corresponding to true relations out of all pairs of argument components in a training essay having a gold relation. As the number of potential RCs far exceeds the number of gold relations in an essay, we undersample the "no relation" class in the following way. Given a pair of argument components A and B between which there is a gold relation, we define A_p to be the closest previous ACC in the essay as generated in Section 4.1.1 such that A_p's text doesn't overlap with A. We also define A_s as the closest succeeding ACC after A such that A_s and A do not overlap. We define B_p and B_s similarly with respect to B. From these ACCs, we generate the the four instances (A_p, B), (A_s, B), (A, B_p), and (A, B_s), all of which have the "no relation" label, as long as the pairs' text sequences do not overlap. We believe the resulting "no relation" training instances are informative since each one is "close" to a gold relation. We represent each instance using S&G's structural, lexical, syntactic, and indicator features for solving the same problem. Briefly, RC structural features describe many of the same things about each ACC as did the ACC structural features, though they also describe the difference between the ACCs (e.g. the difference in punctuation counts). Lexical features consist primarily of the unigrams appearing in each ACC and word pairs, where each word from one ACC is paired with each word from the other. Syntactic and indicator features encode the same information about each ACC as the ACC syntactic and indicator features did.

We now apply the classifier to test essay RCs, which are created as follows. Given that this is a pipelined argument mining system, in order to ensure that the RI system's output is consistent with that of the ACI system, we generate test RCs from all possible pairs of ACCs that the ACI system predicted are real components (i.e. it labeled them something other than "non-argumentative").

5 Joint Inference for Argument Mining

5.1 Motivation

There are two major problems with the pipeline approach described in the previous section. First, many essay-level within-task constraints are not enforced. For instance, the ACI task has the constraint that each essay has exactly one major claim, and the RI task has the constraint that each claim has no more than one parent. This problem arises because our ACI and RI classifiers, like those of S&G, classify each ACI and RI test instance independently of other test instances. We propose to enforce such essay-level within-task constraints in an ILP framework, employing ILP to perform joint inference over the outputs of our ACI and RI classifiers so that the resulting classifications satisfy these constraints.[2]

[2] Note that while we partition *documents* into folds in our cross-validation experiments, S&G partition *instances* into folds. Hence, S&G's evaluation setting prevents them from enforcing essay-level constraints in addition to being unrealistic in practice.

The second problem with the pipeline approach is that errors made early on in the pipeline propagate. For instance, assume that a Support relation exists between two argument components in a test essay. If the pipeline system fails to (heuristically) extract one or both of these argument components, or if it successfully extracts them but misclassifies one or both of them as non-argumentative, then the pipeline system will not be able to identify the relationship between them because no test RCs will be created from them. The above problem arises because the RI classifier assumes the *most probable* output of the ACI classifier for each ACC as input. Hence, one possible solution to this problem is to make use of the *n-best* outputs of the ACI classifier for each argument component type, as this increases the robustness of the pipeline to errors made by the ACI classifier.

We obtain the n-best ACI outputs and employ them as follows. Recall that the ACI system uses a maximum entropy classifier, and therefore its output for each ACC is a list of probabilities indicating how likely it is that the ACC belongs to each of the four classes (premise, claim, major claim, or non-argumentative). This means that it is possible to rank all the ACCs in a text by these probabilities. We use this idea to identify (1) the 3 most likely premise ACCs from each sentence, (2) the 5 most likely claim ACCs from each paragraph, and (3) the 5 most likely major claim ACCs from each essay.[3] Given these most likely ACC lists, we combine pairs of ACCs into test RCs for the RI classifier in the following way. As long as the ACCs do not overlap, we pair (1) each likely premise ACC with every other likely ACC of any type occurring in the same paragraph, and (2) each likely claim ACC with each likely major claim ACC. We then present these test RCs to the RI classifier normally, making no other changes to how the pipeline system works.

Employing n-best ACI outputs, however, introduces another problem: the output of the RI classifier may no longer be *consistent* with that of the ACI classifier because the RI classifier may posit a relationship between two ACCs that the ACI classifier labeled non-argumentative. To enforce this cross-task consistency constraint, we also propose to employ ILP. The rest of this section details our ILP-based joint inference approach for argument mining, which addresses both of the aforementioned problems with the pipeline approach.

5.2 Basic ILP Approach

We perform joint inference over the outputs of the ACI and RI classifiers by designing and enforcing within-task and cross-task constraints in the ILP framework. Specifically, we create one ILP program for each test essay, as described below.

Let Xn_i, Xp_i, Xc_i, and Xm_i be binary indicator variables representing whether the ILP solver believes ACC i has type none, premise, claim, and major claim, respectively. Let Cn_i, Cp_i, Cc_i, and Cm_i be the probabilities that ACC i has type none, premise, claim, and major claim, respectively, as dictated by the ACI maximum entropy classifier's output.[4] Let a be the count of ACCs.

Let $Yn_{i,j}$, $Ys_{i,j}$, $Ya_{i,j}$, $Yrs_{i,j}$, and $Yra_{i,j}$ be binary indicator variables representing whether the ILP solver believes ACCs i and j have no relation, i is supported by j, i is attacked by j, j is supported by i, and j is attacked by i, respectively, where (i, j) appears in the set of RCs B that we presented to the RI system as modified in Section 5.1. We assume all other ACC pairs have no relation. Let $Dn_{i,j}$, $Ds_{i,j}$, $Da_{i,j}$, $Drs_{i,j}$, and $Dra_{i,j}$ be the probabilities that component candidates i and j have no relation, i is supported by j, i is attacked by j, j is supported by i, and j is attacked by i, respectively, as dictated by the modified RI classifier described in Section 5.1.[4]

Given these definitions and probabilities, our ILP program's default goal is to find an assignment of these variables X and Y in order to maximize $P(X) + P(Y)$, where:

$$P(X) = \frac{1}{a}\sum_{i=1}^{a} \log(Cn_iXn_i + Cp_iXp_i + Cc_iXc_i + Cm_iXm_i) \quad (1)$$

[3] We select more premise than claim ACCs (3 per sentence vs 5 per paragraph) because the corpus contains over twice as many premises as claims. We select major claim ACCs only from the first and last paragraph because major claims never occur in middle paragraphs.

[4] We additionally reserve .001 probability mass to distribute evenly among Cn_i, Cp_i, Cc_i, and Cm_i (or $Dn_{i,j}$, $Ds_{i,j}$, $Da_{i,j}$, $Drs_{i,j}$, and $Dra_{i,j}$) to prevent math errors involving taking the log of 0 which might otherwise occur in the formulas below.

$$P(Y) = \frac{1}{|B|} \sum_{(i,j) \in B} \log(Dn_{i,j} Yn_{i,j} + Ds_{i,j} Ys_{i,j} \\ + Da_{i,j} Ya_{i,j} + Drs_{i,j} Yrs_{i,j} + Dra_{i,j} Yra_{i,j}) \tag{2}$$

subject to the *integrity* constraints that: (3) an ACC is either not an argument component or it has exactly one of the real argument component types, (4) a pair of component candidates (i, j) must have exactly one of the five relation types, and (5) if there is a relation between ACCs i and j, i and j must each be real components.[5]

$$Xn_i + Xp_i + Xc_i + Xm_i = 1 \tag{3}$$

$$Yn_{i,j} + Ys_{i,j} + Ya_{i,j} + Yrs_{i,j} + Yra_{i,j} = 1 \tag{4}$$

$$(Xp_i + Xc_i + Xm_i) + (Xp_j + Xc_j + Xm_j) \\ -2(Ys_{i,j} + Ya_{i,j} + Yrs_{i,j} + Yra_{i,j}) \geq 0 \tag{5}$$

In the objective function, a and $|B|$ serve to balance the contribution of the two tasks, preventing one from dominating the other.

5.3 Enforcing Consistency Constraints

So far we have described integrity constraints, but recall that our goal is to enforce consistency by imposing within-task and cross-task constraints, which force the ILP solutions to more closely resemble real essay argument structures. Our consistency constraints fall into four categories.

Our constraints on *major claims* are that: (6) there is exactly one major claim in each essay, (7) major claims always occur in the first or last paragraph, and (8) major claims have no parents.

$$\sum_{i=1}^{a} Xm_i = 1 \tag{6}$$

$$Xm_i = 0 \mid i \notin first\, or\, last\, paragraph \tag{7}$$

$$Ys_{i,j} + Xm_j \leq 1 \ , \ Ya_{i,j} + Xm_j \leq 1 \\ Yrs_{i,j} + Xm_i \leq 1 \ , \ Yra_{i,j} + Xm_i \leq 1 \tag{8}$$

Our constraints on *premises* are that: (9) a premise has at least one parent, and (10) a premise is related only to components in the same paragraph.

$$\sum_{\{i|(i,j) \in B\}} (Ys_{i,j} + Ya_{i,j}) \\ + \sum_{\{k|(j,k) \in B\}} (Yrs_{j,k} + Yra_{j,k}) - Xp_j \geq 0 \tag{9}$$

$$for\ i < j,\ i \notin Par(j) : Xp_j - Yn_{i,j} \leq 0 \\ for\ k > j,\ k \notin Par(j) : Xp_j - Yn_{j,k} \leq 0 \tag{10}$$

where $i < j$ and $j < k$ mean ACC i appears before j, and j appears before k, and $Par(j)$ is the set of ACCs in j's covering paragraph.

Our constraints on *claims* state that: (11) a claim has no more than one parent[6], and (12) if a claim has a parent, that parent must be a major claim.

$$\Big(\Big|\{i|(i,j) \in B\}\Big| + \Big|\{k|(j,k) \in B\}\Big|\Big) Xc_j \\ + \sum_{\{i|(i,j) \in B\}} (Ys_{i,j} + Ya_{i,j}) \\ + \sum_{\{k|(j,k) \in B\}} (Yrs_{j,k} + Yra_{j,k}) \\ \leq \Big|\{i|(i,j) \in B\}\Big| + \Big|\{k|(j,k) \in B\}\Big| + 1 \tag{11}$$

$$for\ j < k,\ Xm_k - Xc_j - Yrs_{j,k} - Yra_{j,k} \geq -1 \\ for\ j > i,\ Xm_i - Xc_j - Ys_{i,j} - Ya_{i,j} \geq -1 \tag{12}$$

The last category, which comprises constraints that do not fit well into any other category, are: (13) the boundaries of actual components never overlap, (14) each paragraph must have at least one claim or major claim, and (15) each sentence may have at most two argument components.[7]

$$for\ i\ overlaps\ j\ ,\ Xn_i + Xn_j \geq 1 \tag{13}$$

$$\forall\ paragraphs\ P\ :\ \sum_{i \in P} Xc_i + Xm_i \geq 1 \tag{14}$$

$$\forall\ sentences\ S\ :\ \sum_{i \in S} Xp_i + Xc_i + Xm_i \leq 2 \tag{15}$$

We solve each ILP program using Gurobi.[8]

[5] Note that because of previous integrity constraints, the first term in constraint 5 is 1 only if we predict that i is a real component, the second term is 1 only if we predict that j is a real component, and the third term is -2 only if we predict that there is a relationship between them. Otherwise, each term is 0. Thus term 3 prevents us from predicting a relationship between i and j unless the first and second terms cancel it out through predicting that i and j are real components.

[6] The coefficient of Xc_j is equal to the number of terms in the two summations on the left hand side of the equation. The intention is that component j's claim status should have equal weight with the relations it might potentially participate in, so it is possible for j to participate as a child in a relation with all other available components unless it is a claim, in which case it can participate in at most one relation as a child.

[7] Unlike the other constraints, the last two constraints are only mostly true: 5% of paragraphs have no claims or major claims, and 1.2% of sentences have 3 or more components.

5.4 F-score Maximizing Objective Function

The objective function we employ in the previous subsection attempts to maximize the average probability of correct assignment of variables over the ACI and RI problems. This kind of objective function, which aims to maximize classification accuracy, was originally introduced by Roth and Yih (2004) in their seminal ILP paper, and has since then been extensively applied to NLP tasks. However, it is arguably not an ideal objective function for our task, where F-score rather than classification accuracy is used as the evaluation metric.

In this section, we introduce a novel method for constructing an ILP objective function that directly maximizes the average F-score over the two problems. Recall that F-score can be simplified to:

$$F = \frac{2TP}{2TP + FP + FN} \tag{16}$$

where TP, FP, and FN are the counts of true positives, false positives, and false negatives respectively. Unfortunately, we cannot use this equation for F-score in an ILP objective function for two reasons. First, this equation involves division, which cannot be handled using ILP since ILP can only handle linear combinations of variables. Second, TP, FP, and FN need to be computed using gold annotations, which we don't have in a test document. We propose to instead maximize F by maximizing the following:

$$G = \alpha 2TP_e - (1-\alpha)(FP_e + FN_e) \tag{17}$$

where TP_e, FP_e, and FN_e, are *estimated* values for TP, FP, and FN respectively, and α attempts to balance the importance of maximizing the numerator vs minimizing the denominator.[9] We ignore the $2TP$ term in the denominator because minimizing it would directly reduce the numerator.

To maximize average F-score, we can therefore attempt to maximize the function $\frac{G_c+G_r}{2}$, where G_c and G_r are the values of G in equation 17 as calculated using the estimated values from the ACI and RI problem respectively.

The question that still remains is, how can we estimate values for TP, FP, and FN mentioned in Equation 17? Our key idea is inspired by the E-step of the Expectation-Maximization algorithm (Dempster et al., 1977): while we cannot compute the actual TP, FP, and FN due to the lack of gold annotations, we can compute their *expected* values using the probabilities returned by the ACI and RI classifiers. Using the notation introduced in Section 5.2, the expected TP, FP, and FN values for the ACI task can be computed as follows:

$$TP_e = \sum_{i,g} Cg_i Xg_i \tag{18}$$

$$FP_e = \sum_{i,g} (1 - Cg_i) Xg_i \tag{19}$$

$$FN_e = \sum_{i,g} \Big(Xg_i \sum_{h \neq g} Ch_i \Big) + \sum_i Xn_i (1 - Cn_i) \tag{20}$$

where g and h can be any argumentative class from the ACI problem (i.e. premise (p), claim (c), or major claim (m)). The formulas we use to calculate TP_e, FP_e, and FN_e for the RI problem are identical except C is replaced with D, X is replaced with Y, and g and h can be any class from the RI problem other than no-relation.

6 Evaluation

6.1 Experimental Setup

Corpus. As mentioned before, we use as our corpus the 90 essays annotated with argumentative discourse structures by S&G. All of our experiments are conducted via five-fold cross-validation on this corpus. In each fold experiment, we reserve 60% of the essays for training, 20% for development (selecting features and tuning α), and 20% for testing.

Evaluation metrics. To calculate F-score on each task using Equation 16, we need to explain what constitutes a true positive, false positive, or false negative on each task. Given that j is a true argument component and i is an ACC, the formulas for the ACI task are:

$$TP = \Big| \{ j \mid \exists i \,| gl(j) = pl(i) \wedge i \doteq j \} \Big| \tag{21}$$

$$FP = \Big| \{ i \big| \, pl(i) \neq n \wedge \nexists j \mid gl(j) = pl(i) \wedge i \doteq j \} \Big| \tag{22}$$

$$FN = \Big| \{ j \mid \nexists i \,| gl(j) = pl(i) \wedge i \doteq j \} \Big| \tag{23}$$

where $gl(j)$ is the gold standard label of j, $pl(i)$ is the predicted label of i, n is the non-argumentative class, and $i \doteq j$ means i is a *match* for j. i and j are considered an *exact match* if they have exactly

[9] We tune α on the development set, allowing it to take any value from 0.7, 0.8, or 0.9, as this range tended to perform well in early experiments.

		ACI						RI					Avg
	System	MC-F	C-F	P-F	P	R	F	S-F	A-F	P	R	F	F
Approx	BASE	11.1	26.9	51.9	64.0	33.6	44.0	6.1	0.8	5.7	6.2	5.8	24.9

Exact	BASE	7.4	24.2	43.2	50.4	29.6	37.3	4.4	0.8	4.1	4.7	4.3	20.8
	OUR	16.9	**37.4**	**53.4**	47.5	**46.7**	**47.1**	**13.6**	0.0	12.7	15.4	**12.9**	**30.0**

Table 3: Five-fold cross-validation average percentages for argument component identification (ACI) and relation identification (RI) for OUR system and the pipeline-based BASEline system. Column abbreviations are Major Claim F-score (MC-F), Claim F-score (C-F), Premise F-score (P-F), Precision (P), Recall (R), F-score (F), Support F-score (S-F), and Attack F-score (A-F).

the same boundaries, whereas they are considered an *approximate match* if they share over half their tokens.

We perform most of our analysis on approximate match results rather than exact match results as it can be difficult even for human annotators to identify exactly the same boundaries for an argument component.[10] We use the same formulas for calculating these numbers for the RI problem except that j and i represent a true relation and an RC respectively, two relations approximately (exactly) match if both their source and target ACCs approximately (exactly) match, and n is the no-relation class.

6.2 Results and Discussion

Approximate and exact match results of the pipeline approach (BASE) and the joint approach (OUR) are shown in Table 3. As we can see, using approximate matching, OUR system achieves highly significant[11] improvements over the pipelined baseline system by a variety of measures.[12] The most important of these improvements is shown in the last column, where our system outperforms the baseline by 13.9% absolute F-score (a relative error reduction of 18.5%). This is the most important result because it most directly measures our performance in pursuit of our ultimate goal, to maximize the average F-score over both the ACI and RI problems. The highly significant improvements in other measures, particularly the improvements of 13.2% and 14.6% in ACI and RI F-score respectively, follow as a consequence of this maximization. Using exact matching, the differences in scores between OUR system and BASE's are smaller and highly significant with respect to a smaller number of measures. In particular, under Exact matching OUR system's performances on the RI-P and RI-R metrics are significant ($p < 0.02$), while under Approx matching, they are highly significant ($p < 0.002$).

6.3 Ablation Results

To analyze the performance gains yielded by each improvement to our system, we show ablation results in Table 4. Each row of the table shows the results of one ablation experiment on the test set. That is, we obtain them by removing exactly one feature set or improvement type from our system.

The **B**aseline feature sets we remove include those for the A**C**I task (C_b) from Section 4.1.2 and those for the **R**I task (R_b) from Section 4.2.[13] The **I**LP improvement sets we remove are the **D**efault ILP (I_d) system[14] from Section 5.2, the **M**ajor claim (I_m), **P**remise (I_p), **C**laim (I_c), and **O**ther (I_o) constraints from Section 5.3 Equations 6−8, 9−10,

[10] Approximate match has been used in evaluating opinion mining systems (e.g., Choi et al. (2006), Yang and Cardie (2013)), where researchers have also reported difficulties in having human annotators identify exactly the same boundaries for an opinion expression and its sources and targets. They have adopted an even more relaxed notion of approximate match: they consider two text spans an approximate match if they share at least one overlapping token.

[11] Boldfaced results in Table 3 are highly significant ($p < 0.002$, paired t-test) compared to the baseline.

[12] All the results in Tables 3 and 4 are averaged across five folds, so it is not true that $F_{avg} = \frac{2P_{avg}R_{avg}}{P_{avg}+R_{avg}}$. Our F-score averaging method is preferable to calculating F-scores using the above formula because the formula can be exploited to give artificially inflated F-scores by alternating between high precision, low recall, and low precision, high recall labelings on different folds.

[13] When we remove a baseline feature set, we represent each instance to the corresponding classifier using no features. As a result, the classifier's predictions are based solely on the frequency of the classes seen during training.

[14] Note that removing the default ILP system (I_d) necessitates simultaneously removing all other ILP-related improvements. Thus, a system without it is equivalent to BASE, but with RCs generated as described in Section 5.1.

Mod	ACI			RI			Avg
	P	R	F	P	R	F	F
ALL	54.9	58.8	56.7	16.7	26.4	20.4	38.6
C_b	**44.0**	**38.5**	**40.9**	14.2	**14.8**	**14.4**	**27.7**
R_b	57.9	58.7	58.2	16.6	24.0	18.2	38.2
I_d	64.0	**33.6**	**44.0**	**6.6**	**21.8**	**10.1**	**27.0**
I_m	**44.6**	**46.7**	**45.6**	**14.7**	27.8	19.2	**32.4**
I_p	51.5	58.4	54.7	**13.2**	26.1	**17.3**	36.0
I_c	**49.0**	**51.5**	**50.2**	**14.2**	27.9	18.8	**34.5**
I_o	**40.5**	65.9	**50.1**	**7.0**	29.2	**11.2**	**30.7**
I_f	61.1	**40.4**	**48.5**	22.3	**15.7**	**18.2**	**33.4**

Table 4: Ablation results. How OUR system performs on one development set as measured by percent Precision, Recall, and F-score if each improvement or feature set is removed.

11−12, and 13−15 respectively, and the **F**-score maximizing objective function from Section 5.4.

Broadly, we see from the last column that all of our improvement sets are beneficial (usually significantly[15]) to the system, as performance drops with their removal. Notice also that whenever removing an ILP improvement set harms average F-score, it also simultaneously harms ACI and RI F-scores, usually significantly. This holds true even when the improvement set deals primarily only with one task (e.g. I_o for the ACI task), suggesting that our system is benefiting from joint inference over both tasks.

6.4 Error Analysis and Future Work

Table 3 shows that OUR system has more trouble with the RI task than the ACI task. A closer inspection of OUR system's RI predictions reveals that its low precision is mostly due to predicted relationships wherein one of the participating ACCs is not a true argument component. Since false positives in the ACI task have an outsized impact on RI precision, it may be worthwhile to investigate ILP objective functions that more harshly penalize false positive ACCs.

The RI task's poor recall has two primary causes. The first is false negatives in the ACI task. It is impossible for an RI system to correctly identify a relationship between two ACs if the ACI system fails to identify either one of them as an AC. We believe ACI recall, and by extension, RI recall, can be improved by exploiting the following observations. First, we noticed that many argument components OUR system fails to identify, regardless of their type, contain words that are semantically similar to words in the essay's topic (e.g., if the topic mentions "school", argument components might mention "students"). Hence, one way to improve ACI recall, and by extension, RI recall, would be to create ACI features using a semantic similarity measure such as the Wikipedia Link-based similarity measure (Milne and Witten, 2008). Second, major claims are involved in 32% of all relationships, but OUR system did an especially poor job at identifying them due to their scarcity. Since we noticed that major claims tend to include strong stancetaking language (e.g., words like "should", "must", and "believe"), it may be possible to improve major claim identification by constructing an arguing language lexicon as in Somasundaran and Wiebe (2010), then encoding the presence of any of these arguing words as ACC features.

The second major cause of OUR system's poor RI recall is its failure to identify relationships between two correctly extracted ACs. We noticed many of the missed relationships involve ACs that mention some of the same entities. Thus, a coreference resolver could help us build features that describe whether two ACCs are talking about the same entities.

7 Conclusion

We presented the *first* results on *end-to-end* argument mining in persuasive student essays using a pipeline approach, improved this baseline approach by designing and employing global consistency constraints to perform joint inference over the outputs of the tasks in an ILP framework and proposed a novel objective function that enables F-score to be maximized directly by an ILP solver. In an evaluation on Stab and Gurevych's corpus of 90 essays, our approach yields an 18.5% relative error reduction in F-score over the pipeline system.

Acknowledgments

We thank the three anonymous reviewers for their detailed comments. This work was supported in part by NSF Grants IIS-1147644 and IIS-1219142.

[15] Boldfaced results are significantly lower than ALL, the system with all improvements left intact, with $p < 0.05$.

Cross-Domain Mining of Argumentative Text through Distant Supervision

Khalid Al-Khatib Henning Wachsmuth Matthias Hagen Jonas Köhler Benno Stein
Faculty of Media, Bauhaus-Universität Weimar, Germany
<firstname>.<lastname>@uni-weimar.de

Abstract

Argumentation mining is considered as a key technology for future search engines and automated decision making. In such applications, argumentative text segments have to be mined from large and diverse document collections. However, most existing argumentation mining approaches tackle the classification of argumentativeness only for a few manually annotated documents from narrow domains and registers. This limits their practical applicability. We hence propose a distant supervision approach that acquires argumentative text segments automatically from online debate portals. Experiments across domains and registers show that training on such a corpus improves the effectiveness and robustness of mining argumentative text. We freely provide the underlying corpus for research.

1 Introduction

Argumentation mining attracts much attention recently: it is an important building block of applications like automated decision making (Bench-Capon et al., 2009) or pro-and-con search engines (Cabrio and Villata, 2012c). In such applications, argumentation mining usually consists of solving three tasks for each document: (1) Identifying all argumentative text segments in the document, (2) classifying the type of each segment, and (3) classifying relations between the segments.

In this paper we focus on the first task taking on the retrieval perspective of a search engine: Given a large-scale collection of documents (e.g., the web) and a query on some topic, return all argumentative text segments relevant to the topic. Among others, a classifier is needed for this task that can distinguish argumentative from non-argumentative segments. Since we cannot presuppose a specific domain or register within a general retrieval scenario, the classifier needs to robustly deal with documents from diverse domains and registers. In this regard the following two key issues arise.

First, existing approaches to classifying argumentativeness usually focus on specific text domains (e.g., education) and registers (e.g., student essays). Therefore, many used features capture not only local linguistic properties of a text segment, but also global document properties (e.g., that a segment is part of the introduction). Such kinds of features tend to be effective only within a certain domain or a particular register while often failing for others.

Second, all major existing approaches follow a supervised learning scheme based on manual annotation of argumentative text segments. However, the annotation of arguments is particularly intricate and thus expensive due to the complex linguistic structure and the partly subjective interpretation of argumentativeness. Different types of argumentative and non-argumentative segments may come in any order, segment boundaries are not always unambiguous, and parts of an argument may be implicit. Studies reveal that annotators need multiple training sessions to identify and classify argumentative segments with moderate inter-annotator agreement, and crowdsourcing-based annotation does not help notably (Habernal et al., 2014). I.e., a high-quality manual annotation will not scale to large numbers of documents from diverse domains and registers.

We propose a solution to the outlined issues. In particular, we follow the idea of distant supervision to construct a large-scale corpus of text segments from diverse domains and registers annotated with respect to argumentativeness. Distant supervision is a well-known idea for training robust statistical classifiers. Here, we exploit online debate portals that (1) contain argumentative and non-argumentative text segments for several controversial topics, and that (2) are organized in a semi-structured form, allowing to derive annotations from it.

In several experiments we compare classifiers trained on the constructed corpus to those trained on existing corpora for argumentation mining. We classify argumentativeness using a rich set of lexical, syntax, and indicator feature types. Our results suggest that the new corpus is the most robust resource for classifying argumentative text segments across domains and registers. In addition, we observe that n-grams seem to be most domain-dependent, while syntax features turn out to be more robust.

The contribution of this paper is three-fold: First, through distant supervision we acquire a large corpus with 28,689 argumentative text segments from the online debate portal idebate.org. The corpus covers 14 separate domains with strongly varying feature distributions. It will be made freely available to other researchers.[1] Second, we obtain a robust classifier for argumentativeness, providing evidence that distant supervision does not only save money and time, but also benefits the effectiveness of cross-domain and cross-register argumentation mining. Third, we evaluate—for the first time—the robustness of several features in classifying argumentativeness across domains and registers.

Altogether, the paper serves as a starting point for bringing argumentation mining to practice. We expect that a robust identification of arguments will be a core module of future search engines, as it allows to provide rationales for retrieved documents. To this end, the search engines also need to identify the most *relevant* arguments for a given topic. The paper concludes with ideas on how to assess argument relevance with resources that are obtained through applying our proposed distant supervision technique to other datasets.

2 Related Work

Argumentation mining is still in an early stage of investigation, although several promising approaches have been proposed in the last years. Our survey of the argumentation mining literature especially covers three respects: (1) favored domains and registers, (2) techniques for annotation acquisition, and (3) the exploitation of debate portals. We combine these research lines in our approach to tackle argumentativeness classification across domains.

The existing argumentation mining approaches achieve classification accuracies ranging from 73% and 86% (Stab and Gurevych, 2014b; Levy et al., 2014; Palau and Moens, 2009) but they deal with texts from one register or one narrow domain only. For instance, Palau and Moens (2009) address the legal domain, Cabrio and Villata (2012b) as well as Boltužić and Šnajder (2014) investigate online debates and discussions, Aharoni et al. (2014) examine Wikipedia articles, Villalba and Saint-Dizier (2012) as well as Wachsmuth et al. (2014a) work on product reviews, Stab and Gurevych (2014a) focus on persuasive essays, and Peldszus (2014) on microtext. In (Wachsmuth et al., 2015), we studied the generality of sentiment-related argumentative structures across domains. In contrast, here we aim at effectiveness in cross-domain argumentation mining, which is useful for practical applications such as argument retrieval from diverse web-scale document collections.

All mining approaches above proceed as follows. Starting point is a complex and often expensive manual annotation of argumentative text segments in a collection of documents, including the segments' roles (e.g., premise or conclusion) and their relations (e.g., support or attack). Then, the classification of argumentativeness, roles, and relations is achieved via supervised machine learning using different linguistic and statistical features. Our approach avoids manual annotation. Instead, we apply distant supervision to automatically acquire annotations.

Distant supervision is a technique to automatically harvest annotations from data that has been compiled and structured intentionally by a user community on the web. Most approaches employing distant supervision so far address the problems of relation extraction (Mintz et al., 2009; Hoffmann et al., 2011) or event extraction (Reschke et al., 2014). A

[1] http://www.uni-weimar.de/medien/webis/corpora

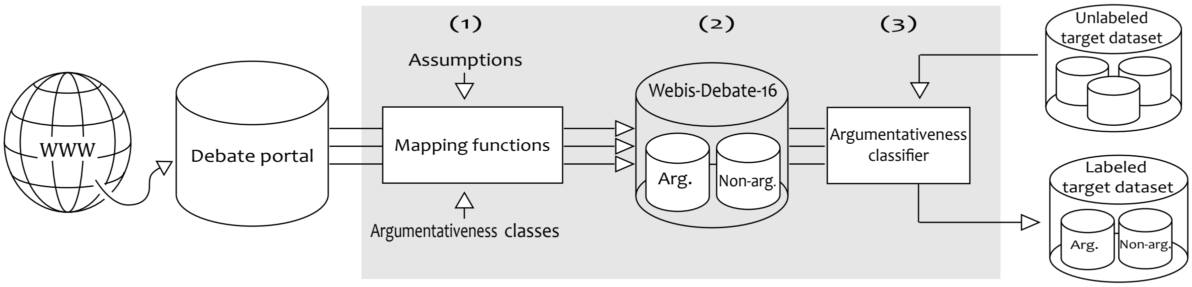

Figure 1. Overview of our distant supervision approach: The mapping functions transform the debate portal content into an annotated corpus for argumentativeness. This corpus is then used to train an argumentativeness classifier.

few others target at sentiment analysis (Marchetti-Bowick and Chambers, 2012) and emotion detection (Purver and Battersby, 2012). In case of the latter, annotations are derived from strong textual indicators like emoticons. In this paper, we exploit metadata from the debate platform idebate.org for mapping texts from the platform to argumentative and non-argumentative classes.

The idea of relying on idebate.org for argument annotation acquisition is in line with related research of Cabrio and Villata (2012c) and Gottipati et al. (2013). In these papers, however, the debate portal is used to infer text-level knowledge only (e.g., stances in debates), but not to generate a complete annotated dataset for argumentativeness.

The work that is most related to ours is the proposal of a method to exploit debate portals for semi-supervised argumentation mining by Habernal and Gurevych (2015). In particular, the authors use word embedding techniques for projecting the texts from debate portals into an annotated argument space, relying on the argument model of Toulmin (1958). On this basis they identify argumentative text segments and their roles. A clear difference to our approach is that Habernal and Gurevych (2015) consider all content of debate portals as argumentative. As a consequence, their approach concentrates mainly on exploiting the debate portals for improving the classification of segment roles, with minor impact on argumentativeness. Moreover, while being comparably effective, our approach aims for simplicity. The reason is that we apply distant supervision to derive a robust resource from the metadata of debate portals only. Thus, we allow for a rich feature space without requiring to use advanced machine learning methods. Finally, Habernal and Gurevych (2015) evaluate their approach only on one dataset from the educational domain, whereas we explicitly aim at robustness across domains. Accordingly, we conduct several experiments on different available corpora (including theirs).

3 Mining Argumentative Text through Distant Supervision

We propose an approach based on the distant supervision paradigm. Our goal is to obtain a classifier that can robustly mine argumentative texts across domains. More precisely, we focus on the task of classifying each segment of a text as being argumentative or not. We assume the text to be separated into segments already.

Our approach consists of three high-level building blocks: (1) Mapping functions that allows an automatic acquisition of argumentativeness annotations from debate portals. (2) A corpus with argumentative and non-argumentative text segments created using the functions. (3) A classifier that can distinguish the two classes of text segments. All building blocks are detailed in the following. Figure 1 depicts an overview of the approach.

3.1 Argumentativeness Mapping Functions

The basic idea of distant supervision is to generate annotations by automatically mapping unlabeled source data to a set of predefined class labels. This requires resources that are related to the given task as well as effective heuristic labeling functions. Typical resources comprise large amounts of data, often in form of user-generated content with semi-structured or structured metadata. Ideally, the resource's metadata substantially eases the mapping to the predefined labels.

In the context of argumentation mining, online debate portals serve as a rich source of argumentative

Class	Metadata	Text
–	Stance	This house believes single-sex schools are good for education.
Non-Argumentative	Introduction	Single-sex schools are schools that only admit those of one specific gender, believing that the educational environment fostered by a single gender is more conducive to learning than a co-educational school. Studies conducted have shown that boys gain more academically from studying in co-education schools, but that girls find segregated schools more conducive to achievement.
Argumentative	Points for	Boys and girls are an unwelcome distraction to each other.
Argumentative	Point	Boys and girls distract each other from their education, especially in adolescence as their sexual and emotional sides develop.
Argumentative	Counterpoint	Any negative effects of co-educational schools have been explained away by studies as the result of other factors, such as classroom size and cultural differences [1]. [1] *Bronski, M., 'Single-sex Schools'. Znet, 25 October 2002.*
Argumentative	Points against	Children need to be exposed to the opposite sex in preparation for later life.
Argumentative	Point	The formative years of children are the best time to expose them to the company of the other gender, in order that they may learn each others' behaviour.
Argumentative	Counterpoint	Children will gain exposure to the opposite sex when they reach adult life; whilst they are young, they should be around those who they feel most comfortable with.

Table 1. Excerpt of a sample discussion from idebate.org: the stance, the introduction, and some points for and against the stance. Except for parts shown in grey, all listed text segments are mapped to the listed classes.

texts on diverse topics. These portals are typically managed by user communities. Textual content can be added via a structured interface that already specifies metadata (e.g., what constitutes a topic or an argument). Thus, mapping text segments from debate portals to classes for argumentation mining is a promising instance of distant supervision.

In particular, we rely on idebate.org. This debate portal has an established community of experienced debaters and volunteers who take care of editing and monitoring semi-structured discussions on various controversial topics, subsumed under 14 high-level themes. A discussion (called "house" in the portal's terminology) starts with a one-sentence *stance* on the respective topic, followed by a more verbose introduction to the topic. Afterwards, points for and against the stance are opposed, both given as a list of arguments. Each argument in turn comes along with points (the argument itself) and counterpoints (counterarguments). Table 1 shows an example.

We downloaded all available discussions from idebate.org. For each discussion, the stance on the topic, the introduction, and the points are extracted from the URL of the web page of the respective discussion. Based on the structure exemplified in Table 1, we stipulate on the following assumptions to automatically map components from the debate portal to annotated argumentativeness instances.

[Component]: *Introduction*

– [Assumption]: The introduction explains the topic and gives important background information in a non-argumentative way.

– [Mapping]: Each sentence in the introduction is an instance of the non-argumentative class.

[Component]: *Points for & Points against*

– [Assumption]: Each point from these lists represents an argument for or against the stance on the topic of discussion.

– [Mapping]: Each point is an instance of the argumentative class.

[Component]: *Point & Counterpoint*

– [Assumption]: The main objective of a point (counterpoint) is to justify (attack) the point in the points-for or points-against list it refers to. We assume that the intention of such a point is to provide reasons for / against an argument.

– [Mapping]: Each sentence in a point / counterpoint is an instance of the argumentative class.

Domain	Documents	Argum. segments	Non-argum. segments

Table 2. Number of documents, argumentative segments, and non-argumentative segments in each domain of our Webis-Debate-16 corpus. Domains correspond to themes from idebate.org.

To optimize the mapping quality, we manually analyzed 50 discussions and then derived three tailored cleansing rules from them: (1) We remove all literature references from the argumentative instances. (2) We delete all special brackets and symbols from the argumentative instances. (3) We delete some keywords from the non-argumentative instances that are used by the community to organize a discussion (e.g., “this house” or “this debate”).

3.2 The Webis-Debate-16 Corpus

As a result of applying the defined mapping functions, we obtained a large argumentation mining corpus, called *Webis-Debate-16*. The corpus contains 28,689 text segments from the 14 themes of idebate.org (23,880 argumentative, 4809 non-argumentative). Each theme is assumed to represent one domain. Table 2 lists the distribution of documents over the domains in the corpus. Regarding the number of annotated text segments, Webis-Debate-16 is the largest dataset published so far for argumentation mining. While our review corpus from (Wachsmuth et al., 2014b) is even larger, its annotations are restricted to sentiment-related argumentation. Table 3 compares Webis-Debate-16 to other real argumentation mining corpora, namely, the Essays corpus (Stab and Gurevych, 2014a), the Web discourse corpus (Habernal and Gurevych, 2015), the European Court of Human Rights (ECHR) corpus (Palau and Moens, 2009), and the Araucaria corpus (Reed and Rowe, 2004). The Webis-Debate-16 corpus will be made freely available online.[2]

Corpus	Documents	Argum. segments	Non-argum. segments
Essays	90	1552	327
Web discourse	340	1882	2074
ECHR	47	1067	1449
Araucaria	641	1931	1010
Webis-Debate-16	445	23880	4809

Table 3. Statistics of our Webis-Debate-16 corpus compared to four existing argumentation mining corpora. ECHR is a legal domain corpus that is not publicly available. More details on the others are given in Section 4.

3.3 A Classifier for Argumentativeness

A wide range of statistical and linguistic features has been suggested for argumentation mining and related tasks such as discourse parsing. We employ supervised machine learning to train an argumentativeness classifier based on the features employed by Stab and Gurevych (2014a), Palau and Moens (2009), and Habernal and Gurevych (2015) that cover the following:

Token n-grams: Unigrams, bigrams, and trigrams as Boolean features. In general, n-grams are the most powerful feature type in many related text classification problems (e.g., sentiment analysis).

Discourse markers: Features that represent the existence of words such as “because”, which are frequently used in argumentative texts.

Syntax: This feature category contains the number of sub-clauses and production rules.

- Number of sub-clauses: Counter for the number of SBAR tags in the constituency parse tree of a text segment, referring to subordinate clauses in the Penn treebank syntactic tagset.
- Production rules: Boolean features capturing the specific production rules extracted from the constituency parse tree.

Part of speech: Features that capture information related to the parts of speech in a text segment:

[2] http://www.uni-weimar.de/medien/webis/corpora

- Verbs: A boolean feature capturing whether a segment contains a verb. Verbs such as “believe” strongly indicate of argumentative text.
- Adverbs: A boolean feature capturing whether a segment contains an adverb. Many adverbs such as “personally” can play a role in identifying argumentative text.
- Modals: A boolean feature capturing whether a segment contains a modal verb. Modal verbs such as “should” can be important for argumentativeness.
- Verb tense: Boolean features capturing whether a segment contains a past or present tense verb.
- First person pronouns: Pronouns such as “I” and “myself” can be good indicators of claims, a major component of argumentative texts.

Using these features, we train a binary statistical classifier for argumentativeness. Given a set of text segments, the classifier decides for each text segment whether it is argumentative or not.

4 Evaluation

We now report on several in-domain and cross-domain experiments with the classification of argumentativeness. The goals are (1) to demonstrate the effectiveness and robustness of training on the Webis-Debate-16 corpus for cross-domain classification, and (2) to analyze the effectiveness of the proposed features across domains and registers.

4.1 Experimental Setup

To evaluate the effect of using the Webis-Debate-16 corpus for training, appropriate argumentation corpora are needed for comparison. We consider an available corpus as appropriate if (1) the corpus is annotated in a way that allows the distinction of argumentative from non-argumentative text segments, and if (2) the corpus comes with clear annotation guidelines and reported inter-annotator agreement. In addition, we aim at corpora that differ in terms of the covered domains and registers to provide an adequate cross-domain setting. While the Araucaria corpus does not meet the second requirement (Reed and Rowe, 2004), two recently published corpora fulfill both; we refer to them as the *Essays* corpus and the *Web discourse* corpus.

Essays: The Argument Annotated Essays corpus of Stab and Gurevych (2014a) consists of 90 manually annotated persuasive student essays from the education domain. Argumentative text segments are assigned with their type (major claim, claim, or premise). Following Stab and Gurevych (2014b), we consider all sentences that do not have an annotation as being non-argumentative, and the annotated segments as argumentative.

Web discourse: The Argument Annotated User-generated Web Discourse corpus of Habernal and Gurevych (2015) consists of 340 documents from six different topics and four registers. The annotation of arguments is conducted based on the argument model of Toulmin (1958) using five types (claim, premise, backing, rebuttal, and refutation). Again, we consider all annotated text segments as being argumentative and sentences without annotation as being non-argumentative.

Only in case of the Essays corpus, the authors already provide a split into a training and a test set (72 essays for training and 18 for testing). For both the Web discourse corpus and our corpus, we randomly split the document set into 80% for training and 20% for testing. As a result, the training set of the Web discourse corpus consists of 272 documents, and its test set of 68 documents, while the training and test sets of our corpus consist of 356 and 89 documents, respectively.

We train classifiers for each of the above feature types and for the full feature set on the training set of each corpus using the default configuration of the naive Bayes implementation of Weka (Hall et al., 2009). Since all corpora are imbalanced in terms of the number of argumentative and non-argumentative text segments, we perform undersampling for all training sets—an effective technique for largely imbalanced datasets (Japkowicz and Stephen, 2002). All feature values are computed based on the output of the StanfordNLP library (Manning and Klein, 2003). For the different classifiers, we measure the resulting classification performance on all three test sets in terms of accuracy and F_1-score.

4.2 In-Domain Results

Table 4 shows the results of the in-domain experiments. For the full feature set, the achieved F_1-score

	Essays		Web discourse		Webis-Debate-16	
Feature type	**Accuracy**	**F_1-score**	**Accuracy**	**F_1-score**	**Accuracy**	**F_1-score**
N-grams	0.640	0.698	0.815	0.816	0.905	0.908
Syntax	0.599	0.664	0.874	0.874	0.855	0.664
Discourse markers	0.390	0.438	0.584	0.444	0.236	0.180
Part of speech	0.625	0.684	0.541	0.543	0.659	0.702
Full feature set	**0.668**	**0.722**	**0.877**	**0.878**	**0.918**	**0.922**

Table 4. The results of all in-domain experiments on the three corpora for each feature type and the full feature set.

of 0.922 and the accuracy of 0.918 on the Webis-Debate-16 corpus are high compared to those on the Essays and Web discourse corpus. This might be a result of guidelines suggested by the debate portal community, which make the corpus quite homogeneous in terms of style.

Using the full feature set leads to the best results on all three corpora. N-grams denote the most effective single feature type on the Essays copus and on the Webis-Debate-16 corpus, while the syntax features outperform the n-grams on the Web discourse corpus. On the Essays and on the Webis-Debate-16 corpus, the syntax features are sometimes better and sometimes worse than the part of speech features. The discourse markers are the least effective single feature type, largely failing on all test sets, especially in terms of F_1-score.

Note that a comparison to the exact values reported by Stab and Gurevych (2014b) for the Essays corpus and by Habernal and Gurevych (2015) for the Web discourse corpus is not be meaningful due to their experimental set-ups with different class sets. However, their reported results for the non-argumentative class are comparable to the performance we achieved: Stab and Gurevych (2014b) achieve an F_1-score of 0.275 with lexical features and 0.426 with syntax features on the Essays corpus, while Habernal and Gurevych (2015) obtain an F_1-score of 0.718 with lexical features and 0.671 with syntax features on the Web discourse corpus.

4.3 Cross-Domain Results

Table 5 shows the results of the cross-domain experiments. For comparison, we again show the in-domain results in grey color.

As usual, the obtained cross-domain effectiveness values are lower than the in-domain values in most cases and the full feature set usually outperforms feature subsets. One notable exception are the results for the part of speech features on the Essays corpus. The cross-domain effectiveness trained on the Webis-Debate-16 corpus is about six points higher than the in-domain effectiveness in terms of F_1-score and four points in terms of accuracy. For testing on the Web discourse corpus, training on the Webis-Debate-16 corpus using the full features gives the best cross-domain performance. For testing on the Webis-Debate-16 corpus, training on the Web discourse corpus using the n-gram feature type achieves the best cross-domain performance.

Overall, the best corpus for cross-domain classification in our evaluation is clearly the Webis-Debate-16 corpus. Training on Webis-Debate-16 leads to the best cross-domain results for the full feature set and three out of four of the single feature types (n-grams, syntax, and part of speech). Only for the discourse markers, the Web discourse corpus performs better in the cross-domain scenario.

Finally, we observe that the n-grams feature type turns out to be the most domain-dependent in our evaluation. In contrast, both the syntax and the part of speech features appear quite robust across domains. The performance of the discourse markers greatly depends on how frequent they are used in the target domain and register.

Although combining the Webis-Debate-16 corpus to the training datasets of the Essays or the Web discourse corpus increased the performance compared to training only on Webis-Debate-16, it did not outperform the in-domain performance for both corpora. For conciseness, we therefore omit to report the results of our respective experiments here.

4.4 Discussion of our Approach to Robustness

As expected, our experiments reveal the domain dependence of feature distributions in classifying argu-

		Test on Essays		**Test on Web discourse**		**Test on Webis-Debate-16**

	Webis-Debate-16	**0.617**	**0.678**	**0.726**	**0.725**	0.918	0.922

Table 5. The results of all cross-domain experiments on the three corpora for each feature type and the full feature set.

mentativeness. This finding emphasizes the importance of explicitly dealing with domain robustness in argumentation mining whenever more than one domain (in terms of a topic, register, or similar) is of interest. To achieve robustness, we have proposed a simple but effective approach that applies distant supervision to create a corpus for classifying argumentativeness. Our results are promising: Classification clearly improves across domains when being trained on our Webis-Debate-16 corpus instead of other available argumentation mining corpora.

The obtained results suggest that our approach can be effectively leveraged to achieve domain robustness. One reason is probably the larger size and domain coverage of our Webis-Debate-16 corpus compared to the other tested corpora. This makes our corpus and the underlying distant supervision idea a valuable resource for research on argumentation. More noise reduction might even further increase the performance of training on the corpus.

In its current form, our corpus contains annotations for distinguishing argumentative from non argumentative text only. While more fine-grained annotations of argumentative texts, such as premise vs. claim, are important for argumentation mining, they cannot be obtained directly from the metadata of idebate.org. Still, the positions of segments in some parts of the debate portal (e.g, point and counterpoint) often indicate whether they are claims or premises. We plan to investigate the exploitation of such information for future versions of the corpus.

So far, we have shown how to create an annotated corpus classifying argumentativeness exploiting one specific debate portal via distant supervision. In principle, our approach is rather general and, thus, could also be applied to other argumentation resources and tasks. Indeed, idebate.org is only one of many web resources with lots of argumentative texts and argumentation-relevant metadata. Aside from debate portals, one such resource is given by Wikipedia talk pages. Very recently, Wikipedia introduced markups within these article discussions, such as *support* or *oppose*. While still being in an early stage, this metadata seems promising to derive argumentative relations from it. We plan to use our distant supervision approach for classifying argumentative relations on such resources. This can then be an important next step to enable the assessment of *argument relevance*—a core building block of an argument retrieval system.

4.5 From Argumentativeness to Relevance

As motivated in the introduction, a retrieval system for arguments not only requires the identification and classification of argumentative text segments. A successful future search engine taking argument features into account additionally needs a way of ranking arguments according to their relevance. In this regard, we propose a “PageRank for arguments” based on the link network of support and attack relations between arguments.

In particular, given robust algorithms to identify arguments and their relations across web pages (e.g., via distant supervision), we could build an *argument graph* for the web. Related research has already used the argumentation framework of Dung (1995) to find accepted arguments based on such a graph on a much smaller scale (Cabrio and Villata, 2012a). However, the size of the web would allow for recursive analysis of the graph with statistical approaches like the famous PageRank algorithm (Page et al., 1999), enabling an assessment of argument relevance. Several research questions arise from this idea (e.g., how to balance support and attack within the analysis) but argument relevance forms a very important future research direction.

5 Conclusion

Most existing approaches tackle argumentation mining in a supervised manner trained on manually annotated documents from a specific domain. Such approaches neither tend to be effective on documents from other domains, nor do they scale to applications that deal with huge document collections, such as search engines. In this paper, we investigate how to achieve robust performance for argumentation mining across domains, focusing on the classification of the argumentativeness of text segments. In particular, we approach the data side of this problem, namely, we apply distant supervision to automatically create a large annotated corpus with argumentative and non-argumentative text segments from several domains, exploiting metadata from the online debate portal idebate.org.

Based on the created corpus and on common manually annotated corpora, we conduct several in-domain and cross-domain argumentativeness experiments. Our results clearly indicate that training on the created Webis-Debate-16 corpus yield the most robust cross-domain classifier. Thereby, our approach serves as a starting point for bringing argumentation mining to practical applications like search engines. The corpus as well as an implementation of the approach will be made freely available. Besides a robust identification of argumentative segments, search engines will also need to decide which arguments are the most relevant to a given query— a very promising future research direction in the field of argumentation mining.

A Study of the Impact of Persuasive Argumentation in Political Debates

Amparo Elizabeth Cano-Basave and **Yulan He**
Aston University, UK
a.cano-basave@aston.ac.uk,y.he@cantab.net

Abstract

Persuasive communication is the process of shaping, reinforcing and changing others' responses. In political debates, speakers express their views towards the debated topics by choosing both the content of their discourse and the argumentation process. In this work we study the use of semantic frames for modelling argumentation in speakers' discourse. We investigate the impact of a speaker's argumentation style and their effect in influencing an audience in supporting their candidature. We model the influence index of each candidate based on their relative standings in the polls released prior to the debate and present a system which ranks speakers in terms of their relative influence using a combination of content and persuasive argumentation features. Our results show that although content alone is predictive of a speaker's influence rank, persuasive argumentation also affects such indices.

1 Introduction

In recent years, researchers have studied political texts detecting ideological positions (Sim et al., 2013; Hasan and Ng, 2013), predicting voting patterns (Thomas et al., 2006; Gerrish and Blei, 2011) and characterising power based on linguistic features (Prabhakaran et al., 2013). While there is a vast amount of theoretical research on the rhetoric of politicians, only recently there has been a growing interest in understanding the argumentation processes involved in political communication by means of computational linguistics (Hasan and Ng, 2013; Boltužić and Šnajder, 2014).

During a debate, a speaker tries to convince the audience of a particular point of view. This normally involves an argumentation process, where the structuring of ideas is built upon logical connections between claims and premises, and a persuasive communication style. In this paper, we study the impact of persuasive argumentation in political debates on candidates' power/influence ranking. As opposed to previous approaches, we propose to characterise political debates based on persuasive argumentation modelled through semantic frames.

Previous work (Rosenberg and Hirschberg, 2009) has analysed political speech transcripts identifying prosodic and lexical-syntactic cues which correlate with political personalities. Prabhakaran et al. (2013) proposed interactions within political debates as predictors of a candidate's relative power or influence rank in polls. More recently they also found topic-shifting to be a good indicator of candidate's relative rankings in polls (Prabhakaran et al., 2014). Argumentation in debates has been studied from the perspective of automatic argument extraction (Cabrio and Villata, 2012) and stance classification (Hasan and Ng, 2013). However, to the best of our knowledge, argumentation has not been explored as a influence rank indicator. Moreover the study of persuasion in the NLP community has been so far limited.

The novelty of our work is the proposal of a method to automatically extract persuasive argumentation features from political debates by means of the use of semantic frames as pivoting features. We have trained a rank Support Vector Machine (SVM) model based on content and persuasive ar-

San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

gumentation features in order to rank debate speakers. Our experimental results on the 20 debates for the Republican primary election show that certain types of persuasive argumentation features such as *Premise* and *Support Relation* appear to be better predictors of a speaker's influence rank compared to basic content features such as unigrams. When combining with content-related features, most persuasive argumentation features give superior performance compared to the baselines.

2 Persuasive Argumentation

Argumentation has been defined as a verbal and social activity of reason which aims to increase the acceptability of a controversial standpoint by putting forward a set of connected propositions intending to justify or refute a standpoint before a rational judge (van Eemeren et al., 1996). Different argumentation theories propose various schemes for describing the underlying structure of an argument (Toulmin., 1958; Walton et al., 2008; Freemen, 2011; Peldszus and Stede, 2013). All these theories generally agree in that an argument can be structured by means of two argument components and two argumentative relations. The argument components include *claims* and *premises*. A claim is a central component of an argument and is characterised as being a controversial statement to be judged as true or false. Moreover a claim cannot be accepted by an audience without additional support. Such support is provided in the form of premises underpinning the validity of the claim. The following sentence illustrates an example[1] of an argument highlighting the claim and premises:

> ‘‘**People aren't investing in America** *because this president has made America a less attractive place for investing and hiring than other places in the world.*” (Former Governor Mitt Romney)

While *argumentation* focuses on the rational support structured to justify or refute a standpoint, *persuasion* focuses on language cues aiming at shaping, reinforcing and changing a response. In persuasive communication such response ranges from perceptions, beliefs, attitudes and behaviours.

Persuasive language is characterised by the use of emotive lexicons (e.g., atrocious, dreadful, sensational, highly effective) where the speaker tries to engage with the audience's emotions (Macagno and Walton, 2014). Often words with emotive meanings can present values and assumptions as uncontroversial, acting therefore as potentially manipulative instruments of argumentation (Macagno, 2010). Other characteristics of persuasive language include the use of alliteration, which is a stylistic device characterised by the repetition of first consonants in series of words. This artistic constraint enables the speaker to sway the audience by feeling an urgency towards a rhetorical situation by intensifying any attitude being signified (Bitzer, 1968; Lanham, 1991). The use of a repeating sounds engages auditory senses leading to the evoking of emotions that engage the audience.

The following is an example of persuasive language[2]:

> “I'm convinced that part of **the *divide* that we're experiencing in the United States**, which is **un**precedented, it's **u**nnatural, and it's **un**-American, is *because we're divided economically, too few jobs, too few opportunities*” (Former Governor Huntsman).

To the best of our knowledge however, the study of the relation of persuasion and argumentation in political debates is limited. One of the main challenges is the lack of annotated corpora which include both argument annotations and persuasive messages annotations. While there has recently been released a corpus of persuasive essays (Stab and Gurevych, 2014) containing annotations for both class-level argument components and argument relations, there is yet none annotated corpora for persuasive arguments in political debates. In order to study whether persuasive cues and persuasive argumentation can be used as predictors of speakers' influence ranking on a debate, we propose to bridge between existing persuasive and political corpora through semantic frame features. The following section introduces the proposed strategy to port annotation between two corpora.

[1] This is extracted from our Debate corpus transcripts. Bold letters represent the argument and italics the premises.

[2] Representing emotive language in italic bold and alliteration in bold underscored.

3 Extracting Persuasive Argumentation Features from Political Debates

In order to study whether persuasive argumentation can be used as predictors of speakers' influence ranking on a debate, we propose to use the persuasive essays corpus compiled by Stab and Gurevych (2014) to study persuasive argumentation in political debates through the use of semantic frames.

3.1 Persuasive Essays (PE) Corpus

A persuasive essay is an essay written with the aim of convincing a reader on adopting a way of thinking regarding a stance taken on a topic. Unlike speech where an audience can be persuaded by means of social features or speech style, essays only rely on the written word depending therefore solely on the writer's persuasive style.

The Persuasive Essays (PE) corpus consists of 90 essays comprising 1,673 sentences. It contains annotations for both class-level argument components and argument relations. The class-level annotations include: 1) major claims; 2) claims; 3) premises and 4) the argumentative relations being either "support" or "attack". Argumentative relations are directed relations between source and target components (e.g., between premises, claims and major claims). The PE argument annotations follows the scheme described in Table 1.

Claim	Controversial Statement which is either true or false, and which should not be accepted or otherwise without additional support
Premise	Justifies the validity of a claim
ForStance	Indicates that an argument supports a claim
AgainstStance	Indicates that an argument refutes a claim
SupportRel.	Indicates which supporting premises belong to a claim
AttackRel.	Indicates which refuting premises belong to a claim

Table 1: Persuasive essays argument annotation scheme.

3.2 Presidential Political Debates (PD) Corpus

Presidential political debates enable candidates to expose and discuss their stances on policy issues contrasting them with other candidates' stances. During a debate, speakers unveil their discourse style as well as the premises supporting their claims. For our experiments, we collected the manual transcripts of debates for the Republican party presidential primary election from The American Presidency Project[3]. This political debates corpus (PD) consists of 20 debates which took place between May 2011 and February 2012. A total of 10 candidates participated in these debates with an average participation of 6.7 candidates per debate. This corpus comprises 30-40 hours of interaction time and an average of 20,466.6 words per debate.

These debates follow a common structure in which a moderator directly addresses questions to the candidates where disruptions to answers are common due to interruptions from other candidates. In this corpus, each debate transcript lists the speakers including moderator and candidates and questions asked during the debate. Each transcript also clearly delimits turns between speakers and moderators as well as mark-up occurrences of the audience's reactions such as booing and laughter.

3.3 Semantic Frames

We propose to make use of the persuasion essays corpus annotations to understand persuasive argumentation in political debates by means of the use of semantic frames. A semantic frame is a description of context in which a word sense is used. We make use of FrameNet (Baker et al., 1998), which consist of over 1000 patterns used in English (e.g., Leadership, Causality, Awareness, and Hostile encounter). In this work we extract such patterns using SEMAFOR (Das et al., 2010).

Consider the sentence in Table 2 in which two semantic frames are detected. Each parsed semantic frame consists of $\{$Frame, SemanticRole, label$\}$ providing a higher level characterisation of a text, highlighting the semantics of the discourse used in this text. If such semantic frames appear to be some of the most prominent features for a certain persuasive argumentation annotation scheme (e.g., "Claim"), then we can extract persuasive argumentation features from the unlabelled Political Debates corpus using semantic frames as pivoting features.

In this work we propose to port annotations between the Persuasive Essays (`PE`) and Political Debates (`PD`) corpora by means of the use of semantic frames as pivoting features.

To represent the `PE` corpus, let $A = \{a_1, .., a_n\}$

[3] http://www.presidency.ucsb.edu/debates.php

Sentence:	What we need in this country is to use this issue as a national security tool.	
FRAME	SEMANTIC ROLE	LABEL
Political_locales	Target	national security
Point_of_dispute	Target	this issue

Table 2: Semantic frames parsed for a sentence extracted from the debates dataset.

be the set of annotation schemes described in Table 1 and let $T_a = \{t_1, .., t_n\}$ be the collection of sentences annotated with argument scheme a. To represent the PD corpus, let's $U_D = \{u_1, .., u_n\}$ be the set of speakers taking part on a debate D. Let $S_{uD} = \{s_1, .., s_n\}$ be the set of sentences generated by speaker u on debate D.

Taking the PE corpus as a reference corpus, we propose to generate a vector representation of each annotation scheme in A for each speaker in each debate of corpus PD by following the steps below: i) Based on tf-idf we extract the most representative semantic frames for each annotation scheme a in PE as the vector SF_a; ii) We compute the weighted representation of each annotation scheme a in the PD corpus as the vector $f^u_{d,a}$ for each speaker u on each debate d as follows: a) First we compute the bag of semantic frames SF^u_d from speaker u in debate d based on the speaker's content on the debate; then b) For each annotation scheme a we weight vector $f^u_{d,a}$ based on the normalised frequency of each semantic frame element in SF^u_d appearing in SF_a.

