The in-domain features perform much worse, especially for the WIKI topics. NPMI assigns very high scores to several incoherent topics, thereby reducing the correlation to almost zero. These topics consist predominantly of Wikipedia markup tags, and the high association is due to word statistics idiosyncratic to the collection.

Once again, aggregating the topic coherence over

[5] The test measures if the aggregate correlation is significantly higher ($p < 0.1$) than a non-aggregate correlation using a one-tailed test.

multiple N values boosts results further. The correlations using aggregation and out-of-domain features again produce the best results for both WIKI and NEWS.

It is important to note that, while these findings were established based on manual annotation of topic coherence, for practical applications, topic coherence would be calculated in a fully-unsupervised manner (averaged over different topic cardinalities), without the use of manual annotations.

5 Conclusion

We investigate the impact of the cardinality of topic words on topic coherence evaluation. We found that human ratings decrease systematically when cardinality increases, although pairwise correlations are relatively high. We discovered that the performance of two automated methods — word intrusion and pairwise NPMI — can be substantially improved if the system scores and human ratings are aggregated over several cardinality settings before computing the correlation. Contrary to the standard practice of using a fixed cardinality setting, our findings suggest that we should assess topic coherence using several cardinality settings and then aggregate over them. The human-judged coherence ratings, along with code to compute topic coherence, are available online.

Abstract

It has been shown that transition-based methods can be used for syntactic word ordering and tree linearization, achieving significantly faster speed compared with traditional best-first methods. State-of-the-art transition-based models give competitive results on abstract word ordering and unlabeled tree linearization, but significantly worse results on labeled tree linearization. We demonstrate that the main cause for the performance bottleneck is the sparsity of SHIFT transition actions rather than heavy pruning. To address this issue, we propose a modification to the standard transition-based feature structure, which reduces feature sparsity and allows lookahead features at a small cost to decoding efficiency. Our model gives the best reported accuracies on all benchmarks, yet still being over 30 times faster compared with best-first-search.

1 Introduction

Word ordering is the abstract language modeling task of making a grammatical sentence by ordering a bag of words (White, 2004; Zhang and Clark, 2015; De Gispert et al., 2014; Bohnet et al., 2010; Filippova and Strube, 2007; He et al., 2009), which is practically relevant to text-to-text applications such as summarization (Wann et al., 2009) and machine translation (Blackwood et al., 2010). Zhang (2013) built a discriminative word ordering model, which takes a bag of words, together with optional POS and dependency arcs on a subset of input words, and yields a sentence together with its dependency parse tree that conforms to input syntactic constraints. The system is flexible with respect to input constraints, performing abstract word ordering when no constraints are given, but gives increasingly confined outputs when more POS and dependency relations are specified. It has been applied to syntactic linearization (Song et al., 2014) and machine translation (Zhang et al., 2014).

One limitation of Zhang (2013) is relatively low time efficiency, due to the use of time-constrained best-first-search (White and Rajkumar, 2009) for decoding. In practice, the system can take seconds to order a bag of words in order to obtain reasonable output quality. Recently, Liu et al. (2015) proposed a transition-based model to address this issue, which uses a sequence of state transitions to build the output. The system of Liu et al. (2015) achieves significant speed improvements without sacrificing accuracies when working with unlabeled dependency trees. With labeled dependency trees as input constraints, however, the system of Liu et al. (2015) gives much lower accuracies compared with Zhang (2013).

While the low accuracy can be attributed to heavy pruning, we show that it can be mitigated by modifying the feature structure of the standard transition-based framework, which scores the output transition sequence by summing the scores of each transition action. Transition actions are treated as an *atomic* output component in each feature instance. This works effectively for most structured prediction tasks, including parsing (Zhang and Clark, 2011a). For word ordering, however, transition actions are significantly more complex and sparse compared

San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

with parsing, which limits the power of the traditional feature model.

We instead break down complex actions into smaller components, merging some components into configuration features which reduces sparsity in the output action and allows flexible lookahead features to be defined according to the next action to be applied. On the other hand, this change in the feature structure prevents legitimate actions to be scored simultaneously for each configuration state, thereby reducing decoding efficiency. Experiments show that our method is slightly slower compared with Liu et al. (2015), but achieves significantly better accuracies. It gives the best results for all standard benchmarks, being over thirty times faster than Zhang (2013). The new feature structures can be applied to other transition-based systems also.

2 Transition-based linearization

Liu et al. (2015) uses a transition-based model for word ordering, building output sentences using a sequence of state transitions. Instead of scoring output syntax trees directly, it scores the transition action sequence for structural disambiguation. Liu et al.'s transition system extends from transition-based parsers (Nivre and Scholz, 2004; Chen and Manning, 2014), where a *state* consists of a *stack* to hold partially built outputs. Transition-based parsers use a *queue* to maintain input word sequences. However, for word ordering, the input is a set without order. Accordingly, Liu et al. uses a *set* to maintain the input. The transition actions are:

- SHIFT-*Word*-POS, which removes *Word* from the *set*, assigns POS to it and pushes it onto the *stack* as the top word S_0;
- LEFTARC-LABEL, which removes the second top of *stack* S_1 and builds a dependency arc $S_1 \xleftarrow{LABEL} S_0$;
- RIGHTARC-LABEL, which removes the top of *stack* S_0 and builds a dependency arc $S_1 \xrightarrow{LABEL} S_0$.

Using the state transition system, the bag of words $\{$*John, loves, Mary*$\}$ can be ordered by (SHIFT-*John*-NNP, SHIFT-*loves*-VBZ, LEFTARC-SBJ, SHIFT-*Mary*-NNP, RIGHTARC-OBJ).

Liu et al. (2015) use a discriminative perceptron model with beam search (Zhang and Clark, 2011a), designing decoding algorithms that accommodate flexible constraints. The features include word(w), pos(p) and dependency label(l) information of words on the stack (S_0, S_1, ... from the top). For example, the word on top of stack is S_0w and the POS of the stack top is S_0p. The full set of feature templates can be found in Table 2 of Liu et al. (2015), reproduced here in Table 1. These templates are called *configuration features*. When instantiated, they are combined with each legal output *action* to score the action. Therefore, actions are atomic in feature instances.

Table 1: Base feature templates.

Formally, given a configuration C, the score of a possible action a is calculated as:

$$Score(a) = \vec{\theta} \cdot \Phi(\vec{C}, a),$$

where $\vec{\theta}$ is the model parameter vector of the model and $\Phi(\vec{C}, a)$ denotes a sparse feature vector that consists of features with *configuration* and *action* components i.e $\Phi(\vec{C}, a)$ is sparse. $\vec{\theta}$ has to be loaded for each a.

For efficiency considerations and following transition-based models, Liu et al. (2015) scores all possible actions given a configuration simultaneously. This is effectively the same as formulating the score into

$$Score(a) = \vec{\theta_a} \cdot \Phi(\vec{C}), a \in A.$$

Here A is the full set of actions and $\Phi(\vec{C})$ is fixed, and $\vec{\theta_a}$ for all a can be loaded simultaneously. In a hash-based parameter model, it significantly improves the time efficiency.

3 Feature structure modification

3.1 Two limitations of the baseline model

There are two major limitations in the feature structure of Liu et al. (2015). First, the SHIFT actions, which consist of the word to shift and its POS, are highly sparse. Since the action is combined with all configuration features, there will be no active feature for disambiguating the shift actions for OOV words. This issue does not exist in transition-based parsers because words are not a part of their transition actions. Second, input constraints are not leveraged by the feature model. Although the dependency relations of the word to shift can be given as inputs, they are used only as constraints to the decoder, but not as features to guide the shift action. Such lookahead information on the to-be-shifted word can be highly useful for disambiguation.

For example, consider the bag of words {*John*, *loves*, *Mary*}. Without constraints, both '*John loves Mary*' and '*Mary loves John*' are valid word ordering results. However, given the constraint (*John*, SBJ, *loves*), the correct answer is reduced to the former. The first action to build the two examples are (SHIFT-*John*-NNP) and (SHIFT-*Mary*-NNP), respectively. According to Liu et al.'s feature model, there is no feature to disambiguate the first SHIFT action if both '*John*' and '*Mary*' are OOV words. The system has to maintain both hypotheses and rely on the search algorithm to disambiguate them after the dependency arcs (*John*, SBJ, *loves*) and (*Mary*, OBJ, *loves*) are built. However, given the syntactic constraint that '*John*' is the subject, the disambiguation can be done right when performing the first SHIFT action. This requires the dependency arc label to be extracted for the word to shift e.g.(*John, Mary*), which is a lookahead feature. In addition, the OOV word '*John*' must be excluded from the feature instance, which implies that the SHIFT-*John*-NNP action must be simplified.

Table 2: Lookahead feature templates

As a second example, information about dependents can also be useful for disambiguating SHIFT actions. In the above case, the fact that the *subject* has not been shifted onto the stack can be a useful indicator for not shifting the verb '*loves*' onto the stack in the beginning. Inspired by the above, we exploit a range of lookahead features from syntactic constraints.

3.2 New feature structure for SHIFT actions

We modify the feature structure of Liu et al. (2015) by breaking down the SHIFT-*Word-POS* action into three components, namely SHIFT, *Word* and *POS*, using only the action type SHIFT as the output action component in feature instances, while combin-

ing *Word* and *POS* with other configuration features to form a set of lookahead features.

For example, consider the configuration feature S_0w, which captures the word on the top of the stack. Under the feature structure of Liu et al., it is combined with each possible action to form features for scoring the action. As a result, for scoring the action SHIFT-Lw-Lp, S_0w is instantiated into S_0w-SHIFT-Lw-Lp, where Lw is the word to shift and Lp is its POS. Under our new feature structure, the action component is reduced to SHIFT only, while Lw and Lp should be used in lookahead features. Now a effectively equivalent configuration feature to Liu et al.'s S_0w is S_0w-Lw-Lp, with the lookahead Lw and Lp. It gives S_0w-Lw-Lp-SHIFT when combined with the action SHIFT.

This new feature structure reformulates the SHIFT action features only. The LEFTARC/ RIGHTARC actions remain LEFTARC/ RIGHTARC-LABEL since they are not sparse. Note that the change is in the *action features* rather than the *actions* themselves. Given the bag of words {*John*, *loves*, *Mary*}, the action SHIFT-*John*-NNP is still different from the action SHIFT-*Mary*-NNP. However, the *action component* of the features becomes SHIFT only, and the words *John*/ *Mary* must be used as lookahead *configuration features* for their disambiguation.

The new feature structure can reduce feature sparsity by allowing lookahead features without word information. For example, a configuration feature S_0w-Lp, which contains only the stack top word and the POS of the lookahead word, can still fire even if the word to shift is OOV, thereby disambiguating OOV words of different POS. In addition, the lookahead Lw and Lp do not have to be combined with every other configuration feature, as with Liu et al. (2015), thereby allowing more flexible feature combination and a leaner model.

3.3 The new features

The new feature structure includes two types of features. The first is the same feature set as Liu et al. (2015), but with the SHIFT action component not having *Word* and *POS* information. We call this type of features as *base features*. The second is a set of *lookahead features*, which are shown in Table 2. Here L_{cls} represents set of arc labels on child nodes (of the word L to shift) that have been shifted on to the stack, L_{clns} represents set of labels on child nodes that have not been shifted, L_{sls} the label set of shifted sibling nodes, L_{slns} the label set of unshifted sibling nodes, L_{cps} the POS set of shifted child nodes, L_{cpns} the POS set of unshifted child nodes, L_{sps} the POS set of shifted sibling nodes and L_{spns} the POS set of unshifted sibling nodes. L_{ps} is a binary feature indicating if the parent has been shifted. L_{lp} represents label on the parent, L_{pp} POS of parent and L_{wp} the parent word form. We define similar lookahead features for S_0. These features are instantiated only for SHIFT actions.

The new feature structure prevents all possible actions from being scored simultaneously, because the lookahead *Word* and *POS* are now in configuration features, rather than output actions, making it necessary to score the shifting of different words or POS separately. This leads to reduced search speed. Nevertheless, our experiments show that they give a desirable tradeoff between efficiency and accuracy.

Note that the new features are much less than a full Cartesian product of lookahead features and the original features. This is a result of manual feature engineering, which allows similar accuracies to be achieved using a much smaller model, thereby increasing the time efficiency.

4 Experiments

Following previous work we conduct experiments on the Penn TreeBank (PTB), using Wall Street Journal sections 2-21 for training, 22 for development and 23 for testing. Gold-standard dependency trees are derived from bracketed sentences using Penn2Malt, and base noun phrases are treated as a single word. The BLEU score is used to evaluate the performance of linearization.

Table 4 shows a difference in scores between transition-based linearization system of Liu et al. (2015) (L15) and best-first system of Zhang (2013) (Z13). L15 performs better for word ordering with unlabeled dependency arcs, but poorly for the task of labeled syntactic linearization.

Table 3 shows a series of development experiments comparing our system with Z13 and L15. We vary the amount of input syntactic constraints by randomly sampling from POS and dependency labels of the development set. Our system gives consistently higher accuracies when compared with both Z13 and L15. Compared to L15, the increase in scores for unconstrained word ordering is due to the introduction of reduced feature sparsity. The improvements on tree linearization tasks involving partial to full dependency constraints are also due to lookahead features that leverage tree information to reduce ambiguity early. Though slower than L15, our system is over 30 times faster compared to Z13.

We compare final test scores with previous methods in the literature in Table 4. Our system improves upon the previous best scores by 8.7 BLEU points for the task of unlabeled syntactic linearization. For the task of labeled syntactic linearization, we achieve the score of 91.8 BLEU points, the highest results reported so far.

	Fully constrained output
ref.	The spinoff also will compete with Fujitsu
L15	The spinoff with Fujitsu compete also will
Ours	The spinoff also will compete with Fujitsu
ref.	Dr. Talcott led a team of researchers from the National Cancer Institute .
L15	a team of researchers from the National Cancer Institute led Dr. Talcott .
Ours	Dr. Talcott led a team of researchers from the National Cancer Institute .

Table 5: Example outputs.

Table 5 contains examples of fully constrained output . In the first example '*will*' is the ROOT node with two child nodes '*also*' and '*compete*'. Lookahead feature for child dependency labels L_{cls}, L_{clns} on the node '*will*' can help order the segment '*also will compete*' correctly in our system. Without such features, the system of L15 yields an output that starts with '*The spinoff with Fujitsu*' which is locally fluent, but leaving the words '*also*' and '*will*' difficult to handle. In the second example, '*Dr. Talcott*' is OOV. Hence system of L15 is not able to score it and thus order it correctly. Our system makes use of both POS and dependency label of '*Dr. Talcott*' to order it correctly.

5 Conclusion

We identified a feature sparsity issue in state-of-the-art transition-based word ordering, proposing a solution by redefining the feature structure and introducing lookahead features. The new method gives the best accuracies on a set of benchmarks, which show that transition-based methods are a fast and accurate choice for syntactic linearization. Future work include the testing of this model in a linearization shared task (Belz et al., 2011) and investigating the integration of large scale training data (Zhang et al., 2012; Liu and Zhang, 2015).

We release our source code under GPL at `https://github.com/SUTDNLP/ZGen/releases/tag/v0.2`.

Abstract

This paper presents a novel approach using recurrent neural networks for estimating the quality of machine translation output. A sequence of vectors made by the prediction method is used as the input of the final recurrent neural network. The prediction method uses bi-directional recurrent neural network architecture both on source and target sentence to fully utilize the bi-directional quality information from source and target sentence. Our experiments show that the proposed recurrent neural networks approach achieves a performance comparable to the existing state-of-the-art models for estimating the sentence-level quality of English-to-Spanish translation.

1 Introduction

Estimating the quality of machine translation output, called *quality estimation* (QE) (Specia et al., 2009; Blatz et al., 2004), is to predict quality scores/categories for unseen machine-translated sentences without reference translations at various granularity levels (sentence-level/word-level/document-level). Quality estimation is of growing importance in the field of machine translation (MT) since MT systems are widely used and the quality of each machine-translated sentence is able to vary considerably.

Previous research on QE, addressed as a regression/classification problem to compute quality scores/categories, has mainly focused on feature extraction and feature selection. Feature extraction is to find the relevant features, such as baseline features (Specia et al., 2013) and latent semantic indexing (LSI) based features (Langlois, 2015), capturing various aspects of quality from source and target sentences[1] and external resources. Feature selection is to select the best features by using selection algorithms, such as Gaussian processes (Shah et al., 2015) and heuristic (González-Rubio et al., 2013), among already extracted features. Finding desirable features has played a key role in the QE research.

In this paper we present a recurrent neural networks approach for estimating the quality of machine translation output at sentence level, which does not require manual effort for finding the best relevant features. The remainder of this paper is organized as follows. In Section 2, we propose a recurrent neural networks approach using a sequence of vectors made by the prediction method as input for quality estimation. And we describe the prediction method using bi-directional recurrent neural networks architecture in Section 3. In Section 4, we report evaluation results, and conclude our paper in Section 5.

2 Recurrent Neural Networks Approach for Estimating Quality Score

Because recurrent neural networks (RNNs) have the strength for handling sequential data (Goodfellow et al., 2015), we apply RNNs to estimate the quality score of translation.

The input of the final RNN is a sequence of vectors that have quality information about whether tar-

[1] In this paper, a 'target sentence' means the machine-translated sentence from a source sentence.

get words in a target sentence are properly translated from a source sentence. We will refer to this sequence of vectors as *quality vectors* ($q_{y_1}, \dots, q_{y_{T_y}}$). Each quality vector q_{y_j}[2] has the quality information about how well a target word y_j in a target sentence $\mathbf{y} = (y_1, \dots, y_{T_y})$ is translated from a source sentence[3] $\mathbf{x} = (x_1, \dots, x_{T_x})$. Quality vectors are generated from the prediction method (of Section 3).

To predict a quality estimation score (QE score) as an HTER score (Snover et al., 2006) in [0,1] for each target sentence, a logistic sigmoid function is used such that

$$\begin{aligned}&\mathrm{QE\,score}(\mathbf{y}, \mathbf{x}) \\ &= \mathrm{QE\,score}'(q_{y_1}, \dots, q_{y_{T_y}}) \\ &= \sigma(W_{QE}^{\top}\, \mathbf{s})\end{aligned} \tag{1}$$

where $\mathbf{s}$ is a summary unit of the whole quality vectors and $W_{QE} \in \mathbb{R}^r$. r is the dimensionality of summary unit.

To get the summary unit $\mathbf{s}$, the hidden state v_j employing p gated hidden units for the target word y_j is computed by

$$v_j = f(q_{y_j}, v_{j-1})\,. \tag{2}$$

The gated hidden unit (Cho et al., 2014) for the activation function f is used to learn long-term dependencies of translation qualities for target words. We consider the QE score as the integrated/condensed value reflecting the sequential quality information of sequential target words. Because the last hidden state v_{T_y} is a summary of the sequential quality vectors, we fix the summary unit $\mathbf{s}$ to the last hidden state v_{T_y}.

3 Prediction method using Bi-directional RNN Architecture to Make Quality Vectors

In this section, we detail the ways to get the quality vectors ($q_{y_1}, \dots, q_{y_{T_y}}$) for computing QE score.

Since the training data for QE[4] are not enough to use a neural networks approach for making quality vectors, we use an alternative based on large-scale parallel corpora such as Europarl. We modify the word prediction method of RNN Encoder-Decoder (Cho et al., 2014) using parallel corpora to make the quality vectors.

In subsection 3.1, we describe the underlying word prediction method of RNN Encoder-Decoder. We i) extend the prediction method to use the additional backward RNN architecture on target sentence in subsection 3.2 and ii) modify to get the quality vectors ($q_{y_1}, \dots, q_{y_{T_y}}$) in subsection 3.3.

[2] $1 \leqq j \leqq T_y$ where T_y is the length of target sentence.

[3] Source(Target) sentence consists of 1-of-$K_x(K_y)$ coded word vectors. $K_x(K_y)$ is the vocabulary sizes of source(target) language.

[4] These data, provided in WMT Quality Estimation Shared Task, consist of source sentences, target sentences, and quality scores.

Figure 1 is the graphical illustration of the proposed RNNs approach.

3.1 Word Prediction Method of RNN Encoder-Decoder

RNN Encoder-Decoder proposed by Cho et al. (2014) is able to predict the target word y_j given a source sentence $\mathbf{x}$ and all preceding target words $\{y_1, ..., y_{j-1}\}$ by using a softmax function. And it is extended by Bahdanau et al. (2015) to use information of relevant source words for predicting the target word y_j such that

$$\begin{aligned} &p(y_j | \{y_1, ..., y_{j-1}\}, \mathbf{x}) \\ &\quad = g(y_{j-1}, \vec{s}_{j-1}, c_j) \, . \end{aligned} \tag{3}$$

g is a nonlinear function predicting the probability of y_j. $\vec{s}_{j-1}$ is the hidden state of the forward RNN on target sentence and contains information of preceding target words $\{y_1, \dots, y_{j-1}\}$. c_j is the context vector which means relevant parts of source sentence associated with the target word y_j. $\vec{s}_{j-1}$ and y_{j-1} are related to all preceding target words $\{y_1, ..., y_{j-1}\}$, and c_j is related to $\mathbf{x}$ in the word prediction function of (3).

3.2 Additional Backward RNN Architecture on Target Sentence

Bahdanau et al. (2015) introduce bi-directional RNN architecture only on source sentence to extend RNN Encoder-Decoder. In our proposed QE model, bi-directional RNN architecture is used both on source and target sentence. By applying bi-directional RNN architecture both on source and target sentence, we can fully and bi-directionally utilize source and target sentence for predicting target words, such that

$$\begin{aligned} &p(y_j | \mathbf{y}_{\not\ni y_j}, \mathbf{x}) \\ &\quad = g([y_{j-1}; y_{j+1}], [\vec{s}_{j-1}; \overleftarrow{s}_{j+1}], c_j) \\ &\quad = \frac{\exp(y_j^\top W_{o_1} W_{o_2} t_j)}{\sum_{k=1}^{K_y} \exp(y_k^\top W_{o_1} W_{o_2} t_j)} \, , \end{aligned} \tag{4}$$

which is the extended version of (3) using the additional backward RNN architecture.[5]

To reflect further all following target words $\{y_{j+1}, \dots, y_{T_y}\}$ when predicting the target word y_j, the hidden state $\overleftarrow{s}_{j+1}$ of the backward RNN and the next target word y_{j+1} are added. $[\vec{s}_{j-1}; \overleftarrow{s}_{j+1}]$ and $[y_{j-1}; y_{j+1}]$ are related to $\mathbf{y}_{\not\ni y_j}$[6], and c_j is related to $\mathbf{x}$ in the word prediction function of (4).

$W_{o_1} \in \mathbb{R}^{K_y \times q}$ and $W_{o_2} \in \mathbb{R}^{q \times l}$ are weight matrices of softmax function. K_y is the vocabulary sizes of target language and q is the dimensionality of quality vectors. l is the dimensionality of maxout units such that

$$t_j = [max\{\tilde{t}_{j,2k-1}, \tilde{t}_{j,2k}\}]_{k=1,\dots,l}^\top \, , \tag{5}$$

where $\tilde{t}_{j,k}$ is the k-th element of a vector $\tilde{t}_j$. And

$$\tilde{t}_j = S'_o[\vec{s}_{j-1}; \overleftarrow{s}_{j+1}] + V'_o[E_{\mathbf{y}} y_{j-1}; E_y y_{j+1}] + C_o c_j, \tag{6}$$

where $S'_o \in \mathbb{R}^{2l \times 2n}$, $V'_o \in \mathbb{R}^{2l \times 2m}$, and $C_o \in \mathbb{R}^{2l \times 2n}$. $E_{\mathbf{y}} \in \mathbb{R}^{m \times K_y}$ is the word embedding matrix on target sentence. m and n are the dimensionality of word embedding and hidden states of forward and backward RNNs. The hidden state $\overleftarrow{s}_{j+1}$ of the backward RNN and next target word y_{j+1} are used in (6).[7]

From the extended prediction method of (4), the probability of the target word y_j is computed by using information of relevant source words in source sentence $\mathbf{x}$ and all target words $\mathbf{y}_{\not\ni y_j}$ surrounding the target word y_j in target sentence.

3.3 Quality Vectors on Target Sentence

Word prediction method predicts the probability of target words as a number between 0 and 1. But we want to get quality vectors of q-dimensionality which have the more intrinsic quality information for target words.

To make quality vectors, we regard that the probability of the target word y_j involves the quality information about whether the target word y_j in target sentence is properly translated from source sentence. Thus, by decomposing the softmax function[8] of (4),

[5] The additional backward RNN on target sentence use the context vectors shared by the forward RNN on target sentence.

[6] $\mathbf{y}_{\not\ni y_j} = \{y_1, \dots, y_{j-1}, y_{j+1}, \dots, y_{T_y}\}$

[7] Original $\tilde{t}_j$ (Bahdanau et al., 2015) is

$$\tilde{t}_j = S_o \vec{s}_{j-1} + V_o E_{\mathbf{y}} y_{j-1} + C_o c_j.$$

[8] In this softmax function, the bias term is not used for the simplicity of deriving the quality vectors. Generally, bias terms are visually omitted in other equations to make the equations uncluttered.

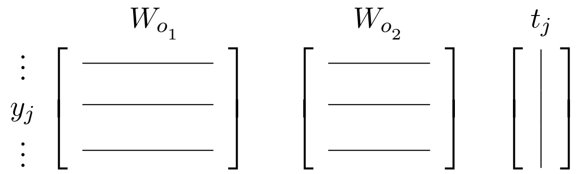

Figure 2: Weight matrices (W_{o_1} and W_{o_2}) of softmax function and maxout unit t_j for the target word y_j

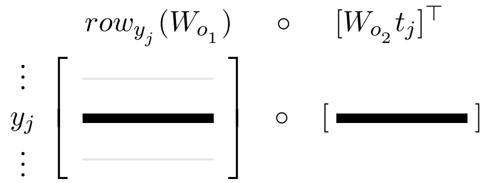

Figure 3: The ways of computing the quality vector q_{y_j} ($\circ$ is an element-wise multiplication)

the quality vector q_{y_j} for the target word y_j is computed by

$$q_{y_j} = \left[\; row_{y_j}(W_{o_1}) \circ [W_{o_2} t_j]^\top \; \right]^\top, \quad (7)$$

where $\circ$ is an element-wise multiplication. All of quality information about possible K_y target words at position j of target sentence is encoded in t_j. Thus, by decoding t_j, we are able to get quality vector q_{y_j} for the target word $y_j \in \mathbb{R}^{K_y}$ at position j of target sentence. Figure 2 and 3 show the ways to compute the quality vector q_{y_j}.

4 Experiments

The proposed RNNs approach was evaluated on the WMT15 Quality Estimation Shared Task[9] at sentence level of English-Spanish.

We trained[10] the proposed model through a two-step process. First, by using English-Spanish parallel corpus of Europarl v7 (Koehn, 2005), we trained bi-directional RNNs having 1000 hidden units on source and target sentence to make quality vectors. Next, by using the training set of WMT15 QE task, to predicte QE scores we trained the final RNN that use the quality vectors generated in previous step as the input and have 100 hidden units.

Table 1 and 2 present the results of the proposed approach (Bi-RNN) and the official results for the scoring and ranking[11] variants of the WMT15 Quality Estimation Shared Task at sentence level. At both variants of the task, the proposed RNNs approach achieved the performance over the baseline performance. Also our experiments showed that the performance of the proposed RNNs approach is included to the best performance group (at the scoring variant of Table 1) or is close to the best performance group (at the ranking variant of Table 2).

5 Conclusion

This paper proposed a recurrent neural networks approach using quality vectors for estimating the quality of machine translation output at sentence level.

[9] `http://www.statmt.org/wmt15/quality-estimation-task.html`

[10] Stochastic gradient descent (SGD) algorithm with adaptive learning rate (Adadelta) (Zeiler, 2012) is used to train the proposed model.

[11] The ranking variant of the QE task measures how close a proposed ranking of target translations from best to worst is to the true ranking.

This approach does not require manual effort for finding the best relevant features which the previous QE research has mainly focused on.

To make quality vectors we used an alternative prediction method based on large-scale parallel corpora, because the QE training data were not enough. By extending the prediction method to use bi-directional RNN architecture both on source and target sentence, we were able to fully utilize the bi-directional quality information from source and target sentence for quality estimation.

The proposed RNNs approach achieved a performance comparable to the existing state-of-the-art models at sentence-level QE. Our experiments have showed that RNNs approach is a meaningful step for QE research. Applying RNNs approach to word-level QE and studying other ways to make quality vectors better are remained for the future study.

Abstract

State-of-the-art word embeddings, which are often trained on bag-of-words (*BOW*) contexts, provide a high quality representation of aspects of the semantics of nouns. However, their quality decreases substantially for the task of verb similarity prediction. In this paper we show that using symmetric pattern contexts (*SPs*, e.g., “X and Y”) improves word2vec verb similarity performance by up to 15% and is also instrumental in adjective similarity prediction. The unsupervised *SP* contexts are even superior to a variety of dependency contexts extracted using a supervised dependency parser. Moreover, we observe that *SPs* and dependency coordination contexts (*Coor*) capture a similar type of information, and demonstrate that *Coor* contexts are superior to other dependency contexts including the set of all dependency contexts, although they are still inferior to *SPs*. Finally, there are substantially fewer *SP* contexts compared to alternative representations, leading to a massive reduction in training time. On an 8G words corpus and a 32 core machine, the *SP* model trains in 11 minutes, compared to 5 and 11 hours with *BOW* and all dependency contexts, respectively.

1 Introduction

In recent years, vector space models (VSMs) have become prominent in NLP. VSMs are often evaluated by measuring their ability to predict human judgments of lexical semantic relations between pairs of words, mostly association or similarity. While many datasets for these tasks are limited to pairs of nouns, the recent SimLex999 word similarity dataset (Hill et al., 2014) also consists of similarity scores for *verb* and *adjective* pairs. State-of-the-art VSMs such as word2vec skip-gram (*w2v-SG*, (Mikolov et al., 2013a)) and GloVe (Pennington et al., 2014) excel at noun-related tasks. However, their performance substantially decreases on *verb* similarity prediction in SimLex999, and their adjective representations have rarely been evaluated (Section 2).

In this paper we show that a key factor in the reduced performance of the *w2v-SG* model on verb representation is its reliance on bag-of-words (*BOW*) contexts: contexts of the represented words that consist of words in their physical proximity. We investigate a number of alternative contexts for this model, including various dependency contexts, and show that simple, automatically acquired symmetric patterns (*SPs*, e.g., “X or Y”, (Hearst, 1992; Davidov and Rappoport, 2006)) are the most useful contexts for the representation of verbs and also adjectives. Moreover, the *SP*-based model is much more compact than the alternatives, making its training an order of magnitude faster.

In particular, we train several versions of the *w2v-SG* model, each with a different context type, and evaluate the resulting word embeddings on the task of predicting the similarity scores of the verb and adjective portions of SimLex999. Our results show that *SP* contexts (SG-*SP*) obtain the best results on both tasks: Spearman’s ρ scores of 0.459 on verbs and 0.651 on adjectives. These results are 15.2% and 4.7% better than *BOW* contexts and 7.3% and 6.5% better than all dependency contexts (*DepAll*). Moreover, the number of *SP* contexts is substantially

Proceedings of NAACL-HLT 2016, pages 499–505,
San Diego, California, June 12-17, 2016.

smaller than the alternatives, making it extremely fast to train: 11 minutes only on an 8G word corpus using a 32 CPU core machine, compared to 5 and 11 hours for *BOW* and *DepAll*, respectively.

Recently, Schwartz et al. (2015) presented a count-based VSM that utilizes *SP* contexts (SRR15). This model excels on verb similarity, outperforming VSMs that use other contexts (e.g., *BOW* and *DepAll*) by more than 20%. In this paper we show that apart from its *SP* contexts, the success of SRR15 is attributed in large to its explicit representation of antonyms (*live/die*); turning this feature off reduces its performance to be on par with SG-*SP*. As opposed to Schwartz et al. (2015), we keep our VSM fixed across experiments (*w2v-SG*), changing only the context type. This allows us to attribute our improved results to one factor: *SP* contexts.

We further observe that *SP* contexts are tightly connected to syntactic *coordination* contexts (*Coor*, Section 3). Following this observation, we compare the *w2v-SG* model with three dependency-based context types: (a) *Coor* contexts; (b) all dependency links (*DepAll*); and (c) all dependency links excluding *Coor* links ($Coor^C$).[1] Our results show that training with *Coor* contexts is superior to training with the other context types, leading to improved similarity prediction of 2.7-4.1% and 4.3-6.9% on verbs and adjectives respectively.

These results demonstrate the prominence of *Coor* contexts in verb and adjective representation: these contexts are even better than their combination with the rest of the dependency-based contexts (the *DepAll* contexts). Nonetheless, although *Coor* contexts are extracted using a supervised dependency parser, they are still inferior to *SP* contexts, extracted automatically from plain text (Section 3), by 4.6% and 2.2% for verb and adjective pairs.

2 Background

Word Embeddings for Verbs and Adjectives. A number of evaluation sets consisting of word pairs scored by humans for semantic relations (mostly association and similarity) are in use for VSM evaluation. These include: RG-65 (Rubenstein and Goodenough, 1965), MC-30 (Miller and Charles, 1991), WordSim353 (Finkelstein et al., 2001), MEN (Bruni et al., 2014) and SimLex999 (Hill et al., 2014).[2]

Nouns are dominant in almost all of these datasets. For example, RG-65, MC-30 and WordSim353 consist of noun pairs almost exclusively. A few datasets contain pairs of verbs (Yang and Powers, 2006; Baker et al., 2014). The MEN dataset, although dominated by nouns, also contains verbs and adjectives. Nonetheless, the human judgment scores in these datasets reflect *relatedness* between words. In contrast, the recent SimLex999 dataset (Hill et al., 2014) contains word *similarity* scores for nouns (666 pairs), verbs (222 pairs) and adjectives (111 pairs). We use this dataset to study the effect of context type on VSM performance in a verb and adjective similarity prediction task.

Context Type in Word Embeddings. Most VSMs (e.g., (Collobert et al., 2011; Mikolov et al., 2013b; Pennington et al., 2014)) define the context of a target word to be the words in its physical proximity (bag-of-words contexts). Dependency contexts, consisting of the words connected to the target word by dependency links (Grefenstette, 1994; Padó and Lapata, 2007; Levy and Goldberg, 2014), are another well researched alternative. These works did not recognize the importance of syntactic coordination contexts (*Coor*).

Patterns have also been suggested as VSM contexts, but mostly for representing *pairs* of words (Turney, 2006; Turney, 2008). While this approach has been successful for extracting various types of word relations, using patterns to represent *single* words is useful for downstream applications. Recently, Schwartz et al. (2015) explored the value of *symmetric* pattern contexts for word representation, an idea this paper develops further.

A recently published approach (Melamud et al., 2016) also explored the effect of the type of context on the performance of word embedding models. Nonetheless, while they also explored bag-of-words and dependency contexts, they did not experiment with *SPs* or coordination contexts, which we find to be most useful for predicting word similarity.

Limitations of Word Embeddings. Recently, a few papers examined the limitations of word embedding models in representing different types of se-

[1] $Coor \cup Coor^C = DepAll$, $Coor \cap Coor^C = \emptyset$

[2] For a comprehensive list see: `wordvectors.org/`

mantic information. Levy et al. (2015) showed that word embeddings do not capture semantic relations such as hyponymy and entailment. Rubinstein et al. (2015) showed that while state-of-the-art embeddings are successful at capturing taxonomic information (e.g., *cow* is an animal), they are much less successful in capturing attributive properties (*bananas* are yellow). In (Schwartz et al., 2015), we showed that word embeddings are unable to distinguish between pairs of words with opposite meanings (antonyms, e.g., good/bad). In this paper we study the difficulties of bag-of-words based word embeddings in representing verb similarity.

3 Symmetric Patterns (*SPs*)

Lexico-syntactic patterns are templates of text that contain both words and wildcards (Hearst, 1992), e.g., "X *and* Y" and "X *for a* Y". Pattern *instances* are sequences of words that match a given pattern, such that concrete words replace each of the wildcards. For example, "**John** *and* **Mary**" is an instance of the pattern "X *and* Y". Patterns have been shown useful for a range of tasks, including word relation extraction (Lin et al., 2003; Davidov et al., 2007), knowledge extraction (Etzioni et al., 2005), sentiment analysis (Davidov et al., 2010) and authorship attribution (Schwartz et al., 2013).

Symmetric patterns (*SPs*) are lexico-syntactic patterns that comply to two constraints: (a) Each pattern has exactly two wildcards (e.g., **X** *or* **Y**); and (b) When two words (*X*,*Y*) co-occur in an *SP*, they are also likely to co-occur in this pattern in opposite positions, given a large enough corpus (e.g., "**X** *or* **Y**" and "**Y** *or* **X**"). For example, the pattern "**X** *and* **Y**" is symmetric as for a large number of word pairs (e.g., (*eat,drink*)) both members are likely to occur in both of its wildcard positions (e.g., "eat *and* drink", "drink *and* eat").

SPs have shown useful for tasks such as word clustering (Widdows and Dorow, 2002; Davidov and Rappoport, 2006), semantic class learning (Kozareva et al., 2008) and word classification (Schwartz et al., 2014). In this paper we demonstrate the value of *SP*-based contexts in vector representations of verbs and adjectives. The rationale behind this context type is that two words that co-occur in an *SP* tend to take the same semantic role in the sentence, and are thus likely to be similar in meaning (e.g., "(John and Mary) sang").

***SP* Extraction.** Many works that applied *SPs* in NLP tasks employed a hand-crafted list of patterns (Widdows and Dorow, 2002; Dorow et al., 2005; Feng et al., 2013). Following Schwartz et al. (2015) we employ the DR06 algorithm (Davidov and Rappoport, 2006), an unsupervised algorithm that extracts *SPs* from plain text. We apply this algorithm to our corpus (Section 4) and extract 11 *SPs*: "X *and* Y", "X *or* Y", "X *and the* Y", "X *or the* Y", "X *or a* Y", "X *nor* Y", "X *and one* Y", "*either* X *or* Y", "X *rather than* Y", "X *as well as* Y", "*from* X *to* Y". A description of the DR06 algorithm is beyond the scope of this paper; the interested reader is referred to (Davidov and Rappoport, 2006).

***SP* Contexts.** We generate *SP* contexts by taking the co-occurrence counts of pairs of words in *SPs*. For example, in the *SP* token "*boys and girls*", the term *girls* is taken as an *SP* context of the word *boys*, and *boys* is taken as an *SP* context of *girls*.

We do not make a distinction between the different *SPs*. E.g., "*boys* **and** *girls*" and "*boys* **or** *girls*" are treated the same. However, we distinguish between left and right contexts. For example, we generate different contexts for the word *girls*, one for left-hand contexts ("**girls** *and boys*") and another for right-hand contexts ("*boys and* **girls**").

***SPs* and Coordinations.** *SPs* and syntactic coordinations (*Coors*) are intimately related. For example, of the 11 *SPs* extracted in this paper by the DR06 algorithm (listed above), the first eight represent coordination structures. Moreover, these *SPs* account for more than 98% of the *SP* instances in our corpus. Indeed, due to the significant overlap between *SPs* and *Coors*, the former have been proposed as a simple model of the latter (Nakov and Hearst, 2005).[3]

Despite their tight connection, *SPs* sometimes fail to properly identify the components of *Coors*. For example, while *SPs* are instrumental in capturing shallow *Coors*, they fail in capturing coordination between phrases. Consider the sentence *John*

[3] Note though that the exact syntactic annotation of coordination is debatable both in the linguistic community (Tesnière, 1959; Hudson, 1980; Mel'čuk, 1988) and also in the NLP community (Nilsson et al., 2006; Schwartz et al., 2011; Schwartz et al., 2012).

walked and Mary ran: the *SP* "X *and* Y" captures the phrase *walked and Mary*, while the *Coor* links the heads of the connected phrases ("*walked*" and "*ran*"). *SPs*, on the other hand, can go beyond *Coors* and capture other types of symmetric structures like "*from* X *to* Y" and "X *rather than* Y".

Our experiments reveal that both *SPs* and *Coors* are highly useful contexts for verb and adjective representation, at least with respect to word similarity. Interestingly, *Coor* contexts, extracted using a supervised dependency parser, are less effective than *SP* contexts, which are extracted from plain text.

4 Experiments

Model. We keep the VSM fixed throughout our experiments, changing only the context type. This methodology allows us to evaluate the impact of different contexts on the VSM performance, as context choice is the only modeling decision that changes across experimental conditions.

Our VSM is the word2vec skip-gram model (*w2v-SG*, Mikolov et al. (2013a)), which obtains state-of-the-art results on a variety of NLP tasks (Baroni et al., 2014). We employ the word2vec toolkit.[4] For all context types other than *BOW* we use the word2vec package of (Levy and Goldberg, 2014),[5] which augments the standard word2vec toolkit with code that allows arbitrary context definition.

Experimental Setup. We experiment with the verb pair (222 pairs) and adjective pair (111 pairs) portions of SimLex999 (Hill et al., 2014). We report the Spearman ρ correlation between the ranks derived from the scores of the evaluated models and the human scores provided in SimLex999.[6]

We train the *w2v-SG* model with five different context types: (a) *BOW* contexts (SG-*BOW*); (b) all dependency links (SG-*DepAll*) (c) dependency-based coordination contexts (i.e., those labeled with *conj*, SG-*Coor*); (d) all dependency links except for coordinations (SG-$\textit{Coor}^C$); and (e) *SP* contexts. Our training corpus is the 8G words corpus generated by the word2vec script.[7]

Model	Verb	Adj.	Noun	Time	#Cont.
SG-*BOW*	0.307	0.604	**0.501**	320	13G
SG-*DepAll*	0.386	0.586	0.499	551	14.5G
SG-*Coor*	0.413	0.629	0.428	23	550M
SG-$\textit{Coor}^C$	0.372	0.56	0.494	677	14G
SG-*SP*	**0.459**	**0.651**	0.415	11	270M
SRR15	0.578	0.663	0.497	—	270M
SRR15$^-$	0.441	0.68	0.421	—	270M

Table 1: Spearman's ρ scores on the different portions of SimLex999. The top part presents results for the word2vec skip-gram model (*w2v-SG*) with various context types (see text). The bottom lines present the results of the count *SP*-based model of Schwartz et al. (2015), with (SRR15) and without (SRR15$^-$) its antonym detection method. The two rightmost columns present the run time of the *w2v-SG* models in minutes (Time) and the number of context instances used by the model (#Cont.).[10] For each SimLex999 portion, the score of the best *w2v-SG* model across context types is highlighted in bold font.

Models (b)-(d) require the dependency parse trees of the corpus as input. To generate these trees, we employ the Stanford POS Tagger (Toutanova et al., 2003)[8] and the stack version of the MALT parser (Nivre et al., 2009).[9] The *SP* contexts are generated using the *SPs* extracted by the DR06 algorithm from our training corpus (see Section 3).

For *BOW* contexts, we experiment with three window sizes (2, 5 and 10) and report the best results (window size of 2 across conditions). For dependency based contexts we follow the standard convention in the literature: we consider the immediate heads and modifiers of the represented word. All models are trained with 500 dimensions, the default value of the word2vec script. Other hyperparameters were also set to the default values of the code packages.

Results. Table 1 presents our results. The SG-*SP* model provides the most useful verb and adjective representations among the *w2v-SG* models. Compared to *BOW* (SG-*BOW*), the most commonly used

[9] `http://www.maltparser.org/index.html`

context type, SG-*SP* results are 15.2% and 4.7% higher on verbs and adjectives respectively. Compared to dependency links (SG-*DepAll*), the improvements are 7.3% and 6.5%. For completeness, we compare the models on the noun pairs portion, observing that SG-*BOW* and SG-*DepAll* are ∼8.5% better than SG-*SP*. This indicates that different word classes require different representations.

The results for SG-*Coor*, which is trained with syntactic coordination (*Coor*) contexts, show that these contexts are superior to all the other dependency links (SG-$Coor^C$) by 4.1% and 6.9% on verbs and adjectives. Importantly, comparing the SG-*Coor* model to the SG-*DepAll* model, which augments the *Coor* contexts with the other syntactic dependency contexts, reveals that SG-*DepAll* is actually inferior by 2.7% and 4.3% in Spearman ρ on verbs and adjectives respectively. Interestingly, *Coor* contexts, which are extracted using a supervised parser, are still inferior by 4.6% and 2.2% to *SPs*, which capture similar contexts but are extracted from plain text.

Table 1 also shows the training times of the various *w2v-SG* models on a 32G memory, 32 CPU core machine. SG-*SP* and SG-*Coor*, which take 11 minutes and 23 minutes respectively to train, are substantially faster than the other *w2v-SG* models. For example, they are more than an order of magnitude faster than SG-*BOW* (320 minutes) and SG-$Coor^C$ (677 minutes). This is not surprising, as there are far fewer *SP* contexts (270M) and *Coor* contexts (550M) than *BOW* contexts (13G) and $Coor^C$ contexts (14G) (#Cont. column).

Finally, the performance of the SG-*SP* model is still substantially inferior to the SRR15 *SP*-based model (Schwartz et al., 2015). As both models use the same *SP* contexts, this result indicates that other modeling decisions in SRR15 lead to its superior performance. We show that this difference is mostly attributed to one feature of SRR15: its method for detecting antonym pairs (*good/bad*). Indeed, the SRR15 model without its antonym detection method (SRR15^-) obtains a Spearman ρ of 0.441, compared to 0.459 of SG-*SP* on verb pairs. For adjectives, however, SRR15^- is 1.7% better than SRR15, increasing the difference from SG-*SP* to 2.9%.[11]

5 Conclusions

We demonstrated the effectiveness of symmetric pattern contexts in word embedding induction. Experiments with the word2vec model showed that these contexts are superior to various alternatives for verb and adjective representation. We further pointed at the connection between symmetric patterns and syntactic coordinations. We showed that coordinations are superior to other syntactic contexts, but are still inferior to symmetric patterns, although the extraction of symmetric patterns requires less supervision.

Future work includes developing a model that successfully combines the various context types explored in this paper. We are also interested in the representation of other word classes such as adverbs for which no evaluation set currently exists. Finally, the code for generating the SG-*SP* embeddings, as well as the vectors experimented with in this paper, are released and can be downloaded from `http://www.cs.huji.ac.il/~roys02/papers/sp_sg/sp_sg.html`

Breaking the Closed World Assumption in Text Classification

Geli Fei and **Bing Liu**
Department of Computer Science
University of Illinois at Chicago
gfei2@uic.edu, liub@cs.uic.edu

Abstract

Existing research on multiclass text classification mostly makes the *closed world* assumption, which focuses on designing accurate classifiers under the assumption that all test classes are known at training time. A more realistic scenario is to expect unseen classes during testing (*open world*). In this case, the goal is to design a learning system that classifies documents of the known classes into their respective classes and also to reject documents from unknown classes. This problem is called *open* (*world*) *classification*. This paper approaches the problem by reducing the open space risk while balancing the empirical risk. It proposes to use a new learning strategy, called *center-based similarity* (CBS) *space learning* (or *CBS learning*), to provide a novel solution to the problem. Extensive experiments across two datasets show that CBS learning gives promising results on multiclass open text classification compared to state-of-the-art baselines.

1 Introduction

With the rapid growth of online information, text classifiers have become one of the most important tools for people to track and organize information. And the emergence of social media platforms has brought increasing diversity and dynamics to the Web. Many social science researchers rely on the collected online user generated content to carry out research on different social phenomenon. In this case, multiclass text classifiers are widely used to gather information of several topics of interest. However, most existing research on multiclass text classification makes the *closed world* assumption, meaning that all the test classes have been seen in training. However, in a more realistic scenario where people use a multiclass classifier to collect information of several topics from a data source that covers a much broader range of topics, it is normal to break the closed world assumption and to see the arrival of documents from unknown classes that have never been seen in training. In this case, a multiclass classifier should not always assign a document to one of the known classes. Instead, it should identify unknown classes of documents and label them as unknown or reject. This is called *open* (*world*) classification.

More precisely, in the traditional multiclass classification setting, the learner assumes a fixed set of classes $Y = \{C_1, C_2, \ldots, C_m\}$, and the task is to construct a m-class classifier using the training data. The resulting classifier is tested/applied on the data from only the m classes. While in *open* classification, we allow the classifier to predict labels/classes from the set of $C_1, C_2, \ldots, C_m, C_{m+1}$ classes, where the $(m+1)^{\text{th}}$ class C_{m+1} represents the unknown which covers documents of all unknown or unseen classes or topics. In other words, every test instance may be predicted to belong to either one of the known classes $y_i \in Y$, or C_{m+1} (unknown).

It is thus not sufficient for a classifier to just return the most likely class label among the m known classes. An option to reject must be provided. An obvious approach to predicting the class label $y \in Y \cup \{C_{m+1}\}$ for an n-dimensional data point $x \in R^n$ is to incorporate a posterior probability estimator $p(y|x)$ and a decision threshold into an existing multiclass learning algorithm (Kwok, 1999; Fumera and Roli, 2002; Huang et al., 2006; Bravo et al., 2008). There are many reasons this technique would not achieve good results in open classification. As we will discuss in the following sections, one of the most important reasons is that the underlying classifier is not robust or is not in-

Proceedings of NAACL-HLT 2016, pages 506–514,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

formed enough to reject unseen classes of documents due to its significant open space risk.

Traditional multiclass learners optimize only on the known classes under the closed world assumption, while a potential learner for open classification has to optimize for both the known classes and for the unknown classes. Some recent research in the field of computer vision studied the problem, which they call *open set recognition* (Scheirer et al., 2013; 2014; Jain et al., 2014) for facial recognition. Classic learners define and optimize over empirical risk, which is measured on the training data. For open classification, it is crucial to consider how to extend the model to capture the risk of the unknown by preventing overgeneralization or overspecialization. In order to tackle this problem, Scheirer et al. (2013) introduced the concept of *open space risk* and formulated an extension of existing one-class and binary SVMs to address the open classification problem. However, as we will see in section 3, their proposed method is weak as the positively labeled open space is still an infinite area.

In this work, we propose a solution to reduce the open space risk while also balancing the empirical risk for open classification. Intuitively, given a positive class of documents, our open space for the positive class is considered as the space that is sufficiently far from the center of the positive documents. In the multiclass classification setting, each of the *m* target classes is surrounded by a ball covering the positively labeled (the target class) area, while any document falling outside of all the *m* balls is considered belonging to the unknown class.

Recent work by Fei and Liu (2015) proposed a new learning strategy called *center-based similarity space learning* (*CBS learning*) to deal with the problem of covariate shift in binary classification. We found that it is also suitable for open classification. Instead of conducting learning in the traditional document space (or *D-space*) with n-gram features, CBS learning learns in a similarity space. Unlike SVM learning in D-space that bounds the positive class only by an infinite half-space formed with the decision hyperplane, which has a huge open space risk, CBS learning finds a closed boundary for the positive class covering only a finite area, which is a spherical area in the original D-space and thus reduce the open space risk significantly. While discussing CBS learning, we will also describe the underlying assumptions made by it which were not stated in our earlier paper (Fei and Liu, 2015). Our final multiclass classifier is called *cbsSVM* (based on SVM).

To the best of our knowledge, this is the first attempt to study multiclass open classification in text from the open space risk management perspective. Our experiments show that *cbsSVM* for multiclass open classification produces superior classifiers to existing state-of-the art methods.

2 Related Work

Compared to research on multiclass classification with the closed world assumption, there is relatively less work on open classification. In this section, we review related work on one-class classification, SVM decision score calibration, and others.

One-class classifiers, which only rely on positive training data, are natural starting solutions to the multiclass open classification task. One-class SVM (Scholkopf et al., 2001) and SVDD (Tax and Duin, 2004) are two representative one-class classifiers. One-class SVM treats the origin in the feature space as the only member of the negative class, and maximizes the margin with respect to it. SVDD tries to place a hypersphere with the minimum radius around almost all the positive training points. It has been shown that the use of Gaussian kernel makes SVDD and One-class SVM equivalent, and the results reported in (Khan and Madden, 2014) demonstrate that SVDD and One-class SVM are comparable when the Gaussian kernel is applied. However, as no negative training data is used, one-class classifiers have trouble producing good separations. We will see in Section 4 that their results are poor.

This work is also related to using thresholded probabilities for rejection. As the decision score produced by SVM is not a probability distribution, several techniques have been proposed to convert a raw decision score to a calibrated probability output (Platt, 2000; Zadrozny and Elkan, 2002; Duan and Keerthi, 2005; Huang et al., 2006; Bravo et al., 2008). Usually a parametric distribution is assumed for the underlying distribution, and raw scores are mapped based on the learned model. A variation of Platt's (2000) approach is the most widely used probability estimator for SVM score calibration. It fits a sigmoid function to the SVM scores during training. Provided with a threshold, a test instance can be rejected if the highest probability of this instance belonging to a class is lower than the threshold in multiclass open classification settings.

Recently, researchers in computer vision (Scheirer et al., 2013; 2014; Jain et al., 2014) made some attempts to solve open classification (which they call *open set recognition*) for visual learning from new angles. Scheirer et al. (2013) introduced the concept of open space risk, and defined it as a relative measure. The proposed model reduces the open space risk by replacing the half-space of a binary linear classifier with a positive region bounded by two parallel hyperplanes. While the positively labeled region for a target class is reduced compared to the half-space in the traditional linear SVM, their open space risk is still infinite. In (Jain et al., 2014), the authors proposed to use Extreme Value Theory (EVT) to estimate the unnormalized posterior probability of inclusion for each class by fitting a Weibull distribution over the positive class scores from a 1-vs-rest multiclass RBF SVM classifier. Scheirer et al. (2014) introduced the Compact Abating Probability (CAP) model, which explains how thresholding the probabilistic output of RBF One-class SVM manages the open space risk. Using the probability output from RBF one-class SVM as a conditioner, the authors combine RBF One-class SVM and a Weibull-calibrated SVM similar to the one in (Jain et al., 2014). For both methods (Jain et al., 2014; Scheirer et al., 2014), decision thresholds need to be chosen based on the prior knowledge of the ratio of unseen classes in testing, which is a weakness of the methods.

Dalvi et al. (2013) proposed Exploratory Learning in the multiclass semi-supervised learning (SSL) setting. In their work, an "exploratory" version of expectation-maximization (EM) is proposed to extend traditional multiclass SSL methods, which deals with the scenario when the algorithm is given seeds from only some of the classes in the data. It automatically explores different numbers of new classes in the EM iterations. The underlying assumption is that a new class should be introduced to hold an instance x when the probability of x belonging to the existing classes is close to uniform. This is quite different from our work. First, it works in the semi-supervised setting and assumes that test data is available during training. Second, it only focuses on improving accuracy on the classes with seed examples.

3 Proposed Method

In this section, we propose our solution for the open classification problem. First we discuss our strategy to reduce the open space risk while balancing the empirical risk of the training data. Then we apply a recently proposed SVM-based learning strategy (Fei and Liu, 2015), which yields the same risk management strategy. We will also discuss its underlying assumptions, which was not addressed in the original paper of Fei and Liu (2015). Lastly, we will show why the proposed solution works for open classification.

3.1 Open Space Risk Formulation

Consider the risk formulation by Scheirer et al. (2013), where apart from the empirical risk, there is risk in labeling the open space (space away from positive training examples) as "positive" for any known class. Due to lack of information on a classification function on the open space, open space risk is approximated by a relative Lebesgue measure (Shackel, 2007). Let S_o be a large ball of radius r_o that contains both the positively labeled open space O and all of the positive training examples; and let f be a measurable classification function where $f_y(x) = 1$ for recognition of class y of interest and $f_y(x) = 0$ otherwise. The probabilistic open space risk $R_O(f)$ of function f for a class y is defined as the fraction (in terms of Lebesgue measure) of positively labeled open space compared to the overall measure of positively labeled space (which includes the space close to the positive examples).

$$R_O(f) = \frac{\int_O f_y(x)dx}{\int_{S_o} f_y(x)dx}$$

The above definition indicates that the more we label open space as positive, the greater open space risk is. However, it does not suggest how to specify the positively labeled open space O.

In this work, we formulate O as the positively labeled area that is sufficiently far from the center of the positive training examples. Let $B_{r_y}(cen_y)$ be a closed ball of radius r_y centered around the center of positive class y (cen_y), which ideally contains all positive examples of class y; S_o be a larger ball $B_{r_O}(cen_y)$ of radius r_o with the same center cen_y. Let classification function $f_y(x) = 1$ when $x \in B_{r_O}\left(cen_y\right)$, and $f_y(x) = 0$ otherwise. Also let h be the positive half space defined by a binary SVM decision hyperplane Ω obtained using positive and negative training examples, and let the size of ball B_{r_O} be bounded by Ω, $B_{r_O} \cap h = B_{r_O}$. We define open space as

$$O = S_o - B_{r_y}\left(cen_y\right)$$

where radius r_O needs to be determined from the training data for each known positive class.

This open space formulation greatly reduces the open space risk compared to traditional SVM and 1-vs-Set Machine in (Scheirer et al., 2013). For traditional SVM, whose classification function $f_y^{SVM}(x) = 1$ when $x \in h$, and positive open space being approximately $h - B_{r_y}\left(cen_y\right)$, which is only bounded by the SVM decision hyperplane Ω. For 1-vs-Set Machine in (Scheirer et al., 2013), whose classification function $f_y^{1-vs-set}(x) = 1$ when $x \in g$, where g is a slab area with thickness δ bounded by two parallel hyperplanes Ω and Ψ ($\Psi \parallel \Omega$) in h. And its positive open space is approximately $g - B_{r_y}\left(cen_y\right)$. Given open space formulations of traditional SVM and 1-vs-Set Machine, we can see that both methods label an unlimited area as positively labeled space, while our formulation reduces it to a bounded spherical area.

Given the above open space definition, the question is how to estimate radius r_O for the positive class. We show that the center-based similarity space learning (CBS learning) recently proposed in (Fei and Liu, 2015) is suitable for the purpose. It was original proposed to deal with the negative covariate shift problem in binary text classification.

Below, we first introduce CBS learning and then discuss why it is suitable for our problem, as well as its underlying assumptions.

3.2 Center-Based Similarity Space Learning

We now discuss CBS learning for binary text classification. Let $D = \{(\mathbf{d}_1, y_1), (\mathbf{d}_2, y_2), \ldots, (\mathbf{d}_n, y_n)\}$ be the set of training examples, where $\mathbf{d}_i$ is the feature vector (e.g., with unigram features) representing a document d_i and $y_i \in \{1, -1\}$ is its class label. This feature vector is called a document space vector (*ds-vector*). Traditional classification directly uses D to build a binary classifier. CBS learning transforms each *ds*-vector $\mathbf{d}_i$ (no change to its class) to a center-based similarity space feature vector (CBS vector) **cbs-v**$_i$. Each feature in the CBS vector is a similarity between a center c_j of the positive class documents and d_i. CBS learning can use multiple document space representations or feature vectors (e.g., one based on unigrams and one based on bigrams) to represent each document, which results in multiple centers for the positive documents. There can also be multiple document similarity functions used to compute similarity values. The detailed learning technique is as follows.

For a document d_i in D, we have a set R_i of p *ds*-vectors $R_i = \{\mathbf{x}_1^i, \mathbf{x}_2^i, \ldots, \mathbf{x}_p^i\}$. Each *ds*-vector $\mathbf{x}_j^i$ denotes one document space representation of the document d_i, e.g., unigram representation or bigram representation. Then the center of positive training documents can be computed, which is represented as a set of p centroids $C = \{\mathbf{c}_1, \mathbf{c}_2, \ldots, \mathbf{c}_p\}$, each of which corresponds to one document space representation in R_i. Rocchio method in information retrieval (Rocchio, 1971; Manning et al. 2008) is used to compute each center $\mathbf{c}_j$ (a vector), which uses the corresponding *ds*-vectors of all training positive and negative documents.

$$\mathbf{c}_j = \frac{\alpha}{|D_+|} \sum_{d_i \in D_+} \frac{\mathbf{x}_j^i}{\left\|\mathbf{x}_j^i\right\|} - \frac{\beta}{|D - D_+|} \sum_{d_i \in D - D_+} \frac{\mathbf{x}_j^i}{\left\|\mathbf{x}_j^i\right\|}$$

where D_+ is the set of documents in the positive class and |.| is the size function. α and β are parameters, which are usually set empirically. It is reported that using *tf-idf* representation, $\alpha = 16$ and $\beta = 4$ usually work quite well (Buckley et al. 1994). The subtraction is used to reduce the influence of those terms that are not discriminative (i.e., terms appearing in both classes).

Based on R_i for any document d_i in both training and testing and the previously computed set C of centers using the training data, we can transform a document d_i from its document space representations R_i to one center-based similarity vector **cbs-v**$_i$ by applying a similarity function Sim on each element $\mathbf{x}_j^i$ of R_i and its corresponding center $\mathbf{c}_j$ in C.

$$\textbf{cbs-v}_i = Sim(R_i, C)$$

Sim has a set of similarity measures. Each measure m_j is applied to p document representations $\mathbf{x}_j^i$ in R_i and their corresponding centers $\mathbf{c}_j$ in C to generate p similarity features (*cbs*-features) in **cbs-v**$_i$.

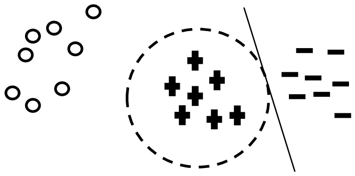

Figure 1: CBS learning reduces open space risk.

For *ds*-features, we use unigrams and bigrams with *tf-idf* weighting as two document representations. We also adopt the five similarity measures in (Fei and Liu, 2015) to gauge the similarity of two vectors. Based on these measures, we produce 10 CBS features to represent a document in the CBS space.

3.3 Why does CBS learning work?

Given the open space definition in Section 3.1, our goal is to estimate the radius r_O of the positively labeled space for the positive class. Now we explain how CBS learning gives an estimate of r_O.

Due to learning in the similarity space with similarities as features, CBS learning generates a boundary based on similarities to separate the positive and negative training data in the similarity space, which is essentially a ball encompassing the positive training data in the original document space. In other words, instead of explicitly minimizing the positively labeled open space risk, CBS learning approximates the radius r_O by learning a score based on similarities in the similarity space, which is equivalent to a limited spherical area in the original document space. The generated model thus not only limits the positively labeled open space on the positive side of Ω (SVM decision hyperplane), but also balances the empirical risk from the positive and negative training examples. In fact, r_O is approximately the distance from the center of positive class to Ω measured in similarities. Figure 1 illustrates the point. The positively labeled/classified region produced by CBS learning is the circle in the original document space, while SVM learning produces a half space bounded by its decision line, which is approximately the tangent line of the circle. Note that as multiple similarity features are used, the spherical area is formed by an integrated similarity produced by SVM, which combines all similarity features.

In order for the method to work well for our multiclass classification, ideally two assumptions should be made about the data. First, the target classes of documents are generated by a mixture model, where each mixture component is responsible for each class of documents. Secondly, after feature normalization each target class of documents is generated by a Gaussian distribution, where the Gaussian mean resides at the center of the class, and its $n \times n$ covariance matrix has equal eigenvalues so that the positive class can have a spherical shape boundary or a ball. Note that we do not make any assumptions about data from non-target classes.

3.4 Multiclass Open Classification

The preceding discussion is based on binary open classification. We follow the standard technique of combining a set of 1-vs-rest binary classifiers to perform multiclass classification with a rejection option for unknown. The SVM scores for each classifier are first converted to probabilities based on a variation of Platt's (2000) algorithm, which is supported in LIBSVM (Chang and Lin, 2011). Let $P(y|\mathbf{x})$ be a probably estimate, where $y \in Y$ is a class label and $\mathbf{x}$ is a feature vector, and let λ be the decision threshold (usually 0.5). Let Y be the set of known classes, C_{m+1} be the unknown class, and y^* is the final predicted class for $\mathbf{x}$. The final classifier (called *cbsSVM*) uses this following for classification.

$$y^* = \begin{cases} argmax_{y \in Y} P(y|\mathbf{x}) & if\ P(y^*|\mathbf{x}) \geq \lambda \\ C_{m+1} & otherwise \end{cases}$$

4 Experiments

In this section, we show the results of the proposed method *cbsSVM* and compare it extensively with state-of-the-art baselines across two datasets.

4.1 Baselines

1-vs-Rest multiclass SVM (*1-vs-rest-SVM*). This is the standard 1-vs-Rest multiclass SVM with Platt Probability Estimation (Platt, 2000), and it is implemented based on LIBSVM[1] (version 3.20) (Chang and Lin, 2011). It works in the same way as the proposed *cbsSVM* (Section 3.4) except that it uses the document space classification. Linear kernel is used as it is shown by many researchers that linear SVM performs the best for text classification

[1] http://www.csie.ntu.edu.tw/~cjlin/libsvmtools/

(Joachims, 1998; Colas and Brazdil, 2006).

1-vs-Set Machine (*1-vs-set-linear*). For this baseline (Scheirer et al., 2013), we use all the default parameter settings in the original paper. That is, the near and far plane pressures are set at $p_A = 1.6$ and $p_\Omega = 4$ respectively; regularization constant $\lambda_r = 1$ and no explicit hard constraints are used on the training error ($\alpha = 0, \beta = 1$).

W-SVM (*wsvm-linear* and *wsvm-rbf*). These two baselines combine RBF one-class SVM with binary SVM (Scheirer et al., 2014). Both linear kernel and RBF kernel are tested. For thresholding the output, two parameters δ_τ and δ_R are required. We set $\delta_\tau = 0.001$, which is used to adjust what data the one-class SVM considers to be related. δ_R is a required decision threshold not only for W-SVM, but also for the next two baselines ($\mathrm{P_I}$-SVM, $\mathrm{P_I}$-OSVM). Two ways of setting δ_R were suggested by the authors. We set it as the prior probability of the number of unseen classes during evaluation (testing). An alternative way is to set it based on an openness score computed using the number of training and testing classes. We tried both methods and found the former gave better results.

$\mathrm{P_I}$-SVM (*P_I-svm-linear* and *P_I-svm-rbf*). This baseline is from (Jain et al., 2014), which estimates the probability of inclusion based on the output of binary SVMs. Two kernels are tested. As stated above, the threshold δ is set as the prior probability of the number of unseen classes in test.

$\mathrm{P_I}$-OSVM (*P_I-osvm-linear* and *P_I-osvm-rbf*). Similar to $\mathrm{P_I}$-SVM, $\mathrm{P_I}$-OSVM (Jain et al., 2014) uses a multiclass one-class SVM before fitting an Extreme Value Theory distribution to estimate the probability of inclusion. Again, two kernel functions are tested and the prior probability of the number of unseen classes is used to set δ. As $\mathrm{P_I}$-OSVM is a variant of the traditional one-class SVM, we do not use one-class SVM as a baseline.

Exploratory Seeded K-Means (Exploratory-EM). In (Dalvi et al., 2013), three well-known multiclass semi-supervised learning methods were extended under the exploratory EM framework. We compare with exploratory version of Seeded K-Means due to its superior performance on 20newsgroup dataset. We also applied the criteria that work the best in the original paper for creating new classes and for model selection, i.e., the MinMax criterion and the AICc criterion. Note that ExploratoryEM works in the semi-supervised setting and uses both the training and test data as labeled and unlabeled data in training. As more than one new class can be introduced during training, for comparison we lump together all instances assigned to new classes as being rejected (unknown). In the experiments, we set the max number of iterations to be 50. Little changes in results are shown after 50 iterations.

All documents use *tf-idf* term weighting scheme with no feature selection. Source code for different baselines (1-vs-Set Machine[2], W-SVM and $\mathrm{P_I}$-SVM[3], and Exploratory learning[4]) was provided by the authors of their original papers.

4.2 Datasets

We perform evaluation using two publically available datasets: 20-newsgroup (Rennie, 2008) and Amazon reviews (Jindal and Liu, 2008). The 20-newsgroup data contains 20 non-overlapping classes with a total of 18828 documents. The Amazon reviews dataset has review documents of 50 types of products or domains. Each type of product has 1000 reviews. For each class in both datasets, we randomly sampled 70% of documents for training, and the rest 30% for testing. Although product reviews are used for experiments, we do not perform sentiment classification. Instead, we still perform the traditional topic based classification. That is, given a review, the system decides what type of product the review is about.

4.3 Experiment settings

Following that in (Jain et al., 2013) and (Dalvi et al., 2013), we conduct open world cross-validation style analysis, holding out some classes in training and mixing them back during testing, and varying the number of training and test classes. Since for a given dataset, the number (percentage) of training classes m and the number of test classes n can vary, there are many ways to generate a train-test partition. We report our results using 10 random train-test partitions for each dataset. We vary the number of test classes for Amazon (10, 20, 30, 40, 50), and for 20-newsgroup (10, 20). We use 25%,

Table 7: 20-newsgroup 20 Domains.

50%, 75% and 100% of the test classes in training.

When 100% of test classes are used in training, the problem reduces to the closed world classification. As most of our baselines such as W-SVM, P$_I$-OSVM and P$_I$-SVM all use prior knowledge to set decision threshold to 0 in the closed world setting, for fair comparison, we also set the threshold to 0 for both 1-vs-rest-SVM and our proposed *cbsSVM* for closed world classification. By doing this, we always assign a known class label to a test instance. For Exploratory Seeded K-Means, we use an option supported in the exploratory learning package that does not allow any new classes to be introduced in learning.

For each train-test partition, we first compute precision, recall and F1 score for each class and then macro-average the results across all classes. Final results are given by averaging the results of 10 random train-test partitions. Due to space limits, we will only show F1 scores in the paper.

For all the methods that use the RBF kernel, the parameters are tuned via cross validation on the training data, yielding $(C = 5, \gamma = 0.2)$ for Amazon and $(C = 10, \gamma = 0.5)$ for 20-newsgroup.

4.4 Results and Discussion

We now show all the results. Results for Amazon is given in Tables 1 to 5, and for 20-newsgroup are given in Tables 6 and 7. As we can see, in most situations (23 of 28 settings) our proposed *cbsSVM* method performs the best. Even when 100% of the test classes are used for training (the traditional closed world classification), *cbsSVM* still performs

the best in almost all settings (6 out of 7) except for 20-newsgroup with 20 classes. In this case, it lost to ExploratoryEM by 1.12%. In fact, it is unfair to compare *cbsSVM* with ExploratoryEM because ExploratoryEM uses the test data in training.

We also analyzed the cases where our technique does not perform well. By comparing Table 1 and Table 6, we see that our method loses to 1-vs-set-linear, wsvm-linear and P_i-svm-linear on both datasets when training on 2 classes (25%) and testing on 10 classes, though in other cases training on 25% known classes can still yield good results. By inspecting the results, we found that in both settings our technique achieves very high recall but low precision on the known classes, while achieves high precision but low recall on the unknown classes. After careful investigation, we found this is caused by the relatively poor approximation of radius r_O when positive and negative training examples are far apart.

To verify the cause, we conducted more experiments on the 20-newsgroup data using the same setting (10 classes for test and 2 for training). The 10 classes are listed in Table 8. We show the results for two sets of experiments. In each set of the experiments, we keep one known class unchanged in training and select different classes as the second class. We show how the results change on the unchanged class as well as the unknown (reject) classes. Table 9 gives the precision, recall, and F1 score for *comp.windows.x* and for the unknown classes. Similarly, Table 10 gives the results for *rec.motorcycles* and for the unknown classes. The first column in both tables are the different second classes used in training. We can see that in both sets of experiments, the precision and F1 score on the unchanged known classes (*comp.windows.x* and *rec.motorcycles*) are better when a more similar class (closer in distance) is selected in training. In particular, *comp.windows.x* achieves the best result when *comp.os.ms-windows.misc* is the second known class, and *rec.motorcycles* achieves the best result when *rec.autos* is the second known class. This is because the radius r_O for each positively labeled space is determined based on the distance between the positive and negative training examples. As related classes are closer in distance, a tighter boundary with smaller r_O can be learned. However, our results show in the cases when only 2 known classes are available, a tight boundary is harder to achieve for either class for *cbsSVM*.

5 Conclusion

In this paper, we proposed to study the problem of multiclass open text classification. In particular, we investigated the problem via reducing the open space risk, and proposed a solution based on center-based similarity space learning. The solution reduced the positive labeled area from an infinite space to a finite space compared to previous work. This markedly reduces the open space risk. With extensive experiments across two public multiclass datasets, we demonstrated that the proposed solution is highly promising. Our future work includes designing a more robust solution that still works well when the number of known classes is small.

Sequential Short-Text Classification with Recurrent and Convolutional Neural Networks

Abstract

Recent approaches based on artificial neural networks (ANNs) have shown promising results for short-text classification. However, many short texts occur in sequences (e.g., sentences in a document or utterances in a dialog), and most existing ANN-based systems do not leverage the preceding short texts when classifying a subsequent one. In this work, we present a model based on recurrent neural networks and convolutional neural networks that incorporates the preceding short texts. Our model achieves state-of-the-art results on three different datasets for dialog act prediction.

1 Introduction

Short-text classification is an important task in many areas of natural language processing, including sentiment analysis, question answering, or dialog management. Many different approaches have been developed for short-text classification, such as using Support Vector Machines (SVMs) with rule-based features (Silva et al., 2011), combining SVMs with naive Bayes (Wang and Manning, 2012), and building dependency trees with Conditional Random Fields (Nakagawa et al., 2010). Several recent studies using ANNs have shown promising results, including convolutional neural networks (CNNs) (Kim, 2014; Blunsom et al., 2014; Kalchbrenner et al., 2014) and recursive neural networks (Socher et al., 2012).

Most ANN systems classify short texts in isolation, i.e., without considering preceding short texts. However, short texts usually appear in sequence (e.g., sentences in a document or utterances in a dialog), and therefore using information from preceding short texts may improve the classification accuracy. Previous works on sequential short-text classification are mostly based on non-ANN approaches, such as Hidden Markov Models (HMMs) (Reithinger and Klesen, 1997; Stolcke et al., 2000; Surendran and Levow, 2006), maximum entropy (Ang et al., 2005), naive Bayes (Lendvai and Geertzen, 2007), and conditional random fields (CRFs) (Kim et al., 2010; Quarteroni et al., 2011).

Inspired by the performance of ANN-based systems for non-sequential short-text classification, we introduce a model based on recurrent neural networks (RNNs) and CNNs for sequential short-text classification, and evaluate it on the dialog act classification task. A dialog act characterizes an utterance in a dialog based on a combination of pragmatic, semantic, and syntactic criteria. Its accurate detection is useful for a range of applications, from speech recognition to automatic summarization (Stolcke et al., 2000). Our model achieves state-of-the-art results on three different datasets.

2 Model

Our model comprises two parts. The first part generates a vector representation for each short text using either the RNN or CNN architecture, as discussed in Section 2.1 and Figure 1. The second part classifies the current short text based on the vector representations of the current as well as a few preceding short texts, as presented in Section 2.2 and Figure 2.

We denote scalars with italic lowercases (e.g.,

San Diego, California, June 12-17, 2016.

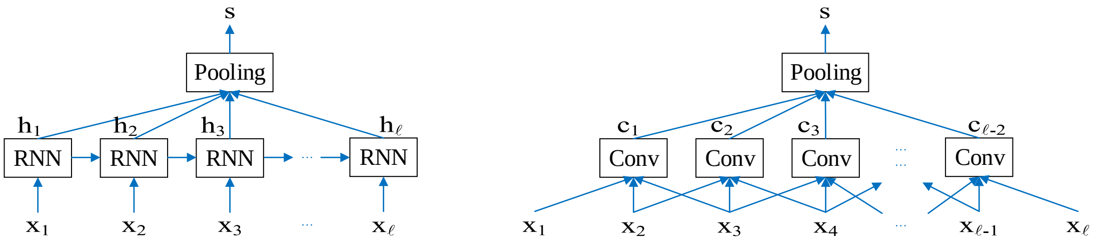

Figure 1: RNN (left) and CNN (right) architectures for generating the vector representation $\mathbf{s}$ of a short text $\mathbf{x}_{1:\ell}$. For CNN, Conv refers to convolution operations, and the filter height $h = 3$ is used in this figure.

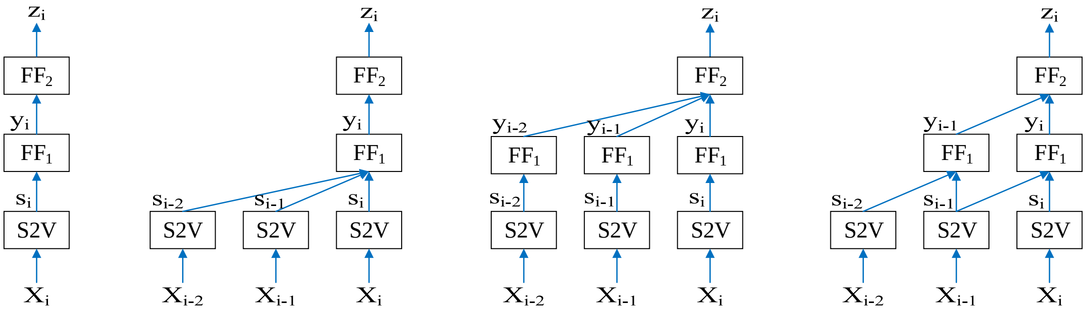

Figure 2: Four instances of the two-layer feedforward ANN used for predicting the probability distribution over the classes $\mathbf{z}_i$ for the i^{th} short-text $\mathbf{X}_i$. S2V stands for short text to vector, which is the RNN/CNN architecture that generates $\mathbf{s}_i$ from $\mathbf{X}_i$. From left to right, the history sizes (d_1, d_2) are $(0, 0)$, $(2, 0)$, $(0, 2)$ and $(1, 1)$. $(0, 0)$ corresponds to the non-sequential classification case.

k, b_f), vectors with bold lowercases (e.g., $\mathbf{s}$, $\mathbf{x}_i$), and matrices with italic uppercases (e.g., W_f). We use the colon notation $\mathbf{v}_{i:j}$ to denote the sequence of vectors $(\mathbf{v}_i, \mathbf{v}_{i+1}, \ldots, \mathbf{v}_j)$.

2.1 Short-text representation

A given short text of length ℓ is represented as the sequence of m-dimensional word vectors $\mathbf{x}_{1:\ell}$, which is used by the RNN or CNN model to produce the n-dimensional *short-text representation* $\mathbf{s}$.

2.1.1 RNN-based short-text representation

We use a variant of RNN called Long Short Term Memory (LSTM) (Hochreiter and Schmidhuber, 1997). For the t^{th} word in the short-text, an LSTM takes as input $\mathbf{x}_t, \mathbf{h}_{t-1}, \mathbf{c}_{t-1}$ and produces $\mathbf{h}_t, \mathbf{c}_t$ based on the following formulas:

$$\begin{aligned}
\mathbf{i}_t &= \sigma(W_i \mathbf{x}_t + U_i \mathbf{h}_{t-1} + \mathbf{b}_i) \\
\mathbf{f}_t &= \sigma(W_f \mathbf{x}_t + U_f \mathbf{h}_{t-1} + \mathbf{b}_f) \\
\tilde{\mathbf{c}}_t &= \tanh(W_c \mathbf{x}_t + U_c \mathbf{h}_{t-1} + \mathbf{b}_c) \\
\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \tilde{\mathbf{c}}_t \\
\mathbf{o}_t &= \sigma(W_o \mathbf{x}_t + U_o \mathbf{h}_{t-1} + \mathbf{b}_o) \\
\mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)
\end{aligned}$$

where $W_j \in \mathbb{R}^{n \times m}$, $U_j \in \mathbb{R}^{n \times n}$ are weight matrices and $\mathbf{b}_j \in \mathbb{R}^n$ are bias vectors, for $j \in \{i, f, c, o\}$. The symbols $\sigma(\cdot)$ and $\tanh(\cdot)$ refer to the element-wise sigmoid and hyperbolic tangent functions, and $\odot$ is the element-wise multiplication. $\mathbf{h}_0 = \mathbf{c}_0 = \mathbf{0}$.

In the pooling layer, the sequence of vectors $\mathbf{h}_{1:\ell}$ output from the RNN layer are combined into a single vector $\mathbf{s} \in \mathbb{R}^n$ that represents the short-text, using one of the following mechanisms: last, mean, and max pooling. Last pooling takes the last vector, i.e., $\mathbf{s} = \mathbf{h}_\ell$, mean pooling averages all vectors, i.e., $\mathbf{s} = \frac{1}{\ell} \sum_{t=1}^{\ell} \mathbf{h}_t$, and max pooling takes the element-wise maximum of $\mathbf{h}_{1:\ell}$.

2.1.2 CNN-based short-text representation

Using a *filter* $W_f \in \mathbb{R}^{h \times m}$ of height h, a convolution operation on h consecutive word vectors starting from t^{th} word outputs the scalar *feature*

$$c_t = \text{ReLU}(W_f \bullet X_{t:t+h-1} + b_f)$$

where $X_{t:t+h-1} \in \mathbb{R}^{h \times m}$ is the matrix whose i^{th} row is $\mathbf{x}_i \in \mathbb{R}^m$, and $b_f \in \mathbb{R}$ is a bias. The symbol $\bullet$ refers to the dot product and $\text{ReLU}(\cdot)$ is the element-wise rectified linear unit function.

We perform convolution operations with n different filters, and denote the resulting features as

$\mathbf{c}_t \in \mathbb{R}^n$, each of whose dimensions comes from a distinct filter. Repeating the convolution operations for each window of h consecutive words in the short-text, we obtain $\mathbf{c}_{1:\ell-h+1}$. The short-text representation $\mathbf{s} \in \mathbb{R}^n$ is computed in the max pooling layer, as the element-wise maximum of $\mathbf{c}_{1:\ell-h+1}$.

2.2 Sequential short-text classification

Let $\mathbf{s}_i$ be the n-dimensional short-text representation given by the RNN or CNN architecture for the i^{th} short text in the sequence. The sequence $\mathbf{s}_{i-d_1-d_2\,:\,i}$ is fed into a two-layer feedforward ANN that predicts the class for the i^{th} short text. The hyperparameters d_1, d_2 are the history sizes used in the first and second layers, respectively.

The first layer takes as input $\mathbf{s}_{i-d_1-d_2\,:\,i}$ and outputs the sequence $\mathbf{y}_{i-d_2\,:\,i}$ defined as

$$\mathbf{y}_j = \tanh\left(\sum_{d=0}^{d_1} W_{-d}\,\mathbf{s}_{j-d} + \mathbf{b}_1\right),\ \forall j \in [i-d_2, i]$$

where $W_0, W_{-1}, W_{-2} \in \mathbb{R}^{k \times n}$ are the weight matrices, $\mathbf{b}_1 \in \mathbb{R}^k$ is the bias vector, $\mathbf{y}_j \in \mathbb{R}^k$ is the *class representation*, and k is the number of classes for the classification task.

Similarly, the second layer takes as input the sequence of class representations $\mathbf{y}_{i-d_2:i}$ and outputs $\mathbf{z}_i \in \mathbb{R}^k$:

$$\mathbf{z}_i = \text{softmax}\left(\sum_{j=0}^{d_2} W_{-j}\,\mathbf{y}_{i-j} + \mathbf{b}_2\right)$$

where $U_0, U_{-1}, U_{-2} \in \mathbb{R}^{k \times k}$ and $\mathbf{b}_2 \in \mathbb{R}^k$ are the weight matrices and bias vector.

The final output $\mathbf{z}_i$ represents the probability distribution over the set of k classes for the i^{th} short-text: the j^{th} element of $\mathbf{z}_i$ corresponds to the probability that the i^{th} short-text belongs to the j^{th} class.

3 Datasets and Experimental Setup

3.1 Datasets

We evaluate our model on the dialog act classification task using the following datasets:

- DSTC 4: Dialog State Tracking Challenge 4 (Kim et al., 2015; Kim et al., 2016).
- MRDA: ICSI Meeting Recorder Dialog Act Corpus (Janin et al., 2003; Shriberg et al., 2004). The 5 classes are introduced in (Ang et al., 2005).
- SwDA: Switchboard Dialog Act Corpus (Jurafsky et al., 1997).

For MRDA, we use the train/validation/test splits provided with the datasets. For DSTC 4 and SwDA, only the train/test splits are provided.[1] Table 1 presents statistics on the datasets.

Dataset	$\lvert C\rvert$	$\lvert V\rvert$	Train	Validation	Test
DSTC 4	89	6k	24 (21k)	5 (5k)	6 (6k)
MRDA	5	12k	51 (78k)	11 (16k)	11 (15k)
SwDA	43	20k	1003 (193k)	112 (23k)	19 (5k)

Table 1: Dataset overview. $|C|$ is the number of classes, $|V|$ the vocabulary size. For the train, validation and test sets, we indicate the number of dialogs (i.e., sequences) followed by the number of utterances (i.e., short texts) in parenthesis.

3.2 Training

The model is trained to minimize the negative log-likelihood of predicting the correct dialog acts of the utterances in the train set, using stochastic gradient descent with the Adadelta update rule (Zeiler, 2012). At each gradient descent step, weight matrices, bias vectors, and word vectors are updated. For regularization, dropout is applied after the pooling layer, and early stopping is used on the validation set with a patience of 10 epochs.

4 Results and Discussion

To find effective hyperparameters, we varied one hyperparameter at a time while keeping the other ones fixed. Table 2 presents our hyperparameter choices.

Hyperparameter	**Choice**	**Experiment Range**
LSTM output dim. (n)	100	50 – 1000
LSTM pooling	max	max, mean, last
LSTM direction	unidir.	unidir., bidir.
CNN num. of filters (n)	500	50 – 1000
CNN filter height (h)	3	1 – 10
Dropout rate	0.5	0 – 1
Word vector dim. (m)	200, 300	25 – 300

Table 2: Experiments ranges and choices of hyperparameters. Unidir refers to the regular RNNs presented in Section 2.1.1, and bidir refers to bidirectional RNNs introduced in (Schuster and Paliwal, 1997).

We initialized the word vectors with the 300-dimensional word vectors pretrained with word2vec

	2	**84.1** (83.5, 84.4)	83.9 (83.4, 84.7)	83.3 (82.6, 84.2)	84.4 (84.1, 84.8)	**84.6** (84.5, 84.7)	84.4 (84.2, 84.7)
SwDA	0	66.3 (65.1, 68.0)	67.9 (66.3, 68.6)	67.8 (66.7, 69.0)	67.0 (65.3, 68.7)	69.1 (68.5, 70.0)	69.7 (69.2, 70.9)
	1	68.4 (67.8, 68.8)	67.8 (65.5, 68.9)	67.3 (65.5, 69.5)	69.9 (69.1, 70.9)	69.8 (69.3, 70.6)	69.9 (68.8, 70.6)
	2	**69.5** (68.9, 70.2)	67.9 (66.5, 69.4)	67.7 (66.9, 68.9)	**71.4** (70.4, 73.1)	71.1 (70.2, 72.1)	70.9 (69.7, 71.7)

Table 3: Accuracy (%) on different architectures and history sizes d_1, d_2. For each setting, we report average (minimum, maximum) computed on 5 runs. Sequential classification ($d_1 + d_2 > 0$) outperforms non-sequential classification ($d_1 = d_2 = 0$). Overall, the CNN model outperformed the LSTM model for all datasets, albeit by a small margin except for SwDA. We also tried gated recurrent units (GRUs) (Cho et al., 2014) and the basic RNN, but the results were generally lower than LSTM.

on Google News (Mikolov et al., 2013a; Mikolov et al., 2013b) for DSTC 4, and the 200-dimensional word vectors pretrained with GloVe on Twitter (Pennington et al., 2014) for MRDA and SwDA, as these choices yielded the best results among all publicly available word2vec, GloVe, SENNA (Collobert, 2011; Collobert et al., 2011) and RNNLM (Mikolov et al., 2011) word vectors.

The effects of the history sizes d_1 and d_2 for the short-text and the class representations, respectively, are presented in Table 3 for both the LSTM and CNN models. In both models, increasing d_1 while keeping $d_2 = 0$ improved the performances by 1.3-4.2 percentage points. Conversely, increasing d_2 while keeping $d_1 = 0$ yielded better results, but the performance increase was less pronounced: incorporating sequential information at the short-text representation level was more effective than at the class representation level.

Using sequential information at both the short-text representation level and the class representation level does not help in most cases and may even lower the performances. We hypothesize that short-text representations contain richer and more general information than class representations due to their larger dimension. Class representations may not convey any additional information over short-text representations, and are more likely to propagate errors from previous misclassifications.

Table 4 compares our results with the state-of-the-art. Overall, our model shows competitive results, while requiring no human-engineered features. Rigorous comparisons are challenging to draw, as many important details such as text preprocessing and train/valid/test split may vary, and many studies fail to perform several runs despite the randomness in some parts of the training process, such as weight initialization.

Model	DSTC 4	MRDA	SwDA
CNN	65.5	**84.6**	**73.1**
LSTM	**66.2**	84.3	69.6
Majority class	25.8	59.1	33.7
SVM	57.0	–	–
Graphical model	–	81.3	–
Naive Bayes	–	82.0	–
HMM	–	–	71.0
Memory-based Learning	–	–	72.3
Interlabeler agreement	–	–	84.0

Table 4: Accuracy (%) of our models and other methods from the literature. The majority class model predicts the most frequent class. SVM: (Dernoncourt et al., 2016). Graphical model: (Ji and Bilmes, 2006). Naive Bayes: (Lendvai and Geertzen, 2007). HMM: (Stolcke et al., 2000). Memory-based Learning: (Rotaru, 2002). All five models use features derived from transcribed words, as well as previous predicted dialog acts except for Naive Bayes. The interlabeler agreement could not be obtained for MRDA, and DSTC 4 was labeled by a single annotator. For the CNN and LSTM models, the presented results are the test set accuracy of the run with the highest accuracy on the validation set.

5 Conclusion

In this article we have presented an ANN-based approach to sequential short-text classification. We demonstrate that adding sequential information improves the quality of the predictions, and the performance depends on what sequential information is used in the model. Our model achieves state-of-the-art results on three different datasets for dialog act prediction.

Abstract

In a multi-label text classification task, in which multiple labels can be assigned to one text, label co-occurrence itself is informative. We propose a novel neural network initialization method to treat some of the neurons in the final hidden layer as dedicated neurons for each pattern of label co-occurrence. These dedicated neurons are initialized to connect to the corresponding co-occurring labels with stronger weights than to others. In experiments with a natural language query classification task, which requires multi-label classification, our initialization method improved classification accuracy without any computational overhead in training and evaluation.

1 Introduction

In multi-label text classification, one text can be associated with multiple labels (*label co-occurrence*) (Zhang and Zhou, 2014). Since label co-occurrence itself contains information, we would like to leverage the label co-occurrence to improve multi-label classification using a neural network (NN). We propose a novel NN initialization method that treats some of the neurons in the final hidden layer as *dedicated neurons* for each pattern of label co-occurrence. These dedicated neurons are initialized to connect to the corresponding co-occurring labels with stronger weights than to others. While initialization of an NN is an important research topic (Glorot and Bengio, 2010; Sutskever et al., 2013; Le et al., 2015), to the best of our knowledge, there has been no attempt to leverage label co-occurrence for NN initialization.

To validate our proposed method, we focus on multi-label Natural Language Query (NLQ) classification in a document retrieval system in which users input queries in natural language and the system returns documents that contain answers to the queries. For NLQ classification, we first train a model from training data that contains pairs of queries and corresponding one or more than one document labels, and then predict the appropriate document labels for new queries with the trained model.

Through experiments with a real-world document retrieval system and publicly available multi-label data set, simply and directly embedding label co-occurrence information into an NN with our proposed method improved accuracy of NLQ classification.

2 Related Work

Along with the recent success in NNs (Collobert et al., 2011; Kim, 2014), NN-based multi-label classification has been proposed. An NN for NLQ classification needs to accept queries with variable length and output their labels. Figure 1 shows a typical NN architecture (Collobert et al., 2011). This NN first transforms words in the input query into word embeddings (Mikolov et al., 2013), then applies Convolutional Neural Network (CNN) and Max-pooling over time to extract fixed-length feature vectors, and feed them into the output layer to predict the label for the query (Collobert and Weston, 2008; Collobert et al., 2011; Yih et al., 2014). To take care of multi-labels, label co-occurrence has been incorporated into loss functions such as *pairwise ranking loss* (Zhang and Zhou, 2006). More recently, Nam et

Proceedings of NAACL-HLT 2016, pages 521–526,
San Diego, California, June 12-17, 2016.

al. (2014) reported that *binary cross entropy* can outperform the pairwise ranking loss by leveraging rectified linear units (ReLUs) for nonlinearity (Nair and Hinton, 2010), *AdaGrad* for optimization (Duchi et al., 2011), and *dropout* for generalization (Srivastava et al., 2014). Considering the training efficiency and superior performance, we used the binary cross entropy as one of the baselines in our experiments in Section 4 in addition to *negative log-likelihood* and *cross entropy*.

Let $\boldsymbol{x}$ denote the feature vector of a query, $\boldsymbol{y}$ be the vector representation of the label, $\boldsymbol{o}$ be the output value of the NN, and Θ be the parameters of the NN. Note that the representation of $\boldsymbol{y}$ differs depending on the loss function. For simplicity in the following explanation, assume that we have a finite set of labels $\Lambda = \{\lambda_1, \lambda_2, \lambda_3, \lambda_4, \lambda_5\}$ and that a query $\boldsymbol{x}$ has multiple labels $\{\lambda_1, \lambda_4\}$:

Negative Log Probability With minimization of negative log probability, a single label is assumed. To circumvent this limitation, we used *copy transformation* (Tsoumakas et al., 2010) and obtained two training examples $((\boldsymbol{x}, \boldsymbol{y}^{(1)}), (\boldsymbol{x}, \boldsymbol{y}^{(2)}))$, where $\boldsymbol{y}^{(1)} = (1, 0, 0, 0, 0)$ and $\boldsymbol{y}^{(2)} = (0, 0, 0, 1, 0)$. The loss for each example becomes $l(\Theta, (\boldsymbol{x}, \boldsymbol{y}^{(1)})) = -\log(o_1)$ and $l(\Theta, (\boldsymbol{x}, \boldsymbol{y}^{(2)})) = -\log(o_4)$, where softmax activation is used to calculate $\boldsymbol{o}$ in the output layer.

Cross Entropy We assumed multi-labels as probabilistic distribution as $\boldsymbol{y} = (0.5, 0, 0, 0.5, 0)$. The cross entropy loss for the training example $(\boldsymbol{x}, \boldsymbol{y})$ becomes $l(\Theta, (\boldsymbol{x}, \boldsymbol{y})) = -\boldsymbol{y} \log(\boldsymbol{o})$, where softmax activation is used in the output layer.

Binary Cross Entropy As Nam et al. (2014) indicated, minimizing binary cross entropy is superior for handling multi-labels. By representing the target labels as $\boldsymbol{y} = (1, 0, 0, 1, 0)$, the binary cross entropy loss for the training example $(\boldsymbol{x}, \boldsymbol{y})$ becomes $l(\Theta, (\boldsymbol{x}, \boldsymbol{y})) = -\sum_{k=1}^{5}(y_k \log(o_k) + (1 - y_k)\log(1 - o_k))$, where sigmoid activation is used in the output layer.

3 Proposed Method

In this section, we explain our proposed method in detail.

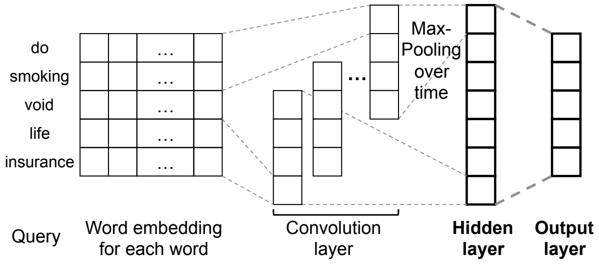

Figure 1: Neural network for NLQ classification. Proposed method is applied to the weight matrix between hidden and output layers as detailed in Figure 2.

Figure 2: Overview of the proposed method. Label co-occurrence patterns of $\{\lambda_1, \lambda_4\}$ and $\{\lambda_2, \lambda_4, \lambda_5\}$ are used in weight initialization, as shown in the above. This initialization corresponds to preparing dedicated neurons for each label co-occurrence pattern, as shown in the below.

3.1 Weight Initialization Leveraging Label Co-occurrence

We propose an NN initialization method to treat some of the neurons in the final hidden layer as dedicated neurons for each pattern of label co-occurrence. These dedicated neurons simultaneously activate the co-occurring labels. Figure 2 shows the key idea of the proposed method. We first investigate the training data and list up patterns of label co-occurrence. Then, for each pattern of label co-occurrence, we initialize a matrix row so that the columns corresponding to the co-occurring labels have a constant weight C and the other columns

Loss Function	1-best Accuracy			Recall@5			Full Accuracy		
Negative Log Likelihood	49.75	→	51.27	69.80	→	71.07	47.03	→	48.65
Cross Entropy	50.51	→	**52.54**	71.32	→	**72.08**	46.96	→	**48.71**
Binary Cross Entropy	49.75	→	50.51	70.81	→	71.32	48.09	→	48.34

Table 1: 1-best accuracy, recall@5, and full accuracy for evaluation data using different loss functions (Random initialization → Proposed initialization). [%]

have a weight of 0, as shown in Figure 2 (above). Note that the remaining rows that are not associated with the pattern of label co-occurrence are randomly initialized. This initialization is equivalent to treating some of the neurons in the final hidden layer as dedicated neurons for each pattern of label co-occurrence, where the dedicated neurons have connections to the corresponding co-occurring labels with an initialized weight C and to others with an initialized weight of 0, as shown in Figure 2 (below). Finally, we conduct normal back-propagation using one of the loss functions, as discussed in the previous section. Note that all the connection weights in the NN including the connection weights between the dedicated neurons and all labels are updated through back-propagation.

Since (1) computation of proposed initialization itself is negligible and (2) computation of back-propagation and the architecture of NN does not change with or without the proposed initialization, our proposed method does not increase computation in training and evaluation.

3.2 Weight Setting for Dedicated Neurons

For the weight value C for initialization, we used the upper bound UB of the normalized initialization (Glorot and Bengio, 2010), which is determined by the number of units in the final hidden layer n_h and output layer n_c as $UB = \frac{\sqrt{6}}{\sqrt{n_h+n_o}}$. Additionally, we changed this value in accordance with the frequency of the label co-occurrence patterns in the training data. The background idea is that the patterns of label co-occurrence that appear frequently (i.e., the number of queries with this pattern of label co-occurrence is large) are more important than less frequent patterns. Assuming that a specific pattern of label co-occurrence appears in the training data f times, we try $f \times UB$ and $\sqrt{f} \times UB$ for initialization to emphasize this pattern.

C	1-best	Recall@5	Full
—	50.51	71.32	46.96
UB	52.54	**72.08**	48.71
$f \times UB$	51.52	70.81	48.39
$\sqrt{f} \times UB$	**53.55**	**72.08**	**50.04**

Table 2: 1-best accuracy, recall@5, and full accuracy for evaluation data with changing initialization value ***C***. [%]

4 Experiments

We conducted experiments with the real-world NLQ classification data and the publicly available data to confirm the advantage of the proposed method.

4.1 Real-world NLQ classification Data

Experimental Setup We used NLQs for a document retrieval system in the insurance domain for the experiments. Users of the system input queries in natural language, and the system returns the labels of the documents that contain answers. We used $3,133$ queries for training and 394 queries for evaluation, $1,695$ and 158 of which had multiple labels, respectively. The number of unique document labels assigned to the training data was 526.

We used the NN shown in Figure 1. The dimension of word embedding was 100, number of kernels for the CNN was $1,000$, which means $1,000$ units exist in the final hidden layer on top of Max-pooling over time, and number of output units was 526. We used this NN configuration in common for all the experiments. The word embedding was pre-trained with the *skip-gram* model of *word2vec* using the dumped English *Wikipedia* data and the documents of the target insurance domain (Mikolov et al., 2013). The NN except the word embedding layer was randomly initialized in accordance with the normalized initialization (Glorot and Bengio, 2010). We used the ReLU for nonlinearity, AdaGrad for optimization, and dropout for generalization. We fixed

Loss Function	# Survived Neurons (# dedicated neurons:252)	Weights-Dedicated [Mean / Variance]	Weights-All [Mean / Variance]
Negative Log Likelihood	194	0.251 / 0.004	-0.024 / 0.023
Cross Entropy	197	0.267 / 0.005	-0.017 / 0.021
Binary Cross Entropy	168	0.279 / 0.015	-0.007 / 0.011

Table 3: Investigation of neural network after back-propagation training.

the number of training epochs to $1,000$[1].

For the proposed method, we investigated the $1,695$ queries with multiple labels in the training data and found 252 patterns of label co-occurrence. We then embedded this information in a $1,000 \times 526$ weight matrix between the final hidden and output layers. In other words, we treated 252 neurons in the final hidden layer as dedicated neurons in weight initialization.

For the hyper-parameter settings, we first tuned the hyper-parameters including L2-regularization and learning rate so that the accuracy of the baseline system with random initialization was maximized. For the proposed initialization, we used the same hyper-parameters obtained in the former tuning.

We used three evaluation metrics that are closely related to the usability of the document retrieval system: (1) *1-best accuracy* judges if the 1-best result of a system is included in the correct labels[2]. (2) *Recall@5* judges if the 5-best results of a system contain at least one of the correct labels. (3) *Full accuracy* investigates the j-best results of a system and judges if they match the correct labels when j labels are assigned to the query [3].

Different Loss Functions Table 1 shows the experimental results using three different loss functions. Comparing the values to the left of the arrows, which did not use the proposed initialization, superiority of binary cross entropy (Nam et al., 2014) was confirmed in full accuracy, while cross entropy was the best in 1-best accuracy in this experiment. As shown to the right of the arrows, we obtained improvement for all loss functions with every evaluation metric with the proposed method. Overall, cross entropy training with the proposed initialization achieved the best in all three metrics, where 1-best accuracy improvement from 50.51% to 52.54% was statistically significant ($p < 0.05$).

Different Weight Initialization Table 2 shows the results of emphasizing the frequent patterns of label co-occurrence. We used the cross entropy loss function, which was the best in the previous experiments. Using $\sqrt{f} \times UB$ yielded further improvement in 1-best accuracy and full accuracy, though using $f \times UB$ deteriorated in all metrics compared with UB. This suggests that there is room for improvement if we can appropriately emphasize frequent patterns of label co-occurrence.

Analysis on Trained Neural Network We investigated if the dedicated neurons for patterns of label co-occurrences still simultaneously activate the corresponding labels after back-propagation. Table 3 shows the analysis on the NNs trained in the experiments for Table 1. In the *# Survived Neurons* columns, we investigated if the dedicated neurons initialized for the pattern of k-label co-occurrence still had the k largest weights to the corresponding k labels after back-propagation. Large portions of dedicated neurons "survived" after back-propagation. In the *Weights* columns, we calculated the mean of the connection weights between the dedicated neurons and corresponding co-occurring labels and compared them with the mean of all connections in this weight matrix. The trained weights for the connections between the dedicated neurons and corresponding co-occurring labels (*Weights-Dedicated*) were much stronger than the average weights (*Weights-All*). This analysis suggests that the proposed initialization yields dedicated neurons

[1] We confirmed that NN training sufficiently saturated after $1,000$ epochs in preliminary experiments. We also compared the best accuracy achieved in $1,000$ epochs for all experimental conditions and confirmed that the same improvement was achieved with the proposed method.

[2] This metric is comparable with *One-error* (Tsoumakas et al., 2010) by 1-best Accuracy = 100 - One-error.

[3] If a query has three labels, the system needs to return 3-best results that contain the three correct labels of the query to obtain 100% full accuracy.

that simultaneously activate the co-occurring labels even after back-propagation.

There can be an overlap in label co-occurrence patterns. One typical case is “A, B” and “A, B, C”, and another case is “D, E”, “F, G”, and “D, E, F, G”. While we prepared the dedicated neurons for each co-occurrence pattern before back-propagation, some overlapped co-occurrences might be explained by the superset or combination of subsets after back-propagation. Table 3 suggests that some of the dedicated neurons did not survive after back-propagation. We confirmed that about half of the label co-occurrence patterns whose dedicated neurons did not survive were covered by the patterns whose neurons survived. “Cover” means that if a neuron for “A, B” did not survive, a neuron for “A, B, C” survived, or if a neuron for “D, E, F, G” did not survive, neurons for “D, E” and “F, G” survived. If we change the network structure by connecting the dedicated neurons only to the corresponding units or preparing the special output units for co-occurring labels (label powerset (Read, 2008)), this flexibility might be lost.

4.2 Publicly Available Data

We used multi-label topic categorization data (*RCV1-v2*) (Lewis et al., 2004) to validate our method. We used the same label assignment and the same training and evaluation data partition with the *LYRL2004* split (Lewis et al., 2004) where $23,149$ training texts and $781,265$ evaluation texts with 103 topic labels are available. We used the bag-of-word (BoW) feature for each text prepared by Chang and Lin (2011) whose dimension was $47,236$ and constructed a feed-forward NN that has an input layer that accepts the BoW feature, hidden layer of $2,000$ units, and output layer of 103 output units with the cross entropy loss function. By embedding the label co-occurrence information between the hidden and output layers with the initial weights set to UB, which corresponded to treating 758 neurons out of $2,000$ hidden units as the dedicated neurons, we improved 1-best accuracy of topic label classification from 93.95% to 94.60%, which was statistically significant ($p < 0.001$).

To the best of our knowledge, 1-best accuracy of 94.18% (5.82% one-error)[4] (Rubin et al., 2012) was the best published result with using the standard LYRL2004 split of RCV1-v2. Our proposed method has advantages in a sufficiently competitive setup.

5 Conclusion

We proposed an NN initialization method to leverage label co-occurrence information. Through experiments using the data of a real-world document retrieval system and publicly available data, we confirmed that our proposed method improved NLQ classification accuracy. The advantage of the proposed method also includes no computational overhead during training and evaluation.

When we have large training data, the number of label co-occurrence patterns can be larger than that of hidden units. In such a case, one option is to select an appropriate set of label co-occurrence patterns with certain criteria such as the frequency in the training data. Another option is to make a larger weight matrix using all patterns and then to reduce its dimension with such as Principal Component Analysis (PCA) in advance of NN training. Our future work also includes setting the initialization weight in a more sophisticated way and combining the proposed method with other NN-based methods (Kim, 2014; Johnson and Zhang, 2015).

Acknowledgments

We would like to show our gratitude to Dr. Ramesh M. Nallapati of IBM Watson for supporting the experiments. We are grateful to Dr. Yuta Tsuboi, Dr. Ryuki Tachibana, and Mr. Nobuyasu Itoh of IBM Research - Tokyo for the fruitful discussion and their comments on this and earlier versions of the paper. We thank the anonymous reviewers for their valuable comments.

[4] Randomly selected $75,000$ texts were used for evaluation, but the results on this subset were confirmed to be almost identical to those on the full evaluation texts (Rubin et al., 2012).

Abstract

Bidirectional long short-term memory (BLSTM) recurrent neural network (RNN) has been successfully applied in many tagging tasks. BLSTM-RNN relies on the distributed representation of words, which implies that the former can be futhermore improved through learning the latter better. In this work, we propose a novel approach to learn distributed word representations by training BLSTM-RNN on a specially designed task which only relies on unlabeled data. Our experimental results show that the proposed approach learns useful distributed word representations, as the trained representations significantly elevate the performance of BLSTM-RNN on three tagging tasks: part-of-speech tagging, chunking and named entity recognition, surpassing word representations trained by other published methods.

1 Introduction

Distributed word representations represent word with a real valued vector, which is also referred to as word embedding. Well learned distributed word representations have been shown capable of capturing semantic and syntactic regularities (Pennington et al., 2014a; Mikolov et al., 2013c) and enhancing neural network model by being used as features (Collobert and Weston, 2008; Bengio and Heigold, 2014; Wang et al., 2015).

Sequence tagging is a basic structure learning task for natural language processing. Many primary processing tasks over sentence such as word segmentation, named entity recognition and part-of-speech tagging can be formalized as a tagging task (Zhao et al., 2006; Huang and Zhao, 2007; Zhao and Kit, 2008b; Zhao and Kit, 2008a; Zhao et al., 2010; Zhao and Kit, 2011). Recently, many state-of-the-art systems of tagging related tasks are implemented with bidirectional long short-term memory (BLSTM) recurrent neural network (RNN), for example, slot filling (Mesnil et al., 2013), part-of-speech tagging (Huang et al., 2015), and dependency parsing (Dyer et al., 2015) etc. All of these systems use distributed representation of words to involve word level information. Better trained word representations would further improve the state-of-the-art performance of these tasks which makes it worthy to research the training methods of word representations.

The existing training methods of word representation can generally be divided into two classes: 1) Matrix factorization methods. These methods utilize low-rank approximation to decompose a large matrix that contains corpus statistics. One typical work is the latent semantic analysis (LSA) (Deerwester et al., 1990) in which the matrix records "term-document" information, i.e., the rows cor-

respond to words, and the columns correspond to different documents in the corpus. Another work is hyperspace analogue to language (HAL) (Lund and Burgess, 1996) which decomposes the matrix recording "term-term" information, i.e., the rows correspond to words and columns correspond to the number of times that a word occurs in the given context. 2) Window-based methods. This type of methods learn representations by training a neural network model to make prediction within local context windows. For example, (Bengio et al., 2003) learns word representation through a feedforward neural network language model which predicts a word given its previous several words. (Collobert et al., 2011) trains a neural network to judge the validity of a given context. (Mikolov et al., 2013a) proposes skip-gram and continuous bag-of-words (CBOW) models based on a single-layer network architecture. The objective of skip-gram model is to predict the context given the word itself, while the objective of CBOW is to predict a word given its context. Aside from these two sets of methods, distributed representation can also be obtained by training recurrent neural network (RNN) language model proposed by (Mikolov et al., 2010) or GloVe model proposed by (Pennington et al., 2014a) which trains a log-bilinear model on word-word co-occurrence counts.

All of these methods suffer from shortcomings that might limit the quality of trained word distributions. The matrix factorization family only uses the statistics of co-occurrence counts, disregarding of the position of word in sentence and word order. The window-based methods only consider local context, which is incapable of involving information outside the context window. While RNN language model theoretically considers all information of the previous sequence, but fails to involve the information of the posterior sequence. The word-word co-occurence counts that GloVe model relies on also only include information within a limited sized context window.

In this paper, we propose a novel method to obtain word representation by training BLSTM-RNN model on a specifically designed tagging task. Since BLSTM-RNN theoretically involves all information of input sentence, our approach avoids those shortages suffered by most current methods.

We firstly introduce the structure of BLSTM-RNN used to learn word representations in section 2. Then the tagging task for training BLSTM-RNN is described in section 3. Experiments are presented in section 4, followed by conclusion.

2 Model Structure

The structure of BLSTM-RNN to train word representation is illustrated in Figure 1. Each input is composed of a word identity x_i^1 and additional real-valued features x_i^2. x_i^1 is represented with one-hot representation which is a binary vector with dimension $|V|$ where V is the vocabulary. The input vector I_i of the network is computed as:

$$I_i = W_1 x_i^1 + W_2 x_i^2$$

where W_1 and W_2 are weight matrixes connecting two layers and are updated with the neural network during training. $W_1 x_i^1$ is also known as the distributed representation of word or word embedding which is a real-valued vector usually with a much smaller dimension than x_i^1. Distributed representation trained in other tasks can be easily incorporated by initializing W_1 with these external representations.

3 Learning Representation

According to the structure shown in Figure 1, W_1 is a matrix of weights that is updated during training, thus the distributed representations contained in W_1 are learned simultaneously with the training of BLSTM-RNN on any supervised learning tasks. However, all such tasks for BLSTM-RNN, to the best of our knowledge, require labeled data which is usually too small in size and hard to obtain. In this section, we propose a tagging task specially for BLSTM-RNN to train distributed representations with unlabeled data.

In this method, BLSTM-RNN is applied to perform a tagging task with only two types of tags to predict: incorrect/correct. The input is a sequence of words which is a normal sentence with several words replaced by words randomly chosen from vocabulary. The words to be replaced are chosen randomly from the sentence. In practice, we generate a random number for each word, and a word is chosen to be replaced if the number is lower than a given

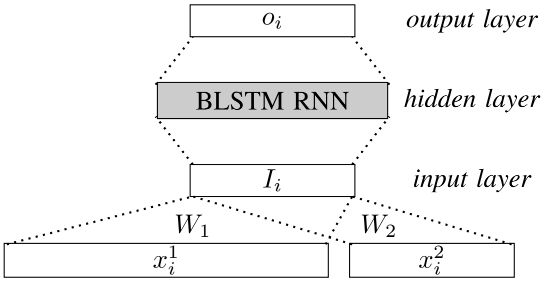

Figure 1: BLSTM-RNN for training word representation.

threshold. For those replaced words, their tags are 0 (incorrect) and for those that are not replaced, their tags are 1 (correct). A simple sample of constructed corpus is shown in Figure 2. Although it is possible that some replaced words are also reasonable in the sentence, they are still considered "incorrect". Then BLSTM-RNN is trained to judge which words have been replaced by minimizing the binary classification error on the training corpus. When the network is trained, W_1 contains all trained word representations. In our experiments, to reduce the vocabulary V, each letter of input word is transferred to its lowercase. The upper case information is kept in an additional features x_i^2 which in practice is a three-dimensional binary vector to indicate if x_i^1 is full lowercase, full uppercase or leading with a capital letter.

Our approach is similar to (Collobert and Weston, 2008) and (Gutmann and Hyvärinen, 2012; Mnih and Teh, 2012; Vaswani et al., 2013). All of these works introduce randomly sampled words and train a neural network on a binary classification task, while (Collobert and Weston, 2008) learns representations for a feedforward network and (Gutmann and Hyvärinen, 2012; Mnih and Teh, 2012; Vaswani et al., 2013) learns normalization parameters instead of representations.

4 Experiments

4.1 Experimental setup

To construct corpus for training word representations, we use North American news (Graff, 2008) which contains about 536 million words as unlabeled data. The North American news data is first tokenized with the Penn Treebank tokenizer script [1]. Consecutive digits occurring within a word are replaced with the symbol "*#*" . For example, both words "*tel92*" and "*tel6*" are converted into "*tel#*". The vocabulary is limited to the most frequent 100,000 words in North American news corpus (Graff, 2008), plus one single "UNK" symbol for replacing all out of vocabulary words. The threshold to determine whether a word is replaced is 0.2, which means about 20% tokens in corpus are replaced with tokens randomly selected from vocabulary. BLSTM-RNN is implemented based on CURRENNT (Weninger et al., 2014), an open source GPU-based toolkit of BLSTM-RNN. The dimension of word representation as well as input layer size of BLSTM-RNN is 100 and hidden layer size is 128.

Three published methods for training word representations are compared: *Skip-gram* (Mikolov et al., 2013a), *CBOW* (Mikolov et al., 2013a) and *GloVe* (Pennington et al., 2014a). They are reported superior in capturing meaningful latent structures than other previous works in (Mikolov et al., 2013a; Pennington et al., 2014a), thus are regarded as the state-of-the-art approach of training word representations. We train the *Skip-gram* and *CBOW* model using the word2vec tool (Mikolov et al., 2013b) with a context window size of 10 and 10 negative samples. For training *GloVe*, we use the GloVe tool (Pennington et al., 2014b) with a context window size 10. These configurations are set by following (Pennington et al., 2014a). Training corpus, vocabulary and dimension of word representations are set the same as that in experiment for training word representations with BLSTM-RNN[2].

4.2 Evaluation

The quality of trained distributed representation is evaluated by the performance of BLSTM-RNN which uses the trained representations on practical tasks. The representations which lead to better performance are considered containing more useful latent information and are judged better. The structure of BLSTM-RNN to test word representations is the same as that in Figure1. To use trained representation, we initialize the weight matrix W_1 with these external representations. For words without corresponding external representations, their representations are initialized with uniformly distributed random values, ranging from -0.1 to 0.1. Three typical tagging tasks are used for the evaluation: part-of-speech tagging (POS), chunking (CHUNK) and named entity recognition (NER).

- The POS tagging experiment is conducted on the Wall Street Journal data from Penn Treebank III (Marcus et al., 1993). Training, development and test sets are split according to in (Collins, 2002). Performance is evaluated by the accuracy of predicted tags on test set.

- CHUNK experiment is conducted on the data of CoNLL-2000 shared task (Sang and Buchholz, 2000). Performance is assessed by the F1 score computed by the evaluation script released by the CoNLL-2000 shared task[3].

- NER experiment is conducted on the CoNLL-2003 shared task (Tjong Kim Sang and De Meulder, 2003). Performance is measured by the F1 score calculated by the evaluation script of the CoNLL-2003 shared task [4].

To focus on the effect of word representation, for all tasks, we use the network with the same hidden structure and input features. The size of input layer is 100, size of BLSTM hidden layer is 128 and output layer size is set as the number of tag types according to the specific tagging task. Input features are composed of word identity and three-dimensional binary vector to indicate if the word is full lowercase, full uppercase or leading with a capital letter.

Table 1 presents the performance of BLSTM-RNN with different distributed representations on these three tasks. *BLSTM* is the baseline system that does not involve external word representations. Among all representations, *BLSTMWE* which is trained by our approach gets the best performance on all three tasks. It shows our approach is more helpful for BLSTM-RNN. Besides, all of the three published word representations also significantly en-

Table 3: Running time of different training methods

hance BLSTM RNN. It confirms the commonly accepted notion that word representation is a useful feature.

4.3 Analysis

Table 2 shows the performance of word representations trained on corpora with different size. *BLSTMWE* (10M), *BLSTMWE* (100M) and *BLSTMWE* (536M) are word representations respectively trained by BLSTM-RNN on the first 10 million words, first 100 million words and all 536 million words of the North American news corpus. As expected, there is a monotonic increase in performance as the corpus size increases. This observation suggests that the result might be further improved by using even bigger unlabeled data.

Table 3 presents running time with different methods to train word representations on 536 million words corpus. BLSTM-RNN is trained on one NVIDIA Tesla M2090 GPU. The other three methods are trained on a 12 core, 2.53GHz Intel Xeon E5649 machine, using 12 threads. Though with the help of GPU, BLSTM-RNN is still slower than the other methods. However, it should be noted that the speed of our approach is acceptable compared with previous neural network language model based methods, including (Bengio et al., 2003; Mikolov et al., 2010; Mnih and Hinton, 2007), as our model uses a much simpler output layer which only has two nodes, avoiding the time consuming computation of the big softmax output layer in language model.

5 CONCLUSION

In this paper, we propose a novel approach to learn distributed word representations with BLSTM-RNN. Word representations are implemented as the layer weights and are obtained as a byproduct of training BLSTM-RNN on a specially designed task, thus theoretically involve information of the whole sentence. The quality of word representations are evaluated by the performance of BLSTM-RNN which uses these representations on three tagging tasks: part-of-speech tagging, chunking and named entity recognition. In experiments, word representations trained by our approach outperform the word representations trained by other published methods. Our work demonstrates an alternative way to improve BLSTM-RNN's performance by learning useful word representations.

Abstract

This paper investigates two different neural architectures for the task of relation classification: convolutional neural networks and recurrent neural networks. For both models, we demonstrate the effect of different architectural choices. We present a new context representation for convolutional neural networks for relation classification (extended middle context). Furthermore, we propose connectionist bi-directional recurrent neural networks and introduce ranking loss for their optimization. Finally, we show that combining convolutional and recurrent neural networks using a simple voting scheme is accurate enough to improve results. Our neural models achieve state-of-the-art results on the SemEval 2010 relation classification task.

1 Introduction

Relation classification is the task of assigning sentences with two marked entities to a predefined set of relations. The sentence "We poured the <e1>milk</e1> into the <e2>pumpkin mixture</e2>.", for example, expresses the relation `Entity-Destination(e1,e2)`. While early research mostly focused on support vector machines or maximum entropy classifiers (Rink and Harabagiu, 2010a; Tratz and Hovy, 2010), recent research showed performance improvements by applying neural networks (NNs) (Socher et al., 2012; Zeng et al., 2014; Yu et al., 2014; Nguyen and Grishman, 2015; Dos Santos et al., 2015; Zhang and Wang, 2015) on the benchmark data from SemEval 2010 shared task 8 (Hendrickx et al., 2010) .