3.4 Semantic Frames and Argument Types

The statistics of the extracted semantic frames from PE for each argument type are presented in Table 3.

Arg. Type	Sentences	Semantic Frames (SF)
Claim	519	404
Premise	1,033	518
ForStance	365	369
AgainstStance	64	173
SupportRel.	1,312	535
AttackRel.	161	275

Table 3: Number of semantic frames extracted from PE.

Such semantic frames provide a vector representation characterising each persuasive argumentation scheme described in Table 1. Table 4 presents a sample of the top semantic frames representing each argumentation type.

Arg. Type	**Top 5 Semantic Frames**
Claim	Reason, Stage_of_Progress, Evaluative_Comparison, Competition, Cause_to_Change
Premise	Removing, Inclusion, Killing, Cognitive_Connection, Causation
ForStance	Cause_to_Make_Progress, Collaboration, Purpose, Kinship, Expensiveness
AgainstStance	Intentionally_Act, Importance, Capability, Leadership, Usefulness
SupportRel.	Dead_or_Alive, Institutions, State_Continue, Taking_Sides, Reliance
AttackRel.	Usefulness, Likelihood, Desiring, Importance, Intentionally_Act

Table 4: Top 5 semantic frames for each argument type of PE.

Using the vector representation of each annotation scheme generated from PE, we computed the persuasive argumentation features for the PD corpus. Table 5 presents a sentence sample for each argument type identified in the PD corpus along with the semantic frames characterising the sentence.

4 Influence Ranking in Political Debates

We study a speaker's influence on an audience based on his/her persuasiveness language and argumentation styles during a political debate. To measure how influential a speaker is on an audience, we make use of the *influence index* (Prabhakaran et al., 2013), which is calculated based on a speakers relative standing on poll released prior to the debate.

Poll scores describe the influence a speaker has to favourably change the electorate position towards his/her campaign. Given a debate D and the set of speakers U_D we retrieve the poll results released prior to the debate and use the percentage of electorate supporting each candidate. If for a given debate there are multiple polls then the index is computed taking the mean of poll scores. Therefore the influence index P of speaker $u \in U_D$ is:

$$P(u) = \frac{1}{|polls(D)|} \sum_{i=1}^{|polls(D)|} p_i \qquad (1)$$

where p_i is the poll percentage assign to speaker u in poll i in the reference polls.

Arg. Type	Sentence	Semantic Frames
Claim	If we can turn Syria and Lebanon away from Iran, we finally have the capacity to get Iran to pull back.	Cause_Change, Manipulation, Capability
Premise	Because they put that money in, the president gave the companies to the UAW, they were part of the reason the companies were in trouble.	Causation, Predicament, Leadership
ForStance	And the reason is because that's how our founding fathers saw this country set up.	Reason, Kinship, Perception_Experience
AgainstStance	I was concerned that if we didn't do something, there were some pretty high risks that not just Wall Street banks, but all banks would collapse.	Emotion_Directed, Intentionally_Affect, Daring
SupportRel.	I went to Washington, testifying in favor of a federal amendment to define marriage as a relationship between man and a woman.	Taking_Sides, Cognitive_Connection, Evidence
AttackRel.	But you can't stand and say you give me everything I want or I'll vote no.	Desiring, Posture, Capability

Table 5: Example sentence for each argument type and its corresponding semantic frames identified from PD. Note that there is no annotation in PD. The argument types here are assigned manually for easy reference.

4.1 Features

We characterise each speaker in each debate based on the content and emotion cues he/she generated. Specifically we analyse each candidate in three dimensions: i) what they said (content features); ii) the persuasiveness of the language they used including persuasive argumentation features and emotive language; iii) and external emotions evoked during the debates. We described each set of features below.

4.1.1 Content Features

We use a set of features which characterise content of a candidate's participation on a debate (Prabhakaran et al., 2013). These include: 1) Unigrams (UG), which represents lexical patterns by counting frequencies of word occurrences; 2) Question Deviation (QD), difference between observed percentage of questions asked to a candidate and the fair share percentage of questions in the debate; 3) Word Deviation (WD), difference between observed percentage of words spoken by a candidate and the fair share percentage of words in the debate; 4) Mention Percentage (MP), a candidate mention counts normalised based on all candidates' mentions in a debate.

4.1.2 Persuasiveness Features

We represent three types of persuativeness features as follows:

1) *Persuasive Argumentation Features*. Following the method described in the previous section, we extract the semantic frame feature vector representing each annotation scheme ($f^u_{d,a}$) for each speaker on each debate. These vectors provide information of different argumentation dimensions. We have extracted a total of 710 semantic frames in PD.

2) *Alliteration*. After removing stopwords, we computed alliteration as repetitions of part of a word or a full word within a sentence.

3) *Emotive Language*. To characterise the use of emotive language, we generated a list of emotion-related semantic frames (e.g., emotion_directed, emotions_by_stimulus, emotions_by_possibility)[4], then for each speaker u in each debate d, we generated an emotion-frame vector weighted by tf-idf.

Once the features for each speaker have been generated, we followed a supervised learning approach for ranking speakers of a debate based on their influence Index, which can be used to denote how well a speakers participation on a debate has impacted the audience endorsement of his/her campaign.

4.1.3 External Emotion Cues

Previous work (Strapparava et al., 2010) has shown that an audiences' social signal reactions to an idea, such as booing or cheering, are good pre-

[4] FrameNet's frame index, http://tinyurl.com/q2ytth9

dictors of hot-spots where persuasion attempts succeeded or at least such attempts were recognised by the audience. In this work, rather than recognising such persuasion hot-spots, we explore these audiences' reaction cues (e.g applause) as potential predictors of a candidate success on a political debate, we refer to such cues as external emotion cues. For each speaker in a debate, we computed the number of i) applauses (APL); ii) booings (BOO); iii) laughs (LAU); and iv) crosstalks (CRO) he/she received during his/her participation on a debate. These counts were normalised based on the total number of each emotion appeared on the debate.

With these features, we train a supervised learning classifier for ranking speakers of the debates based on their influence indices described in the following section.

4.2 Influence Ranking Approach

In ranking, a training set consists of an ordered data set. Let "A is preferred to B" be denoted as " A $\succ$ B". Let D denote a debate with a set of speakers $U_D = \{u_1, u_2, ..u_n\}$ and influence indexes $P(u_i)$ for $1 < i < n$. We specify a training set for ranking as $R = \{(u_i, \gamma_i), .., (u_n, \gamma_n)\}$ where γ_i is the ranking of u_i based on its $P(u_i)$ so $\gamma_i < \gamma_j$ if $u_i \succ u_j$.

We want to find a ranking function F which outputs a score for each instance from which a global ordering of data is constructed. So the target function $F(u_i)$ outputs a score such that $F(u_i) > F(u_j)$ for any $u_i \succ u_j$. In this work we use the Ranking SVM (Joachims, 2006) to estimate the ranking function F.

5 Experimental Setup

For our experiments we used the Persuasive Essays (`PE`) and Political Debates (`PD`) corpora introduced in previous sections. While the `PE` was used as a reference corpus, all our experiments were performed on the `PD` corpus.

All features are computed for the aggregation of a candidate's content in a debate. For content and alliteration features, we first removed stopwords. In particular, for computing unigram features we also stemmed words using a Porter stemmer (Porter, 1997).

To compute persuasive argumentation features we used the collection of semantic frame features for the reference corpus `PE`.

5.1 Evaluation

In this work, the ranking task evaluation for each debate consists on comparing the generated ranked list of candidates, using the *influence ranking approach* introduced above, against a reference ranked list. Such a reference ranked list corresponds to our gold standard of ranked list of candidates generated based on the polled scores for that debate.

Following a 5-fold cross validation, we report results applying four commonly used evaluation metrics for ranking tasks, *nDCG*, *nDCG-3*, *Kendall's Tau* and *Spearman* correlations. The discounted cumulative gain metric (*nDCG*) penalises inversions happening at the top n elements[5] of a ranked list more than those inversions happening at the bottom. While the nDCG metric penalises certain elements in the list, Kendall's tau and Spearman's rank correlations penalises inversions equally across the ranked list.

6 Results and Discussion

6.1 Correlation Analysis

We performed a correlation analysis for the content and persuasive emotion numeric features[6]. We computed the Pearson's product correlation between each feature with the candidate's influence index $P(u)$ derived from the polls. The computed correlations for these features are presented in Figure 1. Darker bars indicate statistical significance correlation at $p < 0.001$; lighter dark bars at $p < 0.05$; and light bars not statistically significant.

These results show that for the content features, both question deviation (QD) and word deviation (WD) correlate moderately with the influence index; while the mention percentage (MP) feature correlates highly with the influence index ($p < 0.05$). For the emotion cues, we obtained statistically significant ($p < 0.05$) moderate correlations between the applause (APL), laugh (LAU), crosstalk (CRO) and

[5] *nDCG-3* therefore assigns a higher penalisation for inversions happening at the top three elements of a ranked list.

[6] Note that we can perform such correlation analysis only with the numeric features but not with vector features.

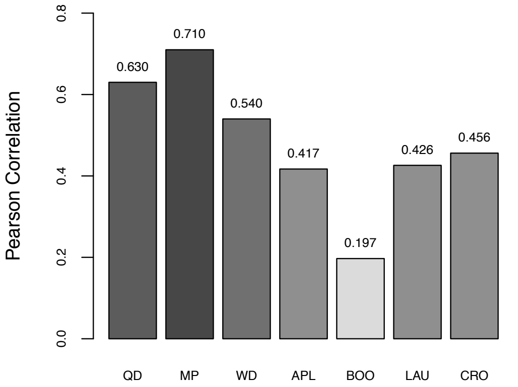

Figure 1: Pearson correlation for content and emotion cues features. Correlation windows: Negligible (0-0.19); Weak (0.2-0.39); Moderate (0.4-0.69); High (>0.69).

the influence index; while the correlation between the booing (BOO) cue and the influence index was not statistically significant. These results indicate that speakers with higher influence index spoke for longer periods of time, in line with existing empirical findings in sociological studies (Ng and Bradac, 1993; Reid and Ng., 2000; Prabhakaran et al., 2013), and were asked a higher number of questions. This analysis also indicates that speakers with higher influence index generated more crosstalk, in line with previous empirical sociological findings (Ng et al., 1995); received more applauses and made the audience laugh more often.

6.2 Influence Ranking Results

Following the results of the correlation analysis, we conducted experiments using those content and emotion cue features presenting statistically significant correlations with the influence index. Apart from these features, we also consider the persuasive argumentation features and a combination of features from both content and persuasion categories. Results for the prediction of influence ranking using these features are presented in Table 6.

For the *content features*, using the simple unigrams gives the best results. The mention percentage (MP) feature also attains competitive performance. A combination of word deviation, question deviation and mention percentage (WD+RD+MP) however degrades the performance. This is in contrast to the results reported in (Prabhakaran et al., 2013) (denoted as [PR13] in Table 6), where the unigram feature gives much worse results and their best results were obtained using WD+RD+MP. One possible reason is that for the unigram feature used in our experiments, we have performed pre-processing by removing stop words and stemming.

For *external emotion cues*, although some emotion cues appeared to be significantly correlated with the influence index in our analysis, they did not outperform the unigram baseline. We suspect that this might be due to the fact that depending on the location of a debate, certain candidates may bring bigger crowds into the debate's venue, therefore emotion cues can be a deliberate biased way of support. Consequently emotion cues happening within the debate venue may not reflect the emotions induced to the audiences that followed the broadcast of the debate.

When analysing the *persuasion features*, alliteration and emotive language features give better results compared to external emotion cues. But they did not outperform the unigram baseline either.

We find that *persuasive argumentation* features alone provide improvement upon the unigram baseline. In particular, in terms of *nDCG* and *nDCG-3*[7], the *premise* and *support relation* types provide the best results for this feature category. In terms of *Tau* and *Spearman*[8] correlations, the *attack relation* type provides the best results. When focusing only on persuasive argumentation features, these results suggest that speakers with higher influence index tend to use well supported arguments (i.e. present more premisses supporting their claims) and/or tend to attack more other candidates by presenting premises refuting a claim.

When *combining features*, we found that the top 100 persuasive argumentation features ranked by *tfidf* together with word deviations and mention percentages significantly improve upon the baselines for particular argumentation cases including Claim, Premise, ForStance, and SupportRel.

The overall best performing features for predicting influence ranking in terms of *nDCG*, *Tau* and *Spearman* was consistently obtained with the com-

[7] Since *nDCG* and *nDCG-3* penalises inversions at the top of the list, good results in these metrics mean predicting accurately the top of the ranked list.

[8] These metrics provide a general evaluation of the accuracy of the full ranked list.

bined feature for the *Premise* type.

Our results improve upon those recently obtained in (Prabhakaran et al., 2014) in both *nDCG* and *Tau* where topic shift patterns have been added for influence ranking (denoted as [PR14] in Table 6).

These results suggest the relevance of “what they said”, the “ persuasiveness style of their arguments” and the relative importance given by others by means of mentions are good predictors of influence ranking in political debates. In particular when combining the lexical content of candidates’ discourse with their persuasive argumentation style, our results indicate that candidates with higher influence ranking tend to present more premises while clearly stating their stance (i.e. supporting a claim) on a particular topic.

7 Conclusions and Future Work

In this paper, we have studied the impact of argumentation in speaker’s discourse and their effect in influencing an audience on supporting their candidature. In particular, we have conducted the study in the domain of political debates. In order to extract persuasive argumentation features from political debates, we have proposed a novel method to port annotations from a persuasive essay corpus using semantic frames as pivot features.

Our experimental results on the 20 debates for the Republican primary election show that when combined with word deviations and mention percentages,most persuasive argumentation features give superior performance compared to the baselines. Particularly with the *Premise* and *SupportRel* types appear to be better predictors of a speaker’s influence rank. In future work, we will aim to improve the accuracy of the extracted persuasive argumentation features by exploring other methods for identifying persuasive argumentations from text.

Abstract

Coherence is established by semantic connections between sentences of a text which can be modeled by lexical relations. In this paper, we introduce the lexical coherence graph (LCG), a new graph-based model to represent lexical relations among sentences. The frequency of subgraphs (coherence patterns) of this graph captures the connectivity style of sentence nodes in this graph. The coherence of a text is encoded by a vector of these frequencies. We evaluate the LCG model on the readability ranking task. The results of the experiments show that the LCG model obtains higher accuracy than state-of-the-art coherence models. Using larger subgraphs yields higher accuracy, because they capture more structural information. However, larger subgraphs can be sparse. We adapt Kneser-Ney smoothing to smooth subgraphs' frequencies. Smoothing improves performance.

1 Introduction

The concept of coherence is based on cohesive semantic relations connecting elements of a text. Cohesive relations are expressed through grammar and the vocabulary of a language. The former is referred to as *grammatical coherence*, the latter as *lexical coherence* (Halliday and Hasan, 1976). Grammatical coherence encompasses coreference, substitution, ellipsis, etc. Lexical coherence comprises semantic connections among words of a text.

In this paper we measure text coherence by modeling *lexical coherence*. Lexical relations specify cohesive relations over the sentences of a text. These lexical relations can be any kind of semantic relation: repetition, synonymy, hyperonymy, meronymy, etc. These lexical items may or may not have the same reference (Halliday and Hasan, 1976).

> *Why does the little boy wriggle all the time? Girls don't.*

In this example the lexical items *boy* and *girls* are semantically related. Although they do not refer to the same entity, they still connect these two sentences.

There is coherence between any pair of lexical items that stand to each other in some lexico-semantic relation (Halliday and Hasan, 1976). For textual purposes it is not required to determine the type of the relation. It is only necessary to recognize semantically related lexical items, and these relations can be learned by cooccurring lexical items.

One can use world knowledge resources to determine semantic relations. This way is expensive in terms of determining the best resource, e.g. WordNet vs. Freebase. WordNet lacks broad coverage in particular with proper names, Freebase is restricted to nominal concepts and entities.

Recent improvements in embedding representations of words let us efficiently compute semantic relations among lexical items in the vector space. These models use a vector of numbers to encode the meaning of words. We use these vectors to check the existence of any kind of semantic relations between two words.

In the following example the sentences are connected because of the semantic relation between *king* and *queen* which can be induced by word em-

Proceedings of NAACL-HLT 2016, pages 1414–1423,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

bedding models (Mikolov et al., 2013; Pennington et al., 2014).

> *...The king was in his counting-house,*
> *counting out his money,*
> *The queen was in the parlour, eating bread*
> *and honey.*

We model lexical coherence between sentences by a lexical coherence graph (LCG). We consider subgraphs of this graph coherence patterns and use their frequency as features representing the connectivity of the graph and, hence, the coherence of a text (Mesgar and Strube, 2015).

An important task for evaluating a coherence model is readability assessment. The goal of this task is to rate texts based on their readability. The more coherent a text, the faster to read and easier to understand it is. Other coherence models (Barzilay and Lapata, 2008; Guinaudeau and Strube, 2013; Mesgar and Strube, 2014) are also evaluated on this task. Pitler and Nenkova (2008) use the entity grid (Barzilay and Lapata, 2008) to capture the coherence of a text for readability assessment. Mesgar and Strube (2015) extend the entity graph (Guinaudeau and Strube, 2013) as coherence model to measure the readability of texts. They encode coherence as a vector of frequencies of subgraphs of the graph representation of a text. We build upon their method and represent the connectivity of sentences in our LCG model by a vector of frequencies of subgraphs.

Although using the frequency of subgraphs of the lexical coherence graph encodes coherence features well, the subgraph frequency method, in general, is suffering from a sparsity problem when the subgraphs get larger. Large subgraphs capture more structural information, but they occur only rarely. We resolve this sparsity issue by adapting Kneser-Ney smoothing (Heafield et al., 2013) to smooth subgraph counts (Section 3). We estimate the probability of unseen subgraphs, i.e. coherence patterns. This prediction lets us measure the coherence of a text even when its corresponding graph representation contains a subgraph which does not occur in the training data. If the unseen coherence pattern is similar to seen ones, smoothing gives it closer probability to seen coherence patterns in comparison to dissimilar unseen ones. This is due to the base probability factor in Kneser-Ney smoothing.

We evaluate our LCG model on the two readability datasets provided by Pitler and Nenkova (2008) and De Clercq et al. (2014), respectively (Section 4). The results (Section 5) indicate that the LCG model outperforms state-of-the-art systems. By applying Kneser-Ney smoothing we solve the sparsity problem. Smoothing allows us to exploit the high informativity of large subgraphs which leads to new state-of-the-art results in readability assessment.

2 Related Work

The entity grid model (Barzilay and Lapata, 2008) is based on entity transitions over sentences. It uses a two dimensional matrix to represent transitions of entities among adjacent sentences. The entity grid is applied to readability assessment by Pitler and Nenkova (2008). The entity graph (Guinaudeau and Strube, 2013) is a graph-based, mainly unsupervised interpretation of the entity grid. This model represents the distribution of entities over sentences in a text with a bipartite graph. Connections between sentences are obtained by information on entites shared by sentences. Guinaudeau and Strube (2013) perform a one-mode projection on sentence nodes and use the average out-degree of the one-mode projection graph to quantify the coherence of the given text. Mesgar and Strube (2015) represent the connectivity of the one-mode projection graph by a vector whose elements are the frequencies of subgraphs in projection graphs. This encoding works much better than the entity graph for the readability task on the *P&N* dataset and even outperforms Pitler and Nenkova (2008) by a large margin. Zhang et al. (2015) state that the entity graph model is limited, because it only captures mentions which refer to the same entity (the entity graph uses a very restricted version of coreference resolution to determine entities). Zhang et al. (2015) use world knowledge *YAGO* (Hoffart et al., 2013), *WikiPedia* (Denoyer and Gallinari, 2006) and *FreeBase* (Bollacker et al., 2008) to capture the semantic relatedness between entities even if they do not refer to the same entity. Main issues with using world knowledge are: the choice knowledge sources, selection of knowledge from the source, coverage, and language-dependence.

Word embedding approaches like *word2vec* and

GloVe (Mikolov et al., 2013; Pennington et al., 2014) show that the semantic connection between words can be captured by word vectors which are obtained by applying a neural network. The ability to train on very large data sets allows the model to learn complex relationships between words.

3 Method

We introduce a new graph representation of semantic connections over lexical items in texts. Afterwards we compute the frequency of all subgraphs, i.e. coherence patterns. The intuition is that subgraphs capture how sentence nodes are connected and, respectively, encode text coherence.

3.1 Graph Model

We model semantic relations between sentences by a graph $G = <V, E>$ where V is the set of sentence nodes and E is the set of edges between sentence nodes. Two nodes of G are adjacent if there is a semantic connection between the corresponding sentences. Two sentences are semantically connected if there is at least one strong semantic relation between the words of these sentences. We model semantic relations between words by their corresponding word embeddings (Pennington et al., 2014). Given word vectors v_a for word a of sentence A and v_b for word b of sentence B, the cosine similarity value, $cos(v_a, v_b)$, between the two word vectors is a measure of semantic connectivity of the two words. The range of $cos(v_a, v_b)$ is between $[-1, +1]$. One interpretation of cosine is the normalized correlation coefficient, which states how well the two words are semantically correlated (Manning and Schütze, 1999). The absolute value of cosine, $|cos(v_a, v_b)|$, encodes how strongly the two words are connected.

The connection between sentences is obtained from connections between their words (Figure 1). Assume sentence A precedes sentence B, each word b of sentence B is connected with word a^* of A, where

$$a^* = \underset{a \in A}{\operatorname{argmax}}\, cos(b, a)$$

Then from all connections between the words of sentences A and B, the connection with the maximum weight among the words of B is selected to connect these two sentences (Figure 2).

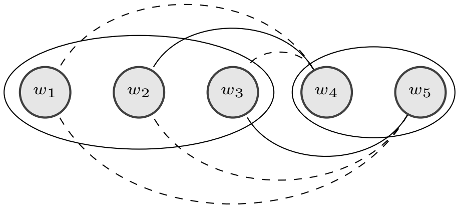

Figure 1: Sentence A with three words $\{w_1, w_2, w_3\}$ and sentence B with two words $\{w_4, w_5\}$. w_4 is highly related to w_2 and w_5 is highly related to w_3.

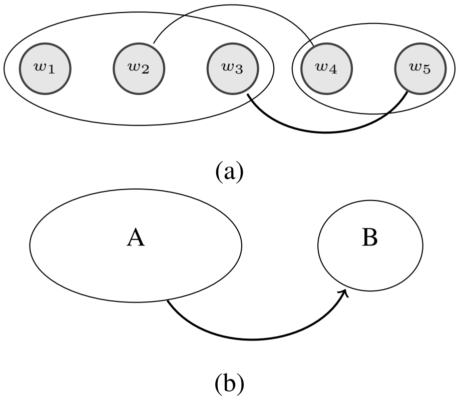

Figure 2: The word relation with the maximum weight (a) represents the connections between sentences (b).

The output of this phase is a graph whose edge weights model the strength of connections between sentences. The edges in this graph are directed to model the order of sentences.

Word embeddings relate each word in sentence A with each word in sentence B. Since the resulting graph is very dense, we filter out edges whose weights are below a threshold[1].

3.2 Coherence Features

Mesgar and Strube (2015) propose that the connection style of an entity graph can be captured by the frequency of all *k-node* subgraphs in this graph. Larger[2] subgraphs[3] can capture more information about the structure of graphs and are more informative coherence patterns than smaller ones. We experiment with $k \in \{3, 4, 5, 6\}$. Text coherence is repre-

[1] We set this threshold to 0.9 to connect only sentences with high confidence.

[2] The size of a subgraph is the number of its nodes.

[3] We compute *induced subgraphs* (Mesgar and Strube, 2015). However, we use the term *subgraph* for brevity.

sented by a vector whose elements are the frequency of subgraphs (coherence patterns) with $k\text{-}node$.

3.3 Smoothing

Although increasing the size k of subgraphs captures more structural information about the connections of sentence nodes, a main risk with large subgraphs is sparsity. Given a sentence graph, many large subgraph types do not occur in this graph. Small subgraph types occur frequently in most sentence graphs in the dataset, but these subgraphs do not capture enough information about the connectivity style of the graphs.

Inspired by Kneser-Ney smoothing in language models (Heafield et al., 2013), each feature vector of a sentence graph can be smoothed. Smoothing deals with the problem of zero counts in the feature vector. It also lets the model having feature values for unseen subgraphs (like OOV in language modeling) which may be seen in the testing phase.

Kneser-Ney smoothing uses a discount factor to discount the raw count of each event (subgraph) and distributes the total discount to all event (subgraph) probabilities by means of a base probability.

The estimated frequency of subgraph sg in a given sentence graph is computed as follows:

$$KN(sg) = \frac{\max\{count(sg) - \alpha, 0\}}{Z} + \frac{M \cdot \alpha}{Z} P_b(sg),$$

where α is the discount factor and M is the number of times that discount factor is applied. Z is a normalization factor to ensure that the distribution sums to one and is obtained as follows:

$$Z = \sum_{sg \in A} count(sg),$$

where A is the set of all subgraphs with $k\text{-}nodes$ and function $count(\cdot)$ computes the number of instances of subgraph sg in the given sentence graph.

$P_b(sg)$ in Kneser-Ney smoothing is the base probability of subgraph sg among all $k\text{-}node$ subgraphs (A). The base probability can be computed based on hierarchical (parent-child) relations in subgraphs. $k\text{-}node$ subgraph sg_i is a parent of $(k{+}1)\text{-}node$ subgraph sg_j, if sg_i is a subgraph of sg_j. Figure 3 shows the parent-child relation between subgraphs via a weighted tree. The root of this tree is a null graph[4]. The weight of a parent-child relation connecting the parent subgraph sg_i and child subgraph sg_j is shown by w_{ij} and computed as follows:

$$w_{ij} = \frac{count(sg_i, sg_j)}{\sum_{sg_l \in A} count(sg_i, sg_l)},$$

where A is all subgraphs with $k\text{-}node$ and k equals the number of nodes of sg_j. Interpretation of weight w_{ij} is the normalized count of sg_i in sg_j with respect to all outgoing edges from sg_i.

The base probability of each subgraph sg_j is the inner product of the Kneser-Ney probabilities of sg_j's parents by the weights of the corresponding relations:

$$P_b(sg_j) = P \cdot W, \tag{1}$$

where P is the vector of probabilities of all parents of sg_j and W is the vector of all corresponding edge weights connecting the parents of sg_j to sg_j.

Since the root node of this tree is the null subgraph, and it is a subgraph of all possible sentence graphs, its base probability is one. Because the edge weights are in the range $[0, 1]$ the sum of the probabilities of all subgraphs with $k\text{-}node$ is always equal to one.

Proof. Assume I and J are the set of all $k\text{-}node$ and $(k{+}1)\text{-}node$ subgraphs. We also assume that I has n subgraphs and $\sum_{i=1}^{n} p(sg_i) = 1$. Considering these assumptions we prove that

$$\sum_{j=1}^{m} p(sg_j) = 1,$$

where m is the number of subgraphs in J.

We start from the left and compute the value of

$$\sum_{j=1}^{m} p(sg_j).$$

Based on the definition of base probability, the value of $p(sg_j)$ is computed based on its parents in I,

$$p(sg_j) = \sum_{i=1}^{n} w_{ij} p(sg_i),$$

where w_{ij} is the weight of the parent-child relation between sg_i and sg_j. Now we have:

[4] A null graph is a graph with no nodes.

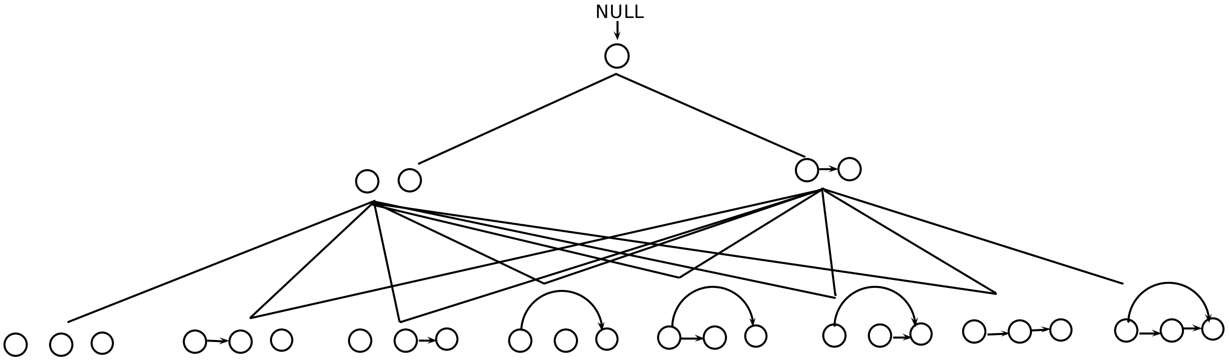

Figure 3: parent child relation.

$$\sum_{j=1}^{m} p(sg_j) = \sum_{j=1}^{m}\sum_{i=1}^{n} w_{ij} p(sg_i).$$

If we exchange the place of the sums and re-write the equation, we have:

$$\sum_{j=1}^{m} p(sg_j) = \sum_{i=1}^{n}\sum_{j=1}^{m} w_{ij} p(sg_i).$$

In this equation $p(sg_i)$ is independent of j (index of the inner sum), so it can be moved out of the inner sum:

$$\sum_{j=1}^{m} p(sg_j) = \sum_{i=1}^{n} p(sg_i) \sum_{j=1}^{m} w_{ij}$$

The inner sum equals 1.

$$\sum_{j=1}^{m} p(sg_j) = \sum_{i=1}^{n} p(sg_i).$$

Based on our assumption the right side of the equation is 1 and

$$\sum_{j=1}^{m} p(sg_j) = 1.$$

So we proved that the sum of the base probability of all k-*node* subgraphs is 1. □

This way, Kneser-Ney smoothing distributes the total discount value by considering the weights of parent-child relations among the subgraphs. The result of applying smoothing is an estimation of the frequency of each subgraph in the sentence graph.

4 Experiments

4.1 Evaluation Task

We evaluate our coherence model on the task of ranking texts by their readability. The intuition is that more coherent texts are easier to read.

Datasets. We run our experiments on two datasets annotated with readability information provided by human annotators: *P&N* (Pitler and Nenkova, 2008) and *De Clercq* (De Clercq et al., 2014).

The dataset *P&N* contains 27 articles randomly selected from the Wall Street Journal corpus[5]. The average number of sentences is about 10 words. Every article is associated with a human score between $[0.0, 5.0]$ indicating the readability score of that article. We create pairs of documents, if the difference between their readability scores is greater than 0.5. If the first document in a pair has the higher score, we label this pair with $+1$, otherwise with -1. The resulting number of text pairs in this dataset is 209.

The dataset *De Clercq* consists of 105 articles from different genres: administrative (17 articles), journalistic (43 articles), manuals (14 articles) and miscellaneous (31 articles). The average number of sentences is about 12. This dataset was annotated by De Clercq et al. (2014) by asking human judges to compare two texts based on their readability. They use five labels:

[5] Pitler and Nenkova (2008)'s dataset contains 30 articles. They remove one. We assume this is `wsj-0382` which does not exist in the Penn Treebank. We furthermore remove `wsj--2090` which does not exist in the final release of the Penn Discourse Treebank. We also remove `wsj-1398` which is a poem and, hence, not very informative for readability assessment.

LME: left text is much easier,

LSE: left text is somewhat easier,

ED: both texts are equally difficult,

RSE: right text is somewhat easier,

RME: right text is much easier.

We map these labels to three class labels:

$+1$**:** for text pairs where the left text is easier to read (LME or LSE),

0**:** for text pairs where both texts are equally difficult to read (ED),

-1**:** for text pairs where the right text is easier to read (RSE or RME).

Properties of this dataset are shown in Table 1.

Genre	No. of articles	No. of text pairs
Administrative	17	272
Journalistic	43	1806
Manuals	14	182
Miscellaneous	31	931

Table 1: Properties of the different genres in the *De Clercq* dataset.

4.2 Experimental Settings

Word Embeddings and Classification. In order to reduce the effect of very frequent words, stop words are filtered by using the SMART English stop word list (Salton, 1971). We use a pretrained model of GloVe for word embeddings. This model is trained on Common Crawl with 840B tokens, 2.2M vocabulary. We represent each word by a vector with length 300 (Pennington et al., 2014). For handling out-of-vocabulary words, we assign a random vector to each word and memorize it for its next occurrence (Kusner et al., 2015). The classification task is done by the SVM implementation in WEKA (SMO) with the linear kernel function. All settings are set to the default values. The evaluation is computed by 10-fold cross validation.

Graph Processing and Smoothing. In order to compare the performance of LCG with the entity graph model, we follow Mesgar and Strube (2015) and use the gSpan method (Yan and Han, 2002) to compute all common subgraphs on each dataset and their frequencies. Note that gSpan does not count all possible $k\text{-}node$ subgraphs, whereas for applying Kneser-Ney smoothing it is necessary to count all possible $k\text{-}node$ subgraphs, because the probability should be distributed among all possible subgraphs. This also helps to estimate the probability of unseen patterns. We use a random sampling method (Shervashidze et al., 2009) to obtain the frequency of subgraphs in a sentence graph. In this regard, we take $10,000$ samples of the given sentence graph by randomly selecting k nodes of the graph to count the occurrence of $k\text{-}node$ subgraphs in this graph. We compute the base probability for at most $k = 6$. We find the best value for d in a greedy manner. First, we initialize d with 0.001. In each iteration we compute the performance. Then we multiply the discount factor by 10. We iterate as long as the discount factor is less than 1000. We report the best performance.

5 Results

In order to compare our method with related work, we run our model on the *P&N* dataset. Table 2 reports the accuracy of *LCG* with different values for k in $k\text{-}node$ subgraphs. This corresponds to coherence patterns spanning different numbers of sentences.

System		Accuracy	
ZeroR		50.24%	
EGrid		83.25%	
$k\text{-}node$	EGraph	EGraph+PRN	LCG
3-node	79.43%	80.38%**	78.95%
4-node	89.00%	89.95%	89.47%
5-node	96.17%**	95.69%**	97.13%

Table 2: *P&N* dataset.

We start in Table 2 with a majority class baseline (*ZeroR*). *EGrid* is our reimplementation of Pitler and Nenkova (2008) which we use as non-trivial baseline. The column *EGraph* is the entity graph model of Mesgar and Strube (2015). In *EGraph+PRN* we extend this model by a pronoun resolution system, so that entities mentioned by pronouns also enter the graph. We apply the Stanford coreference resolution system (Lee et al., 2013). Using the full coreference resolution system, however, decreases performance, hence we only use resolved pronouns. The enriched model with resolved pronouns works slightly better for *3-node* and *4-node* subgraphs, and slightly worse for *5-node* subgraphs than the *EGraph*. The lexical coherence graph model, *LCG*, performs slightly worse than *EGraph* on *3-node* subgraphs. This could be because the graphs in *LCG* have more edges than the graphs in *EGraph*. When graphs are denser *3-node* subgraphs occur in every graph, hence their frequency is less discriminative. As shown in Table 2 larger subgraphs (*4-node* and *5-node*) capture more information and improve upon *EGraph* and for *5-node* subgraphs even upon *EGraph+PRN*. *LCG* significantly ($p\_value = 0.01$) works better than *EGraph+PRN* and *EGraph* using 5-node subgraphs. The difference between *LCG* and *EGraph+PRN* and *EGraph* using 4-node subgraphs is not significant.

Table 3 shows the performance of different models on the *De Clercq* dataset.

System	Accuracy	
ZeroR	42.312%	
k-$node$	EGraph+PRN	LCG
3-node	42.31%	42.31%
4-node	48.07%	49.12%**
5-node	65.77%	76.27%**

Table 3: *De Clercq* dataset.

Again, we use a majority baseline (*ZeroR*) to put our results in context. While the performance of both methods almost does not beat the baseline for *3-node* subgraphs, *4-node*-subgraphs work already better, and *5-node* subgraphs yield reasonable performance on this dataset. Although *EGraph+PRN* and *LCG* reach almost the same performance for *4-node*, the difference between them is statistically significant ($p\_value = 0.01$). With *5-node* subgraphs, *LCG* outperforms *EGraph+PRN* subgraphs by a large margin and gets a very reasonable performance on this dataset.

The general performance on the *De Clercq* dataset is lower than the performance on the the *P&N* dataset. This can have two reasons: first, the ranking task on the *De Clercq* dataset is three-label classification which is more difficult than the binary classification task on the *P&N* dataset. Second, texts in the *De Clercq* dataset are from different genres and coherence patterns may vary across genres. Hence, we take a closer look on the performance on the different genres.

5-node	EGraph+PRN	LCG
Administrative	69.49%	71.69%
Journalistic	65.01%	82.12%
Manuals	54.95%	61.54%
Misc.	70.68%	76.69%

Table 4: Accuracy of *EGraph+PRN* and *LCG* on different genres in the *De Clercq* dataset.

Table 4 shows the performance for *EGraph+PRN* and *LCG* using *5-node* subgraphs on the different genres in the *De Clercq* dataset. The performance of *LCG* is higher than *EGraph+PRN* on all genres. Unlike *EGraph+PRN*, *LCG* gets the best performance on journalistic articles. The lowest performance of both models is obtained on manuals. On administrative articles, performance of *LCG* is slightly better than *EGraph+PRN*. On miscellaneous articles *LCG* performs better than *EGraph+PRN*.

While large subgraphs are very informative for coherence modeling, extracting large subgraphs ($k > 4$) in relatively small datasets leads to a data sparsity problem, as there are very many possible subgraphs to be represented in a high dimensional vector space. Hence, many possible subgraphs have low or even zero counts. The problem for such a vector is that each graph is only similar to itself and not to any other graph. Hence, we observe a drop in performance when the model deals with large subgraphs (*6-node* subgraphs, *LCG1* for *P&N* in Table 5). We solve this problem by smoothing.

In order to apply Kneser-Ney smoothing we use a sampling method to create all possible (connected and disconnected) k-$node$ subgraphs (for *LCG1* and *LCG1** we use connected and disconnected subgraphs, for *LCG* only connected ones).

Table 5 shows the performance of *LCG1* when it is applied to ever larger subgraphs. As can be seen in Table 5, the performance on the *P&N* dataset suddenly drops for *6-node* subgraphs. This is could be caused by the sparsity problem.

When we apply Kneser-Ney smoothing as described in Section 3 the results for all tested values of k are superior for *LCG1** when compared to *LCG1* (Table 5).

Kneser-Ney smoothing improves the performance of the system even with *3-node* subgraphs by a large margin. Smoothing reduces the power of fre-

	P&N		*De Clercq*	
k-*node*	LCG1	LCG1*	LCG1	LCG1*
3-node	84.52%	89.00%	42.31%	49.60%
4-node	95.69%	96.17%	65.10%	66.23%
5-node	97.61%	98.08%	79.33%	79.85%
6-node	93.26%	95.69%	76.67%	78.03%

Table 5: Applying smoothing method yields to higher accuracy for larger subgraphs.

quency and makes the frequency distribution of subgraphs more even. Smoothing reduces the values through all subgraphs by considering parent-child relations between subgraphs to relate similar subgraphs. That is the advantage of the Kneser-Ney method in comparison to the other smoothing methods like Laplace-Smoothing.

For the *P&N* dataset we achieve the best results to date. Pitler and Nenkova (2008) reported 83.25% accuracy, Mesgar and Strube (2015) 89.95%. When smoothing *5-node* subgraphs we are able to report 98.08%. This, however, indicates that this dataset may not be the best one to report performance on. Hence, we now check whether smoothing also improves the performance on the more difficult *De Clercq* dataset.

On this dataset, we basically observe the same trends. Both settings result in better performance than *LCG* (see Table 3).

Note that none of the parameters in this work is tuned on the datasets. One may get better performance by tuning the parameters. The results confirm the intuition that the lexical coherence graph *LCG* captures coherence and models lexical coherence appropriately.

Applying smoothing on graphs of *EGraph+PRN* model increases the performance of this model. But this improvement is not as high as the improvement on the *LCG* graph.

Coherence Patterns. In this part we check the Pearson correlation coefficient between *LCG1* and human judgements of a few frequent subgraphs on the *P&N* dataset. In order to be consistent with Mesgar and Strube (2015), we use the exhaustive value of subgraph frequencies, i.e. *LCG1* for our work.

For the *3-node* subgraphs only one subgraph (Figure 4) in the *LCG1* representation is significantly (and positively) correlated (p-*value*< 0.05) with human scores. For the *4-node* subgraphs, we find six subgraphs which are significantly correlated with readability. Only one is positively correlated, while four are negatively correlated. Interestingly, both positively correlated *3-node* and *4-node* subgraphs have been determined as positively and significantly correlated by Mesgar and Strube (2015) as well. Both also capture a similar coherence pattern, indicating that our method is linguistically sound.

	Pattern	ρ	p-value
3-node		0.43	0.024
4-node		-0.45	0.018
		+0.39	0.047
		-0.43	0.024
		-0.59	0.001
		-0.55	0.003
		-0.55	0.003

Figure 4: Pearson correlation between *3-node* and *4-node* subgraphs and readability scores in the *P&N* dataset.

6 Conclusions and Future Work

In this paper we propose a new graph based coherence model, the lexical coherence graph, LCG. We view coherence as semantic connectedness between words which we model by word embeddings. We take only the strongest connection between sentences to create a graph with connected sentences. Then we extract large subgraphs capturing coherence patterns, which show similarity to patterns described in text linguistics (Daneš, 1974).

While the entity grid works only on sequences of up to three adjacent sentences, we are able to model relationships of up to six non-adjacent sentences. We solve the sparsity problem of large subgraphs by adapting Kneser-Ney smoothing to graphs. Smoothing prevents LCG from losing performance with large subgraphs and leads to superior performance on the Pitler and Nenkova (2008) dataset and to a first reasonable state-of-the-art on the De Clercq et al. (2014) dataset.

In future work we want to apply LCG to essay scoring as well. Also, we see that our adaption of Kneser-Ney smoothing to graphs may be useful for research in subgraph mining in general.

Abstract

While there is increasing interest in automatically recognizing the argumentative structure of a text, recognizing the argumentative purpose of revisions to such texts has been less explored. Furthermore, existing revision classification approaches typically ignore contextual information. We propose two approaches for utilizing contextual information when predicting argumentative revision purposes: developing contextual features for use in the classification paradigm of prior work, and transforming the classification problem to a sequence labeling task. Experimental results using two corpora of student essays demonstrate the utility of contextual information for predicting argumentative revision purposes.

1 Introduction

Incorporating natural language processing into systems that provide writing assistance beyond grammar is an area of increasing research and commercial interest (e.g., (Writelab, 2015; Roscoe et al., 2015)). As one example, the automatic recognition of the purpose of each of an author's revisions allows writing assistance systems to provide better rewriting suggestions. In this paper, we propose context-based methods to improve the automatic identification of revision purposes in student argumentative writing. Argumentation plays an important role in analyzing many types of writing such as persuasive essays (Stab et al., 2014), scientific papers (Teufel, 2000) and law documents (Palau and Moens, 2009). In student papers, identifying revision purposes with respect to argument structure has been used to predict the grade improvement in the paper after revision (Zhang and Litman, 2015).

Existing works on the analysis of writing revisions (Adler et al., 2011; Bronner and Monz, 2012; Daxenberger and Gurevych, 2013; Zhang and Litman, 2015) typically compare two versions of a text to extract revisions, then classify the purpose of each revision in isolation. That is, while limited contextual features such as revision location have been utilized in prior work, such features are computed from the revision being classified but typically not its neighbors. In addition, ordinary classifiers rather than structured prediction models are typically used. To increase the role of context during prediction, in this paper we 1) introduce new contextual features (e.g., the impact of a revision on local text cohesion), and 2) transform revision purpose classification to a sequential labeling task to capture dependencies among revisions (as in Table 1). An experimental evaluation demonstrates the utility of our approach.

2 Related Work

There are multiple works on the classification of revisions (Adler et al., 2011; Javanmardi et al., 2011; Bronner and Monz, 2012; Daxenberger and Gurevych, 2013; Zhang and Litman, 2015). While different classification tasks were explored, similar approaches were taken by extracting features (location, text, meta-data, language) from the revised text to train a classification model (SVM, Random Forest, etc.) on the annotated data. One problem with prior works is that the contextual features used were typically shallow (location), while we cap-

Draft 1	Draft 2
[1] Writer Richard Louv tells us to focus more on nature through his *rhetorical questions*, parallelism, and pathos. **[2]** *Louvs rhetorical questions as us whether we value technology or nature over the other.*	**[1]** Writer Richard Louv emphasises this expanding chasm between people and nature and tries to convince people to go back to nature through his parallelism and pathos.
[First Revision: 1->1,Type: Claim, Modify], **[Second Revision: 2->null,Type: Warrant, Delete]**	

Table 1: Example dependency between *Claim* and *Warrant* revisions. Sentence 1 acts as the *Claim* (argument structure) of Draft 1 and sentence 2 acts as the *Warrant* for the *Claim*. Sentence 1 in Draft 1 is modified to sentence 1 (also acts as the *Claim*) of Draft 2. Sentence 2 in Draft 1 is deleted in Draft 2. The first revision is a *Claim* revision as it modifies the *Claim* of the paper by removing "rhetorical questions." This leads to the second *Warrant* revision, which deletes the *Warrant* for "rhetorical questions."

ture additional contextual information as text cohesion/coherence changes and revision dependencies.

As our task focuses on identifying the argumentative purpose of writing revisions, work in argument mining is also relevant. In fact, many features for predicting argument structure (e.g., location, discourse connectives, punctuation) (Burstein and Marcu, 2003; Moens et al., 2007; Palau and Moens, 2009; Feng and Hirst, 2011) are also used in revision classification. In addition, Lawrence et al. (2014) use changes in topic to detect argumentation, which leads us to hypothesize that different types of argumentative revisions will have different impacts on text cohesion and coherence. Guo et al. (2011) and Park et al. (2015) both utilize Conditional Random Fields (CRFs) for identifying argumentative structures. While we focus on the different task of identifying revisions to argumentation, we similarly hypothesize that dependencies exist between revisions and thus utilize CRFs in our task. While our task is similar to argument mining, a key difference is that the revisions do not always appear near each other. For example, a 5-paragraph long essay might have only two or three revisions located at different paragraphs. Thus, the types of previous revisions cannot always be used as the contextual information. Moreover, the type of the revision is not necessarily the argument type of its revised sentence. For example, a revision on the evidence argument can be just a correction of spelling mistakes.

3 Data Description

Revision purposes. To label our data, we adapt the schema defined in (Zhang and Litman, 2015) as it can be reliably annotated and is argument-oriented. Sentences across paper drafts are aligned manually based on semantic similarity and revision purpose categories are labeled on aligned sentences. The schema includes four categories (*Claims/Ideas*, *Warrant/Reasoning/Backing*, *Rebuttal/Reservation* and *Evidence*) based on Toulmin's argumentation model (Toulmin, 2003), a *General Content* category for revisions that do not directly change the support/rebuttal of the claim (e.g. addition of introductory materials, conclusions, etc.), and three categories (*Conventions*, *Clarity* and *Organization*) based on the *Surface* categorizations in (Faigley and Witte, 1981). As we focus on argumentative changes, we merge all the *Surface* subcategories into one *Surface* category. As Zhang and Litman (2015) reported that both *Rebuttals* and multiple labels for a single revision were rare, we merge *Rebuttal* and *Warrant* into one *Warrant* category[1] and allow only a single (primary) label per revision.

Category	**# in A**	**# in B**
Total	1267	1044
Claims/Ideas	111	76
Warrant/Reasoning/Backing	390	327
Evidence	110	34
General Content	356	216
Surface	300	391

Corpora. Our experiments use two corpora consisting of Drafts 1 and 2 of papers written by high school students taking AP-English courses; papers were revised after receiving and generating peer feedback. Corpus A was collected in our earlier pa-

[1] We also believe that differentiating *Warrant* and *Rebuttal* revisions requires sentiment analysis.

per (Zhang and Litman, 2015), although the original annotations were modified as described above. It contains 47 paper draft pairs about placing contemporaries in Dante's Inferno. Corpus B was collected in the same manor as A with agreement Kappa 0.69. It contains 63 paper draft pairs explaining the rhetorical strategies used by the speaker/author of a previously read lecture/essay. Both corpora were double coded and gold standard labels were created upon agreement of two annotators. Two example annotated revisions from Corpus B are shown in Table 1, while the distribution of annotated revision purposes for both corpora are shown in Table 2.

4 Utilizing Context

4.1 Adding contextual features

Our previous work (Zhang and Litman, 2015) used three types of features primarily from prior work (Adler et al., 2011; Bronner and Monz, 2012; Daxenberger and Gurevych, 2013) for argumentative revision classification. **Location** features encode the location of the sentence in the paragraph and the location of the sentence's paragraph in the essay. **Textual** features encode revision operation, sentence length, edit distance between aligned sentences and the difference in sentence length and punctuation numbers. **Language** features encode part of speech (POS) unigrams and difference in POS tag counts.

We implement this feature set as the baseline as our tasks are similar, then propose two new types of contextual features. The first type (**Ext**) extends prior work by extracting the baseline features from not only the aligned sentence pair representing the revision in question, but also for the sentence pairs before and after the revision. The second type (**Coh**) measures the cohesion and coherence changes in a 2-sentence block around the revision[2].

Utilizing the cohesion and coherence difference. Inspired by (Lee et al., 2015; Vaughan and McDonald, 1986), we hypothesize that different revisions can have different impacts on the cohesion and coherence of the essay. We propose to extract features for both impact on cohesion (lexical) and impact on coherence (semantic). Inspired by (Hearst, 1997), sequences of blocks are created for sentences in both Draft 1 and Draft 2 as demonstrated in Figure 1. Two types of features are extracted. The first type describes the cohesion and coherence between the revised sentence and its adjacent sentences. The similarity (lexical/semantic) between the revised sentence block and the sentence block before ($Sim(Block\_Up, Block\_Up\_Self)$) and after ($Sim(Block\_Down, Block\_Down\_Self)$) are calculated as the cohesion/coherence scores Coh_Up and Coh_Down. The features are extracted separately for Draft 1 and Draft 2 sentences[3]. The second type describes the impact of sentence modification on cohesion and coherence[4]. Features Change_Up and Change_Down are extracted as the division of the cohesion/coherence scores of two drafts ($\frac{Coh\_Up(Draft2)}{Coh\_Up(Draft1)}, \frac{Coh\_Down(Draft2)}{Coh\_Down(Draft1)}$).

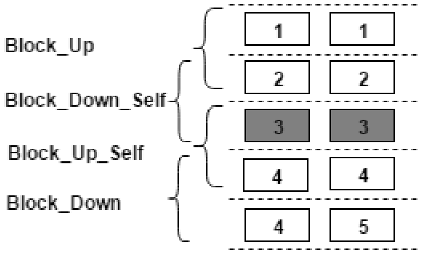

Figure 1: Example of cohesion blocks. A window of size 2 is created for both Draft 1 and Draft 2. Sequence of blocks were created by moving the window at the step of 1 (sentence).

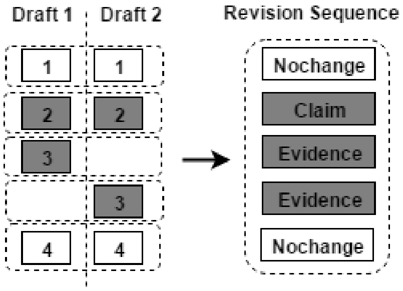

Figure 2: Example of revision sequence transformation. Each square corresponds to a sentence in the essay, the number of the square represents the index of the sentence in the essay. Dark squares are sentences that are changed. In the example, the 2nd sentence of Draft 1 is modified, the 3rd sentence is deleted and a new sentence is added in Draft 2.

A bag-of-word representation is generated for

[2] In this paper we consider the most adjacent sentence only.

[3] For the added and deleted sentences, features of the empty sentence in the other draft are set to 0.

[4] The feature values of sentence additions/deletions are 0.

Results of CRFs on paragraph-level segments are reported (there is no significant difference between essay level and paragraph level). ∗ indicates significantly better than the baseline, **Bold** indicates significantly better than all other results (Paired T-test, $p < 0.05$).

each sentence block after stop-word filtering and stemming. Jaccard similarity is used for the calculation of lexical similarity between sentence blocks. Word embedding vectors (Mikolov et al., 2013) are used for the calculation of semantic similarity. A vector is calculated for each sentence block by summing up the embedding vectors of words that are not stop-words[5]. Afterwards the similarity is calculated as the cosine similarity between the block vectors. This approach has been taken by multiple groups in the SemEval-2015 semantic similarity task (SemEval-2015 Task 1)(Xu et al., 2015).

4.2 Transforming to sequence labeling

To capture dependencies among predicted revisions, we transform the revisions to a consecutive sequence and label it with Conditional Random Fields (CRFs) as demonstrated in Figure 2. For both drafts, sentences are sorted according to their order of occurrence in the essay. Aligned sentences are put into the same row and each aligned pair of sentences is treated as a unit of revision. The “cross-aligned” pairs of sentences[6] (which does not often occur) are broken into deleted and added sentences (i.e, the cross-aligned sentences in Draft 1 are treated as deleted and the sentences in Draft 2 are treated as added.). After generating the sequence, each revision unit in the sequence is assigned the revision purpose label according to the annotations, with unchanged sentence pairs labeled as *Nochange*.

We conducted labeling on both essay-level and paragraph-level sequences. The essay-level treats the whole essay as a sequence segment while the paragraph-level treats each paragraph as a segment. After labeling, the label of each changed sentence pair is marked as the purpose of the revision[7].

5 Experiments and Results

Our prior work (Zhang and Litman, 2014) proposed an approach for the alignment of sentences. The approach achieves 92% accuracy on both corpora. In this paper we focus on the prediction task and assume we have gold-standard sentence alignments[8]. The first four columns of Table 3 show the performance of baseline features with and without our new contextual features using an SVM prediction model[9]. The last four columns show the performance of CRFs[10]. All experiments are conducted using 10-fold (student) cross-validation with 300 features selected using learning gain ratio[11].

For the SVM approach, we observe that the **Coh** features yield a significant improvement over the baseline features in Corpus B, and a non-significant improvement in Corpus A. This indicates that changes in text cohesion and coherence can in-

[5] We also tried the average of embedding vectors but observed no significant difference between the two approaches.

[6] Sentences in Draft 1 switched their positions in Draft 2, the cross-aligned sentences cannot be both in the same row and following their order of occurrence at the same time.

[7] Revisions on cross-aligned pairs are marked as *Surface*.

[8] Similar to settings in (Daxenberger and Gurevych, 2013)

[9] We compared three models used in discourse analysis and revision classification (C4.5 Decision Tree, SVM and Random Forests) (Burstein et al., 2003; Bronner and Monz, 2012; Stab and Gurevych, 2014) and SVM yielded the best performance.

[10] SVM model implemented with Weka (Hall et al., 2009) and CRF model implemented with CRFSuite (Okazaki, 2007)

[11] We tested with parameters 100, 200, 300, 500 on a development dataset disjoint from Corpora A and B and chose 300 which yielded the best performance.

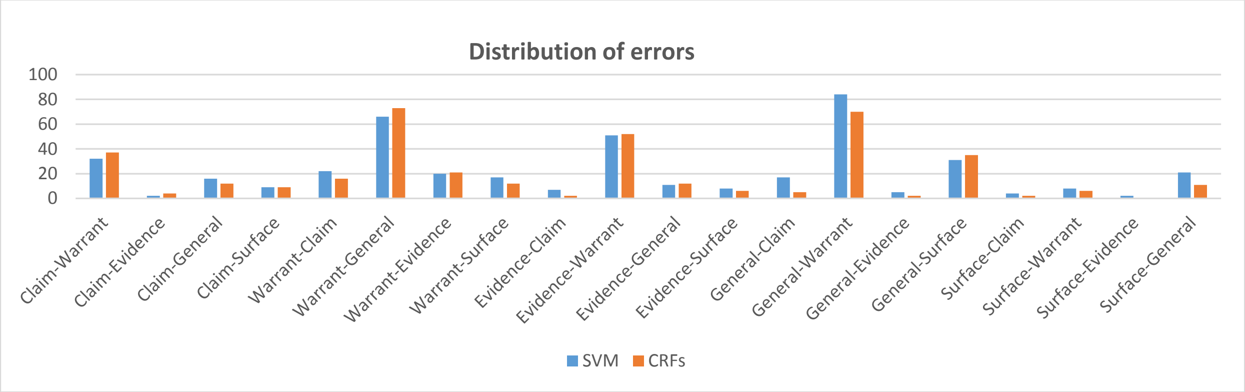

Figure 3: The number of classification errors on Corpus A, "Warrant-General" represents classifying *Warrant* as *General*.

deed improve the prediction of argumentative revision types. The **Ext** feature set - which computes features for not only the revision but also its immediately adjacent sentences - also yields a slight (although not significant) improvement. However, adding the two feature sets together does not further improve the performance using the SVM model. The CRF approach almost always yields the best results for both corpora, with all such CRF results better than all other results. This indicates that dependencies exist among argumentative revisions that cannot be identified with traditional classification approaches.

6 Error Analysis

To have a better understanding of how the sequence labeling approach improves the classification performance, we counted the errors of the cross-validation results on Corpus A (where the revisions are more evenly distributed). Figure 3 demonstrates the comparison of errors made by SVM and CRFs[12].

We notice that the CRF approach makes less errors than the SVM approach in recognizing *Claim* changes (*General-Claim, Evidence-Claim, Warrant-Claim, Surface-Claim*). This matches our intuition that there exists dependency between revisions on supporting materials and revisions on *Claim*. We also observe that same problems exist in both approaches. The biggest difficulty is the differentiation between *General* and *Warrant* revisions, which counts 37.6% of the SVM errors and 40.1% of CRFs errors. It is also common that *Claim* and *Evidence* revisions are classified as *Warrant* revisions. Approaches need to be designed for such cases to further improve the classification performance.

7 Conclusion

In this paper we proposed different methods for utilizing contextual information when predicting the argumentative purpose of revisions in student writing. Adding features that captured changes in text cohesion and coherence, as well as using sequence modeling to capture revision dependencies, both significantly improved predictive performance in an experimental evaluation.

In the future, we plan to investigate whether performance can be further improved when more sentences in the context are included. Also, we plan to investigate whether revision dependencies exist in other types of corpora such as Wikipedia revisions. While the corpora used in this study cannot be published because of the lack of required IRB, we are starting a user study project (Zhang et al., 2016) on the application of our proposed techniques and will publish the data collected from this project.

Acknowledgments

We would like to thank our annotators, especially Jiaoyang Li, who contributed significantly to the building of our corpus. We also want to thank the members of the SWoRD and ITSPOKE groups for their helpful feedback and all the anonymous reviewers for their suggestions. This research is funded by the Learning Research and Development Center of the University of Pittsburgh.

[12] Both use models with all the features.

Automatic Generation and Scoring of Positive Interpretations from Negated Statements

Abstract

This paper presents a methodology to extract positive interpretations from negated statements. First, we automatically generate plausible interpretations using well-known grammar rules and manipulating semantic roles. Second, we score plausible alternatives according to their likelihood. Manual annotations show that the positive interpretations are intuitive to humans, and experimental results show that the scoring task can be automated.

1 Introduction

Negation is an intricate phenomenon present in all human languages (Hoeksema, 2000), and studied from a theoretical perspective since Aristotle. Acquiring and understanding negation is more challenging than language in general: children acquire negation after learning to communicate (Nordmeyer and Frank, 2013), and adults take longer to process negative sentences than positive ones (Clark and Chase, 1972). In any given language, humans communicate in positive terms most of the time, and use negation to express something unusual or an exception (Horn, 1989).