This study investigates two different types of NNs: recurrent neural networks (RNNs) and convolutional neural networks (CNNs) as well as their combination. We make the following contributions:

(1) We propose *extended middle context*, a new context representation for CNNs for relation classification. The extended middle context uses all parts of the sentence (the relation arguments, left of the relation arguments, between the arguments, right of the arguments) and pays special attention to the middle part.

(2) We present *connectionist bi-directional RNN models* which are especially suited for sentence classification tasks since they combine all intermediate hidden layers for their final decision. Furthermore, the ranking loss function is introduced for the RNN model optimization which has not been investigated in the literature for relation classification before.

(3) Finally, we combine CNNs and RNNs using a simple voting scheme and achieve new state-of-the-art results on the SemEval 2010 benchmark dataset.

2 Related Work

In 2010, manually annotated data for relation classification was released in the context of a SemEval shared task (Hendrickx et al., 2010). Shared task participants used, i.a., support vector machines or maximum entropy classifiers (Rink and Harabagiu, 2010a; Tratz and Hovy, 2010). Recently, their results on this data set were outperformed by applying NNs (Socher et al., 2012; Zeng et al., 2014; Yu et al., 2014; Nguyen and Grishman, 2015; Dos Santos et al., 2015).

Proceedings of NAACL-HLT 2016, pages 534–539,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

Zeng et al. (2014) built a CNN based only on the context between the relation arguments and extended it with several lexical features. Kim (2014) and others used convolutional filters of different sizes for CNNs. Nguyen and Grishman (2015) applied this to relation classification and obtained improvements over single filter sizes. Dos Santos et al. (2015) replaced the softmax layer of the CNN with a ranking layer. They showed improvements and published the best result so far on the SemEval dataset, to our knowledge.

Socher et al. (2012) used another NN architecture for relation classification: recursive neural networks that built recursive sentence representations based on syntactic parsing. In contrast, Zhang and Wang (2015) investigated a temporal structured RNN with only words as input. They used a bi-directional model with a pooling layer on top.

3 Convolutional Neural Networks (CNN)

CNNs perform a discrete convolution on an input matrix with a set of different filters. For NLP tasks, the input matrix represents a sentence: Each column of the matrix stores the word embedding of the corresponding word. By applying a filter with a width of, e.g., three columns, three neighboring words (trigram) are convolved. Afterwards, the results of the convolution are pooled. Following Collobert et al. (2011), we perform max-pooling which extracts the maximum value for each filter and, thus, the most informative n-gram for the following steps. Finally, the resulting values are concatenated and used for classifying the relation expressed in the sentence.

3.1 Input: Extended Middle Context

One of our contributions is a new input representation especially designed for relation classification. The contexts are split into three disjoint regions based on the two relation arguments: the left context, the middle context and the right context. Since in most cases the middle context contains the most relevant information for the relation, we want to focus on it but not ignore the other regions completely. Hence, we propose to use two contexts: (1) a combination of the left context, the left entity and the middle context; and (2) a combination of the middle context, the right entity and the right context. Due to the repetition of the middle context, we force the network to pay special attention to it. The two contexts are processed by two independent convolutional and max-pooling layers. After pooling, the results are concatenated to form the sentence representation. Figure 1 depicts this procedure. It shows an examplary sentence: "He had chest pain and `<e1>`headaches`</e1>` from `<e2>`mold`</e2>` in the bedroom." If we only considered the middle context "from", the network might be tempted to predict a relation like `Entity-Origin(e1,e2)`. However, by also taking the left and right context into account, the model can detect the relation `Cause-Effect(e2,e1)`. While this could also be achieved by integrating the whole context into the model, using the whole context can have disadvantages for longer sentences: The max pooling step can easily choose a value from a part of the sentence which is far away from the mention of the relation. With splitting the context into two parts, we reduce this danger. Repeating the middle context increases the chance for the max pooling step to pick a value from the middle context.

3.2 Convolutional Layer

Following previous work (e.g., (Nguyen and Grishman, 2015), (Dos Santos et al., 2015)), we use 2D filters spanning all embedding dimensions. After convolution, a max pooling operation is applied that stores only the highest activation of each filter. We apply filters with different window sizes 2-5 (multi-windows) as in (Nguyen and Grishman, 2015), i.e. spanning a different number of input words.

4 Recurrent Neural Networks (RNN)

Traditional RNNs consist of an input vector, a history vector and an output vector. Based on the representation of the current input word and the previous history vector, a new history is computed. Then, an output is predicted (e.g., using a softmax layer). In contrast to most traditional RNN architectures, we use the RNN for sentence modeling, i.e., we predict an output vector only after processing the whole sentence and not after each word. Training is performed using backpropagation through time (Werbos, 1990) which unfolds the recurrent computations of the history vector for a certain number of time steps. To

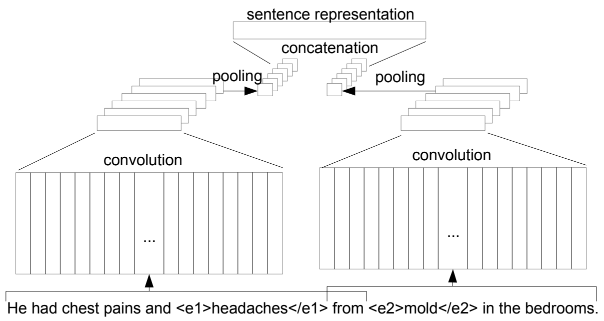

Figure 1: CNN with extended contexts

avoid exploding gradients, we use gradient clipping with a threshold of 10 (Pascanu et al., 2012).

4.1 Input of the RNNs

Initial experiments showed that using trigrams as input instead of single words led to superior results. Hence, at timestep t we do not only give word w_t to the model but the trigram $w_{t-1}w_tw_{t+1}$ by concatenating the corresponding word embeddings.

4.2 Connectionist Bi-directional RNNs

Especially for relation classification, the processing of the relation arguments might be easier with knowledge of the succeeding words. Therefore in bi-directional RNNs, not only a history vector of word w_t is regarded but also a future vector. This leads to the following conditioned probability for the history h_t at time step $t \in [1, n]$:

$$h_{f_t} = f(U_f \cdot w_t + V \cdot h_{f_{t-1}}) \tag{1}$$

$$h_{b_t} = f(U_b \cdot w_{n-t+1} + B \cdot h_{b_{t+1}}) \tag{2}$$

$$h_t = f(h_{b_t} + h_{f_t} + H \cdot h_{t-1}) \tag{3}$$

Thus, the network can be split into three parts: a forward pass which processes the original sentence word by word (Equation 1); a backward pass which processes the reversed sentence word by word (Equation 2); and a combination of both (Equation 3). All three parts are trained jointly. This is also depicted in Figure 2.

Combining forward and backward pass by adding their hidden layer is similar to (Zhang and Wang, 2015). We, however, also add a connection to the previous combined hidden layer with weight H to be able to include all intermediate hidden layers into the final decision of the network (see Equation 3). We call this "connectionist bi-directional RNN".

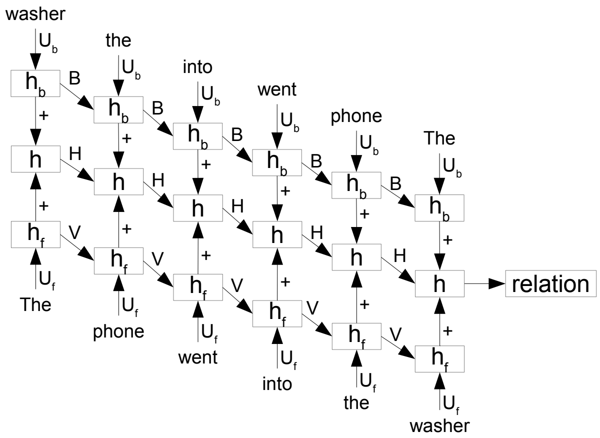

Figure 2: Connectionist bi-directional RNN

In our experiments, we compare this RNN with uni-directional RNNs and bi-directional RNNs without additional hidden layer connections.

5 Model Training

5.1 Word Representations

Words are represented by concatenated vectors: a word embedding and a position feature vector.

Pretrained word embeddings. In this study, we used the word2vec toolkit to train embeddings on an English Wikipedia from May 2014. We only considered words appearing more than 100 times and added a special PADDING token for convolution. This results in an embedding training text of about 485,000 terms and $6.7 \cdot 10^9$ tokens. During model training, the embeddings are updated.

Position features. We incorporate randomly initialized position embeddings similar to Zeng et al. (2014), Nguyen and Grishman (2015) and Dos Santos et al. (2015). In our RNN experiments, we investigate different possibilities of integrating position information: position embeddings, position embeddings with entity presence flags (flags indicating whether the current word is one of the relation arguments), and position indicators (Zhang and Wang, 2015).

5.2 Objective Function: Ranking Loss

Ranking. We applied the ranking loss function proposed in Dos Santos et al. (2015) to train our models. It maximizes the distance between the true label y^+ and the best competitive label c^- given a data point

x. The objective function is

$$
\begin{aligned}
L = \log(1 + \exp(\gamma(m^+ - s_\theta(x)_{y^+}))) \\
+ \log(1 + \exp(\gamma(m^- + s_\theta(x)_{c^-})))
\end{aligned} \tag{4}
$$

with $s_\theta(x)_{y^+}$ and $s_\theta(x)_{c^-}$ being the scores for the classes y^+ and c^- respectively. The parameter γ controls the penalization of the prediction errors and m^+ and m^- are margins for the correct and incorrect classes. Following Dos Santos et al. (2015), we set $\gamma = 2, m^+ = 2.5, m^- = 0.5$. We do not learn a pattern for the class Other but increase its difference to the best competitive label by using only the second summand in Equation 4 during training.

6 Experiments and Results

We used the relation classification dataset of the SemEval 2010 task 8 (Hendrickx et al., 2010). It consists of sentences which have been manually labeled with 19 relations (9 directed relations and one artificial class Other). 8,000 sentences have been distributed as training set and 2,717 sentences served as test set. For evaluation, we applied the official scoring script and report the macro F1 score which also served as the official result of the shared task.

RNN and CNN models were implemented with theano (Bergstra et al., 2010; Bastien et al., 2012). For all our models, we use L2 regularization with a weight of 0.0001. For CNN training, we use mini batches of 25 training examples while we perform stochastic gradient descent for the RNN. The initial learning rates are 0.2 for the CNN and 0.01 for the RNN. We train the models for 10 (CNN) and 50 (RNN) epochs without early stopping. As activation function, we apply tanh for the CNN and capped ReLU for the RNN. For tuning the hyperparameters, we split the training data into two parts: 6.5k (training) and 1.5k (development) sentences. We also tuned the learning rate schedule on dev.

Beside of training single models, we also report ensemble results for which we combined the presented single models with a voting process.

6.1 Performance of CNNs

As a baseline system, we implemented a CNN similar to the one described by Zeng et al. (2014). It consists of a standard convolutional layer with filters with only one window size, followed by a softmax layer. As input it uses the middle context. In contrast to Zeng et al. (2014), our CNN does not have an additional fully connected hidden layer. Therefore, we increased the number of convolutional filters to 1200 to keep the number of parameters comparable. With this, we obtain a baseline result of 73.0. After including 5 dimensional position features, the performance was improved to 78.6 (comparable to 78.9 as reported by Zeng et al. (2014) without linguistic features).

CNN	F1
Baseline (emb dim: 50)	73.0
+ position features	78.6*
+ multi-windows features map	78.7
+ ranking layer	81.9*
+ extended middle context	82.2
+ increase emb dim to 400	83.9*
ensemble	**84.2**

Table 1: F1 score of CNN and its components, * indicates statisticial significance compared to the result in the line above (z-test, $p < 0.05$)

In the next step, we investigate how this result changes if we successively add further features to our CNN: multi-windows for convolution (window sizes: 2,3,4,5 and 300 feature maps each), ranking layer instead of softmax and our proposed extended middle context. Table 1 shows the results. Note that all numbers are produced by CNNs with a comparable number of parameters. We also report F1 for increasing the word embedding dimensionality from 50 to 400. The position embedding dimensionality is 5 in combination with 50 dimensional word embeddings and 35 with 400 dimensional word embeddings. Our results show that especially the ranking layer and the embedding size have an important impact on the performance.

6.2 Performance of RNNs

As a baseline for the RNN models, we apply a unidirectional RNN which predicts the relation after processing the whole sentence. With this model, we achieve an F1 score of 61.2 on the SemEval test set.

Afterwards, we investigate the impact of different position features on the performance of unidirectional RNNs (position embeddings, position embeddings concatenated with a flag indicating whether the current word is an entity or not, and

RNN	F1
uni-directional (Baseline, emb dim: 50)	61.2
uni-directional + position embs	68.3*
uni-directional + position embs + entity flag	73.1*
uni-directional + position indicators	73.4
bi-directional + position indicators	74.2*
connectionist-bi-directional+position indicators	78.4*
+ ranking layer	81.4*
+ increase emb dim to 400	82.5*
ensemble	**83.4**

Table 2: F1 score of RNN and its components, * indicates statisticial significance compared to the result in the line above (z-test, $p < 0.05$)

position indicators (Zhang and Wang, 2015)). The results indicate that position indicators (i.e. artificial words that indicate the entity presence) perform the best on the SemEval data. We achieve an F1 score of 73.4 with them. However, the difference to using position embeddings with entity flags is not statistically significant.

Similar to our CNN experiments, we successively vary the RNN models by using bi-directionality, by adding connections between the hidden layers ("connectionist"), by applying ranking instead of softmax to predict the relation and by increasing the word embedding dimension to 400.

The results in Table 2 show that all of these variations lead to statistically significant improvements. Especially the additional hidden layer connections and the integration of the ranking layer have a large impact on the performance.

6.3 Combination of CNNs and RNNs

Finally, we combine our CNN and RNN models using a voting process. For each sentence in the test set, we apply several CNN and RNN models presented in Tables 1 and 2 and predict the class with the most votes. In case of a tie, we pick one of the most frequent classes randomly. The combination achieves an F1 score of 84.9 which is better than the performance of the two NN types alone. It, thus, confirms our assumption that the networks provide complementary information: while the RNN computes a weighted combination of all words in the sentence, the CNN extracts the most informative n-grams for the relation and only considers their resulting activations.

Classifier	F1
SVM (Rink and Harabagiu, 2010b)	82.2
RNN (Socher et al., 2012)	77.6
MVRNN (Socher et al., 2012)	82.4
CNN (Zeng et al., 2014)	82.7
FCM (Yu et al., 2014)	83.0
bi-RNN (Zhang and Wang, 2015)	82.5
CR-CNN (Dos Santos et al., 2015)	84.1
R-RNN	83.4
ER-CNN	84.2
ER-CNN + R-RNN	**84.9**

Table 3: State-of-the-art results for relation classification

6.4 Comparison with State of the Art

Table 3 shows the results of our models ER-CNN (extended ranking CNN) and R-RNN (ranking RNN) in the context of other state-of-the-art models. Our proposed models obtain state-of-the-art results on the SemEval 2010 task 8 data set without making use of any linguistic features.

7 Conclusion

In this paper, we investigated different features and architectural choices for convolutional and recurrent neural networks for relation classification without using any linguistic features. For convolutional neural networks, we presented a new context representation for relation classification. Furthermore, we introduced connectionist recurrent neural networks for sentence classification tasks and performed the first experiments with ranking recurrent neural networks. Finally, we showed that even a simple combination of convolutional and recurrent neural networks improved results. With our neural models, we achieved new state-of-the-art results on the SemEval 2010 task 8 benchmark data.

Abstract

An increasing amount of research has recently focused on representing affective states as continuous numerical values on multiple dimensions, such as the valence-arousal (VA) space. Compared to the *categorical* approach that represents affective states as several classes (e.g., positive and negative), the *dimensional* approach can provide more fine-grained sentiment analysis. However, affective resources with valence-arousal ratings are still very rare, especially for the Chinese language. Therefore, this study builds 1) an affective lexicon called Chinese valence-arousal words (CVAW) containing 1,653 words, and 2) an affective corpus called Chinese valence-arousal text (CVAT) containing 2,009 sentences extracted from web texts. To improve the annotation quality, a corpus cleanup procedure is used to remove outlier ratings and improper texts. Experiments using CVAW words to predict the VA ratings of the CVAT corpus show results comparable to those obtained using English affective resources.

1 Introduction

Sentiment analysis has emerged as a leading technique to automatically identify affective information from texts (Pang and Lee, 2008; Calvo and D'Mello, 2010; Liu, 2012; Feldman, 2013). In sentiment analysis, affective states are generally represented using either categorical or dimensional approaches.

The categorical approach represents affective states as several discrete classes such as positive, neutral, negative, and Ekman's six basic emotions (e.g., anger, happiness, fear, sadness, disgust and surprise) (Ekman, 1992). Based on this representation, various practical applications have been developed such as aspect-based sentiment analysis (Schouten and Frasincar, 2016; Pontiki et al., 2015), Twitter sentiment analysis (Saif et al., 2013; Rosenthal et al., 2015), deceptive opinion spam detection (Li et al., 2014), and cross-lingual portability (Banea et al., 2013; Xu et al., 2015).

The dimensional approach represents affective states as continuous numerical values in multiple dimensions, such as valence-arousal (VA) space (Russell, 1980), as shown in Fig. 1. The valence represents the degree of pleasant and unpleasant (i.e., positive and negative) feelings, while the arousal represents the degree of excitement and calm. Based on this representation, any affective state can be represented as a point in the VA coordinate plane. For many application domains (e.g., product reviews, political stance detection, etc.), it can be useful to identify highly negative-arousing and highly positive-arousing texts because they are usually of interest to many users and should be given a higher priority. Dimensional sentiment

Proceedings of NAACL-HLT 2016, pages 540–545,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

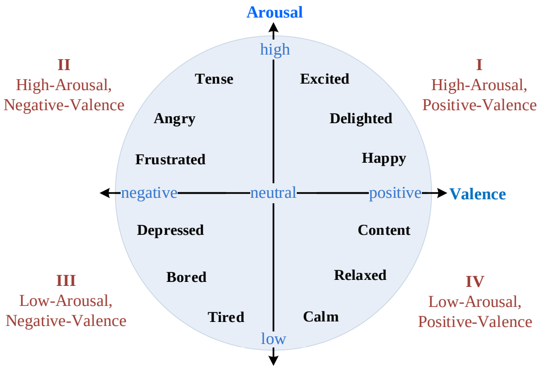

Figure 1: Two-dimensional valence-arousal space.

analysis can accomplish this by recognizing the valence-arousal ratings of texts and ranking them accordingly to provide more intelligent and fine-grained services.

In developing dimensional sentiment applications, affective lexicons and corpora with valence-arousal ratings are useful resources but few exist, especially for the Chinese language. Therefore, this study focuses on building Chinese valence-arousal resources, including an affective lexicon called the Chinese valence-arousal words (CVAW) and an affective corpus called the Chinese valence-arousal text (CVAT). The CVAW contains 1,653 affective words annotated with valence-arousal ratings by five annotators. The CVAT contains 2,009 sentences extracted from web texts annotated with crowd-sourced valence-arousal ratings. To further demonstrate the feasibility of the constructed resources, we conduct an experiment to predict the VA ratings of the CVAT corpus using CVAW words, and compare its performance to a similar evaluation of English affective resources.

To our best knowledge, only one previous study has manually created a small number (162) of Chinese VA words (Wei et al, 2011), and none have focused on creating Chinese VA corpora. This pilot study thus aims to build such resources to enrich the research and development of multi-lingual sentiment analysis in VA dimensions.

The rest of this paper is organized as follows. Section 2 introduces existing affective lexicons and corpora. Section 3 describes the process of building the Chinese affective resource. Section 4 presents the analysis results and feasibility evaluation. Conclusions are finally drawn in Section 5.

2 Related Work

Affective resources are usually obtained by either self-labeling or manual annotation. In the self-labeling approach, users proactively provide their feelings and opinions after browsing the web content. For example, users may read a news article and then offer comments. A user can also review the products available for sale in online stores. In the manual annotation method, trained annotators are asked to create affective annotations for specific language resources for research purposes. Several well-known affective resources are introduced as follows.

SentiWordNet is a lexical resource for opinion mining, which assigns to each synset of WordNet three sentiment ratings: positive, negative, and objective (Esuli and Sebastiani, 2006). Linguistic Inquiry and Word Count (LIWC) calculates the degree to which people use different categories of words across a broad range of texts (Pennebaker et al., 2007). In the LIWC 2007 version, the annotators were asked to note their emotions and thoughts about personally relevant topics. The Affective Norms for English Words (ANEW) provides 1,034 English words with ratings in the dimensions of pleasure, arousal and dominance (Bradley and Lang, 1999). In addition to these English-language sentiment lexicons, a few Chinese lexicons have been constructed. The Chinese LIWC (C-LIWC) dictionary is a Chinese translation of the LIWC with manual revisions to fit the practical characteristics of Chinese usages (Huang et al., 2012). The NTU Sentiment dictionary (NTUSD) has adopted a combination of manual and automatic methods to include positive and negative emotional words (Ku and Chen, 2007). Among the above affective lexicons, only ANEW is dimensional, providing real-valued scores for three dimensions, and the others are categorical, providing information related to sentiment polarity or intensity.

In addition to lexicon resources, several English-language affective corpora have been proposed, such as Movie Review Data (Pang et al. 2002), the MPQA Opinion Corpus (Wiebe et al., 2005), and Affective Norms for English Text (ANET) (Bradley and Lang, 2007). In addition, only ANET provides VA ratings. The above dimensional affective resources ANEW and ANET have been used for both word- and sentence-level VA prediction in previous studies (Wei et al., 2011; Gökçay et al., 2012; Malandrakis et al., 2013; Paltoglou et al., 2013; Yu et al., 2015). In this study, we follow the manual annotation approach to build a Chinese affective lexicon and corpus in the VA dimensions.

3 Affective Resource Construction

This section describes the process of building Chinese affective resources with valence-arousal ratings, including the CVAW and CAVT.

The CVAW is built on the Chinese affective lexicon C-LIWC, and then annotated with VA ratings for each word. Five annotators were trained to rate each word in the valence and arousal dimensions using the Self Assessment Manikin (SAM) model (Lang, 1980). The SAM model provides affective pictures, which can help annotators in determining more precise labels when rating the words. The valence dimension uses a nine degree scale. Values 1 and 9 respectively denote the most negative and positive degrees of affect. Point 5 means a neutral emotion without specific tendency. The arousal dimension uses a similar scale to denote calm and excitement Using this approach, each affective word can be annotated with VA ratings (determined by the average rating values provided by the annotators) to form the CVAW.

To build the CVAT, we first collected 720 web texts from six different categories: news articles, political discussion forums, car discussion forums, hotel reviews, book reviews, and laptop reviews. A total of 2,009 sentences containing the greatest number of affective words found in the C-LIWC lexicon were selected for VA rating. The Google app engine was then used to implement a crowdsourcing annotation platform using the SAM annotation scheme. Volunteer annotators were asked to rate individual sentences from 1 to 9 in terms of valence and arousal. Each sentence was rated by at least 10 annotations. Once the rating process was finished, a corpus cleanup procedure was performed to remove outlier ratings and improper sentences (e.g., those containing abusive or vulgar language). The outlier ratings were identified if they did not fall into the interval of the mean plus/minus 1.5 standard deviations. They were then excluded from the calculation of the average VA ratings for each sentence.

4 Results

4.1 Analysis Results of CVAW

A total of 1,653 words along with the annotated VA ratings were included in the CVAW lexicon, yielding the (mean, standard deviation) = (4.49, 1.81) for valence and (5.48, 1.26) for arousal. To analyze differences between the annotations, we compared the VA values rated by each annotator against their corresponding means across the five annotators to calculate the error rates using the following metrics.

- *Mean Absolute Error* (MAE):

$$MAE = \frac{1}{n}\sum_{i=1}^{n} | A_i - \overline{A_i} | ,$$

- *Root Mean Square Error* (RMSE):

$$RMSE = \sqrt{\sum_{i=1}^{n}\left(A_i - \overline{A_i}\right)^2 \Big/ n} ,$$

where A_i denotes the valence or arousal value of word i rated by an annotator, $\overline{A_i}$ denotes the mean valence or arousal of word i calculated over the five annotators, and n is the total number of words in the CVAW.

	MAE		RMSE	
	Valence	Arousal	Valence	Arousal
Annotator A	0.4934	1.3479	0.6372	1.6411
Annotator B	0.5972	0.7821	0.7488	0.9929
Annotator C	0.5817	1.1393	0.7423	1.4302
Annotator D	0.5188	0.8226	0.6614	1.0374
Annotator E	0.6258	1.0200	0.7970	1.2700
(Mean, SD)	(0.56,0.05)	(1.02, 0.21)	(0.72, 0.06)	(1.27, 0.24)

Politics Forum	439 (22%)	15,413	35.11	1.28	1.61	0.51	1.04	1.32	0.19

Table 2: Results of using the CVAW lexicon to predict the VA ratings of the CVAT corpus.

Table 1 shows the error rates of the annotators in rating the VA values of words in the CVAW. Overall, for all metrics the error rates of arousal ratings were greater than those of valence ratings. In addition, the annotators produced more consistent error rates (around 0.49~0.63 for MAE and 0.64~0.80 for RMSE) in the valence dimension than those (around 0.78~1.35 for MAE and 0.99~1.64 for RMSE) in the arousal dimension. These findings indicate that the degree of arousal was more difficult to distinguish than valence.

Figure 2 shows a scatter plot of words in the CVAW, where each point represents the mean of the VA values as rated by the annotators. Several words (translated from Chinese) were marked in the VA space for reference, e.g., *victory* (7.8, 7.2), *trust* (7.8, 5.8), *pain* (2.4, 6.8), *kill* (1.6, 7.8), *tedious* (3.4, 3), *fault* (3.6, 4.6), *agree* (6.4, 4.4) and *relaxed* (6.2, 2.0).

4.2 Analysis Results of CVAT

A total of 2,009 sentences with VA ratings were included in the CVAT corpus, yielding the (mean, standard deviation) = (4.83, 1.37) for valence and (5.05, 0.95) for arousal. The distribution of the six categories and their word counts in CVAT are shown in Table 2. The largest category was News (27%), while the smallest one was Laptop (9%). Figure 3 shows a scatter plot of VA ratings for all sentences in CVAT. It is similar with the plot of the CVAW, indicating that annotators followed similar guidelines for rating affective words and sentences.

4.3 Results of Using CVAW to Predict the VA Ratings of CVAT

To demonstrate the application of the constructed affective resources, this experiment adopted a simple aggregate-and-average method (Taboada et al. 2011) to predict the VA ratings of the CVAT corpus using CVAW words. In this approach, the valence (or arousal) rating of a given sentence was calculated by averaging the valence (or arousal) ratings of the words matched in the CVAW in that sentence. Once the predicted values of the VA ratings for the sentences were obtained, they were compared to the corresponding actual values in the CVAT to calculate MAE, RMSE and Pearson correlation coefficient *r*, as shown in Table 2. Notice that the sentences which contain no affective words in the CVAW were not included for performance calculation (herein 30 sentences). The results using ANEW to predict the VA rating of 20 English forum discussions were also included for comparison (Paltoglou et al., 2013).

The results show that the average tokens of the CVAT sentences are around 35 which is much smaller than those of the English forum discussions (long texts). Both English and Chinese resources had a similar error rates (MAE and RMSE) for valence, while the English resource outperformed the Chinese resource in terms of arousal rates. In addition, both the English and Chinese resources had a lower correlation for arousal than for valence, indicating again that the arousal dimension is more difficult to predict. Table 2 also shows the performance for each category in CVAT. For valence, Laptop achieved the lowest error rate, while News and Hotel had a higher correlation. The respective ranges of MAE, RMSE and *r* are 0.95~1.48, 1.21~1.77 and 0.30~0.61. For arousal, Book yielded the lowest error rate, while Hotel and Book yielded a better correlation. The respective ranges of MAE, RMSE and *r* are 0.89~1.11, 1.11~1.40 and 0.04~0.22.

5 Conclusions and Future Work

This study presents a Chinese affective lexicon with 1,653 words and a corpus of 2,009 sentences with six different categories, both annotated with valence-arousal values. A corpus cleanup procedure was used to remove outlier ratings and improper texts to improve quality. Experimental results provided a feasibility evaluation and baseline performance for VA prediction using the constructed resources. Future work will focus on building useful dimensional sentiment applications based on the constructed resources.

Improving event prediction by representing script participants

Simon Ahrendt and **Vera Demberg**

Abstract

Automatically learning script knowledge has proved difficult, with previous work not or just barely beating a most-frequent baseline. Script knowledge is a type of world knowledge which can however be useful for various task in NLP and psycholinguistic modelling. We here propose a model that includes participant information (i.e., knowledge about which participants are relevant for a script) and show, on the Dinners from Hell corpus as well as the InScript corpus, that this knowledge helps us to significantly improve prediction performance on the narrative cloze task.

1 Introduction

Scripts represent knowledge about typical event sequences (Schank and Abelson, 1977), for example the sequence of events happening when eating at a restaurant. Script knowledge thereby includes events like *order, bring* and *eat* as well as participants of those events, e.g., *menu, waiter, food, guest*. Script knowledge is a form of structured world knowledge that is useful in NLP applications for natural language understanding tasks (e.g., ambiguity resolution Rahman and Ng, 2012), as well as for psycholinguistic models of human language processing, which need to represent event knowledge to model human expectations (Zwaan et al., 1995; Schütz-Bosbach and Prinz, 2007) of upcoming referents and utterances.

One recent line of research has tried to learn scripts in an unsupervised way from large text collections. The core idea in Chambers and Jurafsky (2008, 2009); Jans et al. (2012) is to use coreference chains to identify events involving the same entity, with the intuition that these events would, if observed in many texts, be likely to represent a prototypical event sequence. Rudinger et al. (2015) show that this method is also applicable for learning specific targeted scripts from a domain-specific corpus, shown at the example of "Dinners From Hell" stories and the restaurant script.

Pichotta and Mooney (2014) (P&M) have demonstrated that using richer event representations containing multiple arguments improves prediciton accuracy on the narrative cloze task over the simpler models by Chambers and Jurafsky (2008). While they represent a script event as a pair of a verb and a dependency (an example of an event chain would be <call,obj>; <bring,subj>; <take,subj>), which is problematic for weak verbs and verb ambiguity, P&M represent events using a multi-argument event representation, e.g., *call(guest,waiter,*); bring(waiter,menu,*); take(waiter,order,*)*.

This richer event representation however still has some shortcomings. As the representation is based on coreference chains, the model runs into difficulties for entities that are in a chain of length one. Entities in a chain are internally mapped onto variables, but all single entities are mapped onto a common category *Other*. This means that all information about such referents is lost, e.g. $enjoy(customer, fish, *)$ can not be distinguished from $enjoy(customer, silence, *)$ when neither fish or silence have appeared before in the text.

The coreference chains provide a good approxi-

Proceedings of NAACL-HLT 2016, pages 546–551,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

mation for identifying events that involve the same participants. But would performance improve substantially if we could represent event participants? This specifically addresses the problem of unlinked coreference chains (e.g., “food”, “it”, “steak”) not appearing in the same coreference chain even though they represent the same role within the script, and the problem of mapping referents which are not part of a chain onto a single “other” representation.

Kampmann et al. (2015) show that referring expressions in a script can be automatically categorized in terms of the role they play within the script by using coreference chains, as well as information from WordNet (telling us e.g., that a *steak* is a kind of *food*).

In this paper, we extend the existing approach by P&M and demonstrate that explicitly labelling participants (instead of using coreference chains) leads to improved event prediction performance. We furthermore provide a systematic evaluation of the effect of automatically-annotated coreference chains vs. gold coreference chains, and automatically-annotated script participants vs. gold participant annotation. We evaluate our approach on the Dinners from Hell corpus (Rudinger et al., 2015), as well as the newly available InScript corpus (Modi et al., 2016).

Following earlier work, we evaluate the quality of script models using the so-called narrative cloze task, where the model has to predict a missing event given surrounding events in the text.

2 Methods

2.1 Participant-labeled Events

In order to capture script-relevant information conveyed by arguments we represent texts as chains of **participant-labeled events (PLEs)**. A PLE is a verb accompanied with the participant labels of its arguments.

The general form of a PLE is $verb(p_{subj}, p_{dobj}, p_{iobj})$, where p_{subj}, p_{dobj} and p_{iobj} are the participant labels of the subject, direct object and indirect object, respectively. For example, in the sentence *The waitress brought us some water*, the corresponding PLE would be $bring(waiter, drink, customer)$.

To automatically create PLEs from our training data, we first extract syntactic relations between verbs and their arguments as well as coreference information using Stanford CoreNLP (Manning et al. (2014)). We then use the max-hypernym heuristic described in Kampmann et al. (2015) to label the arguments with participant roles. This approach assigns to token w the participant label with the highest hyponym-similarity score between the wordnet-synsets associated with the label and one of the synsets of any word present in the coreference chain connected to w.

Where an argument slot of the event is not filled syntactically or the argument is not a participant of the script, a dummy participant O serves as a placeholder to indicate the absence of a labeled argument. Every extracted event that contains at least one participant is included into the chain.

Knowledge about the participants provides a much richer represenation of events. With this representation we are able to generalize from a specific word or entity to its overall role in the script. This way the model can also learn from cases where multiple entities fill one participant role or where a participant occurs in the text only once.

2.2 Predictive Model

Our script model is an adapted version of the bigram model in Jans et al. (2012) with an extension of the skip-gram option to skip all possible intervening events. This means we rank an event e to belong to a given ordered event sequence c at insertion point m according to its score as defined by:

$$Score(e) = \sum_{k=0}^{m} logP(e|c_k) + \sum_{k=m+1}^{n} logP(c_k|e), \tag{1}$$

where c_k denotes the k^{th} event in the chain and the conditional probabilties are estimated by skip-all bigram counts:

$$P(e_2|e_1) = \frac{freq(e_1, e_2)}{\sum_{e'} freq(e_1, e')} \tag{2}$$

with $freq(e_1, e_2)$ being the the number of times e_1 has been encountered prior to e_2 with an arbitrary number of events between them. This counting method might be noisy in case of long documents or a high number of unrelated events but it significantly reduces data sparsity. In our specialized and rather small data sets of between 87 and 133 stories per scenario, sparsity is more of an issue than unrelatedness, so skip-all performs well, but other counting techniques might prove more suitable for different corpora.

In case our model assigns the same score to several events, we backoff to the simple unigram model described in section 4.2.

3 Data

The Dinners from Hell corpus (Rudinger et al., 2015) contains stories from an internet blog about terrible restaurant experiences. The corpus contains 143 stories (out of which 10 are reserved as a development set), which all have to do with the script of going to a restaurant. All non-copula verbs in this corpus are annotated as to whether they are relevant to the restaurant script.

The InScript corpus is a novel resource (Modi et al., 2016), which contains a total of 910 short stories containing on average 12 sentences each. The stories were collected via Mechanical Turk, instructing workers to describe a specific instance of an activity, as if explaining it to a child. The corpus contains 10 different scenario types, for which there are about 90 stories each. This corpus also contains annotation for whether a verb is script-relevant, coreference annotation and participant type information.

4 Evaluation

4.1 Narrative Cloze Task

The evaluation on the narrative cloze task (originally suggested by Chambers and Jurafsky, 2008) expresses how well a model can predict a missing event in a sequence of events. In order to make the methods comparable, all predictions of our model are mapped onto the encoding used by the simple pair event model, e.g. <order,obj>, as follows:

We map an PLE $v(p_{subj}, p_{dobj}, p_{iobj})$ to a verb-dependency pair $< v, d >$ relating to a participant p if p fills the PLE slot of dependency d. We subsequently define the score of a pair event as the maximum score of all PLEs which are mapped to this pair event. When evaluating on pair events, we rank events according to this redefined score.

4.2 Systems

Unigram Model This baseline is a simple model that ranks any event (whether it is a participant-labeled event or a pair event) by its overall frequency in the training data. It was first used in Pichotta and Mooney (2014) and has proven to be a very competitive baseline on the task.

Verb-dependecy Pair Event Model This is a bigram model over verb-dependency pair events as introduced by Jans et al. (2012) and following the general idea of Chambers and Jurafsky (2008). It has been slightly modified to model not only subjects and objects, but also indirect objects. We use the setting Rudinger et al. (2015) has shown performs best: Skip-all as a counting method, a count threshold of 1, a document threshold of 5 and absolute discounting. Note that their results on the same data set differ from ours as we do not include syntactic relations other than 'subj', 'dobj' and 'iobj' into training and evaluation.

Pichotta and Mooney We re-implemented the approach by Pichotta and Mooney (2014) with the exception that we use $v(e_{subj}, e_{dobj}, e_{iobj})$ instead of $v(e_{subj}, e_{obj}, e_{prep})$ to represent events. That is, we do not model prepositional arguments of an event but discriminate between direct and indirect objects of verbs.

Participant-based model Our model, as described in section 2.2.

4.3 Automatic labels vs. gold standard

Automatic Coreference Chains We evaluate how much the results are effected by the quality of the automatic coreference chains produced by the Stanford Parser vs. annotated gold-chains on our data.

Automatic Participant Labelling We furthermore investigate to what extent our approach suffers from imperfect participant labeling, i.e. how good our model could have been if the labeling process was 100%-accurate. Kampmann et al. (2015) report a 0.59 micro F-score on the DinnersFromHell data, leaving an arguably large room for improvement (although they have a ceiling of 0.84 in terms of micro F-score because of a mismatch between their participant label set and the gold-standard labels they evaluate on). To compare against a perfect participant labeler, we use the participant annotation described in the same paper.

4.4 Testing

Following Rudinger et al. (2015), we perform leave-one-out testing at the document level, i.e., we use 133 folds for Dinners from Hell, and between 87 and 97 for InScript scenarios). We use the annotation provided for the corpora to construct a test set for every document as follows: Every verb that has been annotated as script-relevant is regarded as a test case if it takes an argument in any coreference chain of at least length two, and the dependency between the verb and the argument is either 'subj', 'dobj' or 'iobj'. The test then consists of inferring the verb and dependency, given the model's representation of the remaining events in the document after this held-out event is removed.

5 Results

Methods that encode events in a more complex way have a higher risk of running into sparsity issues, i.e. cases where the model has not encountered any of the events in the current context. Table 1 shows Recall@10 as a measure of prediction precision. We can see that our model beats the baseline models by a large margin on this measure. The core advantage of our model are its participant representations, which allow it to make more correct generalizations, and generate less noisy predictions. This is also reflected in its lower coverage: our model does not predict events when the context (including participant labels) has not been observed, while other models may predict based on non-matching participant types, and hence generalize incorrectly.

We also report the Recall@10 with respect to predicting the entire PLE in Table 1 (shown as R@10full), as we believe that inferring more structured events makes for a qualitative improvement on script modelling, we here provide a baseline for later work.

Model	Coverage	R@10	R@10full
this	0.757	0.41	0.18
P&M	0.957	0.26	
Jans	0.809	0.25	
MostFreq	0.936	0.27	0.13

Table 1: Performance for our model is reported with both automatic coreference chains and participant labels; R@10full refers to the evaluation on PLE's instead of pair events.

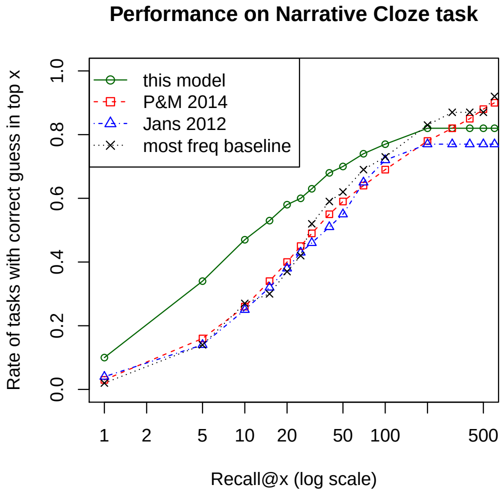

Figure 1: The participant-based method outperforms the other models and most frequent baseline. Performance shown for automatic chains and automatic participants.

Figure 1 shows that the participant model succeeds in ranking the correct event high up more frequently than the other models. If the model cannot make any prediction due to coverage problems, it has to guess from unigram frequencies. This is reflected in our model's lower performance for Recall in sets larger than the top 500. We would however argue that performance at small Recall@x values is much more relevant for most applications, as it may matter little for most tasks where exactly in the low ranks 500-1000 a model manages to rank the correct solution. For future work, this lack of coverage could be compensated for by backing off to the P&M model.

Next, we'd like to see how the automatic versions of the models compare to a setting where the models have access to gold coreference chains and participants given by the annotation. Figure 2 shows that using automatic or gold corefernce chains makes no significant difference, but that there is quite a bit of scope for performance improvements if one can improve on the automatic participant labelling task.

Finally, we evaluated all models also on the 10 scenarios of the InScript dataset, to check whether the good performance of our model generalizes also to other datasets. We find that our model consis-

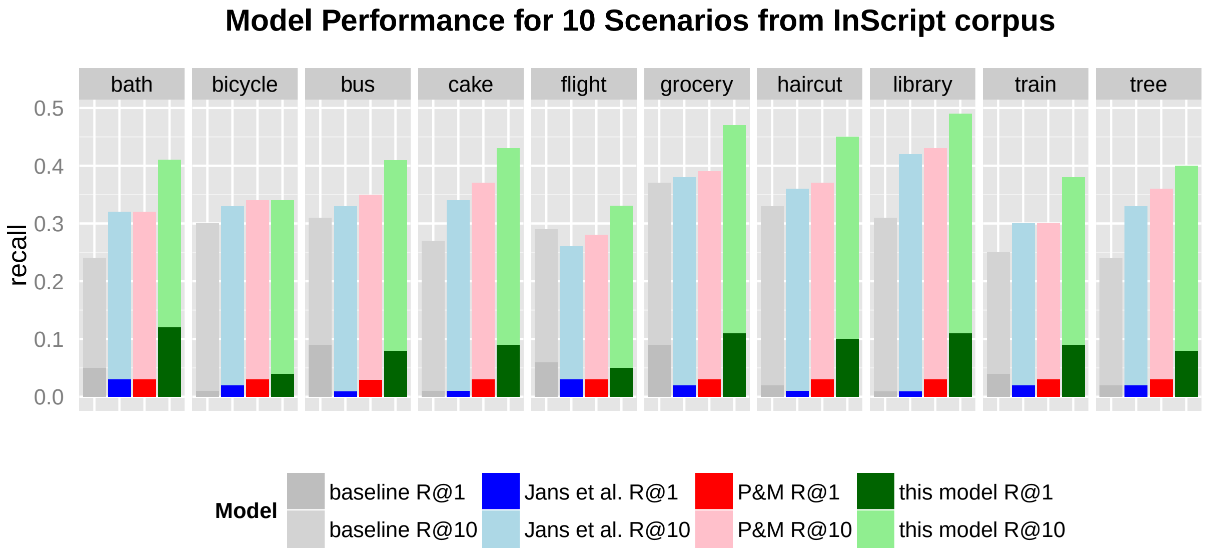

Figure 3: Performance of the different models with automatic participant labelling and automatic coreference chain annotation, on the stories for InScript dataset, showing results by scenario.

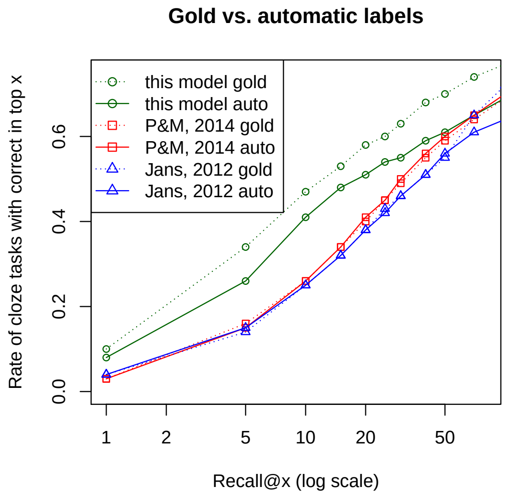

Figure 2: Gold models employ gold coreference chains and participants. There is little to no difference between using gold or automatic corefernce chains, but improving on participant labeling would help to further improve the model.

tently outperforms prior work also on this dataset, in particular with respect to succeeding to rank the correct event very high up on the list in the narrative cloze task. Figure 3 shows the Recall@1 and the Recall@10 measure separately for each of the scenarios from the InScript corpus.

6 Discussion and Conclusions

We have shown that the participant-based model can make much more accurate predictions in the narrative cloze task than previous models which do not have access to participant information; this even holds for automatic participant labelling, where we use a simple WordNet based method suggested in Kampmann et al. (2015). Our evaluation showed that the participant-based model substantially outperforms the state-of-the-art on the narrative cloze task, and that this performance holds for a set of naturalistic texts from blogs as well as for a corpus of narratives collected via crowd-sourcing. The present results hence represent an important step towards automatic inferencing for domains where knowledge of event sequences is relevant.

The automatic participant labeller takes as input a set of script participants, which can for example be acquired using the method of Regneri et al. (2010). The current approach therefore represents a way of combining the existing Mturk-based script acquisition methods by Regneri et al. (2010) with the unsupervised methods suggested in Chambers and Jurafsky (2008); Jans et al. (2012); Pichotta and Mooney (2014). Future work should further develop automated methods for participant labelling.

Abstract

We address the task of annotating images with semantic tuples. Solving this problem requires an algorithm able to deal with hundreds of classes for each argument of the tuple. In such contexts, data sparsity becomes a key challenge. We propose handling this sparsity by incorporating feature representations of both the inputs (images) and outputs (argument classes) into a factorized log-linear model.

1 Introduction

Many important problems in machine learning can be framed as structured prediction tasks where the goal is to learn functions that map inputs to structured outputs such as sequences, trees or general graphs. A wide range of applications involve learning over large state spaces, e.g., if the output is a labeled graph, each node of the graph may take values over a potentially large set of labels. Data sparsity then becomes a challenge, as there will be many classes with very few training examples.

Within this context, we are interested in the task of predicting semantic tuples for images. That is, given an input image we seek to predict what are the events or actions (referred here as *predicates*), who and what are the participants (referred here as *actors*) of the actions and where is the action taking place (referred here as *locatives*). For example, an image might be annotated with the semantic tuples: $\langle run, dog, park\rangle$ and $\langle play, dog, grass\rangle$. We call each field of a tuple an *argument*.

To handle the data sparsity challenge imposed by the large state space, we will leverage an approach that has proven to be useful in multiclass and multilabel prediction tasks (Weston et al., 2010; Akata et al., 2013). The idea is to represent a value for an argument a using a feature vector representation $\phi \in I\!R^n$. We will integrate this argument representation into the structured prediction model.

In summary, our main contribution is to propose an approach that incorporates feature representations of the outputs into a structured prediction model, and apply it to the problem of annotating images with semantic tuples. We present an experimental study using different output feature representations and analyze how they affect performance for different argument types.

2 Semantic Tuple Image Annotation

Task: We will address the task of predicting semantic tuples for images. Following Farhadi et al. (2010), we will focus on a simple semantic representation that considers three basic arguments: predicate, actors and locatives. For example, in the tuple $\langle play, dog, grass\rangle$, "$play$" is the predicate, "$dog$" is the actor and "$grass$" is the locative.

Given this representation, we can formally define our problem as that of learning a function $\theta : X \times P \times A \times L \rightarrow I\!R$ that scores the compatibility between images and semantic tuples. Here X is the space of images; P, A and L are discrete sets of predicate, actor and locative arguments respectively, and $\langle p\ a\ l\rangle$ is a specific tuple instance. The overall learning process is illustrated in Fig. 1.

Dataset: For our experiments we used a subset of the Flickr8k dataset, proposed in Hodosh et al. (2013). This dataset (subset $\mathcal{B}$ in Fig. 1) consists of 8,000 images from Flickr of people and animals

Semantic Tuple Extractor
(Trained using $\mathcal{C}$)

Figure 1: Overview of our approach. First, images $x \in \mathcal{A}$ are represented using image features $\phi_s(x)$, and semantic tuples are obtained applying our semantic tuple extractor (learned from the subset $\mathcal{C}$) to their corresponding captions. The resulting enlarged training set, is used to train our embedded CRF model that maps images to semantic tuples.

(mostly dogs) performing some action, with five crowd-sourced descriptive captions for each one.

We first manually annotated 1,544 captions, corresponding to 311 images (approximately one third of the development set (subset $\mathcal{C}$ in Fig. 1), producing more than 2,000 semantic tuples of predicate, actor and locative. For the experiments we partitioned the images and annotations into training, validation and test sets of 150, 50 and 100 images respectively.

Data augmentation: To enlarge the manually annotated dataset we trained a model able to predict semantic tuples from captions using standard shallow and deep linguistic features (e.g., POS tags, dependency parsing, semantic role labeling). We extract the predicates by looking at the words tagged as verbs by the POS tagger. Then, the extraction of arguments for each predicate is resolved as a classification problem.

More specifically, for each detected predicate in a sentence we regard each noun as a positive or negative training example of a given relation depending on whether the candidate noun is or is not an argument of the predicate. We use these examples to train a SVM classifier that predicts if a candidate noun is an argument of a given predicate based on several linguistic features computed over the syntactic path of the dependency tree that connects them. We run the learned tuple predictor model on all the captions of the Fickr8k dataset to obtain a larger dataset of 8,000 images paired with semantic tuples.

3 Bilinear Models with Output Features

In this section we explain how we incorporate output feature representations into a factorized linear model. For simplicity, we will consider factorized sequence models over sequences of fixed length. However, it should not be hard to see that all the ideas presented here can be easily generalized to other structured prediction settings.

Let $y = [y_1 \ldots y_T]$ be a set of labels and $S = [S_1, \ldots, S_T]$ be the set of possible label values, where $y_i \in S_i$. We are interested in learning a model that computes $P(y|x)$, i.e., the conditional probability of a sequence y given some input x. We will consider factorized log-linear models that take the form:

$$P(y|x) = \frac{exp^{\theta(x,y)}}{\sum_y exp^{\theta(x,y)}} \tag{1}$$

The scoring function $\theta(x, y)$ is modeled as a sum of unary and binary bilinear potentials and is defined as:

$$\theta(x,y) = \sum_{t=1}^{T} v_{y_t}^{\top} W_t \phi(x,t) + \sum_{t=1}^{T} v_{y_t}^{\top} Z_t v_{y_{t+1}} \tag{2}$$

where $v_{y_t} \in I\!R^{n_t}$ is a n_t−dimensional feature representation of label arguments $y_t \in S_t$ and $\phi(x,t) \in I\!R^{d_t}$ is a d_t−dimensional feature representation of the t^{th} input factor of x.

The first set of terms in the above equation are usually referred as unary potentials and measure the compatibility between a single state at t and the feature representation of input factor t. The second set of terms are the binary potentials and measure the compatibility between pairs of states at adjacent factors. The scoring $\theta(x, y)$ function is fully parameterized by the unary parameter matrices $W_t \in I\!R^{n_t \times d_t}$ and the binary parameter matrices $Z_t \in I\!R^{n_t \times n_t}$.

The main idea is to define a feature space where semantically similar labels will be close. Like in the multilabel scenario (Weston et al., 2010; Akata et al., 2013), having full feature representations for arguments will allow us to share information across different classes and generalize better. With a good output feature representation, our model should be able to make sensible predictions about pairs of arguments that it has not observed at training. This is easy to see: consider a case were we have a pair of arguments represented with feature vectors a_1 and a_2 and suppose that we have not observed the factor a_1, a_2 in our training data but we have observed the factor b_1, b_2. Then if a_1 is close in the feature space to argument b_1 and a_2 is close to b_2 our model will predict that a_1 and a_2 are compatible. That is it will assign probability to the factor a_1, a_2 which seems a natural generalization from the observed training data.

Now we show that the rank of W and Z have useful interpretations. Let $W = U\Sigma V$ be the singular value decomposition of W. We can then write unary potentials: $v_y^\top W\phi(x,t)$ as: $v_y^\top U\ \Sigma\ [V\phi(x,t)]$ Thus we can regard the bilinear form as a function computing a weighted inner product over some real embedding $v_y^\top U$ representing state y and some real embedding $[V\phi(x,t)]$ representing input factor t. The rank of W gives us the intrinsic dimensionality of the embedding. Thus if we want to induce shared low-dimensional embeddings across different states it seems reasonable to impose a low rank penalty on W. Similarly, let $Z = U\Sigma V$ be now the singular value decomposition of Z. We can write the binary potentials $v_y^\top Z v_{y'}$ as: $v_y^\top U\ \Sigma\ V v_{y'}$ and thus the binary potentials compute a weighted inner product between a real embedding of state y and a real embedding of state y'. As before, the rank of Z gives us the intrinsic dimensionality of the embedding and, to induce a low dimensional embedding for binary potentials, we will impose a low rank penalty on Z.

After having described the type of scoring functions we are interested in, we now turn our attention to the learning problem. That is, given a training set $D = \{\langle x\ \ y\rangle\}$ of pairs of inputs x and output sequences y we need to learn the parameters $\{W\}$ and $\{Z\}$. For this purpose we will do standard max-likelihood estimation and find the parameters that minimize the conditional negative log-likelihood of the data in D. That is, we will find the $\{W\}$ and $\{Z\}$ that minimize the following loss function $\mathcal{L}(D, \{W\}, \{Z\})$: $-\sum_{\langle x\ y\rangle \in D} logP(y|x; \{W\}, \{Z\})$ Recall that we are interested in learning low-rank unary and binary potentials. To achieve this we take a common approach which is to use as the nuclear norm $|W|_*$ and $|Z|_*$ as a convex approximation of the rank function, the final optimization problem becomes:

$$min_{\{W\}} \mathcal{L}(D, \{W\}) + \sum_t \alpha |W_t|_* + \beta |Z_t|_* \qquad (3)$$

where $\mathcal{L}(D, \{W\}) = \sum_{d \in D} loss(d, \{W\})$ is the negative log likelihood function and α and β are two constants that control the trade off between minimizing the loss and the implicit dimensionality of the embeddings. We use a simple optimization scheme known as Forward Backward Splitting, or FOBOS (Duchi and Singer, 2009).

For our task we will consider a simple factorized scoring function: $\theta(x, \langle p\ \ a\ \ l\rangle)$ that has one factor associated with the *locative-predicate* pair and one factor associated with the *predicate-actor* pair. Since this corresponds to a chain structure, $argmax_{t \in T}\theta(x; \langle p\ a\ l\rangle)$ can be efficiently computed using Viterbi decoding in time $\mathcal{O}(N^2)$, where $N = max(|P|, |A|, |L|)$. Similarly, we can also find the top k predictions in $\mathcal{O}(kN^2)$. Thus for this application the scoring function of the bilinear CRF will take the form of:

$$\begin{aligned} \theta(x, \langle p\ a\ l\rangle) \;=\; & \lambda_{loc}(l)^\top W_{loc}\phi_{loc}(l) \\ & +\lambda_{pre}(p)^\top W_{pre}\phi_{pre}(p) \\ & +\lambda_{act}(a)^\top W_{act}\phi_{act}(a) \\ & +\phi_{loc}(l)^\top W_{pre}^{loc}\phi_{pre}(p) \\ & +\phi_{pre}(p)^\top W_{act}^{pre}\phi_{act}(a) \qquad (4) \end{aligned}$$

The unary potentials measure the compatibility between an image and a semantic argument, the first binary potential measures the compatibility between a locative and a predicate, and the second binary potential measures the compatibility between a predicate and an actor. The scoring function is fully parameterized by the unary parameter matrices $W_{loc} \in I\!R^{d_l \times n_l}$, $W_{pre} \in I\!R^{d_p \times n_p}$ and $W_a \in I\!R^{d_a \times n_a}$ and the binary parameter matrices $W_{pre}^{loc} \in I\!R^{n_l \times n_p}$ and $W_{act}^{pre} \in I\!R^{n_p \times n_a}$. Where, n_l, n_p and n_a are the dimensionality of the locatives, predicates and actors feature representations, respectively and d_l, d_p and

d_a are the dimensionality of the image representations. Notice that if we let the argument representation $\phi_t(r) \in I\!R^{|S_t|}$ be an indicator vector for label argument t, we obtain the usual parametrization of a standard factorized linear model, while having a dense feature representations for arguments instead of indicator vectors will allow us to share information across different classes.

4 Representing Semantic Arguments

We will conduct experiments with two different feature representations: 1) Fully unsupervised *Skip-Gram based Continuous Word Representations* (SCWR) representation (Mikolov et al., 2013) and 2) A feature representation computed using the $\langle caption, semantic\text{-}tuples \rangle$ pairs, that we call *Semantic Equivalence Representation* (SER).

We decided to exploit the dataset of captions paired with semantic tuples to induce a useful feature representation for arguments. The idea is quite simple: we wish to leverage the fact that any pair of semantic tuples associated with the same image will be likely describing the same event. Thus, they are in essence different ways of lexicalizing the same underlying concept. Let's look at a concrete example. Imagine that we have an image annotated with the tuples: $\langle play,\ dog,\ water \rangle$ and $\langle play,\ dog,\ river \rangle$. Since both tuples describe the same image, it is quite likely that both "$river$" and "$water$" refer to the same real world entity, i.e, "$river$" and "$water$" are 'semantically equivalent' for this image. Using this idea we can build a representation $\phi_{loc}(i) \in I\!R^{|L|}$ where the j-th dimension corresponds to the number of times the argument j has been semantically equivalent to argument i. More precisely, we compute the probability that argument j can be exchanged with argument i as: $\frac{[i,j]_{sr}}{\sum_j [i,j]_{sr}}$ Where $[i,j]_{sr}$ is the number of times that i and j have appeared as annotations of the same image and with the same other arguments. For example, for the actor arguments $[i,j]_{sr}$ represents the number of time that actor i and actor j have appeared with the same locative and predicate as descriptions of the same image.

5 Related Work

In recent years, some works have tackled the problem of generating rich textual descriptions of images. One of the pioneers is (Kulkarni et al., 2011), where a CRF model combines the output of several vision systems to produce input for a language generation method. In Farhadi et al. (2010), the authors find the similarity between sentences and images in a "meaning" space, represented by semantic tuples which are very similar to our triplets. Other works focus on a simplified problem: ranking of human-generated captions for images. Hodosh et al. (2013) propose to use Kernel Canonical Correlation Analysis to project images and their captions into a joint representation space, in which images and captions can be related and ranked to perform illustration and annotation tasks. Socher et al. (2014) also address the ranking of images given a sentence and vice-versa using a common subspace learned via Recursive Neural Networks. Other recent works also exploit deep networks to address the problem (Vinyals et al., 2015; Karpathy and Fei-Fei, 2015). Using label embeddings combined with bilinear forms has been previously proposed in the context of multi-class and multilabel image classification (Weston et al., 2010; Akata et al., 2013).

6 Experiments

For image features we use the 4,096-dimensional second to last layer of BVLC implementation of 'AlexNet' ImageNet model, a Convolutional Neural Network (CNN) as described in Jia et al. (2014). To test our method we used the 100 test images that were annotated with ground-truth semantic tuples. To measure performance we first predict the top tuple for each image and then measure accuracy for each argument type (i.e. the number of correct predictions among the top 1 triplets). The regularization parameters of each model were set using the validation set. We compare the performance of the following models: 1) Baseline Separate Predictors (S-Pred): We consider a baseline made of independent predictors for each argument type.

More specifically we train one-vs-all SVMs (we also tried multi-class SVMs but they did not improve performance) to independently predict locatives, predicates and actors. For each argument type and candidate label we have a score computed by the corresponding SVM. Given an image we generate the top tuples that maximize the sum of scores for each argument type; 2) Baseline KCCA: This model implements the Kernel Canonical Correlation Anal-

The tuples in blue were not observed neither in the SP-Dataset nor in the automatically enlarged dataset. Note that all of them are descriptive of what is occurring in the scene.

ysis approach of Hodosh et al. (2013). We first note that this approach is able to rank a list of candidate captions but cannot directly generate tuples. To generate tuples for test images, we first find the caption in the training set that has the highest ranking score for that image and then extract the corresponding semantic tuples from that caption; 3) Indicator Features (IND), this is a standard factorized log-linear model that does not use any feature representation for the outputs; 4) A model that uses the skip-gram continuous word representation of outputs (SCWR); 5) A model that uses that semantic equivalence representation of outputs (SER); 6) A combined model that makes predictions using the best feature representation for each argument type (COMBO).

	S-Pred	KCCA	IND	SCWR	SER	COMBO
LOC	15	23	32	28	**33**	
PRED	11	20	24	**33**	25	
ACT	30	25	**52**	51	50	
MEAN	18.6	22.6	36	37.3	36	**39.3**

Table 1: Comparison of Output Feature Representation.

Table 1 shows the results. We observe that our proposed method performs significantly better than the baselines. The second observation is that the best performing output feature representation is different for different argument types, for the locatives the best representation is SER, for the predicates is the SCWR and for the actors using an output feature representation actually hurts performance. The biggest improvement we get is on the predicate arguments, where we improve almost by 10% in average precision over the baseline using the skip-gram word representation. Overall, the model that uses the best representation performs better than the indicator baseline.

Regarding the rank of the parameter matrices, we observed that the learned models can work well even if we drop the rank to 10% of its maximum rank. This shows that the learned models are efficient in the sense that they can work well with low-dimensional projections of the features.

7 Conclusion

In this paper we have presented a framework for exploiting input and output embeddings in the context of structured prediction. We have applied this framework to the problem of predicting compositional semantic descriptions of images. Our results show the advantages of using output embeddings and inducing low-dimensional embeddings for handling large state spaces in structured prediction problems. The framework we propose is general enough to consider additional sources of information.

Large-scale Multitask Learning for Machine Translation Quality Estimation

Kashif Shah and **Lucia Specia**
Department of Computer Science
University of Sheffield, UK
{kashif.shah,l.specia}@sheffield.ac.uk

Abstract

Multitask learning has been proven a useful technique in a number of Natural Language Processing applications where data is scarce and naturally diverse. Examples include learning from data of different domains and learning from labels provided by multiple annotators. *Tasks* in these scenarios would be the domains or the annotators. When faced with limited data for each task, a framework for the learning of tasks in parallel while using a shared representation is clearly helpful: what is learned for a given task can be transferred to other tasks while the peculiarities of each task are still modelled. Focusing on machine translation quality estimation as application, in this paper we show that multitask learning is also useful in cases where data is abundant. Based on two large-scale datasets, we explore models with multiple annotators and multiple languages and show that state-of-the-art multitask learning algorithms lead to improved results in all settings.

1 Introduction

Quality Estimation (QE) models predict the quality of Machine Translation (MT) output based on the source and target texts only, without reference translations. This task is often framed as a supervised machine learning problem using various features indicating fluency, adequacy and complexity of the source-target text pair, and annotations on translation quality given by human translators. Various kernel-based regression and classification algorithms have been explored to learn prediction models.

The application of QE we focus on here is that of guiding professional translators during the post-editing of MT output. QE models can provide translators with information on how much editing/time will be necessary to fix a given segment, or on whether it is worth editing it at all, as opposed to translating it from scratch. For this application, models are learnt from quality annotations that reflect post-editing effort, for instance, 1-5 judgements on estimated post-editing effort (Callison-Burch et al., 2012) or actual post-editing effort measured as post-editing time (Bojar et al., 2013) or edit distance between the MT output and its post-edited version (Bojar et al., 2014; Bojar et al., 2015).

One of the biggest challenges in this field is to deal with the inherent subjectivity of quality labels given by humans. Explicit judgements (e.g. the 1-5 point scale) are affected the most, with previous work showing that translators' perception of post-editing effort differs from actual effort (Koponen, 2012). However, even objective annotations of actual post-editing effort are subject to natural variance. Take, for example, post-editing time as a label: Different annotators have different typing speeds and may require more or less time to deal with the same edits depending on their level of experience, familiarity with the domain, etc. Post-editing distance also varies across translators as there are often multiple ways of producing a good quality translation from an MT output, even when strict guidelines are given.

In order to address variance among multiple translators, three strategies have been applied: (i) models are built by averaging annotations from multiple

Proceedings of NAACL-HLT 2016, pages 558–567,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

translators on the same data points, as was done in the first shared task on the topic (Callison-Burch et al., 2012); (ii) models are built for individual translators by collecting labelled data for each translator (Shah and Specia, 2014); and (iii) models are built using multitask learning techniques (Caruana, 1997) to put together annotations from multiple translators while keeping track of the translators' identification to account for their individual biases (Cohn and Specia, 2013; de Souza et al., 2015).

The first approach is sensible because, in the limit, the models built should reflect the "average" strategies/preferences of translators. However, its cost makes it prohibitive. The second approach can lead to very accurate models but it requires sufficient training data for each translator, and that all translators are known at model building time. The last approach is very attractive. It is a *transfer learning* (a.k.a. *domain-adaptation*) approach that allows the modelling of data from each individual translator while also modelling correlations between translators such that "similar" translators can mutually inform one another. As such, it does not require multiple annotations of the same data points and can be effective even if only a few data points are available for each translator. In fact, previous work on multitask learning for quality estimation has concentrated on the problem of learning prediction models from little data provided by different annotators.

In this paper we take a step further to investigate multitask learning for quality estimation in settings where data may be abundant for some or most annotators. We explore a multitask learning approach that provides a general, scalable and robust solution regardless of the amount of data available. By testing models on single translator data, we show that while building models for individual translators is a sensible decision when large amounts of data are available, the multitask learning approach can outperform these models by learning from data by multiple annotators. Additionally, besides having translators as "tasks", we address the problem of learning from data for multiple language pairs.

We devise our multitaslk approach within the Bayesian non-parametric machine learning framework of Gaussian Processes (Rasmussen and Williams, 2006). Gaussian Processes have shown very good results for quality estimation in previous work (Cohn and Specia, 2013; Beck et al., 2013; Shah et al., 2013). Our datasets – annotated for post-editing distance – contain nearly 100K data points, two orders of magnitude larger than those used in previous work. To cope with scalability issues resulting from the size of these datasets, we apply a sparse version of Gaussian Processes. We perform extensive experiments on this large-scale data aiming to answer the following research questions:

- What is the best approach to build models to be used by **individual translators**? How much data is necessary to build independent models (one per translator) that can be as accurate as (or better than) models using data from multiple translators?

- When large amounts of data are available, can we still improve over independent and pooled models by learning from metadata to exploit **transfer across translators**?

- Can crosslingual data help improve model performance by exploiting **transfer across language pairs**?

In the remainder of the paper we start with an overview on related work in the area of multitask learning for quality estimation (Section 2), to then describe our approach to multitask learning in the context of Gaussian Processes (Section 3). In Section 4 we introduce our data and experimental settings. Finally in Sections 5 and 6 we present the results of our experiments to answer the above mentioned questions for cross-annotator and crosslingual transfer, respectively.

2 Related Work

As was discussed in Section 1, the problem of variance among multiple translators in QE has recently been approached in three ways. The first two approaches essentially refer to preparation of the data. At WMT12, the first shared task on QE (Callison-Burch et al., 2012), the official dataset was created by collecting three 1-5 (worst-best) discrete judgements on "perceived" post-editing effort for each translated segment. The final score was a scaled average of the three scores, and about 15% of the labelled data was discarded as annotators diverged in their judgemetns by more than one point. While this type of data proved useful and certainly reliable in the limit of the number of annotators, it is too expensive to collect.

Shah and Specia (2014) built QE models using data from n annotators by either pooling all the data together or splitting it into n datasets for n individual annotator models. These models were tested in blind versus non-blind settings, where the former refers to test sets whose annotator identifiers were unknown. They observed a substantial difference in the error scores for each of the individual models. They showed that the task is much more challenging for QE models trained independently when training data for each annotator is scarce. In other words, sufficient data needs to be available to build individual models for all possible translators.

The approach of using multitask learning to build models addresses the data scarcity issue and has been shown effective in previous work. Cohn and Specia (2013) first introduced multitask learning for QE. Their goal was to allow the modelling of various perspectives on the data, as given by multiple annotators, while also recognising that they are rarely independent of one another (annotators often agree) by explicitly accounting for inter-annotator correlations. A set of task-specific regression models were built from data labelled with post-editing time and perceived post-editing effort (1-5). "Tasks" included annotators, the MT system and the actual source sentence, as their data included same source segments translated/edited by multiple systems/editors.

Similarly, de Souza et al. studied multitask learning to deal with data coming from different training/test set distributions or domains, and generally scenarios in which training data is scarce. Offline multitask (de Souza et al., 2014a) and online multitask (de Souza et al., 2015; de Souza et al., 2014b) learning methods for QE were proposed. The later focused on continuous model learning and adaptation from new post-edits in a computer-aided translation environment. For that, they adapted an online passive-aggressive algorithm (Cavallanti et al., 2010) to the multitask scenario. While their setting is interesting and could be considered more challenging because of the online adaptation requirements, ours is different as we can take advantage of already having collected large volumes of data.

Multitask learning has also been used for other classification and regression tasks in language processing, mostly for domain adaptation (Daume III, 2007; Finkel and Manning, 2009), but also more recently for tasks such as multi-emotion analysis (Beck et al., 2014), where the each emotion explaining a text is defined as a task. However, in all previous work the focus has been on addressing task variance coupled with data scarcity, which makes them different from the work we describe in this paper.

3 Gaussian Processes

Gaussian Processes (GPs) (Rasmussen and Williams, 2006) are a Bayesian non-parametric machine learning framework considered the state-of-the-art for regression. GPs have been used successfully for MT quality prediction (Cohn and Specia, 2013; Beck et al., 2013; Shah et al., 2013), among other tasks.

GPs assume the presence of a latent function $f : \mathbb{R}^F \rightarrow \mathbb{R}$, which maps a vector $\mathbf{x}$ from feature space F to a scalar value. Formally, this function is drawn from a GP prior:

$$f(\mathbf{x}) \sim \mathcal{GP}(\mathbf{0}, k(\mathbf{x}, \mathbf{x}')),$$

which is parameterised by a mean function (here, $\mathbf{0}$) and a covariance kernel function $k(\mathbf{x}, \mathbf{x}')$. Each response value is then generated from the function evaluated at the corresponding input, $y_i = f(\mathbf{x}_i) + \eta$, where $\eta \sim \mathcal{N}(0, \sigma_n^2)$ is added white-noise.

Prediction is formulated as a Bayesian inference under the posterior:

$$p(y_*|\mathbf{x}_*, \mathcal{D}) = \int_f p(y_*|\mathbf{x}_*, f)p(f|\mathcal{D}),$$

where $\mathbf{x}_*$ is a test input, y_* is the test response value and $\mathcal{D}$ is the training set. The predictive posterior can be solved analitically, resulting in:

$$\begin{aligned} y_* \sim \mathcal{N}(&\mathbf{k}_*^T(\mathbf{K} + \sigma_n^2 I)^{-1}\mathbf{y}, \\ &k(x_*, x_*) - \mathbf{k}_*^T(\mathbf{K} + \sigma_n^2 I)^{-1}\mathbf{k}_*), \end{aligned}$$

where $\mathbf{k}_* = [k(\mathbf{x}_*, \mathbf{x}_1)k(\mathbf{x}_*, \mathbf{x}_2) \dots k(\mathbf{x}_*, \mathbf{x}_n)]^T$ is the vector of kernel evaluations between the training set and the test input and $\mathbf{K}$ is the kernel matrix over the training inputs (the Gram matrix).

3.1 Multitask Learning

The GP regression framework can be extended to multiple outputs by assuming $f(\mathbf{x})$ to be a vector valued function. These models are commonly referred as *Intrinsic Coregionalization Models (ICM)* in the GP literature (Álvarez et al., 2012).

In this work, we employ a separable multitask kernel, similar to the one used by Bonilla et al. (2008) and Cohn and Specia (2013). Considering a set of D tasks, we define the corresponding multitask kernel as:

$$k((\mathbf{x}, d), (\mathbf{x}', d')) = k_{\text{data}}(\mathbf{x}, \mathbf{x}') \times \mathbf{M}_{d,d'},$$

where k_{data} is a kernel (Radial Basis Function, in our experiments) on the input points, d and d' are task or metadata information for each input and $\mathbf{M} \in \mathbb{R}^{D \times D}$ is the multitask matrix, which encodes task covariances. In our experiments, we first consider each post-editor as a different task, and then use crosslingual data to treat each combination of language and post-editor as a task.

An adequate parametrisation of the multitask matrix is required to perform learning process. We follow the parameterisations proposed by Cohn and Specia (2013) and Beck et al. (2014):

Individual: $\mathbf{M} = \mathbf{I}$. In this setting each task is modelled independently by keeping corresponding task identity.

Pooled: $\mathbf{M} = \mathbf{1}$. Here the task identity is ignored. This is equivalent to pooling all datasets in a single task model.

Multitask: $\mathbf{M} = \tilde{\mathbf{H}}\tilde{\mathbf{H}}^T + \text{diag}(\boldsymbol{\alpha})$, where $\tilde{\mathbf{H}}$ is a $D \times R$ matrix. The vector $\boldsymbol{\alpha}$ enables the degree of independence for each task with respect to the global task. The choice of R defines the *rank* ($= 1$ in our case) which can be understood as the capacity of the manifold with which we model the D tasks. We refer readers to see Beck et al. (2014) for a more detailed explanation of this setting.

3.2 Sparse Gaussian Processes

The performance bottleneck for GP models is the Gram matrix inversion, which is $O(n^3)$ for standard GPs, with n being the number of training instances. For multitask settings this becomes an issue for large datasets as the models replicate the instances for each task and the resulting Gram matrix has dimensionality $nd \times nd$, where d is the number of tasks.

Sparse GPs (Snelson and Ghahramani, 2006) tackle this problem by approximating the Gram matrix using only a subset of m inducing inputs. Without loss of generalisation, consider these m points as the first instances in the training data. We can then expand the Gram matrix in the following way:

$$\mathbf{K} = \begin{bmatrix} \mathbf{K}_{mm} & \mathbf{K}_{m(n-m)} \\ \mathbf{K}_{(n-m)m} & \mathbf{K}_{(n-m)(n-m)} \end{bmatrix}.$$

Following the notation in (Rasmussen and Williams, 2006), we refer $\mathbf{K}_{m(n-m)}$ as $\mathbf{K}_{mn}$ and its transpose as $\mathbf{K}_{nm}$. The block structure of $\mathbf{K}$ forms the basis of the so-called Nyström approximation:

$$\tilde{\mathbf{K}} = \mathbf{K}_{nm}\mathbf{K}_{mm}^{-1}\mathbf{K}_{mn},$$

which results in the following predictive posterior:

$$\begin{aligned} y_* \sim \mathcal{N}(&\mathbf{k}_{m*}^T\tilde{\mathbf{G}}^{-1}\mathbf{K}_{mn}\mathbf{y}, \\ &k(\mathbf{x}_*, \mathbf{x}_*) - \mathbf{k}_{m*}^T\mathbf{K}_{mm}^{-1}\mathbf{k}_{m*} + \\ &\sigma_n^2\mathbf{k}_{m*}^T\tilde{\mathbf{G}}^{-1}\mathbf{k}_{m*}), \end{aligned}$$

where $\tilde{\mathbf{G}} = \sigma_n^2\mathbf{K}_{mm} + \mathbf{K}_{mn}\mathbf{K}_{nm}$ and $\mathbf{k}_{m*}$ is the vector of kernel evaluations between test input $\mathbf{x}_*$ and the m inducing inputs. The resulting training complexity is $O(m^2n)$.

In our experiments, the number of inducing points was set empirically by inspecting where the learning curves (in terms of Pearson's correlation gains) flatten, as shown in Figure 1. We used 300 inducing points in experiments with all the settings (see Section 4.3).

4 Experimental Settings

4.1 Data

Our experiments are based on data from two language pairs: English-Spanish (en-es) and English-French (en-fr). The data was collected and made available by WIPO's (World Intellectual Property Organization) Brands and Design Sector. The domain of the data is trademark applications in English, using one or more of the 45 categories of the

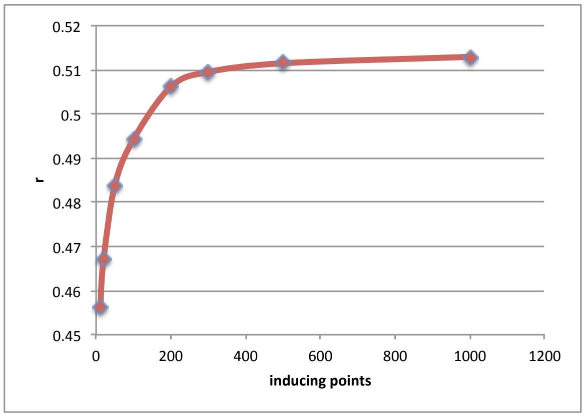

Figure 1: Number of inducing points versus Pearson's correlation

NICE[1] goods and services (e.g. furniture, clothing), and their translations into one of the two languages.

An in-house phrase-based statistical MT system was built by WIPO (Pouliquen et al., 2011), trained on domain-specific data, to translate the English segments. The quality of the translations produced is considered high, with BLEU scores on a 1K-single reference test set reaching 0.71. This is partly attributed to the short length and relative simplicity of the segments in the sub-domains of goods and services. The post-editing was done mostly internally and systematically collected between November 2014 and August 2015. The quality label for each segment is post-editing distance, calculated as the HTER (Snover et al., 2006) between the target segment and its post-edition using the TERCOM tool.[2]

The data was split into 75% for training and 25% for test, with each split maintaining the original data distribution by post-editor. The number of training and test <*source, MT output, post-edited MT, HTER score*> tuples for each of the post-editors (ID) and language pair is given in Table 1. There are 63,763 overlapping English source segments out of 77,656 entries for en-fr and 98,663 entries for en-es. This information is relevant for the crosslingual data experiments, as we discuss in Section 6.

It should be noted that the total number of segments as well as the number of segments per post-editor is significantly higher than those used in previous work. For example, (Cohn and Specia, 2013) used datasets of 6,762 instances (2,254 for each of three translator) and 1,624 instances (299 for each of eight translators), while (Beck et al., 2014) had access to 1000 instances annotated with six emotions.

Lang. Pair	ID	Total	Train	Test
en-es	1	28,423	21,317	7,105
	2	12,904	9,678	3,226
	3	3,939	2,954	984
	4	16,518	12,388	4,129
	5	14,187	10,640	3,546
	6	9,395	7,046	2,348
	7	402	301	100
	8	9,294	6,970	2,323
	9	845	633	211
	10	2,756	2,067	689
	All	98,663	73,997	24,665
en-fr	1	65,280	48,960	16,320
	2	6,336	4,752	1,584
	3	769	576	192
	4	5,271	3,953	1,317
	All	77,656	58,241	19,413

Table 1: Number of en-es and en-fr segments

4.2 Algorithms

For all tasks we used the QuEst framework (Specia et al., 2013) to extract a set of 17 baseline black-box features[3] (Shah et al., 2013) for which we had all the necessary resources for the WIPO domain. These baseline features have shown to perform well in the WMT shared tasks on QE. They include simple counts, e.g. number of tokens in source and target segments, source and target language model probabilities and perplexities, average number of possible translations for source words, number of punctuation marks in source and target segments, among other features reflecting the complexity of the source segment and the fluency of the target segment.

All our models were trained using the GPy[4] toolkit, an open source implementation of GPs written in Python.

4.3 Settings

We built and tested models in the following conditions:

Table 2: Various models and test settings in our experiments

- **Setting-1:** Individual models on individual test sets: each model is trained with data from an individual post-editor and tested on the test set for the same individual post-editor.

- **Setting-2:** Pooled model on individual test sets: model trained with data concatenated from all post-editors and tested on test sets of individual post-editors.

- **Setting-3:** Multitask model on individual test sets: multitask models trained with data from all post-editors and tested on test sets of individual post-editors.

- **Setting-4:** Individual models tested on pooled test set: each model is trained with data from an individual post-editor and tested on a test set with data from all post-editors. This setup aims to find out the performance of individual models when the identifier of the post-editor is not known (e.g. in crowdsourcing settings).

- **Setting-5:** Pooled model on pooled test set: model trained with data concatenated from all post-editors and tested on test set of all post-editors.

- **Setting-6:** Multitask model on pooled test set: Multitask model trained with data from all post-editors and tested on test set from all post-editors together.

- **Setting-7 to 10:** Similar to setting-2, 3, 5, 6 but with additional crosslingual data where pooled and multitask models are trained with both en-es and en-fr datasets together.

- **Setting-11-13:** Similar to setting-9, 6, 10 respectively, but with non-overlapping crosslingual data only.

5 Results with Multiple Annotators

We report results in terms of Pearson's correlation between predicted and true quality labels, as was done in the WMT QE shared tasks (Bojar et al., 2015). The multitask learning models consistently led to improvement over pooled models, and over individual models in most cases. We present the comparisons of the models for various settings in the following. The bars marked with * in each comparison are significantly better than all others with $p < 0.01$ according to the Williams significance test (Williams, 1959).

Individual, pooled and multitask models on individual test sets Results for both language pairs are shown in Figure 2. As expected, in cases where a large number of instances is available from an individual post-editor, individual models tested on individual test sets perform better than pooled models. Overall, multitask learning models show improvement over both individual and pooled models, or the same performance in cases where large amounts of data are available for an individual post-editor. For example, in en-es, for post-editors 9 and 3, which have 845 and 3,939 instances in total, respectively, multitask learning models are considerably better. The same goes for post-editor 3 in en-fr, which has only 769 instances. For very few post-editors with a large number of instances (1,2 and 4 in en-es) multitask learning models perform the same as individual or even pooled models. For all other post-editors, multitask models further improve correlation with humans. These results emphasize

Figure 3: Pearson's correlation with various models on pooled test set

the advantages of multitask learning models, even in cases where the post-editors that will use the models are known in advance (first research question): Clearly, the models for post-editors with fewer instances benefit from the sharing of information from the larger post-editor data sets. As for post-editors with large numbers of instances, in the worst case the performance remains the same.

Individual, pooled and multitask models on pooled test set Here we focus on cases where models are built to be used by any post-editor (second research question). Results in Figure 3 show that when test sets for all post-editors are put together, individual models perform distinctively worse than pooled and multitask learning models. Multitask learning models are significantly better than pooled models for both languages (0.511 vs 0.469 for en-es, and 0.481 vs 0.441 for en-fr). In the case of post-editor 3 for en-fr, the correlation is negative for individual models given the very low number of instances for this post-editor, which is not sufficient to build a general enough model that also works for other post-editors.

Relationship among post-editors In order to gain a better insight into the strength of the relationships among various post-editors and thus into the expected benefits from joint modelling, we plot the learned Corregionalisation matrix for all against all post-editors in Figure 4.[5] It can be observed that there exist various degrees of mutual interdependences among post-editors. For instance, in the case of en-es, post-editor 4 shows a strong relationship with post-editors 6 and 7, a relatively weaker relationship with post-editors 1 and 9, and close to non-existing with post-editors 3, 8 and 10. In the case of en-fr, post-editor 3 shows very weak relationship with all other post-editors, especially 4. This might explain the low Pearson's correlation with individual models for post-editor 3 on pooled test sets.

[5] We note that the Corregionalisation matrix cannot be interpreted as a correlation matrix. Rather, it shows the covariance between tasks.

6 Results with Multiple Languages

To address the last research question, here we present the results on crosslingual models in comparison to single language pair models. The training models contain data from both en-es and en-fr language pairs in the various settings previously described, where for the multitask settings, tasks can be annotators, languages, or both.

Single versus crosslingual pooled and multitask models on individual test sets Figure 5 shows a performance comparison between single language versus crosslingual models on individual test sets.

🟧 cl_mtl_trn-ind_tst	0.4612	0.4401	0.2011	0.4441

Figure 5: Pearson's correlation with single versus crosslingual models on individual en-fr test sets

Due to space constraints, we only present results for the en-fr test sets, but those for the en-es test sets follow the same trend. Multitask models lead to further improvements, particularly visible for post-editor 3 (the one with less training data), where the crosslingual multitask learning model reaches 0.201 Pearson's correlation, while the monolingual multitask learning model performs at 0.171. The performance of the pooled models with crosslingual data also improves on this test set over monolingual pooled models, but the overall figures are lower than with multitask learning, showing that the benefit does not only come from adding more data, but from adequate modelling of the additional data. This shows the potential to learn robust prediction models from datasets with multiple languages.

Single versus crosslingual pooled and multitask models on pooled test set Figure 6 compares single language and crosslingual models on the pooled test sets for both languages. A pooled test set with data from different languages presents a more challenging case. Simply building crosslingual pooled models deteriorates the performance over single pooled models, whereas multitask models marginally improve the performance for en-es and keep the performance of the single language models for en-fr. This again shows that multitask learning is an effective technique for robust prediction models over several training and test conditions.

Single versus crosslingual pooled and multitask models on non-overlapping data on pooled test set We posited that the main reason behind the marginal or non-existing improvement of the crosslingual transfer learning shown in Figure 6 is

Figure 7: Pearson's correlation with non-overlapping language data: single vs crosslingual models on en-es and en-fr on pooled test sets

the large overlap between the source segments in the datasets for the two language pairs, as mentioned in Section 4: 63,763 instances, which comprise 82% of the en-fr instances, and 65% of the en-es instances. This becomes an issue because nearly half of the quality estimation features are based on the source segments. Therefore, we conducted an experiment with only 41,930 non-overlapping segments in the two languages. This experiment is only possible with pooled test sets, as otherwise too few (if any) instances are left for some post-editors. The results, shown in Figure 7, are much more promising. The Figure compares single language and crosslingual multitask and pooled models on the polled test sets for both languages. It is interesting to note that, while the absolute figures are lower when compared to models trained on all data (Figures 5 and 6), the relative improvements of multitask crosslingual models over multitask single language models are much larger.

7 Conclusions

We investigated multitask learning with GP for QE based on large datasets with multiple annotators and language pairs. The experiments were performed with various settings for training QE models to study the cases where data is available in abundance, versus cases with less data. Our results show that multitask learning leads to improved results in all settings against individual and pooled models. Individual models perform reasonably well in cases where a large amount of training data for individual annotators is available. Yet, by learning from data by multiple annotators, multitask learning models still perform better (in most cases) or at least the same as these models. Testing models on data for individual annotators is a novel experimental setting that we explored in this paper. Another novel finding was the advantage of multitask models in crosslingual settings, where individual models performed poorly and pooled models brought little gain.

Conversational Markers of Constructive Discussions

Vlad Niculae and **Cristian Danescu-Niculescu-Mizil**
{vlad|cristian}@cs.cornell.edu
Cornell University

Abstract

Group discussions are essential for organizing every aspect of modern life, from faculty meetings to senate debates, from grant review panels to papal conclaves. While costly in terms of time and organization effort, group discussions are commonly seen as a way of reaching better decisions compared to solutions that do not require coordination between the individuals (e.g. voting)—through discussion, the sum becomes greater than the parts. However, this assumption is not irrefutable: anecdotal evidence of wasteful discussions abounds, and in our own experiments we find that over 30% of discussions are unproductive.

We propose a framework for analyzing conversational dynamics in order to determine whether a given task-oriented discussion is worth having or not. We exploit conversational patterns reflecting the *flow of ideas* and the *balance* between the participants, as well as their linguistic choices. We apply this framework to conversations naturally occurring in an online collaborative world exploration game developed and deployed to support this research. Using this setting, we show that linguistic cues and conversational patterns extracted from the first 20 seconds of a team discussion are predictive of whether it will be a wasteful or a productive one.

1 Introduction

Working in teams is a common strategy for decision making and problem solving, as building on effective social interaction and on the abilities of each member can enable a team to outperform lone individuals. Evidence shows that teams often perform better than individuals (Williams and Sternberg, 1988) and even have high chances of reaching correct answers when all team members were previously wrong (Laughlin and Adamopoulos, 1980). Furthermore, team performance is not a factor of individual intelligence, but of *collective intelligence* (Woolley et al., 2010), with interpersonal interactions and emotional intelligence playing an important role (Jordan et al., 2002).

Yet, as most people can attest from experience, team interaction is not always smooth, and poor coordination can lead to unproductive meetings and wasted time. In fact, Romano Jr and Nunamaker Jr (2001) report that one third of work-related meetings in the U. S. are considered unproductive, while a 2005 Microsoft employee survey reports that 69% of meetings are ineffective.[1] As such, many grow cynical of meetings.

Computational methods with the ability to reliably recognize unproductive discussions could have an important impact on our society. Ideally, such a system could provide actionable information as a discussion progresses, indicating whether it is likely to turn out to be productive, rather than a waste of time. In this paper we focus on the conversational aspects of productive interactions and take the following steps:

- introduce a *constructiveness* framework that allows us to characterize teams where discussion enables better performance than the individuals could reach, and, conversely, teams better off not having discussed at all (Section 3);
- create a setting that is conducive to decision-making discussions, where all steps of the process (e.g., individual answers, intermediate guesses) are observable to researchers: the *StreetCrowd* game (Sections 4–5);

San Diego, California, June 12-17, 2016.

- develop a novel framework for conversational analysis in small group discussions, studying aspects such as the flow of ideas, conversational dynamics, and group balance (Sections 6–7).

We reveal differences in the collective decision process characteristic of productive and unproductive teams, and show that these differences are reflected in their conversational patterns. For example, the language used when new ideas are introduced and adopted encodes important discriminative cues. Measures of interactional balance and language matching (Niederhoffer and Pennebaker, 2002; Danescu-Niculescu-Mizil et al., 2011) also prove to be informative, suggesting that more balanced discussions are most productive. Our results underline the potential held by computational approaches to conversational dynamics. To encourage further work in this direction, we render our dataset of task-oriented discussions and our feature-extraction code publicly available.[2]

2 Related Work

Existing computational work on task-oriented group interaction is largely focused on how well the team performs. Coetzee et al. (2015) deployed and studied the impact of a chat-based team interaction platform in massive open online courses, finding that teams reach more correct answers than individuals, and that the experience is more enjoyable. One often studied experimental setting is the HCRC Map Task Corpus (Anderson et al., 1991), consisting of 128 conversations between pairs of people, where a designated one gives directions to the other. This simplified setting avoids issues like role establishment and leadership. Reitter and Moore (2007) find that successful dialogs are characterized by long-term adaptation and alignment of linguistic structures at syntactic, lexical and character level. A notable feature of this work is the *success prediction* task attempted using only the first 5 minutes of conversation. Other attempts use authority level features inspired from negotiation theory, experimental meta-features, task-specific features (Mayfield et al., 2011), and sociolinguistic spelling differences (Mayfield et al., 2012). Another research path uses negotiation tasks from the Inspire dataset (Kersten and Zhang, 2003), a collection of 1525 online bilateral negotiations where roles are fixed (buyer and seller) and success is defined by the sale going through. Sokolova et al. (2008) use a bag-of-words model and investigate the importance of temporal aspects. Sokolova and Lapalme (2012) measure informativeness, quantified by lexical sets of degrees, scalars and comparatives.

Research on success in groups with more than two members is less common. Friedberg et al. (2012) model the grades of 27 group assignments from a class using measures of average entrainment, finding task-specific words to be a strong cue. Jung (2011) shows how the affective balance expressed in teams correlates with performance on engineering tasks, in 30 teams of up to 4 students. In a related study the balance in the first 5 minutes of an interaction is found predictive of performance (Jung et al., 2012). None of the research we are aware of controls for initial skill or potential of the team members.

In management science, network analysis reveals that certain subgraphs found in long-term, structured teams indicate better performance, as rated by senior managers (Cummings and Cross, 2003); controlled experiments show that optimal structures depend on the complexity of the task (Guetzkow and Simon, 1955; Bavelas, 1950). These studies, as well as much of the research on effective team crowdsourcing (Lasecki et al., 2012; Wang et al., 2011, *inter alia*), do not focus on linguistic and conversational factors.

3 Constructive Discussions

The first hurdle is to reliably quantify how productive group conversations are. In problem-solving, the ultimate goal is to find the correct answer, or, failing that, to come as close to it as possible. To quantify closeness to the correct answer, a *score* is often used, such that better guesses get higher scores; for example, school grades.

In contrast, our goal is to measure how productive a team's interaction is. Scores are measures of correctness, so using them as a proxy for interaction quality is not ideal: a team of straight *A* students can manage to get an *A* on a project without exchanging ideas, while a group of *D* students getting a *B* is

[2] `https://vene.ro/constructive/`

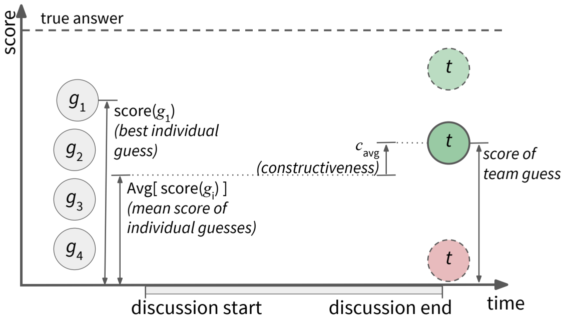

Figure 1: Intuitive sketch for constructiveness. The solid green circle corresponds a team guess following a constructive discussion ($c_{\text{avg}} > 0$), the dashed green circle corresponds to the scenario of a team that outperforms its best member ($c_{\text{best}} > 0$), while the dashed red circle corresponds to a team that underperforms its worst member ($c_{\text{worst}} < 0$).

more interesting. In the latter case, the team's improved performance is likely to come from a good discussion and an efficient exchange of complementary ideas—making the sum greater than the parts.

To capture this intuition we say a team discussion is *constructive* if it results in an improvement over the potential of the individuals. We can then quantify the degree of constructiveness c_{avg} as the improvement of the team score t over the mean of the initial scores g_i of the N individuals in the team:

$$c_{\text{avg}} = \text{score}(t) - \frac{\sum_{i=1}^{N} \text{score}(g_i)}{N}.$$

The higher c_{avg} is, the more the team's answer, *after discussion*, improves upon the individuals' average performance *before discussion*; zero constructiveness ($c_{\text{avg}} = 0$) means the team performed no better than its members did before discussing, while negative constructiveness ($c_{\text{avg}} < 0$) corresponds to non-constructive discussions.[3] Figure 1 sketches the idea visually: the dark green circle corresponds to the team's score after a constructive discussion ($c_{\text{avg}} > 0$), being above the average individual score.

Since individuals answers can sometimes vary widely, we also consider the extreme cases of teams that perform better than the best team member ($c_{\text{best}} > 0$) and worse than the worst member ($c_{\text{worst}} < 0$), where:

$$c_{\text{best}} = \text{score}(t) - \max_i \text{score}(g_i)$$
$$c_{\text{worst}} = \text{score}(t) - \min_i \text{score}(g_i).$$

One way to think of the extreme cases is to imagine a team supervisor that collects the individual answers and aggregates them, without any external information. An oracle supervisor can do no better than choosing the best answer. The discussion and interaction of teams where $c_{\text{best}} > 0$ leads to a better answer than such an oracle could achieve. (One such scenario is illustrated by the dashed light green circle in Figure 1.) Similarly, teams where $c_{\text{worst}} < 0$ waste their time completely, as simply picking one of their members' answers at random is guaranteed to do better. (The dashed red circle in Figure 1 illustrates this scenario.)

The most important aspect of the constructiveness framework, in contrast to traditional measures of correctness or success, is that all constructiveness measures are designed to control for initial performance or potential of the team members, in order to focus on the effect of the discussion.[4]

In settings of importance, the true answer is not known a priori, and this constructiveness cannot be calculated directly. We therefore seek out to model constructiveness using observable conversational and linguistic correlates (Sections 6–7). To develop such a model, we design a large-scale experimental setting where the true answer is available to researchers, but unknown by the players (Section 4).

4 Experimental setting

4.1 StreetCrowd

In order to study the constructiveness of task-oriented group discussion, we need a setting that is conducive to decision-making discussions, where all steps of the process (individual answers, intermediate guesses, group discussions and decisions) are observable. Furthermore, to study at scale, we need to

[3] From an operational perspective, a team can choose, instead of having a discussion, to aggregate individual guesses, e.g., by majority voting or averaging. Non-constructive discussions roughly correspond to cases where such an aggregate guess would actually be better than what the team discussion would accomplish.

[4] Due to its relative nature, constructiveness also accounts for variation in task difficulty in most scenarios. For example, in terms of c_{worst}, when a team cannot even match its worst performing member, this is a sign of poor team interaction even if the task is particularly challenging.

find a class of complex tasks with known solutions that can be automatically generated, but that cannot be easily solved by simply querying search engines.

With these constraints in mind, we built *StreetCrowd*, an online multi-player world exploration game.[5] *StreetCrowd* is played in teams of at least two players and is built around a geographic puzzle: determining your location based on first-person images from the ground level.[6] Each location generates a new puzzle.

Solo phase. Each player has 3 minutes to navigate the surroundings, explore, and try to find clues. This happens independently and without communicating. At the end, the player is asked to make a guess by placing a marker on the world's map, and is prompted for an explanation and for a confidence level. The answer is not yet revealed.

Team phase. The team must then decide on a single, common guess. To accomplish this, all teammates are placed in a chatroom and are provided with a map and a shared marker. Any player can move the marker at any point during the discussion. The game ends when all players agree on the answer, or when the time limit is reached. An example discussion is given in Figure 4.

Guesses are scored according to their distance to the true location using the spherical law of cosines:

$$\mathrm{score}(\mathrm{guess}, \mathrm{true}) = -Rd(\mathrm{guess}, \mathrm{true})$$

where d is the arc distance on a sphere, and R denotes the radius of the earth, assumed spherical. The score is given by the negative distance in kilometers, such that higher means better. To motivate players and emphasize collaboration, the main *StreetCrowd* page displays a leaderboard consisting of the best team players.

The key aspects of the *StreetCrowd* design are:

- The puzzles are complex and can be generated automatically in large numbers;
- The true answers are known to researchers, but hard to obtain without solving the puzzle, allowing for objective evaluation of both individual and group performance;
- Scoring is continuous rather than discrete, allowing us to quantify degrees of improvement and capture incremental effects;
- Each teammate has a different *solo phase* experience and background knowledge, making it possible for the group discussion to shed light on new ideas;
- The puzzles are engaging and naturally conducive to collaboration, avoiding the use of monetary incentives that can bias behavior.

4.2 Preprocessing

In the first 8 months, over 1400 distinct players participated in over 2800 *StreetCrowd* games. We tokenize and part-of-speech tag the conversations.[7] Before analysis, due to the public nature of the game, we perform several filtering and quality check steps.

Discarding trivial games. We remove all games that the developers took part in. We filter games where the team fails to provide a guess, where fewer than two team members engage in the team chat, and puzzles with insufficient samples.

Preventing and detecting cheating. The *StreetCrowd* tutorial asks players to avoid using external resources to look up clues and get an unfair advantage. To prevent cheating, we detect and block chat messages that link to websites, and we employ cookies and user accounts to prevent people from playing the same puzzle multiple times. To identify games that slip through this net, we flag cases where the team, or any individual player, guesses within 10 km of the correct answer, and leaves the window while playing. We further remove a small set of games where the players confess to cheating in the chat.

After filtering, our dataset consists of 1450 games on 70 different puzzles, with an average of 3.9 games per unique player, and 12.1 messages and 64.5 words in an average conversation.

5 Constructiveness in StreetCrowd

We find that, indeed, most of the games are constructive. There are, however, 32% non-constructive

[5] `http://streetcrowd.us/log_in` (the experiment was approved by the IRB).

[6] We embed Google Street View data.

[7] We use the *TweetNLP* toolkit (Owoputi et al., 2013) with a tag set developed for Twitter data. Manual examination reveals this approach to be well suited for online chat data.

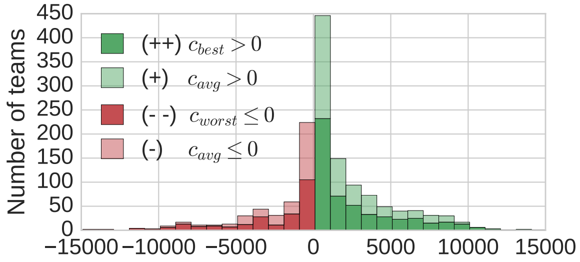

Figure 2: Distribution of team constructiveness.

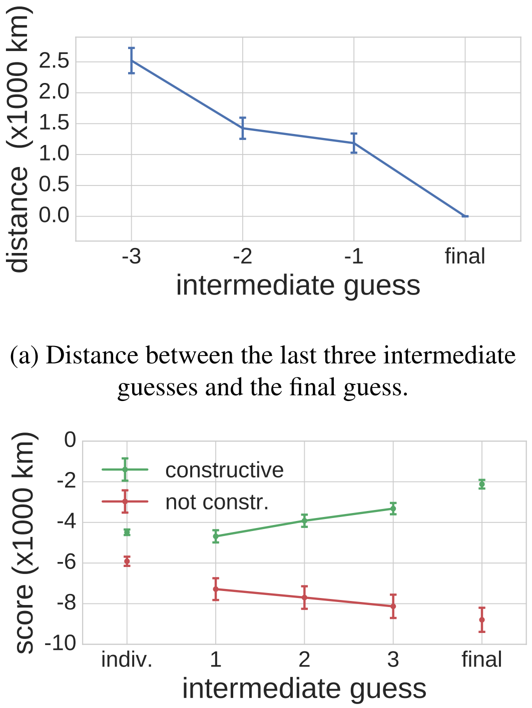
games ($c_{\text{avg}} < 0$); this reflects very closely the survey by Romano Jr and Nunamaker Jr (2001). Interestingly, in 36% of games, the team arrives at a better answer than any of the individual guesses ($c_{\text{best}} > 0$). The flip side is also remarkably common, with 17% of teams performing even worse than the worst individual ($c_{\text{worst}} < 0$). The distribution of constructiveness is shown in Figure 2: the fat tails indicate that cases of large improvements and large deterioration are not uncommon.

Collective decision process. Due to the full instrumentation of the game interface, we can investigate how constructiveness emerges out of the team's interaction. The team's intermediate guesses during discussion confirm that a meaningful process leads to the final team decision: guesses get closer and closer to the final submitted guess (Figure 3a); in other words, the team *converges* to their final guess.

Notably, when considering how *correct* the intermediate guesses are, we notice an important difference between the way constructive and non-constructive teams converge to their final guess (Figure 3b). During their collaborative decision process, constructive teams make guesses that get closer and closer to the correct answer; in contrast, non-constructive teams make guesses that take them farther from the correct answer. This observation has two important consequences. First, it shows that the two types of teams behave differently throughout, suggesting we could potentially detect non-constructive discussions early on, using interaction patterns. Second, it emphasizes the potential practical value of such a task: stopping a non-constructive team early could lead to a better answer than if they would carry on.



(a) Distance between the last three intermediate guesses and the final guess.

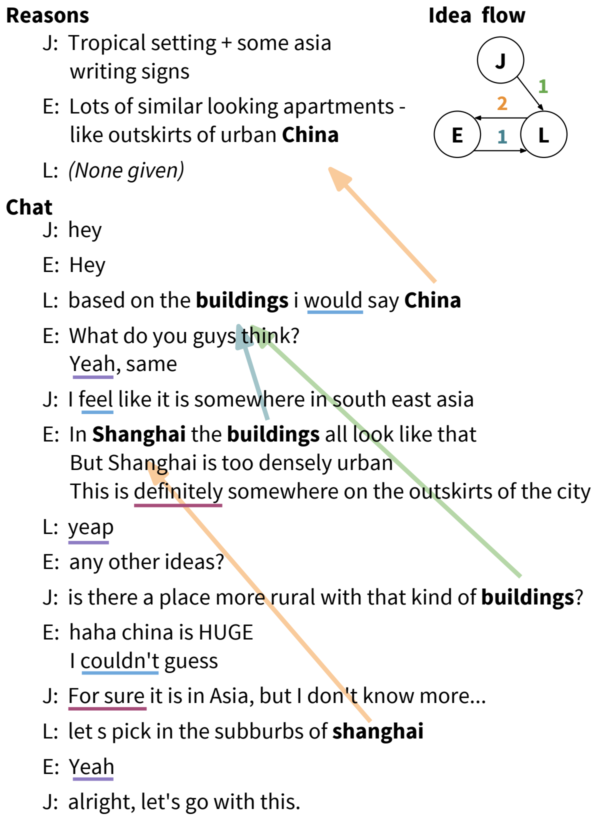
(b) Score of the first three intermediate guesses; the mean score of the initial individual guesses and the score of the final team guess are shown for reference.

Figure 3: Intermediate guesses offer a glimpse at the decision process: (a) guesses converge rather than zig-zag (b) in constructive games, guesses get incrementally better than the mean individual score, while in non-constructive games, they get worse. (Games with ≥ 3 intermediate guesses.)

6 Conversation analysis

The process of team convergence revealed in the previous section suggests a relation between the interaction leading to the final group decision and the relative quality of the outcome. In this section, we develop a conversation analysis framework aimed at characterizing this relation. This framework relies on conversational patterns and linguistic features, while steering away from lexicalized cues that might not generalize well beyond our experimental setting. To enable reproducibility, we make available the feature extraction code and the hand-crafted resources on which it relies.[8]

[8] `https://vene.ro/constructive/`



Reasons

J: Tropical setting + some asia writing signs

E: Lots of similar looking apartments - like outskirts of urban **China**

L: *(None given)*

Chat

J: hey

E: Hey

L: based on the **buildings** i would say **China**

E: What do you guys think?
Yeah, same

J: I feel like it is somewhere in south east asia

E: In **Shanghai** the **buildings** all look like that
But Shanghai is too densely urban
This is definitely somewhere on the outskirts of the city

L: yeap

E: any other ideas?

J: is there a place more rural with that kind of **buildings**?

E: haha china is HUGE
I couldn't guess

J: For sure it is in Asia, but I don't know more...

L: let s pick in the subburbs of **shanghai**

E: Yeah

J: alright, let's go with this.

Figure 4: Example (constructive) conversation and the corresponding flow of ideas. Idea mentions are in bold, and relevant word classess are underlined. Arrow colors map to introducer–adopter pairs, matching the edges in the top-right graph.

6.1 Idea flow

Task-oriented discussions are the the primary way of exchanging ideas and opinions between the group members; some are quickly discarded while others prove useful to the final guess. The arrows in Figure 4 show how ideas are introduced and discussed in that example conversation. We attempt to capture the shape in which the ideas flow in the discussion. In particular, we are interested in how many ideas are discussed, how widely they are adopted, who tends to introduce them, and how.

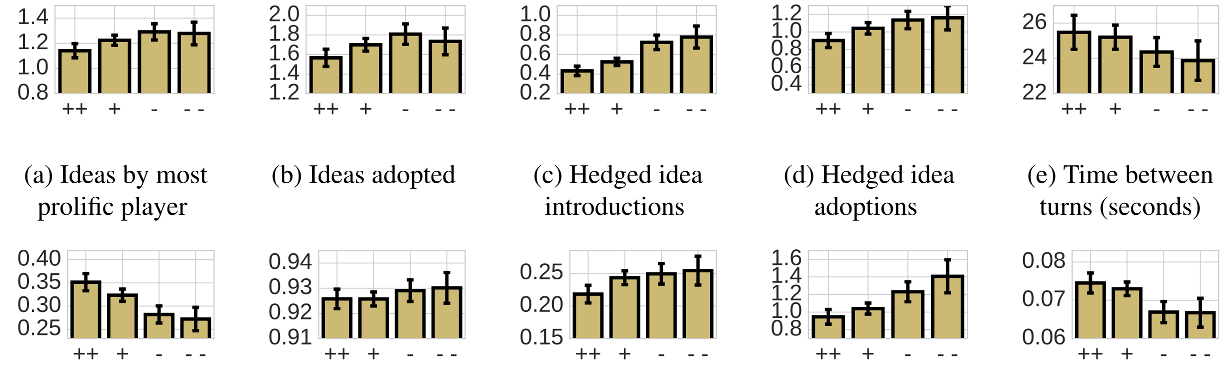
We consider as candidate ideas all nouns, proper nouns, adjectives and verbs that are not stopwords. As soon as a candidate idea introduced by a player is *adopted* by another, we count it. Henceforth, we'll refer to such adopted ideas simply as *ideas*. In general chat domains, state-of-the-art models of conversation structure use unsupervised probabilistic models (Ritter et al., 2010; Elsner and Charniak, 2010). Since *StreetCrowd* conversations are short and focused, the *adoption* filter is sufficient to accurately capture what ideas are being discussed; a manual examination of the ideas reveals almost exclusively place names and words such as *flag*, *sign*, *road*—highly relevant clues in the context of *StreetCrowd*. In Figure 4, three ideas are adopted: *China*, *buildings* and *Shanghai*. The only idea adopted by all players is *buildings*, a good signal that this was the most important clue. A notable limitation is that this approach cannot capture the connections between *Shanghai* and *China*, or *buildings* and *apartments*. Further work is needed to robustly capture such variations in idea flow, as they could reveal trajectories (discussion getting more specific or more vague) or lexical choice disagreement.

Balance in idea contributions between the team members is a good indicator of productive discussions. In particular, in the best teams (the ones that outperform the best player, i.e., $c_{\text{best}} > 0$) the most idea-prolific player introduces fewer ideas, on average, than in the rest of the games (Figure 5a, $p = 0.01$).[9] In Figure 4, *E* is the most prolific player and only introduces two ideas. To further capture the balance in contribution between the team members, we use the entropy of the number ideas introduced by each player. We also count the number of ideas adopted unanimously as an indicator of convergence in the conversation.

In terms of the overall number of ideas discussed, both the best teams (the ones that outperform the best player) and the worst teams (the ones that perform worse than the worst player) discuss fewer ideas than the rest (Figure 5b, $p = 0.006$). Indeed, an ideal interaction would avoid distracting ideas, but in teams with communication breakdowns, members might fail to adequately discuss the ideas that led them to their individual guesses.

The language used to introduce new ideas can indicate confidence or hesitation; in Figure 4, a hedge (*would*) is used when introducing the *buildings* cue. We find that, in teams that outperform the best player, ideas are less likely to be accom-

[9] All p-values reported reported in this section are based on one-sided Mann-Whitney rank statistical significance tests.



(a) Ideas by most prolific player (b) Ideas adopted (c) Hedged idea introductions (d) Hedged idea adoptions (e) Time between turns (seconds)

(f) Guessing entropy (g) Message entropy (h) Max-pair content word matching (i) Overall POS bigram matching (j) Ratio of words related to geography

Figure 5: Averages for some of the predictive features, based on idea flow (a-d), balance (e-i), and lexicons (j). Error bars denote standard errors. Legend: (++): teams that do better than their best member ($N = 525$), (+): constructive ($N = 986$), (-): non-constructive ($N = 464$), (- -): worse than worst member ($N = 248$).

panied by hedge words when introduced (Figure 5c, $p < 10^{-4}$), showing less hesitation. Furthermore, the level of confidence used when players adopt others' ideas is also informative (Figure 5d). Interestingly, overall occurrences of certainty and hedge words (detailed in Section 6.3) are not predictive, suggesting that ideas are good selectors for important discussion segments.

6.2 Interaction dynamics

Balance. Interpersonal balance has been shown to be predictive of team performance (Jung, 2011; Jung et al., 2012) and, similarly, forms of linguistic balance have been shown to characterize stable relationships (Niculae et al., 2015). Here we focus on balance in contributions to the discussion and the decision process. In search of measures applicable to teams of arbitrary sizes, we use binary indicators of whether all players participate in the discussion and in moving the marker, as well as whether at least two players move the marker. To measure team balance with respect to continuous user-level features, we use the entropy of these features:

$$\text{balance}(S) = -\sum_{\bar{s} \in S} \bar{s} \log_{|S|} \bar{s},$$

where, for a given feature, S is the set of its values for each user, normalized to sum to 1. For instance, the chat message entropy is 1 if everybody chats equally, and decreases toward 0 as one or more players dominate. We use the entropy of the number of messages, words per message, and number of intermediate guesses. In teams that outperform the best player, users take turns controlling the marker more uniformly (Figure 5f, $p = 0.006$), adding further evidence that well-balanced teams perform best.

Language matching. We investigate matching at stopword, content word, and POS tag bigram level: the stopword matching at a turn is given by the number of stopwords from the earlier message repeated in the reply, divided by the total number of distinct stopwords to choose from; similarly for the rest. We micro-average over the conversation:

$$\text{match} = \frac{\sum_{(\text{msg},\text{reply}) \in \text{Turns}} |\text{msg} \cap \text{reply}|}{\sum_{(\text{msg},\text{reply}) \in \text{Turns}} |\text{msg}|}.$$

We also micro-average at the player-pair level, and use the maximum pair value as a feature. This gives an indication of how cohesive the closest pair is, which can be a sign of the level of power imbalance between the two (Danescu-Niculescu-Mizil et al., 2012). Figure 5h shows that in teams that outperform the best individual the most cohesive pair matches fewer content words ($p = 0.023$). Overall matching is also significant, notably in terms of part-of-speech bigrams; in teams that outperform the best individual there is less overall matching (Figure 5i, $p = 0.007$). These results suggest that in constructive teams the relationships between the members are less subordinate.

Agreement and confidence. We capture the amount of agreement and disagreement using high-precision keywords and filters validated on a subset of the data. (For instance, the word *sure* marks agreement if found at the beginning of a message, but not otherwise.) In Figure 4, agreement signals are underlined with purple; the team exhibits no disagreement.

The relative position of successive guesses made can also indicate whether the team is refining a guess or contradicting each other. We measure the median distance between intermediate guesses, as well as between guesses made by different players; in constructive teams, the jumps between different player guesses are smaller ($p < 10^{-16}$).

Before the discussion starts, players are asked to self-evaluate their confidence in their individual guesses. Constructive teams have more confident members on average ($p < 10^{-5}$).

6.3 Other linguistic features

Length and variation. We measure the average number of words per message, the total number of words used to express the *solo phase* reasons, and the overall type/token ratio of the conversation. We also measure responsiveness in terms of the mean time between turns and the total number of turns.

Psycholinguistic lexicons. We use hand-crafted lexicons inspired from LIWC (Tausczik and Pennebaker, 2010) to capture certainty and pronoun use. For example, the conversation in Figure 4 has two confident phrases, underlined in red. We also use a custom hedging lexicon adapted from Hyland (2005) for conversational data; hedging words are underlined in blue in Figure 4. To estimate how grounded the conversation is, we measure the average *concreteness* of all content nouns, adjectives, adverbs and verbs, using scalar word and bigram ratings from Brysbaert et al. (2014).[10] Concreteness reflects the degree to which a word denotes something perceptible, as opposed to ideas and concepts. Words like *soil* and *coconut* are highly concrete, while words like *trust* have low concreteness.

Game-specific words. We put together a lexicon of geography terms and place names, to capture task-specific discussion. We use a small set of words specific to the *StreetCrowd* interface, such as *map, marker,* and *game*, to capture phatic communication. Figure 5j shows that constructive teams tend to use more geography terms ($p = 0.008$), possibly because of more on-topic discussion and a more focused vocabulary.

	Full conversation			First 20s		
Features	(++)	(+)	(- -)	(++)	(+)	(- -)

Part-of-speech patterns. We use n-grams of coarse part-of-speech tags as a general way of capturing common syntactic patterns.

7 Predicting constructiveness

7.1 Experimental setup

So far we have characterized the relation between a team's interaction patterns and its level of productivity. This opens the door towards recognizing constructive and non-constructive interactions in realistic settings where the true answer is not known. Ideally, such an automatic system could prompt unproductive teams to reconsider their approach, or to aggregate their individual answers instead. With *early detection*, non-constructive discussions could be stopped or steered on the right track. In order to assess the feasibility of such a challenging task and to compare the predictive power of our features, we consider three classification objectives:

(++): Team outperforms its best member ($c_{\text{best}} > 0$)?

(+): Team is constructive ($c_{\text{avg}} > 0$)?

(- -): Team underperforms its worst member ($c_{\text{worst}} < 0$)?

To investigate *early detection*, we evaluate the classification performance when using data from only the first 20 seconds of the team's interaction.[11]

[10] We scale the ratings to lie in $[0, 1]$. We extrapolate to out-of-vocabulary words by regressing on dependency-based word embeddings (Levy and Goldberg, 2014); this approach is highly accurate (median absolute error of about 0.1).

[11] Measured from the first chat message or guess. For this evaluation, we remove teams where the first 20 seconds contain over 75% of the interaction, to avoid distorting the results with

Since all three objectives are imbalanced (Figure 2), we use the area under the ROC curve (AUC) as the performance metric, and we use logistic regression models. We perform 20 iterations of puzzle-aware shuffled train-validation splitting, followed by 5000 iterations on the best models, to estimate variance. This ensures that the models don't learn to overfit puzzle-specific signals. The combined model uses weighted model averaging. We use grid search for regularization parameters, feature extraction parameters, and combination weights.

7.2 Discussion of the results (Table 1)

We compare to a baseline consisting of the team size, average number of messages per player, and conversation duration. For comparison, a bag-of-words classifier does no better than chance and is on par with the baseline. We refer to idea flow and interaction dynamics features (Section 6.2) as *Interaction*, and to linguistic and lexical features (Section 6.3) as *Linguistic*. The combination model including baseline, interaction, linguistic and part-of-speech n-gram features, is consistently the best and significantly outperforms random guessing (AUC .50) in nearly all settings. While overall scores are modest, the results confirm that our conversational analysis framework has predictive power, and that the high-stakes task of *early prediction* is feasible. The language used when introducing and adopting ideas, together with balance and language matching features, are selected in nearly all settings. The least represented class (- -) has the highest variance in prediction, suggesting that more data collection is needed to successfully capture extreme cases. Useful POS patterns capture the amount of proper nouns and their contexts: proper nouns at the end of messages are indicative of constructiveness, while proper nouns followed by verbs are a negative feature. (The constructive discussion shown in Figure 4 has most proper nouns at the end of messages.)

A manual error analysis of the false positives and false negatives where our best model is most confident points to games with very short conversations and spelling mistakes, confirming that the noisy data problem causes learning and modeling difficulties.

8 Conclusions and Future Work

We developed a framework based on conversational dynamics in order to distinguish between productive and unproductive task-oriented discussions. By applying it to an online collaborative game we designed for this study, we reveal new interactions with conversational patterns. Constructive teams are generally well-balanced on multiple aspects, with team-members participating equally in proposing ideas and making guesses and showing little asymmetry in language matching. Also, the flow of ideas between teammates marks predictive linguistic cues, with the most constructive teams using fewer hedges when introducing and adopting ideas.

We show that such cues have predictive power even when extracted from the first 20 seconds of the conversations. In future work, improved classifiers could lead to a system that can intervene in non-constructive discussions early on, steering them on track and preventing wasted time.

Further improving classification performance on such a difficult task will hinge on better conversation processing tools, adequate for the domain and robust to the informal language style. In particular, we plan to develop and evaluate models for idea flow and (dis)agreement, using more advanced features (e.g., from dependency relations and knowledge graphs).

The *StreetCrowd* game is continuously accumulating more data, enabling further development on conversation analysis. Our full control over the game permits manipulation and intervention experiments that can further advance research on teamwork. In future work, we envision applying our framework to settings where teamwork takes place online, such as open-source software development, Wikipedia editing, or massive open online courses.

Acknowledgements We are particularly grateful to Bob West for the poolside chat that inspired the design of the game, to Daniel Garay, Jinjing Liang and Neil Parker for participating in its development, and to the numerous passionate players. We are also grateful to Natalya Bazarova, David Byrne, Mala Gaonkar, Lillian Lee, Sendhil Mullainathan, Andreas Veit, Connie Yuan, Justine Zhang and the anonymous reviewers for their insightful suggestions. This work was supported in part by a Google Faculty Research Award.

teams who make their decision early, but take longer to submit. The 20 second threshold was chosen as a trade-off in terms of how much interaction it covers in the games.

Vision and Feature Norms: Improving automatic feature norm learning through cross-modal maps

Luana Bulat, Douwe Kiela and Stephen Clark
Computer Laboratory
University of Cambridge
ltf24,douwe.kiela,stephen.clark@cl.cam.ac.uk

Abstract

Property norms have the potential to aid a wide range of semantic tasks, provided that they can be obtained for large numbers of concepts. Recent work has focused on text as the main source of information for automatic property extraction. In this paper we examine property norm prediction from visual, rather than textual, data, using cross-modal maps learnt between property norm and visual spaces. We also investigate the importance of having a complete feature norm dataset, for both training and testing. Finally, we evaluate how these datasets and cross-modal maps can be used in an image retrieval task.