In classical logic, negation is a simple unary operator that reverses the truth value of a proposition. In natural language, negation is always marked (Horn and Wansing, 2015) and it is used to reverse polarity, i.e., turning something affirmative into negative, or something negative into affirmative. Albeit most sentences are affirmative, negation is rather ubiquitous (Morante and Sporleder, 2012): In scientific papers, 13.76% of statements contain a negation (Szarvas et al., 2008); in product reviews, 19% (Councill et al., 2010); and in a selection of Conan Doyle stories, 22.23% (Morante and Daelemans, 2012). In health records, 12.3% of concepts are tagged as negated (Elkin et al., 2005); and in OntoNotes (Hovy et al., 2006), 10.15% of statements contain a verb negated with *not*, *n't* or *never*.

From a theoretical perspective, it is accepted that negation conveys positive meaning (Rooth, 1992; Huddleston and Pullum, 2002). For example, when reading (1) *John doesn't eat meat*, humans intuitively understand that (1a) *John eats something other than meat*, and (1b) *Some people eat meat, but not John*. Extracting positive interpretations from negated statements automatically is not straightforward: a negated statement may convey one or more positive interpretations, and not all positive interpretations are equally likely. For example, from (2) *They didn't order the right parts*, it is very likely that (2a) *They ordered the wrong parts*, but (2b) *Somebody ordered the right parts, but not they* is unlikely.

This paper presents a methodology to automatically extract and score positive interpretations from negated statements, as intuitively done by humans when reading text. A key feature of the work presented here is that it is not tied to any existing approach to extract meaning from text—we generate positive interpretations in plain text, and these positive interpretations can be semantically represented with any existing approach. The main contributions are: (1) procedure to automatically generate plausible positive interpretations from negated statements, (2) annotations scoring plausible positive interpretations,[1] and (3) experiments detailing results with several combinations of features, as well as gold-standard and predicted linguistic information.

2 Background and Definitions

Negation is well-understood in grammars, the valid ways to form a negation are well-documented (Quirk et al., 2000; van der Wouden, 1997). Negation can be expressed by verbs (e.g., avoid doing any look-up), nouns (e.g., the absence of any phonic sequence), adjectives (e.g., it is pointless to argue with a fool), adverbs (e.g., I never tried Persian food before), prepositions (e.g., you can always exchange it without a problem), determiners (e.g., the new law has no direct implications to international shipping), pronouns (e.g., nobody will keep election promises).

Huddleston and Pullum (2002) distinguish four negation types:

- Verbal if the marker of negation is grammatically associated with a verb, e.g., *I did not see anything*, non-verbal if it is associated with a dependent of the verb, e.g., *I saw nothing*.
- Synthetic if the negation mark has a function besides marking a negation, e.g., *[Nobody]*$_{\text{AGENT}}$ *liked it*, analytic otherwise, e.g., *Not many people liked it*.
- Clausal if the negation yields a negative clause, e.g., *The terms aren't negotiable*, subclausal otherwise, e.g., *The terms are non-negotiable*.
- Ordinary if the negation indicates that something is not the case, e.g., *That car does not drive smooth*, metalinguistic if it does not dispute the truth but rather reformulates a statement, e.g., *That TV is not small, it is tiny*.

In this paper, we target verbal, analytic, clausal and both ordinary and metalinguistic negation.

2.1 Positive Interpretations.

In philosophy and linguistics, it is generally accepted that negation conveys positive meanings (Horn, 1989). These positive meanings range from implicatures, i.e., what is suggested in an utterance even though neither expressed nor strictly implied (Blackburn, 2008), to entailments. Other terms used in the literature include implied meanings (Mitkov, 2005), implied alternatives (Rooth, 1985) and semantically similars (Agirre et al., 2013). We do not strictly fit into any of this terminology, we reveal positive interpretations as intuitively done by humans when reading text.

2.2 Scope and Focus.

From a theoretical perspective, it is accepted that negation has scope and focus, and that the focus—not just the scope—yields positive interpretations (Horn, 1989; Rooth, 1992; Taglicht, 1984). Scope is "the part of the meaning that is negated" and focus "the part of the scope that is most prominently or explicitly negated" (Huddleston and Pullum, 2002).

Consider the following statement in the context of the recent refuge crisis: (3) *Mr. Haile was not looking for heaven in Europe*. By definition, scope refers to "all elements whose individual falsity would make the negated statement strictly true", and focus is "the element of the scope that is intended to be interpreted as false to make the overall negative true" (Huddleston and Pullum, 2002). The falsity of any of the truth conditions below makes statement (3) true, thus the scope of the negation is (3a–3d):

3a. Somebody was looking for something somewhere. [verb *looking*]
3b. Mr. Haile was looking for something somewhere. [AGENT of looking, *Mr. Haile*]
3c. Somebody was looking for heaven somewhere. [THEME of looking, *heaven*]
3d. Somebody was looking for something in Europe. [LOCATION of looking, *in Europe*]

Determining the focus is almost always more challenging than the scope. The challenge lies on determining which of the truth conditions (3a–3d) is intended to be interpreted as false to make the negated statement true: all of them qualify, but some are more likely. A natural reading of statement (3) suggests that *Mr. Haile was looking for something (a regular life, a job, etc.) in Europe, but not heaven*. Determining that the focus is *heaven*, i.e., that everything in statement (3) is actually positive except the THEME of *looking*, is the key to reveal the intended positive interpretation. It is worth noting that other foci yield unlikely interpretations, e.g., *Somebody was looking for heaven in Europe, but not Mr. Haile* (3b, AGENT), *Mr. Haile was looking for heaven somewhere, but not in Europe* (3d, LOCATION). Note that (1) scope on its own does not yield positive interpretations, and (2) some negated statements convey several likely positive interpretations, e.g., statement (1) in Section 5, Table 3.

3 Previous Work

Within computational linguistics, approaches to process negation are shallow, or target scope and focus detection. Popular semantic representations such as semantic roles (Palmer et al., 2005; Baker et al., 1998) or AMR (Banarescu et al., 2013) do not reveal the positive interpretations we target in this paper. Shallow approaches are usually application-specific. In sentiment and opinion analysis, negation has been reduced to marking as negated all words between a negation cue and the first punctuation mark (Pang et al., 2002), or within a five-word window of a negation cue (Hu and Liu, 2004). The examples throughout this paper show that these techniques are insufficient to reveal implicit positive interpretations.

3.1 Scope Annotation and Detection

Scope of negation detection has received a lot of attention, mostly using two corpora: BioScope in the medical domain (Szarvas et al., 2008) and CD-SCO (Morante and Daelemans, 2012). BioScope annotates negation cues and linguistic scopes exclusively in biomedical texts. CD-SCO annotates negation cues, scopes, and negated events or properties in selected Conan Doyle stories.

There have been several supervised proposals to detect the scope of negation using BioScope and CD-SCO (Özgür and Radev, 2009; Øvrelid et al., 2010). Automatic approaches are mature (Abu-Jbara and Radev, 2012): F-scores are 0.96 for negation cue detection, and 0.89 for negation cue and scope detection (Velldal et al., 2012; Li et al., 2010). Outside BioScope and CD-SCO, Reitan et al. (2015) present a negation scope detector for tweets, and show that it improves sentiment analysis. As shown in Section 2, scope detection is insufficient to reveal positive interpretations from negated statements.

3.2 Focus Annotation and Detection

While focus of negation has been studied for decades in philosophy and linguistics (Section 2), corpora and automated tools are scarce. Blanco and Moldovan (2011) annotate focus of negation in the 3,993 negations marked with ARGM-NEG semantic role in PropBank (Palmer et al., 2005). Their annotations, PB-FOC, were used in the *SEM-2012 Shared Task (Morante and Blanco, 2012). Their guidelines require annotators to choose as focus the semantic role that "is most prominently negated" or the verb. If several roles may be the focus, they prioritize "the one that yields the most meaningful implicit [positive] information", but do not specify what *most meaningful* means. Consider again statement (1) *John doesn't eat meat*. Their approach would determine that the focus is the THEME of *eat*, *meat*, because it arguably yields the "most meaningful implicit [positive] information" (using our terminology, positive interpretation): *John eats something other than meat*. By design, they ignore other valid positive interpretations, e.g., *Some people eat meat, but not John*. In this paper, we improve upon their work: instead of extracting the "most meaningful" positive interpretation from a negated statement, we generate several positive interpretations and score them according to their likelihood.

Anand and Martell (2012) present a complimentary approach to annotate focus of negation. They refine PB-FOC and argue that positive interpretations arising from scalar implicatures and neg-raising predicates should be separated from those arising from focus detection. According to their annotations, 27.4% of negations with a focus annotated in PB-FOC do not actually have a focus. Blanco and Moldovan (2012) introduce the concept of fine-grained foci and refine the annotations in PB-FOC by annotating foci at the token level, and Matsuyoshi et al. (2014) annotate focus of negation in Japanese. In this paper, we are not concerned about annotating focus of negation per se, but about extracting positive interpretations from negated statements as intuitively understood by humans.

Automatic systems to detect the focus of negation (and reveal up to one positive interpretation) in English texts are trained using PB-FOC. Blanco and Moldovan (2011) obtain an accuracy of 65.5 using supervised machine learning and features derived from gold-standard linguistic information, and Blanco and Moldovan (2014) report an F-measure of 64.1. Rosenberg and Bergler (2012) report an F-measure of 58.4 using 4 linguistically sound heuristics and predicted linguistic information, and Zou et al. (2014) an F-measure of 65.62 using contextual discourse information. Unlike the work presented here, none of these systems attempts to extract and rank several positive interpretations from one negated statement.

Neg. statement	In 1995, Murdoch bought [the rest of Star TV]$_{\text{ARG}_1}$ that [he]$_{\text{ARG}_0}$ did [not]$_{\text{ARGM-NEG}}$ [own]$_{verb}$	
Positive counterpart	after Step 1	In 1995, Murdoch bought the rest of Star TV that he did own
	after Step 2	In 1995, Murdoch bought the rest of Star TV that he owned
	after Step 3	In 1995, Murdoch bought the rest of Star TV that he owned (no change)
Plausible positive interpretations	from ARG$_0$	In 1995, Murdoch bought the rest of Star TV that [somebody] owned, but not *he*
	from ARG$_1$	In 1995, Murdoch bought [something] that he owned, but not *the rest of Star TV*
	from *verb*	In 1995, Murdoch bought the rest of Star TV that he [some verb], but not *owned*

Table 1: Negated statement, and automatically generated positive counterpart and plausible positive interpretations.

4 Corpus Creation

Our goal is to create a corpus of negated statements and their positive interpretations as intuitively understood by humans. We put a strong emphasis on automation. First, given a negated statement, we automatically generate plausible positive interpretations following a battery of linguistically motivated deterministic rules (Section 4.1). Second, we collect manual annotation to score the plausible positive interpretations according to their likelihood (Section 4.2). We then use these manually obtained scores to learn models that automatically score positive interpretations (Section 6).

We decided to work on top of OntoNotes (Hovy et al., 2006) instead of plain text or other corpora for several reasons. First, OntoNotes includes gold linguistic annotations such as part-of-speech tags, parse trees and semantic roles. Second, state-of-the-art role labelers trained with Propbank achieve F-measures of 0.835 (Lewis et al., 2015), and we use semantic roles to generate positive interpretations. Third, unlike BioScope, CD-SCO and PB-FOC (Section 2), OntoNotes includes sentences from several genres, e.g., newswire, broadcast news and conversations, magazines, the web.

4.1 Generating Positive Interpretations

OntoNotes[2] is a large corpus containing 63,918 sentences. Annotating all positive interpretations from all negations is outside of the scope of this paper. Instead, we target selected representative negations.

Selecting Negated Statements. We first selected all verbs negated with ARGM-NEG semantic role and obtained 6,617 verbal negations. After examining the negated verbs, it became clear that negation is not uniformly distributed across verbs in OntoNotes, it roughly follows Zipf's law. In order to alleviate the annotation effort while accounting for all negated verbs in OntoNotes, we randomly selected up to 5 negations for each verb. The number of negated statements selected is 600.

Converting Negated Statements into Their Positive Counterparts. We apply 3 steps inspired after the grammatical rules to form negation detailed by Huddleston and Pullum (2002, Ch. 9):

1. Remove the negation mark by removing the tokens within ARGM-NEG semantic role.
2. Remove auxiliaries, expand contractions, and fix third-person singular and past tense. For example (before: after), *doesn't go*: *goes*, *didn't go*: *went*, *won't go*: *will go*, We use a standard list of irregular verbs,[3] and grammar rules to convert to third-person singular and past tense based on orthographic patterns.
3. Rewrite negatively-oriented polarity-sensitive items. For example (before: after), *anyone*: *someone*, *any longer*: *still*, *yet*: *already*. *at all*: *somewhat*. We use the correspondences between negatively-oriented and positively-oriented polarity-sensitive items by Huddleston and Pullum (2002, pp. 831).

Generating Positive Interpretations. Once the positive counterpart is obtained, we generate positive interpretations by rewriting each semantic role or the (originally negated) verb. Among others, we use the following rewriting rules: ARG$_0$–ARG$_4$: someone / some people / something, ARGM-TMP: at some point of time, ARGM-LOC: somewhere, ARGM-MNR: in some manner, ARGM-CAU: because of something and ARGM-PRP: to do something. Additionally, if the semantic role starts with a preposition, we also include it, e.g., *gave [to John]*$_{\text{ARG}_2}$:

[2] We use the CoNLL-2011 Shared Task distribution (Pradhan et al., 2011), http://conll.cemantix.org/2011/

[3] https://en.wikipedia.org/wiki/English_irregular_verbs

gave to someone, but not John. This methodology generated 1,888 positive interpretations from the 600 selected negations (average: 3.15).

Table 1 exemplifies the 3 steps to transform a negated statement into its positive counterpart, and the positive interpretations generated. Additional examples are provided in Table 3.

We acknowledge that some of the positive interpretations we generate automatically are not as specific or intuitive as carefully crafted, manually generated interpretations could be. For example, from *[John]*$_{\text{ARG}_0}$ *does[n't]*$_{\text{ARGM-NEG}}$ *[know]*$_{verb}$ *[the details about how they met]*$_{\text{ARG}_1}$, the proposed methodology would generate, among others, *John knows about something, but not about the details of how they met*. A better interpretations that we do not generate is *John knows something about how they met, but not the details*. We argue that generating interpretations automatically is the only option in order to incorporate this work into an NLP pipeline, and reserve for future work generating positive interpretations beyond rewriting semantic roles.

4.2 Ranking Positive Interpretations

Once positive interpretations were automatically generated, we asked annotators to rank them. Annotators were presented with one negated statement and one positive interpretation at a time, and were asked *Given the negated statement above, do you think the statement [positive interpretation] below is true?* They only had access to the text in the original negated statement, the positive interpretation, and the previous and next sentences as context. We did not display semantic role information for the original negated statement, its positive counterpart or the semantic role from which the positive interpretation was generated. As we shall see (Section 5.1), context often helps scoring interpretations.

Annotators were required to answer with a score from 0 to 5, were 0 means *absolutely disagree* and 5 means *absolutely agree*. We did not provide descriptions for intermediate scores or used additional categorical labels. This simple guidelines were sufficient to reliably score plausible positive interpretations automatically generated.

Sem. role	#	% sent	Mean	SD
ARG_0	392	65.17%	4.07	1.03
ARG_1	520	86.00%	4.55	0.98
ARG_2	95	15.83%	4.40	1.31
ARG_3	2	0.33%	4.50	0.50
ARG_4	5	0.83%	5.00	0.00
ARGM-ADV	101	15.67%	2.41	1.72
ARGM-CAU	13	2.17%	2.46	1.91
ARGM-DIR	11	1.83%	2.00	2.30
ARGM-EXT	12	2.00%	3.75	1.53
ARGM-LOC	21	3.33%	3.76	1.69
ARGM-MNR	37	6.00%	4.54	1.03
ARGM-PRP	7	1.16%	4.43	0.71
ARGM-TMP	81	12.50%	3.99	1.52
Verb	600	100.00%	2.17	1.41
All	1,888	100.00%	3.52	1.63

Table 2: Basic corpus analysis. For each semantic role, we show the number of positive interpretations generated (#), the percentage of sentences for which a positive interpretation is generated (% sent), and the mean and standard deviation (SD) of the annotated scores.

5 Corpus Analysis

On average, we generated 3.15 positive interpretations per negation (standard deviation: 0.82), and 74% of negations have at least one interpretation scored 4 or higher. Basic counts and statistics for the annotations are provided in Table 2. Overall, we annotated 1,888 positive interpretations generated from 600 sentences, or equivalently, from 600 verbs negated with ARGM-NEG semantic role in OntoNotes. Overall mean score is 3.52 (out of 5) and overall standard deviation, 1.63. The 25th percentile is 2.0, the 50th percentile is 4.0 and the 75th percentile is 5.0. These numbers show that most positive interpretations automatically generated are deemed likely by annotators, and over 25% are scored with a 5 (out of 5).

In general, positive interpretations generated from numbered roles (ARG_0–ARG_4) are scored higher than the ones generated from modifiers (ARGM-ADV, ARGM-CAU, ARGM-DIR, etc.). Also, positive interpretations generated from infrequent roles are generally ranked higher, e.g., ARG_4 and ARG_3 vs. ARG_0, ARGM-PRP and ARGM-MNR vs. ARGM-ADV.

Annotation Quality. In order to ensure annotation quality, we calculated inter-annotator Pearson correlation. Kappa and other agreement measures de-

	Negated statement, context if relevant to determining scores, and all positive interpretations	Score
1	Context, previous statement: *That change will obviously impact third and fourth quarter earnings for the industry in general, he added.* Negated statement: *[He]*$_{\text{ARG}_0}$ *did[n't]*$_{\text{ARGM-NEG}}$ *[forecast]*$_{\text{verb}}$ *[Phillips' results]*$_{\text{ARG}_1}$. Context, next statement: *But security analysts say Phillips will be among the companies hard-hit by weak chemical prices and will probably post a drop in third-quarter earnings.*	
	- Interpretation 1.1 [ARG$_0$]: Somebody forecasted Phillips' results, but not *he*.	5
	- Interpretation 1.2 [ARG$_1$]: He forecasted something, but not *Phillips' results*.	5
2	Negated statement: *In 1995, Murdoch bought [the rest of Star TV]*$_{\text{ARG}_1}$ *[he]*$_{\text{ARG}_0}$ *did [not]*$_{\text{ARGM-NEG}}$ *[own]*$_{\text{verb}}$.	
	- Interpretation 2.1 (ARG$_0$): In 1995, Murdoch bought the rest of Star TV somebody owned, but not *he*.	5
	- Interpretation 2.2 (ARG$_1$): In 1995, Murdoch bought something he owned, but not *the rest of Star TV*.	0
3	Negated statement: *[You]*$_{\text{ARG}_0}$ *[can]*$_{\text{ARGM-MOD}}$*[not]*$_{\text{ARGM-NEG}}$ *[run]*$_{\text{verb}}$ *[a country with 23 million people]*$_{\text{ARG}_1}$ *[with revenues of 16 billion to 20 billion dollars]*$_{\text{ARGM-MNR}}$.	
	- Interpretation 3.1 (ARG$_0$): Somebody can run a country with 23 million people with revenues of 16 billion to 20 billion dollars, but not *You*.	1
	- Interpretation 3.21 (ARG$_1$): You can run something with revenues of 16 billion to 20 billion dollars, but not *a country with 23 million people*.	5
	- Interpretation 3.3 (ARGM-MNR): You can run a country with 23 million people in some manner, but not with *with revenues of 16 billion to 20 billion dollars*.	5
4	Negated statement: *Do [not]*$_{\text{ARGM-NEG}}$ *[utter]*$_{\text{verb}}$ *[a word]*$_{\text{ARG}_1}$.	
	- Interpretation 4.1 (ARG$_1$): Utter something, but not *a word*.	0

Table 3: Annotation examples. We show all positive interpretations automatically generated and their scores (out of 5).

signed for categorical labels are not well-suited for our annotation task, since not all disagreements between numeric scores are the same, e.g., 4 vs. 5 should be counted as relatively high agreement, and 1 vs. 5 should be counted as high disagreement. Overall Pearson correlation is 0.761.

5.1 Annotation Examples

Table 3 presents annotation examples. We show the original negated statement including semantic role annotations from OntoNotes (square brackets), all positive interpretations automatically generated, and their scores. We also include context (previous and next sentence) if it helps determining scores.

Example (1) shows that context sometimes is vital to scoring plausible positive interpretations. Given *He didn't forecast Phillips' results* in isolation, it is uncertain if he forecasted anything at all, or whether somebody forecasted Phillips' results. However, the previous statement makes certain (5/5) the interpretation generated from ARG$_1$: he forecasted earnings for the industry in general. Similarly, the next statement makes very likely (5/5) the interpretation generated from ARG$_0$: other people (security analysts) made forecasts about Phillips. In this example, 2 positive interpretations are generated from one negation, and they are assigned the highest score (5/5).

The positive interpretations generated from example (2) can be annotated without context. Somebody other than Murdoch had to own the rest of Star TV that he bought in 1995 (score 5/5), and people cannot buy what they already own (score 0/5).

Example (3) presents a positive interpretation generated from ARG$_0$ that is scored low (1/5); recall that the mean score for interpretations generated from ARG$_0$ is 4.07 and the standard deviation 1.03 (Table 2). In this negated statement, the indefinite *you* refers to an unspecified person, thus it is not the case that *somebody can run a country with 23 million people with revenues of 16 billion to 20 billion dollars* (Interpretation 3.1, score 1/5). Interpretations 3.2 and 3.3, however, are scored high: annotators correctly understood that given the negated statement, it is the case that *You can run something with revenues of 16 billion to 20 billion dollars, but not a country with 23 million people* (you can run a country with less people with that revenue), and *You can run a country with 23 million people in some manner, but not with revenues of 16 billion to 20 billion dollar* (you could run it with more revenue).

Finally, example (4) presents a short statement from which only one positive interpretations is generated. Annotators were asked whether given *Do not utter a word*, they think *Utter something, but not a word* is true. They correctly annotated that this positive interpretations is invalid (score 0/5). Indeed, the negated statement in example (4) can only be interpreted as an order to not utter anything.

6 Learning to Score Positive Interpretations

We follow a standard supervised machine learning approach. The 1,888 positive interpretations along with their scores become instances, and we divide them into training (80%) and test splits (20%) making sure that all interpretations generated from a sentence are assigned to either the training or test splits. Note that splitting instances randomly would not be sound: training with some interpretations generated from a negated statement, and testing with the rest of interpretations generated from the same statement would be an unfair evaluation.

We trained a Support Vector Machine (SVM) for regression with RBF kernel using scikit-learn (Pedregosa et al., 2011), which in turn uses LIBSVM (Chang and Lin, 2011). The feature set and SVM parameters (C and γ) were tuned using 10-fold cross-validation with the training set, and results were calculated using the test set.

6.1 Feature Selection

We tried features derived exclusively from the negated statement from which the positive interpretation was generated, more specifically, we extract features from the negated *verb* or semantic role (*sem_role*) used to generate the positive interpretation, from both of them (*verb-sem_role*) and from the verb-argument structure of *verb* (*verbarg-struct*), i.e., all semantic roles of *verb*.

Verb features are straightforward and account for the verb word form and part-of-speech tag.

Sem_role features include the label of the semantic role from which the positive interpretation was generated (*sem_role_label*), its length (number of tokens), and the word form and part-of-speech tag of its head. Additionally, we add standard features in semantic role labeling (Gildea and Jurafsky, 2002): the syntactic nodes (NP, PP, etc.) of the semantic role and its parent in the parse tree, as well as the left and right siblings, if any.

Verb-sem_role features are also standard in role labeling. We include a flag indicating whether the verb occurs before or after the semantic role in the negated statement (not in the positive counterpart), syntactic node of the lowest common ancestor between *verb* and *sem_role*, and the syntactic path.

Finally, *verbarg-struct* features encode characteristics of the verb-argument structure to which *verb* and *sem_role* belong to. Namely, we added flags indicating semantic role presence, and features indicating the first and last semantic roles in order of appearance in the negated statement. We also included the syntactic nodes of semantic roles and their heads.

We exemplify all features with Interpretation 3.1 generated from Statement 3 in Table 3:

- *Verb* features: verb_wf=run, verb_pos=VBP.
- *Sem_role* features: label=ARG$_0$, num_tokens=1, head_wf=You, head_pos=PRP, synt_node=NP, synt_node_parent=S, synt_node_left=NONE, synt_node_right=VP
- *Verb-sem_role* features: direction=after, lowest_ancestor=S, synt_path=VP+VP+S-NP
- *Verbarg-struct* features: ARG$_0$=1, ARGM-MOD=1, ARG$_1$=1, ARGM-MNR=1, first=ARG$_0$, last=ARGM-MNR, ARG$_1$_head=country, ARG$_1$_pos=NN, etc.

7 Experimental Results

We report results obtained with several combinations of features in Table 5. We detail results obtained with features extracted from gold-standard and predicted linguistic annotations (part-of-speech tags, parse trees, semantic roles, etc.) as annotated in the *gold* and *auto* files from the CoNLL-2011 Shared Task release of OntoNotes (Pradhan et al., 2011). All models are trained with gold-standard linguistic annotations, and tested with either gold-standard or predicted linguistic annotations.

Testing with gold-standard linguistic annotations. Using only the label of the semantic role from which the positive interpretation was generated (*sem_role_label*), yields a Pearson correlation of 0.603. Using *Verb* features is virtually useless (Pearson correlation: -0.025), this is due to the

Source	Feature description
Verb	Word form and part-of-speech tag of *verb*
sem_role	Semantic role label of sem_role, *sem_role_label*
	Number of tokens in *sem_role*
	Word form and part-of-speech tag of head of *sem_role*
	Syntactic node of *sem_role*, its parent and left and right siblings in the parse tree
verb-sem_role	Whether *verb* occurs before or after than *sem_role* in the negated statement
	Syntactic node of lowest common ancestor of *verb* and *sem_role*
	Syntactic paths from *verb* to *sem_role*
verbarg-struct	Flags indicating whether *verb* has each possible semantic role
	Semantic role labels of the first and last roles of *verb*
	Syntactic nodes and heads of each semantic role attaching to *verb*

Table 4: Features used to score positive interpretations from negated statements. Features are extracted from the negated *verb* or semantic role (*sem_role*) from which the positive interpretation was generated, from both of them (*verb-sem_role*), or from the verb-argument structure of *verb* (verbarg-struct), i.e., from all semantic roles of *verb*.

	Gold	Predicted
sem_role_label feature	0.603	0.642
verb features	-0.025	-0.022
verb + sem_role features	0.630	0.648
verb + sem_role + verb-sem_role features	0.627	0.638
verb + sem_role + verb-sem_role + verbarg-struct features	0.642	0.650

Table 5: Pearson correlations in the test set using gold-standard and predicted linguistic annotations (part-of-speech tags, parse trees and semantic roles). Results are provided using sem_role_label as only feature, and using several features incrementally. Number of test instances with gold-standard linguistic annotations is 378, and with predicted annotations, 268.

fact that our corpus includes at most 5 instances for each negated verb in OntoNotes (Section 4). Adding *sem_role* features yields a correlation of 0.630, and incorporating *verb-sem_role* features is useless (Pearson: 0.627). Considering all features, however, yields the highest correlation, 0.642.

Testing with predicted linguistic annotations. We assigned 20% of instances to the test split, totalling 378 instances (Section 6). However, some of these instances cannot be obtained using predicted role labels: a missing or incorrect semantic role will unequivocally lead to positive interpretations that are not in our corpus and thus evaluation is not straightforward. Results presented with predicted linguistic annotations are calculated using only the 268 (out of 378) positive interpretations that are generated from predicted semantic roles and are also generated (and thus annotated in our corpus) from gold-standard linguistic annotations.

Results using only *sem_role_label* feature (0.642) are better or very similar than using any combination of features (0.638–0.650) except *Verb* features alone, which perform poorly as explained earlier. These results should be taken with a grain of salt: the number of test instances is much lower (268 vs. 378). Additionally, these 268 test instances correspond to positive interpretations generated from semantic roles that were predicted correctly automatically. Role labels are predicted better for shorter sentences without complicated syntactic structure; positive interpretations for this kind sentences are also easier to score, e.g., Statement 4 in Table 3.

8 Conclusions

Humans intuitively understand negated statements in positive terms when reading text. This paper presents an automated methodology to generate plausible positive interpretations from verbal negation, and score them based on their likelihood. We use simple grammar rules and manipulate semantic roles to generate positive interpretations. Experimental results show that these interpretations can be scored automatically using standard supervised machine learning techniques.

An annotation effort shows that most positive interpretations automatically generated are likely (scores $\geq$4), thus the amount of positive meaning revealed by the methodology presented here is substantial (on average, 3.15 interpretations are generated per negation). We believe that more annotations and a learning algorithm that scores jointly all positive interpretations generated from each negation (as opposed to individually) would yield better results.

Abstract

Natural language inference (NLI) is a fundamentally important task in natural language processing that has many applications. The recently released Stanford Natural Language Inference (SNLI) corpus has made it possible to develop and evaluate learning-centered methods such as deep neural networks for natural language inference (NLI). In this paper, we propose a special long short-term memory (LSTM) architecture for NLI. Our model builds on top of a recently proposed neural attention model for NLI but is based on a significantly different idea. Instead of deriving sentence embeddings for the premise and the hypothesis to be used for classification, our solution uses a match-LSTM to perform word-by-word matching of the hypothesis with the premise. This LSTM is able to place more emphasis on important word-level matching results. In particular, we observe that this LSTM remembers important mismatches that are critical for predicting the contradiction or the neutral relationship label. On the SNLI corpus, our model achieves an accuracy of 86.1%, outperforming the state of the art.

1 Introduction

Natural language inference (NLI) is the problem of determining whether from a premise sentence P one can infer another hypothesis sentence H (MacCartney, 2009). NLI is a fundamentally important problem that has applications in many tasks including question answering, semantic search and automatic text summarization. There has been much interest in NLI in the past decade, especially surrounding the PASCAL Recognizing Textual Entailment (RTE) Challenge (Dagan et al., 2005). Existing solutions to NLI range from shallow approaches based on lexical similarities (Glickman et al., 2005) to advanced methods that consider syntax (Mehdad et al., 2009), perform explicit sentence alignment (MacCartney et al., 2008) or use formal logic (Clark and Harrison, 2009).

Recently, Bowman et al. (2015) released the Stanford Natural Language Inference (SNLI) corpus for the purpose of encouraging more learning-centered approaches to NLI. This corpus contains around 570K sentence pairs with three labels: *entailment*, *contradiction* and *neutral*. The size of the corpus makes it now feasible to train deep neural network models, which typically require a large amount of training data. Bowman et al. (2015) tested a straightforward architecture of deep neural networks for NLI. In their architecture, the premise and the hypothesis are each represented by a sentence embedding vector. The two vectors are then fed into a multi-layer neural network to train a classifier. Bowman et al. (2015) achieved an accuracy of 77.6% when long short-term memory (LSTM) networks were used to obtain the sentence embeddings.

A more recent work by Rocktäschel et al. (2016) improved the performance by applying a neural attention model. While their basic architecture is still based on sentence embeddings for the premise and the hypothesis, a key difference is that the embedding of the premise takes into consideration the alignment between the premise and the hypothesis. This so-called *attention-weighted* representation of the premise was shown to help push the accuracy to

Proceedings of NAACL-HLT 2016, pages 1442–1451,
San Diego, California, June 12-17, 2016.

83.5% on the SNLI corpus.

A limitation of the aforementioned two models is that they reduce both the premise and the hypothesis to a single embedding vector before matching them; i.e., in the end, they use two embedding vectors to perform sentence-level matching. However, not all word or phrase-level matching results are equally important. For example, the matching between stop words in the two sentences is not likely to contribute much to the final prediction. Also, for a hypothesis to *contradict* a premise, a single word or phrase-level mismatch (e.g., a mismatch of the subjects of the two sentences) may be sufficient and other matching results are less important, but this intuition is hard to be captured if we directly match two sentence embeddings.

In this paper, we propose a new LSTM-based architecture for learning natural language inference. Different from previous models, our prediction is not based on whole sentence embeddings of the premise and the hypothesis. Instead, we use an LSTM to perform *word-by-word* matching of the hypothesis with the premise. Our LSTM sequentially processes the hypothesis, and at each position, it tries to match the current word in the hypothesis with an attention-weighted representation of the premise. Matching results that are critical for the final prediction will be "remembered" by the LSTM while less important matching results will be "forgotten." We refer to this architecture a match-LSTM, or *m*LSTM for short.

Experiments show that our *m*LSTM model achieves an accuracy of 86.1% on the SNLI corpus, outperforming the state of the art. Furthermore, through further analyses of the learned parameters, we show that the *m*LSTM architecture can indeed pick up the more important word-level matching results that need to be remembered for the final prediction. In particular, we observe that good word-level matching results are generally "forgotten" but important mismatches, which often indicate a *contradiction* or a *neutral* relationship, tend to be "remembered."

2 Model

In this section, we first review LSTM. We then review the word-by-word attention model by Rocktäschel et al. (2016), which is their best performing model. Finally we present our *m*LSTM architecture for natural language inference.

2.1 Background

LSTM: Let us first briefly review LSTM (Hochreiter and Schmidhuber, 1997). LSTM is a special form of recurrent neural networks (RNNs), which process sequence data. LSTM uses a few gate vectors at each position to control the passing of information along the sequence and thus improves the modeling of long-range dependencies. While there are different variations of LSTMs, here we present the one adopted by Rocktäschel et al. (2016). Specifically, let us use $\mathbf{X} = (\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_N)$ to denote an input sequence, where $\mathbf{x}_k \in \mathbb{R}^l$ $(1 \leq k \leq N)$. At each position k, there is a set of internal vectors, including an input gate $\mathbf{i}_k$, a forget gate $\mathbf{f}_k$, an output gate $\mathbf{o}_k$ and a memory cell $\mathbf{c}_k$. All these vectors are used together to generate a d-dimensional hidden state $\mathbf{h}_k$ as follows:

$$\begin{aligned}
\mathbf{i}_k &= \sigma(\mathbf{W}^{\text{i}}\mathbf{x}_k + \mathbf{V}^{\text{i}}\mathbf{h}_{k-1} + \mathbf{b}^{\text{i}}), \\
\mathbf{f}_k &= \sigma(\mathbf{W}^{\text{f}}\mathbf{x}_k + \mathbf{V}^{\text{f}}\mathbf{h}_{k-1} + \mathbf{b}^{\text{f}}), \\
\mathbf{o}_k &= \sigma(\mathbf{W}^{\text{o}}\mathbf{x}_k + \mathbf{V}^{\text{o}}\mathbf{h}_{k-1} + \mathbf{b}^{\text{o}}), \\
\mathbf{c}_k &= \mathbf{f}_k \odot \mathbf{c}_{k-1} + \mathbf{i}_k \odot \tanh(\mathbf{W}^{\text{c}}\mathbf{x}_k + \mathbf{V}^{\text{c}}\mathbf{h}_{k-1} + \mathbf{b}^{\text{c}}), \\
\mathbf{h}_k &= \mathbf{o}_k \odot \tanh(\mathbf{c}_k), \qquad (1)
\end{aligned}$$

where σ is the sigmoid function, $\odot$ is the element-wise multiplication of two vectors, and all $\mathbf{W}^* \in \mathbb{R}^{d\times l}$,$\mathbf{V}^* \in \mathbb{R}^{d\times d}$ and $\mathbf{b}^* \in \mathbb{R}^d$ are weight matrices and vectors to be learned.

Neural Attention Model: For the natural language inference task, we have two sentences $\mathbf{X}^{\text{s}} = (\mathbf{x}^{\text{s}}_1, \mathbf{x}^{\text{s}}_2, \ldots, \mathbf{x}^{\text{s}}_M)$ and $\mathbf{X}^{\text{t}} = (\mathbf{x}^{\text{t}}_1, \mathbf{x}^{\text{t}}_2, \ldots, \mathbf{x}^{\text{t}}_N)$, where $\mathbf{X}^{\text{s}}$ is the premise and $\mathbf{X}^{\text{t}}$ is the hypothesis. Here each $\mathbf{x}$ is an embedding vector of the corresponding word. The goal is to predict a label y that indicates the relationship between $\mathbf{X}^{\text{s}}$ and $\mathbf{X}^{\text{t}}$. In this paper, we assume y is one of *entailment*, *contradiction* and *neutral*.

Rocktäschel et al. (2016) first used two LSTMs to process the premise and the hypothesis, respectively, but initialized the second LSTM (for the hypothesis) with the last cell state of the first LSTM (for the premise). Let us use $\mathbf{h}^{\text{s}}_j$ and $\mathbf{h}^{\text{t}}_k$ to denote the resulting hidden states corresponding to $\mathbf{x}^{\text{s}}_j$ and

$\mathbf{x}^{\mathrm{t}}_k$, respectively. The main idea of the word-by-word attention model by Rocktäschel et al. (2016) is to introduce a series of attention-weighted combinations of the hidden states of the premise, where each combination is for a particular word in the hypothesis. Let us use $\mathbf{a}_k$ to denote such an *attention vector* for word $\mathbf{x}^{\mathrm{t}}_k$ in the hypothesis. Specifically, $\mathbf{a}_k$ is defined as follows[1]:

$$\mathbf{a}_k = \sum_{j=1}^{M} \alpha_{kj} \mathbf{h}^{\mathrm{s}}_j, \quad (2)$$

where α_{kj} is an attention weight that encodes the degree to which $\mathbf{x}^{\mathrm{t}}_k$ in the hypothesis is aligned with $\mathbf{x}^{\mathrm{s}}_j$ in the premise. The attention weight α_{kj} is generated in the following way:

$$\alpha_{kj} = \frac{\exp(e_{kj})}{\sum_{j'} \exp(e_{kj'})}, \quad (3)$$

where

$$e_{kj} = \mathbf{w}^{\mathrm{e}} \cdot \tanh(\mathbf{W}^{\mathrm{s}} \mathbf{h}^{\mathrm{s}}_j + \mathbf{W}^{\mathrm{t}} \mathbf{h}^{\mathrm{t}}_k + \mathbf{W}^{\mathrm{a}} \mathbf{h}^{\mathrm{a}}_{k-1}). \quad (4)$$

Here $\cdot$ is the dot-product between two vectors, the vector $\mathbf{w}^{\mathrm{e}} \in \mathbb{R}^d$ and all matrices $\mathbf{W}^* \in \mathbb{R}^{d \times d}$ contain weights to be learned, and $\mathbf{h}^{\mathrm{a}}_{k-1}$ is another hidden state which we will explain below.

The attention-weighted premise $\mathbf{a}_k$ essentially tries to model the relevant parts in the premise with respect to $\mathbf{x}^{\mathrm{t}}_k$, i.e., the k^{th} word in the hypothesis. Rocktäschel et al. (2016) further built an RNN model over $\{\mathbf{a}_k\}_{k=1}^{N}$ by defining the following hidden states:

$$\mathbf{h}^{\mathrm{a}}_k = \mathbf{a}_k + \tanh(\mathbf{V}^{\mathrm{a}} \mathbf{h}^{\mathrm{a}}_{k-1}), \quad (5)$$

where $\mathbf{V}^{\mathrm{a}} \in \mathbb{R}^{d \times d}$ is a weight matrix to be learned. We can see that the last $\mathbf{h}^{\mathrm{a}}_N$ aggregates all the previous $\mathbf{a}_k$ and can be seen as an attention-weighted representation of the whole premise. Rocktäschel et al. (2016) then used this $\mathbf{h}^{\mathrm{a}}_N$, which represents the whole premise, together with $\mathbf{h}^{\mathrm{t}}_N$, which can be approximately regarded as an aggregated representation of the hypothesis[2], to predict the label y.

2.2 Our Model

Although the neural attention model by Rocktäschel et al. (2016) achieved better results than Bowman et al. (2015), we see two limitations. First, the model still uses a single vector representation of the premise, namely $\mathbf{h}^{\mathrm{a}}_N$, to match the entire hypothesis. We speculate that if we instead use each of the attention-weighted representations of the premise for matching, i.e., use $\mathbf{a}_k$ at position k to match the hidden state $\mathbf{h}^{\mathrm{t}}_k$ of the hypothesis while we go through the hypothesis, we could achieve better matching results. This can be done using an RNN which at each position takes in both $\mathbf{a}_k$ and $\mathbf{h}^{\mathrm{t}}_k$ as its input and determines how well the overall matching of the two sentences is up to the current position. In the end the RNN will produce a single vector representing the matching of the two entire sentences.

The second limitation is that the model by Rocktäschel et al. (2016) does not explicitly allow us to place more emphasis on the more important matching results between the premise and the hypothesis and down-weight the less critical ones. For example, matching of stop words is presumably less important than matching of content words. Also, some matching results may be particularly critical for making the final prediction and thus should be remembered. For example, consider the premise "*A dog jumping for a Frisbee in the snow.*" and the hypothesis "*A cat washes his face and whiskers with his front paw.*" When we sequentially process the hypothesis, once we see that the subject of the hypothesis *cat* does not match the subject of the premise *dog*, we have a high probability to believe that there is a contradiction. So this mismatch should be remembered.

Based on the two observations above, we propose to use an LSTM to sequentially match the two sentences. At each position the LSTM takes in both $\mathbf{a}_k$ and $\mathbf{h}^{\mathrm{t}}_k$ as its input. Figure 1 gives an overview of our model in contrast to the model by Rocktäschel

[1] We present the word-by-word attention model by Rocktäschel et al. (2016) in a different way but the underlying model is the same. Our $\mathbf{h}^{\mathrm{a}}_k$ is their $\mathbf{r}_t$, our $\mathbf{H}^{\mathrm{s}}$ (all of $\mathbf{h}^{\mathrm{s}}_j$) is their $\mathbf{Y}$, our $\mathbf{h}^{\mathrm{t}}_k$ is their $\mathbf{h}_{\mathrm{t}}$, and our α_k is their α_t. Our presentation is close to the one by Bahdanau et al. (2015), with our attention vectors $\mathbf{a}$ corresponding to the context vectors $\mathbf{c}$ in their paper.

[2] Strictly speaking, in the model by Rocktäschel et al. (2016), $\mathbf{h}^{\mathrm{t}}_N$ encodes both the premise and the hypothesis because the two sentences are chained. But $\mathbf{h}^{\mathrm{t}}_N$ places a higher emphasis on the hypothesis given the nature of RNNs.

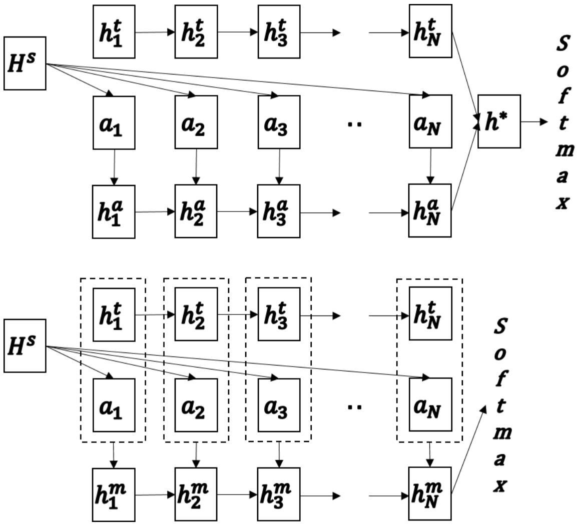

Figure 1: The top figure depicts the model by Rocktäschel et al. (2016) and the bottom figure depicts our model. Here $\mathbf{H}^{\mathrm{s}}$ represents all the hidden states $\mathbf{h}^{\mathrm{s}}_j$. Note that in the top model each $\mathbf{h}^{\mathrm{a}}_k$ represents a weighted version of the premise only, while in our model, each $\mathbf{h}^{\mathrm{m}}_k$ represents the matching between the premise and the hypothesis up to position k.

et al. (2016).

Specifically, our model works as follows. First, similar to Rocktäschel et al. (2016), we process the premise and the hypothesis using two LSTMs, but we do not feed the last cell state of the premise to the LSTM of the hypothesis. This is because we do not need the LSTM for the hypothesis to encode any knowledge about the premise but we will match the premise with the hypothesis using the hidden states of the two LSTMs. Again, we use $\mathbf{h}^{\mathrm{s}}_j$ and $\mathbf{h}^{\mathrm{t}}_k$ to represent these hidden states.

Next, we generate the attention vectors $\mathbf{a}_k$ similarly to Eqn (2). However, Eqn (4) will be replaced by the following equation:

$$e_{kj} = \mathbf{w}^{\mathrm{e}} \cdot \tanh(\mathbf{W}^{\mathrm{s}}\mathbf{h}^{\mathrm{s}}_j + \mathbf{W}^{\mathrm{t}}\mathbf{h}^{\mathrm{t}}_k + \mathbf{W}^{\mathrm{m}}\mathbf{h}^{\mathrm{m}}_{k-1}). \quad (6)$$

The only difference here is that we use a hidden state $\mathbf{h}^{\mathrm{m}}$ instead of $\mathbf{h}^{\mathrm{a}}$, and the way we define $\mathbf{h}^{\mathrm{m}}$ is very different from the definition of $\mathbf{h}^{\mathrm{a}}$.

Our $\mathbf{h}^{\mathrm{m}}_k$ is the hidden state at position k generated from our *m*LSTM. This LSTM models the *matching* between the premise and the hypothesis. Important matching results will be "remembered" by the LSTM while non-essential ones will be "forgotten." We use the concatenation of $\mathbf{a}_k$, which is the attention-weighted version of the premise for the k^{th} word in the hypothesis, and $\mathbf{h}^{\mathrm{t}}_k$, the hidden state for the k^{th} word itself, as input to the *m*LSTM.

Specifically, let us define

$$\mathbf{m}_k \quad = \quad \begin{bmatrix} \mathbf{a}_k \\ \mathbf{h}^{\mathrm{t}}_k \end{bmatrix}. \quad (7)$$

We then build the *m*LSTM as follows:

$$\begin{aligned}
\mathbf{i}^{\mathrm{m}}_k &= \sigma(\mathbf{W}^{\mathrm{mi}}\mathbf{m}_k + \mathbf{V}^{\mathrm{mi}}\mathbf{h}^{\mathrm{m}}_{k-1} + \mathbf{b}^{\mathrm{mi}}), \\
\mathbf{f}^{\mathrm{m}}_k &= \sigma(\mathbf{W}^{\mathrm{mf}}\mathbf{m}_k + \mathbf{V}^{\mathrm{mf}}\mathbf{h}^{\mathrm{m}}_{k-1} + \mathbf{b}^{\mathrm{mf}}), \\
\mathbf{o}^{\mathrm{m}}_k &= \sigma(\mathbf{W}^{\mathrm{mo}}\mathbf{m}_k + \mathbf{V}^{\mathrm{mo}}\mathbf{h}^{\mathrm{m}}_{k-1} + \mathbf{b}^{\mathrm{mo}}), \\
\mathbf{c}^{\mathrm{m}}_k &= \mathbf{f}^{\mathrm{m}}_k \odot \mathbf{c}^{\mathrm{m}}_{k-1} + \mathbf{i}^{\mathrm{m}}_k \odot \tanh(\mathbf{W}^{\mathrm{mc}}\mathbf{m}_k + \mathbf{V}^{\mathrm{mc}}\mathbf{h}^{\mathrm{m}}_{k-1} \\
&\quad + \mathbf{b}^{\mathrm{mc}}), \\
\mathbf{h}^{\mathrm{m}}_k &= \mathbf{o}^{\mathrm{m}}_k \odot \tanh(\mathbf{c}^{\mathrm{m}}_k). \quad (8)
\end{aligned}$$

With this *m*LSTM, finally we use only $\mathbf{h}^{\mathrm{m}}_N$, the last hidden state, to predict the label y.

2.3 Implementation Details

Besides the difference of the LSTM architecture, we also introduce a few other changes from the model by Rocktäschel et al. (2016). First, we insert a special word *NULL* to the premise, and we allow words in the hypothesis to be aligned with this *NULL*. This is inspired by common practice in machine translation. Specifically, we introduce a vector $\mathbf{h}^{\mathrm{s}}_0$, which is fixed to be a vector of 0s of dimension d. This $\mathbf{h}^{\mathrm{s}}_0$ represents *NULL* and is used with other $\mathbf{h}^{\mathrm{s}}_j$ to derive the attention vectors $\{\mathbf{a}_k\}_{k=1}^{N}$.

Second, we use word embeddings trained from GloVe (Pennington et al., 2014) instead of word2vec vectors. The main reason is that GloVe covers more words in the SNLI corpus than word2vec[3].

Third, for words which do not have pre-trained word embeddings, we take the average of the embeddings of all the words (in GloVe) surrounding the unseen word within a window size of 9 (4 on the left and 4 on the right) as an approximation of the embedding of this unseen word. Then we do not update any word embedding when learning our model. Although this is a very crude approximation, it reduces

[3] The SNLI corpus contains 37K unique tokens. Around 12.1K of them cannot be found in word2vec but only around 4.1K of them cannot be found in GloVe.

the number of parameters we need to update, and as it turns out, we can still achieve better performance than Rocktäschel et al. (2016).

3 Experiments

3.1 Experiment Settings

Data: We use the SNLI corpus to test the effectiveness of our model. The original data set contains 570,152 sentence pairs, each labeled with one of the following relationships: *entailment*, *contradiction*, *neutral* and –, where – indicates a lack of consensus from the human annotators. We discard the sentence pairs labeled with – and keep the remaining ones for our experiments. In the end, we have 549,367 pairs for training, 9,842 pairs for development and 9,824 pairs for testing. This follows the same data partition used by Bowman et al. (2015) in their experiments. We perform three-class classification and use accuracy as our evaluation metric.

Parameters: We use the Adam method (Kingma and Ba, 2014) with hyperparameters β_1 set to 0.9 and β_2 set to 0.999 for optimization. The initial learning rate is set to be 0.001 with a decay ratio of 0.95 for each iteration. The batch size is set to be 30. We experiment with $d = 150$ and $d = 300$ where d is the dimension of all the hidden states.

Methods for comparison: We mainly want to compare our model with the word-by-word attention model by Rocktäschel et al. (2016) because this model achieved the state-of-the-art performance on the SNLI corpus. To ensure fair comparison, besides comparing with the accuracy reported by Rocktäschel et al. (2016), we also re-implemented their model and report the performance of our implementation. We also consider a few variations of our model. Specifically, the following models are implemented and tested in our experiments:

- Word-by-word attention ($d = 150$): This is our implementation of the word-by-word attention model by Rocktäschel et al. (2016), where we set the dimension of the hidden states to 150. The differences between our implementation and the original implementation by Rocktäschel et al. (2016) are the following: (1) We also add a *NULL* token to the premise for matching. (2) We do not feed the last cell state of the LSTM for the premise to the LSTM for the hypothesis, to keep it consistent with the implementation of our model. (3) For word representation, we also use the GloVe word embeddings and we do not update the word embeddings. For unseen words, we adopt the same strategy as described in Section 2.3.
- *m*LSTM ($d = 150$): This is our *m*LSTM model with d set to 150.
- *m*LSTM with bi-LSTM sentence modeling ($d = 150$): This is the same as the model above except that when we derive the hidden states $\mathbf{h}^{\mathrm{s}}_j$ and $\mathbf{h}^{\mathrm{t}}_k$ of the two sentences, we use bi-LSTMs (Graves, 2012) instead of LSTMs. We implement this model to see whether bi-LSTMs allow us to better align the sentences.
- *m*LSTM ($d = 300$): This is our *m*LSTM model with d set to 300.
- *m*LSTM with word embedding ($d = 300$): This is the same as the model above except that we directly use the word embedding vectors $\mathbf{x}^{\mathrm{s}}_j$ and $\mathbf{x}^{\mathrm{t}}_k$ instead of the hidden states $\mathbf{h}^{\mathrm{s}}_j$ and $\mathbf{h}^{\mathrm{t}}_k$ in our model. In this case, each attention vector $\mathbf{a}_k$ is a weighted sum of $\{\mathbf{x}^{\mathrm{s}}_j\}_{j=1}^{M}$. We experiment with this setting because we hypothesize that the effectiveness of our model is largely related to the *m*LSTM architecture rather than the use of LSTMs to process the original sentences.

3.2 Main Results

Table 1 compares the performance of the various models we tested together with some previously reported results.

We have the following observations: (1) First of all, we can see that when we set d to 300, our model achieves an accuracy of 86.1% on the test data, which to the best of our knowledge is the highest on this data set. (2) If we compare our *m*LSTM model with our implementation of the word-by-word attention model by Rocktäschel et al. (2016) under the same setting with $d = 150$, we can see that our performance on the test data (85.7%) is higher than that of their model (82.6%). We also tested statistical significance and found the improvement to be statistically significant at the 0.001 level. (3) The performance of *m*LSTM with bi-LSTM sentence modeling compared with the model with standard LSTM sentence modeling when d is set to 150 shows that using bi-LSTM to process the original sentences helps

Model	d	$\|\theta\|_{\text{W+M}}$	$\|\theta\|_{\text{M}}$	Train	Dev	Test
LSTM [Bowman et al. (2015)]	100	10M	221K	84.4	-	77.6
Classifier [Bowman et al. (2015)]	-	-	-	99.7	-	78.2
LSTM shared [Rocktäschel et al. (2016)]	159	3.9M	252K	84.4	83.0	81.4
Word-by-word attention [Rocktäschel et al. (2016)]	100	3.9M	252K	85.3	83.7	83.5
Word-by-word attention (our implementation)	150	340K	340K	85.5	83.3	82.6
*m*LSTM	150	544K	544K	91.0	86.2	85.7
*m*LSTM with bi-LSTM sentence modeling	150	1.4M	1.4M	91.3	86.6	86.0
*m*LSTM	300	1.9M	1.9M	92.0	**86.9**	**86.1**
*m*LSTM with word embedding	300	1.3M	1.3M	88.6	85.4	85.3

Table 1: Experiment results in terms of accuracy. d is the dimension of the hidden states. $|\theta|_{\text{W+M}}$ is the total number of parameters and $|\theta|_{\text{M}}$ is the number of parameters excluding the word embeddings. Note that the five models in the last section were implemented by us while the other results were taken directly from previous papers. Note also that for the five models in the last section, we do not update word embeddings so $|\theta|_{\text{W+M}}$ is the same as $|\theta|_{\text{M}}$. The three columns on the right are the accuracies of the trained models on the training data, the development data and the test data, respectively.

	ground truth		
prediction	*N*	*E*	*C*
N	2628	286	255
E	340	3005	159
C	250	77	2823

Table 2: The confusion matrix of the results by *m*LSTM with $d = 300$. *N*, *E* and *C* correspond to *neutral*, *entailment* and *contradiction*, respectively.

(86.0% vs. 85.7% on the test data), but the difference is small and the complexity of bi-LSTM is much higher than LSTM. Therefore when we increased d to 300 we did not experiment with bi-LSTM sentence modeling. (4) Interestingly, when we experimented with the *m*LSTM model using the pre-trained word embeddings instead of LSTM-generated hidden states as initial representations of the premise and the hypothesis, we were able to achieve an accuracy of 85.3% on the test data, which is still better than previously reported state of the art. This suggests that the *m*LSTM architecture coupled with the attention model works well, regardless of whether or not we use LSTM to process the original sentences.

Because the NLI task is a three-way classification problem, to better understand the errors, we also show the confusion matrix of the results obtained by our *m*LSTM model with $d = 300$ in Table 2. We can see that there is more confusion between *neutral* and *entailment* and between *neutral* and *contradiction* than between *entailment* and *contradiction*. This shows that *neutral* is relatively hard to capture.

3.3 Further Analyses

To obtain a better understanding of how our proposed model actually performs the matching between a premise and a hypothesis, we further conduct the following analyses. First, we look at the learned word-by-word alignment weights α_{kj} to check whether the soft alignment makes sense. This is the same as what was done by Rocktäschel et al. (2016). We then look at the values of the various gate vectors of the *m*LSTM. By looking at these values, we aim to check (1) whether the model is able to differentiate between more important and less important word-level matching results, and (2) whether the model forgets certain matching results and remembers certain other ones.

To conduct the analyses, we choose three examples and display the various learned parameter values. These three sentence pairs share the same premise but have different hypotheses and different relationship labels. They are given in Table 3. The values of the alignment weights and the gate vectors are plotted in Figure 2.

Besides using the three examples, we will also give some overall statistics of the parameter values to confirm our observations with the three examples.

	ID	sentence	label
Premise		A dog jumping for a Frisbee in the snow.	
	Example 1	An animal is outside in the cold weather, playing with a plastic toy.	*entailment*
Hypothesis	Example 2	A cat washed his face and whiskers with his front paw.	*contradiction*
	Example 3	A pet is enjoying a game of fetch with his owner.	*neutral*

Table 3: Three examples of sentence pairs with different relationship labels. The second hypothesis is a contradiction because it mentions a completely different event. The third hypothesis is neutral to the premise because the phrase “with his owner” cannot be inferred from the premise.

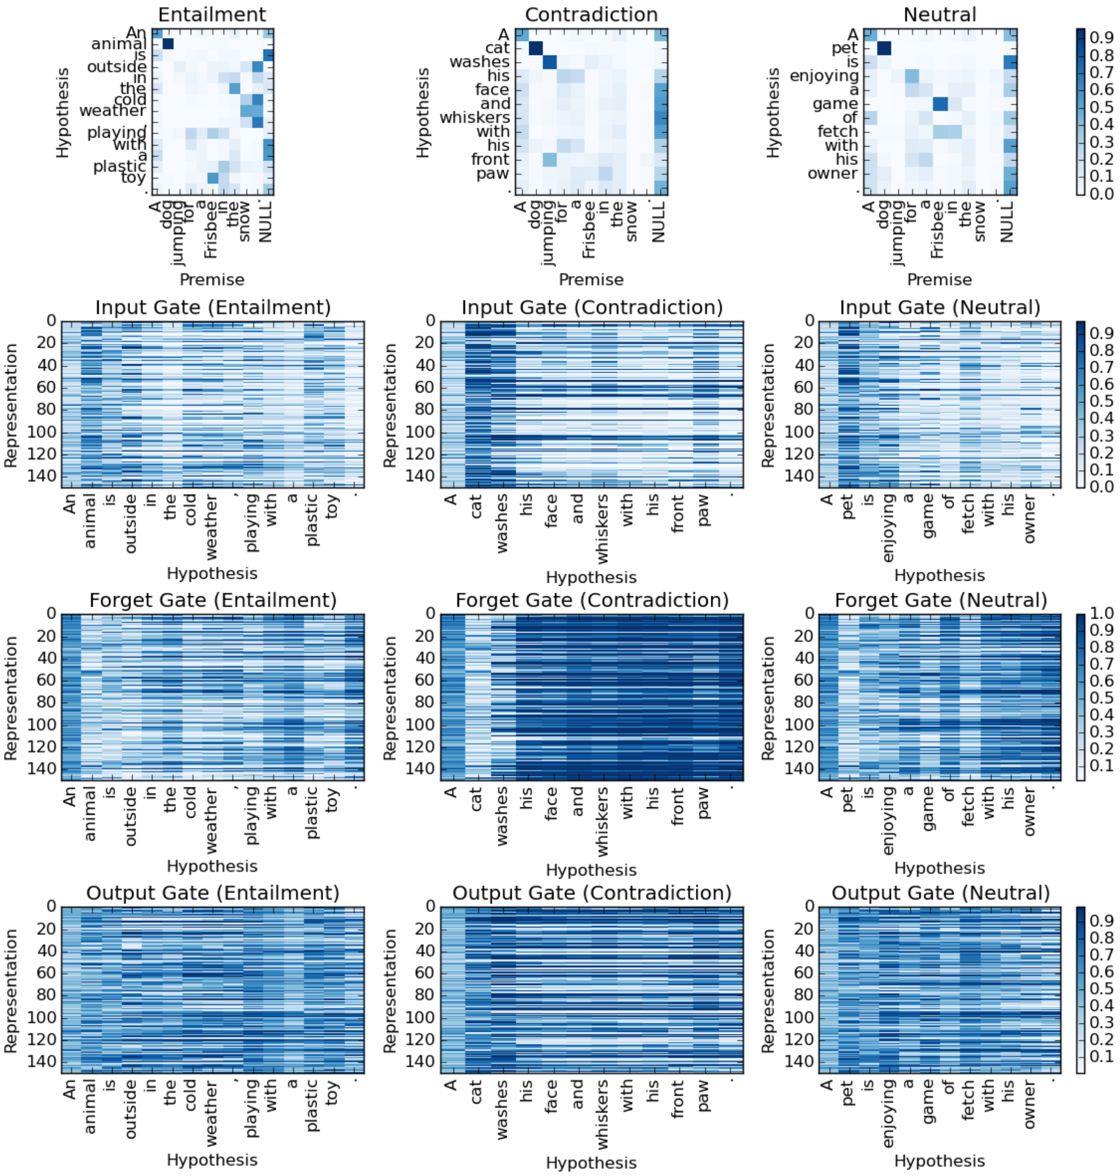

Figure 2: The alignment weights and the gate vectors of the three examples.