1 Introduction

Many cognitive theories of conceptual organisation assume that concepts are distributed representations over semantic primitives, often referred to as features or properties[1] (Tyler et al., 2000; Randall et al., 2004). That is, we can understand the meaning of a concept through its properties. For example, understanding the meaning of BANANA is closely related to understanding that it has properties such as *is a fruit*, *is yellow*, *is long*, *is sweet*, and knowing how these properties overlap with or differ from the properties of other concepts.

A number of property norm datasets, where humans were asked to list attributes of given concepts, have been collected to test this hypothesis (McRae et al., 2005; Vinson and Vigliocco, 2008; Devereux et al., 2013). After having been used to test models of conceptual representation in cognitive science for decades (Randall et al., 2004; Cree et al., 2006), these datasets have proved to be useful in a wide range of semantic NLP tasks as well, including text simplification for limited vocabulary groups. More recently, property norms have been used as a proxy for perceptual information in a number of studies on multi-modal semantics (Andrews et al., 2009; Riordan and Jones, 2011; Silberer and Lapata, 2012; Roller and Im Walde, 2013; Hill and Korhonen, 2014). Such models aim to addres the grounding problem (Harnad, 1990) that distributional semantic models of language (Turney and Pantel, 2010; Clark, 2015) suffer from.

Property norms are a valuable source of semantic information, and can potentially be applied to a variety of NLP tasks, but are expensive to obtain because they involve intensive human annotation. The largest property norm dataset to date consists of just 638 concepts (Devereux et al., 2013), and the most widely cited one presents properties for only 541 concepts (McRae et al., 2005). If we are to use these datasets in large-scale semantic tasks, we would need to extend the currently available property norms by obtaining annotations for more than just a few hundred words.

The alternative to collecting more data through human annotation is to increase the coverage of property norms datasets by automatically inferring properties of concepts from easily accessible resources, such as textual data. Considering the fact that concepts, as well as their properties, are in linguistic form, the task then becomes a bootstrapping

[1] Throughout the paper we will be using the terms *properties*, *features norms* and *attributes* interchangeably.

Proceedings of NAACL-HLT 2016, pages 579–588,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

one where we take advantage of the abundance of freely available textual corpora.

There are two strands of research that attempt to automatically obtain property norm data for new concepts. One approach is to automatically generate feature norms from text corpora by mining text data for a set of generalised property patterns (Kelly et al., 2014; Baroni et al., 2010; Barbu, 2008). Another avenue of research is inspired by Lazaridou et al. (2014) and Mikolov et al. (2013b) and tries to increase the coverage of feature norms through cross-modal mapping from linguistic information (Fagarasan et al., 2015).

Here, we follow recent trends in multi-modal semantics and explore automatic property norm extraction from visual, rather than textual, data. Obtaining property norms from visual information makes intuitive sense: information contained in the property norm datasets can often be attributed to extra-linguistic modalities—a large proportion of relevant properties are visual, auditory or tactile, rather than linguistic (e.g. *is_round, makes_noise, is_yellow*).

We show that such conceptual properties can be more accurately predicted through cross-modal mappings from raw perceptual information (i.e. image data) or multi-modal models (i.e. text and image data combined) rather than from purely textual information (Section 3). Furthermore, we analyse the quality of human collected property norm datasets and conclude that these are sparse and incomplete, meaning that there will be a lot of property annotations missing for a given concept (e.g. *has_legs* is not listed as a property of TORTOISE). We show that having a complete dataset can drastically increase the performance of automatic feature prediction, resulting in a truer evaluation (Section 3.5). Lastly, we demonstrate how property norm datasets could be used in an image retrieval task (Section 4), which opens up intriguing possibilities for retrieving concepts based on their visual properties.

2 Property norms

Property norming studies are set up in the following way: participants are asked to freely write down a list of properties for a given concept, whilst being encouraged to consider different kinds of properties (how the concept feels, smells, what it is used for *etc*).

BANANA	CELLO
is_yellow, 29	a_musical_instrument, 26
a_fruit, 25	has_strings, 16
is_edible, 13	made_of_wood, 16
is_soft, 12	found_in_orchestras, 13
grows_on_trees, 11	is_large, 13
eaten_by_peeling, 10	requires_a_bow, 9

Table 1: Examples of features together with their production frequencies from MCRAE

Besides collecting lists of properties for the concepts of interest, a number of useful property statistics are also collected during these studies. For example, the number of participants that have produced the same property for a given concept (also called *production frequency*) and the number of concepts for which a particular property is listed in the dataset (number of *concepts per feature*) have been proposed as fundamental organising principles of cognitive models (Cree et al., 2006).

One of the most widely used property norm datasets is the one collected by McRae et al. (2005), henceforth MCRAE. It contains feature norms for a set of 541 concrete nouns. Each concept was seen by 30 participants and only features that were listed by at least 5 participants were recorded. The published dataset contains a total of 2526 features, with a mean of 13.7 features per concept. The numbers of features registered for a given concept range between 6 (for concepts like COLANDER or HARMONICA) and 26 (for FAWN). Table 1 lists some examples of properties that have been produced for BANANA and CELLO, taken from the MCRAE dataset.

The largest feature norm dataset published to date was developed by the Cambridge Centre for Speech, Language and Brain (Devereux et al., 2013). It contains semantic properties for 638 concrete concepts, with 415 of these also appearing in MCRAE. The data collection experiment was done similarly to McRae et al. (2005), using a production frequency cutoff of 5. The final dataset lists a total of 4359 features for the 638 concepts, with an average of 2.15 features per concept more than MCRAE. Although most property norm datasets have only collected property norms for nouns, Vinson and Vigliocco

Property type	Count	Examples
ENCYCLOPAEDIC	739	associated_with_vampires
FUNCTION	794	used_for_cutting
SMELL	7	is_musty, smells_bad
SOUND	55	barks, produces_music
TACTILE	39	is_scaly, is_hot, is_soft
TASTE	12	is_delicious, tastes_sour
TAXONOMIC	207	an_insect, a_vegetable
VISUAL(COLOUR)	34	is_black, is_white
VISUAL(FORM)	544	has_a_motor, made_of_lace
VISUAL(MOTION)	95	flies, jumps, runs_fast
TOTAL	2526	-

Table 2: Property types and associated examples from MCRAE

(2008) also include verbs in their study.

All the experiments presented in this paper were conducted on MCRAE. Our choice is motivated by the fact that this dataset has also been used in previous work on automated property norm prediction (Kelly et al., 2014; Fagarasan et al., 2015), besides being one of the largest publicly-available property norm datasets.

One aspect of feature norms that previous work (Kelly et al., 2014; Baroni et al., 2010; Barbu, 2008; Fagarasan et al., 2015) fails to capture is their multimodal nature. Even though the attributes are elicited in a linguistic form, and some properties (e.g. what things look like) are easier to verbalise than others (e.g. what things smell like), these datasets contain a variety of property types, ranging from visual and auditory to encyclopaedic and behavioural. Table 2 shows some examples for each of the 10 property types as defined and annotated in MCRAE. More than 25% of all features are visual (e.g. *is_yellow, is_round, made_of_metal*); hence a natural question that follows is whether images can be used in the property norm prediction task and how their performance compares to that of predicting properties from text.

3 Predicting feature norms from images through cross-modal mapping

Cross-modal maps represent a formalisation of the reference problem. For example, by inducing cross-modal maps between visual vectors and linguistic ones we can learn which images (represented as visual vectors) refer to which concepts (represented as text-based distributional vectors) (Lazaridou et al., 2014). This represents an extension of the object recognition problem, since we want to associate images with semantic representations of their depicted objects, rather than just with their label (Frome et al., 2013; Socher et al., 2014).

	is_yellow	a_fruit	is_edible	is_soft
BANANA	29	25	13	12
APPLE	7	24	0	0
BED	0	0	0	13

Table 3: Subspace of PROPNORM. Important to note that MCRAE is not complete, meaning that even though some properties are true of a given concept, they have not been produced by the human participants (e.g. the *is_edible* property for APPLE holds the value 0).

The benefit of this approach lies in its generalisation power: once a function between the two semantic spaces is learnt, it can be used to see how an unseen concept relates to other concepts, just by looking at an image of that concept. This is referred to as the zero-shot learning task (Palatucci et al., 2009; Lazaridou et al., 2014). Our task is to increase the coverage of the property norm datasets, meaning that we want to predict properties for new (unseen) concepts. For example, the concept WOLF is not included in MCRAE, but it would be desirable to know which of the properties in the dataset apply to it (e.g. *is_animal, has_4_legs*) and which don't (e.g. *a_bird, made_of_metal*).

3.1 Building modality-specific representations

We obtain distributed representations of concepts in the property-norm semantic space (henceforth PROPNORM) by simply treating MCRAE as a bag of 2526 properties, with the production frequencies representing the "co-occurrence counts" (Table 3).

Our visual space (henceforth VISUAL) consists of visual representations for all the 541 concepts in MCRAE, built as follows. First, we retrieve 10 images per concept from Google Images,[2] following previous work (Bergsma and Goebel, 2011; Kiela and Bottou, 2014). The image representations are then obtained by extracting the pre-softmax layer

[2] www.google.com/imghp (images were retrieved on 10 April 2015)

from a forward pass in a convolutional neural network that has been trained on the ImageNet classification task using Caffe (Jia et al., 2014). We aggregate images associated with a concept into an overall visually grounded representation by taking the mean of the individual image representations. The dimensionality of the visual vectors is 4096.

We also build three linguistic spaces (DISTRIB, SVD and EMBED), along the lines of Fagarasan et al. (2015). DISTRIB is a 10K-dimensional "vanilla" distributional semantic space, where the contexts are the top 10K most frequent lemmatised words (excluding stopwords) from the October 2013 Wikipedia dump. We use raw frequency counts with context windows being defined as sentence boundaries. SVD is a 300-dimensional SVD-reduced version of DISTRIB where PPMI has been applied to the raw counts. EMBED stands for the continuous vector representations from the log-linear skip-gram model of Mikolov et al. (2013a). We used the publicly-available[3] representations that were trained on part of the Google News dataset (about 100 billion words).

We will also employ three multi-modal semantic spaces (VISUAL+DISTRIB, VISUAL+SVD, VISUAL+EMBED), in which the visual (VISUAL) and respective linguistic representations (DISTRIB, SVD, EMBED) are combined into a multi-modal representation by concatenating their respective L2-normalized representations.

3.2 Method and evaluation

Following previous work (Fagarasan et al., 2015; Kiela et al., 2015) we use partial least squares regression (PLSR)[4] to learn cross-modal maps to the property-norm space (PROPNORM) from the visual (VISUAL), linguistic (DISTRIB, SVD, EMBED) and multi-modal semantic spaces (VISUAL+DISTRIB, VISUAL+SVD, VISUAL+EMBED). At training time, we take advantage of the fact that we possess both visual/linguistic/multi-modal and property norm information for the concepts in MCRAE. Let's consider the VISUAL→PROPNORM setting as an example. We use this cross-modal vocabulary to learn a mapping function between VISUAL and PROPNORM: this function will learn to map visual dimensions to property dimensions. During testing, we use the learnt function to map the visual information of a previously unseen concept (e.g. CAT) to the property norm space and obtain a *predicted property vector* for that concept. Ideally, we want this predicted property vector to be closer to the gold-standard property vector for CAT than to any other property vector (i.e. the label of its nearest neighbour in PROPNORM to be CAT).

We use the standard evaluation metric for this task: average percentage correct at N (P@N) (Fagarasan et al., 2015; Lazaridou et al., 2014; Kiela et al., 2015). This measures how many of the test instances were ranked within the top *N* highest ranked nearest neighbors (using the cosine measure). All the results reported in Table 4 use the zero-shot learning procedure—for each of the 541 concepts in MCRAE, we train a mapping on the remaining 540 concepts and record whether the correct label is retrieved among the top *N* neighbours—and are averaged over the entire dataset. We also compare to a random baseline, for which a concept's nearest neighbours list is obtained by randomly ranking the list of target words.

Since the cross-modal map allows us to obtain property vectors for any concept, we were also able to evaluate these semantic representations on a standard NLP task, such as the well known conceptual similarity and relatedness task. The MEN test collection (Bruni et al., 2014) contains human similarity ratings for 3000 concept pairs. Performance on this dataset is usually measured by computing the Spearman ρ_s correlation between the ranking produced by the similarity scores of the learnt property vectors and that produced by the human-annotated concept similarity scores. Similarity between concept pairs is calculated using cosine similarity.

For each of the semantic spaces presented in Table 5 we learn a cross-modal map to PROPNORM using all the concepts in MCRAE at training time. During testing, we predict property vectors for all concepts in MEN-NOUNS, a subset of the MEN dataset consisting of 1285 noun pairs that don't occur in MCRAE. Table 5 reports the Spearman ρ_s correlation of the predicted property vectors and the gold-standard relatedness scores on MEN-NOUNS (column →PROPNORM), as well as the correlation of the

Multi-modal	DISTRIB+VISUAL	**0.56**	0.45
	SVD+VISAL	0.57	**0.60**
	EMBED+VISUAL	0.56	**0.60**

Table 5: Performance (Spearman ρ_s correlation) of various uni-modal and multi-modal semantic spaces (column SS), together with that of the property vectors they predict (column →PROPNORM) on a semantic relatedness task (MEN-NOUNS)

original semantic spaces (e.g. DISTRIB or SVD) and the gold standard scores (column SS).

3.3 Quantitative results

The results presented in Table 4 show that visual information is a overall better predictor of a concept's properties than linguistic information. The cross-modal maps from the visual space VISUAL outperform all those from linguistic spaces DISTRIB, SVD, EMBED, and the addition of linguistic information to the visual one (maps from VISUAL+DISTRIB, VISUAL+SVD, VISUAL+EMBED) seem to only slightly improve the performance.

It is also important to point out that, even though the P@1 numbers may appear small, similar results have been reported for other zero-shot cross-modal maps (Lazaridou et al., 2014; Kiela et al., 2015). Overall results are good for higher values of N and the qualitative results (Table 6) demonstrate how well the mapping is performing.

A model will achieve a perfect score on this task if it is able to predict, for a given concept, exactly those features (and associated production frequencies) listed in MCRAE. However, close-to-perfect performance in this task is impossible, since almost 30% of the features only occur with one concept, and hence can't be reconstructed for that particular concept. Consider the case of the *a_baby_deer* property: this only occurs in the MCRAE dataset as an attribute of FAWN. When predicting properties of FAWN as part of the zero-shot learning procedure, the *a_baby_deer* property can't be learned, since it doesn't occur with any other concept.

Columns SS and →PROPNORM in Table 5 report correlations with the MEN-NOUNS ratings. The predicted property vectors obtain a high correlation with the MEN scores, showing that the property vectors do capture lexical similarity well, although not as well as the linguistic vectors, which was expected (Bruni et al., 2012). An useful finding is that in some cases, the predicted property vectors obtain a better correlation with the MEN scores than their predictors (i.e. the VISUAL and multi-modal vectors). This shows a potential strength of the attribute-centric semantic representations: their capability to perform better on some lexical similarity/relatedness tasks than representations that contain raw perceptual information.

3.4 Qualitative results

In order to gain more insight into the differences between the *from vision* and *from language* mappings, we performed two types of qualitative analysis: we looked at the differences in nearest neighbours of the predicted property-norm representations (Table 6), as well as the top predicted properties of a concept (Table 6). In the *from language* setting we learned the mapping using the EMBED space, as it was the best performing linguistic space at P@1 and P@5 as shown in Table 4. We obtained the list of nearest neighbours as follows: at test time, we use the learnt cross-modal map to project the visual or linguistic representation of the unseen concept onto a property-norm representation. Using cosine similarity, we then obtain a ranked list of neighbours from all the 541 gold-standard property vectors. By in-

Concept	Nearest neighbours (from VISION)	Nearest neighbours (from LANGUAGE)
banana	**banana**, lemon, corn, pear, grapefruit, pineapple	pear, apple, avocado, plum, peach, lime, pineapple
cabbage	lettuce, asparagus, spinach, celery, broccoli, cucumber	asparagus, turnip, cauliflower, **cabbage**, celery, spinach
crocodile	alligator, **crocodile**, frog, turtle, iguana, toad	alligator, walrus, otter, platypus, **crocodile**, gorilla, buffalo
cello	violin, guitar, banjo, harp, harpsichord, **cello**, flute	harpsichord, harp, clarinet, flute, banjo, guitar, piano
drum	pot, pan, coin, skillet, bucket, peg, cap_(bottle)	tuba, clarinet, trombone, flute, harpsichord, trumpet, harp
fox	**fox**, cougar, coyote, deer, mink, elk, chipmunk	blackbird, raven, sparrow, pigeon, starling, chickadee
harpoon	sword, machete, **harpoon**, dagger, rifle, knife, gun	spear, dagger, harpoon, rifle, bazooka, crossbow, sword
muzzle	donkey, horse, ox, dog, cat, goat, cow	peg, fox, pin, crowbar, gun, dog, harpoon
pants	jeans, trousers, **pants**, shirt, blouse, jacket, coat	shirt, blouse, shawl, coat, sweater, dress, **pants**
prune	plum, blueberry, nectarine, peach, tangerine, raisin	pear, apple, avocado, lime, peach, pineapple, plum
rice	cauliflower, turnip, pie, **rice**, cabbage, biscuit, plate	turnip, lettuce, eggplant, peas, potato, corn, asparagus
stool	**stool_(furniture)**, table, peg, chair, gate, desk, door	chair, couch, **stool_(furniture)**, sofa, bench, desk, peg
swan	pelican, goose, dove, seagull, partridge, raven, falcon	raven, blackbird, goose, sparrow, pelican, partridge
tortoise	turtle, **tortoise**, crocodile, alligator, otter, frog, walrus	cat, fox, cougar, squirrel, hamster, donkey, turtle
worm	eel, rattlesnake, **worm**, shrimp, bat_(baseball), python	plum, tangerine, mandarin, nectarine, minnow, peach

Concept	Top predicted features (from VISION)	Top predicted features (from LANGUAGE)

Table 6: Comparison of the top predicted features and nearest neighbours when mapping from VISION or from LANGUAGE. Properties marked with * don't appear as attributes of the associated concept in MCRAE.

specting the nearest neighbour predictions, we can check where the unseen concept is mapped to (e.g. BANANA is mapped close to yellow fruits). In order to retrieve the top predicted properties of a concept, we rank the dimensions of PROPNORM according to the weights in the predicted property vector (e.g. the predicted property vector for BANANA has high weights for a_fruit and is_green when mapped from language).

By looking at the nearest neighbour predictions, we observe that, when mapping from visual input, the predicted vector will be mapped into a subspace containing visually-similar things. When mapping from linguistic input, the neighbours tend to be concepts that are semantically related or denoted by words that occur in the same context as the target concept (e.g. worms are found in plums and nectarines).

A notable result is that when mapping from vision, the top neighbours tend to share the same colour (top neighbours for BANANA are yellow fruits, for SWAN are white birds) or shape as the target concept (top neighbours for WORM are long things with no legs). One possible clue as to why vision is better at predicting a concept's properties is given by the fact that it obtains better results on concepts such as PANTS or STOOL, where the only difference to very similar concepts like TROUSERS or CHAIR are visual (a STOOL has no backrest as opposed to a CHAIR).

However, there are cases in which the visual attributes of an object are not very useful in predicting its most important features: e.g. DRUM is mapped into a subspace of round objects (from vision), and not instruments (from language).

Besides the difference in top predicted features, Table 6 also indicates a shortcoming of MCRAE, specifically that this is not complete, meaning that not all properties that apply to a given concept were produced by the human annotators. Most of the top predicted attributes that don't occur in the dataset (those marked with * in Table 6) are highly plausible properties for the given concepts: *tastes_sweet* for BANANA or *has_legs* for TORTOISE. This also means that the model is being unfairly penalised.

In order to obtain a *complete* version of MCRAE, every possible (CONCEPT, *property*) pair would have to be checked for validity and annotated accordingly depending on whether *property* is a valid attribute of CONCEPT.

3.5 Importance of complete data

We were interested in measuring the impact that a *complete* dataset of features would have on the performance of the cross-modal zero-shot learning task. Silberer et al. (2013) conducted a study using a subset of the concepts and properties in MCRAE, whereby every property was annotated if it was a plausible attribute of the concept.

The published dataset (SILBERER) consists of visual attribute annotations for 512 concepts (that also occur in MCRAE) and 693 visual properties. The annotation was done on a per-concept basis by looking at 10 images retrieved from ImageNet (Deng et al., 2009) and selecting all the attributes that were considered to be generally true for the given concept, even if not depicted in the images. For example, *has_a_pit* is a valid visual attribute for PLUM, even though not all retrieved images of plums show the pit.

Dataset	#concs	#props	#(conc,prop) pairs
SILBERER	512	693	7743
SILB-VIS	512	283	5335
M-VIS	512	283	2140
MCRAE	541	2526	7259

Table 7: Comparison of various datasets, according to the number of concepts and properties covered, as well as the pairs of (CONCEPT, *property*) contained

Train	Test	P@1	P@5	P@10	P@20
M-VIS	M-VIS	0.59	7.91	15.02	19.97
M-VIS	SILB-VIS	7.11	27.67	43.68	56.92
SILB-VIS	SILB-VIS	5.93	35.77	54.74	71.54

Table 8: Zeroshot learning performance for the vision to norms cross-modal map on different training and test sets

Since not all of the 693 visual properties covered in SILBERER can be found in MCRAE, we will only be concerned with the subset of SILBERER which contains only those visual properties that also occur in MCRAE, henceforth SILB-VIS. These datasets are *complete*, since they were exhaustively annotated as explained above.

Let us also define M-VIS as the subset of MCRAE that contains the 512 concepts listed in SILBERER and the 283 properties that are common to SILBERER and MCRAE, together with their production frequencies as in MCRAE. This will act as our *incomplete* dataset. Table 7 lists all the aforementioned datasets, together with statistics related to their number of concepts, features and concept-feature pairs. It also demonstrates the sparsity of MCRAE: it contains fewer (CONCEPT, *property*) pairs than SILBERER, even though it contains 4 times more properties.

All the experiments performed using these

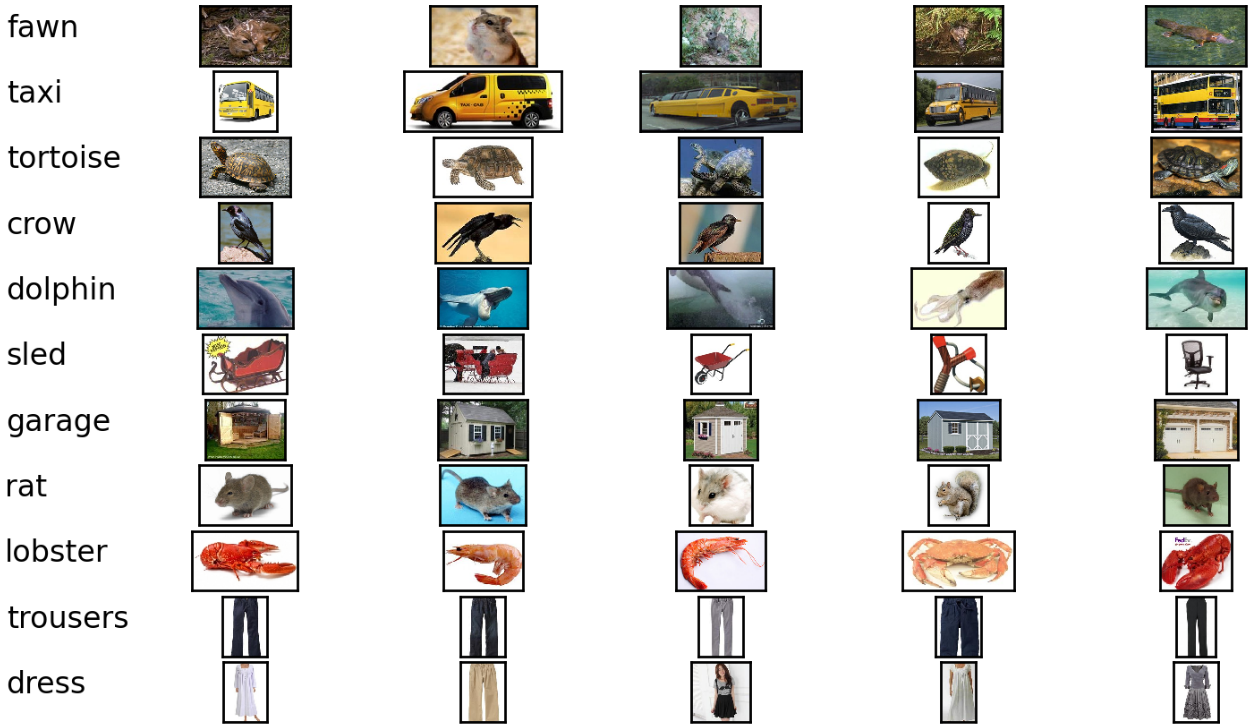

Figure 1: Nearest neighbours of the predicted visual vectors

datasets are listed in Table 8. These are identical in methodology to the zero-shot cross-modal maps from VISUAL to PROPNORM; the only difference being the datasets that these are run on.

The row (train:M-VIS, test:M-VIS) represents the setting where the cross-modal map learning and testing are both done on the incomplete set of data, just like we would do using MCRAE. We notice a huge improvement in performance by using the complete data only at test-time (row (train:M-VIS, test:SILB-VIS)). Note that, in this scenario, the learning is carried out in the same way, but the model can't be penalised for ranking plausible features near the top during test time, since we are testing against a complete dataset. This new setting provides a truer evaluation scenario and demonstrates the weakness in using MCRAE as a test set.

Performance improves even more if the complete dataset is used at training time as well (the row (train:SILB-VIS, test:SILB-VIS)), showing the benefit of also learning the mapping from complete data, as well as evaluating on it.

From	P@1	P@5	P@10	P@20	P@50
PROPNORM	6.13	36.43	54.46	68.40	81.97
DISTRIB	4.08	10.78	17.29	26.21	40.89
SVD	7.81	34.57	47.77	60.60	79.00
EMBED	9.48	31.60	47.21	62.08	78.81

Table 9: Zero-shot learning performance when mapping to the visual space (VISUAL)

4 Property based query engine

An interesting question follows from the good performance of the cross-modal mapping in Section 3, and that is whether we can reliably predict what concepts look like based on their semantic properties. For example, does something that flies, has wings and a beak look like a bird?

This task could be formalised as a property-based query engine, where we can train the cross-modal mapping to learn which concepts refer to which images. We follow the same experimental setup as detailed in Section 3.2 in order to learn a cross-modal map from PROPNORM to VISUAL. We also learn cross-modal maps from the linguistic spaces

(DISTRIB, SVD, EMBED) to VISUAL in order to see whether conceptual properties or linguistic input are better at predicting visual information.

Table 9 shows the results of our quantitative evaluation: the average precentage of correctly retrieved mean visual representations at N.

A qualitative analysis of the PROPNORM to VISUAL cross-modal map is shown in Figure 1. Because there are no images associated with the predicted mean visual representation, we retrieve and display the top neighbouring images. These images look surprisingly good, considering that the representation for TAXI in PROPNORM is a sparse vector where only the features *is_yellow, requires_drivers, used_for_transportation, a_car, requires_money, found_in_New_York, is_expensive, used_for_passengers, a_cab, is_fast* are activated.

5 Conclusions

We have studied the automatic prediction of property norms for unseen concepts, through learning the cross-modal mapping from image data. Following previous work, we evaluated on a zero-shot learning task and show that raw visual information (images) is a better predictor for conceptual properties than linguistic input (text). We also presented a short case study demonstrating the importance of having complete annotations in the property norm datasets, for both testing and training. Lastly, we demonstrated a possible use case for property norm datasets in an image retrieval task.

Our contributions are two-fold: first, we show that property norms can be successfully predicted from non-linguistic modalities and secondly, we quantify the need to have *complete* property norm datasets, where a production frequency of 0 for a (CONCEPT, *property*) pair can always be interpreted as "*property* is not true of CONCEPT".

Cross-lingual Wikification Using Multilingual Embeddings

Abstract

Cross-lingual Wikification is the task of grounding mentions written in non-English documents to entries in the English Wikipedia. This task involves the problem of comparing textual clues across languages, which requires developing a notion of similarity between text snippets across languages. In this paper, we address this problem by jointly training multilingual embeddings for words and Wikipedia titles. The proposed method can be applied to all languages represented in Wikipedia, including those for which no machine translation technology is available. We create a challenging dataset in 12 languages and show that our proposed approach outperforms various baselines. Moreover, our model compares favorably with the best systems on the TAC KBP2015 Entity Linking task including those that relied on the availability of translation from the target language to English.

1 Introduction

Wikipedia has become an indispensable resource in knowledge acquisition and text understanding for both human beings and computers. The task of Wikification or Entity Linking aims at disambiguating mentions (sub-strings) in text to the corresponding titles (entries) in Wikipedia or other Knowledge Bases, such as FreeBase. For English text, this problem has been studied extensively (Bunescu and Pasca, 2006; Cucerzan, 2007; Mihalcea and Csomai, 2007; Ratinov et al., 2011; Cheng and Roth, 2013). It also has been shown to be a valuable component of several natural language processing and information extraction tasks across different domains.

Recently, there has also been interest in the cross-lingual setting of Wikification: given a mention from a document written in a foreign language, the goal is to find the corresponding title in the English Wikipedia. This task is driven partly by the fact that a lot of information around the world may be written in a foreign language for which there are limited linguistic resources and, specifically, no English translation technology. Instead of translating the whole document to English, *grounding* the important entity mentions in the English Wikipedia may be a good solution that could better capture the key message of the text, especially if it can be reliably achieved with fewer resources than those needed to develop a translation system. This task is mainly driven by the Text Analysis Conference (TAC) Knowledge Base Population (KBP) Entity Linking Tracks (Ji et al., 2012; Ji et al., 2015; Ji et al., 2016), where the target languages are Spanish and Chinese.

In this paper, we develop a general technique which can be applied to all languages in Wikipedia even when no machine translation technology is available for them.

The challenges in Wikification are due both to ambiguity and variability in expressing entities and concepts: a given mention in text, e.g., Chicago, may refer to different titles in Wikipedia (Chicago Bulls, the City, Chicago Bears, the band, etc.), and a title can be expressed in the text in multiple ways, such as synonyms and nicknames. These challenges are usually resolved by calculating some similarity between the representation of the mention and candidate titles. For instance, the mention could be represented using its neighboring words, whereas a ti-

Proceedings of NAACL-HLT 2016, pages 589–598,
San Diego, California, June 12-17, 2016.

tle is usually represented by the words and entities in the document which introduces the title. In the cross-lingual setting, an additional challenge arises from the need to match words in a foreign language to an English title.

In this paper, we address this problem by using multilingual title and word embeddings. We represent words and Wikipedia titles in both the foreign language and in English in the same continuous vector space, which allows us to compute meaningful similarity between mentions in the foreign language and titles in English. We show that learning these embeddings only requires Wikipedia documents and language links between the titles across different languages, which are quite common in Wikipedia. Therefore, we can learn embeddings for all languages in Wikipedia without any additional annotation or supervision.

Another notable challenge for the cross-lingual setting that we do not address in this paper is that of *generating* English candidate titles given a foreign mention when there is no corresponding title in the foreign language Wikipedia. If a title exists in both the English and the foreign language Wikipedia, there could be examples of using this title in the foreign language Wikipedia text, and this information could help us determine the possible English titles. For example, Vladimir N. Vapnik exists in both the English Wikipedia (`en/Vladimir_Vapnik`)[1] and the Chinese Wikipedia (`zh/弗拉基米·万普尼克`). In the Chinese Wikipedia, we may see the use of the mention 萬普尼克 as a reference, that is, 萬普尼克 is linked to the title `zh/弗拉基米·万普尼克`. Following the inter-language links in Wikipedia, we can reach the English title `en/Vladimir_Vapnik`. On the other hand, Dan Roth does not have a page in the Chinese Wikipedia, it would have been harder to get to `en/Dan_Roth` from the Chinese mention. In this case, a transliteration model may be needed. Note that the difference between these two cases is only in generating English title candidates from the given foreign mention. The disambiguation method which identifies the most probable title is conceptually the same, so our method could generalize as is to this case.

For evaluation purposes, we focus in this paper on mentions that have corresponding titles in both the English and the foreign language Wikipedia, and concentrate on disambiguating titles across languages. This allows us to evaluate on a large number of Wikipedia documents. Note that under this setting, a natural approach is to do wikification on the foreign language and then follow the language links to obtain the corresponding English titles. However, this approach requires developing a separate wikifier for each foreign language if it uses language-specific features, while our approach is generic and only requires using the appropriate embeddings. Importantly, the aforementioned approach will also not generalize to the cases where the target titles only exist in the English Wikipedia while ours does.

We create a challenging Wikipedia dataset for 12 foreign languages and show that the proposed approach, WikiME (**Wiki**fication using **M**ultilingual **E**mbeddings), consistently outperforms various baselines. Moreover, the results on the TAC KBP2015 Entity Linking dataset show that our approach compares favorably with the best Spanish system and the best Chinese system despite using significantly weaker resources (no need for translation). We note that the need for translation would have prevented the wikification of 12 languages used in this paper.

2 Task Definition and Model Overview

We formalize the problem as follows. We are given a document d in a foreign language, a set of mentions $M_d = \{m_1, \cdots, m_n\}$ in d, and the English Wikipedia. For each mention in the document, the goal is to retrieve the English Wikipedia title that the mention refers to. If the corresponding entity or concept does not exist in the English Wikipedia, “NIL” should be the answer.

Given a mention $m \in M_d$, the first step is to generate a set of title candidates C_m. The goal of this step is to quickly produce a short list of titles which includes the correct answer. We only look at the surface form of the mention in this step, that is, no contextual information is used.

The second and the key is the ranking step where we calculate a score for each title candidate $c \in C_m$, which indicates how relevant it is to the given men-

[1] We use `en/Vladimir_Vapnik` to refer to the title of `en.wikipedia.org/wiki/Vladimir_Vapnik`

tion. We represent the mention using various contextual clues and compute several similarity scores between the mention and the English title candidates based on multilingual word and title embeddings. A ranking model learnt from Wikipedia documents is used to combine these similarity scores and output the final score for each title candidate. We then select the candidate with the highest score as the answer, or output NIL if there is no appropriate candidate.

The rest of paper is structured as follows. Section 3 introduces our approach of generating multilingual word and title embeddings for all languages in Wikipedia. Section 4 presents the proposed cross-lingual wikification model which is based on multilingual embeddings. Evaluations and analyses are presented in Section 5. Section 6 discusses related work. Finally, Section 7 concludes the paper.

3 Multilingual Entity and Word Embeddings

In this section, we describe how we generate a vector representation for each word and Wikipedia title in any language.

3.1 Monolingual Embeddings

The first step is to train monolingual embeddings for each language separately. We adopt the "Alignment by Wikipedia Anchors" model proposed in Wang et al. (2014). For each language, we take all documents in Wikipedia and replace the hyperlinked text with the corresponding Wikipedia title. For example, consider the following Wikipedia sentence: "It is led by and mainly composed of **Sunni** Arabs from **Iraq** and **Syria**.", where the three bold faced mentions are linked to some Wikipedia titles. We replace those mentions and the sentence becomes "It is led by and mainly composed of `en/Sunni_Islam` Arabs from `en/Iraq` and `en/Syria`." We then learn the skip-gram model (Mikolov et al., 2013a; Mikolov et al., 2013b) on this newly generated text. Since a title appears as a token in the transformed text, we will obtain an embedding for each word and title from the model.

The skip-gram model maximizes the following objective:

$$\sum_{(w,c)\in D} \log \frac{1}{1+e^{-v'_c \cdot v_w}} + \sum_{(w,c)\in D'} \log \frac{1}{1-e^{-v'_c \cdot v_w}},$$

where w is the target token (word or title), c is a context token within a window of w , v_w is the target embedding represents w, v'_c is the embedding of c in context, D is the set of training documents, and D' contains the sampled token pairs which serve as negative examples. This objective is maximized with respect to variables v_w's and v'_w's. In this model, tokens in the context are used to predict the target token. The token pairs in the training documents are positive examples, and the randomly sampled pairs are negative examples.

3.2 Multilingual Embeddings

After getting monolingual embeddings, we adopt the model proposed in Faruqui and Dyer (2014) to project the embeddings of a foreign language and English to the same space. The requirement of this model is a dictionary which maps the words in English to the words in the foreign language. Note that there is no need to have this mapping for every word. The aligned words are used to learn the projection matrices, and the matrices can later be applied to the embeddings of each word to obtain the enhanced new embeddings. Faruqui and Dyer (2014) obtain this dictionary by picking the most frequent translated word from a parallel corpus. However, there is a limited or no parallel corpus for many languages. Since our monolingual embedding model consists also of title embeddings, we can use the Wikipedia title alignments between two languages as the dictionary.

Let $A_{en} \in R^{a \times k_1}$ and $A_{fo} \in R^{a \times k_2}$ be the matrices containing the embeddings of the aligned English and foreign language titles, where a is the number of aligned titles and k_1 and k_2 are the dimensionality of English embeddings and foreign language embeddings respectively (i.e., each row is a title embedding). Canonical correlation analysis (CCA) (Hotelling, 1936) is applied to these two matrices:

$$P_{en}, P_{fo} = CCA(A_{en}, A_{fo}),$$

where $P_{en} \in R^{k_1 \times d}$ and $P_{fo} \in R^{k_2 \times d}$ are the projection matrices for English and foreign language

FEATURE TYPE	DESCRIPTIONS
Basic	$Pr(c\|m)$ and $Pr(m\|c)$, the fraction of times the title candidate c is the target page given the mention m, and the fraction of times c is referred by m
Other Mentions	Cosine similarity of $e(c)$ and the average of vectors in $other\text{-}mentions(m)$ The maximum and minimum cosine similarity of the vectors in $other\text{-}mentions(m)$ and $e(c)$
Local Context	Cosine similarity of $e(c)$ and $context_j(m)$, for $j = 30, 100$, and 200
Previous Titles	Cosine similarity of $e(c)$ and the average of vectors in $previous\text{-}titles(m)$ The maximum and minimum cosine similarity of the vectors in $previous\text{-}titles(m)$ and $e(c)$

Table 1: Features for measuring similarity of an English title candidate c and a mention m in the foreign language, where $e(c)$ is the English title embedding of c. $other\text{-}mentions(m)$, $previous\text{-}titles(m)$, and $context_j(m)$ are defined in Section 4.2.

embeddings, and d is the dimensionality of the projected vectors, which is a parameter in CCA.

Let $E_{en} \in R^{n_1 \times k_1}$ be the matrix containing the monolingual embeddings for all words and titles in English, where the number of words and titles is n_1, We obtain the multilingual embeddings of English words and titles by

$$E'_{en} = E_{en}P_{en} \in R^{n_1 \times d}.$$

Similarly, the multilingual embeddings of the foreign words and titles are stored in the rows of

$$E'_{fo} = E_{fo}P_{fo} \in R^{n_2 \times d},$$

where there are n_2 words and titles in the foreign language. The rows of E'_{en} and E'_{fo} are the representations of words and titles that we use to create the similarity features in the ranker.

Faruqui and Dyer (2014) show that the multilingual embeddings perform better than monolingual embeddings on various English word similarity datasets. Since synonyms in English may be translated into the same word in a foreign language, the CCA model could bring the synonyms in English closer in the embedding space. In this paper, we further show that projecting the embeddings of the two languages into the same space helps us computing better similarity between the words and titles across languages and that a bilingual dictionary consisting of pairs of Wikipedia titles is sufficient to induce these embeddings.

4 Cross-lingual Wikification

We now describe the algorithm for finding the English title given a foreign mention.

4.1 Candidate Generation

Given a mention m, the first step is to select a set of English title candidates C_m, a subset of all titles in the English Wikipedia. Ideally the correct title is included in this set. The goal is to produce a manageable number of candidates so that a more sophisticated algorithm can be applied to disambiguate them.

Since we focus on the titles in the intersection of English and the foreign language Wikipedia, we can build indices from the anchor texts in the foreign language Wikipedia. More specifically, we create two dictionaries and apply a two-step approach. The first dictionary maps each hyperlinked mention string in the text to the corresponding English titles. We simply lookup this dictionary by using the query mention m to retrieve all possible titles. The title candidates are initially sorted by $Pr(title|mention)$, the fraction of times the title is the target page of the given mention. This probability is estimated from all Wikipedia documents. The top k title candidates are then returned.

If the first high-precision dictionary fails to generate any candidate, we then lookup the second dictionary. We break each hyperlinked mention string into tokens, and create a dictionary which maps tokens to English titles. The tokens of m are used to query this dictionary. Similarly, the candidates are sorted by $Pr(title|token)$ and the top k candidates are returned.

4.2 Candidate Ranking

Given a mention m and a set of title candidates C_m, we compute a score for each title in C_m which indicates how relevant the title is to m. For a candidate $c \in C_m$, we define the relevance as:

$$s(m, c) = \sum_i w_i \phi_i(m, c), \qquad (1)$$

a weighted sum of the features, ϕ_i, which are based on multilingual title and word embeddings. We represent the mention m by the following contextual clues and use these representation to compute feature values:

- $context_j(m)$: use the tokens within j characters of m to compute the TF-IDF weighted average of their embeddings in the foreign language.
- $other\text{-}mentions(m)$: a set of vectors that represent other mentions. For each mention in the document other than m, we represent it by averaging the embeddings of the tokens in the mention surface string.
- $previous\text{-}titles(m)$: a set of vectors that represent previous entities. For each mention before m, we represent it by the English embedding of the disambiguated title.

Let $e(c)$ be the English embedding of the title candidate c. The features used in Eq. (1) are shown in Table 1. We train a linear ranking SVM model with the proposed features to obtain the weights, w_i, in Eq. (1). Finally, the title which has the highest relevant score is chosen as the answer to m.

5 Experiments

We evaluate the proposed method on the Wikipedia dataset of 12 langugaes and the TAC'15 Entity Linking dataset.

For all experiments, we use the Word2Vec implementation in Gensim[2] to learn the skip-gram model with dimensionality 500 for each language. The CCA code for projecting mono-lingual embeddings is from Faruqui and Dyer (2014)[3] in which the ratio parameter is set to 0.5 (i.e., the resulting multilingual embeddings have dimensionality 250).

We use Stanford Word Segmenter (Chang et al., 2008) for tokenizing Chinese, and use the Java built-in BreakIterator for Thai. For all other languages, tokenization is based on whitespaces. The number of tokens we use to learn the skip-gram model and the number of title alignments used by the CCA are given in Table 2. For learning the weights in Eq. (1), we use the implementation of linear ranking SVM in Lee and Lin (2014). Parameter selection and feature engineering are done by conducting cross-validation on the training data of Spanish Wikipedia dataset.

LANGUAGE	#TOKENS	#ALIGN. TITLES
German	616,347,668	960,624
Spanish	460,984,251	754,740
French	357,553,957	1,088,660
Italian	342,038,537	836,154
Chinese	179,637,674	469,982

Thai	68,991,911	72,072
Arabic	67,954,771	255,935
Turkish	47,712,534	162,677
Tamil	12,665,312	50,570
Tagalog	4,925,785	48,725
Urdu	3,802,679	83,665

Table 2: The number of tokens used in training the skip-gram model and the number of titles which can be aligned to the corresponding English titles via the language links in Wikipedia.

5.1 Wikipedia Dataset

We create this dataset from the documents in Wikipedia by taking the anchors (hyperlinked texts) as the query mentions and the corresponding English Wikipedia titles as the answers. Note that we only keep the mentions for which we can get the corresponding English Wikipedia titles by the language links. As observed in previous work (Ratinov et al., 2011), most of the mentions in Wikipedia documents are easy, that is, the baseline of simply choosing the title that maximizes $Pr(title|mention)$, the most frequent title given the mention surface string, performs quite well. In order to create a more challenging dataset, we randomly select mentions such that the number of easy mentions is about twice the number of hard mentions (those mentions for which the most common title is not the correct title). This generation process is inspired by (and close to) the distribution generated in the TAC KBP2015 Entity Linking Track. Another problem that occurs when creating a dataset from Wikipedia documents is that even though training documents are different from

Tamil	21,373	11,346 (3,776)
Tagalog	4,835	1,074 (358)
Urdu	1,413	1,389 (463)

Table 3: The number of training and test mentions of the Wikipedia dataset. The mentions are from the hyperlinked text in randomly selected Wikipedia documents. We ensure that there are at least one-third of test mentions are hard (cannot be solved by the most common title given the mention).

test documents, many mentions and titles actually overlap. To test that the algorithms really generalize from training examples, we ensure that no (mention, title) pair in the test set appear in the training set. Table 3 shows the number of training mentions, test mentions, and hard mentions in the test set of each language. This dataset is publicly available at `http://bilbo.cs.illinois.edu/~ctsai12/xlwikifier-wikidata.zip`.

The performance of the proposed method (WikiME) is shown in Table 4 along with the following approaches:

MonoEmb: In this method, we use the monolingual embeddings before applying CCA while all the other settings are the same as in WikiME. Since the monolingual embeddings are learnt separately for each language, calculating the cosine similarity of the word embedding in the foreign language and an English title embedding does not produce a good similarity function. The ranker, though, learns that the most important feature is $Pr(title|mention)$, and, consequently, performs well on easy mentions but has poor performance on hard mentions.

WordAlign: Instead of using the aligned Wikipedia titles in generating multilingual embeddings, the CCA model operates on the word alignments as originally proposed in Faruqui and Dyer (2014). We use the word alignments provided by Faruqui and Dyer (2014), which are obtained

LANGUAGE	METHOD	HARD	EASY	TOTAL
German	MonoEmb	35.18	**96.92**	76.34

Table 4: Ranking performance (Precision@1) of different approaches on various languages. Since about one-third of the test mentions are non-trivial, a baseline is 66.67 for all languages, if we pick the most common title given the mention. **Bold** signifies highest score for each column.

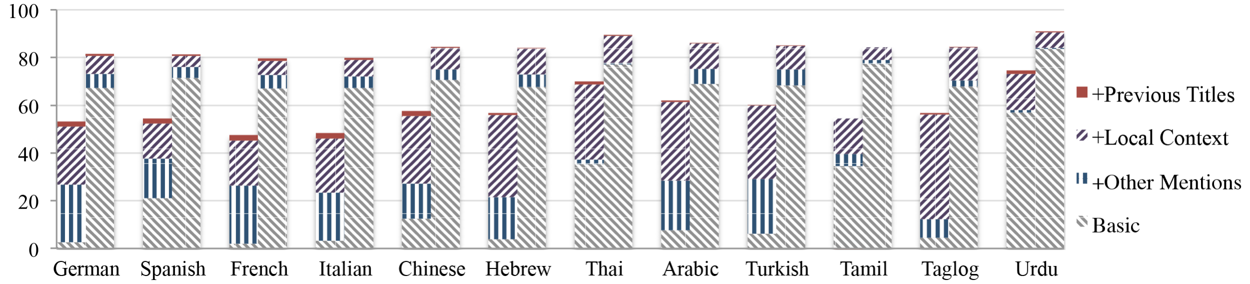

Figure 1: Feature ablation study of WikiME. The left bar of each language shows the performance on hard mentions, whereas the right bar corresponds to the performance of all mentions. The descriptions of feature types are listed in Table 1.

from the parallel news commentary corpora combined with the Europarl corpus for English to German, France, and Spanish. The number of aligned words for German, France, and Spanish are 37,484, 37,582, and 37,554 respectively. WikiME performs statistically significantly better than WordAlign on all three languages.

EsWikifier: We use Illinois Wikifier (Ratinov et al., 2011; Cheng and Roth, 2013) on a Spanish Wikipedia dump and train its ranker on the same set of documents that are used in WikiME.

Ceiling: These rows show the performance of title candidate generation. That is, the numbers indicate the percentage of mentions that have the gold title in its candidate set, therefore upper-bounds the ranking performance.

In sum, WikiME can disambiguate the hard mentions much better than other methods without sacrificing the performance on the easy mentions much. Comparing across different languages, it is important to note that languages which have a smaller size Wikipedia tend to have better performance, despite the degradation in the quality of the embeddings (see below). This is due to the difficulty of the datasets. That is, there is less ambiguity because the number of articles in the corresponding Wikipedia is small.

Figure 1 shows the feature ablation study of WikiME. For each language, we show results on hard mentions (the left bar) and all mentions (the right bar). We do not show the performance on easy mentions since it always stays high and does not change much. We can see that *Local Context* and *Other Mentions* are very effective for most of the languages. In particular, on hard mentions, the performance gain of the three feature groups is from almost 0 to around 50. For the easier dataset such as Urdu, *Basic features* alone work quite well.

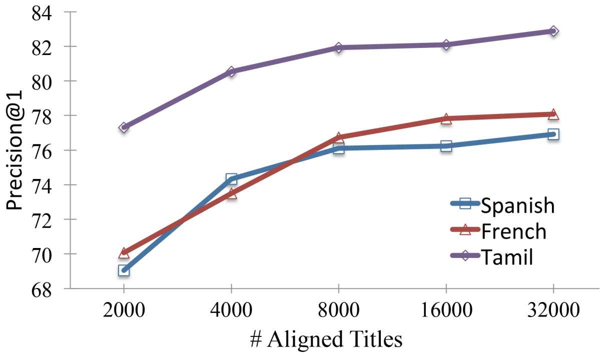

Figure 2: The number of aligned titles used in generating multilingual embeddings versus the performance of WikiME.

Figure 2 shows the performance of WikiME when we vary the number of aligned titles in generating multilingual embeddings. The performance drops a lot when there are only few aligned titles, especially for Spanish and French, where the results are even worse than MonoEmb when only 2000 titles are aligned. This indicates that the CCA method needs enough aligned pairs in order to produce good embeddings. The performance does not change much when there are more than 16,000 aligned titles.

5.2 TAC KBP2015 Entity Linking

To evaluate our system on documents outside Wikipedia, we conduct an experiment on the evaluation documents in TAC KBP2015 Tri-Lingual Entity Linking Track. In this dataset, there are 166 Chinese documents (84 news and 82 discussion forum articles) and 167 Spanish documents (84 news and 83 discussion forum articles). The mentions in this dataset are all named entities of five types: Person, Geo-political Entity, Organization, Location, and Facility.

Table 5 shows the results. Besides the Spanish Wikifier (EsWikifier) that we used in the previous experiment, we implemented another baseline for Spanish Wikification. In this method, we use Google Translate to translate the whole documents from Spanish to English, and then the English Illinois Wikifier is applied to disambiguate the English gold mentions. Note that the target Knowledge Base of this dataset is FreeBase, therefore we use the FreeBase API to map the resulting English or Spanish Wikipedia titles to the corresponding FreeBase ID. If this conversion fails to find the corresponding FreeBase ID, "NIL" is returned instead.

The ranker models used in all three systems are trained on Wikipedia documents. We can see that WikiME outperforms both baselines significantly on Spanish. It is interesting to see that the translation-based baseline performs slightly better than the Spanish Wikifier, which indicates that the machine translation between Spanish and English is quite reliable. Note that this translation-based baseline got the highest score in this shared task when the mention boundaries were not given.

The row "Top TAC'15 System" lists the best scores of the diagnostic setting in which mention boundaries are given (Ji et al., 2016). Since the official evaluation metric considers not only the linked FreeBase IDs but also the entity types, namely, an answer is counted as correct only if the FreeBase ID and the entity type are both correct, we built two simple 5-class classifiers to classify each mention into the five entity types so that we can compare with the state of the art. One classifier uses FreeBase types of the linked FreeBase ID as features, and this classifier is only applied to mentions that are linked to some entry in FreeBase. For NIL mentions, another classifier which uses word form features (words in the mention, previous word, and next word) is applied. Both classifiers are trained on the training data of this task. From the last two rows of Table 5, we can see that WikiME achieves better results than the best TAC participants.

APPROACH	SPANISH	CHINESE
Translation + EnWikifier	79.35	N/A
EsWikifier	79.04	N/A
WikiME	**82.43**	**85.07**
+Typing		
Top TAC'15 System	80.4	83.1
WikiME	**80.93**	**83.63**

Table 5: TAC KBP2015 Entity Linking dataset. All results use gold mentions and the metric is precision@1. The top section only evaluates the linked FreeBase ID. To compare with the best systems in TAC, we also classify each mention into the five entity types. The results which evaluate both FreeBase IDs and entity types are shown in the bottom section.

6 Related Work

Wikification on English documents has been studied extensively. Earlier works (Bunescu and Pasca, 2006; Mihalcea and Csomai, 2007) focus on local features which compare context words with the content of candidate Wikipedia pages. Later, several works (Cucerzan, 2007; Milne and Witten, 2008; Han and Zhao, 2009; Ferragina and Scaiella, 2010; Ratinov et al., 2011) proposed to explore global features, trying to capture coherence among titles that appear in the text. In our method, we compute local and global features based on multilingual embeddings, which allow us to capture better similarity between words and Wikipedia titles across languages.

The annual TAC KBP Entity Linking Track has used the cross-lingual setting since 2011 (Ji et al., 2012; Ji et al., 2015; Ji et al., 2016), where the target foreign languages are Spanish and Chinese. To our best knowledge, most of the participants use one of the following two approaches: (1) Do entity linking in the foreign language, and then find the corresponding English titles from the resulting foreign language titles; and (2) Translate the query documents to English and do English entity linking. The first approach relies on a large enough Knowledge Base in the foreign language, whereas the second depends on a good machine translation system. The approach developed in this paper makes significantly simpler assumptions on the availability of such resources, and therefore can scale also to lower-resource languages, while doing very well also on high-resource languages.

Wang et al. (2015) proposed an unsupervised method which matches a knowledge graph with a graph constructed from mentions and the corresponding candidates of the query document. This approach performs well on the Chinese dataset of TAC'13, but falls into the category (1). Moro et al. (2014) proposed another graph-based approach which uses Wikipedia and WordNet in multiple languages as lexical resources. However, they only focus on English Wikification.

McNamee et al. (2011) aims at the same cross-lingual Wikification setting as we do, where the challenge is in comparing foreign language words with English titles. They treat this problem as a cross-lingual information retrieval problem. That is, given the context words of the target mention in the foreign language, retrieve the most relevant English Wikipedia page. However, their approach requires parallel text to estimate word translation probabilities. In contrast, our method only needs Wikipedia documents and the inter-language links.

Besides the CCA-based multilingual word embeddings (Faruqui and Dyer, 2014) that we extend in Section 3, several other methods also try to embed words in different languages into the same space. Hermann and Blunsom (2014) use a sentence aligned corpus to learn bilingual word vectors. The intuition behind the model is that representations of aligned sentences should be similar. Unlike the CCA-based method which learns monolingual word embeddings first, this model directly learns the cross-lingual embeddings. Luong et al. (2015) propose Bilingual Skip-Gram which extends the monolingual skip-gram model and learns bilingual embeddings using a parallel copora and word alignments. The model jointly considers within language co-occurrence and meaning equivalence across languages. That is, the monolingual objective for each language is also included in their learning objective. Several recent approaches (Gouws et al., 2014; Coulmance et al., 2015; Shi et al., 2015; Soyer et al., 2015) also require a sentence aligned parallel corpus to learn multilingual embeddings. Unlike other approaches, Vulić and Moens (2015) propose a model that only requires comparable corpora in two languages to induce cross-lingual vectors. Similar to our proposed approach, this model can also be applied to all languages in Wikipedia if we treat documents across two Wikipedia languages as a comparable corpus. However, the quality and quantity of this comparable corpus for low-resource languages will be low, we believe.

We choose the CCA-based model because we can obtain multilingual word and title embeddings for all languages in Wikipedia without any additional data beyond Wikipedia. In addition, by decoupling the training of the monolingual embeddings from the cross-lingual alignment we make it easier to improve the quality of the embeddings by getting more text in the target language or a better dictionary between English and the target language. Nevertheless, as cross-lingul wikification provides another testbed for multilingual embeddings, it would be very interesting to compare these recent models on Wikipedia languages.

7 Conclusion

We propose a new, low-resource, approach to Wikification across multiple languages. Our first step is to train multilingual word and title embeddings jointly using title alignments across Wikipedia collections in different languages. We then show that using features based on these multilingual embeddings, our wikification ranking model performs very well on a newly constructed dataset in 12 languages, and achieves state of the art also on the TAC'15 Entity Linking dataset.

An immediate future direction following our work is to improve the title candidate generation process so that it can handle the case where the corresponding titles only exist in the English Wikipedia. This only requires augmenting our method with a transliteration tool and, together with the proposed disambiguation approach across languages, this will be a very useful tool for low-resource languages which have a small number of articles in Wikipedia.

Abstract

Search tasks, comprising a series of search queries serving a common informational need, have steadily emerged as accurate units for developing the next generation of task-aware web search systems. Most prior research in this area has focused on segmenting chronologically ordered search queries into higher level tasks. A more naturalistic viewpoint would involve treating query logs as convoluted structures of tasks-subtasks, with complex search tasks being decomposed into more focused sub-tasks. In this work, we focus on extracting sub-tasks from a given collection of on-task search queries. We jointly leverage insights from Bayesian nonparametrics and word embeddings to identify and extract sub-tasks from a given collection of *on-task* queries. Our proposed model can inform the design of the next generation of task-based search systems that leverage user's task behavior for better support and personalization.

1 Introduction

Search behavior, and information behavior more generally, is often motivated by tasks that prompt search processes that are often lengthy, iterative, and intermittent, and are characterized by distinct stages, shifting goals and multitasking (Kelly et al., 2013; Mehrotra et al., 2016). Current search systems do not provide adequate support for users tackling complex tasks, due to which the cognitive burden of keeping track of such tasks is placed on the searcher. Ideally, a search engine should be able to understand the reason that caused the user to submit a query (i.e., the actual task that caused the query to be issued) and be able to guide users to achieve their tasks by incorporating this information about the actual informational need. Clearly, identifying and analyzing search tasks is an extremely important activity not only for search engine providers but also other web based frameworks like spoken dialogue (Sun et al., 2015) and general recommendation systems (Mehrotra et al., 2014) in their effort to improve user experience on their platforms.

Previous work in the area have proposed a number of methods for identifying and extracting task knowledge from search query sessions (Mehrotra and Yilmaz, 2015b; Wang et al., 2013; Lucchese et al., 2011; Verma and Yilmaz, 2014; Mehrotra and Yilmaz, 2015a). However, while some tasks are fairly trivial and single-shot (e.g. ”latest Taylor Swift album”), others are more complex and often involve multiple steps or sub-tasks (e.g. ”planning a wedding”).

Deciphering sub-tasks from search query logs becomes an important problem since users might exhibit different search preferences as well as expend different amounts of search effort while executing the sub-tasks. For example, while planning a wedding, users might choose to spend more time and effort on searching for a suitable venue, while spending considerably less on the choice of a wedding cake. However, even before we can analyze the variance in search effort across sub-tasks, it becomes imperative to successfully identify and extract sub-tasks for a specific task from search query logs. This turns out to be a complex problem for two reasons. First, the number of sub-tasks in a given task is not a

Proceedings of NAACL-HLT 2016, pages 599–605,
San Diego, California, June 12-17, 2016.

parameter than can be explicitly defined, and is generally task dependent. Second, while similar sounding queries like ”wedding planning checklist” and ”wedding dress” belong to the same task, they inherently represent different sub-tasks. This necessitates the use of advanced distancing techniques, beyond the usual bag-of-words or TF-IDF approaches.

In our current study, we propose a method for extracting search sub-tasks from a given collection of queries constituting a complex search task, using a non-parametric Bayes approach. Our generative model is not restricted by a fixed number of sub-task clusters, and assumes an infinite number of latent groups, with each group described by a certain set of parameters. We specify our non-parametric model by defining a Distance-dependent Chinese Restaurant Process (dd-CRP) prior and a Dirichlet multinomial likelihood (Blei and Frazier, 2011). Further, we draw on recent advancements that emphasize the superiority of embedding based distancing approaches over others, especially when comparing documents with less or no common words (Mikolov et al., 2013). We enrich our non-parametric model by working in the vector embedding space and propose a word-embedding based distance measure (Kusner et al., 2015) to encode query distances for efficient sub-task extraction.