Word Alignment

First, let us look at the top-most plots of Figure 2. These plots show the alignment weights α_{kj} between the hypothesis and the premise, where a darker color corresponds to a larger value of α_{kj}. Recall that α_{kj} is the degree to which the k^{th} word in the hypothesis is aligned with the j^{th} word in the premise. Also recall that the weights α_{kj} are configured such that for the same k all the α_{kj} add up to 1. This means the weights in the same row in these plots add up to 1. From the three plots we can see that the alignment weights generally make sense. For example, in Example 1, "animal" is strongly aligned with "dog" and "toy" aligned with "Frisbee." The phrase "cold weather" is aligned with "snow." In Example 3, we also see that "pet" is strongly aligned with "dog" and "game" aligned with "Frisbee."

In Example 2, "cat" is strongly aligned with "dog" and "washes" is aligned with "jumping." It may appear that these matching results are wrong. However, "dog" is likely the best match for "cat" among all the words in the premise, and as we will show later, this match between "cat" and "dog" is actually a strong indication of a contradiction between the two sentences. The same explanation applies to the match between "washes" and "jumping."

We also observe that some words are aligned with the *NULL* token we inserted. For example, the word "is" in the hypothesis in Example 1 does not correspond to any word in the premise and is therefore aligned with *NULL*. The words "face" and "whiskers" in Example 2 and "owner" in Example 3 are also aligned with *NULL*. Intuitively, if some important content words in the hypothesis are aligned with *NULL*, it is more likely that the relationship label is either contradiction or neutral.

Values of Gate Vectors

Next, let us look at the values of the learned gate vectors of our *m*LSTM for the three examples. We show these values under the setting where d is set to 150. Each row of these plots corresponds to one of the 150 dimensions. Again, a darker color indicates a higher value.

An input gate controls whether the input at the current position should be used in deriving the final hidden state of the current position. From the three plots of the input gates, we can observe that generally for stop words such as prepositions and articles the input gates have lower values, suggesting that the matching of these words is less important. On the other hand, content words such as nouns and verbs tend to have higher values of the input gates, which also makes sense because these words are generally more important for determining the final relationship label.

To further verify the observation above, we compute the average input gate values for stop words and the other content words. We find that the former has an average value of 0.287 with a standard deviation of 0.084 while the latter has an average value of 0.347 with a standard deviation of 0.116. This shows that indeed generally stop words have lower input gate values. Interestingly, we also find that some stop words may have higher input gate values if they are critical for the classification task. For example, the negation word "not" has an average input gate value of 0.444 with a standard deviation of 0.104.

Overall, the values of the input gates confirm that the *m*LSTM helps differentiate the more important word-level matching results from the less important ones.

Next, let us look at the forget gates. Recall that a forget gate controls the importance of the *previous* cell state in deriving the final hidden state of the current position. Higher values of a forget gate indicate that we need to remember the previous cell state and pass it on whereas lower values indicate that we should probably forget the previous cell. From the three plots of the forget gates, we can see that overall the colors are the lightest for Example 1, which is an *entailment*. This suggests that when the hypothesis is an entailment of the premise, the *m*LSTM tends to forget the previous matching results. On the other hand, for Example 2 and Example 3, which are *contradiction* and *neutral*, we see generally darker colors. In particular, in Example 2, we can see that the colors are consistently dark starting from the word "his" in the hypothesis until the end. We believe the explanation is that after the *m*LSTM processes the first three words of the hypothesis, "A cat washes," it sees that the matching between "cat" and "dog" and between "washes" and "jumping" is a strong indication of a contradiction, and therefore these matching results need to be remembered until the end of the *m*LSTM for the final prediction.

We have also checked the forget gates of the other sentence pairs in the test data by computing the average forget gate values and the standard deviations for *entailment*, *neutral* and *contradiction*, respectively. We find that the values are 0.446±0.123, 0.507±0.148 and 0.536±0.170, respectively. For *contradiction* and *neutral*, the forget gates start to have higher values from certain positions of the hypotheses.

Based on the observations above, we hypothesize that the way the *m*LSTM works is as follows. It remembers important mismatches, which are useful for predicting the *contradiction* or the *neutral* relationship, and forgets good matching results. At the end of the *m*LSTM, if no important mismatch is remembered, the final classifier will likely predict *entailment* by default. Otherwise, depending on the kind of mismatch remembered, the classifier will predict either *contradiction* or *neutral*.

For the output gates, we are not able to draw any important conclusion except that the output gates seem to be positively correlated with the input gates but they tend to be darker than the input gates.

4 Related Work

There has been much work on natural language inference. Shallow methods rely mostly on lexical similarities but are shown to be robust. For example, Bowman et al. (2015) experimented with a lexicalized classifier-based method, which only uses lexical information and achieves an accuracy of 78.2% on the SNLI corpus. More advanced methods use syntactic structures of the sentences to help matching them. For example, Mehdad et al. (2009) applied syntactic-semantic tree kernels for recognizing textual entailment. Because inference is essentially a logic problem, methods based on formal logic (Clark and Harrison, 2009) or natural logic (MacCartney, 2009) have also been proposed. A comprehensive review on existing work can be found in the book by Dagan et al. (2013).

The work most relevant to ours is the recently proposed neural attention model-based method by Rocktäschel et al. (2016), which we have detailed in previous sections. Neural attention models have recently been applied to some natural language processing tasks including machine translation (Bahdanau et al., 2015), abstractive summarization (Rush et al., 2015) and question answering (Hermann et al., 2015). Rocktäschel et al. (2016) showed that the neural attention model could help derive a better representation of the premise to be used to match the hypothesis, whereas in our work we also use it to derive representations of the premise that are used to sequentially match the words in the hypothesis.

The SNLI corpus is new and so far it has only been used in a few studies. Besides the work by Bowman et al. (2015) themselves and by Rocktäschel et al. (2016), there are two other studies which used the SNLI corpus. Vendrov et al. (2015) used a *Skip-Thought* model proposed by Kiros et al. (2015) to the NLI task and reported an accuracy of 81.5% on the test data. Mou et al. (2015) used tree-based CNN encoders to obtain sentence embeddings and achieved an accuracy of 82.1%.

5 Conclusions and Future Work

In this paper, we proposed a special LSTM architecture for the task of natural language inference. Based on a recent work by Rocktäschel et al. (2016), we first used neural attention models to derive attention-weighted vector representations of the premise. We then designed a match-LSTM that processes the hypothesis word by word while trying to match the hypothesis with the premise. The last hidden state of this *m*LSTM can be used for predicting the relationship between the premise and the hypothesis. Experiments on the SNLI corpus showed that the *m*LSTM model outperformed the state-of-the-art performance reported so far on this data set. Moreover, closer analyses on the gate vectors revealed that our *m*LSTM indeed remembers and passes on important matching results, which are typically mismatches that indicate a *contradiction* or a *neutral* relationship between the premise and the hypothesis.

With the large number of parameters to learn, an inevitable limitation of our model is that a large training data set is needed to learn good model parameters. Indeed some preliminary experiments applying our *m*LSTM to the SICK corpus (Marelli et al., 2014), a smaller textual entailment benchmark data set, did not give very good results. We believe that this is because our model learns everything from scratch except using the pre-trained word embeddings. A future direction would be to incorporate other resources such as the paraphrase database (Ganitkevitch et al., 2013) into the learning process so that such prior knowledge can be utilized.

Abstract

We introduce a latent activity model for workplace emails, positing that communication at work is purposeful and organized by activities. We pose the problem as probabilistic inference in graphical models that jointly capture the interplay between latent activities and the email contexts they govern, such as the recipients, subject and body. The model parameters are learned using maximum likelihood estimation with an expectation maximization algorithm. We present three variants of the model that incorporate the recipients, co-occurrence of the recipients, and email body and subject. We demonstrate the model's effectiveness in an email recipient recommendation task and show that it outperforms a state-of-the-art generative model. Additionally, we show that the activity model can be used to identify email senders who engage in similar activities, resulting in further improvements in recipient recommendation.

1 Introduction

Activities are a prominent characteristic of a workplace, typically governed by people's job roles and work responsibilities. Examples of workplace activities can include organizing a conference, purchasing equipment, managing candidate interviews, etc. Activities can be viewed as a collaborative work practice involving a set of people each playing a different role in the activity (Dredze et al., 2006). Although emails are an integral part of workplace communication, current email clients offer little support for the activity oriented use of email (Khoussainov and Kushmerick, 2005). Discussions can get split across long email threads and communications about all activities can get intermixed, making activity management difficult (Balakrishnan et al., 2010).

In this work, we model activities as latent probability distributions personalized to the email sender. We present three variants of the activity model, incorporating: (1) email recipients, (2) email recipient pairs which account for co-occurrence of the email recipients, and (3) email body and subject tokens along with email recipient pairs. Additionally, we experiment with lexical (bag of words), syntactic (nouns and verb phrases), and semantic (things of interest in an email) representations of the body and subject tokens of an email. The parameters of the generative model are learned using an expectation maximization (EM) algorithm.

For evaluation, we formulate a real world task setting for email recipient recommendation, where we assume that all but the last recipient of an email has been entered by the sender, and we test the effectiveness of our activity model in recommending the last recipient. Such a system has practical applications, such as reminding an email sender about a potentially forgotten recipient or recommending the next recipient as the sender enters each recipient.

The main contributions of our research are:

- We introduce a latent activity model for emails

Proceedings of NAACL-HLT 2016, pages 1452–1462,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

where the email contexts are governed by workplace activities;

- We present probabilistic modeling that incorporates co-occurring recipients with lexical, syntactic and semantic contexts of an email;
- We identify senders engaging in similar activities using the activity model, and show improvements in recipient recommendation.

2 Related Work

Prior research related to our work can be divided into the following three major areas presented below.

2.1 Activity in Emails

Prior research has treated emails as a communication tool for workplace activities (Moran, 2005) or a task management resource (Bellotti et al., 2003). Kushmerick and Lau (2005) formalized e-commerce activities as finite-state automata, where transitions among states represent messages sent between participants. Dredze et al. (2006) used user generated activity labels and classified emails into activities using overlapping participants and content similarity. Minkov et al. (2008) modeled user created folders and TO-DO items as activities, and created a heterogeneous graph to perform activity-centric search.

Shen et al. (2006) predicted tasks associated with an incoming email by leveraging email sender, recipients and distinct subject words. They found the body words to not provide additional prediction value. Although they used similar information as we do, they used a combination of generative and discriminative models toward task classification, and did not do recipient recommendation. Our activity model designs are closer to the model introduced by Dredze and Wallach (2008), who presented a Dirichlet process mixture model combined with author and thread information. Our designs differ as we use co-occurring recipients in the generative process, and use various linguistic representations of content.

2.2 Generative models for Emails

Latent Dirichlet Allocation (LDA) (Blei et al., 2003) is a frequently used generative topic model. Assuming a Dirichlet prior, LDA models learn probability distributions of words as latent topics in a corpus. In emails, LDA models have been used for learning summary keywords (Dredze et al., 2008), analyzing how topics change over time (Wang and McCallum, 2006), understanding entity relations (Balasubramanyan and Cohen, 2011), analyzing communication networks (Nguyen et al., 2013), for authorship attribution (Seroussi et al., 2012), and discovering topics associated with authors (McCallum et al., 2005).

Other generative models have also been used for analyzing email communication behavior (Navaroli et al., 2012), identifying links between an email sender and a recipient to detect potential anomalous communication (Huang and Zeng, 2006), and resolving personal names in emails (Elsayed et al., 2008). Representing workplace activities of the emails with probabilistic inference in graphical models where observed information is personalized to the email senders is what sets our work apart from previous research in computational models for emails.

2.3 Email Recipient Recommendation

For recommending email recipients, interactions among email participants and content similarity are the signals that have been explored most. Carvalho and Cohen (2007) leveraged content similarity by creating tf-idf centroid vectors and determining k-nearest neighbors of a target email. Pal et al. (2007) presented a discriminative author recipient topic model that uses transfer learning. Desai and Dash (2014) used reverse chronologically arranged implicit groups determined from sent emails. Sofershtein and Cohen (2015) created a ranking function combining temporal and textual features.

Among the generative modeling based approaches, Pal and McCallum (2006) learned probability distributions of recipients, and words in body and subject to predict recipients in email cc lists. Dredze et al. (2008) evaluated the impact of summary keywords generated using LDA, for email recipient prediction. More recently, Graus et al. (2014) predicted email recipients by estimating sender and recipient likelihood using a communication graph, email likelihood using content words, and evaluated performance on the Avocado email corpus. In our work, we use latent activity distributions, and identify senders who engage in similar activities. We compare our recipient prediction results against the generative model of Graus et al. (2014).

3 Problem Setting and Data

3.1 Activity Modeling in Emails

Our motivation for activity modeling in email stems from the assumption that in the workplace, people primarily use emails as a communication tool for their ongoing activities, and an email's recipient list, content, and other context are governed by a given activity. For example, an employee attending a conference may write emails to the conference organizers regarding registration or scheduling, or emails to a hotel for booking confirmation. The communication may span multiple emails, involving many parties, but all under the same activity.

We model the activities as a latent probabilistic variable over the email recipients and content, personalized to the email sender. Let D be the set of all emails in a corpus containing N emails, generated by $S = \{s_i \mid 1 \leq i \leq S_D\}$ senders, and sent to $R = \{r_i \mid 1 \leq i \leq R_D\}$ recipients. Let $B = \{b_i \mid 1 \leq i \leq B_D\}$, and $T = \{t_i \mid 1 \leq i \leq T_D\}$ represent the body and subject vocabulary of the emails respectively. Let K be the number of latent activities for each sender. We model the activities as probability distributions over email components S, R, B and T.

3.2 Corpus Description and Data Sets

For our experiments, we use the Avocado email corpus, available from the LDC catalog.[1] The corpus contains emails from a defunct IT company referred to as "Avocado". For learning the activity model, we extract emails from 7/1/2000 – 5/1/2001 to create a training data set, and from 5/1/2001 – 6/30/2001 for development/tuning. In this work, we did not consider threaded conversations, only retained the first email in a thread and discarded the rest.

Number of	Train	Train + Dev
Total emails	18,593	22,283
Unique senders	120	129
Unique recipients	3,157	3,658
Unique body words	31,386	36,005
Unique subject words	6,969	7,724
Emails per sender	154.94	172.74
Emails per recipient	5.89	6.09

Table 1: Data set statistics.

As additional filtering steps, we only kept emails written by the Avocado employees, allowing us to confine the scope of the activities within the company. To control sparsity and noise, for each email, we enforced a a minimum of two recipients, and a maximum of ten recipients.[2] In a practical system, we consider it reasonable that a model only activates after some history of email is sent by a user. We therefore removed emails by the senders having fewer than 25 emails in the training data. From email bodies and subjects, we removed stopwords, and words appearing fewer than 5 times or more than 100 times.[3] When a recipient's same email alias was present multiple times, we took it only once, as well as removed a sender's email alias from the recipients list if it was present there. In this work, we focused on recipients from only the "TO" field, and did not include recipients from the "CC" or "BCC" field. Table 1 presents statistics of the data sets.

4 Activity Models

Our key assumption in modeling the activities in email is that different components of an email contain specific types of information that can help to characterize the activities that drive user behavior. In our generative process of the activity model, for an email $d \in D$, a sender $s \in S$ is first generated from a multinomial distribution with probability vector σ, then an activity a is generated from a sender personalized multinomial distribution with probability vector θ_s. Let $R_d \subseteq R$, $B_d \subseteq B$ and $T_d \subseteq T$ be the set[4] of recipients, body and subject tokens of d respectively. The generation of the email contexts (recipients and body/subject tokens) varies based on the specific design of each variant of our model. In a first simplistic model, we assume that recipient $r \in R_d$, body token $b \in B_d$ and subject token $t \in T_d$ for an email can be generated from the multinomial distributions with probability vectors $\lambda_{s,a}$, $\phi_{s,a}$, and $\tau_{s,a}$ respectively, that are conditioned s and a. Point estimates for σ can be directly

[1] https://catalog.ldc.upenn.edu/LDC2015T03

[2] When an email has many recipients, it is often indicative of general announcements or system generated emails, which are less directly relevant to an employee's activities. Some emails in the Avocado dataset have more than 500 recipients.

[3] A heuristic we used to remove words that are too general.

[4] Multiset for body and subject tokens.

calculated from a training corpus, whereas θ, λ, ϕ, and τ are the unknown parameters of the model.

4.1 Model 1: Rec

In our first model Rec, we assume that the latent activities can be learned as a probability distribution over the recipients alone. The generative process is:

```
Model 1: Rec
For each email document $d \in D$
    sender $s$ ~ Multinomial$(\sigma)$
    activity $a$ ~ Multinomial$(\theta_s)$
    For $1 \ldots |R_d|$
        recipient $r$ ~ Multinomial$(\lambda_{s,a})$
```

Figure 1 presents the plate diagram of the model. The joint probability of the Rec model is the product of the conditional distributions:

$$P(s, a, r|\sigma, \theta, \lambda) = P(s|\sigma)P(a|s, \theta) \prod_{r \in R_d} P(r|s, a, \lambda)$$

The probability of a sender s, an activity a given s, and a recipient r given s and a are defined below[5]:

$$P(s = \hat{s}) = \prod_{i=1}^{S_D} \sigma_i^{I[i=\hat{s}]},\ s.t. \sum_i \sigma_i = 1$$

$$P(a = \hat{a}|s = \hat{s}) = \prod_{i=1}^{K} \theta_{\hat{s},i}^{I[i=\hat{a}]},\ s.t. \forall_s \sum_i \theta_{s,i} = 1$$

$$P(r = \hat{r}|s = \hat{s}, a = \hat{a}) = \prod_{i=1}^{R_D} \lambda_{\hat{s},\hat{a},i}^{I[i=\hat{r}]},$$

$$s.t. \quad \forall_{s,a} \quad \sum_i \lambda_{s,a,i} = 1$$

Inference: Let d^n be the n^{th} email, where $d^n = \{s^n, R_d^n\}$. We apply Bayes' rule to find the posterior distribution over the activities $P^n(a|d)$, which is directly proportional to the joint distribution $P^n(a, d)$. We can exactly compute this distribution by evaluating the joint distribution for every value of a and the observed document d^n.

Learning: Point estimates for σ can be directly obtained from the training corpus. We estimate the parameters θ and λ by maximizing the $(\log)$ probability of observing D. We write the $\log(D)$ as:

$$\log P(D) = \sum_{n=1}^{N} \sum_a P^n(a|s, R_d) \log P^n(a, s, R_d)$$

We use the Expectation-Maximization (EM) algorithm to set the parameters. Starting with a random initialization of the parameters (with Gaussian noise), EM iterates between the E-step in which $P^n(a|s, R_d)$ is computed for each email with fixed parameter values computed in the previous M-step, and the M-step in which the parameters are updated with fixed $P^n(a|s, R_d)$ values computed in the E-step. The parameter updates are obtained by taking the derivative of log $P(D)$ with respect to each parameter, and setting the resultant to 0, providing us with the following parameter updates:

$$\theta_{s^n,i} = \frac{\sum_{n=1}^{N} \sum_a P^n(a|d) I[i = a]}{\sum_{n=1}^{N} \sum_a P^n(a|d)}$$

$$\lambda_{s^n,a,i} = \frac{\sum_{n=1}^{N} \sum_a P^n(a|d) \sum_{r \in R} I[i = r]}{|R_d^n| \sum_{n=1}^{N} \sum_a P^n(a|d)}$$

We run EM until the change in $\log P(D)$ is less than our convergence threshold 10^{-5}.

4.2 Model 2: CoRec

Using co-occurring recipients in generative models for emails has been rarely explored in previous work. Pal and McCallum (2006) modeled co-recipient information as a probability distribution of recipients conditioned on the other recipients, and noted that this information improved their email cc prediction performance. In our $CoRec$ model, we model co-recipients as pairs of recipients generated from a probability distribution conditioned on the sender and the activity. Let $L = \{(r_i, r_j) \mid 1 \leq i \leq R_D, 1 \leq j \leq R_D\}$ having L_D pairs of recipients in the corpus. For an email d, $L_d \subseteq L$ is the set of recipient pairs in d. The $CoRec$ model first generates a sender s from the probability distribution σ, then an activity a from a distribution over latent activities θ_s personalized to s, and finally recipient pairs $r_p \in L_d$ from a distribution over recipient pairs $\omega_{s,a}$ conditioned on s and a. The generative process is summarized below:

[5] I is an indicator variable

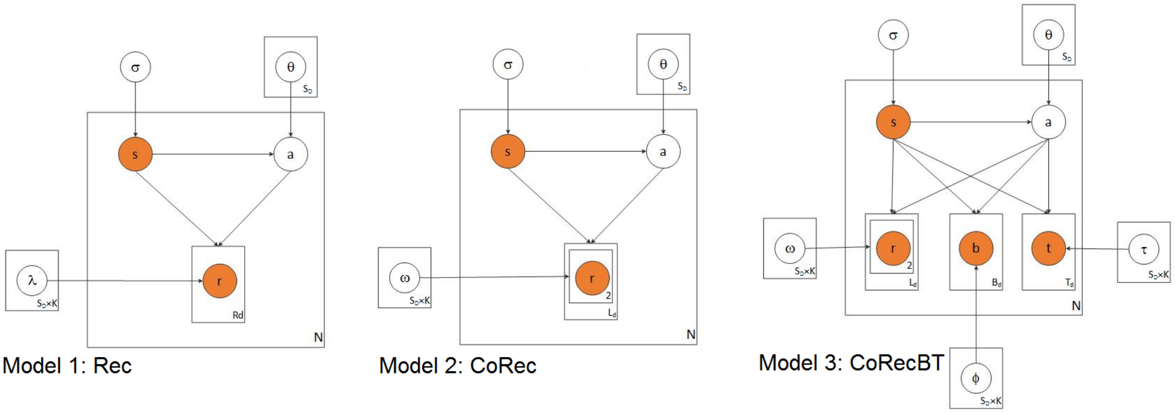

Figure 1: Activity model plate diagrams.

```
Model 2: CoRec
For each email document $d$
    sender $s$ ~ Multinomial($\sigma$)
    activity $a$ ~ Multinomial($\theta_s$)
    For 1 . . . $|L_d|$
        recipient pair $r_p$ ~ Multinomial($\omega_{s,a}$)
```

The joint probability of the $CoRec$ model is:

$$P(s,a,r_p|\sigma,\theta,\omega) = P(s|\sigma)P(a|s,\theta) \prod_{r_p\in L_d} P(r_p|s,a,\omega)$$

This adds over the Rec model the probability of a recipient pair r_p given s and a, defined below:

$$P(r_p = \hat{r}_p|s=\hat{s}, a=\hat{a}) = \prod_{i=1}^{L_D} \omega_{\hat{s},\hat{a},i}^{I[i=\hat{r}_p]}, \quad s.t. \quad \forall_{s,a} \quad \sum_i \omega_{s,a,i} = 1$$

The EM algorithm is applied in the same way as in the Rec model. During the M-step, update for θ remains the same. The update for ω is given below:

$$\omega_{s^n,a,i} = \frac{\sum_{n=1}^{N}\sum_a P^n(a|d)\sum_{r_p\in L} I[i=r_p]}{|L_d^n|\sum_{n=1}^{N}\sum_a P^n(a|d)}$$

4.3 Model 3: CoRecBT

Finally, in the $CoRecBT$ model, we further incorporate body and subject of emails. The generative process of the model is:

```
Model 3: CoRecBT
For each email document $d$
    sender $s$ ~ Multinomial($\sigma$)
    activity $a$ ~ Multinomial($\theta_s$)
    For 1 . . . $|L_d|$
        recipient pair $r_p$ ~ Multinomial($\omega_{s,a}$)
    For 1 . . . $|B_d|$
        body token $b$ ~ Multinomial($\phi_{s,a}$)
    For 1 . . . $|T_d|$
        subject token $t$ ~ Multinomial($\tau_{s,a}$)
```

The joint probability of the $CoRecBT$ model:

$$P(s,a,r_p,b,t|\sigma,\theta,\omega,\phi,\tau) = P(s|\sigma)P(a|s,\theta) \prod_{r_p\in L_d} P(r_p|s,a,\omega) \prod_{b\in B_d} P(b|s,a,\phi) \prod_{t\in T_d} P(t|s,a,\tau)$$

where the probability of a body token b and subject token t given s and a defined as:

$$P(b=\hat{b}|s=\hat{s},a=\hat{a}) = \prod_{i=1}^{B} \phi_{\hat{s},\hat{a},i}^{I[i=\hat{b}]}$$

$$P(t=\hat{t}|s=\hat{s},a=\hat{a}) = \prod_{i=1}^{T} \tau_{\hat{s},\hat{a},i}^{I[i=\hat{t}]},$$

$$s.t. \quad \forall_{s,a}\sum_i \phi_{s,a,i} = 1, \forall_{s,a}\sum_i \tau_{s,a,i} = 1$$

During the M-step of the EM algorithm, updates for θ and ω remain the same as the $CoRec$ model. The updates for ϕ and τ are given below:

$$\phi_{s^n,a,i} = \frac{\sum_{n=1}^{N} \sum_a P^n(a|d) \sum_{b \in B} I[i = b]}{|B_d^n| \sum_{n=1}^{N} \sum_a P^n(a|d)}$$

$$\tau_{s^n,a,i} = \frac{\sum_{n=1}^{N} \sum_a P^n(a|d) \sum_{t \in T} I[i = t]}{|T_d^n| \sum_{n=1}^{N} \sum_a P^n(a|d)}$$

4.4 Subject and Body Token Representations

Previous work in modeling email content mostly explored bag of words (e.g., (Graus et al., 2014)) or tf-idf vectors (e.g., (Carvalho and Cohen, 2007)) as the content representation of an email. For modeling activities in emails, we experiment with different linguistic representations of the email content. They are:

- Lexical: as the lexical representation, we use the bag of words (BOW) from email body and subject, after Penn Tree Bank (PTB) style tokenization.

- Syntactic: using heuristics on the output of a PTB constituent parser (Quirk et al., 2012), we identify Nouns (N) and Verb Phrases (VP) in email body and subject.

- Semantic: we identify phrases in emails that represent topics, concept and entities discussed in the emails. We refer to them as *Thing of Interest (TOI)*. To extract these key phrases, we use Web search queries as a source of information. Using queries as a dictionary of possible key phrases is useful but has limited coverage since many topics/concepts are discussed in emails but absent or not widely available in Web search queries. Instead of using queries directly, we use them to construct a training set of key phrases and their content and we train a discriminative model to identify the key phrases. We treat each query as a key phrase and the surrounding text from Web results as context. We use a sample of hundreds of thousands of search queries from the usage logs of a commercial Web search engine. Only queries tagged as English and from the United States locale were retained to remove geographic or linguistic variations. Queries were kept only if they have been submitted by at least 100 different users in one month. For each query, the text from the Web page that is most relevant to the query and that contains the exact query text is collected as the context for the query. Relevance is estimated by the percentage of time the page has received a long dwell time click (greater than 30 seconds) for the query. If no relevant pages exist, the query is ignored. To generate negative examples, random n-grams were extracted from web pages. We experimented with a large number of features including: first word of the phrase, last word of the phrase, n-gram features (n=1 to 3), the word right before/after the phrase, the part-of-speech tag of the first word in the phrase, the part-of-speech tag of the last word in the phrase, n-gram features (n ranges from 1 to 3) over the sequence of part-of-speech tags representing the phrase and the part-of-speech tags of the word right before/after the phrase, phrase length, how many times it appeared in the body/title, and the relative location of the first occurrence of the phrase in the body. We trained a logistic regression classifier using these features and the data described above. The trained classifier is then applied to our email data to identify the *Thing of Interest (TOI)* phrases.

4.5 Discussion

Full Bayesian Treatment: In the above models, we learn point estimates for the parameters $(\sigma, \theta, \omega, \phi, \tau)$. One can take a Bayesian approach and treat these parameters as variables (for instance, with Dirichlet prior distributions), and perform Bayesian inference. However, exact inference will become intractable and we would need to resort to methods such as variational inference or sampling. We found this extension unnecessary, as we had a sufficient amount of training data to estimate all parameters reliably. In addition, our approach enabled us to learn (and perform inference in) the model with large amounts of data with reasonable computing time.

5 Recipient Recommendation

To evaluate the effectiveness of our activity model, we formulate a recipient recommendation task.

Task Definition: For a test email document d containing the list of recipients R_d, a modified list of recipients R_d^* is created by removing the last recipient $r^* \in R_d$. Given d with R_d^*, the task objective is to recommend r^* as the next recipient for d.

5.1 Our Methods

To recommend a recipient for a test email document d written by sender s_d, we first create a candidate recipient list by combining recipients who received an email from s_d, and recipients who co-occurred with an observed recipient $r \in R_d^*$ in the training corpus. Sender s_d and any $r \in R_d^*$ are excluded from the candidate list. Next, we determine the probability distribution of the activities in d using:

$$P(a|d) = \frac{P(s, a, d|\sigma, \theta, \omega, \phi, \tau)}{\sum_a P(s, a, d|\sigma, \theta, \omega, \phi, \tau)}$$

Each candidate recipient r^* is then ranked by a score using two different methods defined below. The ranked list is used as our final recommended recipients. The two scoring methods are:

Reg Method: In the Reg method, we score using the chain rule[6]:

$$P(r^*|d) \propto \sum_a P(a|d) \prod_{r \in R_d} P(r^*, r|s, a)$$

We smooth the above function using the following linear interpolation:

$$\begin{aligned} P(r^*, r|a, s) = \alpha_1 \times P(r^*, r|a, s) + (1 - \alpha_1) \times \\ (\alpha_2 \times P(r^*, r) + (1 - \alpha_2) \times P(r_{rare})) \end{aligned}$$

Here, $P(r_{rare})$ is the lowest probability of any recipient in the training data. We calculate α_i with a sigmoid logistic function, allowing us to determine when to rely more on the learned probabilities:

$$\alpha_i = \frac{1}{1 + e^{-k(x - x_0)}}$$

For α_1, x is the pointwise mutual information (PMI) between s and r in training data, with steepness parameter $k = 50$. For α_2, x is the frequency of r in training data, with $k = .5$. Sigmoid's midpoint x_0 is the first quartile ($Q1$) of the PMI and recipient frequency distributions respectively. The above values for k have been determined from the shape of the sigmoid curves in the training data.

Sim Method: In the Sim method, we explore the idea that the activity model can be used to identify other senders with similar activities as s_d, who we refer to as *similar senders*, S_d^*. To identify the similar senders, we evaluate senders who maximize the log likelihood of the test document d by calculating $\log P(s, d)$ for all $s \in S$, and identify the top 5 with the highest scores to add to S_d^*. The observed sender s_d is not included in S_d^*. We then calculate $P_s(r^*|d)$ for each $s \in S_d^*$ using the Reg method, along with a weight w_s:

$$w_s = \frac{\log P(s, d)}{\sum_{s \in S_d^*} \log P(s, d)}$$

The final scoring function for the Sim method is:

$$P(r^*|d) = \alpha P_{s_d}(r^*|d) + (1 - \alpha) \sum_{s \in S_d^*} w_s P_s(r^*|d)$$

Here, α is determined with the frequency of s_d in training data, using the sigmoid function with $k = 0.5$ and x_0 as the $Q1$ of the frequency distribution.

5.2 Baseline Systems

As simple baseline systems to compare with our methods, we use 1) a random recipient baseline; 2) ranked recipients by $P(r = r^*)$; and 3) ranked recipients by $P(r = r^*|s = s_d)$, where the probabilities are calculated from the training data. We evaluate two additional generative baselines using 4) $P(r = r^*|R_d^*)$, and 5) $P(r = r^*|s = s_d, R_d^*)$ by applying Bayes' theorem, and assuming conditional independence among $r \in R_d^*$. For these methods, we used similar interpolation smoothing as before.

We additionally implemented the generative model presented by Graus et al. (2014) for recipient recommendation, which for test email d uses:

$$P(r^*|s_d, d) \propto P(d|r^*, s_d) \times P(s_d|r^*) \times P(r^*)$$

Graus estimated $P(d|r^*, s_d)$ by $P(b|r^*, s_d)$ where b is an observed term in the email. The evaluation task was different from ours as they predicted all recipients of an email. In our evalua-

[6] Scoring function for the Rec model uses $P(r^*|s, a)$

Method	Precision@1	Precision@2	Precision@5	Precision@10	MRR

tion task, we recommend the last recipient, allowing us to use the already observed recipients R_d^* for estimating $P(d|r^*, s_d)$. Consequently, we present 3 additional baselines adopting Graus' method: 6) $GrausB(BOW)$ method uses body words, 7) $GrausB(VP - TOI)$ uses the verb phrases and things of interest, and finally 8) $GrausR$ method uses R_d^* for estimating $P(d|r^*, s_d)$. $GrausR$ is equivalent to how we calculate our fifth baseline, $P(r = r^*|s = s_d, R_d^*)$, with the only difference of the smoothing function.

6 Experimental Results

6.1 Experimental Setup

To evaluate recipient recommendation, we create a test data set by extracting emails from 7/1/2001 – 8/31/2001 from the Avocado data set. First we train our activity model with the training data and determine the optimum number of activities for each method by evaluating recipient recommendation on the development data. The number of activities per model is shown in Table 3. We then combine training and tuning data to create a new training data set in order to minimize the time difference between training and test emails. From the test data, we removed emails that had a sender or recipient never appearing in the training data. Although this limits the scope of the recipient recommendation evaluation task, predicting a recipient for a sender who never appeared in the training data is beyond our current modeling scope and practical settings. The final test set contains 1923 emails with 14.91 emails per sender.

Model	K
Rec	10
CoRec	3
CoRecBT (BOW)	20
CoRecBT (NP-VP-TOI)	7
CoRecBT (VP-TOI)	4

Table 3: No. of activities used for recipient recommendation.

With the ranked lists of recipients generated by each method, we calculate precision@X (X= 1, 2, 5, 10), and MRR (Mean Reciprocal Rank). Precision@X is defined as percentage of emails having the actual recipient in the top X ranked recipients.

6.2 Recipient Recommendation Results

Table 2 presents the recipient recommendation results for different methods. The first 5 rows show that the generative baselines from row (4) and (5) performed much better than the simple baselines (row (1)–(3)), yielding up to .2871 MRR. Comparatively, the GrausB(BOW) baseline in row (6) that uses body words, did not perform well, which is consistent with the finding by Shen et al. (2006) about

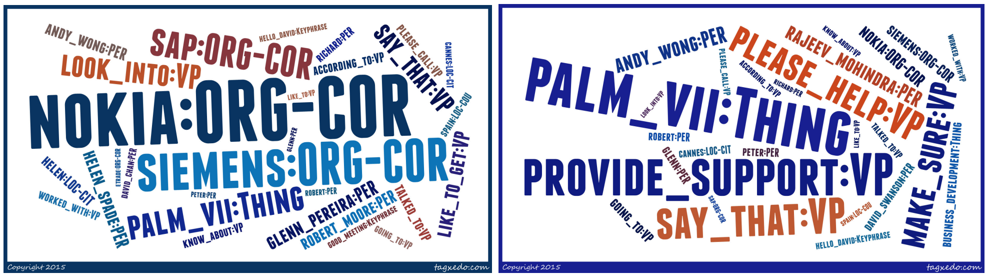

Figure 2: Word clouds of activity tokens.

body words not providing additional value in their task classification work. However, the GrausB(VP–TOI) in row (7) shows that using body terms more selectively has the potential for improving performance. Comparatively, the use of observed recipients (GrausR in row (8)) substantially improved recommendation results, yielding the highest MRR, precision@1, and precision@2 scores, while the generative baseline in row (5) retained the highest precision@5 and precision@10 scores.

Next, rows (9) to (13) show results for the activity models that use the Reg scoring. First, the Rec model outperformed the simple baselines from rows (1) to (3) as well as the GrausB methods from rows (6) and (7), but did not perform better than the generative baselines from rows (4) and (5) or GrausR. All the $CoRec$ models performed better at recommending a recipient at top of the ranked lists with higher precision@1 and precision@2 scores, which are more practically useful for recommendation purposes, and also resulted in higher MRR scores.

Finally, the rows (14) and (15) show the results with the Sim scoring, and we observe a substantial improvement across the board, with verb phrase and thing of interest as the body context yielding our best results. This model achieved 3.31% additional improvements in MRR, and 3.38% additional improvements in precision@1 over the best baseline results. This demonstrates that the learned activity model can be used to identify senders who are likely to engage in similar activities, improving recipient recommendation performance further.

Figure 2 shows examples of activity tokens from the emails of a sender in our training corpus, using word clouds. This is meant to serve as a case analysis, but it is not straightforward to interpret word clouds. When inspecting, we found that the names of potential customers (Nokia, Siemens, SAP) in the first example are prominent in some of the emails of the sender in the raw data. The recipients in these emails form a small cluster of people who are mainly involved in discussions around a particular event (Mobile Business Forum) where these companies are amongst the sponsors.

The second example, from the same sender, shows a coherent set of recipients. But in this case, the model seemed to have conflated multiple topics (such as the Palm VII device and support issues). We suspect that the cause for this confusion lies in the strong and coherent cluster of recipients which forces divergent topics to coalesce. While the combined signals of co-recipients and topic words improve the overall activity model, in some of the individual cases it leads to one signal improperly dominating the other.

7 Conclusion and Future Work

We presented a latent activity model for workplace emails where the activities are modeled as probability distributions over email recipients and other contexts, personalized to the email sender. Our model incorporates co-occurring recipients as part of the generative process, and can be used to identify senders who participate in similar activities, resulting in improved performance in email recipient recommendation. Our experiments suggest that syntactic and semantic knowledge such as verb phrases and thing of interests in emails can model the activities much better than bag-of-words, as demonstrated by the recipient recommendation results. Learning topics and sub-activities under workplace activities is a promising research direction which we will explore in future work.

Clustering Paraphrases by Word Sense

Anne Cocos and Chris Callison-Burch
Computer and Information Science Department, University of Pennsylvania

Abstract

Automatically generated databases of English paraphrases have the drawback that they return a single list of paraphrases for an input word or phrase. This means that all senses of polysemous words are grouped together, unlike WordNet which partitions different senses into separate synsets. We present a new method for clustering paraphrases by word sense, and apply it to the Paraphrase Database (PPDB). We investigate the performance of hierarchical and spectral clustering algorithms, and systematically explore different ways of defining the similarity matrix that they use as input. Our method produces sense clusters that are qualitatively and quantitatively good, and that represent a substantial improvement to the PPDB resource.

1 Introduction

Many natural language processing tasks rely on the ability to identify words and phrases with equivalent meaning but different wording. These alternative ways of expressing the same information are called paraphrases. Several research efforts have produced automatically generated databases of English paraphrases, including DIRT (Lin and Pantel, 2001), the Microsoft Research Paraphrase Phrase Tables (Dolan et al., 2004), and the Paraphrase Database (Ganitkevitch et al., 2013; Pavlick et al., 2015a). A primary benefit of these automatically generated resources is their enormous scale, which provides superior coverage compared to manually compiled resources like WordNet (Miller, 1995). But automatically generated paraphrase resources currently have the drawback that they group all senses of polysemous words together, and do not partition paraphrases into groups like WordNet does with its synsets. Thus a search for paraphrases of the noun *bug* would yield a single list of paraphrases that includes *insect, glitch, beetle, error, microbe, wire, cockroach, malfunction, microphone, mosquito, virus, tracker, pest, informer, snitch, parasite, bacterium, fault, mistake, failure* and many others. The goal of this work is to group these paraphrases into clusters that denote the distinct senses of the input word or phrase, as shown in Figure 1.

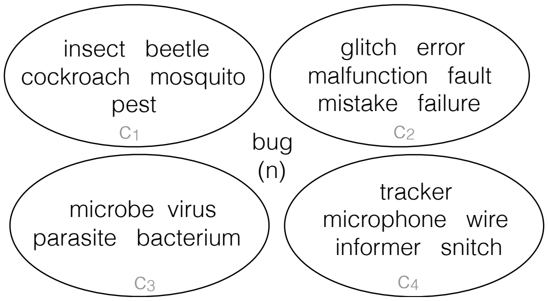

Figure 1: Our goal is to partition paraphrases of an input word like *bug* into clusters representing its distinct senses.

We develop a method for clustering the paraphrases from the Paraphrase Database (PPDB). PPDB contains over 100 million paraphrases generated using the bilingual pivoting method (Bannard and Callison-Burch, 2005), which posits that two English words are potential paraphrases of each other if they share one or more foreign translations. We apply two clustering algorithms, Hierarchical Graph Factorization Clustering (Yu et al., 2005; Sun and Korhonen, 2011) and Self-Tuning Spectral Clustering (Ng et al., 2001; Zelnik-Manor and Perona, 2004), and systematically explore different ways of defining the similarity matrix that they use as input. We exploit a variety of features from PPDB to cluster its paraphrases by sense, including its im-

Proceedings of NAACL-HLT 2016, pages 1463–1472,
San Diego, California, June 12-17, 2016.

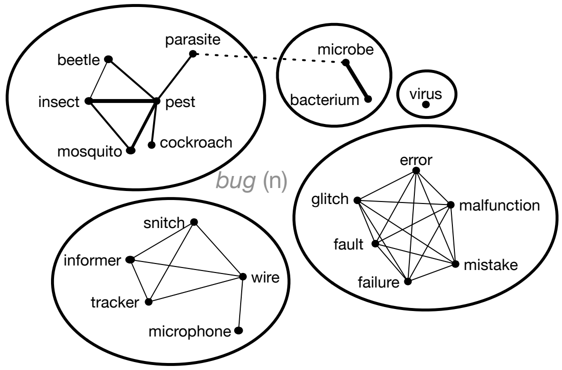

Figure 2: SEMCLUST connects all paraphrases that share foreign alignments, and cuts edges below a dynamically-tuned cutoff weight (dotted lines). The resulting connected components are its clusters.

plicit graph structure, aligned foreign words, paraphrase scores, predicted entailment relations, and monolingual distributional similarity scores.

Our goal is to determine which algorithm and features are the most effective for clustering paraphrases by sense. We address three research questions:

- Which similarity metric is best for sense clustering? We systematically compare different ways of defining matrices that specify the similarity between pairs of paraphrases.
- Are better clusters produced by comparing second-order paraphrases? We use PPDB's graph structure to decide whether *mosquito* and *pest* belong to the same sense cluster by comparing lists of paraphrases for the two words.
- Can entailment relations inform sense clustering? We exploit knowledge like *beetle* is-an *insect*, and that there is no entailment between *malfunction* and *microbe*.

Our method produces sense clusters that are qualitatively and quantitatively good, and that represent a substantial improvement to the PPDB resource.

2 Related Work

The paraphrases in PPDB are already partitioned by syntactic type, following the work of Callison-Burch (2008). He showed that applying syntactic constraints during paraphrase extraction via the pivot method improves paraphrase quality. This means that paraphrases of the noun *bug* are separated from paraphrases of the verb *bug*, which consist of verbs like *bother, trouble, annoy, disturb*, and others. However, organizing paraphrases this way still leaves the issue of mixed senses within a single part of speech. This lack of sense distinction makes it difficult to decide when a paraphrase in PPDB would be an appropriate substitute for a word in a given sentence. Some researchers resort to crowdsourcing to determine when a PPDB substitution is valid (Pavlick et al., 2015c).

Our sense clustering work is closely related to the task of word sense induction (WSI), which aims to discover all senses of a target word from large corpora. One family of common approaches to WSI aims to discover the senses of a word by clustering the monolingual contexts in which it appears (Navigli, 2009). Another uncovers a word's senses by clustering its foreign alignments from parallel corpora (Diab, 2003). A more recent family of approaches to WSI represents a word as a feature vector of its substitutable words, i.e. paraphrases (Melamud et al., 2015; Yatbaz et al., 2012). In this paper we take inspiration from each of these families of approaches, and we explore them when measuring word similarity in sense clustering.

The work most closely related to ours is that of Apidianaki et al. (2014), who used a simple graph-based approach to cluster pivot paraphrases on the basis of contextual similarity and shared foreign alignments. Their method represents paraphrases as nodes in a graph and connects each pair of words sharing one or more foreign alignments with an edge weighted by contextual similarity. Concretely, for paraphrase set P, it constructs a graph $G = (V, E)$ where vertices $V = \{p_i \in P\}$ are words in the paraphrase set and edges connect words that share foreign word alignments in a bilingual parallel corpus. The edges of the graph are weighted based on their contextual similarity (computed over a monolingual corpus). In order to partition the graph into clusters, edges in the initial graph G with contextual similarity below a threshold T' are deleted. The connected components in the resulting graph G' are taken as the sense clusters. The threshold is dynamically tuned using an iterative procedure (Apidianaki and He, 2010).

As evaluated against reference clusters derived from SEMEVAL 2007 Lexical Substitution gold data (McCarthy and Navigli, 2007), their method, which we call SEMCLUST, outperformed simple most-frequent-sense, one-sense-per-paraphrase, and random baselines. Apidianaki et al. (2014)'s work corroborated the existence of sense distinctions in the paraphrase sets, and highlighted the need for further work to organize them by sense. In this paper, we improve on their method using more advanced clustering algorithms, and by systematically exploring a wider range of similarity measures.

3 Graph Clustering Algorithms

To partition paraphrases by sense, we use two advanced graph clustering methods rather than using Apidianaki et al. (2014)'s edge deletion approach. Both of them allow us to experiment with a variety of similarity metrics.

3.1 Hierarchical Graph Factorization Clustering

The Hierarchical Graph Factorization Clustering (HGFC) method was developed by Yu et al. (2006) to probabilistically partition data into hierarchical clusters that gradually merge finer-grained clusters into coarser ones. Sun and Korhonen (2011) applied HGFC to the task of clustering verbs into Levin (1993)-style classes. Sun and Korhonen extended the basic HGFC algorithm to automatically discover the latent tree structure in their clustering solution and incorporate prior knowledge about semantic relationships between words. They showed that HGFC far outperformed agglomerative clustering methods on their verb data set. We adopt Sun and Korhonen's implementation of HGFC for our experiments.

HGFC takes as input a nonnegative, symmetric adjacency matrix $W = \{w_{ij}\}$ where rows and columns represent paraphrases $p_i \in P$, and entries w_{ij} denote the similarity between paraphrases $sim_D(p_i, p_j)$. The algorithm works by factorizing W into a bipartite graph, where the nodes on one side represent paraphrases, and nodes on the other represent senses. The output of HGFC is a set of clusterings of increasingly coarse granularity, which we can also represent with a tree structure. The algorithm automatically determines the number of clusters at each level. For our task, this has the benefit that a user can choose the cluster granularity most appropriate for the downstream task (as illustrated in Figure 5). Another benefit of HGFC is that it probabilistically assigns each paraphrase to a cluster at each level of the hierarchy. If some p_i has high probability in multiple clusters, we can assign p_i to all of them (Figure 3c).

3.2 Spectral Clustering

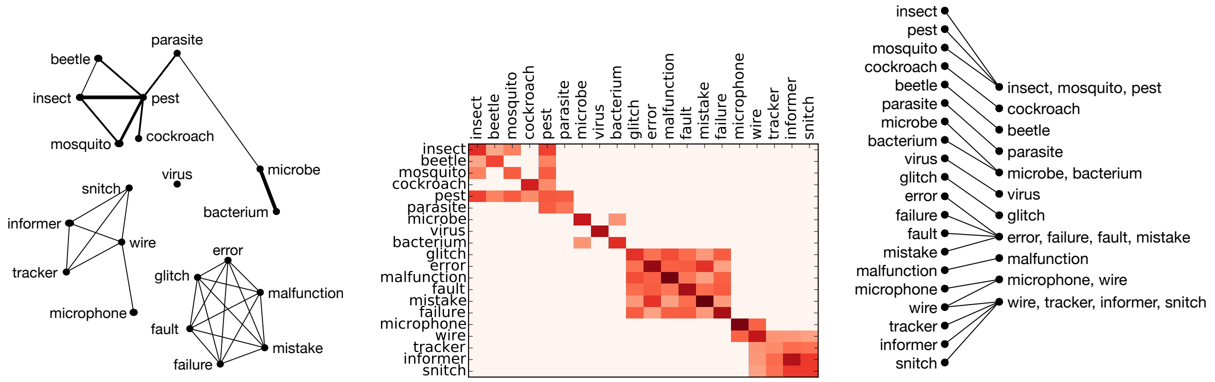
The second clustering algorithm that we use is Self-Tuning Spectral Clustering (Zelnik-Manor and Perona, 2004). Like HGFC, spectral clustering takes an adjacency matrix W as input, but the similarities end there. Whereas HGFC produces a hierarchical clustering, spectral clustering produces a flat clustering with k clusters, with k specified at runtime. The Zelnik-Manor and Perona (2004)'s self-tuning method is based on Ng et al. (2001)'s spectral clustering algorithm, which computes a normalized Laplacian matrix L from the input W, and executes K-means on the largest k eigenvectors of L. Intuitively, the largest k eigenvectors of L should align with the k senses in our paraphrase set.

4 Similarity Measures

Each of our clustering algorithms take as input an adjacency matrix W where the entries w_{ij} correspond to some measure of similarity between words i and j. For the paraphrases in Figure 1, W is a 20x20 matrix that specifies the similarity of every pair of paraphrases like *microbe* and *bacterium* or *microbe* and *malfunction*. We systematically investigated four types of similarity scores to populate W.

4.1 Paraphrase Scores

Bannard and Callison-Burch (2005) defined a *paraphrase probability* in order to quantify the goodness of a pair of paraphrases, based on the underlying translation probabilities used by the bilingual pivoting method. More recently, (Pavlick et al., 2015a) used supervised logistic regression to combine a variety of scores so that they align with human judgements of paraphrase quality. PPDB 2.0 provides this score for each pair of words in the database. The PPDB 2.0 score is a nonnegative real number that



(a) Undirected graph for query word *bug*. Wider lines signify stronger similarity.

(b) The corresponding adjacency matrix W. Darker cells signify stronger similarity.

(c) The bipartite graph induced by the first iteration of HGFC. Note *wire* is assigned to two clusters.

Figure 3: The graph, corresponding adjacency matrix W, and bipartite graph created by the first iteration of HGFC for query word *bug (n)*

can be used directly as a similarity measure:

$$w_{ij} = \begin{cases} PPDB_{2.0}Score(i,j) & (i,j) \in \text{PPDB} \\ 0 & \text{otherwise} \end{cases}$$

PPDB 2.0 does not provide a score for a word with itself, so we set $PPDB_{2.0}Score(i,i)$ to be the maximum $PPDB_{2.0}Score(i,j)$ such that i and j have the same stem.

4.2 Second-Order Paraphrase Scores

Work by Rapp (2003) and Melamud et al. (2015) showed that comparing words on the basis of their *shared* paraphrases is effective for WSI. We define two novel similarity metrics that calculate the similarity of words i and j by comparing their second-order paraphrases. Instead of comparing *microbe* and *bacterium* directly with their PPDB 2.0 score, we look up all of the paraphrases of *microbe* and all of the paraphrases of *bacterium*, and compare those two lists.

Specifically, we form notional *word-paraphrase* feature vectors v_i^p and v_j^p where the features correspond to words with which each is connected in PPDB, and the value of the k^{th} element of v_i^p equals $PPDB_{2.0}Score(i,k)$. We can then calculate the cosine similarity or Jensen-Shannon divergence between vectors:

$$sim_{PPDB.cos}(i,j) = cos(v_i^p, v_j^p)$$

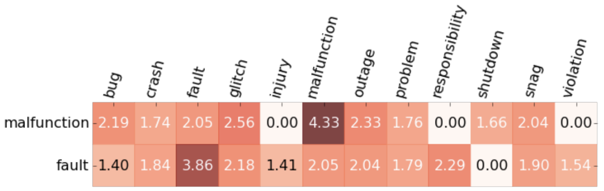


Figure 4: Comparing second-order paraphrases for *malfunction* and *fault* based on *word-paraphrase* vectors. The value of vector element v_{ij} is $PPDB_{2.0}Score(i,j)$.

$$sim_{PPDB.js}(i,j) = 1 - JS(v_i^p, v_j^p)$$

where $JS(v_i^p, v_j^p)$ is calculated assuming that the paraphrase probability distribution for word i is given by its normalized *word-paraphrase* vector v_i^p.

4.3 Similarity of Foreign Word Alignments

When an English word is aligned to several foreign words, sometimes those different translations indicate a different word sense (Yao et al., 2012). Using this intuition, Gale et al. (1992) trained an English WSD system on a bilingual corpus, using the different French translations as labels for the English word senses. For instance, given the English word *duty*, the French translation *droit* was a proxy for its *tax* sense and *devoir* for its *obligation* sense.

PPDB is derived from bilingual coropra. We recover the aligned foreign words and their associated translation probabilities that underly each PPDB entry. For each English word in our dataset, we get each foreign word that it aligns to in the Spanish and Chinese bilingual parallel corpora used by Ganitkevitch and Callison-Burch (2014). We use this to define a novel foreign word alignment similarity metric, $sim_{TRANS}(i,j)$ for two English paraphrases i and j. This is calculated as the cosine similarity of the *word-alignment* vectors v_i^a and v_j^a where each feature in v^a is a foreign word to which i or j aligns, and the value of entry v_{if}^a is the translation probability $p(f|i)$.

$$sim_{TRANS}(i,j) = cos(v_i^a, v_j^a)$$

4.4 Monolingual Distributional Similarity

Lastly, we populate the adjacency with a distributional similarity measure based on WORD2VEC (Mikolov et al., 2013). Each paraphrase i in our data set is represented as a 300-dimensional WORD2VEC embedding v_i^w trained on part of the Google News dataset. Phrasal paraphrases that did not have an entry in the WORD2VEC dataset are represented as the mean of their individual word vectors. We use the cosine similarity between WORD2VEC embeddings as our measure of distributional similarity.

$$sim_{DISTRIB}(i,j) = cos(v_i^w, v_j^w)$$

5 Determining the Number of Senses

The optimal number of clusters for a set of paraphrases will vary depending on how many senses there ought to be for an input word like *bug*. It is generally recognized that optimal sense granularity depends on the application (Palmer et al., 2001). WordNet has notoriously fine-grained senses, whereas most word sense disambiguation systems achieve better performance when using coarse-grained sense inventories (Navigli, 2009). Depending on the task, the sense clustering for query word *coach* in Figure 5b with $k = 5$ clusters may be preferable to the alternative with $k = 3$ clusters. An ideal algorithm for our task would enable clustering at varying levels of granularity to support different downstream NLP applications.

Both of our clustering algorithms can produce sense clusters at varying granularities. For HGFC this requires choosing which level of the resulting tree structure to take as a clustering solution, and for spectral clustering we must specify the number of clusters prior to execution.[1] To determine the optimal number of clusters, we use the mean Silhouette Coefficient (Rousseeuw, 1987) which balances optimal inter-cluster tightness and intra-cluster distance. The Silhouette Coefficient is calculated for each paraphrase p_i as

$$s(p_i) = \frac{b(p_i) - a(p_i)}{max\{a(p_i), b(p_i)\}}$$

where $a(p_i)$ is p_i's average intra-cluster distance (average distance from p_i to each other p_j in the same cluster), and $b(p_i)$ is p_i's lowest average inter-cluster distance (distance from p_i to the nearest external cluster centroid). For each clustering algorithm, we choose as the 'solution' the clustering which produces the highest mean Silhouette Coefficient. The Silhouette Coefficient calculation takes as input a matrix of pairwise distances, so we simply use $1 - W$ where the adjacency matrix W is calculated using one of the similarity methods we defined.

6 Incorporating Entailment Relations

Pavlick et al. (2015b) added a set of automatically predicted semantic entailment relations for each entry in PPDB 2.0. The entailment types that they include are *Equivalent, Forward Entailment, Reverse Entailment, Exclusive*, and *Independent*. While a negative entailment relationship (*Exclusive* or *Independent*) does not preclude words from belonging to the same sense of some query word, a positive entailment relationship (*Equivalent, Forward/Reverse Entailment*) does give a strong indication that the words belong to the same sense.

We seek a straightforward way to determine whether entailment relations provide information that is useful to the final clustering algorithm. Both of our algorithms take an adjacency matrix W as input, so we add entailment information by simply

[1] For spectral clustering there has been significant study into methods for automatically determining the optimal number of clusters, including analysis of eigenvalues of the graph Laplacian, and finding the rotation of the Laplacian that brings it closest to block-diagonal (Zelnik-Manor and Perona, 2004). We experimented with these and other cluster analysis methods such as the Dunn Index (Dunn, 1973) in our work, but found that using the simple Silhouette Coefficient produced clusterings that were competitive with the more intensive methods, in far less time.

multiplying each pairwise entry by its entailment probability. Specifically, we set

$$w_{ij} = \begin{cases} (1 - p_{ind}(i,j))sim_D(i,j) & (i,j) \in \text{PPDB} \\ 0 & \text{otherwise} \end{cases}$$

where $p_{ind}(i,j)$ gives the PPDB 2.0 probability that there is an $Independent$ entailment relationship between words i and j. Intuitively, this should increase the similarity of words that are very likely to be entailing like *fault* and *failure*, and decrease the similarity of non-entailing words like *cockroach* and *microphone*.

7 Experimental Setup

We follow the experimental setup of Apidianaki et al. (2014). We focus our evaluation on a set of query words drawn from the LexSub test data (McCarthy and Navigli, 2007), plus 16 additional handpicked polysemous words.

7.1 Gold Standard Clusters

One challenge in creating our clustering methodology is that there is no reliable PPDB-sized standard against which to assess our results. WordNet synsets provide a well-vetted basis for comparison, but only allow us to evaluate our method on the 38% of our PPDB dataset that overlaps it. We therefore evaluate performance on two test sets.

WordNet+ Our first test set is designed to assess how well our solution clusters align with WordNet synsets. We chose 185 polysemous words from the SEMEVAL 2007 dataset and an additional 16 handpicked polysemous words. For each we formed a paraphrase set that was the intersection of their PPDB 2.0 XXXL paraphrases with their WordNet synsets, and their immediate hyponyms and hypernyms. Each reference cluster consisted of a WordNet synset, plus the hypernyms and hyponyms of words in that synset. On average there are 7.2 reference clusters per paraphrase set.

CrowdClusters Because the coverage of WordNet is small compared to PPDB, and because WordNet synsets are very fine-grained, we wanted to create a dataset that would test the performance of our clustering algorithm against large, noisy paraphrase sets and coarse clusters. For this purpose we randomly selected 80 query words from the SEMEVAL 2007 dataset and created paraphrase sets from their unfiltered PPDB2.0 XXL entries. We then iteratively organized each paraphrase set into reference senses with the help of crowd workers on Amazon Mechanical Turk. On average there are 4.0 reference clusters per paraphrase set. A full description of our method is included in the supplemental materials.

7.2 Evaluation Metrics

We evaluate our method using two standard metrics: the paired F-Score and V-Measure. Both were used in the 2010 SemEval Word Sense Induction Task (Manandhar et al., 2010) and by Apidianaki et al. (2014). We give our results in terms of weighted average performance on these metrics, where the score for each individual paraphrase set is weighted by the number of reference clusters for that query word.

Paired F-Score frames the clustering problem as a classification task (Manandhar et al., 2010). It generates the set of all word pairs belonging to the same reference cluster, $F(S)$, and the set of all word pairs belonging to the same automatically-generated cluster, $F(K)$. Precision, recall, and F-score can then be calculated in the usual way, i.e. $P = \frac{F(K) \cap F(S)}{F(K)}$, $R = \frac{F(K) \cap F(S)}{F(S)}$, and $F = \frac{2 \cdot P \cdot R}{P + R}$.

V-Measure assesses the quality of a clustering solution against reference clusters in terms of clustering homogeneity and completeness (Rosenberg and Hirschberg, 2007). Homogeneity describes the extent to which each cluster is composed of paraphrases belonging to the same reference cluster, and completeness refers to the extent to which points in a reference cluster are assigned to a single cluster. Both are defined in terms of conditional entropy. V-Measure is the harmonic mean of homogeneity h and completeness c; V-Measure $= \frac{2 \cdot h \cdot c}{h + c}$.

7.3 Baselines

We evaluate the performance of HGFC on each dataset against the following baselines:

Most Frequent Sense (MFS) assigns all paraphrases $p_i \in P$ to a single cluster. By definition, the completeness of the MFS clustering is 1.

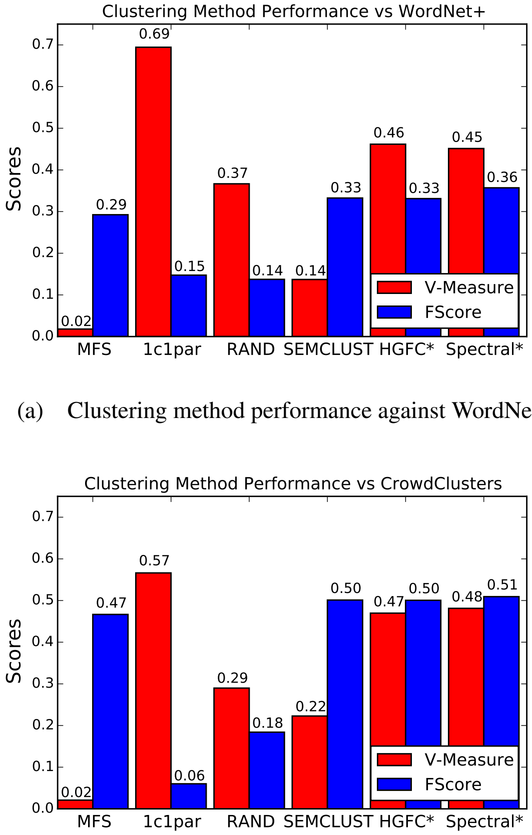
One Cluster per Paraphrase (1C1PAR) assigns each paraphrase $p_i \in P$ to its own cluster. By definition, the homogeneity of 1C1PAR clustering is 1.

Random (RAND) For each query term's paraphrase set, we generate five random clusterings of $k = 5$ clusters. We then take F-Score and V-Measure as the average of each metric calculated over the five random clusterings.

SEMCLUST We implement the SEMCLUST algorithm (Apidianaki et al., 2014) as a state-of-the-art baseline. Since PPDB contains only pairs of words that share a foreign word alignment, in our implementation we connect paraphrase words with an edge if the pair appears in PPDB. We adopt the WORD2VEC distributional similarity score $sim_{DISTRIB}$ for our edge weights.

8 Experimental Results

Figure 6 shows the performance of the two advanced clustering algorithms against the baselines. Our best configurations[2] for HGFC and Spectral outperformed all baselines except 1C1PAR V-Measure, which his biased toward solutions with many small clusters (Manandhar et al., 2010), and performed only marginally better than SEMCLUST in terms of F-Score alone. The dominance of 1C1PAR V-Measure is greater for the WordNet+ dataset which has smaller reference clusters than CrowdClusters. Qualitatively, we find that methods that strike a balance between high F-Score and high V-Measure tend to produce the 'best' clusters by human judgement. If we consider the average of F-Score and V-Measure as a comprehensive performance measure, our methods outperform all baselines.



(a) Clustering method performance against WordNet+

(b) Clustering method performance against CrowdClusters

Figure 6: Hierarchical Graph Factorization Clustering and Spectral Clustering both significantly outperform all baselines except 1C1PAR V-Measure.

[2] Our top-scoring Spectral method, Spectral*, uses entailments, $PPDB_{2.0}Score$ similarities, and $sim_{DISTRIB}$ to choose k. Our best HGFC method, HGFC*, uses entailments, $sim_{DISTRIB}$ similarities, and $PPDB_{2.0}Score$ to choose k.

Method	F-Score	V-Measure	Avg # Clusters
$PPDB_{2.0}Score$	0.410	0.437	5.960
$sim_{DISTRIB}$	0.376	0.440	5.707
$sim_{PPDB.cos}$	0.389	0.428	7.204
$sim_{PPDB.JS}$	0.385	0.425	7.143
sim_{TRANS}	0.358	0.375	6.247
SEMCLUST	0.417	0.180	2.279
Reference	1.0	1.0	5.611

Table 1: Average performance and number of clusters produced by our different similarity methods.

On our dataset, the state-of-the-art SEMCLUST baseline tended to lump many senses of the query word together, and produced scores lower than in the original work. We attribute this to the fact that the original work extracted paraphrases from EuroParl, which is much smaller than PPDB, and thus created adjacency matrices W which were sparser than those produced by our method. Directly applied, SEMCLUST works well on small data sets, but does not scale well to the larger, noisier PPDB data. More advanced graph-based clustering methods produce better sense clusters for PPDB.

The first question we sought to address with this work was which similarity metric is the best for sense clustering. Table 1 reports the average F-Score and V-Measure across 40 test configurations for each similarity calculation method.[3] On average across test sets and clustering algorithms, the paraphrase similarity score ($PPDB_{2.0}Score$) performs better than monolingual distributional similarity ($sim_{DISTRIB}$) in terms of F-Score, but the results are reversed for V-Measure. This is also shown in the best HGFC and Spectral configurations, where the two similarity scores are swapped between them.

Next, we investigated whether comparing second-order paraphrases would produce better clusters than simply using $PPDB_{2.0}Score$ directly. Table 1 also compares the two methods that we had for computing the similarity of second order paraphrases – cosine similarity ($sim_{PPDB.cos}$) and Jensen-Shannon divergence ($sim_{PPDB.JS}$). On average across test sets and clustering algorithms, using the direct paraphrase score gives stronger V-Measure and F-score than the second-order methods. It also produces coarser clusters than the second-order PPDB similarity methods.

Finally, we investigated whether incorporating automatically predicted entailment relations would improve cluster quality, and we found that it did. All other things being equal, adding entailment information increases F-Score by .014 and V-Measure by .020 on average (Figure 7). Adding entailment information had the greatest improvement to HGFC methods with $sim_{DISTRIB}$ similarities, where it improved F-Score by an average of .03 and V-Measure by an average of .05.

9 Discussion and Future Work

We have presented a novel method for clustering paraphrases in PPDB by sense. When evaluated against WordNet synsets, the sense clusters produced by the Spectral Clustering algorithm give a 64% relative improvement in F-Score over the closest baseline, and those produced by the HGFC algorithm give a 50% improvement in F-Score. We systematically analyzed a variety of similarity metrics as input to HGFC and Spectral Clustering, and showed that incorporating predicted entailment relations from PPDB boosts the performance of sense clustering.

Our sense clustering provides a significant improvement to the PPDB resource that may improve its applicability to downstream NLP tasks. One possible application of sense-clustered PPDB entries is the lexical substitution task, which seeks to identify appropriate word substitutions. Given a target word in context, it would be reasonable to suggest substitutes from the target word's PPDB sense cluster most closely related to the target context. There are many possible ways to choose the best cluster for a given context, ranging from simply choosing the cluster whose members have highest average pointwise mutual information with the context, to a more complex approach based on training cluster representations using a pseudo-word approach as in Melamud et al. (2015). We leave this application for future work.

10 Software and Data Release

With publication of this paper we are releasing paraphrase clusters for all PPDB 2.0 XXL entries,

[3] Our Supplementary Materials file provides the full set of results for all 200 configurations that we tested.

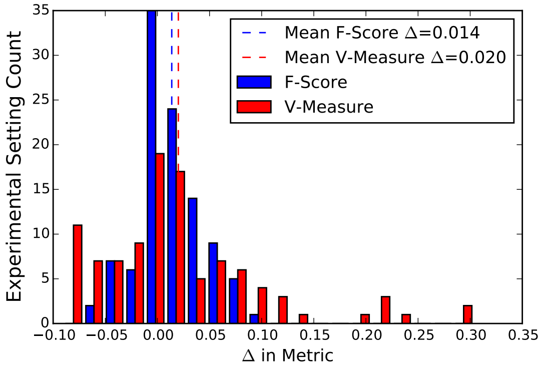


Figure 7: Histogram of metric change by adding entailment information across all experiments.

clustering code, and an interface for crowdsourcing paraphrase clusters using Amazon Mechanical Turk.

11 Supplementary Material

Our Supplementary Material provides additional detail on our similarity metric calculation, clustering algorithm implementation, and CrowdCluster reference cluster data development. We also provide full evaluation results across the entire range of our experiments, a selection of sense clusters output by our methods, and example content of our WordNet+ and CrowdCluster paraphrase sets.

Unsupervised Learning of Prototypical Fillers for Implicit Semantic Role Labeling

Niko Schenk and **Christian Chiarcos**
Applied Computational Linguistics Lab
Goethe University Frankfurt am Main, Germany
{n.schenk,chiarcos}@em.uni-frankfurt.de

Abstract

Gold annotations for supervised implicit semantic role labeling are extremely sparse and costly. As a lightweight alternative, this paper describes an approach based on unsupervised parsing which can do without iSRL-specific training data: We induce prototypical roles from large amounts of explicit SRL annotations paired with their distributed word representations. An evaluation shows competitive performance with supervised methods on the SemEval 2010 data, and our method can easily be applied to predicates (or languages) for which no training annotations are available.

1 Introduction

Semantic role labeling (SRL) (Gildea and Jurafsky, 2002) has become a well-established and highly important NLP component which directly benefits various downstream applications, such as text summarization (Trandabăţ, 2011), recognizing textual entailment (Sammons et al., 2012) or QA systems (Shen and Lapata, 2007; Moreda et al., 2011). Its goal is to detect verbal or nominal predicates, together with their associated arguments and semantic roles, either by PropBank/Nombank (Palmer et al., 2005; Meyers et al., 2004) or FrameNet (Baker et al., 1998) analysis. In its traditional form, however, SRL is restricted to the *local syntactic context of the predicate* as in the following example from Ruppenhofer et al. (2010):

> [$_{\text{GOAL}/\textbf{NI}}$In the centre of this room] there was an upright beam, [$_{\text{THEME}}$which] had been **placed** [$_{\text{TIME}}$at some period] as a support for the old worm-eaten baulk of timber which spanned the roof.

In a FrameNet-style analysis of the sentence, the predicate *place* evokes the PLACING frame, with two frame elements (roles) overtly expressed (THEME and TIME) but with one role – GOAL – beyond the embedded relative clause and thus beyond the scope of the SRL parser. Such implicit roles, or *null instantiations* (NIs) (Fillmore, 1986; Ruppenhofer, 2005) are much harder to detect automatically, as they require to broaden the analysis to the surrounding discourse, commonly also to preceding (or following) sentences.

State-of-the-art approaches to implicit SRL (iSRL) are supervised and need a groundwork of hand-annotated training data – which is costly, extremely sparse, limited to only a handful of predicates, and requires careful feature engineering (Gerber and Chai, 2012; Silberer and Frank, 2012; Li et al., 2015). A first attempt has been made to combine the scarce resources available (Feizabadi and Padó, 2015), but given the great diversity of predicate-specific roles and enormous complexity of the task, the main issues remain (Chen et al., 2010).

A promising exploratory effort recently made by Gorinski et al. (2013) aims to overcome the annotation bottleneck by using distributional methods to infer evidence for elements filling null instantiated roles. The authors do not rely on gold annotations but instead learn distributional properties of fillers induced from a large corpus.

Our Contribution: We propose an extension of the distributional idea for unsupervised iSRL to loosen the need for annotated training data. Specifically, we

Proceedings of NAACL-HLT 2016, pages 1473–1479,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

propose to induce predicate and role-specific **prototypical fillers** from large amounts of SRL annotated texts in order to resolve null instantiations as (semantically and syntactically) similar elements found in the context. Parts of our approach have been successfully applied in traditional SRL (Hermann et al., 2014), but not yet to implicit roles. Our work differs from Gorinski et al. (2013) in that we extend discrete context vectors to SRL-guided embeddings and experiment with a variety of different configurations. We intend *not* to set a new benchmark beating the current state-of-the-art for *supervised* iSRL, but rather provide a simple and alternative strategy which does not rely on manually annotated gold data. Still, we demonstrate that our method is highly competitive with supervised methods on one out of two standard evaluation sets and that it can easily be extended to other predicates for which no implicit gold annotations are available.

2 Method

2.1 Prototypical Fillers

We use large amounts of *explicit* SRL annotations to compute predicate-specific *protofillers* (prototypical fillers) for each frame element (role) individually:

$$\vec{v}^{\textit{protofiller}} = \frac{1}{N}\sum_{i=0}^{N} E(w_i) \tag{1}$$

where N is the total number of tokens filling a particular role and $E(\cdot)$ is an embedding function which maps a word w_i to its distributed representation, i.e., a precomputed vector of d dimensions. Note that only those words contribute to the protofiller of a frame element which occur in this role.

2.2 Identifying Null Instantiations

Our approach generalizes over labeled filler instances of the frame (PLACING in the example) as found in corpus data, e.g., *placed on the middle picture*, *planted on the top of the church*, *hung over the river*, *laid on the table*, etc. We exploit their syntactic (here: prepositional) and semantic properties (inanimate, spacial NPs) in order to capture a composed meaning and thus to approximate the correct implicit role *in the centre of this room.* We measure similarity between a trained protofiller $\vec{v}^p$ and a candidate constituent $\vec{v}^c$ by cosine similarity $\cos(\theta) = \frac{\vec{v}^p \cdot \vec{v}^c}{\|\vec{v}^p\| \|\vec{v}^c\|}$ and predict a candidate as null instantiation which maximizes the inner product with the protofiller. As candidate constituents for an implicit argument we initially consider all terminal and non-terminal nodes in a context window of the predicate, ruling out those categories which never occur as implicit arguments, which do contain the target predicate and/or which are already overt arguments. The result set comprises mainly nouns, verbs and PPs. Candidate constituents in our evaluation data are available from their respective (manual) syntax annotation, but could easily be extracted using automated phrase-structure parsers. The candidate *vectors* for arbitrary length n-grams are derived in the same way (by means of Equation 1).

2.3 Training Resources & Tools

In accordance with domain-specific evaluation data, we chose to learn protofillers on two distinct corpora: *The Corpus of Late Modern English Texts, CLMET* (Smet, 2005) (≈35M tokens, 18th–20th century novels) and a subset of the English *Gigaword corpus* (Graff and Cieri, 2003) (≈500M tokens of Newswire texts). We label the first one with SEMAFOR[1] (Das et al., 2014), a FrameNet-style semantic parser. We employ MATE[2] (Björkelund et al., 2009) to obtain a PropBank/NomBank analysis for each sentence in Gigaword.

	CLMET	Gigaword
# explicit roles	21.9M	264.0M
# predicate instances	9.5M	122.5M
# roles per predicate	2.3	2.2
# predicates per sentence	7.6	4.2

Table 1: Statistics on the number of explicit fillers used for training protofillers.

Table 1 highlights general statistics on the number of predicates collected from both corpora. Two observations are worth noting: While on average the number of explicitly realized roles/frame elements per predicate/frame in both data sets is similar, we find more predicate instances in CLMET than in Gigaword. This is due to the FrameNet lexicon and its more fine-grained modeling of lexical units, as

[1] `http://www.cs.cmu.edu/~ark/SEMAFOR/`

[2] `https://code.google.com/p/mate-tools/`

opposed to PropBank. Also note that FrameNet currently specifies 9.7 frame elements per lexical frame[3] which – despite the fact that this number also comprises non-core arguments – is much larger than what can explicitly be labeled by the SRL systems.

Regarding the distributional component, we experimented with a variety of distributed word representations: We chose out of the box vectors; Collobert et al. (2011), dependency-based word embeddings (Levy and Goldberg, 2014) and the pre-trained Google News vectors from *word2vec*[4] (Mikolov et al., 2013). Using the same tool, we also trained custom embeddings (bag-of-words and skip-gram) with 50 dimensions on our two corpora.

3 Evaluation

In order to assess the usefulness of our approach, a quantitative evaluation has been conducted on two iSRL test sets which have become a de facto standard in this domain: a collection of fiction novels from the SemEval 2010 Shared Task with manual annotations of null instantiations (Ruppenhofer et al., 2010), and Gerber and Chai (2010)'s augmented NomBank data set. Table 2 shows some general statistics on the number of implicit roles and candidate phrases involved in our experiments. As to have a comparison with the supervised approaches referred to in this study, we also provide the size of the training data.

	SemEval	NomBank
# predicate instances		
in training set	1,370	816
in test set	1,703	437
# implicit arguments		
in training set	245	650
in test set	259	246
# of candidate phrases per predicate instance	27.6	52.2
proportion of single tokens	63.4%	47.9%
proportion of phrases	36.6%	52.1%
∅ length of candidate phrase (in tokens)	5.8	7.1

Table 2: Statistics on implicit arguments and candidate phrases from the test sections of the two evaluation sets.

3.1 SemEval Data

In Table 4, we report the classification scores for the (*NI-only*) null instantiation *linking* task on the SemEval data, given the parsed candidate phrases and the gold information about the missing frame element.[5] For space reasons, we only include the results of our best-performing configuration, obtained from protofillers trained on the late modern English texts and Collobert et al. (2011) embeddings (C&W) with the search space for candidate NIs limited to the current and previous sentence. As a reference, we compare our results to the two best models (M_1 and $M_{1'}$) by Silberer and Frank (2012), the vector-based resolver (VEC) by Gorinski et al. (2013) – which is most similar to ours – and, finally, their ensemble combination of four semantically informed resolvers by majority vote (4X).

		P	R	F_1
Silberer and Frank (2012)	M_1	30.8	25.1	**27.7**
Silberer and Frank (2012)	$M_{1'}$	**35.6**	20.1	25.7
Gorinski et al. (2013)	VEC	21.0	18.0	19.0

Table 4: NI linking performance on the SemEval test data.

The figures in Table 4 suggest that our approach clearly outperforms the vector-based method by Gorinski et al. (2013) and is best in terms of overall recognition rate (recall) among all systems. One potential reason for that might be that, in contrast to the VEC resolver, we do not compute mere context vectors but do rely on the valuable annotations obtained from explicit SRL structures. Also, we do not restrict our analysis to *head* words only, as we have seen that syntactic information from function words is crucial for the resolution of null instantiated roles, too. Moreover, our distributional protofiller method is highly competitive with state-of-the-art performance by Silberer and Frank (2012), yet does not yield better results in terms of F_1 score. Note however that, in contrast to their approach, ours is largely unsupervised and does neither rely on gold coreference chains, nor do we need to train on im-

Table 3: Classification scores for implicit argument labeling on the NomBank test section. Baseline B from Gerber & Chai (2010): uses previous occurrence of same predicate. Gerber & Chai (2010): supervised logistic regression classifier trained on implicit fillers. Laparra & Rigau (2013): algorithm based on coherence relationship between predicates and fillers. Our best-performing protofillers are obtained by Collobert et al. (2011) embeddings (**Proto C&W**) and custom trained vectors (**Proto W2Vcbow**) using Gigaword SRL annotations.

plicit semantic roles in a supervised setting. An error analysis of our method reveals that it is particularly effective for NIs encountered in the *same sentence* as the target predicate (44.4% accuracy), which seems plausible given the contextual setup in which protofillers are derived.

3.2 NomBank Data

Compared to the SemEval data, Gerber and Chai (2010)'s augmented NomBank resource covers only ten nominal predicates, which allows us to nicely visualize the distributional profile based on their prototypical fillers. For each predicate, we simply concatenate all per role computed protofillers and apply multidimensional scaling to project the so obtained vectors onto two dimensions (cf. Figure 1).

We observe that the predicate grouping is now based on the prototypical fillers that they co-occur with: In the Wall Street Journal texts, *loss*, *loan* and *investment* are similar because their proto-agents (A0 fillers) who lose, lend and invest resp. are semantically shared (i.e. companies, banks). Similarly, *bid*, *cost* and *fund* are related in that the targets or commodities (A2) are all money-financed. Finally, the predicates *sale* and *plan* are to be expected as outliers as they are less homogeneous in their prototypical argument structure.

We have empirically evaluated our protofiller method also on this data set: Table 3 reports the classification scores for implicit argument resolution compared to the state-of-the-art (Laparra and Rigau, 2013). We restrict the search for implicit arguments to certain predicate-specific parts-of-speech, since some syntactic constituents (e.g., SBAR) never occur as implicit arguments. For choosing the final implicit arguments for each individual predicate instance, we follow the same deterministic strategy as described in Gerber and Chai (2010), which informally states that, if a certain role is not overtly expressed (within a chain of mentions of the same predicate in previous sentences), it is an implicit

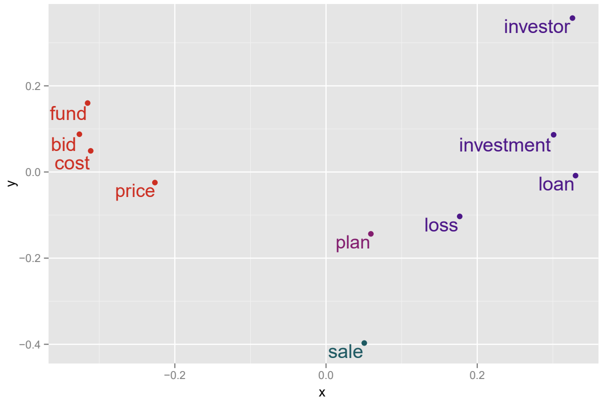

Figure 1: Clustered projection of the ten nominal predicates from Gerber and Chai (2010) in protofiller space.

candidate. POS lists and cosine similarity thresholds which trigger an actual prediction have been optimized on the development set. The context window for candidate NIs is optimal for the current and previous two sentences in our setting, which explains why the the number of candidate constituents is approximately twice as large for the NomBank predicates (cf. Table 2).

Our best-performing protofillers are again obtained by Collobert et al. (2011) embeddings substituting explicit SRL annotations in the Gigaword corpus, and with custom-trained embeddings using the continuous bag-of-words model. Overall, our results significantly exceed the highly informed baseline but cannot beat the state-of-the art on this test set. For some predicates, the protofillers seem to generalize better (higher recall), and in particular for the low-frequency predicates (*fund*), precision can be increased. Also, we found that the dependency-based word embeddings do perform slightly worse (not shown), compared to our optimal two configurations. This might be due to the fact that the inherent properties of dependency-based contexts mostly focus on relations between semantically valuable nouns, ignoring ("skipping") functional words and categories.[6] The same pertains to the pre-computed Google News vectors which come with a frequency cutoff excluding stop words, again a constraint which is harmful for the correct identification of implicit roles. Furthermore, skip-gram embeddings perform significantly worse than the embeddings derived by the continuous bag-of-words implementation (relative decrease in F_1 by more than 30%). Finally, we observed that inferring implicit roles for nominal predicates is much more challenging because our collected fillers exhibit a much greater variation. For example, the protoagents of *loan* can roughly be divided into two categories, institutions and countries. This in turn introduces noise and has a negative effect on the quality of the singleton protofillers which by vector average capture neither of the two groups perfectly. Promising alternatives could operate on (topic-like) protofiller **clusters** which we leave for future work.

4 Summary & Conclusion

We have described a lightweight approach for the resolution of implicit semantic roles which does not rely on manual gold annotations. For each predicate-specific role, our method generalizes over explicit SRL-guided annotations incorporating pre-trained word embeddings. This allows us to capture their idiosyncratic properties and use the so-inferred protofillers to find null instantiated roles by means of distributional similarity.

Our method has proven to be generally useful, in particular on the SemEval data, where it is competitive with supervised systems. Its greatest benefit stems from its simplicity and from that fact that it allows to induce null-instantiated roles for arbitrary predicates. As it is applicable even if no iSRL training data is available, it represents a promising technique to address iSRL data scarcity issues.

In our experiment, we employed PropBank/NomBank-style (i)SRL annotations, and our general design clearly benefits from using small-scale inventories of semantic roles. It should be noted though, that our approach is not restricted to any particular SRL tagset, but can be equally applied to other role inventories with similar degrees of consistence and size. Beyond SRL annotations in a strict sense, this might even extend to syntactic dependency annotations that are occasionally taken as a substitute for semantic roles proper. In particular, we see potential in combining our experiments with on-going efforts to cross-lingual projection, adaptation and harmonization of syntax annotations along the lines of Sukhareva and Chiarcos (2014, 2016) and related approaches based on frameworks such as the Universal Dependencies (Nivre, 2015, UD).[7] If successful, an adaptation using grammatical relations rather than semantic roles represents a promising possibility to create iSRL annotation and iSRL annotation tools for other languages, as Universal Dependencies are becoming increasingly available for major and low-resourced languages and can be projected to others.

The protofillers involved in this study are available at: `http://acoli.cs.uni-frankfurt.de/resources`.

[6] This is also nicely illustrated in Levy and Goldberg (2014).

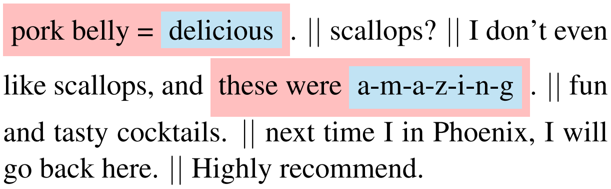
Abstract

We propose a hierarchical attention network for document classification. Our model has two distinctive characteristics: (i) it has a hierarchical structure that mirrors the hierarchical structure of documents; (ii) it has two levels of attention mechanisms applied at the word- and sentence-level, enabling it to attend differentially to more and less important content when constructing the document representation. Experiments conducted on six large scale text classification tasks demonstrate that the proposed architecture outperform previous methods by a substantial margin. Visualization of the attention layers illustrates that the model selects qualitatively informative words and sentences.

1 Introduction

Text classification is one of the fundamental task in Natural Language Processing. The goal is to assign labels to text. It has broad applications including topic labeling (Wang and Manning, 2012), sentiment classification (Maas et al., 2011; Pang and Lee, 2008), and spam detection (Sahami et al., 1998). Traditional approaches of text classification represent documents with sparse lexical features, such as n-grams, and then use a linear model or kernel methods on this representation (Wang and Manning, 2012; Joachims, 1998). More recent approaches used deep learning, such as convolutional neural networks (Blunsom et al., 2014) and recurrent neural networks based on long short-term memory (LSTM) (Hochreiter and Schmidhuber, 1997) to learn text representations.



pork belly = delicious . || scallops? || I don't even like scallops, and these were a-m-a-z-i-n-g . || fun and tasty cocktails. || next time I in Phoenix, I will go back here. || Highly recommend.

Figure 1: A simple example review from Yelp 2013 that consists of five sentences, delimited by period, question mark. The first and third sentence delivers stronger meaning and inside, the word *delicious, a-m-a-z-i-n-g* contributes the most in defining sentiment of the two sentences.

Although neural-network–based approaches to text classification have been quite effective (Kim, 2014; Zhang et al., 2015; Johnson and Zhang, 2014; Tang et al., 2015), in this paper we test the hypothesis that better representations can be obtained by incorporating knowledge of document structure in the model architecture. The intuition underlying our model is that not all parts of a document are equally relevant for answering a query and that determining the relevant sections involves modeling the interactions of the words, not just their presence in isolation.

Our primary contribution is a new neural architecture (§2), the Hierarchical Attention Network (HAN) that is designed to capture two basic insights about document structure. First, since documents have a hierarchical structure (words form sentences, sentences form a document), we likewise construct a document representation by first building representations of sentences and then aggregating those into a document representation. Second, it is observed that different words and sentences in a documents are differentially informative. Moreover, the impor-

Proceedings of NAACL-HLT 2016, pages 1480–1489,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

tance of words and sentences are highly context dependent, i.e. the same word or sentence may be differentially important in different context (§3.5). To include sensitivity to this fact, our model includes two levels of attention mechanisms (Bahdanau et al., 2014; Xu et al., 2015) — one at the word level and one at the sentence level — that let the model to pay more or less attention to individual words and sentences when constructing the representation of the document. To illustrate, consider the example in Fig. 1, which is a short Yelp review where the task is to predict the rating on a scale from 1–5. Intuitively, the first and third sentence have stronger information in assisting the prediction of the rating; within these sentences, the word `delicious`, `a-m-a-z-i-n-g` contributes more in implying the positive attitude contained in this review. Attention serves two benefits: not only does it often result in better performance, but it also provides insight into which words and sentences contribute to the classification decision which can be of value in applications and analysis (Shen et al., 2014; Gao et al., 2014).

The key difference to previous work is that our system uses *context* to discover *when* a sequence of tokens is relevant rather than simply filtering for (sequences of) tokens, taken out of context. To evaluate the performance of our model in comparison to other common classification architectures, we look at six data sets (§3). Our model outperforms previous approaches by a significant margin.

2 Hierarchical Attention Networks

The overall architecture of the Hierarchical Attention Network (HAN) is shown in Fig. 2. It consists of several parts: a word sequence encoder, a word-level attention layer, a sentence encoder and a sentence-level attention layer. We describe the details of different components in the following sections.

2.1 GRU-based sequence encoder

The GRU (Bahdanau et al., 2014) uses a gating mechanism to track the state of sequences without using separate memory cells. There are two types of gates: the reset gate r_t and the update gate z_t. They together control how information is updated to the state. At time t, the GRU computes the new state as

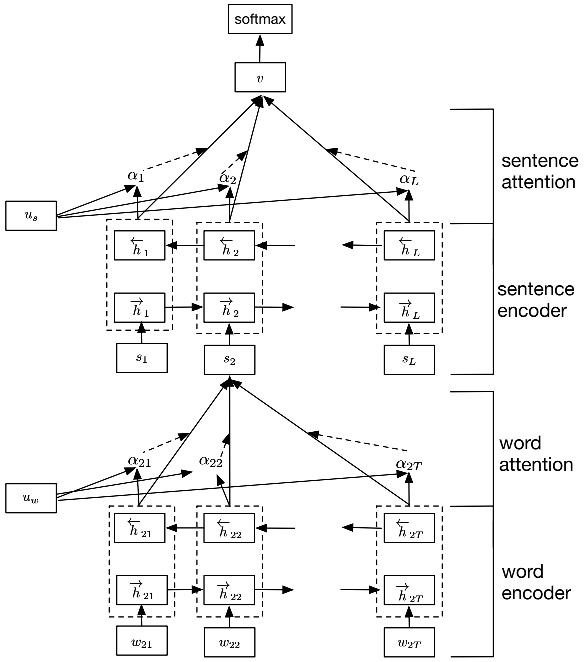


Figure 2: Hierarchical Attention Network.

$$h_t = (1 - z_t) \odot h_{t-1} + z_t \odot \tilde{h}_t. \tag{1}$$

This is a linear interpolation between the previous state h_{t-1} and the current new state $\tilde{h}_t$ computed with new sequence information. The gate z_t decides how much past information is kept and how much new information is added. z_t is updated as:

$$z_t = \sigma(W_z x_t + U_z h_{t-1} + b_z), \tag{2}$$

where x_t is the sequence vector at time t. The candidate state $\tilde{h}_t$ is computed in a way similar to a traditional recurrent neural network (RNN):

$$\tilde{h}_t = \tanh(W_h x_t + r_t \odot (U_h h_{t-1}) + b_h), \tag{3}$$

Here r_t is the reset gate which controls how much the past state contributes to the candidate state. If r_t is zero, then it forgets the previous state. The reset gate is updated as follows:

$$r_t = \sigma(W_r x_t + U_r h_{t-1} + b_r) \tag{4}$$

2.2 Hierarchical Attention

We focus on document-level classification in this work. Assume that a document has L sentences

s_i and each sentence contains T_i words. w_{it} with $t \in [1, T]$ represents the words in the ith sentence. The proposed model projects the raw document into a vector representation, on which we build a classifier to perform document classification. In the following, we will present how we build the document level vector progressively from word vectors by using the hierarchical structure.

Word Encoder Given a sentence with words $w_{it}, t \in [0, T]$, we first embed the words to vectors through an embedding matrix W_e, $x_{ij} = W_e w_{ij}$. We use a bidirectional GRU (Bahdanau et al., 2014) to get annotations of words by summarizing information from both directions for words, and therefore incorporate the contextual information in the annotation. The bidirectional GRU contains the forward GRU $\overrightarrow{f}$ which reads the sentence s_i from w_{i1} to w_{iT} and a backward GRU $\overleftarrow{f}$ which reads from w_{iT} to w_{i1}:

$$\begin{aligned} x_{it} &= W_e w_{it}, t \in [1, T], \\ \overrightarrow{h}_{it} &= \overrightarrow{\text{GRU}}(x_{it}), t \in [1, T], \\ \overleftarrow{h}_{it} &= \overleftarrow{\text{GRU}}(x_{it}), t \in [T, 1]. \end{aligned}$$

We obtain an annotation for a given word w_{it} by concatenating the forward hidden state $\overrightarrow{h}_{it}$ and backward hidden state $\overleftarrow{h}_{it}$, i.e., $h_{it} = [\overrightarrow{h}_{it}, \overleftarrow{h}_{it}]$, which summarizes the information of the whole sentence centered around w_{it}.

Note that we directly use word embeddings. For a more complete model we could use a GRU to get word vectors directly from characters, similarly to (Ling et al., 2015). We omitted this for simplicity.

Word Attention Not all words contribute equally to the representation of the sentence meaning. Hence, we introduce attention mechanism to extract such words that are important to the meaning of the sentence and aggregate the representation of those informative words to form a sentence vector. Specifically,

$$u_{it} = \tanh(W_w h_{it} + b_w) \tag{5}$$

$$\alpha_{it} = \frac{\exp(u_{it}^\top u_w)}{\sum_t \exp(u_{it}^\top u_w)} \tag{6}$$

$$s_i = \sum_t \alpha_{it} h_{it}. \tag{7}$$

That is, we first feed the word annotation h_{it} through a one-layer MLP to get u_{it} as a hidden representation of h_{it}, then we measure the importance of the word as the similarity of u_{it} with a word level context vector u_w and get a normalized importance weight α_{it} through a softmax function. After that, we compute the sentence vector s_i (we abuse the notation here) as a weighted sum of the word annotations based on the weights. The context vector u_w can be seen as a high level representation of a fixed query "what is the informative word" over the words like that used in memory networks (Sukhbaatar et al., 2015; Kumar et al., 2015). The word context vector u_w is randomly initialized and jointly learned during the training process.

Sentence Encoder Given the sentence vectors s_i, we can get a document vector in a similar way. We use a bidirectional GRU to encode the sentences:

$$\begin{aligned} \overrightarrow{h}_i &= \overrightarrow{\text{GRU}}(s_i), i \in [1, L], \\ \overleftarrow{h}_i &= \overleftarrow{\text{GRU}}(s_i), t \in [L, 1]. \end{aligned}$$

We concatenate $\overrightarrow{h}_i$ and $\overleftarrow{h}_j$ to get an annotation of sentence i, i.e., $h_i = [\overrightarrow{h}_i, \overleftarrow{h}_i]$. h_i summarizes the neighbor sentences around sentence i but still focus on sentence i.

Sentence Attention To reward sentences that are clues to correctly classify a document, we again use attention mechanism and introduce a sentence level context vector u_s and use the vector to measure the importance of the sentences. This yields

$$u_i = \tanh(W_s h_i + b_s), \tag{8}$$

$$\alpha_i = \frac{\exp(u_i^\top u_s)}{\sum_i \exp(u_i^\top u_s)}, \tag{9}$$

$$v = \sum_i \alpha_i h_i, \tag{10}$$

where v is the document vector that summarizes all the information of sentences in a document. Similarly, the sentence level context vector can be randomly initialized and jointly learned during the training process.

2.3 Document Classification

The document vector v is a high level representation of the document and can be used as features for document classification:

$$p = \text{softmax}(W_c v + b_c). \tag{11}$$

We use the negative log likelihood of the correct labels as training loss:

$$L = -\sum_d \log p_{dj}, \tag{12}$$

where j is the label of document d.

3 Experiments

3.1 Data sets

We evaluate the effectiveness of our model on six large scale document classification data sets. These data sets can be categorized into two types of document classification tasks: sentiment estimation and topic classification. The statistics of the data sets are summarized in Table 1. We use 80% of the data for training, 10% for validation, and the remaining 10% for test, unless stated otherwise.

Yelp reviews are obtained from the Yelp Dataset Challenge in 2013, 2014 and 2015 (Tang et al., 2015). There are five levels of ratings from 1 to 5 (higher is better).

IMDB reviews are obtained from (Diao et al., 2014). The ratings range from 1 to 10.

Yahoo answers are obtained from (Zhang et al., 2015). This is a topic classification task with 10 classes: Society & Culture, Science & Mathematics, Health, Education & Reference, Computers & Internet, Sports, Business & Finance, Entertainment & Music, Family & Relationships and Politics & Government. The document we use includes question titles, question contexts and best answers. There are 140,000 training samples and 5000 testing samples. The original data set does not provide validation samples. We randomly select 10% of the training samples as validation.

Amazon reviews are obtained from (Zhang et al., 2015). The ratings are from 1 to 5. 3,000,000 reviews are used for training and 650,000 reviews for testing. Similarly, we use 10% of the training samples as validation.

3.2 Baselines

We compare HAN with several baseline methods, including traditional approaches such as linear methods, SVMs and paragraph embeddings using neural networks, LSTMs, word-based CNN, character-based CNN, and Conv-GRNN, LSTM-GRNN. These baseline methods and results are reported in (Zhang et al., 2015; Tang et al., 2015).

3.2.1 Linear methods

Linear methods (Zhang et al., 2015) use the constructed statistics as features. A linear classifier based on multinomial logistic regression is used to classify the documents using the features.

BOW and BOW+TFIDF The 50,000 most frequent words from the training set are selected and the count of each word is used features. Bow+TFIDF, as implied by the name, uses the TFIDF of counts as features.

n-grams and n-grams+TFIDF used the most frequent 500,000 n-grams (up to 5-grams).

Bag-of-means The average word2vec embedding (Mikolov et al., 2013) is used as feature set.

3.2.2 SVMs

SVMs-based methods are reported in (Tang et al., 2015), including **SVM+Unigrams, Bigrams, Text Features, AverageSG, SSWE**. In detail, **Unigrams** and **Bigrams** uses bag-of-unigrams and bag-of-bigrams as features respectively.

Text Features are constructed according to (Kiritchenko et al., 2014), including word and character n-grams, sentiment lexicon features etc.

AverageSG constructs 200-dimensional word vectors using word2vec and the average word embeddings of each document are used.

SSWE uses sentiment specific word embeddings according to (Tang et al., 2014).

3.2.3 Neural Network methods

The neural network based methods are reported in (Tang et al., 2015) and (Zhang et al., 2015).

CNN-word Word based CNN models like that of (Kim, 2014) are used.

CNN-char Character level CNN models are reported in (Zhang et al., 2015).

Data set	classes	documents	average #s	max #s	average #w	max #w	vocabulary
Yelp 2013	5	335,018	8.9	151	151.6	1184	211,245
Yelp 2014	5	1,125,457	9.2	151	156.9	1199	476,191
Yelp 2015	5	1,569,264	9.0	151	151.9	1199	612,636
IMDB review	10	348,415	14.0	148	325.6	2802	115,831
Yahoo Answer	10	1,450,000	6.4	515	108.4	4002	1,554,607
Amazon review	5	3,650,000	4.9	99	91.9	596	1,919,336

Table 1: Data statistics: #s denotes the number of sentences (average and maximum per document), #w denotes the number of words (average and maximum per document).

LSTM takes the whole document as a single sequence and the average of the hidden states of all words is used as feature for classification.

Conv-GRNN and LSTM-GRNN were proposed by (Tang et al., 2015). They also explore the hierarchical structure: a CNN or LSTM provides a sentence vector, and then a gated recurrent neural network (GRNN) combines the sentence vectors from a document level vector representation for classification.

3.3 Model configuration and training

We split documents into sentences and tokenize each sentence using Stanford's CoreNLP (Manning et al., 2014). We only retain words appearing more than 5 times in building the vocabulary and replace the words that appear 5 times with a special UNK token. We obtain the word embedding by training an unsupervised word2vec (Mikolov et al., 2013) model on the training and validation splits and then use the word embedding to initialize W_e.

The hyper parameters of the models are tuned on the validation set. In our experiments, we set the word embedding dimension to be 200 and the GRU dimension to be 50. In this case a combination of forward and backward GRU gives us 100 dimensions for word/sentence annotation. The word/sentence context vectors also have a dimension of 100, initialized at random.

For training, we use a mini-batch size of 64 and documents of similar length (in terms of the number of sentences in the documents) are organized to be a batch. We find that length-adjustment can accelerate training by three times. We use stochastic gradient descent to train all models with momentum of 0.9. We pick the best learning rate using grid search on the validation set.

3.4 Results and analysis

The experimental results on all data sets are shown in Table 2. We refer to our models as **HN-**$\{$**AVE, MAX, ATT**$\}$. Here HN stands for Hierarchical Network, AVE indicates averaging, MAX indicates max-pooling, and ATT indicates our proposed hierarchical attention model. Results show that HN-ATT gives the best performance across all data sets.

The improvement is regardless of data sizes. For smaller data sets such as Yelp 2013 and IMDB, our model outperforms the previous best baseline methods by 3.1% and 4.1% respectively. This finding is consistent across other larger data sets. Our model outperforms previous best models by 3.2%, 3.4%, 4.6% and 6.0% on Yelp 2014, Yelp 2015, Yahoo Answers and Amazon Reviews. The improvement also occurs regardless of the type of task: sentiment classification, which includes Yelp 2013-2014, IMDB, Amazon Reviews and topic classification for Yahoo Answers.

From Table 2 we can see that neural network based methods that do *not* explore hierarchical document structure, such as LSTM, CNN-word, CNN-char have little advantage over traditional methods for large scale (in terms of document size) text classification. E.g. SVM+TextFeatures gives performance 59.8, 61.8, 62.4, 40.5 for Yelp 2013, 2014, 2015 and IMDB respectively, while CNN-word has accuracy 59.7, 61.0, 61.5, 37.6 respectively.

Exploring the hierarchical structure only, as in HN-AVE, HN-MAX, can significantly improve over LSTM, CNN-word and CNN-char. For example, our HN-AVE outperforms CNN-word by 7.3%, 8.8%, 8.5%, 10.2% than CNN-word on Yelp 2013, 2014, 2015 and IMDB respectively. Our model HN-ATT that further utilizes attention mechanism

Table 2: Document Classification, in percentage

combined with hierarchical structure improves over previous models (LSTM-GRNN) by 3.1%, 3.4%, 3.5% and 4.1% respectively. More interestingly, in the experiments, HN-AVE is equivalent to using non-informative global word/sentence context vectors (e.g., if they are all-zero vectors, then the attention weights in Eq. 6 and 9 become uniform weights). Compared to HN-AVE, the HN-ATT model gives superior performance across the board. This clearly demonstrates the effectiveness of the proposed global word and sentence importance vectors for the HAN.

3.5 Context dependent attention weights

If words were inherently important or not important, models without attention mechanism might work well since the model could automatically assign low weights to irrelevant words and vice versa. However, the importance of words is highly context dependent. For example, the word `good` may appear in a review that has the lowest rating either because users are only happy with part of the product/service or because they use it in a negation, such as `not good`. To verify that our model can capture context dependent word importance, we plot the distribution of the attention weights of the words `good` and `bad` from the test split of Yelp 2013 data set as shown in Figure 3(a) and Figure 4(a). We can see that the distribution has a attention weight assigned to a word from 0 to 1. This indicates that our model captures diverse context and assign context-dependent weight to the words.

For further illustration, we plot the distribution when conditioned on the ratings of the review. Subfigures 3(b)-(f) in Figure 3 and Figure 4 correspond to the rating 1-5 respectively. In particular, Figure 3(b) shows that the weight of `good` concentrates on the low end in the reviews with rating 1. As the rating increases, so does the weight distribution. This means that the word `good` plays a more important role for reviews with higher ratings. We can observe the converse trend in Figure 4 for the word `bad`. This confirms that our model can capture the context-dependent word importance.

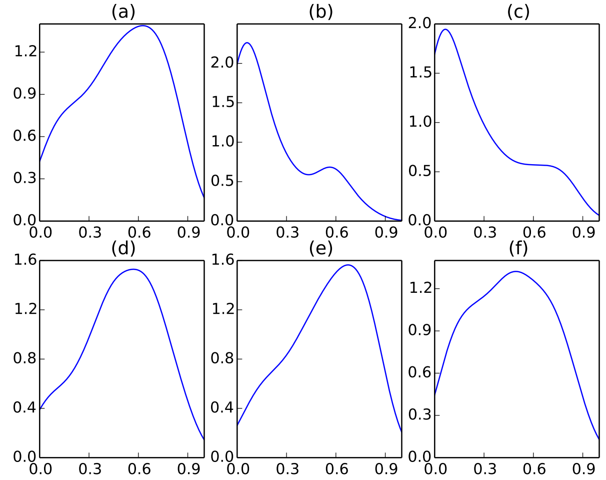

Figure 3: Attention weight distribution of good. (a) — aggregate distribution on the test split; (b)-(f) stratified for reviews with ratings 1-5 respectively. We can see that the weight distribution shifts to *higher* end as the rating goes higher.

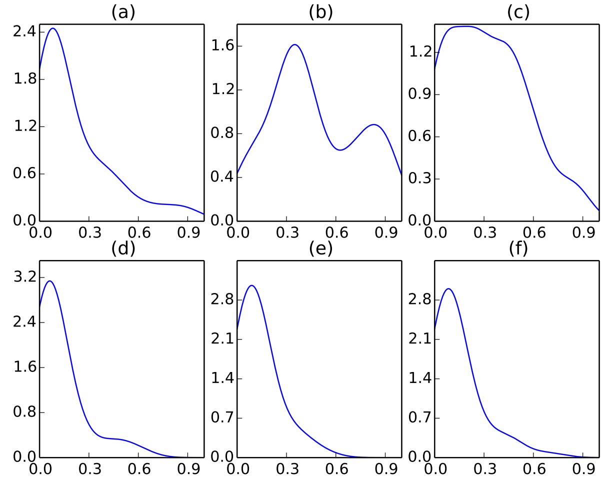

Figure 4: Attention weight distribution of the word bad. The setup is as above: (a) contains the aggregate distribution, while (b)-(f) contain stratifications to reviews with ratings 1-5 respectively. Contrary to before, the word bad is considered important for poor ratings and less so for good ones.

3.6 Visualization of attention

In order to validate that our model is able to select informative sentences and words in a document, we visualize the hierarchical attention layers in Figures 5 and 6 for several documents from the Yelp 2013 and Yahoo Answers data sets.

Every line is a sentence (sometimes sentences spill over several lines due to their length). Red denotes the sentence weight and blue denotes the word weight. Due to the hierarchical structure, we normalize the word weight by the sentence weight to make sure that only important words in important sentences are emphasized. For visualization purposes we display $\sqrt{p_s}p_w$. The $\sqrt{p_s}$ term displays the important words in unimportant sentences to ensure that they are not totally invisible.

Figure 5 shows that our model can select the words carrying strong sentiment like delicious, amazing, terrible and their corresponding sentences. Sentences containing many words like cocktails, pasta, entree are disregarded. Note that our model can not only select words carrying strong sentiment, it can also deal with complex across-sentence context. For example, there are sentences like i don't even like scallops in the first document of Fig. 5, if looking purely at the single sentence, we may think this is negative comment. However, our model looks at the context of this sentence and figures out this is a positive review and chooses to ignore this sentence.

Our hierarchical attention mechanism also works well for topic classification in the Yahoo Answer data set. For example, for the left document in Figure 6 with label 1, which denotes Science and Mathematics, our model accurately localizes the words zebra, strips, camouflage, predator and their corresponding sentences. For the right document with label 4, which denotes Computers and Internet, our model focuses on web, searches, browsers and their corresponding sentences. Note that this happens in a *multiclass* setting, that is, detection happens before the selection of the topic!

4 Related Work

Kim (2014) use neural networks for text classification. The architecture is a direct application of CNNs, as used in computer vision (LeCun et al., 1998), albeit with NLP interpretations. Johnson and Zhang (2014) explores the case of directly using a high-dimensional one hot vector as input. They find that it performs well. Unlike word level modelings, Zhang et al. (2015) apply a character-level CNN for text classification and achieve competitive results. Socher et al. (2013) use recursive neural networks for text classification. Tai et al. (2015)

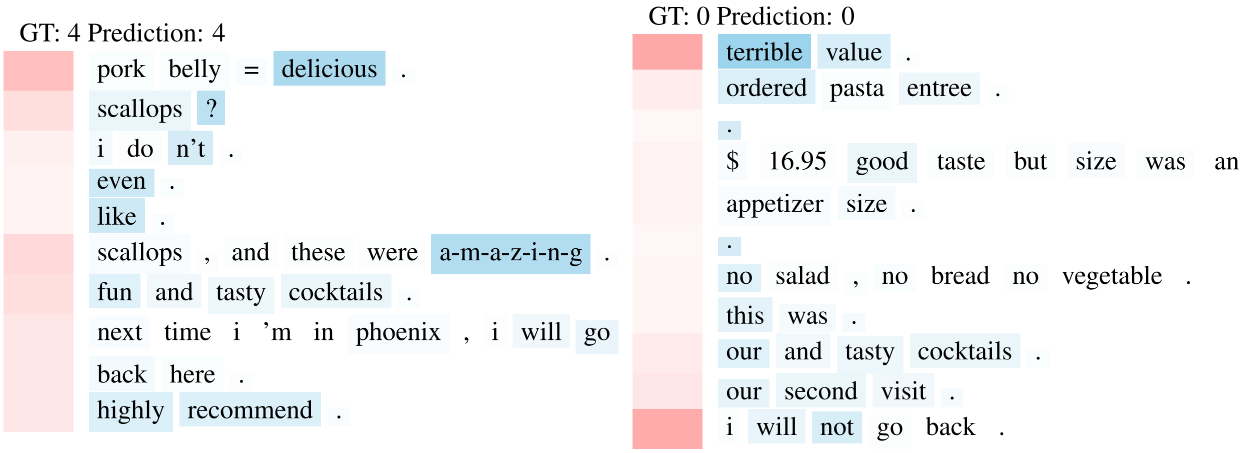

Figure 5: Documents from Yelp 2013. Label 4 means star 5, label 0 means star 1.

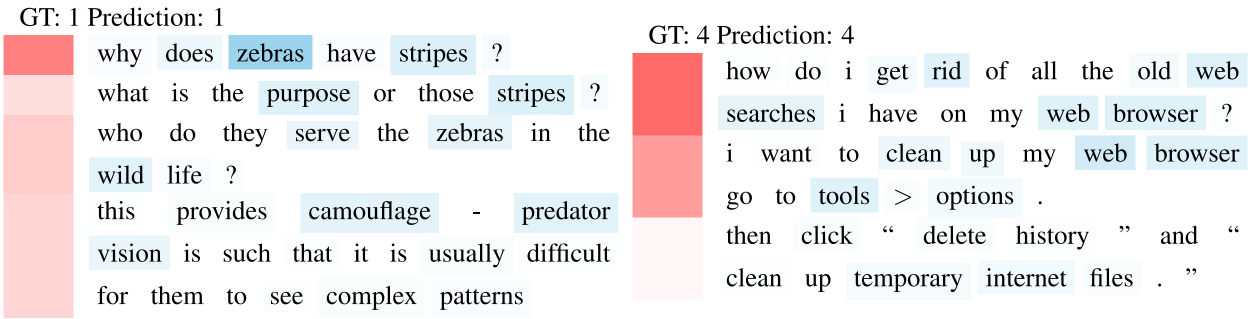

Figure 6: Documents from Yahoo Answers. Label 1 denotes Science and Mathematics and label 4 denotes Computers and Internet.

explore the structure of a sentence and use a tree-structured LSTMs for classification. There are also some works that combine LSTM and CNN structure to for sentence classification (Lai et al., 2015; Zhou et al., 2015). Tang et al. (2015) use hierarchical structure in sentiment classification. They first use a CNN or LSTM to get a sentence vector and then a bi-directional gated recurrent neural network to compose the sentence vectors to get a document vectors. There are some other works that use hierarchical structure in sequence generation (Li et al., 2015) and language modeling (Lin et al., 2015).

The attention mechanism was proposed by (Bahdanau et al., 2014) in machine translation. The encoder decoder framework is used and an attention mechanism is used to select the reference words in original language for words in foreign language before translation. Xu et al. (2015) uses the attention mechanism in image caption generation to select the relevant image regions when generating words in the captions. Further uses of the attention mechanism include parsing (Vinyals et al., 2014), natural language question answering (Sukhbaatar et al., 2015; Kumar et al., 2015; Hermann et al., 2015), and image question answering (Yang et al., 2015). Unlike these works, we explore a *hierarchical* attention mechanism (to the best of our knowledge this is the first such instance).

5 Conclusion

In this paper, we proposed hierarchical attention networks (HAN) for classifying documents. As a convenient side-effect we obtained better visualization using the highly informative components of a document. Our model progressively builds a document vector by aggregating important words into sentence vectors and then aggregating important sentences vectors to document vectors. Experimental results demonstrate that our model performs significantly better than previous methods. Visualization of these attention layers illustrates that our model is effective in picking out important words and sentences.

Abstract

We compare different word embeddings from a standard window based skipgram model, a skipgram model trained using dependency context features and a novel skipgram variant that utilizes additional information from dependency graphs. We explore the effectiveness of the different types of word embeddings for word similarity and sentence classification tasks. We consider three common sentence classification tasks: question type classification on the TREC dataset, binary sentiment classification on Stanford's Sentiment Treebank and semantic relation classification on the SemEval 2010 dataset. For each task we use three different classification methods: a Support Vector Machine, a Convolutional Neural Network and a Long Short Term Memory Network. Our experiments show that dependency based embeddings outperform standard window based embeddings in most of the settings, while using dependency context embeddings as additional features improves performance in all tasks regardless of the classification method.
Our embeddings and code are available at https://www.cs.york.ac.uk/nlp/extvec

1 Introduction

Representing words as low dimensional vectors (also known as word embeddings) has been a widely adopted technique in NLP. Word representations can be used as features for classification tasks such as named entity recognition or chunking (Turian et al., 2010), and as a pretraining method for initializing deep neural network representations (Collobert et al., 2011; Kim, 2014). Word embeddings provide better generalization to unseen examples since they can capture general semantic and syntactic properties of words. One of the most popular methods of learning word embeddings is the skipgram model of Mikolov et al. (2013a; 2013b) where embeddings are trained by making predictions of context words appearing in a window around a target word.

The standard skipgram model ignores syntax and only partially takes into consideration the sequential structure of text, but still captures certain syntactic properties of words. A significant amount of previous research has explored methods for directly taking syntax into account for word embedding learning (Pham et al., 2015; Cheng and Kartsaklis, 2015; Hashimoto et al., 2014). One simple method is based on traditional count-based distributional semantic spaces and utilizes words with syntactic types from a dependency parse graph as context features (Padó and Lapata, 2007; Baroni and Lenci, 2010). This method has also been applied to skipgram models, where word embeddings are optimized to predict dependency context features instead of other words (Levy and Goldberg, 2014).

Syntax-based embeddings have been shown to have different properties in word similarity evaluations than their window based counterparts, better capturing the functional properties of words. However, it is not clear if they provide any advantage for NLP tasks. We show that using dependency context features can be a general method of providing syntactic information for several sentence classification

Proceedings of NAACL-HLT 2016, pages 1490–1500,
San Diego, California, June 12-17, 2016.

tasks. Furthermore, the dependency context embeddings improve performance with all classifiers we tested.

We consider the usage of word and dependency context features for three common sentence classification tasks: TREC question type classification, binary sentiment prediction on Stanford Sentiment Treebank, and SemEval 2010 relation identification. We evaluate different methods of using the dependency context embeddings as extra features besides word embeddings to inject information into sentence classifiers about the syntactic structure of a sentence. The advantage of such a method is that it can be applied to any classifier that utilizes standard word embeddings. We evaluate the usefulness of syntax-based word embeddings and dependency context embeddings with three different sentence classification methods: a Support Vector Machine (SVM), a Convolutional Neural Network (CNN) and a Long Short Term Memory network (LSTM).

In order to better utilize the structure of dependency graphs, we propose an extended version of the simple dependency based skipgram of Levy et al. (2014). This extended version considers co-occurrences in a dependency graph between pairs of words, words and dependency context features, and between different dependency context features. This scheme results in word embeddings that share properties between window based models and dependency graph based ones. More importantly, it provides additional structural information for the dependency context feature embeddings making them more effective when used in sentence classification tasks.

Our evaluation provides several insights on the role of syntax for embeddings and how they can be used for sentence classification. First, we confirm past claims about the different properties between dependency and window based skipgram embeddings in word similarity tasks. Second, we show that dependency based embeddings perform better in question classification and relation identification than window based ones. These results are robust across multiple classification methods. We show that combining dependency context feature embeddings together with word embeddings provide a simple and effective way to improve sentence classification performance. Finally, the performance gain is higher for the extended dependency based skipgram developed in this paper.

2 Related Work

Estimating word representations from text has been the focus of a lot of research in NLP. Traditional count-based models learn representations by applying SVD in a word-word co-occurrence matrix (Turney et al., 2010). More recently, neural models have been used to learn word embeddings by optimizing for a word prediction task (Collobert et al., 2011; Mnih and Teh, 2012; Mikolov et al., 2013a). However, the most commonly used word representation techniques like word2vec's skipgram and CBoW take little consideration of syntactic structure.

Several modifications have been proposed so that word embedding learning algorithms can better utilize syntax or the sequence structure of sentences. One such model is the dependency based skipgram of Levy and Goldberg (2014) which we further extend in this paper. Evaluation of this model is limited to word similarity or lexical substitution in context (Melamud et al., 2015), and little is known about performance within other NLP tasks. Hashimoto et al. (2014) proposed a log-bilinear language model based on predicate-argument structures and report improvements on phrase similarity tasks compared to standard skipgram. In Ling et al. (2015), skipgram and CBoW models are adapted to include position specific weights for the words inside the co-occurrence window and the resulting embeddings provide slight improvements for parsing and POS tagging tasks. The C-PHRASE model (Pham et al., 2015) is another modification of the CBoW model that uses an external parser to replace windows with syntactic constituents. In Cheng and Kartsaklis (2015), a recursive neural network structured according to a sentence's parse learns word embeddings by composing into valid sentences rather than distorted ones.

Structured skipgram models (Levy and Goldberg, 2014; Ling et al., 2015) have a notable difference with other approaches of incorporating structural information into embeddings (e.g. C-PHRASE), since they also produce embeddings of the structural context features at the prediction layer. We show that in the case of dependency contexts, these structural features can provide valuable information to sentence classifiers. In our extended dependency based skipgram, we do not make a distinction between words and structural features in the training process, which results into better performing dependency context embeddings when used in sentence classification. Another difference of our skipgram model with other structured skipgram variants is that we keep the long distance word contexts used in standard window based skipgram training with the purpose of capturing both functional and topic related semantic properties of words.