2 Related Work

Web search logs have been extensively studied to generate insights and provide explicit cues about the information seeking behavior of users, that would improve their search experiences. There have been attempts to extract in-session tasks (Jones and Klinkner, 2008; Lucchese et al., 2011; Spink et al., 2005), and cross-session tasks (Wang et al., 2013; Kotov et al., 2011; Li et al., 2014) from query sequences based on classification and clustering methods. Hagen *et al.* (Hagen et al., 2013) have recently presented a cascading method for logical session detection that can also be applied to search mission detection. Kotov et al (Kotov et al., 2011) and Agichtein et al (Agichtein et al., 2012) have studied the problem of cross-session task extraction via binary same-task classification. Unfortunately, pairwise predictions alone cannot generate the partition of tasks, and post-processing is needed to obtain the final task partitions (Liao et al., 2012).

Some previous attempts have been made to support people engaged in complex tasks by allowing them to take notes and record results that they already examined (Donato et al., 2010), or to provide task continuation assistance (Morris et al., 2008). Jones et al. (Jones and Klinkner, 2008) was the first work to consider the notion that there may be multiple sub-tasks associated with a user’s informational needs. However, they fall short of proposing a method to identify a task from queries. Since most of these task extraction methods are based on relating a user’s current query to one of her previous tasks, these methods cannot be directly used in finding and extracting sub-tasks. As a result, while task extraction methods abound, very little has been done to explicitly identify the sub-tasks from within complex search tasks.

3 Extracting Sub-tasks

Consider a collection of queries (Q) issued by search engine users, trying to accomplish certain search tasks. Quite often, these search tasks (e.g. planing a trip) are complex and conceptually decompose into a set of sub-tasks (e.g. booking flights, finding places of interest etc), each of which warrants the user to further issue multiple queries to solve. It is important to note that while the queries are observed, the inherent sub-tasks and their numbers are latent. Given a collection of *on-task* queries, extracted using a standard task extraction algorithm, our goal is to extract these sub-tasks from the *on-task* query collection.

The distance dependent Chinese restaurant process (dd-CRP) (Blei and Frazier, 2011) was recently introduced to model random partitions of non-exchangeable data. To extract sub-tasks, we consider the dd-CRP model in an embedding-space setting and place a dd-CRP prior over the search tasks.

3.1 Nonparametric Priors for Sub-tasks

The Chinese restaurant process (CRP) is a distribution on all possible partitions of a set of objects (in our case, queries). The generative process can be described via a restaurant with an infinite number of tables (in our case, sub-tasks). Customers (queries) i

enter the restaurant in sequence and select a table z_i to join. They pick an occupied table with a probability proportional to the number of customers already sitting there, or a new table with probability proportional to a scaling parameter α. The dd-CRP alters the CRP by modeling customer links not to tables, but to other customers.

In our sub-task extraction problem, each task is associated with a dd-CRP and its tables are embellished with IID draws from a base distribution over mixture component parameters. Let z_i denote the ith query assignment, the index of the query with whom the ith query is linked. Let d_{ij} denote the distance measurement between queries i and j, let D denote the set of all distance measurements between queries, and let f be a decay function. The distance dependent CRP independently draws the query assignments to sub-tasks conditioned on the distance measurements,

$$p(z_i = j|D, \alpha) \propto \begin{cases} f(d_{ij}) & \text{if } j \neq i \\ \alpha & \text{if } j = i \end{cases}$$

Here, d_{ij} is an externally specified distance between queries i and j, and α determines the probability that a customer links to themselves rather than another customer. The monotonically decreasing decay function $f(d)$ mediates how the distance between two queries affects their probability of connecting to each other. The overall link structure specifies a partition: two queries are clustered together in the same sub-task if and only if one can reach the other by traversing the link edges. $R(q_{1:N})$ maps query assignments to sub-task assignments.

Given a decay function f, distances between queries D, scaling parameter α, and an exchangeable Dirichlet distribution with parameter λ, N M-word queries are drawn as follows,

1. For $i \in [1, N]$, draw $z_i \sim dist - CRP(\alpha, f, D)$.
2. For $i \in [1, N]$,
   (a) If $z_i \notin R^*_{q_{1:N}}$, set the parameter for the ith query to $\theta_i = \theta_{q_i}$. Otherwise draw the parameter from the base distribution, $\theta_i \sim Dirichlet(\lambda)$.
   (b) Draw the ith query terms, $w_i \sim Mult(M, \theta_i)$.

We experimented with 3 different values of alpha and reported the best performing results. We next define the distance and decay functions which help us find task-specific query distances.

3.2 Quantifying Task Based Query Distances

Word embeddings capture lexico-semantic regularities in language, such that words with similar syntactic and semantic properties are found to be close to each other in the embedding space. We leverage this insight and propose a novel query-query distance metric based on such embeddings. We train a skip-gram word embeddings model where a query term is used as an input to a log-linear classifier with continuous projection layer and words within a certain window before and after the words are predicted. We next describe how we use these query term embedding vectors to define query distances.

For a search task like "planning a wedding", frequent queries include *wedding checklist*, *wedding planning* and *bridal dresses*. Ideally, checklist and planning related queries constitute a different subtask than bridal dresses. Given the overall context of weddings, words like *checklist* and *dresses* are more informative than generic words like *weddings*. To this end, we classify each word as **background word** or **subtask-specific word** using a simple frequency based approach on the given collection of *on-task* query terms and use a weighted combination of their embedding vectors to encode a query's vector:

$$V_q = \frac{1}{n_{terms}} \sum_i \frac{n_{q_{t_i}}}{\Sigma_q n_q} V_{t_i} \quad (1)$$

where t_i is the i-th term in the query q, $n_{q_{t_i}}$ is the number of queries in the current task which contain the term t_i. We encode each query by its corresponding embedding vector representation V_q and take the cosine distance of these vectors while defining d_{ij}. We consider a simple window decay $f(d) = 1[d < a]$ to only considers queries that are separated from the current query for a given sub-task, by a distance of, at most, a .

3.3 Posterior Inference

The posterior of the proposed dd-CRP model is intractable to compute because the dd-CRP places a prior over a combinatorial number of possible customer configurations. We employ a Gibbs sampler,

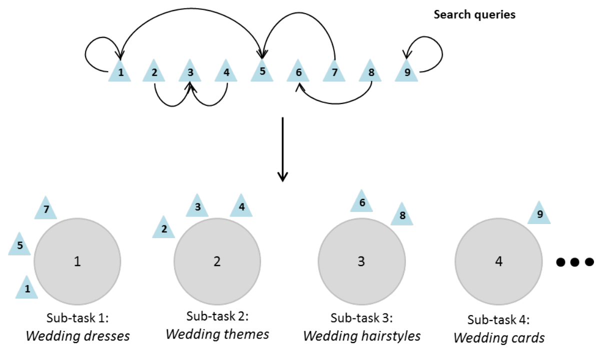

Figure 1: Visual formulation of the proposed approach. The tables represent the different sub-tasks while each triangle represents the search queries. Query assignment leads to sub-task assignments.

wherein we iteratively draw from the conditional distribution of each latent variable, given the other latent variables and observations.
The Gibbs sampler iteratively draws from

$$\begin{aligned} p(z_i^{new}|z_{-i},x) &\propto p(z_i^{new}|D,\alpha) \\ & p(x|t(z_{-i}\cup z_i^{new}),G_0) \end{aligned} \tag{2}$$

The first term is the dd-CRP prior and the second is the likelihood of observations (x) under the partition, and $t(z)$ is the sub-task formed from the assignments z. We employ a Dirichlet-Multinomial conjugate distribution to model the likelihood of query terms.

Queries are assigned to sub-tasks by considering sets of queries that are reachable from each other through the query assignments. Notice that many configurations of query assignments might lead to the same sub-task assignment. Finally, query assignments can produce a cycle, e.g., query 1 linking with 2 and query 2 linking with 1. This still determines a valid sub-task assignment: all queries linked in a cycle are assigned to the same sub-task. Figure 1 provides a pictorial representation of the sub-task assignment process.

4 Experimental Evaluation

In this section, we evaluate the robustness of the proposed sub-task extraction framework. In addition to qualitative analysis of the extracted sub-tasks, we perform a user judgment study to evaluate the quality of the extracted sub-tasks.

4.1 Dataset & Baselines

We make use of the AOL log dataset which consists of 20M web queries collected over three months (Pass et al., 2006). The dataset comprises of five fields viz. the search query string, the query time stamp, the rank of the selected item (if any), the domain of the selected items URL (if any), and a unique user identifier. We augment on-task queries extracted from the AOL logs with the related searches output from different search engines by making use of their APIs.

To compare the performance of the proposed subtask extraction algorithm, we baseline against a number of methods including state-of-the-art task extraction systems, in addition to parametric and non-parametric clustering approaches:

1 **QC-HTC** (Lucchese et al., 2011): a frequently used search task identification method.

2 **LDA** (Blei et al., 2003): a topic model based baseline which aggregates queries (similar to tweet aggregation as proposed in (Mehrotra et al., 2013)) in a session to form a document and learns an LDA model on top of it.

3 **vanilla-CRP**: a vanilla non-parametric CRP model (Wang and Blei, 2009).

4 **Proposed Approach**: the proposed embedding based dd-CRP model.

4.2 Qualitative Evaluation

Table 1 shows some exemplar sub-tasks identified by the proposed model and the baseline methods using a CRP, QC-HTC and a LDA process. Each task is visualized using four search queries that were most frequently executed in relation to that sub-task, but not in any specific order among themselves. The task selected for this illustration was that of planning a wedding, and the three sub-tasks identified using our proposed method, for this particular task were wedding hairstyles, wedding dresses, and wedding cards. In comparison, however, the baseline methods failed to identify diagnostic clusters. For instance, LDA grouped wedding insurance, wedding planning books and wedding cards as a single sub-task, while CRP grouped wedding planning kits, wedding dresses and wedding decorations into

Proposed Approach			LDA		
sub-task 1	**sub-task 2**	**sub-task 3**	**sub-task 1**	**sub-task 2**	**sub-task 3**
wedding hairstyles	used wedding dresses	wedding card holders	wedding insurance	christian wedding vows	make wedding invitations
wedding hair dos	colorful bridal gowns	indian wedding program	destination wedding	brides	wedding cakes pictures
curly wedding hairstyles	preowned wedding dresses	wedding program	wedding planning book	cheap wedding dresses	planners
pictures of wedding hair	wedding attire	regency wedding cards	party supply stores	tea length wedding dresses	wedding colors
CRP			**QC-HTC**		
sub-task 1	**sub-task 2**	**sub-task 3**	**sub-task 1**	**sub-task 2**	**sub-task 3**
wedding planning kit	wedding theme	wedding insurance	wedding insurance	christian wedding vows	cheap dresses
destination wedding	wedding guide	weddings in vegas	destination wedding	plus size bridesmaid	wedding cakes pictures
wedding table decorations	save the date ideas	wedding cakes pictures	financing wedding rings	wedding colors	pricing weddings
1930s wedding pictures	wedding vacation	planning a wedding	party supply stores	tea length wedding dresses	wedding dresses discounts

Table 1: Qualitative Analysis of Sub-Tasks extracted by different approaches.

a single sub-task. Our proposed method, however, demonstrated remarkably good discriminant validity, as is clear from Table 1.

4.3 User Study

Evaluation of tasks and sub-tasks is an open research question. Owing to the absence of ground truth data on sub-task classification, we resort to user judgments in order to validate the quality of sub-tasks extracted. We select a sub-task at random and then choose a randomly selected pair of queries from that sub-task. Next, we ask the judges, recruited via AMT[1], to affirm or deny if the two queries should be assigned to the same sub-task category. We repeat this process for a total of 100 iterations and compare the results with the ones predicted by our proposed approach, as well as with the ones predicted by the baselines.

We report the proportion of correct matches (i.e. proportion of times our predicted sub-task classifications matched the expert judgments) in Fig. 2. The label agreement among the judges was 85.4% and the performance differences were statistically significant. It is clear that our proposed method outperforms both, task extraction & topic model based baselines in making correct sub-task classifications.

5 Results & Discussion

Web search tasks are often complex and comprise several constituent sub-tasks. In this paper we offer a non-parametric Bayesian approach to identifying sub-tasks by grouping search queries using an embedding based dd-CRP approach. The proposed model combines insights from Bayesian nonparametrics and distributional semantics to extract sub-tasks which are not only meaningful but are also coherent. We evaluate our proposed method on the popular AOL search log dataset augmented with related search queries and demonstrate superiority over comparable approaches such as LDA and CRP. Further, we contend that our proposed approach is significantly more useful in online environments where the number of sub-tasks is never known apriori and impossible to ascertain or approximate.

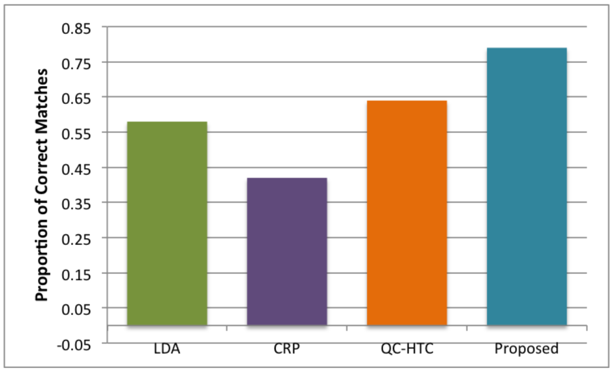

Figure 2: Judgments results for sub-task validity across compared approaches.

In future work, we intend to consider hierarchical extensions for extracting hierarchies of tasks-subtasks. Further, using an embedding based distancing scheme, we offer an improvement in empirical performance over prior clustering approaches that have used either a bag-of-words or TF-IDF based solution. Our method offers search engine providers with a novel method to identify and analyze user task-behavior, and better support task decisions on their platforms.

Probabilistic Models for Learning a Semantic Parser Lexicon

Abstract

We introduce several probabilistic models for learning the lexicon of a semantic parser. Lexicon learning is the first step of training a semantic parser for a new application domain and the quality of the learned lexicon significantly affects both the accuracy and efficiency of the final semantic parser. Existing work on lexicon learning has focused on heuristic methods that lack convergence guarantees and require significant human input in the form of lexicon templates or annotated logical forms. In contrast, our probabilistic models are trained directly from question/answer pairs using EM and our simplest model has a concave objective that guarantees convergence to a global optimum. An experimental evaluation on a set of 4th grade science questions demonstrates that our models improve semantic parser accuracy (35-70% error reduction) and efficiency (4-25x more sentences per second) relative to prior work despite using less human input. Our models also obtain competitive results on GEO880 without any dataset-specific engineering.

1 Introduction

Semantic parsing has recently gained popularity as a technique for mapping from natural language to a formal meaning representation language, e.g., in order to answer questions against a database (Zelle and Mooney, 1993; Zettlemoyer and Collins, 2005). In order to train a semantic parser, one must first provide a *lexicon*, which is a mapping from words in the language to statements in the meaning representation language. This mapping defines the grammar of the parser and thereby determines the set of meaning representations that can be produced for any given sentence. Therefore, a good lexicon is necessary to achieve both high accuracy and parsing speed. However, the lexicon is unobserved in real semantic parsing applications, leading us to ask: *how do we learn a lexicon for a semantic parser?*

This paper presents several novel probabilistic models for learning a semantic parser lexicon. Existing lexicon learning algorithms are heuristic in nature and require either annotated logical forms or manually-specified lexicon entry templates during training. In contrast, our models do not require such templates and can be trained from question/answer pairs and other forms of weak supervision. Training consists of optimizing an objective function with Expectation Maximization (EM), thereby guaran-

Proceedings of NAACL-HLT 2016, pages 606–616,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

teeing convergence to a local optimum. Furthermore, the objective function for our simplest model is *concave*, guaranteeing convergence to a global optimum. Our approach generates a probabilistic context-free grammar that represents the space of correct semantic parses for each question; once trained, our approach derives lexicon entries from the most likely parse of each question (Figure 1).

We present an experimental evaluation of our lexicon learning models on a data set of food chain questions from a 4th grade science domain. These questions concern relations between organisms in an ecosystem and have challenging lexical diversity and question length. Our models improve semantic parser accuracy (35-70% error reduction) over prior work despite using less human input. Furthermore, our best model produces a lexicon that contains 40x fewer entries than the most accurate baseline, resulting in a semantic parser that is 4x faster. Our models also obtain competitive results on GEO880 without any dataset-specific engineering.

2 Prior Work

Work on lexicon learning falls into two categories:

Pipelined approaches build a lexicon before training the parser, either by manually defining it (Lee et al., 2014; Angeli et al., 2012) or by using a collection of heuristics. The heuristics often take the form of *lexicon templates*, which are rules that create lexicon entries by pattern-matching training examples (Liang et al., 2011; Krishnamurthy and Mitchell, 2012; Krishnamurthy and Kollar, 2013). These approaches require new lexicon templates for each application. More complex heuristic algorithms have been proposed based on word alignments (Wong and Mooney, 2006; Wong and Mooney, 2007) or common substructures in the meaning representation (Chen and Mooney, 2011); these algorithms all require annotated logical forms.

Joint approaches simultaneously learn a lexicon and the parameters of a semantic parser. Typically, these algorithms use lexicon templates to generate a set of lexicon entries for each example, then heuristically select a subset of these entries to include in the global lexicon while training the parser (Zettlemoyer and Collins, 2005; Zettlemoyer and Collins, 2007; Artzi and Zettlemoyer, 2013b; Artzi et al., 2014). UBL takes a different approach that performs top-down, iterative splits of an annotated logical form for each training example (Kwiatkowski et al., 2010; Kwiatkowski et al., 2011). Artzi et al. (2015) combine templates with top-down splitting. The heuristic search performed by these algorithms can be difficult to control and we empirically found that these algorithms often selected overly-specific lexicon entries (see Section 4.4).

Other work has avoided the lexicon learning problem altogether by searching over all possible meaning representations (Kate and Mooney, 2006; Clarke et al., 2010; Goldwasser et al., 2011; Berant and Liang, 2014; Pasupat and Liang, 2015; Reddy et al., 2014). The challenge of this approach is that the space of meaning representations for a sentence can be very large, making parsing less efficient and learning more difficult. A practical compromise is to combine a (possibly minimal) lexicon with flexible parsing operations (Liang et al., 2011; Zettlemoyer and Collins, 2007; Poon, 2013; Parikh et al., 2015).

Our lexicon learning models are closely related to machine translation word alignment models (Brown et al., 1993) – our key insight is that *lexicon learning is equivalent to word alignment where the tokenization of one of the sentences is unobserved*. Thus, our models simultaneously "tokenize" the logical form – using a splitting process similar to UBL – and align the resulting logical form "tokens" to words.

3 Probabilistic Models for Lexicon Learning

This section describes our lexicon learning models. For concreteness, we focus on learning a lexicon for a Combinatory Categorial Grammar (CCG) semantic parser with lambda calculus logical forms as the meaning representation; however, our models are applicable to other semantic parsing formalisms and meaning representation languages.

Our models learn a CCG lexicon from a data set of question/label pairs $\{(\mathbf{w}^i, L^i)\}_{i=1}^n$. Each question is a sequence of words, $\mathbf{w}^i = [w_1^i, w_2^i, ...]$, and each label is a *set* of logical forms, $L^i = \{\ell_1^i, ...\}$. Labeling each question with a set of logical forms generalizes many weak supervision settings, including ambiguous supervision (Kate and Mooney, 2007) and ques-

Training Example:

$\mathbf{w}$ = What is the predator of bass ?
L = $\{\lambda x.\textsc{eats}(x, \textsc{bass}),$
$\lambda x.\textsc{cause}(\textsc{increase}(\textsc{bass}), \textsc{increase}(x)),$
$...\}$

Generated Grammar:

Unary rules:
$L \rightarrow \lambda x.\textsc{eats}(x, \textsc{bass})$
$L \rightarrow \lambda x.\textsc{cause}(\textsc{increase}(\textsc{bass}), \textsc{increase}(x))$

Nonterminal rules:
$\lambda x.\textsc{eats}(x, \textsc{bass}) \rightarrow \textsc{bass}\ \ \lambda f.\lambda x.\textsc{eats}(x, f)$
$\lambda x.\textsc{eats}(x, \textsc{bass}) \rightarrow \lambda f.\lambda x.\textsc{eats}(x, f)\ \ \textsc{bass}$
$\textsc{bass} \rightarrow \textsc{skip}\ \ \textsc{bass}$
...

Terminal rules:
$\lambda x.\textsc{eats}(x, \textsc{bass}) \rightarrow$ what
$\lambda x.\textsc{eats}(x, \textsc{bass}) \rightarrow$ is
$\textsc{skip} \rightarrow$ what
...

Figure 2: Training example (top) and several of the rules in its logical form derivation grammar (bottom).

tion/answer pairs (Liang et al., 2011).[1] The output of learning is a collection of lexicon entries $w := C : \ell$ mapping word w to syntactic category C and logical form ℓ.

Our models are generative models of questions given a label, $P(\mathbf{w}|L)$. The key component of each model is a probabilistic context-free grammar (PCFG) over *correct* logical form derivations. A parse tree in this grammar simultaneously represents (1) the choice of a logical form $\ell \in L$, (2) the way ℓ is constructed from smaller parts, and (3) the alignment between these parts and words in the question. Training each model amounts to learning the rule probabilities of this grammar, including which logical forms are likely to generate which words. Parsing an example with the trained grammar produces an alignment between words and logical forms that is used to construct a lexicon.

3.1 Logical Form Derivation Grammar

The logical form derivation grammar is a PCFG constructed to represent the set of correct logical form derivations – i.e., correct semantic parses – of each training example. The grammar's nonterminals are logical forms and its binary production rules represent ways that pairs of logical forms can combine in the semantic parser. The grammar's terminals are words and its terminal production rules represent lexicon entries. The complete grammar is a union of many smaller grammars, each of which is constructed to represent the logical form derivations of a single example. Figure 2 shows a training example and a portion of the grammar generated for it, and Figure 1 shows a parse tree in the grammar.

Our algorithm for constructing the PCFG for a training example $(\mathbf{w}, L)$ uses a top-down approach that iteratively splits logical forms in L. Assume we are given a procedure $\textsc{split}(f)$ that outputs a list of ways to split f into a pair of logical forms (g, h). Grammar generation performs the following steps:

1. **Model weak supervision.** Add L to the grammar as a nonterminal and add a unary rule $L \rightarrow \ell$ for all $\ell \in L$.

2. **Enumerate logical form splits.** For all $\ell \in L$, perform a depth-first search over logical forms starting at ℓ. To explore a logical form f during the search, use $\textsc{split}(f)$ to produce a collection of g, h pairs. For each g, h pair, add the binary rules $f \rightarrow g\ h$ and $f \rightarrow h\ g$ to the grammar, then add g and h to the search queue for later exploration.

3. **Create lexicon entries.** Add a terminal rule $f \rightarrow w$ to G for every word in the question, $w \in \mathbf{w}$, and logical form f encountered during the search above.

4. **Allow word skipping.** Add a special $\textsc{skip}$ nonterminal, along with the rules $f \rightarrow f\ \textsc{skip}$, $f \rightarrow \textsc{skip}\ f$ and $\textsc{skip} \rightarrow w$ for all logical forms f and words $w \in \mathbf{w}$.

The $\textsc{split}$ procedure required above depends on the meaning representation language, but is application-independent. For our lambda calculus representation, $\textsc{split}(f)$ returns a list of logical forms g, h such that $f = g(h)$. We use similar constraints as Kwiatkowski et al. (2011) to keep the number of splits manageable. Note that $\textsc{split}$ could also include composition by returning g, h

[1] In the second case, the set L can be generated by enumerating logical forms and evaluating each one to determine if it produces the correct answer. See Section 5 for a discussion of the benefits and limitations of this process.

pairs such that $f = \lambda x.g(h(x))$; however, we did not explore this possibility in this paper.

An important property of this grammar is that it *excludes many logical form derivations that cannot lead to the label*. For example, the grammar in Figure 2 does not let us apply $\lambda x.\text{EATS}(x, \text{BASS})$ to BASS – even though this operation would be permitted by CCG – because there is no way to reach the label L from the result $\text{EATS}(\text{BASS}, \text{BASS})$. This property reduces the number of possible parses of a question relative to a CCG parser with the same lexicon entries, making parsing more efficient.

The logical form derivation grammar G is constructed by applying the above process to every example in the data set. Let $P(t|L;\theta)$ denote the probability of generating tree t from G given $\text{ROOT}(t) = L$ and parameters θ. This probability factors into a product of production rule probabilities:

$$P(t|L;\theta) = \prod_{(f \to g\ h) \in t} P(f \to g\ h;\theta) \times \prod_{(f \to w) \in t} P(f \to w;\theta)$$

In the above equation, $P(f \to g\ h;\theta)$ and $P(f \to w;\theta)$ represent the conditional probability of selecting a production rule given the nonterminal f. We use $P(\mathbf{w}, t|L;\theta)$ to denote $P(t|L;\theta)$ where the terminals of t are equal to the question $\mathbf{w}$. In the following, sums over trees t are implicitly over all trees permitted by G.

3.2 Independent Model

The independent model assumes that each word w_j of a question $\mathbf{w}$ is generated independently from a parse tree t chosen uniformly at random given the label L. This simple model allows two words in the same question to be generated by different trees. The probability of a question given a label is:

$$P(\mathbf{w}|L;\theta) = \prod_{j=1}^{|\mathbf{w}|} \sum_{f} P(f \to w_j;\theta) \#(f, j, L, |\mathbf{w}|)$$

The final term $\#(f, j, L, |\mathbf{w}|)$ is the fraction of trees with root L and $|\mathbf{w}|$ terminals where the jth terminal symbol is generated by nonterminal f. This term appears due to the assumption that trees are drawn uniformly at random. The parameters θ of this model are the terminal production rule probabilities, which are modeled as a conditional probability table: $P(f \to w;\theta) = \theta_{f,w}$ where $\sum_w \theta_{f,w} = 1$.

The independent model is a generalization of IBM Model 1 (Brown et al., 1993) to the lexicon learning problem, and – like IBM Model 1 – its loglikelihood function is *concave* (see Appendix A). Therefore, the EM algorithm will converge to a global optimum of the data loglikelihood under this model.

3.3 Coupled Model

The coupled model generates the entire question $\mathbf{w}$ from a single parse tree t that is generated given L. This model removes the previous model's naïve assumption that each word is generated independently. The probability of a question given a label under this model is:

$$P(\mathbf{w}|L;\theta) = \sum_{t} P(\mathbf{w}, t|L;\theta)$$

Theoretically, we could learn both of the production rule distributions that compose $P(\mathbf{w}, t|L;\theta)$ in this formulation. However, in practice, the large number of nonterminals makes it challenging to learn a conditional probability table for the binary production rules. Therefore, we again assume the trees are drawn uniformly at random and only learn a conditional probability table for the terminal production rules.

3.4 Coupled Loglinear Model

The coupled loglinear model replaces the conditional probability tables of the coupled model with loglinear models. Loglinear models can share parameters across different – but intuitively similar – production rules. For example, both $\lambda x.\text{EATS}(x, \text{BASS})$ and $\lambda x.\text{EATS}(x, \text{FROG})$ should have similar distributions over production rules when BASS is appropriately replaced by FROG. We can produce this effect with loglinear models by assigning similar feature vectors to these rules.

This model uses *three* locally-normalized loglinear models to parameterize the distribution over production rules. First, a rule model decides whether or not to apply a terminal production rule. Next, given this model's response, a second loglinear model decides which of the chosen kind of rules to apply. This approach ensures that each nonterminal symbol has a proper conditional probability distribution over rules. The production rule distributions are parameterized as:

$$P(f \rightarrow w; \theta) = \frac{\exp(\theta_r^T \phi_r(f) + \theta_t^T \phi_t(f, w))}{Z_r Z_t(f)}$$
$$P(f \rightarrow g\ h; \theta) = \frac{\exp(\theta_n^T \phi_n(f, g, h))}{Z_r Z_n(f)}$$

In the above equation, the r, t and n subscripts indicate terms of the rule, terminal and nonterminal models, respectively. The Z_r, $Z_t(f)$ and $Z_n(f)$ terms denote the partition functions of each model, and ϕ_r, ϕ_n and ϕ_t are functions mapping nonterminals and production rules to feature vectors. We use indicator features for logical form patterns, where each pattern is produced by replacing all of a logical form's subexpressions below a certain depth with their types.

3.5 Training with Expectation Maximization

We train all three models by maximizing data log-likelihood with EM (Dempster et al., 1977). Training the independent model is equivalent to training a mixture of multinomials where each word of each question has its own prior over cluster assignments. Let θ^m represent the model parameters on the mth training iteration. The E-step calculates expected count of each terminal production rule:

$$E_{f,w} \leftarrow \sum_{i,j:w_j^i = w} P(f \rightarrow w_j^i; \theta^m) \#(f, j, L^i, |\mathbf{w}^i|)$$

The term $\#(f, j, L^i, |\mathbf{w}^i|)$ – representing the fraction of trees where nonterminal f generates the jth word of question i – can be calculated by parsing each example once using the inside/outside algorithm. The M-step re-estimates the terminal production rule probabilities using these expected counts:

$$\theta_{f,w}^{m+1} \leftarrow \frac{E_{f,w}}{\sum_{w'} E_{f,w'}}$$

Training the coupled models is a standard application of EM to learning the parameters of a latent probabilistic CFG. The E-step calculates the expected number of occurrences of each production rule in each example:

$$E_{f,g,h} \leftarrow \sum_{i,t} \#(f \rightarrow g\ h, t) P(t | \mathbf{w}^i, L^i; \theta^m)$$
$$E_{f,w} \leftarrow \sum_{i,t} \#(f \rightarrow w, t) P(t | \mathbf{w}^i, L^i; \theta^m)$$

In the above equation, the function $\#(f \rightarrow w; t)$ returns the number of occurrences of $f \rightarrow w$ in t. These expected counts can be computed efficiently using the inside/outside algorithm.[2] The M-step of the coupled model is the same as that of the independent model above. The M-step of the coupled loglinear model solves an optimization problem to fit the loglinear models to the computed expectations (Berg-Kirkpatrick et al., 2010):

$$\theta^{m+1} \leftarrow \arg\max_{\theta} \quad \sum_{f,w} E_{f,w} \log P(f \rightarrow w; \theta) + \sum_{f,g,h} E_{f,g,h} \log P(f \rightarrow g\ h; \theta)$$

This problem factors into three separate optimization problems: a binary logistic regression for the rule model, and estimating two conditional distributions over nonterminal and terminal production rules. We use L-BFGS to solve these problems.

3.6 Producing a Lexicon

Given parameters θ and a data set $\{(\mathbf{w}^i, L^i)\}_{i=1}^n$, we produce a CCG lexicon from the terminal production rules of the most probable parse of each example. First, we parse each question $\mathbf{w}^i$ conditioning on the parse tree root being L^i. Second, we generate lexicon entries from the highest scoring parse tree for each example. We identify the nonterminal f that generates each word $w \in \mathbf{w}$ and, if $f \neq$ SKIP, create a lexicon entry $w := C : f$. As in previous work, we derive the syntactic category C from the semantic type of the logical form (Kwiatkowski et

[2] A further efficiency improvement is to note that, when parsing an example, it is sufficient to use the subset of G that was generated for it.

$\mathbf{w}$: Which organism in the diagram is eaten by the blackbird?
ℓ: $\lambda x.\text{EATS}(\text{BLACKBIRD}, x)$
c: sun → grains → blackbird → hawk → falcon
a: grains

$\mathbf{w}$: The __ is neither a producer or a consumer.
ℓ: $\lambda x.\text{NOT}(\text{ANIMAL}(x) \vee \text{PLANT}(x))$,
c: sun → grasses → hartebeest → lion
a: sun

$\mathbf{w}$: If the sun is blocked by clouds for a long period of time, which animal will be most quickly threatened by starvation?
ℓ: $\lambda x.\text{CAUSE}(\text{DECREASE}(\text{SUN}), \text{DECREASE}(x))$
c: sun → algae → shrimp → smelt → salmon
a: algae

$\mathbf{w}$: If the seals were killed off, the population of penguin would most likely
ℓ: $\lambda f.\text{CAUSE}(\text{DECREASE}(\text{SEAL}), f(\text{PENGUIN}))$
c: sun → algae → squid → penguin → seal
a: increase

Figure 3: Examples from FOODCHAINS. Each example consists of a question $\mathbf{w}$, logical form ℓ, food chain c and answer a.

al., 2011). The argument directions of C are determined by walking up the tree and noting the relative position of each of its arguments. Figure 1 shows an example of a predicted parse tree and the lexicon entries generated from it.

4 Evaluation

We compare our lexicon learning models against several baselines on two data sets: FOODCHAINS, containing 4th grade science food chain questions, and GEO880, containing geography questions. These data sets each present different challenges for lexicon learning: FOODCHAINS has more difficult language – long questions and more lexical variation – while GEO880 has more complex logical forms. Our results demonstrate that our models perform better than several baselines with difficult language while simultaneously performing reasonably well with complex logical forms.

Code, data and other supplementary material for this paper is available at `http://www.allenai.org/paper-appendix/naacl2016-lexicon`.

	FOODCHAINS	GEO880
Examples	774	880
Word types	446	279
Word types w/o entity names	357	157
Tokens per question	11.6	7.56
Predicates in ontology	15	38
Constants per logical form	4.0	7.7

Table 1: Data statistics for FOODCHAINS and GEO880.

4.1 Data

We collected a new data set, FOODCHAINS, that contains 774 food chain questions designed to imitate actual questions from the New York State Grade 4 Regents Exam. Each example in the data set consists of a natural language question and a food chain, which is a list of organisms that eat each other. The questions are multiple choice and the answer options are either animals from the food chain or a direction of change, e.g., “increase.” Each question also has a logical form annotated by the first author, which is necessary to train some of the baseline systems. The denotation of each predicate – and therefore logical form – is a deterministic function of the food chain. Figure 3 shows some examples from this data set.

FOODCHAINS was created using Mechanical Turk. We first manually created 25 distinct food chains of various lengths containing different organisms and a set of question templates – questions with a blank – based on real Regents questions. In the first task, Turk workers were shown a randomly-selected food chain, question template, and answer, and were asked to complete the question by filling in the blank. In the second task, workers paraphrased questions from the first task, thereby eliminating the templated structure and increasing lexical variation (similar to Wang et al., (2015)). In the third task, a worker validated each question by answering it.

Statistics of FOODCHAINS are presented in Table 1 alongside corresponding statistics of GEO880 (Zelle and Mooney, 1996; Tang and Mooney, 2001; Zettlemoyer and Collins, 2005). FOODCHAINS differs from GEO880 in two significant and interesting ways. First, although the data set contains relatively few predicates, there are many ways to reference each predicate – for example, consider the diversity in references to DECREASE in Figure 3. Second, the questions are long but contain many uninformative

Model	Accuracy
Independent Model (§3.2)	78.7%
Coupled Model (§3.3)	79.0%
Coupled Loglinear Model (§3.4)	**81.7%**

Table 2: Comparison of semantic parser accuracy on FOODCHAINS when trained using our three proposed probabilistic models for lexicon learning.

words that can safely be ignored by the parser.

4.2 Methodology

We compare lexicon learning algorithms by performing an end-to-end evaluation, measuring the question answering accuracy of a CCG semantic parser trained with the learned lexicon. The parser has a rich set of features, including lexicon entry features, dependency features, and dependency distance features. The parser is also permitted to skip words in the question for a learned per-word cost. We train the parser by optimizing data loglikelihood with 100 epochs of stochastic gradient descent.

All experiments on FOODCHAINS are performed using 5-fold cross validation. All questions about a single food chain appear in the same fold, ensuring that the questions in the held-out fold reference unseen food chains.

4.3 Comparing Probabilistic Models

Our initial experiment compares the three probabilistic models proposed in Section 3 on FOODCHAINS. We generated three lexicons by training each model using 10 iterations of EM. We used a smoothing parameter of 0.1 when estimating conditional probability tables, and an L2 regularization parameter of 10^{-6} when estimating loglinear models. We also initialized the coupled model with the optimum of the independent model. All of these models are trained without labeled logical forms, instead using an automatically enumerated set of logical forms that evaluate to the correct answer.

Table 2 presents the result of this evaluation. All three models perform roughly similarly, with the coupled loglinear model slightly outperforming the others. The competitive performance of the independent model is interesting because its concave objective function is easy to optimize. The remaining experiments compare against the coupled loglinear model, which we dub PAL, short for "Probabilistic Alignments for Lexicon learning."

Model	Logical forms?	Lexicon Templates?	Accuracy	PAL % Err. Red.
PAL	**No**	**No**	**81.7%**	–
POS	**No**	Yes	70.5%	38.0%
UBL	Yes	**No**	40.6%	69.1%
ZC2007	Yes	Yes	49.4%	63.8%
ADP2014	**No**	Yes	32.4%	72.9%

Table 3: Semantic parser accuracy comparison for several lexicon learning algorithms on FOODCHAINS. The middle two columns note the human input required by each algorithm and the final column notes the relative error reduction of PAL over each baseline.

4.4 Lexicon Learning Baselines

Our second experiment compares PAL with four baseline lexicon learning algorithms. The first baseline, POS, defines a set of lexicon entries for each word in the training set based on its part-of-speech tag (Liang et al., 2011). We iteratively developed these templates to cover the data set, and the lexicon generated by these templates can correctly parse 96% of the examples in FOODCHAINS. The remaining three baselines, ZC2007 (Zettlemoyer and Collins, 2007), UBL (Kwiatkowski et al., 2011), and ADP2014 (Artzi et al., 2014), are joint lexicon and parameter learning algorithms. We used the UW SPF (Artzi and Zettlemoyer, 2013a) implementations of UBL and ZC2007. For these two models, we trained our parser using the learned lexicon to ensure consistency of implementation details.[3] We initialized UBL's parameters using GIZA++ (Och and Ney, 2003) as in the original paper. The lexicon entry templates for ZC2007 and ADP2014 are derived from the POS templates to ensure coverage of the questions; these algorithms allow each template to apply to 1-4 word phrases.

Table 3 compares the accuracy of semantic parsers trained with these baseline approaches to PAL. Our model outperforms all of the baselines, beating the most accurate baseline, POS, by more

[3] We also postprocessed the lexicon entries to improve performance, for example, by removing lexicon entries that skip words. In both cases, our parser was more accurate than the UW SPF parser.

Model	Lexicon Size	Parse Time (ms)
POS	4,282	7.8
UBL	3,356	14.9
ZC2007	2,949	43.4
ADP2014	401	1.1
Independent Model	410	6.7
Coupled Model	318	3.1
PAL	184	1.8

Table 4: Lexicon size excluding entity names and parse time per question on FOODCHAINS averaged across folds per model. Our models produce smaller lexicons that lead to faster semantic parsers.

than 10 points. Note that all of these baselines also use more human input than our model, either in the form of lexicon templates or logical forms. Table 4 compares the average number of lexicon entries and semantic parser speed of the baselines with our models. PAL produces the most compact lexicon and second fastest parser, which is 4x faster than POS, the baseline with the highest accuracy. The correlation between lexicon size and parse time is imperfect due to word frequency and co-occurrence effects.

The three joint lexicon and parameter learning algorithms perform poorly on our data set for two reasons. First, the long question length increases the difficulty of finding good lexicon entries. The algorithms with lexicon templates were frequently unable to find a correct parse for long questions, even with a large beam size – we ran ADP2014 with a beam size of 10000. (Note that POS does not suffer from this problem because it only generates lexicon entries for a few parts of speech, so most of the words in a question are ignored by default.) Second, these algorithms' discriminative objectives inherently prefer lexicon entries with highly specific word sequences. This preference interacts poorly with the uninformative words in the data set, leading these algorithms to produce many lexicon entries for long phrases that do not generalize well. The lexicon sizes in Table 4 are suggestive of this problem for ZC2007 and UBL; ADP2014 also has this problem, but its voting mechanism prunes lexicon entries much more aggressively. We tried to solve this problem for ZC2007 and ADP2014 by restricting lexicon templates to apply to at most 1 word, but this change actually reduced accuracy. An investigation of this phenomenon found that reducing the length of the templates made it even more difficult for these models to find correct parses for long questions.

Model	Accuracy
UBL (Kwiatkowski et al., 2011)	88.6%
ZC2007 (Zettlemoyer and Collins, 2007)	86.1%
PAL	81.8%
w/ factored lexicon	85.4%

Table 5: Logical form accuracy on GEO880 compared to previously reported CCG parsing results. Both UBL and ZC2007 use special CCG extensions to improve performance; adding one of these to PAL brings its accuracy near that of these systems.

In contrast to these baselines, our models do not suffer from either of these problems because the logical form derivation grammar restricts the search to *correct* derivations and our generative objective prefers frequently-occurring lexicon entries. Our models actually consider a *larger* space of possible lexicon entries than ZC2007 and ADP2014 with 1 word templates, yet find better lexicon entries.

4.5 Geo880 Evaluation

We performed an additional evaluation on GEO880 to demonstrate that our models can work with more complex logical forms. GEO880 is a good data set for this evaluation because its logical forms contain, on average, about twice as many constants as FOODCHAINS. We applied PAL to generate a lexicon for this data set using its included logical form labels, then trained a CCG semantic parser with this lexicon. Table 5 compares the accuracy of this parser with previous CCG lexicon learning results on this data set using the standard 600/280 train/test split. The comparison to PAL is inexact because both prior systems use CCG parsers with special extensions that improve performance on this data set. UBL uses factored lexicon entries that generalize better to certain infrequent entries, and ZC2007 includes relaxed parsing operators that fix common parsing errors. Examining the errors made by our parser, we found many cases where these extensions would help. We therefore trained another CCG parser using a lexicon generated by postprocessing PAL's lexicon to include factored lexicon entries. This parser achieves an accuracy close to previous work.

5 Discussion

We introduce several probabilistic models for learning a semantic parser lexicon that can be trained from question/answer pairs and other forms of weak supervision. Our experimental results demonstrate that our models improve semantic parser accuracy and efficiency relative to prior work on data sets with more challenging language, despite using less human input. Furthermore, we find that our independent model is nearly as effective as more complex models, but has a concave objective function that guarantees training converges to a global optimum.

A possible complaint about our approach is that, when training from question/answer pairs, it is not practical to enumerate all logical forms that produce the correct answer. We believe this complaint is misguided because enumerating logical forms is unavoidable in the question/answer setting. *Every* algorithm uses an enumerate-and-test approach to identify correct logical forms; this process occurs in the gradient computation of semantic parser training and in template-based lexicon learning algorithms such as ADP2014. The critical question is not *whether* enumeration is used, but rather *how* logical forms are enumerated. Many strategies are possible and different strategies are likely to be effective on different data sets. In fact, the failure of template-based algorithms on FOODCHAINS is largely a failure of their template-guided enumeration strategy to find correct logical forms. Choosing an enumeration strategy and related questions – e.g., does semantic parser parameter learning affect the enumeration? – are empirical questions that must be decided on a task-specific basis.

A recent trend in semantic parsing has been to avoid lexicon learning, instead directly searching the space of all possible logical forms. However, we think that lexicon learning still serves a valuable purpose. Fundamentally, a lexicon constrains the space of logical forms searched by a semantic parser; these constraints improve efficiency and can improve accuracy as long as they do not exclude correct logical forms. Thus, a promising approach to building a semantic parser is to automatically learn a lexicon using one of our models, then (perhaps) manually specify new parsing operations to correct any problems with the learned lexicon. We plan to apply this approach in the future to construct semantic parsers for more challenging tasks.

Appendix A: Proof of Concavity

The loglikelihood $O(\theta)$ of the independent model is:

$$\begin{aligned} O(\theta) &= \sum_{i=1}^{n} \log P(\mathbf{w}^i | L^i; \theta) \\ &= \sum_{i=1}^{n} \sum_{j=1}^{|\mathbf{w}^i|} \log \sum_{f} \theta_{f, w_j^i} \#(f, j, L^i, |\mathbf{w}^i|) \end{aligned}$$

Each $\log$ term above is concave in θ because $\log$ is a concave function applied to an affine function of θ. (Note that the $\#(f, j, L^i, |\mathbf{w}^i|)$ terms do not depend on θ.) Finally, $O(\theta)$ is concave because it is a sum of concave functions.

Unsupervised Compound Splitting With Distributional Semantics Rivals Supervised Methods

Martin Riedl and **Chris Biemann**

Computer Science Department, Technische Universität Darmstadt
Hochschulstrasse 10, D-64289 Darmstadt, Germany
{riedl,biem}@cs.tu-darmstadt.de

Abstract

In this paper we present a word decompounding method that is based on distributional semantics. Our method does not require any linguistic knowledge and is initialized using a large monolingual corpus. The core idea of our approach is that parts of compounds (like "candle" and "stick") are semantically similar to the entire compound, which helps to exclude spurious splits (like "candles" and "tick"). We report results for German and Dutch: For German, our unsupervised method comes on par with the performance of a rule-based and a supervised method and significantly outperforms two unsupervised baselines. For Dutch, our method performs only slightly below a rule-based optimized compound splitter.

1 Introduction

Germanic and agglutinative languages (e.g. German, Swedish, Finnish, Korean) have a productive morphology that allows the formation of not space-separated compounds in a much larger extent than e.g. in English. The task of separating such compounds into their corresponding single word (sub-) units is called compound splitting or decompounding.

Decompounding showed impact in several NLP applications, e.g. ASR (Adda-Decker and Adda, 2000), MT (Koehn and Knight, 2003) or IR (Monz and de Rijke, 2001), and is generally perceived as a crucial component for the processing of respective languages. However, most existing systems rely on dictionaries or are trained in a supervised fashion. Both approaches require substantial manual work and do not adapt to vocabulary change. In this paper we introduce an unsupervised method for decompounding that relies on distributional semantics. For the computation of the semantic model we solely rely on a tokenized monolingual corpus and do not require any further linguistic processing. Most previous research on compound splitting concentrates on the detection of lemmas that form the compound. Whereas this is important for several tasks, in this work we focus on the splitting of a compound into its word units without any base form reduction, arguing that lemmatization is either part of the task pipeline anyways (e.g. IR) or not required (e.g. for ASR).

2 Related Work

Approaches to automatic decompounding can be classified into corpus-driven approaches and supervised approaches. Corpus-driven approaches are usually informed by a frequency list (Koehn and Knight, 2003), by a probabilistic model (Schiller, 2005), by parallel corpora (Koehn and Knight, 2003; Macherey et al., 2011) or by the existence of periphrases (i.e. reformulations) in large monolingual corpora (Holz and Biemann, 2008). As with other tasks, supervised approaches are usually superior to unsupervised approaches if sufficient training material is provided. A straightforward yet effective supervised decompounding system is contained in the ASV Toolbox (Biemann et al., 2008), which uses trie-based datastructures for recursively splitting compounds based on learned splits. Alfonseca

Proceedings of NAACL-HLT 2016, pages 617–622,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

et al. (2008) combine several signals, including web anchor text, in an SVM-based supervised splitter. A widely used German decompounder is JWordSplitter[1], which is based on word lists of compound parts as well as manually crafted blacklists and whitelists. The NL Splitter[2] uses similar technology for Dutch compound decomposition. An unsupervised approach is presented in (Koehn and Knight, 2003): out of several splits as given by matching parts of the compound to a vocabulary list, they pick the split with the highest geometric mean of word frequencies, which is entirely corpus-driven but ignores semantic relations between the compound and its parts. Another unsupervised system is proposed by Daiber et al. (2015). They propose an analogy-based approach, which relies on word embeddings.

Decompounding is evaluated either intrinsically or in a task that benefits from it, e.g. IR (Monz and de Rijke, 2001), MT (Koehn and Knight, 2003; Macherey et al., 2011) or ASR (Adda-Decker and Adda, 2000; Ordelman et al., 2003).

3 Method

The introduced method, called `SECOS` (SEmantic COmpound Splitter)[3], is based on the hypothesis that compounds are similar to their constituting word units. Our method is based on a distributional thesaurus (DT) that is computed, based on the distributional hypothesis (Harris, 1951), using a monolingual background corpus and does not require any language-specific rules or preprocessing. We exemplify the method based on the compound noun *Bundesfinanzministerium* (*federal finance ministry*), which is assembled of the words *Bundes* (*federal*), *Finanz* (*finance*) and *Ministerium* (*ministry*).

Our method consists of three stages: First we extract a candidate word set that defines the possible word units of compounds. We present several approaches to generate such candidates. Second, we use a general method that splits the compound based on a candidate word set. Using the different candidate sets, we obtain different compound splits. Finally, we define a mechanism that ranks these splits and returns the top-ranked one.

3.1 Candidate Extraction

For the extraction of all candidates in C, we use a distributional thesaurus (DT) that is computed on a background corpus. We present three approaches for the generation of candidate sets.

When we retrieve the l most similar terms for a word w from a DT, we observe well-suited candidates that are nested in w. For example *Bundesfinanzministerium* is similar to *Bund*, *Bundes* and *Finanzministerium*. Extracting the most similar terms that are nested in w results in the first split candidate set, called *similar candidate units*.

However, only for few terms we observe nested candidates in the most similar words. Thus, we require methods to generate "back-off" candidates.

First, we introduce the *extended similar candidate units*. Here, we extract the l most similar terms for w and then grow this set by again adding their respective l most similar words. Based on these terms, we extract all words that are nested in w. This results into more but less precise decompounding candidates.

As the coverage might still be insufficient to decompound all words (e.g. entirely unseen compounds), we propose a method to generate a global dictionary of single atomic word units. For this, we iterate over the entire vocabulary of the background corpus, apply the compound splitter (see Section 3.2) to all words where we find *similar candidate units*. Then, we add these detected units to the dictionary. Finally, for word w subject to decompounding, we first extract all nested words NW from this dictionary. Then, we remove all words in NW that are nested itself in NW, resulting in the candidate set we call *generated dictionary*.

3.2 Compound Splitting

Here, we introduce the decompounding algorithm for a given candidate set. For decompounding the word w, we require a set of candidate words C. Each word in the candidate set needs to be a substring of w. We do not include candidates in C that have less than ml characters. Additionally, we apply a frequency threshold of wc. These mechanisms are intended to rule out spurious parts and 'words'

word w	Bundesfinanzministerium
candidates C w. ml=3	Finanzministerium, Ministerium, Bunde, Bund, Bundes, Minister
split possibilities	Bund-e-s-finanz-minister-ium
Merging character n-grams	
suffix-prefix prefix-suffix	Bundes-finanz-ministerium Bund-esfinanz-ministerium

Table 1: Examples of the output of our algorithms for the example term *Bundesfinanzministerium.*

that are in fact short abbreviations. We show candidates, extracted from the *similar candidate unit*, with $ml = 3$ for the example term in Table 1. Then, we iterate over each candidate $c_i \in C$ and add its beginning and ending position within w to the set S. This set is then used to identify possible split positions of w. For this, we iterate from left to right and add all split possibilities to the word w. This approach over-generates split points, as can be observed for the example word, which is split into 6 units: *Bund-e-s-finanz-minister-ium*.

To merge character n-grams, we use a suffix- and prefix-based method. The suffix merging method appends all character n-grams with n below ms to the left word. The prefix method merges all character n-grams with n below mp to the word on the right side. To avoid remaining prefixes/suffixes, we apply the opposite method afterwards. For the German language, the suffix-prefix ordering mostly yields the best output. The suffix-prefix-based approach results to *Bundes-finanz-ministerium* and the prefix-suffix method to *Bund-esfinanz-ministerium*. However for some words, the prefix-suffix generates the correct compound split, e.g. for the word *Zuschauer-er-wartung* (*audience* + *he* + *service*), which is correctly decompounded as *Zuschauer-erwartung* (*audience+expectation*).

In order to select the correct split, we compute the geometric mean of the joint probability for each split variation. For this we use word counts from a background corpus. In addition to the geometric mean formula introduced in (Koehn and Knight, 2003), we apply a smoothing factor[4] ϵ to each frequency in order to assign non-zero values to unknown units. This yields the following formula for a compound w, which is decomposed into the units $w_i, \ldots, w_N$:

$$p(w) = \left(\prod_{i}^{N} \frac{wordcount(w_i) + \epsilon}{total\_wordcount + \epsilon * \#words} \right)^{\frac{1}{N}} \quad (1)$$

Here, $\#word$ denotes the total number of words in the background corpus and $total\_wordcount$ is the sum of all word counts. Then, we select the split variation with the highest geometric mean.[5] In our example, this is the prefix-suffix-merged candidate *Bundes-finanz-ministerium.*

3.3 Split Ranking

We have examined schemes of priority ordering for integrating information from different candidate sets, e.g. using the *similar candidate units* first and only apply the other candidate sets if no split was found. However, preliminary experiments revealed that it was always beneficial to generate splits based on all three candidate sets and use the geometric mean scoring as outlined above to select the best split as decomposition of a word.

4 Datasets

For testing the performance of our method, we chose four datasets. The first dataset was manually labeled by Holz and Biemann (2008) and consists of 700 German nouns from different frequency bands. The second dataset consists of 158,653 nouns from the German newspaper magazine c't[6] and was created by Marek (2006). As third dataset we use a noun compound dataset of 54,571 nouns from GermaNet[7], which has been constructed by Henrich and Hinrichs (2011).[8] While converting these datasets for the task of compound splitting, we do not separate words in the gold standard, which comprise of prepositions, e.g. the word *Abgang (outflow)* is not split into *Ab-gang (off walk)*. To show the language independency of our method, we apply it to a

[4] We set $\epsilon = 0.01$. Using values in the range of $\epsilon = [0.0001, 1]$ we observe marginally higher scores using smaller values.

[5] Whereas our method mostly does not assume language knowledge, we uppercase the first letter of each w_i, when we apply our method on German texts.

[8] We follow Schiller (2005) and remove all words including dashs. This only affects the GermaNet dataset and reduces the effective test set to 53,118 nouns.

Dutch compound dataset proposed by van Zaanen et al. (2014). This dataset comprises of 21,997 nouns.

5 Experimental Setting

The corpus-based DT is computed following the approach by Biemann and Riedl (2013). For each word, we use the left and the right neighboring word as context representation to compute the DT. For the generation of the split candidates we rely on the $l = 200$ most similar entries for each word.

The German DT is computed based on 70 million newspaper sentences, which are extracted from the Leipzig Corpora Collection (LCC) (Richter et al., 2006). For the generation of the Dutch DT, we use the Dutch web corpus (Schäfer and Bildhauer, 2013), which is composed from 259 million sentences.[9]

We evaluate the performance of the algorithms using precision and recall as defined by Koehn and Knight (2003). As unsupervised baselines we use the split ranking by (Koehn and Knight, 2003), called KK, and the semantic analogy-based splitter (SAS) from Daiber et al. (2015).[10] As advanced systems we apply the lexicon- and rule-based JWordSplitter (JWS) and the supervised decompounding algorithm (ASV), introduced by Holz and Biemann (2008).[11] For all algorithms, we converted the splits to capture all characters in the words, reverting base forms to full forms. For Dutch, we apply the KK baseline and the NL Splitter.

6 Method Tuning

We use the small dataset with the 700 German nouns to find the best parameter settings of our method. The highest F1-scores are obtained using candidates with a frequency above 50 (wc=50) and that have more than 4 characters (ml=5). Further we append only prefixes and suffixes equal or shorter than 3 characters (ms=3 and mp=3).

The highest precision is achieved with the similar candidate units (see Table 2). However, the recall is lowest as for many words no information is available. Using the extended similarities, the precision decreases and the recall increases. The best overall performance is achieved with the generated dictionary, which yields an F1-measure of 0.9384. The selection mechanism using the geometric mean scoring brings F1-measure up to 0.9515 on this dataset.

	KK	0.9579	0.7735	0.8559
	SECOS	0.9624	0.8272	0.8897

Table 3: Results for three German datasets and for one Dutch dataset. The significantly best results are marked with an asterisk (*).

For the 700 nouns we achieve the highest precision, recall and F1-measure using our method. However, we have tuned our parameters on this dataset. Our improvement in terms of F-score is not significant[12] with respect to the ASV system, but with re-

[9] available at: `http://webcorpora.org/`.

[10] `https://github.com/jodaiber/semantic_compound_splitting`

[11] `http://wortschatz.uni-leipzig.de/~cbiemann/software/toolbox/`.

[12] We perform a Wilcoxon signed-rank test between the F1-

spect to all other systems on this dataset. Nevertheless, JWS is based on a manually created dictionary and ASV uses a supervised algorithm. On this dataset, ASV outperforms JWS. Due to their low recall, both unsupervised baselines (SAS and KK) achieve significantly lower F1-scores than SECOS.

Using the c't dataset we observe a different trend. Here, the best results are observed by using JWS followed by ASV and our method. Nevertheless, our method yields the highest precision value. Again, SAS and KK score lowest.

For the GermaNet dataset, our method significantly outperforms all others. Similar to the evaluation with the 700 nouns, JWS performs lower than the decompounding method from the ASV toolbox. Whereas our method obtains lower recall than ASV and JWS, it still significantly outperforms the unsupervised baselines and yields the overall highest precision.

In a last experiment, we show the performance on the Dutch dataset. As no trained models for JWS and ASV are available, we did not use these tools but compare to NL splitter, achieving a competitive precision but lower recall. This is caused by many short split candidates that are not detected due to the ml parameter. However, our method still beats the KK baseline significantly.

8 Error Analysis

In order to understand the errors of our method, we analyzed the compounds that have been split incorrectly. Considering the 700 German compounds our method splits 12.17% incorrectly, for the Dutch dataset, we observe the highest percentage of 32.60% incorrectly split compounds (see Table 4).

In addition, we analyzed how many compounds have been split in fewer parts (*under-split*), more parts (*over-split*) than the gold data or have the same number of splits, which, however, are incorrect (*wrongly-split*). For all datasets we observe a general trend: our method tends to suppress splitting compounds, due to the parameters *ms* and *mp* that suppress very short parts. Compounds that are split at entirely incorrect positions constitute the lowest error class. We also analyzed for incorrectly split compounds how often our method missed a split, performed a wrong split and split correctly (see bottom three lines in Table 4). This analysis supports the previous finding: most errors of our SECOS method consist of missed splits.

dataset	**700**	**c't**	**GermaNet**	**Dutch**
	number of compounds			
# incorrect	85	35177	12532	7258
% incorrect	12.17	22.17	23.26	32.60
under-split	47	23773	7972	5849
over-split	33	7843	3578	806
wrongly-split	5	3561	982	603
	number of splits			
missed	55	29213	8968	6612
wrong	43	12703	4669	1520
correct	43	20381	3777	1743

Table 4: Number of compounds that have been split incorrectly with respect to the gold data. We report numbers of how many of these compounds are split fewer (*under-split*), more often (*over-split*) or equally (*wrongly-split*) in comparison to the gold standard. In addition, we show the total number of missed, wrong and correct splits for these compounds.

9 Conclusion

In this paper we have introduced an unsupervised method for decompounding words that is based on distributional semantics. We show the impact of its components and tune its parameters on a small German dataset. On two large German datasets, we demonstrate a performance of our method that is competitive to supervised and rule-based tools and outperforms two unsupervised baselines by a large margin. Further, we demonstrated its language-independence by achieving a good performance on a Dutch dataset. In the future, we would like to assess the impact of SECOS in task-based settings as well as apply it to other compounding languages.

Weighting Finite-State Transductions With Neural Context

Pushpendre Rastogi and **Ryan Cotterell** and **Jason Eisner**
Department of Computer Science, Johns Hopkins University
{pushpendre,ryan.cotterell,eisner}@jhu.edu

Abstract

How should one apply deep learning to tasks such as morphological reinflection, which stochastically edit one string to get another? A recent approach to such sequence-to-sequence tasks is to compress the input string into a vector that is then used to generate the output string, using recurrent neural networks. In contrast, we propose to keep the traditional architecture, which uses a finite-state transducer to score *all possible output strings*, but to augment the scoring function with the help of recurrent networks. A stack of bidirectional LSTMs reads the input string from left-to-right and right-to-left, in order to summarize the *input context* in which a transducer arc is applied. We combine these learned features with the transducer to define a probability distribution over *aligned* output strings, in the form of a weighted finite-state automaton. This reduces hand-engineering of features, allows learned features to examine unbounded context in the input string, and still permits exact inference through dynamic programming. We illustrate our method on the tasks of morphological reinflection and lemmatization.

1 Introduction

Mapping one character sequence to another is a structured prediction problem that arises frequently in NLP and computational linguistics. Common applications include grapheme-to-phoneme (G2P), transliteration, vowelization, normalization, morphology, and phonology. The two sequences may have different lengths.