Our work is also related to methods of providing explicit syntactic information to sentence classifiers. Most of the previously proposed approaches rely on tree-structured neural architectures to drive composition of word embeddings to a sentence representation (Socher et al., 2012; Tai et al., 2015; Li et al., 2015). We use a different approach where syntactic information is provided only through embeddings. Our approach is not orthogonal to using tree-structured models and the two of them could be applied together. An advantage of providing syntactic information through embeddings is that large amounts of automatically parsed textual data can be utilized in order to learn representations of dependency types.

3 Embedding Models

The skipgram model of Mikolov et al. (2013a; 2013b) optimizes vector representations of words (word embeddings) such that they can predict other context words occurring in a small window. The architecture consists of a single hidden layer feedforward network without any non-linearity applied on the hidden layer. The input to the network is the index of a target word (a one-hot vector) and the output is a vector of probabilities of appearance for context words. The network learns word embeddings by maximizing the log probability of a context word c given a target word t observed in a large corpus of textual data D. To avoid the large computational cost of applying a softmax for the whole vocabulary, a commonly used strategy is to train with negative sampling. For each target-context pair (t, c) coming from the observed data D, a small number of context words is sampled from unobserved data $D^{'}$ according to a simple distribution and then used as the negative classes.

The probability of the target context pair (t, c) being observed in the data is given by:

$$P(D = 1 \mid t, c) = \sigma(v_t \cdot v_c) \tag{1}$$

where v_t and v_c are target and context word embeddings, and σ is the sigmoid function. For a negative sampled pair (t, c), the probability of the pair not being observed in the data is given by:

$$P(D = 0 \mid t, c) = 1 - \sigma(v_t \cdot v_c) \tag{2}$$

The objective becomes:

$$\arg\max_{v_t, v_c} \sum_{t,c \in D} \log \sigma(v_t \cdot v_c) + \sum_{t,c \in D'} \log \sigma(-v_t \cdot v_c) \tag{3}$$

The network learns two sets of weights for each word: one for embedding words to a low dimensional representation in the hidden layer that we will refer to as the embedding layer weights, and one for assigning a probability to context words that we will refer to as the prediction layer weights. Both sets of weights assign representations to words such that words that have similar co-occurrence patterns with other words are closer in the embedding space. Typically, the embedding layer weights are used as feature representations of words for other other tasks. Due to its scalability to large corpora and the good performance of its derived word embeddings in several NLP tasks the skipgram model has become a standard solution for unsupervised learning of word representations.

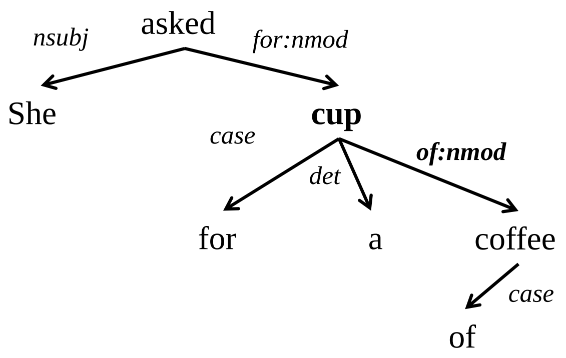
While typical training of skipgarm is performed by optimizing for the prediction of other words in a window around the target word, it is possible to use other contextual features, such as contexts from dependency graphs of sentences.

We consider three variations of skipgram based on different target-context pairs:

3.1 Window-5 based skipgram (Win5)

This is a standard skipgram model that considers target-context word pairs inside a window of 5 words to the right and to the left of the target word. The window size for every target instance in the corpus is uniformly sampled from the [1,5] range, effectively providing a weighting scheme for context

input sentence: She asked for a **cup** of coffee



Win5 "cup" contexts: *She, asked, for, a, of, coffee*

LG "cup" contexts: *case_for, det_a, of:nmod_coffee, for:nmod^{-1}_asked*

EXT "cup" contexts: *She, asked, for, a, of, coffee, case_for, det_a, of:nmod_coffee, for:nmod^{-1}_asked*

EXT "of:nmod_coffee" contexts: *cup, case_for, det_a, for:nmod^{-1}_asked*

Figure 1: A sentence and its dependency parse graph. The contexts of the word "cup" are shown for each model. In addition, for the EXT model the contexts of the "of:nmod_coffee" dependency context feature are shown.

words according to their distance from the target word.

3.2 Skipgram with dependency contexts (LG)

Levy and Golberg's (2014) modification to the skipgram model replaces context words in a window by dependency contexts. A dependency context is a discrete symbol denoting a word and its syntactic role in a dependency parse graph (e.g. $nsubj\_she$, $of : nmod\_coffee$, $of : nmod^{-1}\_cup$). The directionality of dependency edges is encoded by introducing features with inverse relations. Training of this skipgram variant is similar to window based approaches, but each word is considered as a node in a dependency graph obtained by a parser, and embeddings are optimized to predict their corresponding word's immediate syntactic contexts (Figure 1). The network's weight matrices have different shapes, where representations coming from the embedding layer weights correspond to word embeddings, while representations coming from the prediction layer weights to dependency context embeddings.

3.3 Extended Dependency Skipgram (EXT)

We propose another variation of skipgram based on dependency graphs that utilizes additional cooccurrences compared to the LG variant. Each target word is taken as a node in the dependency graph and then optimize word embeddings such that they maximize the probability of other words within distance one and two in the graph. As with the Win5 model, we apply a weighting according to distance, with words having distance one from the target counted twice. This word-word prediction behaves similarly to the Win5 model, but considers the dependency parse to filter coincidental co-occurrences. The second type of predictions that embeddings are optimized for is similar to the LG model, where each word predicts its dependency contexts. We also optimize for a third type of context prediction where for each node, dependency contexts become the targets and predict the rest of dependency contexts of the same node. An example of the different target-context pairs that each skipgarm variant utilizes can be seen in Figure 1. The three types of target-context pairs for the extended dependency skipgram are interleaved during training. The weight matrices of this network are symmetric resulting in two embeddings per word and dependency context feature.

3.4 Implementation Details

We trained 300 dimensional versions of the above skipgram variants on English Wikipedia August 2015 dump of 2 billion words. Vocabularies consist of words and dependency contexts that appear more than 100 times (approximately 220k words and 1.3m dependency contexts). Training was done by applying negative sampling with 15 negative samples per target-context pair for 10 iterations over the entire corpus using stochastic gradient descent. The following commonly used methods (Mikolov et al., 2013b; Levy et al., 2015) were applied during training: drawing negative samples according to their unigram distribution raised to the power of 0.75, linear decay of learning rate with initial $\alpha = 0.25$, and subsampling of target words with probability given by $p = \frac{f-10^{-5}}{f} - \sqrt{\frac{10^{-5}}{t}}$ where f is the word's frequency. Dependency parsing for LG and EXT training was done with the Stanford Neural Network dependency parser (Chen and Manning, 2014) using Universal Dependency tags (De Marneffe et al., 2014).

4 Word Similarity Evaluation

We evaluate the effect of the different contextual features for skipgram word embeddings in two word similarity datasets: WordSim-353 (Finkelstein et al., 2001) and SimLex-999 (Hill et al., 2015). For both datasets, we compare the cosine similarity of word embeddings for a pair of words to human judgements and report Spearman's correlation in Table 1. The two datasets use a different notion of word similarity for scoring. Wordsim-353 mostly captures topical similarity (or relatedness), giving high similarity to pair of words like *clothes-closet*. SimLex-999 uses a more strict version of similarity, often called substitutional similarity, where the pair *clothes-closet* has a low similarity score and pairs like *shore-coast* have high similarity. Win5 skipgram version achieves a higher correlation for WordSim-353 compared to LG, but the results are reversed for SimLex-999. This agrees with previous research that shows that syntactic contexts correlate better with substitutional similarity judgements than using words in a window as contexts (Levy and Goldberg, 2014). As expected, the extended model represents a middle ground solution between the two. While similarity based evaluation makes obvious that different contextual features capture different properties of words, it is not clear which kind similarity notion is more useful when word representations are used as features for NLP tasks. We answer this question for sentence level classification tasks in the next section.

Embeddings	WordSim-353	SimLex-999
Win5	**0.714**	0.389
LG	0.621	**0.460**
EXT	0.678	0.414

Table 1: Spearman correlation for the 3 skipgram variants on WordSim-353 and SimLex-999 word similarity evaluation tasks.

5 Sentence Classification

We consider three common sentence classification tasks: TREC question type classification (QC), binary sentiment classification on Stanford's Sentiment Treebank (SST), and relation identification between pairs of nominals (RI) using the SemEval 2010 dataset. The experiments aim to answer two questions. First, to assess the effect of different context features for word embeddings when used in sentence classification tasks, given their different behaviour on word similarity evaluation. Second, to experiment with methods of using the dependency context embeddings themselves as a way to provide classifiers with dependency syntactic information. We carry out experiments with three different classification methods: SVMs with averaged embeddings, the Convolutional Neural Network of Kim (2014), and a Long Short Term Memory recurrent neural network (Hochreiter and Schmidhuber, 1997). These classifiers have some distinct characteristics. The SVM does not take into account the structure of the sentence, nor does it build any internal representations. On the other hand, both the CNN and LSTM networks operate on sequences of words and build internal representations before predicting the class label distribution. However, they do not have access to explicit syntactic information.

We first give a description of the classification methods and the way embeddings are used as features, followed by the description of the tasks and results.

5.1 Classification Methods

SVM with averaged embeddings We create a sentence representation by averaging embeddings of sentence features (words and dependency contexts). This can be considered the equivalent of a Bag-of-Words sentence representation in the embedding space, hence called Bag-of-Embeddings (BoE). We then train a classifier by applying a Support Vector Machine with a Gaussian kernel:

$$K(\mathbf{x}, \mathbf{x}^{'}) = \exp(-\gamma \|\mathbf{x} - \mathbf{x}^{'}\|^2) \tag{4}$$

For hyperparameter tuning, we set parameter γ of the kernel to $1/k$, where k is the number of features (dimensionality of embeddings), and then perform cross validation for the c parameter using the standard Win5 word embeddings in the question classification task.

Convolutional Neural Network (CNN) We use the simple Convolutional Neural Network of Kim (2014) that has been shown to perform well in multiple sentence classification tasks. The network's input is a sentence matrix X formed by concatenating k-dimensional word embeddings. Then a convolutional filter $W \in \mathbb{R}^{h \times k}$ is applied to every possible sequence of length h to get a feature map:

$$c_i = tanh(W \cdot X + b) \tag{5}$$

followed by a max-over-time pooling operation to get the feature with the highest value:

$$\hat{c} = \max \mathbf{c} \tag{6}$$

The pooled features of different filters are then concatenated and passed to a fully connected softmax layer to perform the classification. The network uses multiple filters with different sequence sizes covering different size of windows in the sentence. All hyperparameters of the network are the same as used in the original paper (Kim, 2014): stochastic dropout (Srivastava et al., 2014) with $p = 0.5$ on the penultimate layer, 100 filters for each filter region with filter regions of width 2,3 and 4. Optimization is performed with Adadelta (Zeiler, 2012) on mini-batches of size 50.

Long Short Term Memory (LSTM) LSTM networks (Hochreiter and Schmidhuber, 1997) are recurrent neural networks where recurrent units consist of a memory cell c and three gates i, o and f. Given a sequence of input embeddings $\mathbf{x}$, LSTM outputs a sequence of states $\mathbf{h}$ given by the following equations:

$$\begin{pmatrix} \mathbf{i_t} \\ \mathbf{f_t} \\ \mathbf{o_t} \\ \tilde{\mathbf{c_t}} \end{pmatrix} = \begin{pmatrix} \sigma \\ \sigma \\ \sigma \\ tanh \end{pmatrix} W \cdot \begin{pmatrix} \mathbf{h_{t-1}} \\ \mathbf{x_t} \end{pmatrix} \tag{7}$$

$$\mathbf{c_t} = \mathbf{f_t} \odot \mathbf{c_{t-1}} + \mathbf{i_t} \odot \tilde{\mathbf{c_t}} \tag{8}$$

$$\mathbf{h_t} = \mathbf{o_t} \odot tanh(\mathbf{c_t}) \tag{9}$$

where $W \in \mathbb{R}^{4k \times 2k}$, $\tilde{\mathbf{c_t}}$ is a candidate state for the memory cell and $\odot$ is element-wise vector multiplication. The distribution of labels for the whole sentence is computed by a fully connected softmax layer on top of the final hidden state after applying stochastic dropout with $p = 0.25$. We use 150 dimensions for the size of $\mathbf{h}$, Adagrad (Duchi et al., 2011) for optimization and mini-batch size of 100.

5.2 Sentence Feature Representations

We provide syntactic information to each classifier in the following manner. First we parse each sentence to get a dependency graph. Each node in the graph is associated with a word w having an embedding $\mathbf{v_w}$ and a set of dependency context features $d_1, d_2, ..., d_C$ with embeddings $\mathbf{v_{d_1}}, \mathbf{v_{d_2}}, ..., \mathbf{v_{d_C}}$ exactly like during the dependency based skipgram training process. We then create a representation $\mathbf{x}$ of that node using different combinations of its associated word and dependency context embeddings:

- *Words*: Using only word embeddings

$$\mathbf{x} = \mathbf{v_w} \tag{10}$$

- *Dep*: A node's representation becomes the average of its associated dependency context embeddings:

$$\mathbf{x} = \frac{1}{C} \sum_{c=1}^{C} \mathbf{v_{d_c}} \tag{11}$$

- *Wavg*: Combination of the word and dependency context embeddings by a weighted average scheme that assigns equal contribution to the word and dependency context part:

$$\mathbf{x} = \frac{1}{2}\mathbf{v_w} + \frac{1}{2C} \sum_{c=1}^{C} \mathbf{v_{d_c}} \tag{12}$$

- *Conc*: Similar to the Wavg, but dependency context embeddings are first averaged and then concatenated to the word embedding to form a single vector:

$$\mathbf{x} = \mathbf{v_w} \oplus \frac{1}{C}\sum_{c=1}^{C}\mathbf{v_{d_c}} \tag{13}$$

  where $\oplus$ is the concatenation operator. This method keeps the word and syntactic part separate at the expense of doubling the dimensionality.

The above methods are used with the LG and EXT variants to create context specific node representations. For the EXT model, both word and dependency context embeddings used come from the embedding layer weights. The *Words* method is the only one that can be applied to the Win5 model. It is the most commonly used method to utilize word representations as features and our baseline. To make the comparison more fair for the Win5 model we include two additional variations that utilize both the embedding and prediction layer weights as an ensemble method for creating a word's representation:

- *Win5 AvgE*: Ensemble made by averaging word embeddings from the embedding and prediction layer weights of Win5 skipgram:

$$\mathbf{x} = \frac{1}{2}(\mathbf{v_w} + \mathbf{v_{w'}}) \tag{14}$$

- *Win5 ConcE*: Another ensemble made by concatenating word embeddings from the embedding and prediction layer weights of Win5 skipgram:

$$\mathbf{x} = \mathbf{v_w} \oplus \mathbf{v_{w'}} \tag{15}$$

Ensemble techniques have been reported to outperform simple word representations in some word similarity tasks (Levy et al., 2015). Since the EXT skipgram version uses symmetric weight matrices for the embedding and prediction layer, ensemble methods like the above could also be applied, but are not considered for these experiments. Note that contrary to the dependency based models, these ensemble methods do not create context specific representations.

The dependency graph's node representations are used as a sequence of embeddings respecting the order of the sentence to become the input for the CNN and LSTM. For the SVM BoE, word and dependency contexts of the whole sentence are averaged separately for the *Words* and *Dep* method, and then averaged again for the *Wavg* method or concatenated for the *Conc* method. As we are evaluating performance of embeddings, we do not perform updates during training of CNNs and LSTMs.

5.3 Datasets and Results

TREC Question Classification The TREC Question Classification dataset (Li and Roth, 2002) consists of 5452 training questions and 500 test questions. The task is to classify each question with one of six labels (e.g. location, definition, ...) depending on the answer they seek. For CNNs and LSTMs 10% of the training data were used as the dev set to pick the best model among different iterations. Classification accuracy results for each input representations and classification method can be seen in Table 2. We also report the state of the art result by the dependency convolutional neural network of Mu et al. (2015). Their model consists of a convolutional neural network that takes a dependency tree at the input layer instead of a sequence, and uses heuristics to choose the subset of nodes where pooling is applied.

Embeddings	SVM	CNN	LSTM
Win5 Words	81.4	92.8	88.4
Win5 AvgE	81.4	91.2	88.8
Win5 ConcE	82.4	92.6	90.4
LG Words	86.8	93.8	90.6
LG Dep	85.2	89.0	87.2
LG Wavg	87.2	93.4	91.2
LG Conc	84.0	94.6	92.0
EXT Words	88.4	94.2	91.8
EXT Dep	87.6	90.6	89.8
EXT Wavg	89.0	**95.0**	92.2
EXT Conc	**91.6**	93.2	**94.4**
tree CNN	**96.0**		

Table 2: Accuracy on 6-way TREC question classification task. Tree CNN is a CNN operating on dependency trees (Mou et al., 2015).

SST-2 The Stanford Sentiment Treebank dataset (Socher et al., 2013) has fine grained sentiment polarity scores for movie reviews on the phrasal and sentence level. The binary version of the task considers only positive and negative sentiment labels, resulting in a 6920/872/1821 split for training/dev/testing sets. All the models were trained using only the sentence level annotations. Classification accuracies for all models are reported in Table 3. The state of the art for this dataset comes from Kim (2014) using the same convolutional neural network as we do, but also utilizing the phrasal level annotations which provide about an order of magnitude larger training set. In addition, this specific configuration of the network (multichannel) uses two channels at the input layer, one updating the word embeddings during training and one that keeps them static as we do in our experiments.

Embeddings	SVM	CNN	LSTM
Win5 Words	80.1	83.5	76.1
Win5 AvgE	79.5	83.2	76.9
Win5 ConcE	80.3	82.9	77.6
LG Words	78.5	84.5	77.2
LG Dep	76.0	76.8	69.1
LG Wavg	78.9	82.0	78.6
LG Conc	79.8	82.7	79.7
EXT Words	80.5	84.1	77.6
EXT Dep	77.7	77.2	69.6
EXT Wavg	**80.6**	**84.6**	75.7
EXT Conc	**80.6**	83.5	**79.8**
CNN-multichannel	**88.1**		

Table 3: Accuracy on Stanford Sentiment Treebank binary classification task. CNN-multichannel is the best result reported in Kim (2014).

SemEval 2010 Relation Identification The SemEval 2010 Relation Identification task (Hendrickx et al., 2009) considers the classification of semantic relations between pairs of nominals into 19 classes. The classes are formed by 9 types of relations (e.g. cause-effect, component-whole, ...) with directionality taken into account and an extra OTHER class. We only used the shortest dependency path between the two nominals as the input to classifiers. In table 4, we report results using the official SemEval metric of macro-averaged F1-Score for (9+1)-way classification, taking directionality into account. The best reported result for this dataset is 85.6 F1-score by Xu et al. (2015) also using a convolutional network on a sequence of word embeddings from the shortest dependency path between the pair of nominals. They also introduce negative samples during training by reversing the subject and object of the relation and WordNet features. Without using WordNet features their model achieves 84.0 F1-score.

Embeddings	SVM	CNN	LSTM
Win5 Words	72.23	81.60	77.30
Win5 AvgE	71.09	79.46	76.67
Win5 ConcE	72.74	81.33	78.09
LG Words	75.29	84.18	79.94
LG Dep	75.19	79.13	74.77
LG Wavg	77.61	83.17	79.69
LG Conc	**78.71**	83.41	78.57
EXT Words	74.93	83.69	80.24

EXT Wavg	77.42	**84.31**	79.59
EXT Conc	78.53	83.93	**80.53**
CNN-NS-WN	**85.6**		

Table 4: F1 score for SemEval 2010 Relation Identification task. CNN-NS-WN is CNN with negative sampling and WordNet features (Xu et al., 2015).

6 Discussion

Our evaluation shows that dependency context embeddings can provide valuable syntactic information for sentence classification tasks using the three classification methods described. Out of the three tasks, Question Classification and Relation Identification showed great improvements when using dependency context embeddings compared to the baseline, while sentiment classification only showed moderate improvements. This is in agreement with previous research (Li et al., 2015), where explicit syntactic information was provided to classifiers by using tree structured networks and showed that syntax provides small improvements for binary sentiment classification in Stanford's Sentiment Treebank.

It is notable that for QC and RI, using only word embeddings that are trained with syntactic information (LG and EXT *Words* models) still outperform the baseline window based skipgram. Using the dependency context embeddings as a means to represent the dependency parse of sentences consistently outperforms the baseline method across the three tasks and for every classification method. This indicates that this additional syntactic information cannot be recovered by the CNN and LSTM even though they have access to the sequential structure of sentences, at least when trained on datasets of this size. As expected, the SVM BoE benefits the most by the addition of dependency context embeddings since these are its only source of structural information.

The dependency context embeddings from the EXT model outperform the LG model, both when used alone and when in combination with the word embeddings. This can be attributed to the additional information they are exposed to during training.

The effectiveness of the *Wavg* compared to the *Conc* method for combining word and dependency context embeddings seems to depend on the classification method. In genearal, we observe that the CNN performs better with *Wavg*, while SVM and LSTM with *Conc*. On the other hand, the ensemble methods of the Win5 model (*AvgE* and *ConcE*) do not provide any consistent advantage over the baseline. In most cases, *AvgE* slightly hurts performance while *ConcE* slighty improves it.

Our evaluation also suggests that best performing models in word similarity tasks do not necessarily achieve the best performance in other NLP tasks. When considering only word embeddings as features for sentence classification (*Words* method), we observe that the EXT model on average performs better than the Win5 and LG models, while the opposite is true for word similarity evaluation. This indicates that providing additional contextual information for training embeddings results in less specialized embeddings for particular types of semantic similarity evaluations, but can be useful for a wide range of sentence level classification tasks.

While the purpose of our experiments is a comparison of embeddings and little hyperparameter tuning was done for the classifiers, results of the CNN using EXT Wavg representations for QC (95.0) and RI (84.31) are close to the best reported results with specifically engineered systems for these tasks: 96.0 for QC (Mou et al., 2015) and 85.6 for RI (Xu et al., 2015). As our method does not depend on a specific classification setting it would be interesting to see if those approaches can further improve using dependency based representations.

7 Conclusions

We compare a window based, a dependency based and an extended dependency based skipgram model in word similarity and sentence classification tasks of question classification, binary sentiment prediction and semantic relation identification. For the sentence classification, we use three classifiers (SVM, CNN, LSTM) and experiment with several methods of utilizing dependency context feature embeddings to create representations that capture the syntactic role of words in dependency graphs. We reaffirm that dependency based models produce word embeddings that better capture functional properties of words and that window based models better capture topical similarity. The dependency based word embeddings largely improved the performance of the three classifiers for question classification and semantic relation identification, but only marginally for sentiment prediction. Finally, using dependency context features along with the word embeddings we observed better performance for the three classifiers in each task.

Abstract

Traditional convolutional neural network (CNN) based query classification uses linear feature mapping in its convolution operation. The recurrent neural network (RNN), differs from a CNN in representing word sequence with their ordering information kept explicitly. We propose using a deep long-short-term-memory (DLSTM) based feature mapping to learn feature representation for CNN. The DLSTM, which is a stack of LSTM units, has different order of feature representations at different depth of LSTM unit. The bottom LSTM unit equipped with input and output gates, extracts the first order feature representation from current word. To extract higher order nonlinear feature representation, the LSTM unit at higher position gets input from two parts. First part is the lower LSTM unit's memory cell from previous word. Second part is the lower LSTM unit's hidden output from current word. In this way, the DLSTM captures the nonlinear nonconsecutive interaction within *n*-grams. Using an architecture that combines a stack of the DLSTM layers with a tradition CNN layer, we have observed new state-of-the-art query classification accuracy on benchmark data sets for query classification.

1 Introduction

Convolutional neural networks (CNNs) have achieved significant improvements for query classification. CNNs capture the correlations of spatial or temporal structures with different resolutions using their temporal convolution operators. A pooling strategy on these local correlations extracts invariant regularities.

However, CNNs use simple linear operations on *n*-gram vectors that are formed by concatenating word vectors. The linear operation together with the concatenation may not be sufficient to model the nonconsecutive dependency and interaction within the *n*-grams. For example, in the query "not a total loss", nonconsecutive dependency "not loss" is the key information that is not well addressed by the linear operation with simple concatenation.

In this paper, we propose to use deep long-short-term-memory (DLSTM) based feature mapping to capture high order nonlinear feature representations. LSTM (Hochreiter and Schmidhuber, 1997) is one type of recurrent neural networks (RNNs) that have achieved remarkable performance in natural language processing and speech recognition (Sutskever et al., 2014; Graves et al., 2013).

The DLSTM is a stack of LSTM units where different order of nonlinear feature representation is captured by LSTM units at different depth. The bottom LSTM unit extracts the first order feature representation from current word. The LSTM unit at the higher position captures the higher order feature representation relying on the outputs from LSTM units at lower position, specifically, the memory cell from lower LSTM unit at previous word position and the hidden output from lower LSTM unit at current word position. Using DLSTM, linear feature mapping in traditional CNN can be obviously extended to nonlinear feature mapping. Moreover, the memory cell together with different gates in LSTM unit are able to model the nonconsecutive feature interaction and

Proceedings of NAACL-HLT 2016, pages 1501–1511,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

information decaying based on context. For example, in the query "not so good", the proposed DLSTM is expected to keep the information of "not" and "good" in the memory, and to decay the information about "so" via the forget gates.

Similar to CNNs where multiple convolution operations are used, we propose to stack different DLSTM feature mappings together to model multiple level nonlinear feature representations. The bottom DLSTM layer takes the original word sequence as input. The DLSTM layer at lower position fed its output to the adjacent higher DLSTM layer. In the proposed models, the concatenation of the multiple level feature representations are further reduced by the pooling operation. The prediction output is finally made based on the reduced feature representations.

We evaluated the proposed method on three benchmark data sets: Standford Sentiment Treebank dataset (Socher et al., 2013), TREC (Text Retrieval Conference) question type classification data set (Li and Roth, 2002) and ATIS (Airline Travel Information Systems) dataset (Hemphill et al., 1990). On Standford Sentiment Treebank dataset, our model obtains 51.9% accuracy on fine-grained classification and 88.7% accuracy on binary classification. The SVM based method uses a large amount of engineered features, and it outperforms LSTM and RNN based methods on TREC question type classification dataset. The DLSTM outperforms other neural network based methods without using engineered features. On ATIS data, DLSTM achieves 97.9% F1 score, which is better than the previous best F1 score of 95.6% using the same data settings.

2 Related Work

Deep neural networks (Bengio, 2009; Deng and Yu, 2014; Hinton et al., 2006) dominates natural language processing (Socher, 2012; Collobert et al., 2011; Gao et al., 2014). They have achieved cutting-edge performance in various tasks such as language modeling (Mikolov et al., 2010; Sundermeyer et al., 2012), machine translation (Bahdanau et al., 2014; Cho et al., 2014; Jean et al., 2015), slot filling (Yao et al., 2014a; Shi et al., 2015a) and syntactic parsing (Wang et al., 2015; Collobert et al., 2011). For query classifications, recurrent neural networks (RNNs) and convolutional neural networks (CNNs) have emerged as top performing architectures (Zhang and Wallace, 2016; Kim, 2014; Kalchbrenner et al., 2014; Ravuri and Stolcke, 2015a).

Due to its superior ability to memorize long distance dependencies, LSTMs have been applied to extract the sentence-level continuous representation (Ravuri and Stolcke, 2015a; Tang et al., 2015; Tai et al., 2015). When the LSTM is applied to model a sentence, memory cell from the ending word in the sentence carries the information of the whole sentence. The LSTM hidden vector from the ending word is directly used as sentence feature representation in (Ravuri and Stolcke, 2015a). Alternatively, a sentence is represented by the average of LSTM hidden vectors from its words (Tang et al., 2015). Inspired from recursive neural networks (Socher et al., 2011a), LSTM is further combined with a tree structure to model sentence representation (Tai et al., 2015).

CNNs have been originally developed for image processing (Lecun et al., 1998). They are firstly applied by Collobert et al. (2008; 2011) for natural language processing tasks using max-over-time pooling method to aggregate convolution layer vectors. CNNs have also been applied to spoken language understanding (Shi et al., 2015b), information retrieval (Shen et al., 2014) and semantic parsing (Yih et al., 2015). Kalchbrenner et al. (2014) proposed to extend CNNs max-over-time pooling to *k*-max pooling for sentence modeling. Remarkable query classification performance on different benchmark datasets have been achieved by integrating CNNs with different feature mapping channels and pre-trained word vectors (Zhang and Wallace, 2015; Kim, 2014). Recently, Mou et al. (2015) proposed to model sentences by tree structured CNNs.

CNNs and LSTMs are complementary in their modeling capabilities; CNNs are good at capturing local invariant regularities and LSTMs are good at modeling temporal features. The combination of CNNs and LSTMs achieves improved performances in speech recognition (Sainath et al., 2015) and query classification (Tang et al., 2015; Zhou et al., 2015). In these models, the basic architecture is the LSTM that models sequence representation from local features captured by CNNs.

Different from the above methods, our method use LSTM units to model the nonlinear and non-consecutive local features. CNNs are placed on top of these local features for query classification. Our motivation is to use LSTM replace the linear feature mapping in convolution operation where the feature mapping is a multiplication of the word vectors with a filter matrix. So our proposed model is still CNN based model but using DLSTM as feature mapping for convolution operation.

Our work is closely related to tensor product based CNNs (Lei et al., 2015) that expand CNN feature representation capacity with non-consecutive *n*-grams. They improve the query modeling from two aspects. Firstly, tensor products enable the nonlinear feature vector interactions between adjacent words. Secondly, an exponentially decaying weight is applied to represent non-consecutive *n*-gram features. Instead of using tensor products as feature mapping, we propose to apply DLSTM to address these two aspects. Nonlinear feature mapping can be achieved by the DLSTM that equipped with nonlinear activation function. The nonconsecutive feature interaction is well addressed by the memory cell and different gates in LSTM unit. In particular, the forget gate is able to decay the information according to the context rather than a fixed decaying weight in tensor product based CNNs.

3 CNN Based Query Classification Using DLSTM Feature Mapping

3.1 Linear Feature Mapping in CNN

Let k-dimensional vector $x_t \in \mathbb{R}^k$ be the continuous feature representation of the tth word in a sentence. A sentence with l words is represented by $x_{0:l-1} = [x_0; x_2; ...; x_{l-1}]$ that is a concatenation of all word vectors. The traditional CNN (Collobert et al., 2011; Kim, 2014) takes such sentence feature vector as input.

Different filters $M_j \in \mathbb{R}^{nd*h}$ are applied in convolution operation to map each n-gram feature vector $x_{t:t+n-1}, t \in (0, l-n)$ to an h-dimensional feature vector $c_{t,j}$.

$$c_{t,j} = M_j^T \cdot x_{t:t+n-1} + b_j, \tag{1}$$

where b_j is the bias in filter j.

The resulting feature vector $c_{t,j}$ are often passed through non-linear element-wise transformations (e.g. the hyperbolic tangent and rectifier linear unit) as well as pooling operations. After aggregation or reduction by different pooling operations such as the max-over-time pooling (Collobert et al., 2011; Kim, 2014) and the average pooling (Lei et al., 2015), a constant dimensional feature vector is generated for sentences with various lengths.

In traditional CNNs, the concatenated word vectors are mapped linearly to feature coordinates as shown in Equation (1). Such linear feature mapping can be improved from the following two aspects, one is to extend linear mapping to nonlinear mapping. The other one is to improve the consecutive feature mapping to nonconsecutive feature mapping. For example, in the query “not a total loss”, “not loss” is the key sentiment. By using nonconsecutive feature representation, the information about “not loss” could be addressed. Lei et al. (2015) extends the linear feature mapping to tensor based feature mapping. To model the nonconsecutive *n*-grams, a decaying weight is applied to control the information carryover. In this paper, we propose to replace the linear feature mapping using DLSTM that captures the nonlinear and nonconsecutive feature interaction within *n*-grams. Rather than setting a fixed decaying weight, the proposed architecture is able to control the information decaying according to the context information.

3.2 Feature Mapping Based on Deep Long Short Term Memory

Figure 1 gives the basic architecture of a three-order nonlinear feature mapping in DLSTM. The bottom LSTM$_0$ extract the first order information from word input vector x_t. It is equipped with input gate and output gate. The input gate automatically controls the information saving in memory cell that will be passed to higher order LSTM unit. The output gate modifies the information from the memory cell to represent current word.

$$i_{0,t} = sigmoid(W_i x_t + b_i) \tag{2}$$

$$\tilde{c}_{0,t} = \tanh(W_c x_t + b_c) \tag{3}$$

$$c_{0,t} = i_{0,t} * \tilde{c}_{0,t} \tag{4}$$

$$o_{0,t} = sigmoid(W_o x_t + V_o c_{0,t} + b_o) \tag{5}$$

$$h_{0,t} = o_{0,t} * \tanh(c_{0,t}) \tag{6}$$

On top of the bottom LSTM$_0$ unit, we analogously

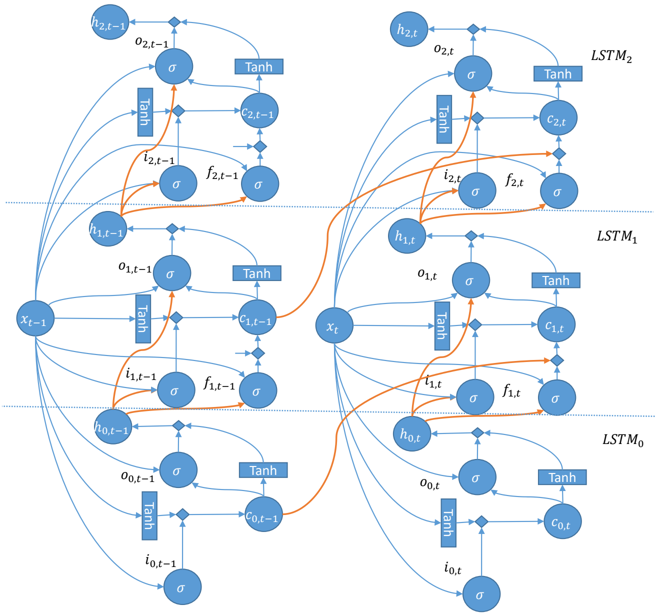

Figure 1: DLSTM based nonlinear feature mapping for bigram "$x_{t-1}x_t$". Three LSTM units are used to extract features from each word position. The bottom LSTM_0 is used for first order feature extraction from the current word. The output from the lower LSTM unit at current word position and the memory cell from lower LSTM at previous word position are fed to the higher LSTM units. Such information propagation is highlighted in the figure by bold orange lines.

stack two LSTM units LSTM_1 and LSTM_2 to extract nonlinear feature representations from bigram and trigram, respectively. The LSTM_j is formulated as follows:

$$i_{j,t} = sigmoid(W_i x_t + U_i h_{j-1,t} + b_i) \quad (7)$$

$$\tilde{c}_{j,t} = \tanh(W_c x_t + U_c h_{j-1,t} + b_c) \quad (8)$$

$$f_{j,t} = sigmoid(W_f x_t + U_f h_{j-1,t} + b_f) \quad (9)$$

$$c_{j,t} = i_{j,t} * \tilde{c}_{j,t} * c_{j-1,t-1} + f_{j,t} * c_{j-1,t} \quad (10)$$

$$o_{j,t} = sigmoid(W_o x_t + U_o h_{j-1,t} + V_o c_{j,t} + b_o) \quad (11)$$

$$h_{j,t} = o_{j,t} * \tanh(c_{j,t}) \quad (12)$$

Due to the effect from different gates that controls the information saving, expressing and decaying, LSTM_1 and LSTM_2 are able to model the non-consecutive interaction in n-grams. Take "not so good" as a example. LSTM_0 extract the nonlinear feature mapping from word "good" as $h_{0,2}$. The LSTM_1 takes $c_{0,1}$ (carries the information from word "so") and $h_{0,2}$ as input. Due to the effect of forget gate, we expect the output $h_{1,2}$ from LSTM_1 to address more on word "good" rather than "so". By further stacking LSTM_2, information about the word "not" and "good" should be emphasized by the proposed DLSTM.

Note the sum of the resulting outputs from these LSTM units is used as the high order feature representation of a n-gram ending with word x_t. So the original sequence input $x_{0:l-1}$ is mapped to a sequence of feature vector $z_{0:l-1} = [z_0, z_1, ..., z_{l-1}]$, where $z_j = h_{0,j} + h_{1,j} + h_{2,j}$.

The proposed DLSTM architecture is characterized by the following two features:

1. Weight Sharing: LSTM_1 and LSTM_2 are identical LSTM units that share the same weights. The bottom LSTM unit LSTM_0 also shares the corresponding weights with other LSTM units such as W_i, W_c and W_o. By sharing weights among different LSTM units, we can effectively reduce the risk of model over-fitting issue. At the same time, LSTM is good at capturing temporal regularities. By sharing weights, the LSTM units can learn the temporal dependencies from being exposed to different order of n-grams during the training.

2. Memory Cell Interaction: To model the nonlinear feature interaction in n-gram vectors, traditional LSTM unit is modified by Equation (10) in which the memory cell stores the interaction of different order memory cells. In this way, the feature interaction in n-grams is characterized by the memory cell interactions.

To stack the LSTM unit deeper, the depth-gated LSTM (Yao et al., 2015) and the highway network (Srivastava et al., 2015; Zhang et al., 2015) also allow the memory cell flow across LSTM units at different depth. There are three basic differences between these architectures with the proposed DLSTM. Firstly, in their architectures, LSTM units at different depth are different LSTMs that have different weight matrices. In our model, the LSTM units in DLSTM share weight matrices with each other. Secondly, in their proposed architecture, the memory cell is carried over to higher LSTM unit for facilitating model training. Because the networking training becomes more difficult with increasing model depth. In our

DLSTM, the LSTM unit at higher position takes the memory cell from lower LSTM unit mainly for feature interaction in n-grams. Finally, an additional "depth" gate is applied in their architecture to control the information flow across different layers. In our model, the input gate in higher LSTM unit controls the interaction between the memory cells extracted from previous word and current word.

3.3 The Architecture

Figure 3 gives the whole architecture of the proposed query classification system. A DLSTM layer first maps the input sequence to a sequence of high order nonlinear feature representations z^0. Instead of being directly used for query classification, the feature representation z^0 is further processed by a stack of DLSTM layers illustrated in previous section. In such stacked DLSTM layers, the output z^i of the ith DLSTM layer, is used as the input for the $i+1$th DLSTM layer parameterized by a different set of weight matrices. As shown in Figure 3, the resulting feature representations $z^0, z^1, ..., z^d$ of all these layers are concatenated. Finally, an average pooling is applied to reduce the sentence feature representation to a fixed dimensional vector that is further fed to a softmax function to obtain the prediction output.

3.4 Learning and Regularization

In the classification layer, the prediction output is obtained by the following softmax function.

$$softmax(y)_j = \frac{\exp(y_j)}{\sum_{i=1}^{i=m} \exp(y_i)}, \qquad (13)$$

where y is a m-dimensional vector. The model is trained by minimizing cross-entropy on the given training data set. To avoid overfitting during training, $L2$ regularization and dropout (Hinton et al., 2012) are used. The $L2$ regularization is applied to constrain all weight matrices using the same regularization weight. The dropout is only applied to the output of each DLSTM layer.

In the training, the model weights are updated using mini-batch stochastic gradient descent (SGD). We adapt a per-feature learning rate control method (AdaGrad) (Duchi et al., 2011) to dynamically tune the learning rate as follows:

$$\alpha_{t,i} = \frac{\alpha}{\sqrt{\sum_{j=1}^{t} g_{j,i}^2 + \varepsilon}}, \qquad (14)$$

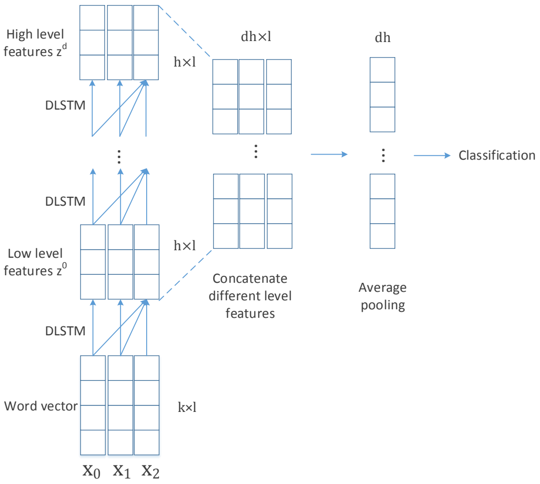

Figure 2: CNN based query classification using DLSTM feature mapping. The input sequence is represented by a $k \times l$ matrix where column t is the word vector for the tth word in the sequence. The word vectors are mapped by a stack of DLSTM layers to multi-level feature representations $z^0, ..., z^d$. As illustrated in Figure 1, each level feature representation is the sum of outputs from different LSTM units. The multi-level features are concatenated and reduced to a dh-dimensional vector where d is the number of DLSTM layers, h is the output size of each LSTM unit. A classification layer gives the prediction output.

where $\alpha_{t,i}$ is the learning rate for weight i at epoch t. $\sum_{j=1}^{t} g_{j,i}$ sums all the historical gradients of weight i. A small positive ε is applied to make the AdaGrad robust. ε is usually set to $1e-5$.

4 Experiments

4.1 Datasets

We evaluate the proposed query classification models on sentence sentiment classification, question type categorization and query intent detection tasks.

For sentence sentiment classification, the Stanford Sentiment Treebank (Socher et al., 2013) is used. In this dataset, 11855 English sentences are annotated at both sentence level and phrases level with fine-grained labels (very positive, positive, neutral, negative and very negative). We use the provided data split, which has 8544 sentences for training, 1101 sentences for developing and 2210 sentences for testing. This dataset also provides a binary classification variant that ignores the neutral sentences. The binary classification task in this dataset has 6920 sentences for training, 872 sentences for developing and 1821 sentences for testing. There are in total 17835 unique running words for fine-grained dataset and 16185 for binary version dataset.

For query intent detection, ATIS (airline travel information system) dataset (Hemphill et al., 1990; Yao et al., 2014b) is used. This dataset is mainly about the air travel domain with 26 different intents such as "flight", "$ground_service$" and "city". There are 893 utterances for testing (ATIS-III, Nov93 and Dec94), and 4978 utterances for training (rest of ATIS-III and ATIS-II). There are 899 unique running words and 22 intents in the training data.

The question type classification task is to classify a question into a specific type, which is a very important step in question answering system. In TREC (Text Retrieval Conference) data (Li and Roth, 2002), all the questions are divided into 6 categories, including "human", "entity", "location", "description", "abbreviation" and "numeric". The dataset in total has 5952 questions, 5452 of them for training, the rest for testing. The vocabulary size of TREC dataset is 9592.

Following previous work (Iyyer et al., 2015; Tai et al., 2015; Lei et al., 2015), we used word vectors pre-trained on large unannotated corpora to achieve better generalization capability. In this paper, we used a publicly available 300 dimensional GloVe word vectors that are trained using Common Crawl with 840B tokens and 2.2M vocabulary size.

4.2 Settings

We implemented our model based on Theano library (Bastien et al., 2012). All our models are trained on Nvidia Tesla K40m.

We performed extensive hyperparameter selection based on Stanford Sentiment Treebank Binary version of validation data. The selected hyperparameters were directly used for all datasets. To investigate the robustness of the proposed method, we ran each configuration 10 times using different random initialization (random seed ranges from 1 to 10).

For final models, we set the initial learning rate to 0.1, $L2$ regularization weight to $1e-5$, the dropout probability to 0.5 and mini-batch size to 64. We use hidden layer size 256 for all the models described in the experiments. The number of the DLSTM layers and the number of the LSTM units in each DLSTM are both set to 3. So basically there are 9 LSTM units are used for each word position.

For all models, we set maximum iteration number 100 to terminate the training process. For sentiment classification task, during the training, the model with the best classification accuracy on validation data was used as final model for testing. For question type classification and query intent detection, there wasn't validation data. So we simply use the model trained at the 100th iteration as the final model for testing.

model	Acc
discriminative(Tur et al., 2010)	95.5
SVM (Shi et al., 2015b)	95.6
joint-RNN(Shi et al., 2015b)	95.2
ours	**97.9**

Table 2: ATIS intent classification accuracy comparison of different models.

Table 1 lists results for sentiment classification.

There are four blocks in the table. The bottom block gives the results from our model. The third blocks are methods related to CNNs. The second block shows the results from recursive neural network based approaches. The other baseline methods are listed in the top block.

The top block shows that the traditional methods such as SVM using ngram features and neural network using bag-of-words features (**Nbow**) perform much worse than **Para-vec** and **DAN** using word vectors that are pre-trained on large amount of unlabeled data. **Para-vec** builds a logistic regression on top of paragraph vectors. **DAN** is a deep neural network takes the average of word vectors as input.

In addition to pre-trained word vectors, syntactic compositional information can be used to improve the sentiment classification accuracy. **RAE** is a tree structured Antoencoder model based on pre-trained word vectors from Wikipedia. **MVRNN** further improves the recursive neural network by assigning each node with a matrix to learn the meaning change of neighboring words and phrases. To address large amount of different vectors and matrices involved in **MVRNN**, **RNTN** proposed to use one single tensor based function to model all nodes. By making the tree-structured recursive neural networks deeper, significant improvement has been achieved by **DRNN**. According to our knowledge, the best compositional information based model is achieved by **RLSTM** that combines LSTM unit with tree-structure.

By comparing the classification accuracy between second blocks and third blocks, we see that CNN based models in general perform better than recursive neural network based methods. Another advantage of CNN based methods is that they can be generalized to any language without dependency over compositional information. **DCNN** uses a dynamic *k*-max pooling operator function in CNN. To explore the task specific word vectors and the general word vectors pre-trained on large News dataset, **CNN-MC** equips CNN with two feature mapping channels. **CNN-nostatic** gives the results by only making use of general word vectors. The best published classification results are achieved by **TCNN** that is tensor based CNN.

In this paper, the proposed method is closely related to **TCNN**. Instead of using tensor products to replace linear convolution operation, our method exploits the nonlinear feature mapping through DLSTM. Rather than setting specific decaying weight to model non-consecutive *n*-gram features in tensor based CNN, the different gates automatically adjust the information storing, removing and outputting according to context.

Following the work of **TCNN**, to leverage the phrases level annotation in Standford Sentiment Treebank, all phrases and their corresponding labels are added to training data as additional sequences. The bottom line of Table 1 shows that our models achieved the state-of-the-art performance on sentiment classification task.

For the best settings described above, we ran each model 10 times with different random initialization. The average and standard deviation for fine-grained classification are 50.7% and 1.04%, for binary classification 88% and 0.41%. Comparing with **TCNN**, our model is more sensitive to the parameter random initialization. In the future, some efforts should be used to analyze and address this issue.

4.4 Results on ATIS

ATIS dataset is widely used to test spoken language understanding system. As shown in Table 2, SVM using *n*-grams performs better than simple RNN and CNN based approach. **joint-RNN** is a query classification and slot filling joint training model where CNN is applied on top of slot tagging RNN for query classification. In this way, **joint-RNN** actually implicitly makes use of slot tag information for query classification. However, **joint-RNN** doesn't take ad-

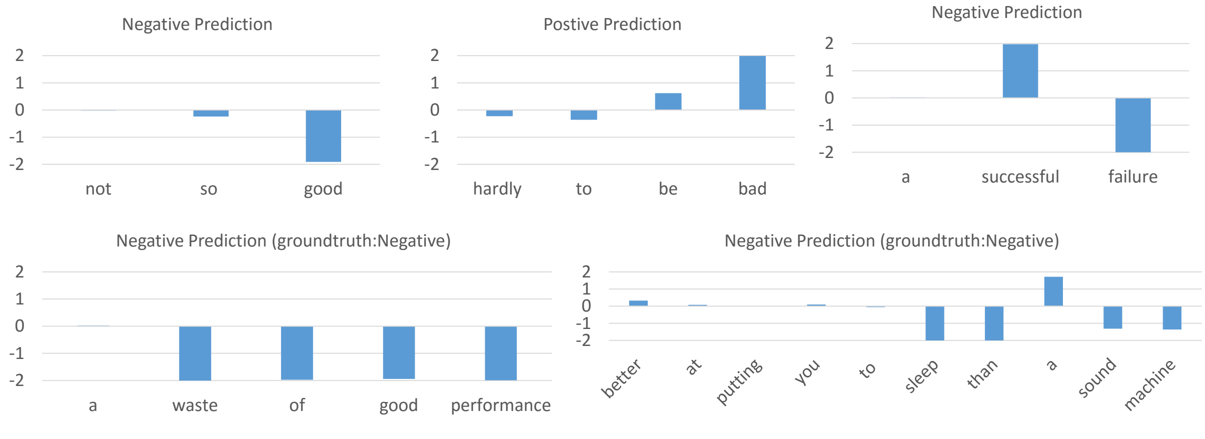

Figure 4: Example predictions given by our model trained on Stanford Sentiment Treebank fine-grained data. The expected sentiment score of each word is plotted in the figure. The score range from -2 to 2, where a score -2 means very "negative", 0 stands for "neutral" and 2 means "very positive".

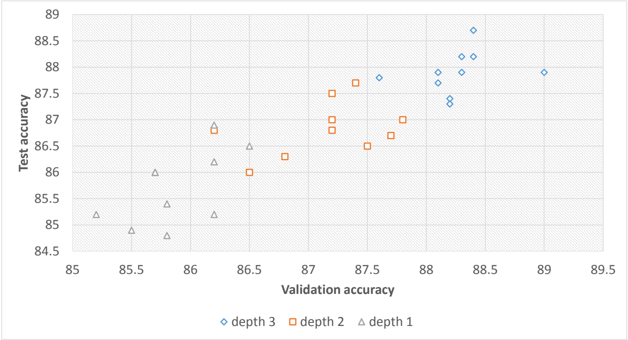

Figure 3: Stanford Sentiment Treebank Binary Classification accuracy comparison among models using the same parameter configuration except the number of DLSTM layers. For each number of DLSTM layers, 10 models are run independently using different random initialization. Horizontal axis gives the validation accuracy. Vertical axis shows the test accuracy.

vantage of word vectors trained on large amount of unlabeled data. Based on pre-trained word vectors, our models obtain more than 2% absolute classification accuracy improvement over the published best model.

In ATIS data, about 70% of queries is categorized to "flight" intent. Recent work using RNN for utterance classification (Ravuri and Stolcke, 2015b; Ravuri and Stolcke, 2015a) simplifies it to a "flight" VS "others" binary classification task. In their paper, using word based LSTM, they achieve 97.55% classification accuracy. By using extra name entity features, word based gated RNN obtains 98.42% classification accuracy.

4.5 Results on TREC Question Type Classification

Table 3 gives the TREC question type classification accuracy of our models with other baseline models. Different from the sentiment classification task, the shallow models using diverse engineered feature performs better than CNN and LSTM based models. Previous best classification results on TREC data is achieved by **SVM** using unigrams, bigrams, wh-word, head word, POS tags, hypernyms, WordNet synsets and a bunch of hand-coded rules.

AdaSent is a self adaptive hierarchical sentence model based on gating networks with level pooling. As shown in Table 3, CNN and LSTM achieve similar performances on question type classification. Recently **CLSTM** achieves substantial improvement over previous neural network based methods. In **CLSTM**, CNN is used to extract high level phrase representation. Such local segment representation is fed into LSTM to model whole sequence representation. Different with **CLSTM** that is an LSTM based sequence model with CNN for local feature extraction, our model is CNN based model using DLSTM for non-linear feature mapping. Our model outperforms previous neural network based models without relying on task specific feature engineering.

4.6 Deep Architecture

One critical hyperparameter in the proposed method is the number of DLSTM layers. On sentiment binary classification task, we run our model 10 times by keeping all the hyperparameters the same except the number of DLSTM layers using different random initialization. As observed from Figure 3, the better performance is achieved by deeper architecture. Our model achieves the best classification result by stacking 3 DLSTM layers that actually leverages 9 different LSTM units to extract the nonlinear feature from *n*-grams.

4.7 Examples

Figure 4 demonstrates some examples and their sentiments predicted by our model trained on fine-grained classification data. In order to see how the nonlinear feature mapping captures the sentiment at each word position in the query, we follow the strategy used in (Lei et al., 2015) where the softmax function is directly applied on the concatenated feature mapping without passing through the average pooling layer. So the sentiment distribution p_t at tth word is computed as $p_t = W^T[z_t^0, z_t^1, ..., z_t^d]$. The expected value over the probability distribution $\sum_{s=-2}^{2} s.p_t$ is used as the sentiment score that is plotted in Figure 4. In the figure, the sentiment score ranges from -2 to 2, where -2 means very negative, 2 mean very positive and 0 means neutral.

Five examples are illustrated in the figure where the first row gives the synthetic examples to show that our model is able to model the nonconsecutive interaction within *n*-grams. For example, in query "hardly to be bad", even though word "hardly" is not directly modifying word "bad", our model still be able to capture such sentiment changes.

The second row of the figure shows the examples from fine-grained classification testing data. Both the example show that our model to some degree can capture sentiment of the satire. Especially the last example, our model actually gives negative prediction, even no word in the query really means negative.

5 Conclusions

We have proposed a deep long-short-term-memory (DLSTM) nonlinear nonconsecutive feature mapping architecture to replace traditional linear mapping in the convolutional neural network based query classification. Each LSTM unit in the DLSTM is responsible for capturing different order feature representation from word segments. The bottom LSTM unit equipped with input gate and output gate, extracts the nonlinear feature from unigram. The higher LSTM unit in the DLSTM takes the outputs from lower LSTM units as input. In such way, the higher LSTM unit is able to capture nonlinear feature representation from higher order *n*-grams. The sum of different LSTM units is used as the output of the DLSTM layer. The DLSTM output rather than being directly used as input to convolutional neural network for query classification, is passed through a stacked DLSTM layers. The query is finally represented by the concatenation of the outputs from the stacked DLSTM layers.

We evaluated the proposed models on three benchmark datasets–Stanford Sentiment Treebank dataset, TREC dataset and ATIS dataset. On both sentiment classification dataset and ATIS dataset, our model achieved the state-of-the-art performance. On TREC question type classification, SVM based model using extra engineered features still performed better than our model. But we noticed that the proposed method outperformed all the other neural network based approaches.

Abstract

The goal of sentence and document modeling is to accurately represent the meaning of sentences and documents for various Natural Language Processing tasks. In this work, we present Dependency Sensitive Convolutional Neural Networks (DSCNN) as a general-purpose classification system for both sentences and documents. DSCNN hierarchically builds textual representations by processing pretrained word embeddings via Long Short-Term Memory networks and subsequently extracting features with convolution operators. Compared with existing recursive neural models with tree structures, DSCNN does not rely on parsers and expensive phrase labeling, and thus is not restricted to sentence-level tasks. Moreover, unlike other CNN-based models that analyze sentences locally by sliding windows, our system captures both the dependency information within each sentence and relationships across sentences in the same document. Experiment results demonstrate that our approach is achieving state-of-the-art performance on several tasks, including sentiment analysis, question type classification, and subjectivity classification.

1 Introduction

Sentence and document modeling systems are important for many Natural Language Processing (NLP) applications. The challenge for textual modeling is to capture features for different text units and to perform compositions over variable-length sequences (e.g., phrases, sentences, documents). As a traditional method, the bag-of-words model treats sentences and documents as unordered collections of words. In this way, however, the bag-of-words model fails to encode word orders and syntactic structures.

By contrast, order-sensitive models based on neural networks are becoming increasingly popular thanks to their ability to capture word order information. Many prevalent order-sensitive neural models can be categorized into two classes: Recursive models and Convolutional Neural Networks (CNN) models. Recursive models can be considered as generalizations of traditional sequence-modeling neural networks to tree structures. For example, (Socher et al., 2013) uses Recursive Neural Networks to build representations of phrases and sentences by combining neighboring constituents based on the parse tree. In their model, the composition is performed in a bottom-up way from leaf nodes of tokens until the root node of the parsing tree is reached. CNN based models, as the second category, utilize convolutional filters to extract local features (Kalchbrenner et al., 2014; Kim, 2014) over embedding matrices consisting of pretrained word vectors. Therefore, the model actually splits the sentence locally into n-grams by sliding windows.

However, despite their ability to account for word orders, order-sensitive models based on neural networks still suffer from several disadvantages. First, recursive models depend on well-performing parsers, which can be difficult for many languages or noisy domains (Iyyer et al., 2015; Ma et al., 2015). Besides, since tree-structured neural networks are vulnerable to the vanishing gradient problem (Iyyer et al., 2015), recursive models require heavy label-

Proceedings of NAACL-HLT 2016, pages 1512–1521,
San Diego, California, June 12-17, 2016.

ing on phrases to add supervisions on internal nodes. Furthermore, parsing is restricted to sentences and it is unclear how to model paragraphs and documents using recursive neural networks. In CNN models, convolutional operators process word vectors sequentially using small windows. Thus sentences are essentially treated as a bag of n-grams, and the long dependency information spanning sliding windows is lost.

These observations motivate us to construct a textual modeling architecture that captures long-term dependencies without relying on parsing for both sentence and document inputs. Specifically, we propose Dependency Sensitive Convolutional Neural Networks (DSCNN), an end-to-end classification system that hierarchically builds textual representations with only root-level labels.

DSCNN consists of a convolutional layer built on top of Long Short-Term Memory (LSTM) networks. DSCNN takes slightly different forms depending on its input. For a single sentence (Figure 1), the LSTM network processes the sequence of word embeddings to capture long-distance dependencies within the sentence. The hidden states of the LSTM are extracted to form the low-level representation, and a convolutional layer with variable-size filters and max-pooling operators follows to extract task-specific features for classification purposes. As for document modeling (Figure 2), DSCNN first applies independent LSTM networks to each subsentence. Then a second LSTM layer is added between the first LSTM layer and the convolutional layer to encode the dependency across different sentences.

We evaluate DSCNN on several sentence-level and document-level tasks including sentiment analysis, question type classification, and subjectivity classification. Experimental results demonstrate the effectiveness of our approach comparable with the state-of-the-art. In particular, our method achieves highest accuracies on MR sentiment analysis (Pang and Lee, 2005), TREC question classification (Li and Roth, 2002), and subjectivity classification task SUBJ (Pang and Lee, 2004) compared with several competitive baselines.

The remaining part of this paper is the following. Section 2 discusses related work. Section 3 presents the background including LSTM networks and convolution operators. We then describe our architectures for sentence modeling and document modeling in Section 4, and report experimental results in Section 5.

2 Related Work

The success of deep learning architectures for NLP is first based on the progress in learning distributed word representations in semantic vector space (Bengio et al., 2003; Mikolov et al., 2013; Pennington et al., 2014), where each word is modeled with a real-valued vector called a word embedding. In this formulation, instead of using one-hot vectors by indexing words into a vocabulary, word embeddings are learned by projecting words onto a low dimensional and dense vector space that encodes both semantic and syntactic features of words.

Given word embeddings, different models have been proposed to learn the composition of words to build up phrase and sentence representations. Most methods fall into three types: unordered models, sequence models, and Convolutional Neural Networks models.

In unordered models, textual representations are independent of the word order. Specifically, ignoring the token order in the phrase and sentence, the bag-of-words model produces the representation by averaging the constituting word embeddings (Landauer and Dumais, 1997). Besides, a neural-bag-of-words model described in (Kalchbrenner et al., 2014) adds an additional hidden layer on top of the averaged word embeddings before the softmax layer for classification purposes.