Traditionally, such settings have been modeled with weighted finite-state transducers (WFSTs) with parametric edge weights (Mohri, 1997; Eisner, 2002). This requires manual design of the transducer states and the features extracted from those states. Alternatively, deep learning has recently been tried for sequence-to-sequence transduction (Sutskever et al., 2014). While training these systems could discover contextual features that a hand-crafted parametric WFST might miss, they dispense with important structure in the problem, namely the *monotonic input-output alignment*. This paper describes a natural hybrid approach that marries simple FSTs with features extracted by recurrent neural networks.

Our novel architecture allows efficient modeling of globally normalized probability distributions over string-valued output spaces, simultaneously with automatic feature extraction. We evaluate on morphological reinflection and lemmatization tasks, showing that our approach strongly outperforms a standard WFST baseline as well as neural sequence-to-sequence models with attention. Our approach also compares reasonably with a state-of-the-art WFST approach that uses task-specific latent variables.

2 Notation and Background

Let Σ_{x} be a discrete input alphabet and Σ_{y} be a discrete output alphabet. Our goal is to define a conditional distribution $p(\mathbf{y} \mid \mathbf{x})$ where $\mathbf{x} \in \Sigma_{\text{x}}^*$ and $\mathbf{y} \in \Sigma_{\text{y}}^*$ and x and y may be of different lengths.

We use italics for characters and boldface for strings. x_i denotes the i^{th} character of $\mathbf{x}$, and $\mathbf{x}_{i:j}$ denotes the substring $x_{i+1}x_{i+2}\cdots x_j$ of length $j-i \geq 0$. Note that $\mathbf{x}_{i:i} = \varepsilon$, the empty string. Let $n = |\mathbf{x}|$.

Our approach begins by hand-specifying an *unweighted* finite-state transducer (FST), F, that nondeterministically maps any well-formed input $\mathbf{x}$ to all appropriate outputs $\mathbf{y}$. An FST is a directed graph whose vertices are called states, and whose arcs are each labeled with some pair $\mathbf{s}:\mathbf{t}$, representing a possible edit of a source substring $\mathbf{s} \in \Sigma_{\text{x}}^*$ into a target substring $\mathbf{t} \in \Sigma_{\text{y}}^*$. A path π from the FST's initial state to its final state represents an alignment of $\mathbf{x}$ to $\mathbf{y}$, where $\mathbf{x}$ and $\mathbf{y}$ (respectively) are the concatenations of the $\mathbf{s}$ and $\mathbf{t}$ labels of the arcs along π. In

Proceedings of NAACL-HLT 2016, pages 623–633,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

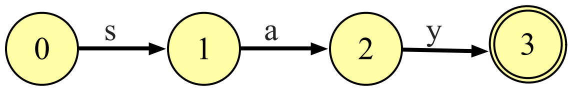

Figure 1: An automaton encoding the English word `say`.

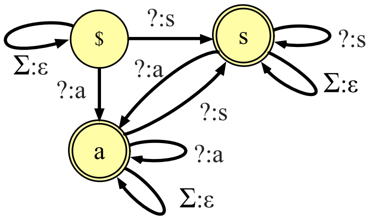

Figure 2: An example transducer F, whose state remembers the most recent *output* character (or \$ if none). Only a few of the states are shown, with all arcs among them. The Σ wildcard matches any symbol in Σ_{x}; the "?" wildcard matches the empty string ε *or* any symbol in Σ_{x}.

general, two strings $\mathbf{x}, \mathbf{y}$ can be aligned through exponentially many paths, via different edit sequences.

If we represent $\mathbf{x}$ as a straight-line finite-state automaton (Figure 1), then composing $\mathbf{x}$ with F (Figure 2) yields a new FST, G (Figure 3). The paths in G are in 1-1 correspondence with exactly the paths in F that have input $\mathbf{x}$. G can have cycles, allowing outputs of unbounded length.

Each path in G represents an alignment of $\mathbf{x}$ to some string in Σ_{y}^*. We say $p(\mathbf{y} \mid \mathbf{x})$ is the *total* probability of all paths in G that align $\mathbf{x}$ to $\mathbf{y}$ (Figure 4).

But how to define the probability of a path? Traditionally (Eisner, 2002), each arc in F would also be equipped with a weight. The weight of a path in F, or the corresponding path in G, is the sum of its arcs' weights. We would then define the probability $p(\pi)$ of a path π in G as proportional to $\exp w(\pi)$, where $w(\cdot) \in \mathbb{R}$ denotes the weight of an object.

The weight of an arc $\textcircled{h}\xrightarrow{\mathbf{s}:\mathbf{t}}\textcircled{h'}$ in F is traditionally defined as a function of features of the edit $\mathbf{s}:\mathbf{t}$ and the names (h, h') of the source and target states. In effect, h summarizes the alignment between the prefixes of $\mathbf{x}$ and $\mathbf{y}$ that precede this edit, and h' summarizes the alignment of the suffixes that follow it.

Thus, while the weight of an edit $\mathbf{s}:\mathbf{t}$ may depend on context, it traditionally does so only through h and h'. So if F has k states, then the edit weight can only distinguish among k different types of preceding or following context.

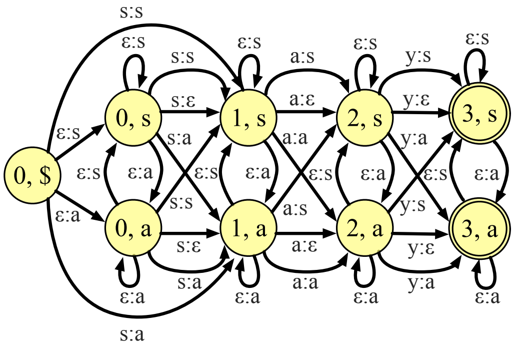

Figure 3: An example of the transducer G, which pairs the string $\mathbf{x}$=`say` with infinitely many possible strings $\mathbf{y}$. This G was created as the composition of the straight-line input automaton (Figure 1) and the transducer F (Figure 2). Thus, the state of G tracks the states of those two machines: the position in $\mathbf{x}$ and the most recent output character. To avoid a tangled diagram, this figure shows only a few of the states (the start state plus all states of the form $\textcircled{i,s}$ or $\textcircled{i,a}$), with all arcs among them.

3 Incorporating More Context

That limitation is what we aim to correct in this paper, by augmenting our representation of context. Our *contextual weighting* approach will assign weights directly to G's arcs, instead of to F's arcs.

Each arc of G can be regarded as a "token" of an edit arc in F: it "applies" that edit to *a particular substring of* $\mathbf{x}$. It has the form $\textcircled{i,h}\xrightarrow{\mathbf{s}:\mathbf{t}}\textcircled{j,h'}$, and represents the replacement of $\mathbf{x}_{i:j} = \mathbf{s}$ by $\mathbf{t}$. The finite-state composition construction produced this arc of G by combining the arc $\textcircled{h}\xrightarrow{\mathbf{s}:\mathbf{t}}\textcircled{h'}$ in F with the path $\textcircled{i}\overset{\mathbf{s}}{\rightsquigarrow}\textcircled{j}$ in the straight-line automaton representing $\mathbf{x}$. The latter automaton uses integers as state names: it is $\textcircled{0}\xrightarrow{x_1}\textcircled{1}\xrightarrow{x_2}\dots\xrightarrow{x_n}\textcircled{n}$.

Our top-level idea is to make the weight of this arc in G depend also on $(\mathbf{x}, i, j)$, so that it can consider unbounded input context around the edit's location. Arc weights can now consider arbitrary features of the input $\mathbf{x}$ and the position i, j—exactly like the potential functions of a linear-chain conditional random field (CRF), which also defines $p(\mathbf{y} \mid \mathbf{x})$.

Why not just use a CRF? That would only model a situation that enforced $|\mathbf{y}| = |\mathbf{x}|$ with each character y_i aligned to x_i, since the emissions of a CRF correspond to edits $\mathbf{s} : \mathbf{t}$ with $|\mathbf{s}| = |\mathbf{t}| = 1$. An FST can also allow edits with $|\mathbf{s}| \neq |\mathbf{t}|$, if desired, so it can be fit to $(\mathbf{x}, \mathbf{y})$ pairs of different lengths with unknown

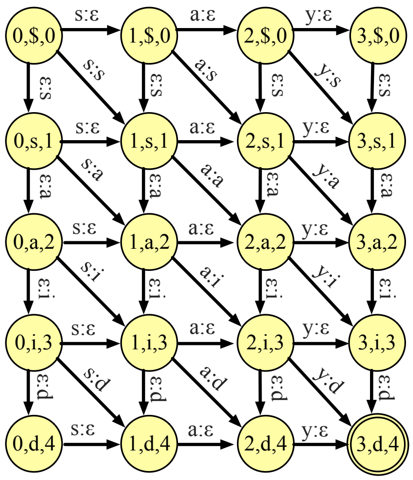

Figure 4: A compact lattice of the exponentially many paths in the transducer G of Figure 3 that align input string $\mathbf{x}$=say with output string $\mathbf{y}$=said. To find $p(\mathbf{y} \mid \mathbf{x})$, we must sum over these paths (i.e., alignments). The lattice is created by composing G with $\mathbf{y}$, which selects all paths in G that output $\mathbf{y}$. Note that horizontal movement makes progress through $\mathbf{x}$; vertical movement makes progress through $\mathbf{y}$. The lattice's states specialize states in G so that they also record a position in $\mathbf{y}$.

alignment, summing over their possible alignments.

A standard weighted FST F is similar to a dynamic linear-chain CRF. Both are unrolled against the input $\mathbf{x}$ to get a dynamic programming lattice G. But they are not equivalent. By weighting G instead of F, we combine the FST's advantage (aligning unequal-length strings $\mathbf{x}, \mathbf{y}$ via a latent path) with the CRF's advantage (arbitrary dependence on $\mathbf{x}$).

To accomplish this weighting in practice, sections 4–5 present a trainable neural architecture for an arc weight function $w = f(\mathbf{s}, \mathbf{t}, h, h', \mathbf{x}, i, j)$. The goal is to extract continuous features from *all* of $\mathbf{x}$. While our specific architecture is new, we are not the first to replace hand-crafted log-linear models with trainable neural networks (see section 9).[1]

Note that as in a CRF, our arc weights cannot consider arbitrary features of $\mathbf{y}$, only of $\mathbf{x}$. Still, a weight's dependence on states h, h' does let it depend on a *finite* amount of information about $\mathbf{y}$ (also possible in CRFs/HCRFs) and its alignment to $\mathbf{x}$.

In short, our model $p(\mathbf{y} \mid \mathbf{x})$ makes the weight of an $\mathbf{s}:\mathbf{t}$ edit, applied to substring $\mathbf{x}_{i:j}$, depend *jointly* on $\mathbf{s}:\mathbf{t}$ and *two* summaries of the edit's context:

- a finite-state summary (h, h') of its context in the aligned $(\mathbf{x}, \mathbf{y})$ pair, as found by the FST F
- a vector-valued summary of the context in $\mathbf{x}$ only, as found by a recurrent neural network

The neural vector is generally a richer summary of the context, but it considers only the *input*-side context. We are able to efficiently extract these rich features from the *single* input $\mathbf{x}$, but not from each of the *very many* possible outputs $\mathbf{y}$. The job of the FST F is to compute additional features that also depend on the output.[2] Thus our model of $p(\mathbf{y} \mid \mathbf{x})$ is defined by an FST together with a neural network.

4 Neural Context Features

Our arc weight function f will make use of a vector $\boldsymbol{\gamma}_{i:j}$ (computed from $\mathbf{x}, i, j$) to characterize the substring $\mathbf{x}_{i:j}$ that is being replaced, in context. We define $\boldsymbol{\gamma}_{i:j}$ as the concatenation of a left vector $\boldsymbol{\alpha}_j$ (describing the prefix $\mathbf{x}_{0:j}$) and a right vector $\boldsymbol{\beta}_i$ (describing the suffix $\mathbf{x}_{i:n}$), which characterize $\mathbf{x}_{i:j}$ jointly with its left or right context. We use $\boldsymbol{\gamma}_i$ to abbreviate $\boldsymbol{\gamma}_{i-1:i}$, just as x_i abbreviates $\mathbf{x}_{i-1:i}$.

To extract $\boldsymbol{\alpha}_j$, we read the string $\mathbf{x}$ one character at a time with an LSTM (Hochreiter and Schmidhuber, 1997), a type of trainable recurrent neural network that is good at extracting relevant features from strings. $\boldsymbol{\alpha}_j$ is the LSTM's output after j steps (which read $\mathbf{x}_{0:j}$). Appendix A reviews how $\boldsymbol{\alpha}_j \in \mathbb{R}^q$ is computed for $j = 1, \ldots, n$ using the recursive, differentiable update rules of the LSTM architecture.

We also read the string $\mathbf{x}$ *in reverse* with a second LSTM. $\boldsymbol{\beta}_i \in \mathbb{R}^q$ is the second LSTM's output after $n - i$ steps (which read reverse$(\mathbf{x}_{i:n})$).

We regard the two LSTMs together as a BiLSTM function (Graves and Schmidhuber, 2005) that reads $\mathbf{x}$ (Figure 5). For each bounded-length substring $\mathbf{x}_{i:j}$, the BiLSTM produces a characterization $\boldsymbol{\gamma}_{i:j}$ of that substring in context, in $O(n)$ *total* time.

We now define a "deep BiLSTM," which stacks up K BiLSTMs. This deepening is aimed at extracting the kind of rich features that Sutskever et al.

[1] For CRFs, this sacrifices the convexity of the log-likelihood training objective. But for FSTs, that objective was usually nonconvex to begin with, because the alignment path is latent.

[2] Each arc of G is used in a known input context, but could be reused in many output contexts—different *paths* in G. Those contexts are only guaranteed to share h, h'. So the arc weight cannot depend on any *other* features of the output context.

(2014) and Vinyals et al. (2015) found so effective in a different structured prediction architecture.

The kth-level BiLSTM (Figure 6) reads a sequence of input vectors $\mathbf{x}_1^{(k)}, \mathbf{x}_2^{(k)}, \ldots, \mathbf{x}_n^{(k)} \in \mathbb{R}^{d^{(k)}}$, and produces a sequence of vectors $\boldsymbol{\gamma}_1^{(k)}, \boldsymbol{\gamma}_2^{(k)}, \ldots, \boldsymbol{\gamma}_n^{(k)} \in \mathbb{R}^{2q}$. At the initial level $k = 1$, we define $\mathbf{x}_i^{(1)} = \mathbf{e}_{x_i} \in \mathbb{R}^{d^{(1)}}$, a vector embedding of the character $x_i \in \Sigma_{\mathrm{x}}$. For $k > 1$, we take $\mathbf{x}_i^{(k)}$ to be $\boldsymbol{\gamma}_i^{(k-1)}$, concatenated with $\mathbf{x}_i^{(k-1)}$ for good measure. Thus, $d^{(k)} = 2q + d^{(k-1)}$.

After this deep generalization, we define $\boldsymbol{\gamma}_{i:j}$ to be the concatenation of all $\boldsymbol{\gamma}_{i:j}^{(k)}$ (rather than just $\boldsymbol{\gamma}_{i:j}^{(K)}$).

This novel deep BiLSTM architecture has more connections than a pair of deep LSTMs, since $\boldsymbol{\alpha}_i^{(k)}$ depends not only on $\boldsymbol{\alpha}_i^{(k-1)}$ but also on $\boldsymbol{\beta}_i^{(k-1)}$. Thus, while we may informally regard $\boldsymbol{\alpha}_i^{(k)}$ as being a deep summary of the prefix $\mathbf{x}_{0:i}$, it actually depends indirectly on all of $\mathbf{x}$ (except when $k = 1$).

5 The Arc Weight Function

Given the vector $\boldsymbol{\gamma}_{i:j}$, we can now compute the weight of the edit arc $\textcircled{\scriptsize i,h} \xrightarrow{\mathbf{s}:\mathbf{t}} \textcircled{\scriptsize j,h'}$ in G, namely $w = f(\mathbf{s}, \mathbf{t}, h, h', \mathbf{x}, i, j)$. Many reasonable functions are possible. Here we use one that is inspired by the log-bilinear language model (Mnih and Hinton, 2007):

$$w = (\mathbf{e}_{\mathbf{s}}, \boldsymbol{\gamma}_{i,j}, \mathbf{e}_{x_i}, \mathbf{e}_{x_{j+1}}) \cdot \mathbf{r}_{\mathbf{t},h,h',\mathrm{type}(\mathbf{s}:\mathbf{t})} \qquad (1)$$

The first argument to the inner product is an embedding $\mathbf{e}_{\mathbf{s}} \in R^{d^{(1)}}$ of the source substring $\mathbf{s}$, concatenated to the edit's neural context and also (for good measure) its local context.[3] For example, if $|\mathbf{s}| = 1$, i.e. $\mathbf{s}$ is a single character, then we would use the embedding of that character as $\mathbf{e}_{\mathbf{s}}$. Note that the embeddings $e_{\mathbf{s}}$ for $|\mathbf{s}| = 1$ are also used to encode the local context characters and the level-1 BiLSTM input. We learn these embeddings, and they form part of our model's parameter vector $\boldsymbol{\theta}$.

The second argument is a *joint* embedding of the other properties of the edit: the target substring $\mathbf{t}$, the edit arc's state labels from F, and the type of the edit (INS, DEL, or SUB: see section 8). When replacing $\mathbf{s}$ in a particular context, which fixes the first argument, we will prefer those replacements whose $\mathbf{r}$ embeddings yield a high inner product w. We will learn the $\mathbf{r}$ embeddings as well; note that their dimensionality must match that of the first argument.

The model's parameter vector $\boldsymbol{\theta}$ includes the $O((d^{(K)})^2)$ parameters from the $2K$ LSTMs, where $d^{(K)} = O(d^{(1)} + Kq)$. It also $O(d^{(1)}S)$ parameters for the embeddings $\mathbf{e}_{\mathbf{s}}$ of the S different input substrings mentioned by F, and $O(d^{(K)}T)$ for the embeddings $\mathbf{r}_{\mathbf{t},h,h',\mathrm{type}(\mathbf{s}:\mathbf{t})}$ of the T "actions" in F.

6 Training

We train our model by maximizing the conditional log-likelihood objective,

$$\sum_{(\mathbf{x},\mathbf{y}^*) \in \text{dataset}} \log p(\mathbf{y}^* \mid \mathbf{x}) \qquad (2)$$

Recall that $p(\mathbf{y}^* \mid \mathbf{x})$ sums over all alignments. As explained by Eisner (2002), it can be computed as the pathsum of the composition $G \circ \mathbf{y}^*$ (Figure 4), divided by the pathsum of G (which gives the normalizing constant for the distribution $p(\mathbf{y} \mid \mathbf{x})$). The pathsum of a weighted FST is the total weight of all paths from the initial state to a final state, and can be computed by the forward algorithm.[4]

[3] Our present implementation handles INS edits (for which $j = i$) a bit differently, using $(\mathbf{e}_{x_{i+1}}, \boldsymbol{\gamma}_{i:i+1}, \mathbf{e}_{x_i}, \mathbf{e}_{x_{i+2}})$ rather than $(\mathbf{e}_{\varepsilon}, \boldsymbol{\gamma}_{i:i}, \mathbf{e}_{x_i}, \mathbf{e}_{x_{i+1}})$. This is conveniently the same vector that is used for all other competing edits at this i position (as they all have $|\mathbf{s}| = 1$ in our present implementation); it provides an extra character of lookahead.

[4] If an FST has cycles, such as the self-loops in the example of Figure 3, then the forward algorithm's recurrence equations become cyclic, and must be solved as a linear system rather than sequentially. This is true regardless of how the FST's weights

Eisner (2002) and Li and Eisner (2009) also explain how to compute the partial derivatives of $p(\mathbf{y}^* \mid \mathbf{x})$ with respect to the arc weights, essentially by using the forward-backward algorithm. We backpropagate further from these partials to find the gradient of (2) with respect to all our model parameters. We describe our gradient-based maximization procedure in section 10.3, along with regularization.

Our model does not have to be trained with the conditional log likelihood objective. It could be trained with other objectives such as empirical risk or softmax-margin (Li and Eisner, 2009; Gimpel and Smith, 2010), or with error-driven updates such as in the structured perceptron (Collins, 2002).

7 Inference and Decoding

For a new input $\mathbf{x}$ at test time, we can now construct a weighted FST, G, that defines a probability distribution over all *aligned* output strings. This can be manipulated to make various predictions about $\mathbf{y}^*$ and its alignment.

In our present experiments, we find the most probable (highest-weighted) path in G (Dijkstra, 1959), and use its output string $\hat{\mathbf{y}}$ as our prediction. Note that Dijkstra's algorithm is exact; no beam search is required as in some neural sequence models.

On the other hand, $\hat{\mathbf{y}}$ may not be the most probable string—extracting that from a weighted FST is NP-hard (Casacuberta and de la Higuera, 1999). The issue is that the total probability of each $\mathbf{y}$ is split over many paths. Still, this is a well-studied problem in NLP. Instead of the Viterbi approximation, we could have used a better approximation, such as crunching (May and Knight, 2006) or variational decoding (Li et al., 2009). We actually did try crunching the 10000-best outputs but got no significant improvement, so we do not report those results.

8 Transducer Topology

In our experiments, we choose F to be a simple contextual edit FST as illustrated in Figure 2. Just as in Levenshtein distance (Levenshtein, 1966), it allows all edits $\mathbf{s} : \mathbf{t}$ where $|\mathbf{s}| \leq 1, |\mathbf{t}| \leq 1, |\mathbf{s}| + |\mathbf{t}| \neq 0$. We consider the edit type to be INS if $\mathbf{s} = \varepsilon$, DEL if $\mathbf{t} = \varepsilon$, and SUB otherwise. Note that copy is a SUB edit with $\mathbf{s} = \mathbf{t}$.

For a "memoryless" edit process (Ristad and Yianilos, 1996), the FST would require only a single state. By contrast, we use $|\Sigma_\mathrm{x}| + 1$ states, where each state records the most recent output character (initially, a special "beginning-of-string" symbol $\$$). That is, the state label h is the "history" output character immediately before the edit $\mathbf{s} : \mathbf{t}$, so the state label h' is the history before the *next* edit, namely the final character of $h\mathbf{t}$. For edits other than DEL, $h\mathbf{t}$ is a bigram of $\mathbf{y}$, which can be evaluated (in context) by the arc weight function $w = f(\mathbf{s}, \mathbf{t}, h, h', \mathbf{x}, i, j)$.

Naturally, a weighted version of this FST F is far too simple to do well on real NLP tasks (as we show in our experiments). The magic comes from instead weighting G so that we can pay attention to the input context $\gamma_{i:j}$.

The above choice of F corresponds to the "$(0, 1, 1)$ topology" in the more general scheme of Cotterell et al. (2014). For practical reasons, we actually modify it to limit the number of consecutive INS edits to 3.[5] This trick bounds $|\mathbf{y}|$ to be $< 4 \cdot (|\mathbf{x}| + 1)$, ensuring that the pathsums in section 6 are finite regardless of the model parameters. This simplifies both the pathsum algorithm and the gradient-based training (Dreyer, 2011). Less importantly, since G becomes acyclic, Dijkstra's algorithm in section 7 simplifies to the Viterbi algorithm.

9 Related Work

Our model adds to recent work on linguistic sequence transduction using deep learning.

Graves and Schmidhuber (2005) combined BiLSTMs with HMMs. Later, "sequence-to-sequence" models were applied to machine translation by Sutskever et al. (2014) and to parsing by Vinyals et al. (2015). That framework did not model any alignment between $\mathbf{x}$ and $\mathbf{y}$, but adding an "attention" mechanism provides a kind of soft alignment that has improved performance on MT (Bahdanau et al., 2015). Faruqui et al. (2016) apply these methods to morphological reinflection (the only other application to morphology we know of). Grefenstette

are defined. (For convenience, our experiments in this paper avoid cycles by limiting consecutive insertions: see section 8.)

[5] This multiplies the number of states 4-fold, since each state must also record a count in $[0, 3]$ of immediately preceding INS edits. No INS edit arc is allowed from a state with counter 3. The counter is not considered by the arc weight function.

et al. (2015) recently augmented the sequence-to-sequence framework with a continuous analog of stack and queue data structures, to better handle long-range dependencies often found in linguistic data.

Some recent papers have used LSTMs or BiLSTMs, as we do, to define probability distributions over action sequences that operate directly on an input sequence. Such actions are aligned to the input. For example, Andor et al. (2016) score edit sequences using a globally normalized model, and Dyer et al. (2015) evaluate the local probability of a parsing action given past actions (and their result) and future words. These architectures are powerful because their LSTMs can examine the *output* structure; but as a result they do not permit dynamic programming and must fall back on beam search.

Our use of dynamic programming for efficient exact inference has long been common in non-neural architectures for sequence transduction, including FST systems that allow "phrasal" replacements $\mathbf{s} : \mathbf{t}$ where $|\mathbf{s}|, |\mathbf{t}| > 1$ (Chen, 2003; Jiampojamarn et al., 2007; Bisani and Ney, 2008). Our work augments these FSTs with neural networks, much as others have augmented CRFs. In this vein, Durrett and Klein (2015) augment a CRF parser (Finkel et al., 2008) to score constituents with a feedforward neural network. Likewise, FitzGerald et al. (2015) employ feedforward nets as a factor in a graphical model for semantic role labeling. Many CRFs have incorporated feedforward neural networks (Bridle, 1990; Peng et al., 2009; Do and Artieres, 2010; Vinel et al., 2011; Fujii et al., 2012; Chen et al., 2015, and others). Some work augments CRFs with BiLSTMs: Huang et al. (2015) report results on part-of-speech tagging and named entity recognition with a linear-chain CRF-BiLSTM, and Kong et al. (2015) on Chinese word segmentation and handwriting recognition with a semi-CRF-BiLSTM.

10 Experiments

We evaluated our approach on two morphological generation tasks of reinflection (section 10.1) and lemmatization (section 10.2). In the reinflection task, the goal is to transduce verbs from one inflected form into another, whereas the lemmatization task requires the model to reduce an inflected verb to its root form.

We compare our WFST-LSTM against two standard baselines, a WFST with hand-engineered features and the Moses phrase-based MT system (Koehn et al., 2007), as well as the more complex latent-variable model of Dreyer et al. (2008). The comparison with Dreyer et al. (2008) is of noted interest since their latent variables are structured particularly for morphological transduction tasks—we are directly testing the ability of the LSTM to structure its hidden layer as effectively as linguistically motivated latent-variables. Additionally, we provide detailed ablation studies and learning curves which show that our neural-WFSA hybrid model can generalize even with very low amounts of training data.

10.1 Morphological Reinflection

Following Dreyer (2011), we conducted our experiments on the following transduction tasks from the CELEX (Baayen et al., 1993) morphological database: 13SIA $\mapsto$ 13SKE, 2PIE $\mapsto$ 13PKE, 2PKE $\mapsto$ z and rP $\mapsto$ pA.[6] We refer to these tasks as 13SIA, 2PIE, 2PKE and rP, respectively.

Concretely, each task requires us to map a German inflection into another inflection. Consider the 13SIA task and the German verb `abreiben` ("to rub off"). We require the model to learn to map a past tense form `abrieb` to a present tense form `abreibe`—this involves a combination of stem change and affix generation. Sticking with the same verb `abreiben`, task 2PIE requires the model to transduce `abreibt` to `abreiben`—this requires an insertion and a substitution at the end. The tasks 2PKE and rP are somewhat more challenging since performing well on these tasks requires the model to learn complex transduction: `abreiben` to `abzureiben` and `abreibt` to `abgerieben`, respectively. These are complex transductions with phenomenon like infixation in specific contexts (`ab`**`zu`**`rieben`) and circumfixation (`ab`**`ge`**`rieb`**`en`**) along with additional stem and affix changes. See Dreyer (2011) for more details and examples of these tasks.

We use the datasets of Dreyer (2011). Each exper-

[6] Glossary: 13SIA=*1st/3rd sg. ind. past*; 13SKE=*1st/3rd sg. subjunct. pres.*; 2PIE=*2nd pl. ind. pres.*; 13PKE=*1st/3rd pl. subjunct. pres.*; 2PKE=*2nd pl. subjunct. pres.;* z=*infinitive*; rP=*imperative pl.*; pA=*past part.*

iment sampled a different dataset of 2500 examples from CELEX, dividing this into 500 training + 1000 validation + 1000 test examples. Like them, we report exact-match accuracy on the test examples, averaged over 5 distinct experiments of this form. We also report results when the training and validation data are swapped in each experiment, which doubles the training size.

10.2 Lemmatization

Lemmatization is a special case of morphological reinflection where we map an inflected form of a word to its lemma (canonical form), i.e., the target inflection is fixed. This task is quite useful for NLP, as dictionaries typically list only the lemma for a given lexical entry, rather than all possible inflected forms. In the case of German verbs, the lemma is taken to be the infinitive form, e.g., we map the past participle `abgerieben` to the infinitive `abreiben`.

Following Dreyer (2011), we use a subset of the lemmatization dataset created by Wicentowski (2002) and perform 10-fold experiments on four languages: Basque (5843), English (4915), Irish (1376) and Tagalog (9545), where the numbers in parenthesis indicate the total number of data pairs available. For each experimental fold the total data was divided into train, development and test sets in the proportion of 80:10:10 and we report test accuracy averaged across folds.

10.3 Settings and Training Procedure

We set the hyperparameters of our model to $K = 4$ (stacking depth), $d^{(1)} = 10$ (character embedding dimension), and $q = 15$ (LSTM state dimension). The alphabets Σ_{x} and Σ_{y} are always equal; their size is language-dependent, typically ≈ 26 but larger in languages like Basque and Irish where our datasets include properly accented characters. With $|\Sigma| = 26$ and the above settings for the hyperparameters, the number of parameters in our models is $352, 801$.

We optimize these parameters through stochastic gradient descent of the negative log-likelihood objective, and regularize the training procedure through dropout accompanied with gradient clipping and projection of parameters onto L2-balls with small radii, which is equivalent to adding a group-ridge regularization term to the training objective. The learning rate decay schedule, gradient clipping threshold, radii of L2-balls, and dropout frequency were tuned by hand on development data.

Model	**13SIA**	**2PIE**	**2PKE**	**rP**
Moses15	85.3	94.0	82.8	70.8
Dreyer (Backoff)	82.8	88.7	74.7	69.9

Dreyer (Lat-Region)	**87.5**	93.4	**87.4**	**84.9**
BiLSTM-WFST	85.1	**94.4**	85.5	83.0
Model Ensemble	85.8	**94.6**	86.0	83.8
BiLSTM-WFST (2 × Data)	*87.6*	*94.8*	*88.1*	*85.7*

Table 1: Exact match accuracy on the morphological reinflection task. All the results in the first half of the table are taken from Dreyer (2011), whose experimental setup we copied exactly. The Moses15 result is obtained by applying the SMT toolkit Moses (Koehn et al., 2007) over letter strings with 15-character context windows. Dreyer (Backoff) refers to the *ngrams+x* model which has access to all the "backoff features." Dreyer (Lat-Class) is the *ngrams+x+latent class* model, and Dreyer (Lat Region) refers to the *ngrams+x+latent class + latent change region* model. The "Model Ensemble" row displays the performance of an ensemble including our full model and the 7 models that we performed ablation on. In each column, we boldfaced the highest result and those that were not significantly worse (sign test, $p < 0.05$). Finally, the last row reports the performance of our BiLSTM-WFST when trained on twice the training data.

In our present experiments, we made one change to the architecture. Treating copy edits like other SUB edits led to poor performance: the system was unable to learn that all SUB edits with $\mathbf{s} = \mathbf{t}$ were extremely likely. In the experiments reported here, we addressed the problem by simply tying the weights of all copy edits regardless of context, bypassing (1) and instead setting $w = c$ where c is a learned parameter of the model. See section 11 for discussion.

10.4 Results

Table 1 and 2 show our results. We can see that our proposed BiLSTM-WFST model always outperforms all but the most complex latent-variable model of Dreyer (2011); it is competitive with that model, but only beats it once individually. All of Dreyer's models include output trigram features, while we only use bigrams.

Figure 7 shows learning curves for the 13SIA and 2PKE tasks: test accuracy when we train on less data. Curiously, at 300 data points the performance of our model is tied to Dreyer (2011). We also note

Model	Basque	English	Irish	Tagalog
Base (W)	85.3	91.0	43.3	0.3
WFAffix (W)	80.1	93.1	70.8	81.7
ngrams (D)	91.0	92.4	96.8	80.5
ngrams + x (D)	91.1	93.4	97.0	83.0
ngrams + x + l (D)	**93.6**	**96.9**	**97.9**	88.6
BiLSTM-WFST	91.5	94.5	**97.9**	**97.4**

Table 2: Lemmatization results on Basque, English, Irish and Tagalog. Comparison systems marked with (W) are taken from Wicentowski (2002) and systems marked with a (D) are taken from Dreyer (2011). We outperform baselines on all languages and are competitive with the latent-variable approach (ngrams + x + l), beating it in two cases: Irish and Tagalog.

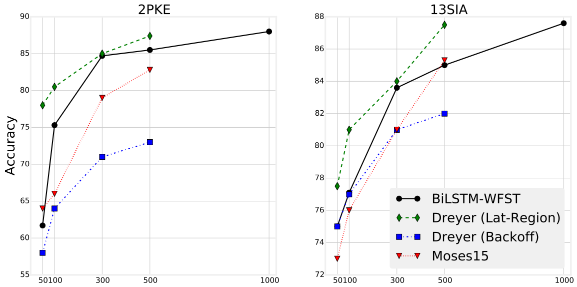

Figure 7: Learning Curves

that our model always outperforms the Moses15 baseline on all training set sizes except on the 2PKE task with 50 training samples.

In general, the results from our experiments are a promising indicator that LSTMs are capable of extracting linguistically relevant features for morphology. Our model outperforms all baselines, and is competitive with and sometimes surpasses the latent-variable model of Dreyer et al. (2008) *without* any of the hand-engineered features or linguistically inspired latent variables.

On morphological reinflection, we outperform all of Dreyer et al's models on 2PIE, but fall short of his latent-change region model on the other tasks (outperforming the other models). On lemmatization, we outperform all of Wicentowski's models on all the languages and all of Dreyer et al.'s models on Irish and Tagalog, but, but not on English and Irish. This suggests that perhaps further gains are possible through using something like Dreyer's FST as our F. Indeed, this would be compatible with much recent work that gets best results from a *combination* of automatically learned neural features and hand-engineered features.

10.5 Analysis of Results

We analyzed our lemmatization errors for all the languages on one fold of the datasets. On the English lemmatization task, 7 of our 27 errors simply copied the input word to the output: `ate`, `kept`, `went`, `taught`, `torn`, `paid`, `strung`. This suggests that our current aggressive parameter tying for copy edits may predict a high probability for a copy edit even in contexts that should not favor it.

Also we found that the FST sometimes produced non-words while lemmatizing the input verbs. For example it mapped `picnicked` ↦ `picnick`, `happen` ↦ `hapen`, `exceed` ↦ `excy` and `lining` ↦ `lin`. Since these strings would be rare in a corpus, many such errors could be avoided by a reranking approach that combined the FST's path score with a string frequency feature.

In order to better understand our architecture and the importance of its various components, we performed an ablation study on the validation portions of the morphological induction datasets, shown in Table 3. We can see in particular that using a BiLSTM instead of an LSTM, increasing the depth of the network, and including local context all helped to improve the final accuracy.

"Deep BiLSTM w/ Tying" refers to our complete model. The other rows are ablation experiments—architectures that are the same as the first row except in the specified way. "Deep BiLSTM (No Context)" omits local context $\mathbf{e}_{x_i}, \mathbf{e}_{x_{j+1}}$ from (1). "Deep BiLSTMs w/o Copying" does not concatenate a copy of $\mathbf{x}_i^{(k-1)}$ into $\mathbf{x}_i^{(k)}$ and simplifies $\boldsymbol{\gamma}_{i:j}$ to be $\boldsymbol{\gamma}_{i:j}^{(K)}$ only. "Shallow BiLSTM" reduces K from 4 to 1. "Bi-Deep LSTM" replaces our deep BiLSTM with two deep LSTMs that run in opposite directions but do not interact with each other. "Deep MonoLSTM" redefines β_i to be the empty vector,g i.e. it replaces the deep BiLSTM with a deep left-to-right LSTM. "Shallow MonoLSTM" replaces the deep BiLSTM with a shallow left-to-right LSTM. "No LSTM (Local Context)" omits $\gamma_{i:j}$ from the weight function altogether. "Deep BiLSTM w/o Tying" does not use the parameter tying heuristic for copy edits. "No LSTM (No Context)" is the simplest model that we consider. It removes $\gamma_{i:j}, \mathbf{e}_{x_i}$ and $\mathbf{e}_{x_{j+1}}$ and in fact, it is precisely a weighting of the edits in our original FST F, without further considering the context in which an edit is applied.

Finally, to compare the performance of our method to baseline neural encoder-decoder models, we trained 1-layer and 4-layer neural sequence-to-sequence models with and without attention, using the publicly available `morph-trans` toolkit (Faruqui et al., 2016). We show the performance of these models in the lower half of the table. The results consistently show that sequence-to-sequence transduction models that lack the constraints of monotonic alignment perform worse than our proposed models on morphological transduction tasks.

11 Future Work

As neither our FST-LSTM model or the latent-variable WFST model of Dreyer et al. (2008) uniformly outperforms the other, a future direction is to improve the FST we use in our model—e.g., by augmenting its states with explicit latent variables. Other improvements to the WFST would be to increase the amount of history h stored in the states, and to allow $\mathbf{s}, \mathbf{t}$ to be longer than a single character, which would allow the model to segment $\mathbf{x}$.

We are not committed to the arc weight function in (1), and we believe that further investigation here could improve performance. The goal is to define the weight of $\textcircled{h}\xrightarrow{\mathbf{s}:\mathbf{t}}\textcircled{h'}$ in the context summarized by $\boldsymbol{\alpha}_i, \boldsymbol{\beta}_j$ (the context around $\mathbf{x}_{i:j} = \mathbf{s}$) and/or $\boldsymbol{\alpha}_j, \boldsymbol{\beta}_i$ (which incorporate $\mathbf{s}$ as well).

Any parametric function of the variables $(\mathbf{s}, \mathbf{t}, h, h', \boldsymbol{\alpha}_i, \boldsymbol{\alpha}_j, \boldsymbol{\beta}_i, \boldsymbol{\beta}_j)$ could be used—for example, a neural network or a multilinear function. This function might depend on learned embeddings of the separate objects $\mathbf{s}, \mathbf{t}, h, h'$, but also on learned joint embeddings of pairs of these objects (which adds finer-grained parameters), or hand-specified properties of the objects such as their phonological features (which adds backoff parameters).

A basic approach along the lines of (1) would use an inner product of some encoding of the arc $(\mathbf{s}, \mathbf{t}, h, h')$ with some encoding of the context $(\mathbf{s}, h, h', \boldsymbol{\alpha}_i, \boldsymbol{\alpha}_j, \boldsymbol{\beta}_i, \boldsymbol{\beta}_j)$. Note that this formulation lets the objects $\mathbf{s}, h, h'$ play a dual role—they may appear as part of the arc and/or as part of the context. This is because we must judge whether $\mathbf{s} = \mathbf{x}_{i:j}$ (with "label" $\textcircled{h}\longrightarrow\textcircled{h'}$) is an appropriate input segment given the string context around $\mathbf{x}_{i:j}$, but if this segment is chosen, in turn it provides additional context to judge whether $\mathbf{t}$ is an appropriate output.

High-probability edits $\mathbf{s} : \mathbf{t}$ typically have $\mathbf{t} \approx \mathbf{s}$: a perfect copy, or a modified copy that changes just one or two features such as phonological voicing or orthographic capitalization. Thus, we are interested in learning a shared set of embeddings for $\Sigma_{\mathrm{x}} \cup \Sigma_{\mathrm{y}}$, and making the arc weight depend on features of the "discrepancy vector" $\mathbf{e}_{\mathbf{t}} - \mathbf{e}_{\mathbf{s}}$, such as this vector's components[7] and their absolute magnitudes, which would signal discrepancies of various sorts.

12 Conclusions

We have presented a hybrid FST-LSTM architecture for string-to-string transduction tasks. This approach combines classical finite-state approaches to transduction and newer neural approaches. We weight the same FST arc *differently* in different contexts, and use LSTMs to *automatically* extract features that determine these weights. This reduces the need to engineer a complex topology for the FST or to hand-engineer its weight features. We evaluated one such model on the tasks of morphological reinflection and lemmatization. Our approach outperforms several baselines and is competitive with (and sometimes surpasses) a latent-variable model hand-crafted for morphological transduction tasks.

[7] In various directions—perhaps just the basis directions, which might come to encode distinctive features, via training.

Abstract

Morphological inflection generation is the task of generating the inflected form of a given lemma corresponding to a particular linguistic transformation. We model the problem of inflection generation as a character sequence to sequence learning problem and present a variant of the neural encoder-decoder model for solving it. Our model is language independent and can be trained in both supervised and semi-supervised settings. We evaluate our system on seven datasets of morphologically rich languages and achieve either better or comparable results to existing state-of-the-art models of inflection generation.

1 Introduction

Inflection is the word-formation mechanism to express different grammatical categories such as tense, mood, voice, aspect, person, gender, number and case. Inflectional morphology is often realized by the concatenation of bound morphemes (prefixes and suffixes) to a root form or stem, but nonconcatenative processes such as ablaut and infixation are found in many languages as well. Table 1 shows the possible inflected forms of the German stem *Kalb* (calf) when it is used in different cases and numbers. The inflected forms are the result of both ablaut (e.g., *a*→*ä*) and suffixation (e.g., *+ern*).

	singular	plural
nominative	Kalb	Kälber
accusative	Kalb	Kälber
dative	Kalb	Kälbern
genitive	Kalbes	Kälber

Table 1: An example of an inflection table from the German noun dataset for the word *Kalb* (calf).

Inflection generation is useful for reducing data sparsity in morphologically complex languages. For example, statistical machine translation suffers from data sparsity when translating morphologically-rich languages, since every surface form is considered an independent entity. Translating into lemmas in the target language, and then applying inflection generation as a post-processing step, has been shown to alleviate the sparsity problem (Minkov et al., 2007; Toutanova et al., 2008; Clifton and Sarkar, 2011; Fraser et al., 2012; Chahuneau et al., 2013a). Modeling inflection generation has also been used to improve language modeling (Chahuneau et al., 2013b), identification of multi-word expressions (Oflazer et al., 2004), among other applications.

The traditional approach to modeling inflection relies on hand-crafted finite state transducers and lexicography, e.g., using *two-level morphology* (Koskenniemi, 1983; Kaplan and Kay, 1994). Such systems are appealing since they correspond to linguistic theories, but they are expensive to create, they can be fragile (Oflazer, 1996), and the composed transducers can be impractically large. As an alternative, machine learning models have been proposed to generate inflections from root forms as string transduction (Yarowsky and Wicentowski, 2000; Wicentowski, 2004; Dreyer and Eisner, 2011; Durrett and DeNero, 2013; Ahlberg et al., 2014; Hulden, 2014; Ahlberg et al., 2015; Nicolai et al., 2015). However, these impose either assumptions about the set of possible morphological processes

Proceedings of NAACL-HLT 2016, pages 634–643,
San Diego, California, June 12-17, 2016.

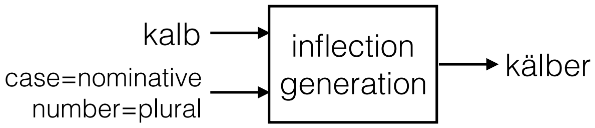

Figure 1: A general inflection generation model.

(e.g. affixation) or require careful feature engineering.

In this paper, we present a model of inflection generation based on a neural network sequence to sequence transducer. The root form is represented as sequence of characters, and this is the input to an encoder-decoder architecture (Cho et al., 2014; Sutskever et al., 2014). The model transforms its input to a sequence of output characters representing the inflected form (§4). Our model makes no assumptions about morphological processes, and our features are simply the individual characters. The model is trained on pairs of root form and inflected forms obtained from inflection tables extracted from Wiktionary.[1] We improve the supervised model with unlabeled data, by integrating a character language model trained on the vocabulary of the language.

Our experiments show that the model achieves better or comparable results to state-of-the-art methods on the benchmark inflection generation tasks (§5). For example, our model is able to learn long-range relations between character sequences in the string aiding the inflection generation process required by Finnish vowel harmony (§6), which helps it obtain the current best results in that language.

2 Inflection Generation: Background

Durrett and DeNero (2013) formulate the task of supervised inflection generation for a given root form, based on a large number of training inflection tables extracted from Wiktionary. Every inflection table contains the inflected form of a given root word corresponding to different linguistic transformations (cf. Table 1). Figure 1 shows the inflection generation framework. Since the release of the Wiktionary dataset, several different models have reported performance on this dataset. As we are also using this dataset, we will now review these models.

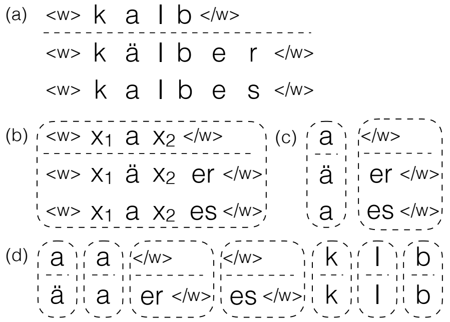

Figure 2: Rule extraction: (a) Character aligned-table; (b) Table-level rule of AFH14, AFH15 (c) Vertical rules of DDN13 and (d) Atomic rules of NCK15.

We denote the models of Durrett and DeNero (2013), Ahlberg et al. (2014), Ahlberg et al. (2015), and Nicolai et al. (2015), by DDN13, AFH14, AFH15, and NCK15 respectively. These models perform inflection generation as string transduction and largely consist of three major components: (1) Character alignment of word forms in a table; (2) Extraction of string transformation rules; (3) Application of rules to new root forms.

The first step is learning character alignments across inflected forms in a table. Figure 2 (a) shows alignment between three word forms of *Kalb*. Different models use different heuristic algorithms for alignments such as edit distance, dynamic edit distance (Eisner, 2002; Oncina and Sebban, 2006), and longest subsequence alignment (Bergroth et al., 2000). Aligning characters across word forms provide spans of characters that have changed and spans that remain unchanged. These spans are used to extract rules for inflection generation for different inflection types as shown in Figure 2 (b)–(d).

By applying the extracted rules to new root forms, inflected words can be generated. DDN13 use a semi-Markov model (Sarawagi and Cohen, 2004) to predict what rules should be applied, using character n-grams ($n = 1$ to 4) as features. AFH14 and AFH15 use substring features extracted from words to match an input word to a rule table. NCK15 use a semi-Markov model inspired by DDN13, but additionally use target n-grams and joint n-grams as features sequences while selecting the rules.

Motivation for our model. Morphology often makes references to segmental features, like place or manner of articulation, or voicing status (Chom-

[1] www.wiktionary.org

sky and Halle, 1968). While these can be encoded as features in existing work, our approach treats segments as vectors of features "natively". Our approach represents every character as a bundle of continuous features, instead of using discrete surface character sequence features. Also, our model uses features as part of the transduction rules themselves, whereas in existing work features are only used to rescore rule applications.

In existing work, the learner implicitly specifies the class of rules that can be learned, such as "delete" or "concatenate". To deal with phenomenona like segment lengthening in English: *run* → *running*; or reduplication in Hebrew: *Kelev* → *Klavlav*, *Chatul* → *Chataltul*; (or consonant gradation in Finnish), where the affixes are induced from characters of the root form, one must engineer a new rule class, which leads to poorer estimates due to data sparsity. By modeling inflection generation as a task of generating a character sequence, one character at a time, we do away with such problems.

3 Neural Encoder-Decoder Models

Here, we describe briefly the underlying framework of our inflection generation model, called the recurrent neural network (RNN) encoder-decoder (Cho et al., 2014; Sutskever et al., 2014) which is used to transform an input sequence $\vec{x}$ to output sequence $\vec{y}$. We represent an item by x, a sequence of items by $\vec{x}$, vectors by $\mathbf{x}$, matrices by $\mathbf{X}$, and sequences of vectors by $\vec{\mathbf{x}}$.

3.1 Formulation

In the encoder-decoder framework, an encoder reads a variable length input sequence, a sequence of vectors $\vec{\mathbf{x}} = \langle \mathbf{x}_1, \cdots, \mathbf{x}_T \rangle$ (corresponding to a sequence of input symbols $\vec{x} = \langle x_1, \cdots, x_T \rangle$) and generates a fixed-dimensional vector representation of the sequence. $\mathbf{x}_t \in \mathbb{R}^l$ is an input vector of length l. The most common approach is to use an RNN such that:

$$\mathbf{h}_t = f(\mathbf{h}_{t-1}, \mathbf{x}_t) \tag{1}$$

where $\mathbf{h}_t \in \mathbb{R}^n$ is a hidden state at time t, and f is generally a non-linear transformation, producing $\mathbf{e} := \mathbf{h}_{T+1}$ as the input representation. The decoder is trained to predict the next output y_t given the encoded input vector $\mathbf{e}$ and all the previously predicted outputs $\langle y_1, \cdots y_{t-1} \rangle$. In other words, the decoder defines a probability over the output sequence $\vec{y} = \langle y_1, \cdots, y_{T'} \rangle$ by decomposing the joint probability into ordered conditionals:

$$p(\vec{y}|\vec{x}) = \prod\nolimits_{t=1}^{T'} p(y_t|\mathbf{e}, \langle y_1, \cdots, y_{t-1} \rangle) \tag{2}$$

With a decoder RNN, we can first obtain the hidden layer at time t as: $\mathbf{s}_t = g(\mathbf{s}_{t-1}, \{\mathbf{e}, \mathbf{y}_{t-1}\})$ and feed this into a softmax layer to obtain the conditional probability as:

$$p(y_t = i|\mathbf{e}, \vec{y}_{<t}) = \text{softmax}(\mathbf{W}_s \mathbf{s}_t + \mathbf{b}_s)_i \tag{3}$$

where, $\vec{y}_{<t} = \langle y_1, \cdots, y_{t-1} \rangle$. In recent work, both f and g are generally LSTMs, a kind of RNN which we describe next.

3.2 Long Short-Term Memory (LSTM)

In principle, RNNs allow retaining information from time steps in the distant past, but the nonlinear "squashing" functions applied in the calculation of each $\mathbf{h}_t$ result in a decay of the error signal used in training with backpropagation. LSTMs are a variant of RNNs designed to cope with this "vanishing gradient" problem using an extra memory "cell" (Hochreiter and Schmidhuber, 1997; Graves, 2013). Past work explains the computation within an LSTM through the metaphors of deciding how much of the current input to pass into memory or forget. We refer interested readers to the original papers for details.

4 Inflection Generation Model

We frame the problem of inflection generation as a sequence to sequence learning problem of character sequences. The standard encoder-decoder models were designed for machine translation where the objective is to translate a sentence (sequence of words) from one language to a semantically equivalent sentence (sequence of words) in another language. We can easily port the encoder-decoder translation model for inflection generation. Our model predicts the sequence of characters in the inflected string given the characters in the root word (input).

However, our problem differs from the above setting in two ways: (1) the input and output character

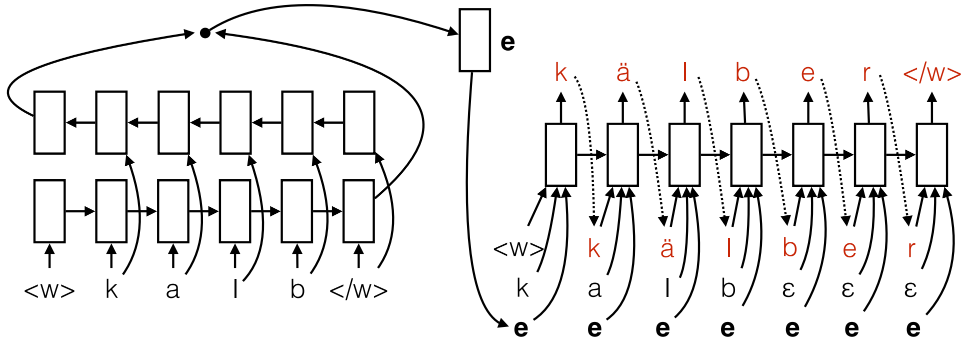

Figure 3: The modified encoder-decoder architecture for inflection generation. Input characters are shown in black and predicted characters are shown in red. • indicates the append operation.

sequences are mostly similar except for the inflections; (2) the input and output character sequences have different semantics. Regarding the first difference, taking the word *play* as an example, the inflected forms corresponding to past tense and continuous forms are *played* and *playing*. To better use this correspondence between the input and output sequence, we also feed the input sequence directly into the decoder:

$$\mathbf{s}_t = g(\mathbf{s}_{t-1}, \{\mathbf{e}, \mathbf{y}_{t-1}, \mathbf{x}_t\}) \qquad (4)$$

where, g is the decoder LSTM, and $\mathbf{x}_t$ and $\mathbf{y}_t$ are the input and output character vectors respectively. Because the lengths of the input and output sequences are not equal, we feed an ϵ character in the decoder, indicating null input, once the input sequence runs out of characters. These ϵ character vectors are parameters that are learned by our model, exactly as other character vectors.

Regarding the second difference, to provide the model the ability to learn the transformation of semantics from input to output, we apply an affine transformation on the encoded vector $\mathbf{e}$:

$$\mathbf{e} \leftarrow \mathbf{W}_{trans}\mathbf{e} + \mathbf{b}_{trans} \qquad (5)$$

where, $\mathbf{W}_{trans}, \mathbf{b}_{trans}$ are the transformation parameters. Also, in the encoder we use a bi-directional LSTM (Graves et al., 2005) instead of a uni-directional LSTM, as it has been shown to capture the sequence information more effectively (Ling et al., 2015; Ballesteros et al., 2015; Bahdanau et al., 2015). Our resultant inflection generation model is shown in Figure 3.

4.1 Supervised Learning

The parameters of our model are the set of character vectors, the transformation parameters $(\mathbf{W}_{trans}, \mathbf{b}_{trans})$, and the parameters of the encoder and decoder LSTMs (§3.2). We use negative log-likelihood of the output character sequence as the loss function:

$$-\log p(\vec{y}|\vec{x}) = -\sum_{t=1}^{T'} \log p(y_t|\mathbf{e}, \vec{y}_{<t}) \qquad (6)$$

We minimize the loss using stochastic updates with AdaDelta (Zeiler, 2012). This is our purely supervised model for inflection generation and we evaluate it in two different settings as established by previous work:

Factored Model. In the first setting, we learn a separate model for each type of inflection independent of the other possible inflections. For example, in case of German nouns, we learn 8, and for German verbs, we learn 27 individual encoder-decoder inflection models (cf. Table 3). There is no parameter sharing across these models. We call these factored models of inflection generation.

Joint Model. In the second setting, while learning a model for an inflection type, we also use the information of how the lemma inflects across all other inflection types i.e., the inflection table of a root form is used to learn different inflection models. We model this, by having the same encoder in the encoder-decoder model across all inflection models.[2] The encoder in our model is learning a

[2] We also tried having the same encoder and decoder across inflection types, with just the transformation matrix being dif-

$p_{\text{LM}}(\vec{y})$	$p(\vec{y}\|\vec{x})$
len($\vec{y}$) - len($\vec{x}$)	levenshtein($\vec{y}$, $\vec{x}$)
same-suffix($\vec{y}$, $\vec{x}$)?	subsequence($\vec{y}$, $\vec{x}$)?
same-prefix($\vec{y}$, $\vec{x}$)?	subsequence($\vec{x}$, $\vec{y}$)?

Table 2: Features used to rerank the inflected outputs. $\vec{x}$, $\vec{y}$ denote the root and inflected character sequences resp.

representation of the input character sequence. Because all inflection models take the same input but produce different outputs, we hypothesize that having the same encoder can lead to better estimates.

4.2 Semi-supervised Learning

The model we described so far relies entirely on the availability of pairs of root form and inflected word form for learning to generate inflections. Although such supervised models can be used to obtain inflection generation models (Durrett and DeNero, 2013; Ahlberg et al., 2015), it has been shown that unlabeled data can generally improve the performance of such systems (Ahlberg et al., 2014; Nicolai et al., 2015). The vocabulary of the words of a language encode information about what correct sequences of characters in a language look like. Thus, we learn a language model over the character sequences in a vocabulary extracted from a large unlabeled corpus. We use this language model to make predictions about the next character in the sequence given the previous characters, in following two settings.

Output Reranking. In the first setting, we first train the inflection generation model using the supervised setting as described in §4.1. While making predictions for inflections, we use beam search to generate possible output character sequences and rerank them using the language model probability along with other easily extractable features as described in Table 2. We use pairwise ranking optimization (PRO) to learn the reranking model (Hopkins and May, 2011). The reranker is trained on the beam output of dev set and evaluated on test set.

Language Model Interpolation. In the second setting, we interpolate the probability of observing the next character according to the language model with the probability according to our inflection generation model. Thus, the loss function becomes:

Dataset	root forms	Infl.
German Nouns (DE-N)	2764	8
German Verbs (DE-V)	2027	27
Spanish Verbs (ES-V)	4055	57
Finnish NN & Adj. (FI-NA)	6400	28
Finnish Verbs (FI-V)	7249	53
Dutch Verbs (NL-V)	11200	9
French Verbs (FR-V)	6957	48

Table 3: The number of root forms and types of inflections across datasets.

$$-\log p(\vec{y}|\vec{x}) = \frac{1}{Z}\sum_{t=1}^{T'} - \log p(y_t|\mathbf{e}, \vec{y}_{<t}) - \lambda \log p_{\text{LM}}(y_t|\vec{y}_{<t}) \quad (7)$$

where $p_{LM}(y_t|\vec{y}_{<t})$ is the probability of observing the word y_t given the history estimated according to a language model, $\lambda \geq 0$ is the interpolation parameter which is learned during training and Z is the normalization factor. This formulation lets us use any off-the-shelf pre-trained character language model easily (details in §5).

4.3 Ensembling

Our loss functions (equ. 6 & 7) formulated using a neural network architecture are non-convex in nature and are thus difficult to optimize. It has been shown that taking an ensemble of models which were initialized differently and trained independently leads to improved performance (Hansen and Salamon, 1990; Collobert et al., 2011). Thus, for each model type used in this work, we report results obtained using an ensemble of models. So, while decoding we compute the probability of emitting a character as the product-of-experts of the individual models in the ensemble: $p_{ens}(y_t|\cdot) = \frac{1}{Z}\prod_{i=1}^{k} p_i(y_t|\cdot)^{\frac{1}{k}}$ where, $p_i(y_t|\cdot)$ is the probability according to i-th model and Z is the normalization factor.

5 Experiments

We now conduct experiments using the described models. Note that not all previously published models present results on all settings, and thus we compare our results to them wherever appropriate.

Hyperparameters. Across all models described in this paper, we use the following hyperparameters.

ferent (equ. 5), and observed consistently worse results.

In both the encoder and decoder models we use single layer LSTMs with the hidden vector of length 100. The length of character vectors is the size of character vocabulary according to each dataset. The parameters are regularized with ℓ_2, with the regularization constant 10^{-5}.[3] The number of models for ensembling are $k = 5$. Models are trained for at most 30 epochs and the model with best result on development set is selected.

5.1 Data

Durrett and DeNero (2013) published the Wiktionary inflection dataset with training, development and test splits. The development and test sets contain 200 inflection tables each and the training sets consist of the remaining data. This dataset contains inflections for German, Finnish and Spanish. This dataset was further augmented by (Nicolai et al., 2015), by adding Dutch verbs extracted from CELEX lexical database (Baayen et al., 1995), French verbs from Verbsite, an online French conjugation dictionary and Czech nouns and verbs from the Prague Dependnecy Treebank (Hajič et al., 2001). As the dataset for Czech contains many incomplete tables, we do not use it for our experiments. These datasets come with pre-specified training/dev/test splits, which we use. For each of these sets, the training data is restricted to 80% of the total inflection tables, with 10% for development and 10% for testing. We list the size of these datasets in Table 3.