In contrast, sequence models, such as standard Recurrent Neural Networks (RNN) and Long Short-Term Memory networks, construct phrase and sentence representations in an order-sensitive way. For example, thanks to its ability to capture long-distance dependencies, LSTM has re-emerged as a popular choice for many sequence-modeling tasks, including machine translation (Bahdanau et al., 2014), image caption generation (Vinyals et al., 2014), and natural language generation (Wen et al., 2015). Besides, RNN and LSTM can be both converted to tree-structured networks by using parsing information. For example, (Socher et al., 2013) applied Recursive Neural Networks as a variant of the standard RNN structured by syntactic trees to the sentiment analysis task. (Tai et al., 2015) also generalizes LSTM to Tree-LSTM where each LSTM unit combines information from its children units.

Recently, CNN-based models have demonstrated remarkable performances on sentence modeling and classification tasks. Leveraging convolution operators, these models can extract features from variable-length phrases corresponding to different filters. For example, DCNN in (Kalchbrenner et al., 2014) constructs hierarchical features of sentences by one-dimensional convolution and dynamic k-max pooling. (Yin and Schütze, 2015) further utilizes multichannel embeddings and unsupervised pretraining to improve classification results.

3 Preliminaries

In this section, we describe two building blocks for our system. We first discuss Long Short-Term Memory as a powerful network for modeling sequence data, and then formulate convolution and max-over-time pooling operators for the feature extraction over sequence inputs.

3.1 Long Short-Term Memory

Recurrent Neural Network (RNN) is a class of models to process arbitrary-length input sequences by recursively constructing hidden state vectors $\mathbf{h}_t$. At each time step t, the hidden state $\mathbf{h}_t$ is an affine function of the input vector $\mathbf{x}_t$ at time t and its previous hidden state $\mathbf{h}_{t-1}$, followed by a non-linearity such as the hyperbolic tangent function:

$$\mathbf{h}_t = \tanh(\mathbf{W}\mathbf{x}_t + \mathbf{U}\mathbf{h}_{t-1} + b) \tag{1}$$

where $\mathbf{W}$, $\mathbf{U}$ and b are parameters of the model.

However, traditional RNN suffers from the exploding or vanishing gradient problems, where the gradient vectors can grow or decay exponentially as they propagate to earlier time steps. This problem makes it difficult to train RNN to capture long-distance dependencies in a sequence (Bengio et al., 1994; Hochreiter, 1998).

To address this problem of capturing long-term relations, Long Short-Term Memory (LSTM) networks, proposed by (Hochreiter and Schmidhuber, 1997) introduce a vector of memory cells and a set of gates to control how the information flows through the network. We thus have the input gate $\mathbf{i}_t$, the forget gate $\mathbf{f}_t$, the output gate $\mathbf{o}_t$, the memory cell $\mathbf{c}_t$, the input at the current step t as $\mathbf{x}_t$, and the hidden state $\mathbf{h}_t$, which are all in $\mathbb{R}^d$. Denote the sigmoid function as σ, and the element-wise multiplication as $\odot$. At each time step t, the LSTM unit manipulates a collection of vectors described by the following equations:

$$\begin{aligned}
\mathbf{i}_t &= \sigma\left(\mathbf{W}^{(i)}\mathbf{x}_t + \mathbf{U}^{(i)}\mathbf{h}_{t-1} + b^{(i)}\right)\\
\mathbf{f}_t &= \sigma\left(\mathbf{W}^{(f)}\mathbf{x}_t + \mathbf{U}^{(f)}\mathbf{h}_{t-1} + b^{(f)}\right)\\
\mathbf{o}_t &= \sigma\left(\mathbf{W}^{(o)}\mathbf{x}_t + \mathbf{U}^{(o)}\mathbf{h}_{t-1} + b^{(o)}\right)\\
\mathbf{u}_t &= \tanh\left(\mathbf{W}^{(u)}\mathbf{x}_t + \mathbf{U}^{(u)}\mathbf{h}_{t-1} + b^{(u)}\right)\\
\mathbf{c}_t &= \mathbf{i}_t \odot \mathbf{u}_t + \mathbf{f}_t \odot \mathbf{c}_{t-1}\\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned} \tag{2}$$

Note that the gates $\mathbf{i}_t$, $\mathbf{f}_t$, $\mathbf{o}_t \in [0,1]^d$ and they control at time step t how the input is updated, how much the previous memory cell is forgotten, and the exposure of the memory to form the hidden state vector respectively.

3.2 Convolution and Max-over-time Pooling

Convolution operators have been extensively used in object recognition (LeCun et al., 1998), phoneme recognition (Waibel et al., 1989), sentence modeling and classification (Kalchbrenner et al., 2014; Kim, 2014), and other traditional NLP tasks (Collobert and Weston, 2008). Given an input sentence of length s: $[w_1, w_2, ..., w_s]$, convolution operators apply a number of filters to extract local features of the sentence.

In this work, we employ one-dimensional wide convolution described in (Kalchbrenner et al., 2014). Let $\mathbf{h}_t \in \mathbb{R}^d$ denote the representation of w_t, and $\mathbf{F} \in \mathbb{R}^{d \times l}$ be a filter where l is the window size. One-dimensional wide convolution computes the feature map $\mathbf{c}$ of length $(s + l - 1)$

$$\mathbf{c} = [c_1, c_2, ..., c_{s+l-1}] \tag{3}$$

for the input sentence.

Specifically, in wide convolution, we stack $\mathbf{h}_t$ column by column, and add $(l-1)$ zero vectors to both ends of the sentence respectively. This formulates an input feature map $\mathbf{X} \in \mathbb{R}^{d \times (s+2l-2)}$. Thereafter, one-dimensional convolution applies the filter $\mathbf{F}$ to each set of consecutive l columns in $\mathbf{X}$ to produce

$(s-l-1)$ activations. The k-th activation is produced by

$$\mathbf{c}_k = f\left(b + \sum_{i,j} (\mathbf{F} \odot \mathbf{X}_{k:k+l-1})_{i,j}\right) \qquad (4)$$

where $\mathbf{X}_{k:k+l-1} \in \mathbb{R}^{d \times l}$ is the k-th sliding window in $\mathbf{X}$, and b is the bias term. $\odot$ performs element-wise multiplications and f is an nonlinear function such as Rectified Linear Units (ReLU) or the hyperbolic tangent.

Then, the max-over-time pooling selects the maximum value in the feature map

$$c_{\mathbf{F}} = \max(\mathbf{c}) \qquad (5)$$

as the feature corresponding to the filter $\mathbf{F}$.

In practice, we apply many filters with different window sizes l to capture features encoded in l-length windows of the input.

4 Model Architectures

Convolutional Neural Networks have demonstrated state-of-the-art performances in sentence modeling and classification. Despite the fact that CNN is an order-sensitive model, traditional convolution operators extract local features from each possible window of words through filters with predefined sizes. Therefore, sentences are effectively processed like a bag of n-grams, and long-distance dependencies can be only captured if we have long enough filters.

To capture long-distance dependencies, much recent effort has been dedicated to building tree-structured models from the syntactic parsing information. However, we observe that these methods suffer from three problems. First, they require an external parser and are vulnerable to parsing errors (Iyyer et al., 2015). Besides, tree-structured models need heavy supervisions to overcome vanishing gradient problems. For example, in (Socher et al., 2013), input sentences are labeled for each subphrase, and softmax layers are applied at each internal node. Finally, tree-structured models are restricted to sentence level, and cannot be generalized to model documents.

In this work, we propose a novel architecture to address these three problems. Our model hierarchically builds text representations from input words without parsing information. Only labels at the root level are required at the top softmax layer, so there is no need for labeling subphrases in the text. The system is not restricted to sentence-level inputs: the architecture can be restructured based on the sentence tokenization for modeling documents.

4.1 Sentence Modeling

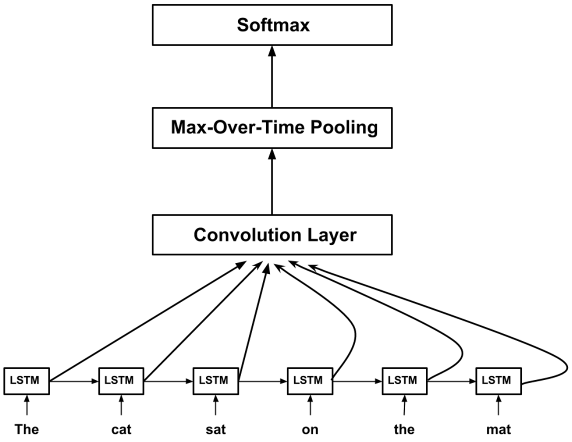

Figure 1: An example for sentence modeling. The bottom LSTM layer processes the input sentence and feed-forwards hidden state vectors at each time step. The one-dimensional wide convolution layer and the max-over-time pooling operation extract features from the LSTM output. For brevity, only one version of word embedding is illustrated in this figure.

Let the input of our model be a sentence of length s: $[w_1, w_2, ..., w_s]$, and c be the total number of word embedding versions. Different versions come from pre-trained word vectors such as word2vec (Mikolov et al., 2013) and GloVe (Pennington et al., 2014).

The first layer of our model consists of LSTM networks processing multiple versions of word embedding. For each version of word embedding, we construct an LSTM network where the input $\mathbf{x}_t \in \mathbb{R}^d$ is the d-dimensional word embedding vector for w_t. As described in the previous section, the LSTM layer will produce a hidden state representation $\mathbf{h}_t \in \mathbb{R}^d$ at each time step. We collect hidden state representations as the output of LSTM layers:

$$\mathbf{h}^{(i)} = [\mathbf{h}_1^{(i)}, \mathbf{h}_2^{(i)}, ..., \mathbf{h}_t^{(i)}, ..., \mathbf{h}_s^{(i)}] \qquad (6)$$

for $i = 1, 2, ..., c$.

A convolution neural network follows as the second layer. To deal with multiple word embeddings, we use filter $\mathbf{F} \in \mathbb{R}^{c \times d \times l}$, where l is the window size. Each hidden state sequence $\mathbf{h}^{(i)}$ produced by the i-th version of word embeddings forms one channel of the feature map. These feature maps are stacked as c-channel feature maps $\mathbf{X} \in \mathbb{R}^{c \times d \times (s+2(l-1))}$.

Similar to the single channel case, activations are computed as a slight modification of equation 4:

$$\mathbf{c}_k = f\left(b + \sum_{i,j,r} (\mathbf{F} \odot \mathbf{X}_{k:k+l-1})_{i,j,r}\right) \quad (7)$$

A max-over-time pooling layer is then added on top of the convolution neural network. Finally, the pooled features are used in a softmax layer for classification. A sentence modeling example is illustrated in Figure 1.

4.2 Document Modeling

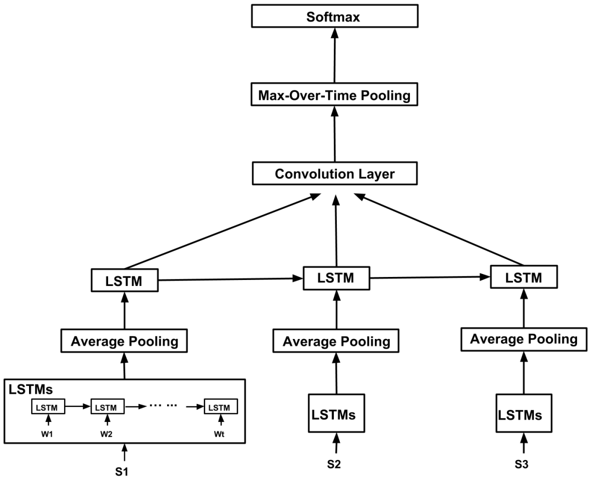

Figure 2: A schematic for document modeling hierarchy, which can be viewed as a variant of the one for sentence modeling. Independent LSTM networks process subsentences separated by punctuation. Hidden states of LSTM networks are averaged as the sentence representations, from which the high-level LSTM layer creates the joint meaning of sentences.

Our model is not restricted to sentences; it can be restructured to model documents. The intuition comes from the fact that as the composition of words builds up the semantic meaning for sentences, the composition of sentences establishes the semantic meaning for documents (Li et al., 2015).

Now suppose that the input of our model is a document consisting of n subsentences: $[s_1, s_2, ..., s_n]$. Subsentences can be obtained by splitting the document using punctuation (comma, period, question mark, and exclamation point) as delimiters.

We employ independent LSTM networks for each subsentence in the same way as the first layer of the sentence modeling architecture. For each subsentence we feed-forward the hidden states of the corresponding LSTM network to the average pooling layer. Take the first sentence of the document as an example,

$$\mathbf{h}_{s1}^{(i)} = \frac{1}{\text{len}(s1)} \sum_{j=1}^{\text{len}(s1)} \mathbf{h}_{s1,j}^{(i)} \quad (8)$$

where $\mathbf{h}_{s1,j}^{(i)}$ is the hidden state of the first sentence at time step j, and $\text{len}(s1)$ denotes the length of the first sentence. In this way, after the averaging pooling layers, we have a representation sequence consisting of averaged hidden states for subsentences,

$$\mathbf{h}^{(i)} = [\mathbf{h}_{s1}^{(i)}, \mathbf{h}_{s2}^{(i)}, ..., \mathbf{h}_{sn}^{(i)}] \quad (9)$$

for $i = 1, 2, ..., c$.

Thereafter, a high-level LSTM network comes into play to capture the joint meaning created by the sentences.

Similar as sentence modeling, a convolutional layer is placed on top of the high-level LSTM for feature extraction. Finally, a max-over-time pooling layer and a softmax layer follow to pool features and perform the classification task. Figure 2 gives the schematic for the hierarchy.

5 Experiments

5.1 Datasets

Movie Review Data (MR) proposed by (Pang and Lee, 2005) is a dataset for sentiment analysis of movie reviews. The dataset consists of 5,331 positive and 5,331 negative reviews, mostly in one sentence. We follow the practice of using 10-fold cross validation to report results.

Stanford Sentiment Treebank (SST) is another popular sentiment classification dataset introduced

Table 1: Experiment results of DSCNN compared with other models. Performance is measured in accuracy (%). Models are categorized into five classes. The first block is baseline methods including SVM and Naive Bayes and their variations. The second is the class of Recursive Neural Networks models. Constituent parsers and phrase-level supervision are needed. The third category is LSTMs. CNN models are fourth block, and the last category is a collection of other models achieving state-of-the-art results. **SVM**: Support Vector Machines with unigram features (Socher et al., 2013) **NB**: Naive Bayes with unigram features(Socher et al., 2013) **NBSVM-bi**: Naive Bayes SVM and Multinomial Naive Bayes with bigrams (Wang and Manning, 2012) **SVM$_S$**: SVM with features including uni-bi-trigrams, POS, parser, and 60 hand-coded rules (Silva et al., 2011) **Standard-RNN**: Standard Recursive Neural Network (Socher et al., 2013) **MV-RNN**: Matrix-Vector Recursive Neural Network (Socher et al., 2012) **RNTN**:Recursive Neural Tensor Network (Socher et al., 2013) **DRNN**: Deep Recursive Neural Network (Irsoy and Cardie, 2014) **Standard-LSTM**: Standard Long Short-Term Memory Network (Tai et al., 2015) **bi-LSTM**: Bidirectional LSTM (Tai et al., 2015) **Tree-LSTM**: Tree-Structured LSTM (Tai et al., 2015) **SA-LSTM**: Sequence Autoencoder LSTM (Dai and Le, 2015). For fair comparison, we report the result on **MR** trained without unlabeled data from IMDB or Amazon reviews. **DCNN**: Dynamic Convolutional Neural Network with k-max pooling (Kalchbrenner et al., 2014) **CNN-MC**: Convolutional Neural Network with static pretrained and fine-tuned pretrained word-embeddings (Kim, 2014) **MVCNN**: Multichannel Variable-Size Convolution Neural Network (Yin and Schütze, 2015) **Dep-CNN**: Dependency-based Convolutional Neural Network (Ma et al., 2015). Dependency parser is required. The result is for the combined model ancestor+sibling+sequential. **Neural-BoW** : Neural Bag-of-Words Models (Kalchbrenner et al., 2014) **DAN**: Deep Averaging Network (Iyyer et al., 2015) **Paragraph-Vector**: Logistic Regression on Paragraph-Vector (Le and Mikolov, 2014) **WRRBM+BoW(bnc)**: word representation Restricted Boltzmann Machine combined with bag-of-words features (Dahl et al., 2012) **Full+Unlabeled+BoW(bnc)**:word vector based model capturing both semantic and sentiment, trained on unlabeled examples, and with bag-of-words features concatenated (Maas et al., 2011)

by (Socher et al., 2013). The sentences are labeled in a fine-grained way (SST-5): {very negative, negative, neutral, positive, very positive}. The dataset has been split into 8,544 training, 1,101 validation, and 2,210 testing sentences. Without neutral sentences, SST can also be used in binary mode (SST-2), where the split is 6,920 training, 872 validation, and 1,821 testing.

Furthermore, we apply DSCNN on question type classification task on TREC dataset (Li and Roth, 2002), where sentences are questions in the following 6 classes: {abbreviation, entity, description, location, numeric}. The entire dataset consists of 5,452 training examples and 500 testing examples.

We also benchmark our system on the subjectivity classification dataset (SUBJ) released by (Pang and Lee, 2004). The dataset contains 5,000 subjective sentences and 5,000 objective sentences. We report 10-fold cross validation results as the baseline does.

For document-level dataset, we use Large Movie Review (IMDB) created by (Maas et al., 2011). There are 25,000 training and 25,000 testing examples with binary sentiment polarity labels, and 50,000 unlabeled examples. Different from Stanford Sentiment Treebank and Movie Review dataset, every example in this dataset has several sentences.

5.2 Training Details and Implementation

We use two sets of 300-dimensional pre-trained embeddings, word2vec[1] and GloVe[2], forming two channels for our network. For all datasets, we use 100 convolution filters each for window sizes of 3, 4, 5. Rectified Linear Units (ReLU) is chosen as the nonlinear function in the convolutional layer.

For regularization, before the softmax layers, we employ Dropout operation (Hinton et al., 2012) with dropout rate 0.5, and we do not perform any l_2 constraints over the parameters. We use the gradient-based optimizer Adadelta (Zeiler, 2012) to minimize cross-entropy loss between the predicted and true distributions, and the training is early stopped when the accuracy on validation set starts to drop.

As for training cost, our system processes around 4000 tokens per second on a single GTX 670 GPU. As an example, this amounts to 1 minute per epoch on the TREC dataset, converging within 50 epochs.

5.3 Pretraining of LSTM

We experiment with two variants of parameter initialization of sentence level LSTMs. The first variant (DSCNN in Table 1) initializes the weight matrices in LSTMs as random orthogonal matrices. In the second variant (DSCNN-Pretrain in Table 1), we first train sequence autoencoders (Dai and Le, 2015) which read input sentences at the encoder and reconstruct the input at the decoder. We pretrain separately on each task based on the same train/valid/test splits. The pretrained encoders are used to be the start points of LSTM layers for later supervised classification tasks.

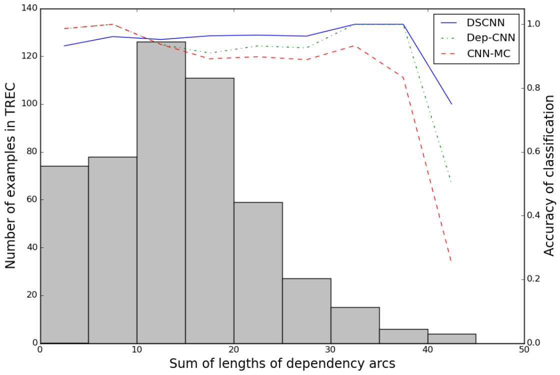

Figure 3: Number of sentences in TREC, and classification performances of DSCNN-Pretrain/Dep-CNN/CNN-MC as functions of dependency lengths. DSCNN and Dep-CNN clearly outperforms CNN-MC when the dependency length in the sentence grows.

5.4 Results and Discussions

Table 1 reports the results of DSCNN on different datasets, demonstrating its effectiveness in comparison with other state-of-the-art methods.

5.4.1 Sentence Modeling

For sentence modeling tasks, DSCNN beats all baselines on MR and TREC, and achieves the same best result on SUBJ as MVCNN. In SST-2, DSCNN only reports a slightly lower accuracy than MVCNN. In MVCNN, however, the author uses more resources including five versions of word embeddings. For SST-5, DSCNN is second only to

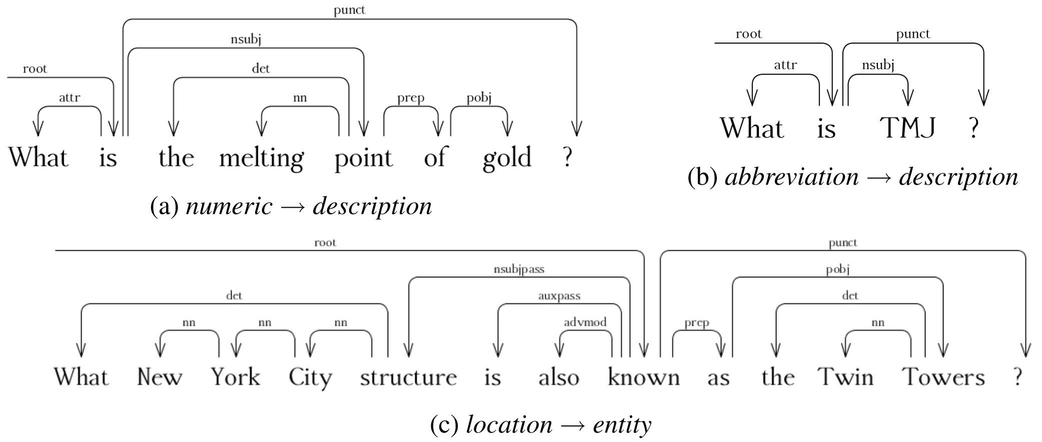
(a) *description → entity*

(b) *numeric → location*

(c) *entity → location*

(d) *entity → human*

Figure 4: TREC examples that are misclassified by CNN-MC but correctly classified by DSCNN. For example, CNN-MC labels (a) as *entity* while the ground truth is *description*. Dependency Parsing is done by ClearNLP (Choi and Palmer, 2012).



(a) *numeric → description*

(b) *abbreviation → description*

(c) *location → entity*

Figure 5: TREC examples that are misclassified by DSCNN. For example, DSCNN labels (a) as *description* while the ground truth is *numeric*. Dependency Parsing is done by ClearNLP (Choi and Palmer, 2012).

Tree-LSTM, which nonetheless relies on parsers to build tree-structured neural models.

The benefit of DSCNN is illustrated by its consistently better results over the sequential CNN models including DCNN and CNN-MC. The superiority of DSCNN is mainly attributed to its ability to maintain long-term dependencies. Figure 3 depicts the correlation between the dependency length and the classification accuracy. While CNN-MC and DSCNN are similar when the sum of dependency arc lengths is below 15, DSCNN gains obvious advantages when dependency lengths grow for long and complex sentences. Dep-CNN is also more robust than CNN-MC, but it relies on the dependency parser and predefined patterns to model longer linguistic structures.

Figure 4 gives some examples where DSCNN makes correct predictions while CNN-MC fails. In the first example, CNN-MC classifies the question as *entity* due to its focus on the noun phrase “worn or outdated flags”, while DSCNN captures the long dependency between “done with” and “flags”, and assigns the correct label *description*. Similarly in the second case, due to "Nile", CNN-MC labels the question as *location*, while the dependency between "depth of" and "river" is ignored. As for the third example, the question involves a complicated and long attributive clause for the subject "artery". CNN-MC gets easily confused and predicts the type as *location* due to words "from" and "to", while DSCNN keeps correct. Finally, "Lindbergh" in the last example make CNN-MC bias to *human*.

We also sample some misclassified examples of DSCNN in Figure 5. Example (a) fails because the numeric meaning of "point" is not captured by the word embedding. Similarly, in the second example, the error is due to the out-of-vocabulary word "TMJ" and it is thus apparently difficult for DSCNN to figure out that it is an abbreviation. Example (c) is likely to be an ambiguous or mistaken annotation. The finding here agrees with the discussion in Dep-CNN work (Ma et al., 2015).

5.4.2 Document Modeling

For document modeling, the result of DSCNN on IMDB against other baselines is listed on the last column of Table 1. Documents in IMDB consist of several sentences and thus very long: the average length is 241 tokens per document and the maximum length is 2526 words (Dai and Le, 2015). As a result, there is no result reported using CNN-based models due to prohibited computation time, and most previous works are unordered models including variations of bag-of-words.

DSCNN outperforms bag-of-words model (Maas et al., 2011), Deep Averaging Network (Iyyer et al., 2015), and word representation Restricted Boltzmann Machine model combined with bag-of-words features (Dahl et al., 2012). The key weakness of bag-of-words prevents those models from capturing long-term dependencies.

Besides, Paragraph Vector (Le and Mikolov, 2014) and SA-LSTM (Dai and Le, 2015) achieve better results than DSCNN. It is worth mentioning that both methods, as unsupervised learning algorithms, can gain much positive effects from unlabeled data (they are using 50,000 unlabeled examples in IMDB). For example in (Dai and Le, 2015), with additional data from Amazon reviews, the error rate of SA-LSTM on MR dataset drops by 3.6%.

6 Conclusion

In this work, we present DSCNN, Dependency Sensitive Convolutional Neural Networks for purpose of text modeling at both sentence and document levels. DSCNN captures long-term inter-sentence and intra-sentence dependencies by processing word vectors through layers of LSTM networks, and extracts features by convolutional operators for classification. Experiments show that DSCNN consistently outperforms traditional CNNs, and achieves state-of-the-art results on several sentiment analysis, question type classification and subjectivity classification datasets.

Abstract

We introduce a novel, simple convolution neural network (CNN) architecture – *multi-group norm constraint CNN (MGNC-CNN)* – that capitalizes on multiple sets of word embeddings for sentence classification. MGNC-CNN extracts features from input embedding sets independently and then joins these at the penultimate layer in the network to form a final feature vector. We then adopt a group regularization strategy that differentially penalizes weights associated with the subcomponents generated from the respective embedding sets. This model is much simpler than comparable alternative architectures and requires substantially less training time. Furthermore, it is flexible in that it does not require input word embeddings to be of the same dimensionality. We show that MGNC-CNN consistently outperforms baseline models.

1 Introduction

Neural models have recently gained popularity for Natural Language Processing (NLP) tasks (Goldberg, 2015; Collobert and Weston, 2008; Cho, 2015). For sentence classification, in particular, Convolution Neural Networks (CNN) have realized impressive performance (Kim, 2014; Zhang and Wallace, 2015). These models operate over *word embeddings*, i.e., dense, low dimensional vector representations of words that aim to capture salient semantic and syntactic properties (Collobert and Weston, 2008).

An important consideration for such models is the specification of the word embeddings. Several options exist. For example, Kalchbrenner et al. (2014) initialize word vectors to random low-dimensional vectors to be fit during training, while Johnson and Zhang (2014) use fixed, one-hot encodings for each word. By contrast, Kim (2014) initializes word vectors to those estimated via the word2vec model trained on 100 billion words of Google News (Mikolov et al., 2013); these are then updated during training. Initializing embeddings to pre-trained word vectors is intuitively appealing because it allows transfer of learned distributional semantics. This has allowed a relatively simple CNN architecture to achieve remarkably strong results.

Many pre-trained word embeddings are now readily available on the web, induced using different models, corpora, and processing steps. Different embeddings may encode different aspects of language (Padó and Lapata, 2007; Erk and Padó, 2008; Levy and Goldberg, 2014): those based on bag-of-words (BoW) statistics tend to capture associations (*doctor* and *hospital*), while embeddings based on dependency-parses encode similarity in terms of use (*doctor* and *surgeon*). It is natural to consider how these embeddings might be *combined* to improve NLP models in general and CNNs in particular.

Contributions. We propose MGNC-CNN, a novel, simple, scalable CNN architecture that can accommodate multiple off-the-shelf embeddings of variable sizes. Our model treats different word embeddings as distinct groups, and applies CNNs independently to each, thus generating corresponding feature vectors (one per embedding) which are then

Proceedings of NAACL-HLT 2016, pages 1522–1527,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

concatenated at the classification layer. Inspired by prior work exploiting regularization to encode structure for NLP tasks (Yogatama and Smith, 2014; Wallace et al., 2015), we impose different regularization penalties on weights for features generated from the respective word embedding sets.

Our approach enjoys the following advantages compared to the only existing comparable model (Yin and Schütze, 2015): (i) It can leverage diverse, readily available word embeddings with different dimensions, thus providing flexibility. (ii) It is comparatively simple, and does not, for example, require *mutual learning* or *pre-training*. (iii) It is an order of magnitude more efficient in terms of training time.

2 Related Work

Prior work has considered combining latent representations of words that capture syntactic and semantic properties (Van de Cruys et al., 2011), and inducing multi-modal embeddings (Bruni et al., 2012) for general NLP tasks. And recently, Luo et al. (2014) proposed a framework that combines multiple word embeddings to measure text similarity, however their focus was not on classification.

More similar to our work, Yin and Schütze (2015) proposed *MVCNN* for sentence classification. This CNN-based architecture accepts multiple word embeddings as inputs. These are then treated as separate 'channels', analogous to RGB channels in images. Filters consider all channels simultaneously. MVCNN achieved state-of-the-art performance on multiple sentence classification tasks. However, this model has practical drawbacks. (i) MVCNN requires that input word embeddings have the same dimensionality. Thus to incorporate a second set of word vectors trained on a corpus (or using a model) of interest, one needs to either find embeddings that happen to have a set number of dimensions or to estimate embeddings from scratch. (ii) The model is complex, both in terms of implementation and runtime. Indeed, this model requires pre-training and mutual-learning and requires days of training time, whereas the simple architecture we propose requires on the order of an hour (and is easy to implement).

3 Model Description

We first review standard one-layer CNN (which exploits a single set of embeddings) for sentence classification (Kim, 2014), and then propose our augmentations, which exploit multiple embedding sets.

Basic CNN. In this model we first replace each word in a sentence with its vector representation, resulting in a sentence matrix $\mathbf{A} \in \mathbb{R}^{s \times d}$, where s is the (zero-padded) sentence length, and d is the dimensionality of the embeddings. We apply a convolution operation between linear filters with parameters $\mathbf{w}_1, \mathbf{w}_2, ..., \mathbf{w}_k$ and the sentence matrix. For each $\mathbf{w}_i \in \mathbb{R}^{h \times d}$, where h denotes 'height', we slide filter i across $\mathbf{A}$, considering 'local regions' of h adjacent rows at a time. At each local region, we perform element-wise multiplication and then take the element-wise sum between the filter and the (flattened) sub-matrix of $\mathbf{A}$, producing a scalar. We do this for each sub-region of $\mathbf{A}$ that the filter spans, resulting in a *feature map* vector $\mathbf{c}_i \in \mathbb{R}^{(s-h+1) \times 1}$. We can use multiple filter sizes with different heights, and for each filter size we can have multiple filters. Thus the model comprises k weight vectors $\mathbf{w}_1, \mathbf{w}_2, ...\mathbf{w}_k$, each of which is associated with an instantiation of a specific filter size. These in turn generate corresponding feature maps $\mathbf{c}_1, \mathbf{c}_2, ...\mathbf{c}_k$, with dimensions varying with filter size. A *1-max pooling* operation is applied to each feature map, extracting the largest number o_i from each feature map i. Finally, we combine all o_i together to form a feature vector $\mathbf{o} \in \mathbb{R}^k$ to be fed through a softmax function for classification. We regularize weights at this level in two ways. (1) *Dropout*, in which we randomly set elements in $\mathbf{o}$ to zero during the training phase with probability p, and multiply p with the parameters trained in $\mathbf{o}$ at test time. (2) An l2 norm penalty, for which we set a threshold λ for the l2 norm of $\mathbf{o}$ during training; if this is exceeded, we rescale the vector accordingly. For more details, see (Zhang and Wallace, 2015).

MG-CNN. Assuming we have m word embeddings with corresponding dimensions $d_1, d_2, ...d_m$, we can simply treat each word embedding independently. In this case, the input to the CNN comprises multiple sentence matrices $\mathbf{A_1}, \mathbf{A_2}, ...\mathbf{A_m}$, where each $\mathbf{A}_l \in \mathbb{R}^{s \times d_l}$ may have its own width d_l. We then apply different groups of filters $\{\mathbf{w}_1\}, \{\mathbf{w}_2\}, ...\{\mathbf{w}_m\}$ independently to each $\mathbf{A}_l$, where $\{\mathbf{w}_l\}$ denotes the set of filters for $\mathbf{A}_l$. As in basic CNN, $\{\mathbf{w}_l\}$ may have multiple filter sizes, and multiple filters of each size may be introduced. At the classification layer we then obtain a feature vector $\mathbf{o}_l$ for each embedding set, and we can simply concatenate these together to form the final feature vector $\mathbf{o}$ to feed into the softmax function, where $\mathbf{o} = \mathbf{o_1} \oplus \mathbf{o_2} ... \oplus \mathbf{o_m}$. This representation contains feature vectors generated from all sets of embeddings under consideration. We call this method *multiple group CNN* (MG-CNN). Here groups refer to the features generated from different embeddings. Note that this differs from 'multi-channel' models because at the convolution layer we use different filters on each word embedding matrix independently, whereas in a standard multi-channel approach each filter would consider all channels simultaneously and generate a scalar from all channels at each local region. As above, we impose a max l2 norm constraint on the final feature vector $\mathbf{o}$ for regularization. Figure 1 illustrates this approach.

MGNC-CNN. We propose an augmentation of MG-CNN, *Multi-Group Norm Constraint CNN* (MGNC-CNN), which differs in its regularization strategy. Specifically, in this variant we impose *grouped* regularization constraints, independently regularizing subcomponents $\mathbf{o}_l$ derived from the respective embeddings, i.e., we impose separate max norm constraints λ_l for each $\mathbf{o}_l$ (where l again indexes embedding sets); these λ_l hyper-parameters are to be tuned on a validation set. Intuitively, this method aims to better capitalize on features derived from word embeddings that capture discriminative properties of text for the task at hand by penalizing larger weight estimates for features derived from less discriminative embeddings.

4 Experiments

4.1 Datasets

Stanford Sentiment Treebank Stanford Sentiment Treebank (SST) (Socher et al., 2013). This concerns predicting movie review sentiment. Two datasets are derived from this corpus: (1) **SST-1**, containing five classes: *very negative*, *negative*, *neutral*, *positive*, and *very positive*. (2) **SST-2**, which has only two classes: *negative* and *positive*. For both, we remove phrases of length less than 4 from the training set.[1] **Subj** (Pang and Lee, 2004). The aim here is to classify sentences as either *subjective* or *objective*. This comprises 5000 instances of each. **TREC** (Li and Roth, 2002). A question classification dataset containing six classes: *abbreviation*, *entity*, *description*, *human*, *location* and *numeric*. There are 5500 training and 500 test instances. **Irony** (Wallace et al., 2014). This dataset contains 16,006 sentences from reddit labeled as ironic (or not). The dataset is imbalanced (relatively few sentences are ironic). Thus before training, we under-sampled negative instances to make classes sizes equal. Note that for this dataset we report the Area Under Curve (AUC), rather than accuracy, because it is imbalanced.

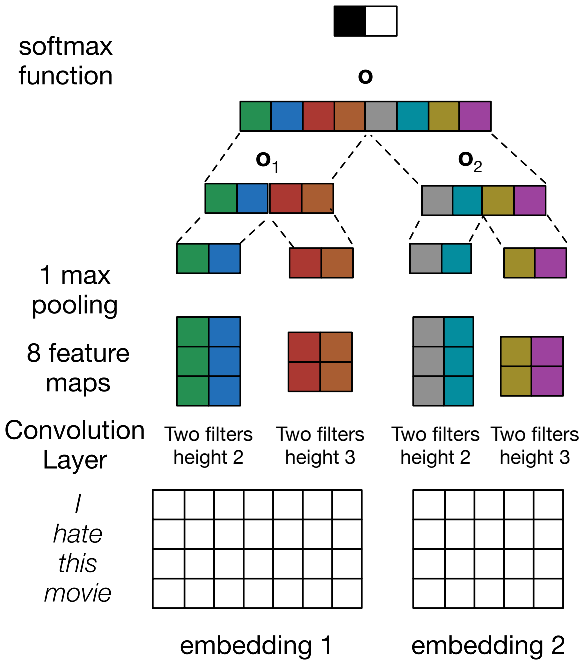

Figure 1: Illustration of MG-CNN and MGNC-CNN. The filters applied to the respective embeddings are completely independent. MG-CNN applies a max norm constraint to $\mathbf{o}$, while MGNC-CNN applies max norm constraints on $\mathbf{o_1}$ and $\mathbf{o_2}$ independently (group regularization). Note that one may easily extend the approach to handle more than two embeddings at once.

4.2 Pre-trained Word Embeddings

We consider three sets of word embeddings for our experiments: (i) **word2vec**[2] is trained on 100 billion tokens of Google News dataset; (ii) **GloVe** (Pennington et al., 2014)[3] is trained on aggregated global word-word co-occurrence statistics from Common Crawl (840B tokens); and (iii) **syntactic** word embedding trained on dependency-parsed corpora. These three embedding sets happen to all be 300-dimensional, but our model could accommodate arbitrary and variable sizes.

We pre-trained our own syntactic embeddings following (Levy and Goldberg, 2014). We parsed the ukWaC corpus (Baroni et al., 2009) using the Stanford Dependency Parser v3.5.2 with Stanford Dependencies (Chen and Manning, 2014) and extracted (word, relation+context) pairs from parse trees. We "collapsed" nodes with prepositions and notated inverse relations separately, e.g., "dog barks" emits two tuples: *(barks, nsubj_dog)* and *(dog, nsubj^{-1}_barks)*. We filter words and contexts that appear fewer than 100 times, resulting in ~173k words and 1M contexts. We trained 300d vectors using word2vecf[4] with default parameters.

4.3 Setup

We compared our proposed approaches to a standard CNN that exploits a single set of word embeddings (Kim, 2014). We also compared to a baseline of simply concatenating embeddings for each word to form long vector inputs. We refer to this as Concatenation-CNN *C-CNN*. For all multiple embedding approaches (C-CNN, MG-CNN and MGNC-CNN), we explored two combined sets of embedding: word2vec+Glove, and word2vec+syntactic, and one three sets of embedding: word2vec+Glove+syntactic. For all models, we tuned the l2 norm constraint λ over the range $\{\frac{1}{3}, 1, 3, 9, 81, 243\}$ on a validation set. For instan-

[4] https://bitbucket.org/yoavgo/word2vecf/

tiations of MGNC-CNN in which we exploited two embeddings, we tuned both λ_1, and λ_2; where we used three embedding sets, we tuned λ_1, λ_2 and λ_3.

We used standard train/test splits for those datasets that had them. Otherwise, we performed 10-fold cross validation, creating nested development sets with which to tune hyperparameters. For all experiments we used filters sizes of 3, 4 and 5 and we created 100 feature maps for each filter size. We applied 1 max-pooling and dropout (rate: 0.5) at the classification layer. For training we used backpropagation in mini-batches and used AdaDelta as the stochastic gradient descent (SGD) update rule, and set mini-batch size as 50. In this work, we treat word embeddings as part of the parameters of the model, and update them as well during training. In all our experiments, we only tuned the max norm constraint(s), fixing all other hyperparameters.

4.4 Results and Discussion

We repeated each experiment 10 times and report the mean and ranges across these. This replication is important because training is stochastic and thus introduces variance in performance (Zhang and Wallace, 2015). Results are shown in Table 1, and the corresponding best norm constraint value is shown in Table 2. We also show results on *Subj*, *SST-1* and *SST-2* achieved by the more complex model of (Yin and Schütze, 2015) for comparison; this represents the state-of-the-art on the three datasets other than TREC.

We can see that **MGNC-CNN and MG-CNN always outperform baseline methods (including C-CNN), and MGNC-CNN is usually better than MG-CNN**. And on the *Subj* dataset, MG-CNN actually achieves slightly better results than (Yin and Schütze, 2015), with far less complexity and required training time (MGNC-CNN performs comparably, although no better, here). On the TREC dataset, the best-ever accuracy we are aware of is 96.0% (Mou et al., 2015), which falls within the range of the result of our MGNC-CNN model with three word embeddings. On the *irony* dataset, our model with three embeddings achieves 4% improvement (in terms of AUC) compared to the baseline model. On *SST-1* and *SST-2*, our model performs slightly worse than (Yin and Schütze, 2015). However, we again note that their performance is achieved using a much more complex model which involves pre-training and mutual-learning steps. This model takes days to train, whereas our model requires on the order of an hour.

We note that the method proposed by Astudillo *et al.* (2015) is able to accommodate multiple embedding sets with different dimensions by projecting the original word embeddings into a lower-dimensional space. However, this work requires training the optimal projection matrix on laebled data first, which again incurs large overhead.

Of course, our model also has its own limitations: in MGNC-CNN, we need to tune the norm constraint hyperparameter for all the word embeddings. As the number of word embedding increases, this will increase the running time. However, this tuning procedure is embarrassingly parallel.

5 Conclusions

We have proposed MGNC-CNN: a simple, flexible CNN architecture for sentence classification that can exploit multiple, variable sized word embeddings. We demonstrated that this consistently achieves better results than a baseline architecture that exploits only a single set of word embeddings, and also a naive concatenation approach to capitalizing on multiple embeddings. Furthermore, our results are comparable to those achieved with a recently proposed model (Yin and Schütze, 2015) that is much more complex. However, our simple model is easy to implement and requires an order of magnitude less training time. Furthermore, our model is much more flexible than previous approaches, because it can accommodate variable-size word embeddings.

Abstract

We show how eye-tracking corpora can be used to improve sentence compression models, presenting a novel multi-task learning algorithm based on multi-layer LSTMs. We obtain performance competitive with or better than state-of-the-art approaches.

1 Introduction

Sentence compression is a basic operation in text simplification which has the potential to improve statistical machine translation and automatic summarization (Berg-Kirkpatrick et al., 2011; Klerke et al., 2015), as well as helping poor readers in need of assistive technologies (Canning et al., 2000). This work suggests using eye-tracking recordings for improving sentence compression for text simplification systems and is motivated by two observations: (i) *Sentence compression is the task of automatically making sentences easier to process by shortening them.* (ii) *Eye-tracking measures* such as first-pass reading time and time spent on regressions, i.e., during second and later passes over the text, *are known to correlate with perceived text difficulty* (Rayner et al., 2012).

These two observations recently lead Klerke et al. (2015) to suggest using eye-tracking measures as metrics in text simplification. We go beyond this by suggesting that eye-tracking recordings can be used to induce better models for sentence compression for text simplification. Specifically, we show how to use existing eye-tracking recordings to improve the induction of Long Short-Term Memory models (LSTMs) for sentence compression.

Our proposed model *does not require* that the gaze data and the compression data come from the same source. Indeed, in this work we use gaze data from readers of the Dundee Corpus to improve sentence compression results on several datasets. While not explored here, an intriguing potential of this work is in deriving sentence simplification models that are personalized for individual users, based on their reading behavior.

Several approaches to sentence compression have been proposed, from noisy channel models (Knight and Marcu, 2002) over conditional random fields (Elming et al., 2013) to tree-to-tree machine translation models (Woodsend and Lapata, 2011). More recently, Filippova et al. (2015) successfully used LSTMs for sentence compression on a large scale parallel dataset. We do not review the literature here, and only compare to Filippova et al. (2015).

Our contributions

- We present a novel multi-task learning approach to sentence compression using labelled data for sentence compression and a disjoint eye-tracking corpus.
- Our method is fully competitive with state-of-the-art across three corpora.
- Our code is made publicly available at `https://bitbucket.org/soegaard/gaze-mtl16`.

2 Gaze during reading

Readers fixate longer at rare words, words that are semantically ambiguous, and words that are mor-

Proceedings of NAACL-HLT 2016, pages 1528–1533,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

phologically complex (Rayner et al., 2012). These are also words that are likely to be replaced with simpler ones in sentence simplification, but it is not clear that they are words that would necessarily be removed in the context of sentence compression.

Demberg and Keller (2008) show that syntactic complexity (measured as dependency locality) is also an important predictor of reading time. Phrases that are often removed in sentence compression—like fronted phrases, parentheticals, floating quantifiers, etc.—are often associated with non-local dependencies. Also, there is evidence that people are more likely to fixate on the first word in a constituent than on its second word (Hyönä and Pollatsek, 2000). Being able to identify constituent borders is important for sentence compression, and reading fixation data may help our model learn a representation of our data that makes it easy to identify constituent boundaries.

In the experiments below, we learn models to predict the first pass duration of word fixations and the total duration of regressions to a word. These two measures constitute a perfect separation of the total reading time of each word split between the first pass and subsequent passes. Both measures are described below. They are both discretized into six bins as follows with only non-zero values contributing to the calculation of the standard deviation (SD):

0: measure = 0 or
1: measure < 1 SD below reader's average or
2: measure < .5 SD below reader's average or
3: measure < .5 above reader's average or
4: measure > .5 SD above reader's average or
5: measure > 1 SD above reader's average

First pass duration measures the total time spent reading a word first time it is fixated, including any immediately following re-fixations of the same word. This measure correlates with word length, frequency and ambiguity because long words are likely to attract several fixations in a row unless they are particularly easily predicted or recognized. This effect arises because long words are less likely to fit inside the fovea of the eye. Note that for this measure the value 0 indicates that the word was not fixated by this reader.

Words	FIRST PASS	REGRESSIONS
Are	4	4
tourists	2	0
enticed	3	0
by	4	0
these	2	0
attractions	3	0
threatening	3	3
their	5	0
very	3	3
existence	3	5
?	3	5

Figure 1: Example sentence from the Dundee Corpus

Regression duration measures the total time spent fixating a word after the gaze has already left it once. This measure belongs to the group of late measures, i.e., measures that are sensitive to the later cognitive processing stages including interpretation and integration of already decoded words. Since the reader by definition has already had a chance to recognize the word, regressions are associated with semantic confusion and contradiction, incongruence and syntactic complexity, as famously experienced in garden path sentences. For this measure the value 0 indicates that the word was read at most once by this reader.

See Table 1 for an example of first pass duration and regression duration annotations for one reader and sentence.

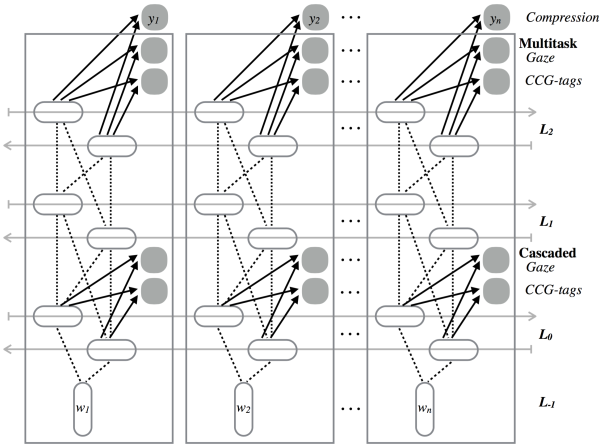

Figure 2: Multitask and cascaded bi-LSTMs for sentence compression. Layer L_{-1} contain pre-trained embeddings. Gaze prediction and CCG-tag prediction are auxiliary training tasks, and loss on all tasks are propagated back to layer L_0.

3 Sentence compression using multi-task deep bi-LSTMs

Most recent approaches to sentence compression make use of syntactic analysis, either by operating directly on trees (Riezler et al., 2003; Nomoto, 2007; Filippova and Strube, 2008; Cohn and Lapata, 2008; Cohn and Lapata, 2009) or by incorporating syntactic information in their model (McDonald, 2006; Clarke and Lapata, 2008). Recently, however, Filippova et al. (2015) presented an approach to sentence compression using LSTMs with word embeddings, but without syntactic features. We introduce a third way of using syntactic annotation by jointly learning a sequence model for predicting CCG supertags, in addition to our gaze and compression models.

Bi-directional recurrent neural networks (bi-RNNs) read in sequences in both regular and reversed order, enabling conditioning predictions on both left and right context. In the forward pass, we run the input data through an embedding layer and compute the predictions of the forward and backward states at layers $0, 1, \ldots$, until we compute the softmax predictions for word i based on a linear transformation of the concatenation of the of standard and reverse RNN outputs for location i. We then calculate the objective function derivative for the sequence using cross-entropy (logistic loss) and use backpropagation to calculate gradients and update the weights accordingly. A deep bi-RNN or k-layered bi-RNN is composed of k bi-RNNs that feed into each other such that the output of the ith RNN is the input of the $i + 1$th RNN. LSTMs (Hochreiter and Schmidhuber, 1997) replace the cells of RNNs with LSTM cells, in which multiplicative gate units learn to open and close access to the error signal.

Bi-LSTMs have already been used for fine-grained sentiment analysis (Liu et al., 2015), syntactic chunking (Huang et al., 2015), and semantic role labeling (Zhou and Xu, 2015). These and other recent applications of bi-LSTMs were constructed for solving a single task in isolation, however. We instead train deep bi-LSTMs to solve additional tasks to sentence compression, namely CCG-tagging and gaze prediction, using the additional tasks to regularize our sentence compression model.

Specifically, we use bi-LSTMs with three layers. Our baseline model is simply this three-layered model trained to predict compressions (encoded as label sequences), and we consider two extensions thereof as illustrated in Figure 2. Our first extension, MULTI-TASK-LSTM, includes the gaze prediction task during training, with a separate logistic regression classifier for this purpose; and the other, CASCADED-LSTM, predicts gaze measures from the inner layer. Our second extension, which is superior to our first, is basically a one-layer bi-LSTM for predicting reading fixations with a two-layer bi-LSTM on top for predicting sentence compressions.

At each step in the training process of MULTI-TASK-LSTMand CASCADED-LSTM, we choose a random task, followed by a random training instance of this task. We use the deep LSTM to predict a label sequence, suffer a loss with respect to the true labels, and update the model parameters. In CASCADED-LSTM, the update for an instance of CCG super tagging or gaze prediction only affects the parameters of the inner LSTM layer.

Both MULTI-TASK-LSTM and CASCADED-LSTM do multi-task learning (Caruana, 1993). In multi-task learning, the induction of a model for one task is used as a regularizer on the induction of a model for another task. Caruana (1993) did multi-task learning by doing parameter sharing across several deep networks, letting them share hidden layers; a technique also used by Collobert et al. (2011) for various NLP tasks. These models train task-specific classifiers on the output of deep networks (informed by the task-specific losses). We extend their models by moving to sequence prediction and allowing the task-specific sequence models to also be deep models.

4 Experiments

4.1 Gaze data

We use the Dundee Corpus (Kennedy et al., 2003) as our eye-tracking corpus with tokenization and measures similar to the Dundee Treebank (Barrett et al., 2015). The corpus contains eye-tracking recordings of ten native English-speaking subjects reading 20 newspaper articles from *The Independent*. We use data from nine subjects for training and one subject for development. We do not evaluate the gaze prediction because the task is only included as a way of regularizing the compression model.

S:	Regulators Friday shut down a small Florida bank, bringing to 119 the number of US bank failures this year amid mounting loan defaults.

BROADCAST	412	19	0.27	0.29
GOOGLE	1000	25	0.42	0.87

Table 2: Dataset characteristics. Sentence length is for source sentences.

4.2 Compression data

We use three different sentence compression datasets, ZIFF-DAVIS (Knight and Marcu, 2002), BROADCAST (Clarke and Lapata, 2006), and the publically available subset of GOOGLE (Filippova et al., 2015). The first two consist of manually compressed newswire text in English, while the third is built heuristically from pairs of headlines and first sentences from newswire, resulting in the most aggressive compressions, as exemplified in Table 1. We present the dataset characteristics in Table 2. We use the datasets as released by the authors and do not apply any additional pre-processing. The CCG supertagging data comes from CCGbank,[1] and we use sections 0-18 for training and section 19 for development.

4.3 Baselines and system

Both the baseline and our systems are three-layer bi-LSTM models trained for 30 iterations with pretrained (SENNA) embeddings. The input and hidden layers are 50 dimensions, and at the output layer we predict sequences of two labels, indicating whether to delete the labeled word or not. Our baseline (BASELINE-LSTM) is a multi-task learning bi-LSTM predicting both CCG supertags and sentence compression (word deletion) at the outer layer. Our first extension is MULTITASK-LSTM predicting CCG supertags, sentence compression, and reading measures from the outer layer. CASCADED-LSTM, on the other hand, predicts CCG supertags and reading measures from the initial layer, and sentence compression at the outer layer.

4.4 Results and discussion

Our results are presented in Table 3. We observe that across all three datasets, including all three annotations of BROADCAST, gaze features lead to improvements over our baseline 3-layer bi-LSTM. Also, CASCADED-LSTM is consistently better than MULTITASK-LSTM. Our models are fully competitive with state-of-the-art models. For example, the best model in Elming et al. (2013) achieves 0.7207 on ZIFF-DAVIS, Clarke and Lapata (2008) achieves 0.7509 on BROADCAST,[2] and the LSTM model in Filippova et al. (2015) achieves 0.80 on GOOGLE with much more training data. The high numbers on the small subset of GOOGLE reflects that newswire headlines tend to have a fairly predictable relation to

LSTM	Gaze	ZIFF-DAVIS	BROADCAST			GOOGLE
Baseline		0.5668	0.7386	0.7980	0.6802	0.7980
Multitask	FP	0.6416	0.7413	0.8050	0.6878	0.8028
	REGR.	0.7025	0.7368	0.7979	0.6708	0.8016
Cascaded	FP	0.6732	**0.7519**	0.8189	**0.7012**	**0.8097**
	REGR.	**0.7418**	0.7477	**0.8217**	0.6944	0.8048

Table 3: Results (F_1). For all three datasets, the inclusion of gaze measures (first pass duration (FP) and regression duration (Regr.)) leads to improvements over the baseline. All models include CCG-supertagging as an auxiliary task. Note that BROADCASTwas annotated by three annotators. The three columns are, from left to right, results on annotators 1–3.

the first sentence. With the harder datasets, the impact of the gaze information becomes stronger, consistently favouring the cascaded architecture, and with improvements using both first pass duration and regression duration, the late measure associated with interpretation of content. Our results indicate that multi-task learning can help us take advantage of inherently noisy human processing data across tasks and thereby maybe reduce the need for task-specific data collection.

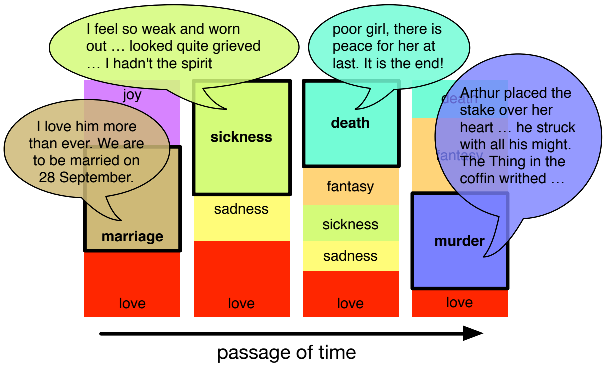
Abstract

Understanding how a fictional relationship between two characters changes over time (e.g., from best friends to sworn enemies) is a key challenge in digital humanities scholarship. We present a novel unsupervised neural network for this task that incorporates dictionary learning to generate interpretable, accurate relationship trajectories. While previous work on characterizing literary relationships relies on plot summaries annotated with predefined labels, our model jointly learns a set of global relationship descriptors as well as a trajectory over these descriptors for each relationship in a dataset of raw text from novels. We find that our model learns descriptors of events (e.g., marriage or murder) as well as interpersonal states (love, sadness). Our model outperforms topic model baselines on two crowdsourced tasks, and we also find interesting correlations to annotations in an existing dataset.

1 Describing Character Relationships

When two characters in a book break bread, is their meal just a result of biological needs or does it mean more? Cognard-Black et al. (2014) argue that this simple interaction reflects the diversity and background of the characters, while Foster (2009) suggests that the tone of a meal can portend either good or ill for the rest of the book. To support such theories, scholars use their literary expertise to draw connections between disparate books: Gabriel Conroy's dissonance from his family at a sumptuous feast in Joyce's *The Dead*, the frustration of Tyler's mother in *Dinner at the Homesick Restaurant*, and the grudging respect for a blind man eating meatloaf in Carver's *Cathedral*.



I feel so weak and worn out … looked quite grieved … I hadn't the spirit
poor girl, there is peace for her at last. It is the end!
I love him more than ever. We are to be married on 28 September.
Arthur placed the stake over her heart … he struck with all his might. The Thing in the coffin writhed …

murder
love
passage of time

Figure 1: An example trajectory depicting the dynamic relationship between Lucy and Arthur in Bram Stoker's *Dracula*, which starts with love and ends with Arthur killing the vampiric Lucy. Each column describes the relationship state at a particular time by weights over a set of descriptors (larger weights shown as bigger boxes). Our goal is to learn—without supervision—both the descriptors and the trajectories from raw fictional texts.

However, these insights do not come cheap. It takes years of careful reading and internalization to make connections across books, which means that relationship symmetries and archetypes are likely to remain hidden in the millions of books published every year unless literary scholars are actively searching for them.

Natural language processing techniques have been increasingly used to assist in these literary investigations by discovering patterns in texts (Jockers, 2013). In Section 6 we review existing techniques that classify or cluster relationships between characters in books using a fixed set of labels (e.g., friend or en-

Proceedings of NAACL-HLT 2016, pages 1534–1544,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

emy). However, such approaches ignore interactions between characters that lie outside of the established lexicon and cannot account for the dynamic nature of relationships that evolve through the course of a book, such as the vampiric downfall of Lucy and Arthur's engagement in *Dracula* (Figure 1) or Winston Smith's rat-induced betrayal of Julia in *1984*.

To address these issues, we propose the task of unsupervised relationship modeling, in which a model jointly learns a set of *relationship descriptors* as well as *relationship trajectories* for pairs of literary characters. Instead of assigning a single descriptor to a particular relationship, the trajectories learned by the model are sequences of descriptors as in Figure 1.

The Bayesian *hidden topic Markov model* (**HTMM**) of Gruber et al. (2007) emerges as a natural choice for our task because it is capable of computing relationship descriptors (in the form of topics) and has an additional temporal component. However, our experiments show that the descriptors learned by the **HTMM** are not coherent and focus more on events or environments (e.g., meals, outdoors) than interpersonal states like happiness and sadness.

Motivated by recent advances in deep learning, we propose the *relationship modeling network* (**RMN**), which is a novel variant of a deep recurrent autoencoder that incorporates dictionary learning to learn relationship descriptors. We show that the **RMN** achieves better descriptor coherence and trajectory accuracy than the **HTMM** and other topic model baselines in two crowdsourced evaluations described in Section 4. In Section 5 we show qualitative results and make connections to existing literary scholarship.

2 A Dataset of Character Interactions

Our dataset consists of 1,383 fictional works pulled from Project Gutenberg and other Internet sources. Project Gutenberg has a limited selection (outside of science fiction) of mostly classic literature, so we add more contemporary novels from various genres such as mystery, romance, and fantasy to our dataset.

To identify character mentions, we run the BookNLP pipeline of Bamman et al. (2014), which includes character name clustering, quoted speaker identification, and coreference resolution.[1] For every detected character mention, we define a span as beginning 100 tokens before the mention and ending 100 tokens after the mention. We do not use sentence or paragraph boundaries because they vary considerably depending on the author (e.g., William Faulkner routinely wrote single sentences longer than many of Hemingway's paragraphs). All spans in our dataset contain mentions to exactly two characters. This is a rather strict requirement that forces a reduction in data size, but spans in which more than two characters are mentioned are generally noisier.

Once we have identified usable spans in the dataset, we apply a second filtering step that removes relationships containing fewer than five spans. Without this filter, our dataset is dominated by fleeting interactions between minor characters; this is undesirable since our focus is on longer, mutable relationships. Finally, we filter our vocabulary by removing the 500 most frequently occurring words, as well as all words that occur in fewer than 100 books. The latter step helps correct for variation in time period and genre (e.g., "thou" and "thy" found in older works like the *Canterbury Tales*). Our final dataset contains 20,013 relationships and 380,408 spans, while our vocabulary contains 16,223 words.[2]

3 Relationship Modeling Networks

This section mathematically describes how we apply the **RMN** to relationship modeling on our dataset. Our model is similar in spirit to topic models: for an input dataset, the output of the **RMN** is a set of relationship descriptors (topics) and—for each relationship in the dataset—a trajectory, or a sequence of probability distributions over these descriptors (document-topic assignments). However, the **RMN** uses recent advances in deep learning to achieve better control over descriptor coherence and trajectory smoothness (Section 4).

3.1 Formalizing the Problem

Assume we have two characters c_1 and c_2 in book b. We define S_{c_1,c_2} as a sequence of token spans where each span $s_t \in S_{c_1,c_2}$ is itself a set of tokens

[1] While this pipeline works reasonably well, it is unreliable for first-person narratives; we leave the necessary improvements to character name clustering, which are further expanded upon in Vala et al. (2015), for future work.

“A Confederacy of Dunces”
Mrs. Reilly looked at her son slyly and asked, "Ignatius, you sure you not a communiss?" "Oh, my God!" Ignatius bellowed. "Every day I am subjected to a McCarthyite witchhunt in this crumbling building. No!"

Figure 2: An example of the RMN's computations at a single time step. The model approximates the vector average of an input span ($\boldsymbol{v}_{s_t}$) as a linear combination of descriptors from **R**. The descriptor weights $\boldsymbol{d}_t$ define the relationship state at each time step and—when viewed as a sequence—form a relationship trajectory.

$\{w_1, w_2, \ldots, w_l\}$ of fixed size l that contains mentions (either directly or by coreference) to both c_1 and c_2. In other words, S_{c_1,c_2} includes the text of every scene, chronologically ordered, in which c_1 and c_2 are present together.

3.2 Model Description

As in other neural network models for natural language processing, we begin by associating each word type *w* in our vocabulary with a real-valued embedding $\boldsymbol{v}_w \in \mathbb{R}^d$. These embeddings are rows of a $V \times d$ matrix **L**, where V is the vocabulary size. Similarly, characters and books have their own embeddings in rows of matrices **C** and **B**. We want **B** to capture global context information (e.g., “Moby Dick” takes place at sea) and **C** to capture immutable aspects of characters not related to their relationships (e.g., Javert is a police officer). Finally, the RMN learns embeddings for relationship descriptors, which requires a second matrix **R** of size $K \times d$ where K is the number of descriptors, analogous to the number of topics in topic models.

Each input to the RMN is a tuple that contains identifiers for a book and two characters, as well as the spans corresponding to their relationship: $(b, c_1, c_2, S_{c_1,c_2})$. Given one such input, our objective is to reconstruct S_{c_1,c_2} using a linear combination of relationship descriptors from **R** as shown in Figure 2; we now describe this process formally.

3.2.1 Modeling Spans with Vector Averages

We compute a vector representation for each span s_t in S_{c_1,c_2} by averaging the embeddings of the words in that span,

$$\boldsymbol{v}_{s_t} = \frac{1}{l}\sum_{w \in s_t} \boldsymbol{v}_w. \qquad (1)$$

Then, we concatenate $\boldsymbol{v}_{s_t}$ with the character embeddings $\boldsymbol{v}_{c_1}$ and $\boldsymbol{v}_{c_2}$ as well as the book embedding $\boldsymbol{v}_b$ and feed the resulting vector into a standard feed-forward layer to obtain a hidden state $\boldsymbol{h}_t$,

$$\boldsymbol{h}_t = f(\mathbf{W}_h \cdot [\boldsymbol{v}_{s_t}; \boldsymbol{v}_{c_1}; \boldsymbol{v}_{c_2}; \boldsymbol{v}_b]). \qquad (2)$$

In all experiments, the transformation matrix W_h is $d \times 4d$, and we set f to the ReLu function, $\mathrm{ReLu}(x) = \max(0, x)$.

3.2.2 Approximating Spans with Relationship Descriptors

Now that we can obtain representations of spans, we move on to learning descriptors using a variant of dictionary learning (Olshausen and Field, 1997; Elad and Aharon, 2006), where our descriptor matrix **R** is the dictionary and we are trying to approximate input spans as a linear combination of items from this dictionary.

Suppose we compute a hidden state for every span s_t in S_{c_1,c_2} (Equation 2). Now, given an $\boldsymbol{h}_t$, we compute a weight vector $\boldsymbol{d}_t$ over K relationship descriptors with some composition function g, which is fully specified in the next section. Conceptually, each $\boldsymbol{d}_t$ is a *relationship state*, and a *relationship trajectory* is a sequence of chronologically-ordered relationship states as shown in Figure 1. After computing $\boldsymbol{d}_t$, we use it to compute a reconstruction vector $\boldsymbol{r}_t$ by taking a weighted average over relationship descriptors,

$$\boldsymbol{r}_t = \mathbf{R}^{\mathsf{T}}\boldsymbol{d}_t. \qquad (3)$$

Our goal is to make $\boldsymbol{r}_t$ similar to $\boldsymbol{v}_{s_t}$. We use a contrastive max-margin objective function similar to previous work (Weston et al., 2011; Socher et al., 2014). We randomly sample spans from our dataset and compute the vector average $\boldsymbol{v}_{s_n}$ for each sampled span as in Equation 1. This subset of span vectors is N. The unregularized objective J is a hinge loss that minimizes the inner product between $\boldsymbol{r}_t$ and the negative samples while simultaneously maximizing the inner product between $\boldsymbol{r}_t$ and $\boldsymbol{v}_{s_t}$,

$$J(\theta) = \sum_{t=0}^{|S_{c_1,c_2}|} \sum_{n \in N} \max(0, 1 - \boldsymbol{r}_t \boldsymbol{v}_{s_t} + \boldsymbol{r}_t \boldsymbol{v}_{s_n}), \quad (4)$$

where θ represents the model parameters.

3.2.3 Computing Weights over Descriptors

What function should we choose for our composition function g to represent a relationship state at a given time step? On the face of it, this seems trivial; we can project h_t to K dimensions and then apply a softmax or some other nonlinearity that yields nonnegative weights.[3] However, this method ignores the relationship states at previous time steps. To model the temporal aspect of relationships, we can add a recurrent connection,

$$\boldsymbol{d}_t = \text{softmax}(\mathbf{W}_d \cdot [\boldsymbol{h}_t; \boldsymbol{d}_{t-1}]) \quad (5)$$

where $\mathbf{W}_d$ is of size $K \times (d + K)$ and $\text{softmax}(\boldsymbol{q}) = {}^{\exp \boldsymbol{q}}/\sum_{j=1}^{k} \exp \boldsymbol{q}_j$.

Our hope is that this recurrent connection will carry some of the previous relationship state over to the current time step. It should be unlikely for two characters in love at time t to fall out of love at time $t+1$ even if s_{t+1} does not include any love-related words. However, because the objective function in Equation 4 maximizes similarity with the current time step's input, the model is not forced to learn a smooth interpolation between the previous state and the current one. A natural remedy is to have the model predict the *next* time step's input instead, but this proves hard to optimize.

We instead *force* the model to use the previous relationship state by modifying Equation 5 to include a linear interpolation between $\boldsymbol{d}_t$ and $\boldsymbol{d}_{t-1}$,

$$\begin{aligned}\boldsymbol{d}_t = \alpha \cdot \text{softmax}(\mathbf{W}_d \cdot [\boldsymbol{h}_t; \boldsymbol{d}_{t-1}]) + \\ (1 - \alpha) \cdot \boldsymbol{d}_{t-1}.\end{aligned} \quad (6)$$

Here, α is a scalar between 0 and 1. We experiment with setting α to a fixed value of 0.5 as well as allowing the model to learn α as in

$$\alpha = \sigma(\boldsymbol{v}_\alpha^\mathsf{T} \cdot [\boldsymbol{h}_t; \boldsymbol{d}_{t-1}; \boldsymbol{v}_{s_t}]), \quad (7)$$

where σ is the sigmoid function and $\boldsymbol{v}_\alpha$ is a vector of dimensionality $2d + K$. Fixing $\alpha = 0.5$ initially and then tuning it after other parameters have converged improves training stability; for the specific hyperparameters we use see Section 4.[4]

3.2.4 Interpreting Descriptors and Enforcing Uniqueness

Recall that each descriptor is a d-dimensional row of $\mathbf{R}$. Because our objective function J forces these descriptors to be in the same vector space as that of the word embeddings $\mathbf{L}$, we can interpret them by looking at nearest neighbors in $\mathbf{L}$ using cosine distance as the similarity metric.

To discourage learning descriptors that are too similar to each other, we add another penalty term X to our objective function,

$$X(\theta) = \left\| \mathbf{R}\mathbf{R}^\mathsf{T} - \mathbf{I} \right\|, \quad (8)$$

where $\mathbf{I}$ is the identity matrix. This term comes from the component orthogonality constraint in independent component analysis (Hyvärinen and Oja, 2000).

We add J and X together to obtain our final training objective L,

$$L(\theta) = J(\theta) + \lambda X(\theta), \quad (9)$$

where λ is a hyperparameter that controls the magnitude of the uniqueness penalty.

4 Evaluating Descriptors and Trajectories

Because no previous work explores the interpretability of unsupervised relationship modeling over time, evaluating the RMN is tricky. Further compounding the problem is the subjective nature of the task; for example, is a trajectory that ignores a key event better than one that hallucinates episodes absent from source text?

[3] We experiment with a variety of nonlinearities but find that the softmax yields the most interpretable results due to its predisposition to select a single descriptor.

[4] This strategy is reminiscent of alternative minimization strategies for dictionary learning (Agarwal et al., 2014), where the dictionary and weights are learned separately by keeping the other fixed.

With these issues in mind, we conduct three evaluations to show that our output is reasonable. First, we conduct a crowdsourced interpretability experiment that shows RMNs produce significantly more coherent descriptors than three topic model baselines. A second crowdsourced task indicates that our model produces trajectories that match plot summaries more accurately than topic models. Finally, we qualitatively compare the RMN's output to existing static annotations of literary relationships and find both expected and surprising results.

4.1 Topic Model Baselines

Before moving onto the evaluations, we briefly describe three baseline models, all of which are Bayesian generative models. Latent Dirichlet allocation (Blei et al., 2003, LDA) learns a single document-topic distribution per document; we can apply LDA to our dataset by concatenating all spans from a relationship into a single document. Similarly, NUBBI (Chang et al., 2009a) learns separate sets of topics for relationships and individual characters.[5]

LDA and NUBBI are incapable of taking into account the chronological ordering of the spans because they view all relationships tokens as exchangeable. While we can compare the *descriptors* learned by these models to those of the RMN, we cannot evaluate their *trajectories*. We turn instead to the hidden topic Markov model (Gruber et al., 2007, HTMM), which foregoes the bag-of-words assumption of LDA and NUBBI in favor of modeling topic segments within a document as a Markov chain. This model outputs a smooth sequence of topic assignments over a document, so we can compare the *trajectories* it learns on our dataset to those of the RMN.

4.2 Experimental Settings

In our descriptor interpretability experiments, we vary the number of descriptors (topics) for all models ($K = 10, 30, 50$). We train LDA and NUBBI for 100 iterations with a collapsed Gibbs sampler, and the HTMM uses the default setting of 100 EM iterations.

For the RMN, we initialize the word embedding matrix $\mathbf{L}$ with 300-dimensional GloVe embeddings trained on the Common Crawl (Pennington et al., 2014). The character and book embeddings ($\mathbf{C}$ and $\mathbf{B}$) are initialized randomly. We fix α to 0.5 for the first 15 epochs of training; after the descriptor matrix $\mathbf{R}$ has converged, we fix $\mathbf{R}$ and tune α using Equation 6 for 15 more epochs.[6] Since the topic model baselines do not have access to character and book metadata, for fair comparison we also train a "generic" version of the RMN (GRMN) where the metadata embeddings are removed from Equation 2. The uniqueness penalty λ is set to 10^{-4}.

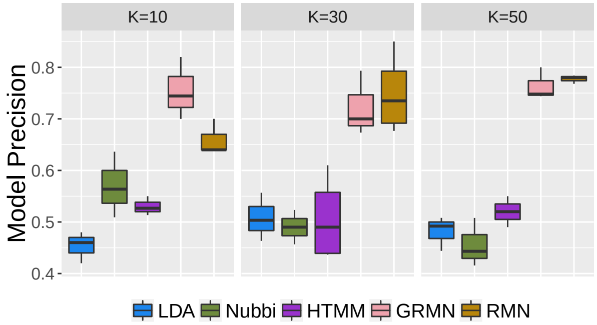

Figure 3: Model precision results from our word intrusion task. The RMN learns more interpretable descriptors than three topic model baselines.

All of the RMN model parameters except $\mathbf{L}$ are optimized using Adam (Kingma and Ba, 2014) with a learning rate of 0.001 for 30 epochs; the word embeddings are not fine-tuned during training.[7] We also apply word dropout (Iyyer et al., 2015) to the input spans, removing words from the vector average computation in Equation 1 with probability 0.5.

4.3 Do Descriptors Make Sense?

The goal of our first experiment is to compare the descriptors $\mathbf{R}$ learned by the RMN to the topics learned by the topic model baselines. We conduct a word intrusion experiment (Chang et al., 2009b): workers identify an "intruder" word from a set of words that—other than the intruder—come from the same topic. For the topic models, the five most probable words are joined by a highly-probable word from a different topic as the intruder. We use the same procedure for the RMN and GRMN, except that cosine similarity to

[5] NUBBI requires additional spans that mention only a single character to differentiate character topics from relationship topics. None of the other models receives these extra data.

[6] Preliminary experiments show that learning α and $\mathbf{R}$ simultaneously results in less interpretable descriptors.

[7] Tuning $\mathbf{L}$ ruins descriptor interpretability; pretrained embeddings are likely already a good solution for our problem.

RMN			**HTMM**		
Label	**MP**	**Nearest Neighbors**	**Label**	**MP**	**Most Probable Words**
sadness	1.0	regretful rueful pity pained despondent	violence	1.0	sword shot blood shouted swung
love	1.0	love delightful happiness enjoyed	boats	1.0	ship boat captain deck crew
murder	1.0	autopsy arrested homicide murdered	food	1.0	kitchen mouth glass food bread
worship	0.1	toil pray devote yourselves gather	sci-fi	0.0	suppose earth robots computer certain
moodiness	0.3	glumly snickered quizzically guiltily	fantasy	0.0	agreed magician dragon castle talent
informal	0.4	kinda damn heck guess shitty	military	0.1	ship captain lucky hour general

Table 1: Three high-precision (top) and three low-precision (bottom) descriptors for the **RMN** and **HTMM**, along with labels from an external evaluator and model precision (MP) computed via word intrusion experiments. The **RMN** is able to learn a variety of interpersonal states (e.g., love, sadness), while the **HTMM**'s most coherent topics are about concrete objects or events.

descriptor embeddings replaces topic-word probability. To control for randomness in the training process, we train three of each model, so the final experiment consists of 1,350 tasks ($K = 10, 30, 50$ descriptors per trial, three trials per model).

We collect judgments from ten different workers for each task using the Crowdflower platform.[8] Our evaluation metric, model precision (MP), is the fraction of workers that select the correct intruder word for a descriptor k. Low model precision signals descriptors that lack cohesive themes.

On average, the **RMN**'s descriptors are much more interpretable than those of the baselines, as it achieves a mean model precision of 0.73 (Figure 3) across all values of K. There is little difference between the model precision of the three topic model baselines, which hover around 0.5. There is also little difference between the **GRMN** and **RMN**; however, visualizing the learned character and book embeddings as in Figure 6 may be insightful for literary scholars. We show example high and low precision descriptors for the **RMN** and **HTMM** in Table 1; a full list is included in the supplementary material.

4.4 Do Trajectories Make Sense?

While the previous evaluation focused only on descriptor quality, our next experiment compares the trajectories learned by the best **RMN** model from the intrusion experiment (measured by highest mean model precision) to those learned by the best **HTMM** model, which is the only baseline capable of learning relationship trajectories. Workers read a plot summary and choose which model's trajectory best represents the relationship in question. We use the $K = 30$ setting because it provides the best balance between descriptor variety and trajectory interpretability.

For this evaluation, we crawl Wikipedia, Goodreads, and SparkNotes for plot summaries associated with our 1,383 books. We then remove all relationships where each involved character is not mentioned at least five times in the summary, which results in a final evaluation set of 125 relationships.[9] We present workers with two characters, a plot summary, and a visualization of trajectories learned by the **RMN** and the **HTMM** (Figure 4). The workers then select the trajectory that best matches the relationship described by the summary.

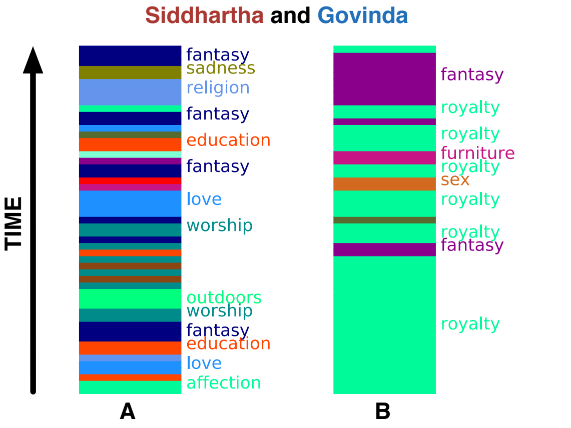
To generate the visualizations, we first have an external annotator label each descriptor from both models with a single word as in Table 1. For fairness, the annotator is unaware of the underlying models. For the **RMN**, we visualize trajectories by displaying the label of the argmax over descriptor weights $\boldsymbol{d}_t$ at each time step t. Similarly, for the **HTMM**, we display the most probable topic at each time step.[10]

The results of this task with seven workers per comparison favor the **RMN**: for 87 out of the 125 evaluated relationships (69.6%), the workers choose the **RMN**'s trajectory over the **HTMM**'s. We compute the Fleiss κ value (Fleiss, 1971) to correct our inter-annotator agreement for chance and find that

[8] http://www.crowdflower.com

[9] Without this filtering step, workers do not have enough information to compare the two models since most of the characters in our dataset are not mentioned in summaries.

[10] To reduce visual clutter, we ignore descriptors that persist for only a single time step.



Summary: Govinda is Siddhartha's best friend and sometimes his follower. Like Siddhartha, Govinda devotes his life to the quest for understanding and enlightenment. He leaves his village with Siddhartha to join the Samanas, then leaves the Samanas to follow Gotama. He searches for enlightenment independently of Siddhartha but persists in looking for teachers who can show him the way. In the end, he is able to achieve enlightenment only because of Siddhartha's love for him.

Figure 4: An example from the Crowdflower summary matching task; workers are asked to choose the trajectory (here, "A" is generated by the **RMN** and "B" by the **HTMM**) that best matches a provided summary that describes the relationship between Siddartha and Govinda (from *Siddartha* by Hesse).

$\kappa = 0.32$, indicating fair agreement among the workers. Furthermore, thirty-four relationships had unanimous agreement among the seven workers; of these, twenty-six were unanimous in favor of the **RMN** compared to only eight for the **HTMM**.

4.5 What Makes a Relationship Positive?

While the previous two experiments show that the **RMN** is more interpretable and accurate than baseline models, we have not yet shown that its insights can aid in drawing connections across various books and genres. As a first step in this direction, we investigate what makes a relationship positive or negative by comparing trajectories from the **RMN** and **HTMM** to static affinity annotations from a recently-released dataset (Massey et al., 2015) of fictional relationships. Expected correlations (e.g., murder and sadness are strongly negative descriptors) emerge alongside surprising ones (politics is negative, religion is positive).

The affinity labeling task of Massey et al. (2015) requires workers to describe a given relationship as positive, negative, or neutral. We consider only non-neutral relationships for which two annotators agree on the affinity label and remove all books not present in our own dataset. This filtering step results in 120 relationships, 78% of which are positive and the remaining 22% negative.

Model	Positive	Negative
RMN	education, love, religion, sex	politics, murder, sadness, royalty
HTMM	love, parental, business, outdoors	love, politics, violence, crime

Table 2: Descriptors most characteristic of positive and negative relationships, computed using existing annotations. Compared to the **RMN**, the **HTMM** struggles to coherently characterize negative relationships. Interestingly, both models show negative predispositions for political relationships, perhaps due to genre bias or class differences.

Since the annotations are static, we first aggregate our trajectories across all time steps. We compute K-dimensional "average positive" and "average negative" weight vectors $\boldsymbol{a}_p$ and $\boldsymbol{a}_n$ by averaging the relationship states $\boldsymbol{d}_t$ for the **RMN** and the document-topic distributions for the **HTMM** across all time steps for relationships labeled with a particular affinity. Then, we compute the vector difference $\boldsymbol{a}_p - \boldsymbol{a}_n$ and sort it to produce a ranked list of descriptors, where descriptors with positive differences occur more frequently in positive relationships. Table 2 shows the most positive and most negative descriptors; of particular interest is the large negative weight associated with political relationships from both models.

5 Qualitative Analysis

Our experiments show the superiority of the **RMN** over various topic model baselines in both descriptor interpretability and trajectory accuracy, but what causes the improved performance? In this section, we analyze similarities between the **RMN** and **HTMM** and look at qualitative examples where the **RMN** succeeds and fails. We also connect the findings of our affinity experiment to existing literary scholarship.

Both models are equally proficient at learning and assigning event-based descriptors (e.g., crime, violence, food). More specifically, the **RMN** and **HTMM** agree on environmental descriptions (e.g., boats, outdoors) and graphic sexual scenes (Figure 5, middle).

However, the **RMN** is more sophisticated with in-

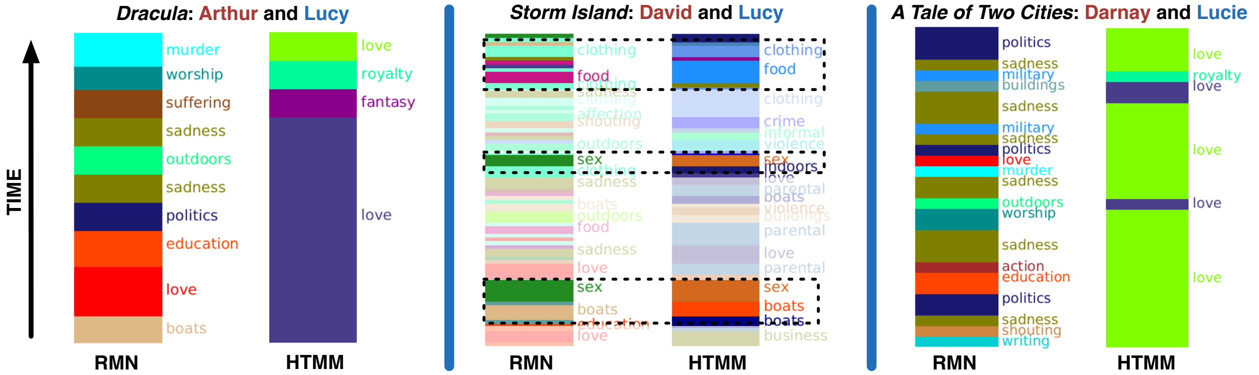


Figure 5: *Left*: the **RMN** is able to model Arthur and Lucy's trajectory reasonably well compared to our manually-created version in Figure 1. *Middle*: both models agree on event-based descriptors such as food and sex. *Right*: a failure case for the **RMN** in which it is unable to learn that Lucie Manette and Charles Darnay are in love.

terpersonal relationships. None of the topic model baselines learns negative emotional descriptors such as sadness or suffering, which explains the inaccurate **HTMM** trajectory of Arthur and Lucy in the left-most panel of Figure 5. All of the topic model baselines learn duplicate topics; in Table 2, one love descriptor is highly positive while a duplicate is strongly negative.[11] The **RMN** circumvents this problem with its uniqueness penalty (Equation 8).

While the increased descriptor variety is a positive, sometimes it leads the **RMN** astray. The model largely ignores the love between Charles Darnay and Lucie Manette in Dickens' *A Tale of Two Cities* due to book's sad tone; meanwhile, the **HTMM**'s trajectory, while vastly simplified, does pick up on the romance (Figure 5, right). While the **RMN**'s learnable book and character embeddings should help, the signal in a span cannot lead to the "proper" descriptor.

Both the **RMN** and **HTMM** learn that politics is strongly negative (Table 2). Existing scholarship supports this finding: Victorian-era authors, for example, are "obsessed with *otherness* . . . of antiquated social and legal institutions, and of autocratic and/or dictatorial abusive government" (Zarifopol-Johnston, 1995), while in science fiction, "dystopia——precisely because it is so much more common (than utopia)——bears the aspect of lived experience" (Gordin et al., 2010). Our affinity data comes primarily from Victorian novels (e.g., by Dickens and George Eliot), leading us to believe that that the models are behaving reasonably. Finally, returning to the "extra" meaning of meals discussed in Section 1, food occurs *slightly* more frequently in positive relationships.

6 Related Work

There are two major areas upon which our work builds: computational literary analysis and deep neural networks for natural language processing.

Most previous work in computational literary analysis has focused either on characters or events. In the former category, graphical models and classifiers have been proposed for learning character personas from novels (Bamman et al., 2014; Flekova and Gurevych, 2015) and film summaries (Bamman et al., 2013). The **NUBBI** model of Chang et al. (2009a) learns topics that statically describe characters and their relationships. Because these models lack temporal components (the focus of our task), we compare instead against the **HTMM** of Gruber et al. (2007).

Closest to our own work is the supervised structured prediction problem of Chaturvedi et al. (2016), in which features are designed to predict dynamic sequences of positive and negative interactions between two characters in plot summaries. Other research in this area includes social network construction from novels (Elson et al., 2010; Srivastava et al., 2016) and film (Krishnan and Eisenstein, 2015), as well as attempts to summarize and generate stories (Elsner, 2012).

While some of the relationship descriptors learned by our model are character-centric, others are more events-based, depicting actions rather than feelings;

[11] This "duplicate love" phenomenon persists even when we reduce the number of topics.

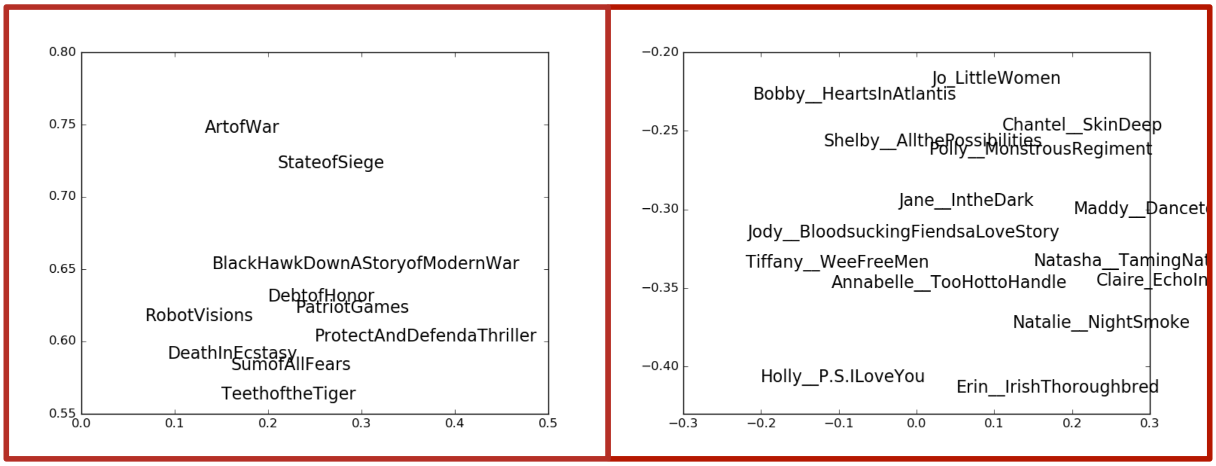

Figure 6: Clusters from PCA visualizations of the **RMN**'s learned book (left) and character (right) embeddings. We see a cluster of books about war and violence (many of which are authored by Tom Clancy) as well as a cluster of lead female characters from primarily romance novels. These visualizations show that the **RMN** can recover useful static representations of characters and books in addition to the dynamic relationship trajectories.

such descriptors have been the focus of much previous work (Schank and Abelson, 1977; Chambers and Jurafsky, 2008; Chambers and Jurafsky, 2009; Orr et al., 2014). Our model is more closely related to the plot units framework (Lehnert, 1981; Goyal et al., 2013), which annotates events with emotional states.

The **RMN** builds on deep recurrent autoencoders such as the hierarchical LSTM autoencoder of Li et al. (2015); however, it is more efficient because of the span-level vector averaging. It is also similar to recent neural topic model architectures (Cao et al., 2015; Das et al., 2015), although these models are limited to static document representations. We hope to apply the **RMN** to nonfictional datasets as well; in this vein, Iyyer et al. (2014) apply a neural network to sentences from nonfiction political books for ideology prediction.

More generally, topic models and related generative models are a central tool for understanding large corpora from science (Talley et al., 2011) to politics (Nguyen et al., 2014). We show representation learning models like **RMN** can be just as interpretable as LDA-based models. Other applications for which researchers have prioritized interpretable vector representations include text-to-vision mappings (Lazaridou et al., 2014) and word embeddings (Fyshe et al., 2015; Faruqui et al., 2015).

7 Conclusion

We formalize the task of unsupervised relationship modeling, which involves learning a set of relationship descriptors as well as a trajectory over these descriptors for each relationship in an input dataset. We present the **RMN**, a novel neural network architecture for this task that generates more interpretable descriptors and trajectories than topic model baselines. Finally, we show that the output of our model can lead to interesting insights when combined with annotations in an existing dataset.

Learning to Compose Neural Networks for Question Answering

Department of Electrical Engineering and Computer Sciences
University of California, Berkeley
{jda,rohrbach,trevor,klein}@eecs.berkeley.edu

Abstract

We describe a question answering model that applies to both images and structured knowledge bases. The model uses natural language strings to automatically assemble neural networks from a collection of composable modules. Parameters for these modules are learned jointly with network-assembly parameters via reinforcement learning, with only (world, question, answer) triples as supervision. Our approach, which we term a *dynamic neural module network*, achieves state-of-the-art results on benchmark datasets in both visual and structured domains.

1 Introduction

This paper presents a compositional, attentional model for answering questions about a variety of world representations, including images and structured knowledge bases. The model translates from questions to dynamically assembled neural networks, then applies these networks to world representations (images or knowledge bases) to produce answers. We take advantage of two largely independent lines of work: on one hand, an extensive literature on answering questions by mapping from strings to logical representations of meaning; on the other, a series of recent successes in deep neural models for image recognition and captioning. By constructing neural networks instead of logical forms, our model leverages the best aspects of both linguistic compositionality and continuous representations.

Our model has two components, trained jointly: first, a collection of neural "modules" that can be freely composed (Figure 1b); second, a network layout predictor that assembles modules into complete deep networks tailored to each question (Figure 1a).

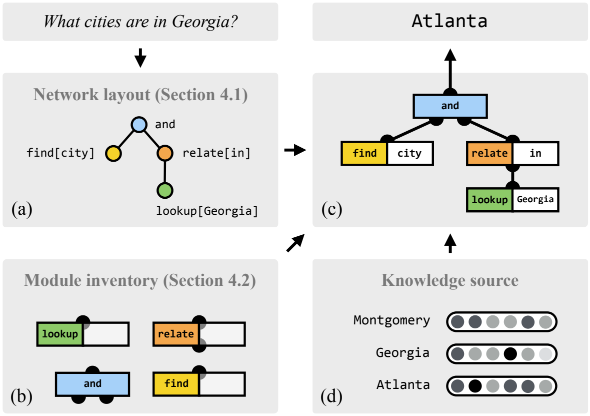

Figure 1: A learned syntactic analysis (a) is used to assemble a collection of neural modules (b) into a deep neural network (c), and applied to a world representation (d) to produce an answer.

Previous work has used manually-specified modular structures for visual learning (Andreas et al., 2016). Here we:

- *learn* a network structure predictor jointly with module parameters themselves
- *extend* visual primitives from previous work to reason over structured world representations

Training data consists of (world, question, answer) triples: our approach requires no supervision of network layouts. We achieve state-of-the-art performance on two markedly different question answering tasks: one with questions about natural images, and another with more compositional questions about United States geography.[1]

2 Deep networks as functional programs

We begin with a high-level discussion of the kinds of composed networks we would like to learn.

[1] We have released our code at http://github.com/jacobandreas/nmn2

Andreas et al. (2016) describe a heuristic approach for decomposing visual question answering tasks into sequence of modular sub-problems. For example, the question *What color is the bird?* might be answered in two steps: first, "where is the bird?" (Figure 2a), second, "what color is that part of the image?" (Figure 2c). This first step, a generic **module** called `find`, can be expressed as a fragment of a neural network that maps from image features and a lexical item (here *bird*) to a distribution over pixels. This operation is commonly referred to as the *attention mechanism*, and is a standard tool for manipulating images (Xu et al., 2015) and text representations (Hermann et al., 2015).

The first contribution of this paper is an extension and generalization of this mechanism to enable fully-differentiable reasoning about more structured semantic representations. Figure 2b shows how the same module can be used to focus on the entity *Georgia* in a non-visual grounding domain; more generally, by representing every entity in the universe of discourse as a feature vector, we can obtain a distribution over entities that corresponds roughly to a logical set-valued denotation.

Having obtained such a distribution, existing neural approaches use it to immediately compute a weighted average of image features and project back into a labeling decision—a `describe` module (Figure 2c). But the logical perspective suggests a number of novel modules that might operate on attentions: e.g. combining them (by analogy to conjunction or disjunction) or inspecting them directly without a return to feature space (by analogy to quantification, Figure 2d). These modules are discussed in detail in Section 4. Unlike their formal counterparts, they are differentiable end-to-end, facilitating their integration into learned models. Building on previous work, we learn behavior for a collection of heterogeneous modules from (world, question, answer) triples.

The second contribution of this paper is a model for learning to assemble such modules compositionally. Isolated modules are of limited use—to obtain expressive power comparable to either formal approaches or monolithic deep networks, they must be composed into larger structures. Figure 2 shows simple examples of composed structures, but for realistic question-answering tasks, even larger networks are required. Thus our goal is to automatically induce variable-free, tree-structured computation descriptors. We can use a familiar functional notation from formal semantics (e.g. Liang et al., 2011) to represent these computations.[2] We write the two examples in Figure 2 as

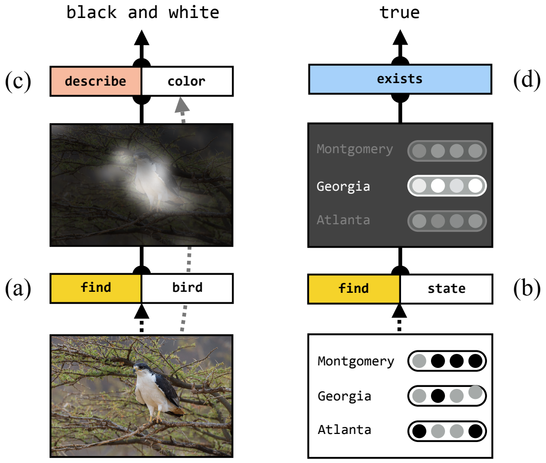

Figure 2: Simple neural module networks, corresponding to the questions *What color is the bird?* and *Are there any states?* (a) A neural `find` module for computing an attention over pixels. (b) The same operation applied to a knowledge base. (c) Using an attention produced by a lower module to identify the color of the region of the image attended to. (d) Performing quantification by evaluating an attention directly.

```
(describe[color] find[bird])
```

and

```
(exists find[state])
```

respectively. These are **network layouts**: they specify a structure for arranging modules (and their lexical parameters) into a complete network. Andreas et al. (2016) use hand-written rules to deterministically transform dependency trees into layouts, and are restricted to producing simple structures like the above for non-synthetic data. For full generality, we will need to solve harder problems, like transforming *What cities are in Georgia?* (Figure 1) into

```
(and
    find[city]
    (relate[in] lookup[Georgia]))
```

In this paper, we present a model for learning to select such structures from a set of automatically generated candidates. We call this model a **dynamic neural module network**.

[2] But note that unlike formal semantics, the behavior of the primitive functions here is itself unknown.

3 Related work

There is an extensive literature on database question answering, in which strings are mapped to logical forms, then evaluated by a black-box execution model to produce answers. Supervision may be provided either by annotated logical forms (Wong and Mooney, 2007; Kwiatkowski et al., 2010; Andreas et al., 2013) or from (world, question, answer) triples alone (Liang et al., 2011; Pasupat and Liang, 2015). In general the set of primitive functions from which these logical forms can be assembled is fixed, but one recent line of work focuses on inducing new predicates functions automatically, either from perceptual features (Krishnamurthy and Kollar, 2013) or the underlying schema (Kwiatkowski et al., 2013). The model we describe in this paper has a unified framework for handling both the perceptual and schema cases, and differs from existing work primarily in learning a differentiable execution model with continuous evaluation results.

Neural models for question answering are also a subject of current interest. These include approaches that model the task directly as a multiclass classification problem (Iyyer et al., 2014), models that attempt to embed questions and answers in a shared vector space (Bordes et al., 2014) and attentional models that select words from documents sources (Hermann et al., 2015). Such approaches generally require that answers can be retrieved directly based on surface linguistic features, without requiring intermediate computation. A more structured approach described by Yin et al. (2015) learns a query execution model for database tables without any natural language component. Previous efforts toward unifying formal logic and representation learning include those of Grefenstette (2013) and Krishnamurthy and Mitchell (2013).

The visually-grounded component of this work relies on recent advances in convolutional networks for computer vision (Simonyan and Zisserman, 2014), and in particular the fact that late convolutional layers in networks trained for image recognition contain rich features useful for other downstream vision tasks, while preserving spatial information. These features have been used for both image captioning (Xu et al., 2015) and visual question answering (Yang et al., 2015).

Most previous approaches to visual question answering either apply a recurrent model to deep representations of both the image and the question (Ren et al., ; Malinowski et al., 2015), or use the question to compute an attention over the input image, and then answer based on both the question and the image features attended to (Yang et al., 2015; Xu and Saenko, 2015). Other approaches include the simple classification model described by Zhou et al. (2015) and the dynamic parameter prediction network described by Noh et al. (2015). All of these models assume that a fixed computation can be performed on the image and question to compute the answer, rather than adapting the structure of the computation to the question.

As noted, Andreas et al. (2016) previously considered a simple generalization of these attentional approaches in which small variations in the network structure per-question were permitted, with the structure chosen by (deterministic) syntactic processing of questions. Other approaches in this general family include the "universal parser" sketched by Bottou (2014), and the recursive neural networks of Socher et al. (2013), which use a fixed tree structure to perform further linguistic analysis without any external world representation. We are unaware of previous work that succeeds in simultaneously learning both the parameters for and structures of instance-specific neural networks.

4 Model

Recall that our goal is to map from questions and world representations to answers. This process involves the following variables:

1. w a world representation
2. x a question
3. y an answer
4. z a network layout
5. θ a collection of model parameters

Our model is built around two distributions: a **layout model** $p(z|x;\theta_\ell)$ which chooses a layout for a sentence, and a **execution model** $p_z(y|w;\theta_e)$ which applies the network specified by z to w.

For ease of presentation, we introduce these models in reverse order. We first imagine that z is always observed, and in Section 4.1 describe how to evaluate and learn modules parameterized by θ_e within fixed structures. In Section 4.2, we move to the real scenario, where z is unknown. We describe how to predict layouts from questions and learn θ_e and θ_ℓ jointly without layout supervision.

4.1 Evaluating modules

Given a layout z, we assemble the corresponding modules into a full neural network (Figure 1c), and apply it to the knowledge representation. Intermediate results flow between modules until an answer is produced at the root. We denote the output of the network with layout z on input world w as $\llbracket z \rrbracket_w$; when explicitly referencing the substructure of z, we can alternatively write $\llbracket m(h^1, h^2) \rrbracket$ for a top-level module m with submodule outputs h^1 and h^2. We then define the execution model:

$$p_z(y|w) = (\llbracket z \rrbracket_w)_y \tag{1}$$

(This assumes that the root module of z produces a distribution over labels y.) The set of possible layouts z is restricted by module *type constraints*: some modules (like `find` above) operate directly on the input representation, while others (like `describe` above) also depend on input from specific earlier modules. Two base types are considered in this paper are <u>Attention</u> (a distribution over pixels or entities) and <u>Labels</u> (a distribution over answers).

Parameters are tied across multiple instances of the same module, so different instantiated networks may share some parameters but not others. Modules have both *parameter arguments* (shown in square brackets) and ordinary inputs (shown in parentheses). Parameter arguments, like the running `bird` example in Section 2, are provided by the layout, and are used to specialize module behavior for particular lexical items. Ordinary inputs are the result of computation lower in the network. In addition to parameter-specific weights, modules have global weights shared across all instances of the module (but not shared with other modules). We write $A, a, B, b, \ldots$ for global weights and u^i, v^i for weights associated with the parameter argument i. $\oplus$ and $\odot$ denote (possibly broadcasted) elementwise addition and multiplication respectively. The complete set of global weights and parameter-specific weights constitutes θ_e. *Every* module has access to the world representation, represented as a collection of vectors $w^1, w^2, \ldots$ (or W expressed as a matrix). The nonlinearity σ denotes a rectified linear unit.

The modules used in this paper are shown below, with names and type constraints in the first row and a description of the module's computation following.

Lookup ($\rightarrow$ <u>Attention</u>)

`lookup[i]` produces an attention focused entirely at the index $f(i)$, where the relationship f between words and positions in the input map is known ahead of time (e.g. string matches on database fields).

$$\llbracket \texttt{lookup[}i\texttt{]} \rrbracket = e_{f(i)} \tag{2}$$

where e_i is the basis vector that is 1 in the ith position and 0 elsewhere.

Find ($\rightarrow$ <u>Attention</u>)

`find[i]` computes a distribution over indices by concatenating the parameter argument with each position of the input feature map, and passing the concatenated vector through a MLP:

$$\llbracket \texttt{find[}i\texttt{]} \rrbracket = \text{softmax}(a \odot \sigma(Bv^i \oplus CW \oplus d)) \tag{3}$$

Relate (<u>Attention</u> $\rightarrow$ <u>Attention</u>)

`relate` directs focus from one region of the input to another. It behaves much like the `find` module, but also conditions its behavior on the current region of attention h. Let $\bar{w}(h) = \sum_k h_k w^k$, where h_k is the k^{th} element of h. Then,

$$\begin{aligned} \llbracket \texttt{relate[}i\texttt{]}(h) \rrbracket = \text{softmax}(a \odot \\ \sigma(Bv^i \oplus CW \oplus D\bar{w}(h) \oplus e)) \end{aligned} \tag{4}$$

And (<u>Attention</u>* $\rightarrow$ <u>Attention</u>)

`and` performs an operation analogous to set intersection for attentions. The analogy to probabilistic logic suggests multiplying probabilities:

$$\llbracket \texttt{and}(h^1, h^2, \ldots) \rrbracket = h^1 \odot h^2 \odot \cdots \tag{5}$$

Describe (<u>Attention</u> $\rightarrow$ <u>Labels</u>)

`describe[i]` computes a weighted average of w under the input attention. This average is then used to predict an answer representation. With $\bar{w}$ as above,

$$\llbracket \texttt{describe[}i\texttt{]}(h) \rrbracket = \text{softmax}(A\sigma(B\bar{w}(h) + v^i)) \tag{6}$$

Exists (<u>Attention</u> $\rightarrow$ <u>Labels</u>)

`exists` is the existential quantifier, and inspects the incoming attention directly to produce a label, rather than an intermediate feature vector like `describe`:

$$\llbracket \texttt{exists]}(h) \rrbracket = \text{softmax}\Big(\big(\max_k h_k\big)a + b\Big) \tag{7}$$

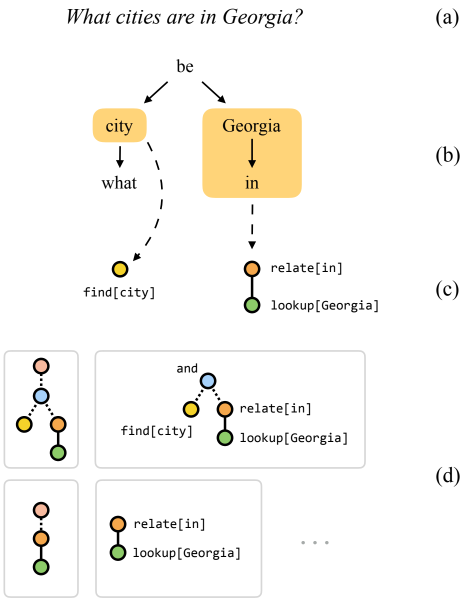

Figure 3: Generation of layout candidates. The input sentence (a) is represented as a dependency parse (b). Fragments of this dependency parse are then associated with appropriate modules (c), and these fragments are assembled into full layouts (d).

With z observed, the model we have described so far corresponds largely to that of Andreas et al. (2016), though the module inventory is different—in particular, our new `exists` and `relate` modules do not depend on the two-dimensional spatial structure of the input. This enables generalization to non-visual world representations.

Learning in this simplified setting is straightforward. Assuming the top-level module in each layout is a `describe` or `exists` module, the fully- instantiated network corresponds to a distribution over labels conditioned on layouts. To train, we maximize $\sum_{(w,y,z)} \log p_z(y|w;\theta_e)$ directly. This can be understood as a parameter-tying scheme, where the decisions about which parameters to tie are governed by the observed layouts z.

4.2 Assembling networks

Next we describe the layout model $p(z|x;\theta_\ell)$. We first use a fixed syntactic parse to generate a small set of candidate layouts, analogously to the way a semantic grammar generates candidate semantic parses in previous work (Berant and Liang, 2014).

A semantic parse differs from a syntactic parse in two primary ways. First, lexical items must be mapped onto a (possibly smaller) set of semantic primitives. Second, these semantic primitives must be combined into a structure that closely, but not exactly, parallels the structure provided by syntax. For example, *state* and *province* might need to be identified with the same field in a database schema, while *all states have a capital* might need to be identified with the correct (*in situ*) quantifier scope.

While we cannot avoid the structure selection problem, continuous representations simplify the lexical selection problem. For modules that accept a vector parameter, we associate these parameters with *words* rather than semantic tokens, and thus turn the combinatorial optimization problem associated with lexicon induction into a continuous one. Now, in order to learn that *province* and *state* have the same denotation, it is sufficient to learn that their associated parameters are close in some embedding space—a task amenable to gradient descent. (Note that this is easy only in an optimizability sense, and not an information-theoretic one—we must still learn to associate each independent lexical item with the correct vector.) The remaining combinatorial problem is to arrange the provided lexical items into the right computational structure. In this respect, layout prediction is more like syntactic parsing than ordinary semantic parsing, and we can rely on an off-the-shelf syntactic parser to get most of the way there. In this work, syntactic structure is provided by the Stanford dependency parser (De Marneffe and Manning, 2008).

The construction of layout candidates is depicted in Figure 3, and proceeds as follows:

1. Represent the input sentence as a dependency tree.
2. Collect all nouns, verbs, and prepositional phrases that are attached directly to a wh-word or copula.
3. Associate each of these with a layout fragment: Ordinary nouns and verbs are mapped to a single `find` module. Proper nouns to a single `lookup` module. Prepositional phrases are mapped to a depth-2 fragment, with a `relate` module for the preposition above a `find` module for the enclosed head noun.
4. Form subsets of this set of layout fragments. For each subset, construct a layout candidate by

joining all fragments with an `and` module, and inserting either a `measure` or `describe` module at the top (each subset thus results in two parse candidates.)

All layouts resulting from this process feature a relatively flat tree structure with at most one conjunction and one quantifier. This is a strong simplifying assumption, but appears sufficient to cover most of the examples that appear in both of our tasks. As our approach includes both categories, relations and simple quantification, the range of phenomena considered is generally broader than previous perceptually-grounded QA work (Krishnamurthy and Kollar, 2013; Matuszek et al., 2012).

Having generated a set of candidate parses, we need to score them. This is a ranking problem; as in the rest of our approach, we solve it using standard neural machinery. In particular, we produce an LSTM representation of the question, a feature-based representation of the query, and pass both representations through a multilayer perceptron (MLP). The query feature vector includes indicators on the number of modules of each type present, as well as their associated parameter arguments. While one can easily imagine a more sophisticated parse-scoring model, this simple approach works well for our tasks.

Formally, for a question x, let $h_q(x)$ be an LSTM encoding of the question (i.e. the last hidden layer of an LSTM applied word-by-word to the input question). Let $\{z_1, z_2, \ldots\}$ be the proposed layouts for x, and let $f(z_i)$ be a feature vector representing the ith layout. Then the score $s(z_i|x)$ for the layout z_i is

$$s(z_i|x) = a^\top \sigma(Bh_q(x) + Cf(z_i) + d) \tag{8}$$

i.e. the output of an MLP with inputs $h_q(x)$ and $f(z_i)$, and parameters $\theta_\ell = \{a, B, C, d\}$. Finally, we normalize these scores to obtain a distribution:

$$p(z_i|x;\theta_\ell) = e^{s(z_i|x)} \Big/ \sum_{j=1}^{n} e^{s(z_j|x)} \tag{9}$$

Having defined a layout selection module $p(z|x;\theta_\ell)$ and a network execution model $p_z(y|w;\theta_e)$, we are ready to define a model for predicting answers given only (world, question) pairs. The key constraint is that we want to minimize evaluations of $p_z(y|w;\theta_e)$ (which involves expensive application of a deep network to a large input representation), but can tractably evaluate $p(z|x;\theta_\ell)$ for all z (which involves application of a shallow network to a relatively small set of candidates). This is the opposite of the situation usually encountered semantic parsing, where calls to the query execution model are fast but the set of candidate parses is too large to score exhaustively.

In fact, the problem more closely resembles the scenario faced by agents in the reinforcement learning setting (where it is cheap to score actions, but potentially expensive to execute them and obtain rewards). We adopt a common approach from that literature, and express our model as a stochastic policy. Under this policy, we first *sample* a layout z from a distribution $p(z|x;\theta_\ell)$, and then apply z to the knowledge source and obtain a distribution over answers $p(y|z,w;\theta_e)$.

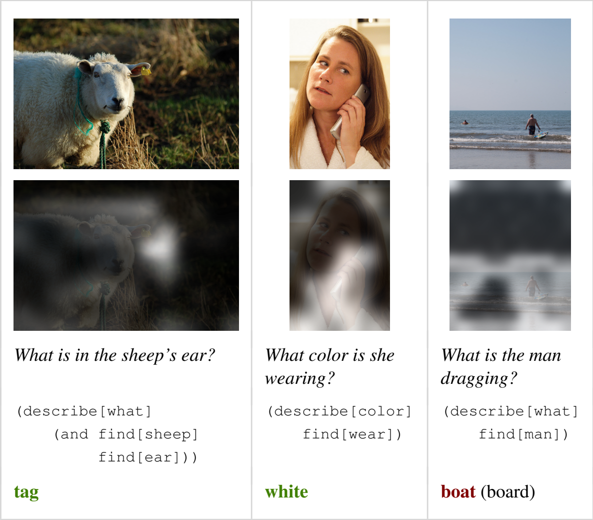
After z is chosen, we can train the execution model directly by maximizing $\log p(y|z,w;\theta_e)$ with respect to θ_e as before (this is ordinary backpropagation). Because the hard selection of z is non-differentiable, we optimize $p(z|x;\theta_\ell)$ using a policy gradient method. The gradient of the reward surface J with respect to the parameters of the policy is

$$\nabla J(\theta_\ell) = \mathbb{E}[\nabla \log p(z|x;\theta_\ell) \cdot r] \tag{10}$$

(this is the REINFORCE rule (Williams, 1992)). Here the expectation is taken with respect to rollouts of the policy, and r is the reward. Because our goal is to select the network that makes the most accurate predictions, we take the reward to be identically the negative log-probability from the execution phase, i.e.

$$\mathbb{E}[(\nabla \log p(z|x;\theta_\ell)) \cdot \log p(y|z,w;\theta_e)] \tag{11}$$

Thus the update to the layout-scoring model at each timestep is simply the gradient of the log-probability of the chosen layout, scaled by the accuracy of that layout's predictions. At training time, we approximate the expectation with a single rollout, so at each step we update θ_ℓ in the direction $(\nabla \log p(z|x;\theta_\ell)) \cdot \log p(y|z,w;\theta_e)$ for a single $z \sim p(z|x;\theta_\ell)$. θ_e and θ_ℓ are optimized using ADADELTA (Zeiler, 2012) with $\rho = 0.95$, $\varepsilon = 1\text{e}{-6}$ and gradient clipping at a norm of 10.



What is in the sheep's ear?
What color is she wearing?
What is the man dragging?

```
(describe[what]
    (and find[sheep]
         find[ear]))
```

```
(describe[color]
    find[wear])
```

```
(describe[what]
    find[man])
```

Figure 4: Sample outputs for the visual question answering task. The second row shows the final attention provided as input to the top-level `describe` module. For the first two examples, the model produces reasonable parses, attends to the correct region of the images (the ear and the woman's clothing), and generates the correct answer. In the third image, the verb is discarded and a wrong answer is produced.

5 Experiments

The framework described in this paper is general, and we are interested in how well it performs on datasets of varying domain, size and linguistic complexity. To that end, we evaluate our model on tasks at opposite extremes of both these criteria: a large visual question answering dataset, and a small collection of more structured geography questions.

5.1 Questions about images

Our first task is the recently-introduced Visual Question Answering challenge (VQA) (Antol et al., 2015). The VQA dataset consists of more than 200,000 images paired with human-annotated questions and answers, as in Figure 4.

We use the VQA 1.0 release, employing the development set for model selection and hyperparameter tuning, and reporting final results from the evaluation server on the test-standard set. For the experiments described in this section, the input feature representations w_i are computed by the the fifth convolutional layer of a 16-layer VGGNet after pooling (Simonyan and Zisserman, 2014). Input images are scaled to 448×448 before computing their representations. We found that performance on this task was best if the candidate layouts were relatively simple: only `describe`, `and` and `find` modules are used, and layouts contain at most two conjuncts.

	test-dev				test-std
	Yes/No	Number	Other	All	All
Zhou (2015)	76.6	35.0	42.6	55.7	55.9
Noh (2015)	80.7	37.2	41.7	57.2	57.4
NMN	77.7	37.2	39.3	54.8	55.1
NMN*	79.7	37.1	42.8	57.3	–
D-NMN	80.5	37.4	43.1	57.9	**58.0**

Table 1: Results on the VQA test server. NMN is the parameter-tying model from Andreas et al. (2015), while NMN* is a reimplementation using the same image processing pipeline as D-NMN. The model with dynamic network structure prediction achieves the best published results on this task.

One weakness of this basic framework is a difficulty modeling prior knowledge about answers (of the form *bears are brown*). This kinds of linguistic "prior" is essential for the VQA task, and easily incorporated. We simply introduce an extra hidden layer for recombining the final module network output with the input sentence representation $h_q(x)$ (see Equation 8), replacing Equation 1 with:

$$\log p_z(y|w,x) = (Ah_q(x) + B[\![z]\!]_w)_y \qquad (12)$$

(Now modules with output type <u>Labels</u> should be understood as producing an answer embedding rather than a distribution over answers.) This allows the question to influence the answer directly.

Results are shown in Table 1. The use of dynamic networks provides a small gain, most noticeably on yes/no questions. We achieve state-of-the-art results on this task, outperforming a highly effective visual bag-of-words model (Zhou et al., 2015), a model with dynamic network parameter prediction (but fixed network structure) (Noh et al., 2015), and a previous approach using neural module networks with no structure prediction (Andreas et al., 2016). For this last model, we report both the numbers from the original paper, and a reimplementation of the model that uses the same image preprocessing as the dynamic module network experiments in this paper. A more conventional attentional model has also been applied to this task (Yang et al., 2015); while we also outperform their reported performance, the evaluation uses different train/test split, so results are not directly comparable.

	Accuracy	
Model	GeoQA	GeoQA+Q
LSP-F	48	–
LSP-W	51	–
NMN	51.7	35.7
D-NMN	**54.3**	**42.9**

Table 2: Results on the GeoQA dataset, and the GeoQA dataset with quantification. Our approach outperforms both a purely logical model (LSP-F) and a model with learned perceptual predicates (LSP-W) on the original dataset, and a fixed-structure NMN under both evaluation conditions.

Some examples are shown in Figure 4. In general, the model learns to focus on the correct region of the image, and tends to consider a broad window around the region. This facilitates answering questions like *Where is the cat?*, which requires knowledge of the surroundings as well as the object in question.

5.2 Questions about geography

The next set of experiments we consider focuses on GeoQA, a geographical question-answering task first introduced by Krishnamurthy and Kollar (2013). This task was originally paired with a visual question answering task much simpler than the one just discussed, and is appealing for a number of reasons. In contrast to the VQA dataset, GeoQA is quite small, containing only 263 examples. Two baselines are available: one using a classical semantic parser backed by a database, and another which induces logical predicates using linear classifiers over both spatial and distributional features. This allows us to evaluate the quality of our model relative to other perceptually grounded logical semantics, as well as strictly logical approaches.

The GeoQA domain consists of a set of entities (e.g. states, cities, parks) which participate in various relations (e.g. north-of, capital-of). Here we take the world representation to consist of two pieces: a set of category features (used by the `find` module) and a different set of relational features (used by the `relate` module). For our experiments, we use a subset of the features originally used by Krishnamurthy et al. The original dataset includes no quantifiers, and treats the questions *What cities are in Texas?* and *Are there any cities in Texas?* identically. Because we are interested in testing the parser's ability to predict a variety of different structures, we introduce a new version of the dataset, GeoQA+Q, which distinguishes these two cases, and expects a Boolean answer to questions of the second kind.

Is Key Largo an island?

```
(exists (and lookup[key-largo] find[island]))
```

yes: correct

What national parks are in Florida?

```
(and find[park] (relate[in] lookup[florida]))
```

everglades: correct

What are some beaches in Florida?

```
(exists (and lookup[beach]
             (relate[in] lookup[florida])))
```

yes (daytona-beach): wrong parse

What beach city is there in Florida?

```
(and lookup[beach] lookup[city]
     (relate[in] lookup[florida]))
```

[none] (daytona-beach): wrong module behavior

Figure 5: Example layouts and answers selected by the model on the GeoQA dataset. For incorrect predictions, the correct answer is shown in parentheses.

Results are shown in Table 2. As in the original work, we report the results of leave-one-environment-out cross-validation on the set of 10 environments. Our dynamic model (D-NMN) outperforms both the logical (LSP-F) and perceptual models (LSP-W) described by (Krishnamurthy and Kollar, 2013), as well as a fixed-structure neural module net (NMN). This improvement is particularly notable on the dataset with quantifiers, where dynamic structure prediction produces a 20% relative improvement over the fixed baseline. A variety of predicted layouts are shown in Figure 5.

6 Conclusion

We have introduced a new model, the *dynamic neural module network*, for answering queries about both structured and unstructured sources of information. Given only (question, world, answer) triples as training data, the model learns to assemble neural networks on the fly from an inventory of neural models, and simultaneously learns weights for these modules so that they can be composed into novel structures. Our approach achieves state-of-the-art results on two tasks. We believe that the success of this work derives from two factors:

Continuous representations improve the expressiveness and learnability of semantic parsers: by replacing discrete predicates with differentiable neural network fragments, we bypass the challenging combinatorial optimization problem associated with induction of a semantic lexicon. In structured world representations, neural predicate representations allow the model to invent reusable attributes and relations not expressed in the schema. Perhaps more importantly, we can extend compositional question-answering machinery to complex, continuous world representations like images.

Semantic structure prediction improves generalization in deep networks: by replacing a fixed network topology with a dynamic one, we can tailor the computation performed to each problem instance, using deeper networks for more complex questions and representing combinatorially many queries with comparatively few parameters. In practice, this results in considerable gains in speed and sample efficiency, even with very little training data.

These observations are not limited to the question answering domain, and we expect that they can be applied similarly to tasks like instruction following, game playing, and language generation.