For semi-supervised experiments, we train a 5-gram character language model with Witten-Bell smoothing (Bell et al., 1990) using the SRILM toolkit (Stolcke, 2002). We train the character language models on the list of unique word types extracted from the Wikipedia dump for each language after filtering out words with characters unseen in the inflection generation training dataset. We obtained around 2 million unique words for each language.

5.2 Results

Supervised Models. The individual inflected form accuracy for the factored model (§4.1) is shown in Table 4. Across datasets, we obtain either comparable or better results than NCK15 while obtaining on average an accuracy of 96.20% which is higher than both DDN13 and NCK15. Our factored model performs better than DDN13 and NCK15 on datasets with large training set (ES-V, FI-V, FI-NA, NL-V, FR-V) as opposed to datasets with small training set (DE-N, DE-V). In the joint model setting (cf. Table 5), on average, we perform better than DDN13 and AFH14 but are behind AFH15 by 0.11%. Our model improves in performance over our factored model for DE-N, DE-V, and ES-V, which are the three smallest training datasets. Thus, parameter sharing across different inflection types helps the low-resourced scenarios.[4]

	DDN13	NCK15	Ours
DE-V	94.76	**97.50**	96.72
DE-N	88.31	**88.60**	88.12

Semi-supervised Models. We now evaluate the utility of character language models in inflection generation, in two different settings as described earlier (§4.2). We use the factored model as our base model in the following experiments as it performed

[3] Using dropout did not improve our results.

[4] Although NCK15 provide results in the joint model setting, they also use raw data in the joint model which makes it incomparable to our model and other previous models.

	AFH14	NCK15	Interpol	Rerank
DE-V	97.87	**97.90**	96.79	97.11
DE-N	91.81	**89.90**	88.31	89.31
ES-V	99.58	99.90	99.78	**99.94**
FI-V	96.63	**98.10**	96.66	97.62
FI-NA	93.82	93.60	94.60	**95.66**
Avg.	**95.93**	95.88	95.42	**95.93**
NL-V	–	96.60	**96.66**	96.64
FR-V	–	**99.20**	98.81	98.94
Avg.	–	**96.45**	96.08	**96.45**

Table 6: Individual form prediction accuracy for **factored semi-supervised** models.

Model	Accuracy
Encoder-Decoder	79.08
Encoder-Decoder Attention	95.64
Ours W/O Encoder	84.04
Ours	**96.20**

Table 7: Avg. accuracy across datasets of the encoder-decoder, attentional encoder-decoder & our model without encoder.

better than the joint model (cf. Table 4 & 5). Our reranking model which uses the character language model along with other features (cf. Table 2) to select the best answer from a beam of predictions, improves over almost all the datasets with respect to the supervised model and is equal on average to AFH14 and NCK15 semi-supervised models with 96.45% accuracy. We obtain the best reported results on ES-V and FI-NA datasets (99.94% and 95.66% respectively). However, our second semi-supervised model, the interpolation model, on average obtains 96.08% and is surprisingly worse than our supervised model (96.20%).

Comparison to Other Architectures. Finally it is of interest how our proposed model compares to more traditional neural models. We compare our model against a standard encoder-decoder model, and an encoder-decoder model with attention, both trained on root form to inflected form character sequences. In a standard encoder-decoder model (Sutskever et al., 2014), the encoded input sequence vector is fed into the hidden layer of the decoder as input, and is not available at every time step in contrast to our model, where we additionally feed in $\mathbf{x}_t$ at every time step as in equ. 4. An attentional model computes a weighted average of the hidden layer of the input sequence, which is then used along with the decoder hidden layer to make a prediction (Bahdanau et al., 2015). These models also do not take the root form character sequence as inputs to the decoder. We also evaluate the utility of having an encoder which computes a representation of the input character sequence in a vector $\mathbf{e}$ by removing the encoder from our model in Figure 3. The results in Table 7 show that we outperform the encoder-decoder model, and the model without an encoder substantially. Our model is slightly better than the attentional encoder-decoder model, and is simpler as it does not have the additional attention layer.

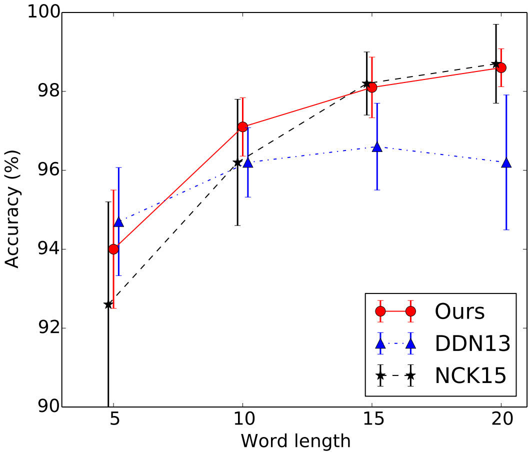

Figure 4: Plot of inflection prediction accuracy against the length of gold inflected forms. The points are shown with minor offset along the x-axis to enhance clarity.

6 Analysis

Length of Inflected Forms. In Figure 4 we show how the prediction accuracy of an inflected form varies with respect to the length of the correct inflected form.To get stable estimates, we bin the inflected forms according to their length: < 5, $[5, 10)$, $[10, 15)$, and ≥ 15. The accuracy for each bin is macro-averaged across 6 datasets[5] for our factored model and the best models of DDN13 and NCK15. Our model consistently shows improvement in performance as word length increases and is significantly better than DDN13 on words of length more than 20 and is approximately equal to NCK15. On words of length < 5, we perform worse than DDN13

[5] We remove DE-N as its the smallest and shows high variance in results.

but better than NCK15. On average, our model has the least error margin across bins of different word length as compared to both DDN13 and NCK15. Using LSTMs in our model helps us make better predictions for long sequences, since they have the ability to capture long-range dependencies.

Finnish Vowel Harmony. Our model obtains the current best result on the Finnish noun and adjective dataset, this dataset has the longest inflected words, some of which are > 30 characters long. Finnish exhibits *vowel harmony*, i.e, the occurrence of a vowel is controlled by other vowels in the word. Finnish vowels are divided into three groups: front (ä, ö, y), back (a, o, u), and neutral (e, i). If back vowels are present in a stem, then the harmony is back (i.e, front vowels will be absent), else the harmony is front (i.e, back vowels will be absent). In compound words the suffix harmony is determined by the final stem in the compound. For example, our model correctly inflects the word *fasisti* (fascist) to obtain *fasisteissa* and the compound *tärkkelyspitoinen* (starch containing) to *tärkkelyspitoisissa*. The ability of our model to learn such relations between these vowels helps capture vowel harmony. For FI-NA, our model obtains 99.87% for correctly predicting vowel harmony, and NCK15 obtains 98.50%.We plot the character vectors of these Finnish vowels (cf. Figure 5) using t-SNE projection (van der Maaten and Hinton, 2008) and observe that the vowels are correctly grouped with visible transition from the back to the front vowels.

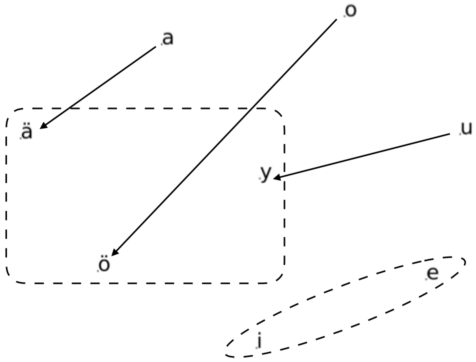

Figure 5: Plot of character vectors of Finnish vowels. Their organization shows that front, back and neutral vowel groups have been discovered. The arrows show back and front vowel correspondences.

7 Related Work

Similar to the encoder in our framework, Rastogi et al. (2016) extract sub-word features using a forward-backward LSTM from a word, and use them in a traditional weighted FST to generate inflected forms. Neural encoder-decoder models of string transduction have also been used for sub-word level transformations like grapheme-to-phoneme conversion (Yao and Zweig, 2015; Rao et al., 2015).

Generation of inflectional morphology has been particularly useful in statistical machine translation, both in translation from morphologically rich languages (Goldwater and McClosky, 2005), and into morphologically rich languages (Minkov et al., 2007; Toutanova et al., 2008; Clifton and Sarkar, 2011; Fraser et al., 2012). Modeling the morphological structure of a word has also shown to improve the quality of word clusters (Clark, 2003) and word vector representations (Cotterell and Schütze, 2015).

Inflection generation is complementary to the task of morphological and phonological segmentation, where the existing word form needs to be segmented to obtained meaningful sub-word units (Creutz and Lagus, 2005; Snyder and Barzilay, 2008; Poon et al., 2009; Narasimhan et al., 2015; Cotterell et al., 2015; Cotterell et al., 2016). An additional line of work that benefits from implicit modeling of morphology is neural character-based natural language processing, e.g., part-of-speech tagging (Santos and Zadrozny, 2014; Ling et al., 2015) and dependency parsing (Ballesteros et al., 2015). These models have been successful when applied to morphologically rich languages, as they are able to capture word formation patterns.

8 Conclusion

We have presented a model that generates inflected forms of a given root form using a neural network sequence to sequence string transducer. Our model obtains state-of-the-art results and performs at par or better than existing inflection generation models on seven different datasets. Our model is able to learn long-range dependencies within character sequences for inflection generation which makes it specially suitable for morphologically rich languages.

Abstract

In this paper, we address the task of language-independent, knowledge-lean and unsupervised compound splitting, which is an essential component for many natural language processing tasks such as machine translation. Previous methods on statistical compound splitting either include language-specific knowledge (e.g., linking elements) or rely on parallel data, which results in limited applicability. We aim to overcome these limitations by learning compounding morphology from inflectional information derived from lemmatized monolingual corpora. In experiments for Germanic languages, we show that our approach significantly outperforms language-dependent state-of-the-art methods in finding the correct split point and that word inflection is a good approximation for compounding morphology.

1 Introduction

Compounding represents one of the most productive word formation types in many languages. In particular, Germanic languages (e.g., German or Dutch) show high productivity in closed compounding, i.e., in creating one-word compounds such as the German *Armutsbekämpfungsprogramm* 'poverty elimination program'. Previous studies on German corpora reveal that almost half of the corpus types are compounds, whereas individual compounds are very infrequent (Baroni et al., 2002). Therefore, an automatic compound analysis is indispensable and represents an essential component in many natural language processing (NLP) tasks such as machine translation (MT) or information retrieval (IR).

Besides determining the concatenated constituent forms, i.e., the correct split points (e.g., *Armuts* | *bekämpfungs* | *programm*), a compound splitter needs to normalize each part (e.g., *Armut* + *Bekämpfung* + *Programm*), because down-stream applications such as MT systems expect lemmatized words as input. However, normalization of constituent forms is non-trivial and usually requires language-specific knowledge (e.g., linking elements). State-of-the-art lemmatizers, designed for regular word inflection, would fail, because constituent forms often contain linking elements leading to a non-paradigmatic word form of the corresponding lexeme (e.g., *Armuts* 'poverty + *s*' never occurs as an isolated token in German corpora, since the *s*-suffix, often used for genitive or pluralization, is not used with *Armut*). Moreover, morphological operations during compounding vary a lot across languages and lexemes: we find cases that start from the lemma and have additions (e.g., linking elements), truncations (e.g., reductions to a verbal stem), word-internal operations (e.g., Umlautung) and combinations thereof (e.g., the first constituent of the German *Weihnachts*|*baum* 'Christmas tree', *Weihnachten*, undergoes both the *en*-truncation and the *s*-suffixation).

In this paper, we present a language-independent, unsupervised compound splitter that normalizes constituent forms by tolerantly retrieving candidate lemmas using an Ngram index and weighting string differences with inflectional information derived from lemmatized corpora.

Most previous work on compound splitting includes language-specific knowledge such as large

Proceedings of NAACL-HLT 2016, pages 644–653,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

lexicons and morphological analyzers (Fritzinger and Fraser, 2010) or hand-crafted lists of linking elements and rules for modeling morphological transitions (Koehn and Knight, 2003; Stymne, 2008; Weller and Heid, 2012), which makes the approaches language-dependent. Macherey et al., (2011) were the first to overcome this limitation by learning morphological compounding operations automatically by retrieving compounds and their constituents from parallel corpora including English as support language.

We would like to take this one step further by avoiding the usage of parallel data, which are known to be sparse and frequently domain-specific, while Bretschneider and Zillner (2015) showed that compounding morphology varies between different domains. Instead, we exploit lemmatized corpora and use word inflection as an approximation to compounding morphology. This way, we are able to process compounds of any type of domain.

Our contributions are as follows. Firstly, we develop a language-independent and unsupervised compound splitter that does not rely on parallel data. As we will show, our system significantly outperforms language-dependent, knowledge-rich state-of-the-art methods in predicting the best split point. Secondly, in a controlled experiment, we show that compound splitting based on inflectional morphology performs similarly to splitting based on an extensive hand-crafted set of rules for compounding morphology. Thirdly, we perform a comprehensive, intrinsic evaluation of compound splitting, which is often missing in previous work that focuses on task-based evaluation (e.g., MT), and thus evaluates performance only indirectly. We compare splitting performance for several languages for two disciplines: (1) prediction of the correct split points and (2) normalization of the constituent forms. To the best of our knowledge, we are the first to evaluate these disciplines separately.

The paper is structured as follows. Section 2 outlines previous work on compound splitting. Section 3 discusses some theoretical assumptions on which we base our splitting method. Section 4 shows two efficient and flexible data structures used for our statistical compound splitter, which is described in Section 5. Section 6 presents some splitting experiments performed on German, Dutch and Afrikaans. Finally, Section 7 concludes and points to future work.

2 Related work

In the following discussion, we focus on splitting approaches that address morphological transformations, as these are most relevant for our work. Previous work on compound splitting can be roughly divided into two groups: (1) *statistical* approaches that are mainly based on large corpora and (2) *linguistically based* splitters, usually relying on knowledge-rich morphological analyzers or rules.

Statistical approaches generate all possible splits and rank them according to corpus statistics. Although independent of lexical resources, most methods contain morphological knowledge in terms of linking elements. The most influential statistical splitter is developed by Koehn and Knight (2003) who addressed German compound splitting by scoring splits according to the geometric mean of the potential constituents' frequencies. For normalization, they selected the two fillers ⊕s and ⊕es. Stymne (2008) performed several experiments to measure the impact of varying parameters of Koehn and Knight's (2003) algorithm for factored statistical MT. Instead of using two single fillers, she implemented the collection of the 20 most frequent morphological transformations for German compounding as presented by Langer (1998). She observed that splitting parameters should not necessarily be the same for translating in different directions. Bretschneider and Zillner (2015) compared the splitting performance between Koehn and Knight's (2003) two fillers and Langer's (1998) collection, illustrating the necessity of an exhaustive set of linking elements. Moreover, they showed that Langer's (1998) data is still not sufficient for domain-specific targets. Macherey et al., (2011) were the first to overcome the need for manual morphological input and the limitation to a fixed set of linking elements by learning morphological operations automatically from parallel corpora including a support language which creates open compounds and has only little inflection, such as English. We take this one step further by avoiding the dependence on such parallel corpora, known to be sparse, and by approximating compounding morphology with word inflection learned from monolingual preprocessed data.

Linguistically based splitters are usually relying on a lexical database or a set of linguistic rules. While these splitters outperform statistical approaches (Escartín, 2014), they are designed for a specific language and thus less applicable to other languages. Nießen and Ney (2000) used the morpho-syntactic analyzer GERTWOL (Mariikka Haapalainen and Ari Majorin, 1995) for splitting compounds. Schmid (2004) developed the morphological analyzer SMOR, that enumerates linguistically motivated compound splits. Fritzinger and Fraser (2010) combined SMOR with Koehn and Knight's (2003) statistical approach and outperformed both individual methods. Weller and Heid (2012) extended the splitter of Koehn and Knight (2003) with a list of PoS-tagged lemmas and a handcrafted set of morphological transition rules. While our approach similarly exploits lemma and PoS information, we avoid the manual input of transition rules.

3 Theoretical preliminaries

The splitting architecture, data structure, features and evaluation we propose in this paper are based on a number of assumptions and considerations that we would like to discuss first.

3.1 Morphological transformation

Closed (or concatenative) compounding is the main spelling form in many languages around the world, e.g., Germanic languages such as *German*, *Dutch*, *Swedish*, *Afrikaans* or *Danish*, Uralic languages such as *Estonian* or *Finnish*, Hellenic languages such as *Modern Greek*, Slavic languages such as *Russian* and many more. Most closed-compounding languages use morphological transformations. German or Dutch often insert a linking element between the constituents while Greek reduces the first constituent to its morphological stem and adds a compound marker. In contrast to conjugations of irregular verbs (such as *to be*), there is only a minor string difference (e.g., in terms of edit distance (ED)) between constituent form and corresponding lemma (usually they differ in at most two characters). This minimal difference makes it possible to interpret constituent normalization as a kind of tolerant string retrieval (which is presented for the case of spelling correction within IR by Manning et al., (2008)). This is why we are using an Ngram index for retrieving the candidate lemmas with the highest string similarity to the constituent form.

3.2 Inflectional morphology

Relying exclusively on the highest string similarity for the normalization, would lead to candidate lemmas that result from linguistically unmotivated operations, e.g., the German *Hühner* 'chickens' would be normalized to the most string-similar lemma *Hüne* 'giant' (ED=2) and not to the correct but less string-similar lemma *Huhn* 'chicken' (ED=3). Thus, a linguistic restrictor is indispensable for finding the underlying lemma for a given constituent.

In many languages, inflectional morphology shares operations with compounding morphology, e.g., the German *Hühner* in *Hühner|suppe* 'chicken soup' is equivalent to the plural form of *Huhn*. But even for non-paradigmatic constituent forms (e.g., *Armuts* 'poverty'), we can find cases of inflection that use the transformation at hand (e.g., the genitive form of window: *Fensters*).

We thus decided to approximate compounding morphology by using inflectional morphology as derived from lemmatized corpus tokens. We realize that the inflectional approximation does not work for all closed-compounding languages but it does for a large subset that is known to have a large variety of linking elements and is therefore most in need of unsupervised morphology induction, the Germanic languages. Moreover, our flexible system can be easily supported with morphological information, which is suitable for languages like Greek, that use a special compound marker.

3.3 Compound headedness

Most closed-compounding languages usually follow the **r**ight**h**and **h**ead **r**ule (RHHR), i.e., the head of a compound is the right-most constituent and encodes the principal semantics and the PoS of the compound. As done by previous splitting approaches (Stymne, 2008; Weller and Heid, 2012), we assume the RHHR and allow only splits for which the right-hand side constituents has the same PoS as the compound.

3.4 Splitting depth

The granularity of the morphological analysis needed differs with the type of application. For MT, a compound should not be split deeper than into parts for which a translation is known, whereas for linguistic research, a deeper morphological analysis is desirable.

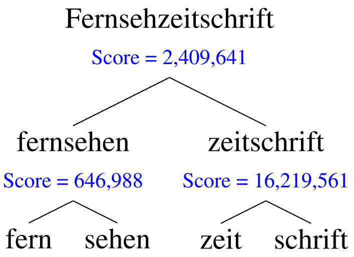

Figure 1: Linguistically motivated split

For example, while an MT system needs a binary split for the German *Fernsehzeitschrift* 'television journal', for a linguistic analysis, a split into four parts as given in Figure 1 is also valid and introduces etymological clues (e.g., how far is *Zeit* 'time' related to *Zeitschrift* 'journal'). Our flexible approach caters for all tasks[1].

3.5 Constituent length balance

While compounds can be build up from almost any semantic concept pair, we observed a bias towards constituent pairs having a similar word length.

For the German, Dutch and Afrikaans compound splitting gold standards (described in Section 6.2) comprising m split compounds, we randomly recombine all modifiers with all heads to a set of m recombinations. For both original compounds and recombined compounds, we measure the character difference in length between modifier and head form.

Compound set	German	Dutch	Afrikaans
Original	2.62	2.26	2.87
Recombination	3.43	2.74	2.92

Table 1: Average constituent length difference in characters

As shown in Table 1, all original compounds have a smaller difference than the recombinations. Therefore, we decided to promote compound splits with more balanced constituent lengths.

4 Data preparation

4.1 Ngram index

As described in Section 3.1, we tolerantly retrieve candidate lemmas using an Ngram index, in order to limit the search space and allow for a quick candidate lookup during splitting.

Ngram	Lemma length (LL)	Lemmas
ˆhund	4	hund#13162
ˆhund	11	hundeführer#251, hundehalter#81, hundesteuer#64
ˆh⋆hn	4	hahn#2078, huhn#1839, hohn#506

Table 2: Examples from the German Ngram index

As search key, we use Ngrams of variable length ($N \leq 15$). Word-initial Ngrams are indicated by ˆ and word-final Ngrams end on \$. By using Ngrams, we are able to capture any kind of transformation a lemma can undergo when involved in compounding.

Sometimes, a transformation includes a character replacement within the word (e.g., Umlautung). This leads to a very small set of Ngrams a constituent has in common with its underlying lemma. For example *Hühner* and *Huhn* only have the bigrams ˆh and hn in common, which is also true for many irrelevant words such as *ˆHaarschnitt* 'haircut'. In order to reduce noise and increase efficiency, we include the wildcard $*$ for a single character in Ngrams[2]. This way, *Hühner* and *Huhn* have the common 5gram ˆH⋆hn. As a further cue, we consider the lemma length (assuming that there is only a minor difference to the constituent's length).

For a given lemmatized and PoS-tagged corpus, we index all content words (i.e., nouns, adjectives and verbs) by generating all Ngrams and mapping them to a list of frequency-ranked lemma-freq pairs. Table 2 shows some examples for German[3].

[1] As the splitting depth is very dependent on the task at hand and the gold standard we used is not created with a specific task in mind, we do not evaluate our system with respect to splitting depth but treat it as given. Our system cuts off subtrees with the lowest splitting score until the desired splitting depth is achieved.

[2] For efficiency reasons, we add wildcard Ngrams only for $3 \leq N \leq 7$.

[3] Note that the lemmas include compounds, because these are necessary for our binary recursive splitter, described in Section 5.

Language	MOP	Corpus frequency	Examples
German	u/ü:$/er$	117K	<Huhn, Hühner> ‘chicken’, <Buch, Bücher> ‘book’
	um$/en$	264K	<Studium, Studien> ‘study’, <Medium, Medien> ‘medium’
Dutch	$/en$	1.6M	<arts, artsen> ‘doctor’, <band, banden> ‘tyre’
Afrikaans	$/se$	34K	<proses, prosesse> ‘process’

Table 3: Examples of MOPs for German, Dutch and Afrikaans

4.2 Morphological operation patterns

Macherey et al., (2011) describe a representation of compounding morphology using a single character replacement at either the beginning, the middle or the end of a word. For our experiments, we adopt this format. Since it is possible that a morphological operation takes place at several positions of a word, we combine all atomic replacements into a pattern describing a series of operations. This transformation from a word Σ to a word Ω is referred to as **m**orphological **o**peration **p**attern (MOP). For compiling an MOP, we use the Levenshtein edit distance algorithm including the four operations INSERT (adding a character), DELETE (removing a character), REPLACE (exchanging a character σ_i by ω_i) and COPY (retaining a character). In a backtrace step, we determine the first set of operations that lead to a minimum edit distance. Except for COPY, we interpret all operations as replacements (insertion and deletion are replacements of or by an empty element ϵ respectively). We merge all adjacent replacements by concatenating the source and target characters. Word-initial source and target sequences start with ^ and word-final sequences end on $. Sequences of adjacent COPY operations are represented by ‘:’ and separate the merged replacements. For example, in *Hühner*|*suppe*, the modifier lemma *Huhn* is transformed to *Hühner* by replacing u by ü (i.e., Umlautung) and adding the suffix er. The corresponding MOP is ‘u/ü:$/er$’. The second column in Table 3 shows some additional German, Dutch and Afrikaans examples of MOPs.

As discussed in Section 3.2, we try to approximate compounding MOPs using inflectional MOPs. In a lemmatized corpus, for each lemmatized word token, we determine the MOP that represents the transformation from lemma to word form. We collect all inflectional MOPs with their token-based corpus frequency. The third column in Table 3 shows the corpus frequencies for the corresponding MOPs.

5 Compound splitting method

Our compound splitter can process compounds composed of any content word type (i.e., nouns, verbs and adjectives) and of any number of constituents, and provides both the split points (e.g., *Hühner*|*suppe*) and the normalized constituents (e.g., *Huhn* + *Suppe*). The splitter is designed recursively, which allows us to represent the compound split both hierarchical (i.e., as a tree structure) and as a linear sequence. Figure 2 shows the architecture of our splitting algorithm. The recursive main method starts with the target word as a single constituent and recursively splits the constituents produced by the binary splitter (Section 5.1) until an atomic result is returned. The binary splitter has two subtasks: (1) for each potential constituent form, a set of candidate lemmas is retrieved (Section 5.2) and (2) all candidate lemma combinations are ranked and the best split is returned (Section 5.3).

5.1 Binary splitter

We first generate all possible binary splits with a minimum constituent length of 2 (e.g., for *Ölpreis* ‘oil price’, we generate *Öl*|*preis*, …, *Ölpre*|*is*) and add a non-split option. For each potential constituent among the generated splits, we retrieve the M most probable lemmas as described in Section 5.2. We consider all M^2 lemma combinations of all possible splits and rank them as described in Section 5.3. The highest-ranked split is returned.

5.2 Candidate lemma retrieval

In this step, we retrieve the M most probable candidate lemmas for a given constituent. For this task, we make use of the Ngram index, described in Section 4.1. Instead of applying MOPs directly which would be the classical and more efficient way, we decided to look up candidates using the Ngram in-

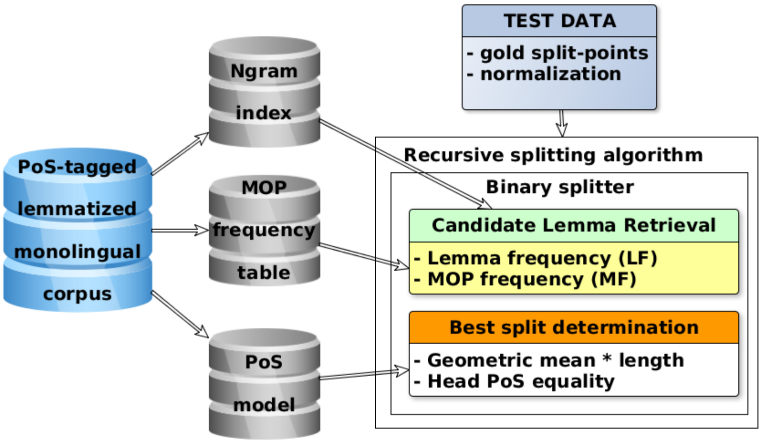

Figure 2: Architecture of our splitting algorithm

dex first, thereby following the assumption that there is only a minor string difference between lemma and constituent form (cf. Section 3.1). In a second step, the inflectional MOPs are used to rank the candidate lemmas. While following this order, we put less weight on our approximation and thereby avoid false lemmas due to irrelevant inflectional MOPs. The pseudocode for the candidate lemma retrieval is given in Algorithm 1.

Algorithm 1 Candidate lemma retrieval

```
 1: Constituent $c$
 2: LLs ← lemma lengths, $\pm\Delta$ around len($c$)
 3: CLs ← [ ]                                  ▷ the candidate lemmas
 4: for $L \leftarrow len(c)$ to 1 do
 5:     LGs ← generate all $L$grams of $c$
 6:     for Lg in LGs do
 7:         CLs ← CLs + top$\lambda$(IDX[Lg][LLs])
 8:     if len(CLs) $> 1$ then
 9:         break                  ▷ otherwise, L is decremented
10: score(CLs)                      ▷ according to a lemma model
11: rank(CLs)                            ▷ according to the scores
12: return top$M$(CLs)
```

For a given constituent c, we search for lemmas with a minimum lemma length (LL) of 2 which ranges between $\pm\Delta$ around the length of c (lines 1-2). All retrieved candidate lemmas are stored in the list CLs (line 3). Starting with the L = len(c), we inspect all Lgrams of c (lines 4-5). For a given Lgram, we retrieve the top λ most frequent lemmas that have a length $\pm\Delta$ around the length of c (lines 6-7). If there are no lemmas retrieved, we decrement L (lines 8-9)[4]. All retrieved candidate lemmas are scored (line 10) according to our lemma model, for which we present two lemma features.

$$LP(l_i) = cf(l_i) \cdot count(l_i, \texttt{CLs}) \qquad (1)$$

The first feature is based on the lemma prominence (LP) as given in (1), i.e., we multiply the corpus frequency (cf) of a lemma l_i (as given in the Ngram index) with the token number of l_i in CLs (i.e., with the prominence of l_i among all inspected Lgrams).

The second feature estimates the suitability of the MOP (MS) transforming the candidate lemma l_i to the constituent form at hand, c, (represented as '$MOP[l_i, c]$'), as given in (2). As the first component, we use the corpus frequency extracted with the inflectional MOPs as described in Section 4.2. We rescale the MOP frequency with the resulting edit distance between the candidate lemma l_i and the constituent form at hand, c, (represented as $ED(l_i, c)$)[5]. As motivated in Section 3.1, we expect MOPs having a small edit distance to be more prominent in compounding. Such MOPs are not necessarily most frequent in inflection, e.g., the frequent irregular Afrikaans verb *wees* (*to be*) leads to MOPs like MOP[*wees*,*is*] = ^wee/^i, which has an ED of 3.

$$MS(l_i) = \frac{cf(MOP[l_i, c])}{ED(l_i, c) + 1} \qquad (2)$$

[4] For noise reduction due to lemmatizer errors, we can predefine a minimum number of L decrements.

[5] For avoiding a division by zero, we add 1.

All candidate lemmas are finally scored as product of lemma prominence and MOP suitability, as given in (3).

$$score(l_i) = LP(l_i) \cdot MS(l_i) \tag{3}$$

We rank all candidate lemmas and return the top M candidates (lines 11-12).

5.3 Best split determination

In the final step, we determine the best split among all split combinations (i.e., pairs of retrieved candidate lemmas for modifier (l_m) and head (l_h), and corresponding split point) and the non-split option. For this task, we use a combination model, which considers the interaction between l_m and l_h. Inspired by Koehn and Knight (2003), as a first feature, we take the geometric mean of the products of lemma score multiplied by the length of the corresponding constituent form, as given in (4). The length factor promotes splits with more balanced lengths (as motivated in Section 3.5), which mitigates the impact of short and high-frequent words on the overall score. For binary splits, we use the constituent set $con = \{l_m, l_h\}$ and for the non-split option, we use $con = \{l_h\}$.

$$geoLen(con) = \sqrt[|con|]{\prod_{l_i \in con} score(l_i) \cdot len(c_{l_i})} \tag{4}$$

The second feature is based on the assumption that the PoS of a compound word Ψ usually equals the PoS of its head l_h, as discussed in Section 3.3. Since our splitter works out of context, we try to subsume all possible PoS tags by representing them as a distribution over the PoS probabilities $p(\text{PoS}|\text{word}) = \frac{freq(PoS \cap word)}{freq(word)}$ acquired from the monolingual PoS-tagged corpus. The value of the head-PoS-equality (hEQ) feature is defined as the the cosine similarity between the PoS probability distributions of compound word Ψ and head l_h, $hEQ(\Psi, l_h)$. If the PoS tag of the compound is unknown, we take 1.0 as default value.

$$split(con) = geoLen(con) \cdot hEQ(\Psi, l_h) \tag{5}$$

Finally, all candidate lemma combinations (including the non-split option) are ranked according to the splitting score given in (5). The highest-scored split is returned as output of the binary splitter, being subject to the recursive process. Figure 3 shows an example of the recursive splitter output for the German compound *Studienbescheinigungsablaufdatum* ‘enrollment certification expiration date’ with the related MOPs.

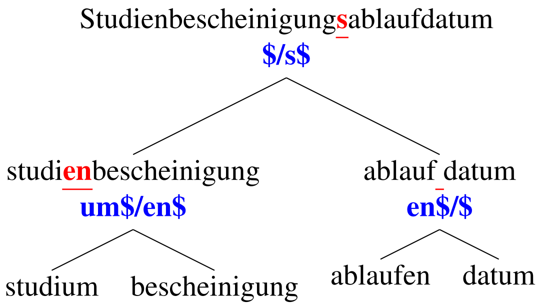

Figure 3: Example of a split tree structure with related MOPs

6 Experiments

In our experiments, we focus on German, Dutch and Afrikaans, but expect to see similar performance for other Germanic languages.

6.1 Data

We use the German and Dutch version of Wikipedia[6] and the Afrikaans Taalkommissie corpus[7]. For tokenizing, PoS-tagging and lemmatizing Wikipedia, we use Treetagger (Schmid, 1995).

Corpus	# tokens	# types		
language	words	words	lemmas	MOPs
German	665M	9.0M	8.8M	1201
Dutch	114M	2.0M	1.9M	920
Afrikaans	57M	748K	696K	459

Table 4: Corpus statistics

We tokenize the Taalkommissie corpus using the approach of Augustinus and Dirix (2013). We PoS-tag the corpus using the tool described in Eiselen and Puttkammer (2014) and use the lemmatizer of Peter Dirix, the second author of the previous paper.

Table 4 shows some statistics of the three preprocessed corpora. Since the Afrikaans corpus is one order of magnitude smaller than the German corpus, we expect a lower performance for the Afrikaans splitter.

[6] {de,nl}.wikipedia.org

[7] Taalkommissie van die Suid-Afrikaanse Akademie vir Wetenskap en Kuns (2011)

System	SPAcc			NormAcc		
	@1	@2	@3	@1	@2	@3

(F) LP.MS$_{\text{GS}}$	95.4%	99.0%	99.4%	87.8%	95.6%	97.2%

Table 5: German results for binary compound splitting, scores δ^{Φ} outperform the system Φ significantly

6.2 Gold standard

For evaluating our splitting method on **German**, we use the binary split compound set developed for GermaNet[8] by Henrich and Hinrichs (2011). After removing hyphenated compounds[9], it comprises **51,230** binary split samples. For **Dutch** and **Afrikaans**, we use the split point gold standards developed by Verhoeven et al., (2014), which comprise **21,941** samples for Dutch and **17,369** for Afrikaans.

6.3 Evaluation measures

We evaluate the splitting quality with respect to two disciplines: (1) determination of the correct split points and (2) normalization of the resulting modifier constituents[10]. For both disciplines, we use the accuracy measure as described in Koehn and Knight (2003). The split point accuracy (**SPAcc**) refers to the correctness of the split points (on word level) and the normalization accuracy (**NormAcc**) measures the amount of both correct split points and modifier lemmas. All systems presented in this paper provide a ranked list of splits. This allows for a more fine-grained ranking evaluation of the binary splitting decisions with respect to the first n positions. Accuracy@n refers to the amount of correct splits among the top n splits. We stop at $n = 3$, because we do not expect to see a crucial difference in the performance gap for higher values of n.

6.4 Parameter setting and models in comparison

There are three parameters presented in the candidate lemma retrieval. For efficiency reasons, we set the number of lemmas retrieved per Lgram and lemma length (λ) to 20 and the final number of retrieved candidate lemmas (M) to 3. For the maximum difference in length between lemma and constituent form, we observed that $\Delta = 2$ covers all compounding operations for Germanic languages.

For German, we compare our system based on inflectional MOPs (LP.MS$_{\text{infl}}$) against the LP baseline (LP.$\varnothing$), which lacks a linguistic restrictor after candidate lemma lookup from the Ngram index, against an upper bound (LP.MS$_{\text{GS}}$), which uses the MOPs and frequencies derived from the normalizations in the gold standard and against a version that uses a hand-crafted set of MOPs and frequencies derived from Langer's (1998) set of fillers (LP.MS$_{\text{Langer}}$). In addition, we compare our system against previous work: the splitting methods of Fritzinger and Fraser (2010) and of Weller and Heid (2012)[11]. For Dutch and Afrikaans, we compare with the SPAcc numbers of Verhoeven et al., (2014).

6.5 Results and discussion

Table 5 shows the **German** results for the binary compound splitting. We present the split point accuracy (SPAcc) and the normalization accuracy (NormAcc) for the splits ranked @1-3. We first compare LP.MS$_{\text{infl}}$ against the previous work of FF2010 and WH2012. Our system significantly[12] outperforms both systems with respect to SPAcc and reaches

[8] sfs.uni-tuebingen.de/GermaNet

[9] We consider hyphenated compounds as trivial cases of splitting that can be disregarded for our purpose.

[10] Since for Germanic languages compounding morphology is exclusively found on the modifier, we disregard the head.

[11] We use an updated version of Weller and Heid (2012) developed and provided to us by Marion Di Marco.

[12] Approximate randomization test (Yeh, 2000), $p < 0.05$

99.4% for SPAcc@3. While for NormAcc@1 our splitter's performance is less than 2 percentage point lower than the system of FF2010, which heavily relies on language-dependent and knowledge-rich resources, we significantly outperform both systems in comparison for NormAcc@2 and NormAcc@3. This proves that one can attain state-of-the-art performance on compound splitting by using language-independent and unsupervised methods, and in particular by means of inflectional information.

In an error analysis, it turned out that FF2010 (i.e., SMOR) cannot process 2% of the gold samples. However on a common processable test set, we still find our system to outperform FF2010 significantly, which indicates that the difference in performance is not just a matter of coverage. WH2012 leaves several compounds unsplit, for which our splitter provides the correct analysis. This is partly due to the hand-crafted transition rules of WH2012, which cannot capture all morphological operations, such as in *Hilfs*|*bereitschaft* 'cooperativeness', for which the MOP `e$/s$` (i.e., the combination of *e*-truncation and *s*-suffixation) is not even covered by Langer's (1998) published collection.

To evaluate whether our assumption about the usability of inflectional MOPs holds, we run some controlled experiments with two variants of our system, shown in the last two lines of Table 5. The exhaustive set of inflectional MOPs (LP.MS$_{\text{infl}}$) shows competitive performance in SPAcc with the hand-crafted set of Langer (1998) (LP.MS$_{\text{Langer}}$) and with the upper bound (LP.MS$_{\text{GS}}$). The latter outperforms LP.MS$_{\text{infl}}$ by only 1 percentage point in NormAcc.

Our separate evaluation of SPAcc and NormAcc reveals a lower performance for the normalization across all systems, as this is a much harder discipline. In addition, we can conclude that normalization requires more linguistic knowledge: while the LP-baseline (LP.∅) underperforms heavily, both FF2010 and LP.MS$_{Langer}$, systems with a lot of lexical and morphological information, outperform all systems in comparison at NormAcc@1.

For illustrating the multilingual applicability of our splitter, we perform an experiment on Dutch and Afrikaans. Table 6 shows the SPAcc[13] results for N-ary splits. While Verhoeven et al., (2014) use a supervised approach for predicting the correct split points, our unsupervised splitter outperforms their **Dutch** results significantly[14]. Although Dutch and Afrikaans are similar languages, the SPAcc achieved by our system for **Afrikaans** is 3.6% worse than the method presented by Verhoeven et al., (2014). This result is partly due to the crucial corpus size differences presented in Table 4.

System	`Dutch`	`Afrikaans`
LP.MS$_{\text{infl}}$	**93.4%**	84.7%
Verh.et.al.2014	91.5%	**88.3%**

Table 6: SPAcc results for N-ary splits in Dutch and Afrikaans

7 Conclusion

We presented a language-independent, unsupervised compound splitter based on inflectional morphology that significantly outperforms state-of-the-art methods in finding the correct split points, relying only on monolingual PoS-tagged and lemmatized corpora. We provided a comprehensive, intrinsic evaluation of several systems in comparison for several languages on two separate disciplines: split point determination and constituent normalization. As a result, we draw the conclusions that inflectional morphology is a practical approximation for compounding in Germanic languages and overcomes the necessity of manual input, because both hand-crafted sets of compounding operations and operations derived from the gold standard lead to small differences in performance only. In future work, we plan to adapt our methods for learning compounding morphology for languages such as Greek, that have a special compound marker.

Acknowledgments

We thank the anonymous reviewers for their helpful feedback. We also thank our colleague Stefan Müller for the discussions and feedback, and Marion Di Marco and Fabienne Cap for providing their splitting methods. This research was funded by the German Research Foundation (Collaborative Research Centre 732, Project D11).

[13] The Dutch and Afrikaans gold standard only provides split points and no reliable normalized constituents.

Phonological Pun-derstanding

Abstract

Many puns create humor through the relationship between a pun and its phonologically similar target. For example, in "Don't take geologists for granite" the word "granite" is a pun with the target "granted". The recovery of the target in the mind of the listener is essential to the success of the pun. This work introduces a new model for automatic target recovery and provides the first empirical test for this task. The model draws upon techniques for automatic speech recognition using weighted finite-state transducers, and leverages automatically learned phone edit probabilities that give insight into how people perceive sounds and into what makes a good pun. The model is evaluated on a small corpus where it is able to automatically recover a large fraction of the pun targets.

1 Introduction

From the high culture of Shakespeare's plays (Tanaka, 1992), to the depths of the YouTube comments section, from advertising slogans (Keller, 2009) to conversations with nerdy parents, puns are a versatile rhetorical device and their understanding is essential to any comprehensive approach to computational humor. Humor has been described as "one of the most interesting and puzzling research areas in the field of natural language understanding" (Yang et al., 2015). Puns, in particular, offer an interesting subject for study since their humor derives from wordplay and double-meaning.

An important class of puns, known as paronomasic puns, are those where one entity, the pun, is phonologically similar to another, the target (Joseph, 2008). Consider an example from Crosbie (1977):

> "Sign by gate to nudist colony: Come in. We are Never Clothed."

Here, "clothed" is the pun and "closed" is the target. Paronomasic puns are distinguished from homographic puns such as

> "Two silkworms had a race. They ended up in a tie."

which puns on the two definitions of the word "tie". When the pun and target are homophonic this is called a *perfect* pun, and when nearly homophonic an *imperfect* pun (Zwicky and Zwicky, 1986) (or a *heterophonic* pun (Hempelmann, 2003)). The focus of this work is to propose and evaluate a model for target recovery of both perfect and imperfect paronomasic puns, assuming that the location of the pun word or word sequence.

Ritchie (2005) classifies puns in terms of whether they are *self-contained*, i.e., based on general knowledge and humorous in a variety of circumstances, or *contextually integrated*, i.e. relying on a specific context such as a visual context, knowledge of a recent event or discussion. Many puns of this type are associated with cartoons or images, e.g. a cartoon with pies and cakes in the street having the caption

> "The streets were oddly desserted"

(desserted/deserted). Contextually integrated puns lose their humor out of context because the pun is difficult to detect. However, target recovery is often still possible, and thus this distinction does not play a major role in the current study.

If a listener fails to recover the target of the pun then the statement fails in its humor. The two chief

Proceedings of NAACL-HLT 2016, pages 654–663,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

clues that the listener must rely on to perform target recovery are the phonetic information and language context. This is analogous to the way in which someone listening to speech uses the acoustic information and language context to recover a sequence of words from an audio source. In the words of Hempelmann (2003), "the recovery of the target in heterophonic puns is just a specific case of the complex task of hearing." The similarity between hearing and target recovery suggests the use of methods from automatic speech recognition in building a model for automatic target recovery.

The goal of this paper is to develop and test a computational model for target recovery in puns. Sentences with the position of the pun marked are given as input and the model must output the target word sequence. As the focus is on paronomasic puns, the relationship between the pun and the target is primarily phonological, but surrounding language context is also important for recovering the target. This work has applications in natural language understanding of texts that contain humor. Furthermore, the insights gained from our model are useful for improving pun generation in computational humor systems.

2 Prior Work

Zwicky and Zwicky (1986) provided an analysis of the properties of paronomasic puns, especially with regard to the markedness of phonological segments. They assembled a corpus of 2140 instances of segmental relationships from imperfect pun/target pairs for their analysis. By counting how many times each phoneme was used in a pun or target, the authors observe a behavior they refer to as ousting, a strong asymmetry in phoneme substitution likelihood. For instance, punners will rarely replace a 'T' phoneme (IPA t) in the target word with 'TH' (θ) in the pun, but regularly replace 'TH' with 'T.' An example of such a pun is

"I lost my temper in a fit of whiskey"

(fit/fifth)). Because of this asymmetry, we say that 'T' ousts 'TH.' Zwicky and Zwicky correlate the ousting behavior evident in their pun data with the phonological notion of *markedness*. Markedness can be defined (if oversimplified) as "the tendency for phonetic terms to be pronounced in a simple, natural way" with regard to physiological, acoustic, and perceptual factors (*marked* segments are more complex) (Anderson and Lightfoot, 2002). They conclude that marked segments tend to oust unmarked segments (e.g. voiced stops oust their voiceless counterparts).

This is followed-up by Sobkowiak (1991), whose manual alignment of the phoneme sequences of 3,850 pun/target pairs allows for a more careful study of the ousting behavior. This corpus, where whole sequences of phonemes are aligned between puns and targets, is a much richer resource for analyzing ousting than the segment-only data used in (Zwicky and Zwicky, 1986). Sobkowiak's improved data provides evidence against the conclusions of Zwicky and Zwicky (1986). Rather, "it seems that it is not the case that 'marked ousts unmarked' in paronomasic puns." Sobkowiak goes on to show that puns more frequently involve changes to vowels than consonants, noting that their information load (i.e. contribution to target recoverability) is lighter. Our data corroborates Sobkowiak's claims regarding the role of markedness in punning as well as the mutability of vowels, and provides more details about the specific nature of substitutions in a large corpus of puns.

Building off of Sobkowiak's work, Hempelmann (2003) studies target recoverability, arguing that a good model for target recovery provides necessary groundwork for effective automatic pun generation. He proposes a preliminary phonetic edit cost table to be one part of a scoring system. The model is based on the phoneme edit counts from Sobkowiak (1991) with an ad-hoc formula for transforming the counts into substitution costs. However, Hempelmann makes no effort to empirically test his model at the recovery task. The model uses a subset of 1,182 puns from the 3,850 identified by Sobkowiak. This subset is the data used for training our phonetic edit models and we use Hempelmann's cost function as a baseline.

The task of automatic target recovery of paronomasic puns has not been previously attempted. Recently, Miller and Gurevych (2015) studied methods for automatic understanding of homographic puns using methods from word-sense disambiguation. Paronomasia is intentionally excluded from their data.

3 Target Recovery

Following the convention of Miller and Gurevych (2015), we assume that the position of the pun in the input sentence is known. The target recovery task is to identify the pun target given the pun and its left and right word contexts.

3.1 Model

The model has three parts: a phonetic edit model, a phonetic lexicon and a language model. The recovered target T^* is the word (or words) with the maximum probability given the pun P according to

$$T^* = \underset{T}{\operatorname{argmax}}\, p(T|P) = \underset{T}{\operatorname{argmax}}\, p(P|T)p(T),$$

where $p(P|T)$ is the phonetic edit model and $p(T)$ is the language model. The factorization into a language model and a phonetic edit model is similar to the classic approach to automatic speech recognition.

The implementation of the model uses weighted finite-state transducers (WFSTs) which have been adopted as a useful structure for speech decoding due to their ability to efficiently represent each of the relevant knowledge sources, i.e. phonetic information, phonetic lexicon and language model, in a single framework (Mohri et al., 2002; Hori et al., 2007). Finite-state transducers are finite-state machines with an input and an output tape. We will use WFSTs for our pun target recovery model. Each of the phonetic edit model (PEM), phonetic lexicon (L) and language model (LM) can be represented as WFSTs, which are joined together by applying the composition operation. The weights on the PEM and LM are negative log-likelihoods, and the lexicon has no weighting. Each of these models will be explained in further detail below. The target is given by the shortest path in the WFST:

$$(\mathrm{LC} \oplus \mathrm{P} \circ \mathrm{L}^{-1} \circ \mathrm{PEM} \circ \mathrm{L} \oplus \mathrm{RC}) \circ \mathrm{LM},$$

where P is the pun and LC and RC are the left and right word contexts. The symbols $^{-1}$, $\circ$ and $\oplus$ denote the inverse, composition, and concatenation operations respectively.

The sequence of operations $\mathrm{P} \circ \mathrm{L}^{-1} \circ \mathrm{PEM} \circ \mathrm{L}$ converts a pun to its phonetic form, expands it to a lattice based on phonetic confusions, and then converts the phone lattice to a lattice of possible target words. By concatenating the left and right word contexts and composing with the language model, each path through the WFST is a target word sequence with a weight equal to the combined phonetic edit and language model scores. The ability to handle multi-word puns and/or targets (e.g., the word sequence "no bell" can be matched to "Nobel", using an example from (Yang et al., 2015)) is made possible because the lexicon WFST L allows multiword sequences.

Since the scores are negative log likelihoods, the target hypothesis is just the shortest path in the WFST. We score the model based on its accuracy at identifying the target which must be an exact match, ignoring punctuation. We disallow the possibility that the pun is hypothesized as a target, i.e. homographic puns, in order to focus on the class of puns whose relationship with their targets is primarily phonological. The OpenFst library is used to perform all of the WFST operations (Allauzen et al., 2007).

3.2 Phonetic Edit Model

The purpose of the phonetic edit model is to estimate the probability of the pun phoneme sequence given a candidate target phoneme sequence. We prefer to learn a model from the data rather than adopt an existing model that relies on phonetic features and edit costs that were derived by hand (Kondrak, 2000). As shown by Ristad and Yianilos (1998), a memoryless WFST model can learn a probability distribution over edit operations with a principled objective, namely, to maximize the likelihood of the source/target sequences in the training data. In our case, the training data is pun/target phoneme sequences. Memoryless, in this context, refers to the fact that the model is not conditioning on previous symbols, i.e. there is only a single state in the WFST. The model assumes that the phoneme sequence of the pun is generated through the stochastic application of insertions, deletions, and substitutions to the target phoneme sequence. During learning, the model estimates the function $p(y|x)$ where y is a phoneme from the pun and x is a phoneme from the target. When $x = \epsilon$ this is an insertion of y and when $y = \epsilon$ it is a deletion of x.

Training uses the expectation-maximization algorithm following the equations given by Oncina and Sebban (2005) to estimate the conditional probability distribution instead of the joint one as originally derived by Ristad and Yianilos. The model is trained to maximize the probability of the pun targets given their sources subject to the constraint that the model encode a probability distribution over all possible string pairs. In the expectation step, puns are aligned with their targets given the current model. Then, the maximization step re-estimates the edit probabilities given the current alignment. Edit probabilities are initialized by giving a high probability to keeping the same phoneme and uniform small probabilities to all possible edits. (We initialized by giving ten times the probability to preserving the same phoneme as to any possible edit operation.) Following the convention of Sobkowiak (1991), vowels can not align with consonants and vice-versa.

The training data consists of the 1,182 target pun pairs taken from Appendix E of Hempelmann (Hempelmann, 2003). These are a subset of the puns that Sobkowiak took mostly from Crosbie's "Dictionary of Puns" and analyzed in his work.

3.3 Phonetic Lexicon

The lexicon models the pronunciation of each word in the vocabulary. Pronunciations come from the CMU pronunciation dictionary (Weide, 1998). This dictionary has an inventory of 39 phonemes. If a pun is not in the vocabulary of the dictionary, for example if it is not a word, then its pronunciation is generated automatically using the LOGIOS lexicon tool.[1] The same is not true for the targets, since they are unknown beforehand. Thus, when the lexicon is used to map puns to phonemes the vocabulary size is essentially unlimited. But, when it is used to map the phoneme lattice into a word lattice of potential targets then the fixed vocabulary from the language model is used.

The CMU dictionary includes multiple pronunciations for some words. All pronunciations are used with unweighted parallel paths. The version of the dictionary used here includes stress markers and syllable boundaries (Bartlett et al., 2009). In the simplest version of our model, this information is ignored in order to reduce the number of learned parameters in the PEM.

After composing with the phonetic edit model and the lexicon, we do a conservative pruning of the WFST to remove highly improbable word sequences based on the phonetic score and run epsilon removal on the resulting lattice. This reduces the memory footprint and allows use of a larger language model.

3.4 Language Model

A 230 million word corpus was formed from comments obtained from Reddit, an online discussion forum. These comments were collected from a wide variety of forums, known as subreddits. Reddit contributors tend to use a casual conversational style that is a good match for the language used in common puns. All of the text data from Reddit was tokenized using the NLTK tokenizer (Bird et al., 2009). The tokenizer splits contractions into two tokens but we kept these as a single token to match the pronunciation dictionary. We remove case information. Punctuation is removed when evaluating the correctness of the hypothesized targets, but punctuation symbols are included in the language model. It provides a useful context break in punning riddles where the pun/target typically follows a question mark or other punctuation.

The vocabulary is set by intersecting the vocabulary from the CMU pronunciation dictionary with the set of tokens that occur at least 30 times in the language model training data. This gives us a 36,175 word vocabulary. As Sobkowiak (1991) observed, the target tends to have a much higher unigram probability than the pun. This means that the vocabulary size need not be too large to cover most of the targets.

The language model is a trigram model with modified Kneser-Ney smoothing (Chen and Goodman, 1999). Entropy pruning is used to reduce the size of the language model (Stolcke, 2000). It is important to perform the determinization and minimization operations on the LM after converting it into the FST representation, in order to reduce the size of the model (Mohri et al., 2008). Because we are using a trigram model, only two words of context are needed on each side of the pun.

3.5 Extending the Phoneme Edit Model with Syllable Structure and Stress

For a listener to recognize the phonological distinctness of the pun and the target, they should preferably differ in a perceptually salient position such as a stressed syllable. In particular, we expect that puns would take advantage of the increased acoustic energy in the onset and nucleus of a stressed syllable and utilize these positions for phoneme changes.

To analyze this effect we used a syllabified version of the CMU pronunciation dictionary (Bartlett et al., 2009). We took the 1-best phonetic alignment of the training data and split it according to the syllable boundaries of the pun. Then we computed the probability of a phoneme change according to the position in the syllable and the stress. Consonants in the onset of a stressed syllable have a 40.3% probability of changing between the target and pun. The nucleus of a stressed syllable of has a 36.8% probability of substitution. This is compared to a 31.8% probability of substitution for phonemes in unstressed syllables and coda positions.

To incorporate this into an extension of the phonetic edit model, we created a three state model. There is one default state and two special states for the stressed syllable onset and nucleus respectively. The phoneme edit probabilities $p(y|x)$ were scaled according to the state s and renormalized so that $p(y|x, s)$ is a valid probability distribution. When a substitution does occur, we assume that the choice of target phoneme is independent of the syllable position and stress. The net effect of the syllable extension to the PEM is to encourage substitution of onsets and nuclei of stressed syllables and discourage it otherwise.

4 Experiments

4.1 Data

We collected 75 puns from various joke websites such as Tumblr, Reddit, and Twitter and soliciting examples from friends and colleagues.[2] These were collected without reference to the sources used by Sobkowiak to assemble the puns used in building the phonetic edit model. This data was used for test data only and is completely separate from the training data used by the language model and the phonetic edit model. (It would be nice to have used some of the 1,182 puns from Sobkowiak for test data but only the isolated pun/target pairs were provided without the necessary word contexts.) Pun locations were marked in each sentence as the minimal set of words that change between the pun and the target.

Note that the phonetic edit model is trained on exclusively imperfect puns but it is tested on both perfect and imperfect puns (24 perfect and 51 imperfect). This creates a mismatch between the training data and the test data. Target recovery is harder on imperfect puns but having a mix of both types better reflects what is commonly found in the wild.

4.2 Baseline Model

As a baseline model we replace our phonetic edit model with the cost function proposed by Hempelmann, which we replicated based on details given in Appendix G of his thesis (Hempelmann, 2003). This cost function, which Hempelmann refers to as "preliminary," is the only published phonetic edit model for paronomasic puns. The cost table is based on the phoneme pair alignment counts from the 1,182 training pairs that were aligned by hand. The phoneme alignment counts are converted to costs by using simple ad-hoc equations. Vowel pair counts are transformed to costs using $cost = 0.3 - 0.3 * count/161$ and other pairs use $cost = count^{-0.6}$. Our model improves upon the baseline by avoiding heuristic transformations. Since the phoneme symbol set used by Hempelmann (based on (Sobkowiak, 1991)) differs from that used in the CMU dictionary, the Hempelmann costs are mapped to match the CMU inventory.

4.3 Results

We report the performance of our model in Table 1 using accuracy and mean reciprocal rank as metrics. If the correct target did not appear in our n-best list then we use a value of zero for its reciprocal rank. Ties are broken randomly. The baseline uses Hempelmann's phonetic cost model plus the LM, and we include two ablation models that use just the LM or just the PEM. The other two models use the LM with either the memoryless PEM or the PEM with the syllable extension.

[2] Data available at http://ssli.ee.washington.edu/data/puns.

	Accuracy			
Model	**Perfect**	**Imperfect**	**Overall**	**MRR**
LM Only	13.0%	7.7%	9.3%	0.127
PEM Only	43.5%	9.6%	20.0%	0.282
LM + Hempelmann	47.8%	7.7%	29.3%	0.389
LM + PEM	73.9%	65.4%	68.0%	0.729
LM + Syll. PEM	73.9%	65.4%	68.0%	0.733

Table 1: Accuracy and mean reciprocal rank (MRR) for target recovery

Using the language model only gives poor performance. It is only able to recover the target when the target happens to be an idiomatic expression. The PEM-only model does significantly better than using the LM only, highlighting the importance of phonetics in paronomasic puns. In the full system, Hempelmann's cost matrix does not fare well compared to the PEM model. The Hempelmann cost matrix does a poor job of separating likely targets from the rest of the vocabulary. Thus, many times the true target is pruned before the application of the language model.

The LM + PEM model recovers the target more than two-thirds of the time and has a mean reciprocal rank of 0.729. When using the syllable extension to the PEM, the results agree on the rank of the target for all but five puns. For those five, the model with the syllable extension improves the rank compared to the basic PEM. Two puns from that set of five are

> "If you've seen one shopping center you've seen a mall"
>
> "How does Moses make his tea? Hebrews it."

(a mall/'em all and Hebrews/he brews, respectively). The hypothesized targets "immoral" and "he abuse" outrank the true target for these puns in the basic PEM model but not in the syllable one because they change more phonemes in unstressed syllables.

Perfect puns are easier to recover than imperfect ones. The LM + PEM model does well on both perfect and imperfect puns. As to be expected, the PEM only model does very poorly on imperfect puns and the LM only model does equally poorly on both perfect and imperfect.

Table 2 shows the top ranked hypothesis for a sample pun using the LM + PEM model, where the cost in this table is the negative log-likelihood. In this case, the top ranked hypothesis was correct. The second highest ranked hypothesis is a misspelling of the target that is common enough for the language model to also give it a high score.

An example where the model makes a mistake is:

> "A Freudian slip is where you say one thing but mean your mother"

The pattern of "one thing . . . another" is common in English but, in this case, the target "another" is too far away from "one thing" for the relationship to be captured by the tri-gram language model.

5 Analysis

A consequence of using a stochastic model for phonetic edit costs is that there is a non-zero edit cost between a phoneme and itself and that cost is different depending on the phoneme. This highlights the fact that we model the edit (or transformation) probabilities of the pun/target corpus rather than phonological similarity (which would be a symmetric cost function). The analysis below shows that the edit model is in fact capturing more than simple phonological similarity.

5.1 Phoneme Edit Probabilities

Figures 1 and 2 show the probability of observing a source phoneme (i.e. a phoneme appearing in the pun) given each target phoneme for the vowel and consonant pairs respectively. The numbers are to be interpreted as percentages and values less than 1 are not shown. The '.' symbol is used for epsilon transitions and indicates segment insertions and deletions.

Vowels. Regarding vowels, our data corroborates some of the findings of Sobkowiak (1991). The lower numbers along the diagonal in Figure 1 relative to Figure 2 indicates the violability of vowels (39%) relative to consonants (34%) in paronomasic puns. Our data also confirms that, where puns are concerned, marked segments do not necessarily

Rank	Cost	Hypothesis
1	21.0	. . . ONLY GOT **MYSELF** TO BLAME
2	23.2	. . . ONLY GOT **MY SELF** TO BLAME
3	24.2	. . . ONLY GOT **A MYSELF** TO BLAME
4	24.2	. . . ONLY GOT **MY YOURSELF** TO BLAME
Source		. . . ONLY GOT **MY SHELF** TO BLAME

Table 2: Top ranked target LM + PEM hypotheses for the pun "A book fell on my head. I've only got my shelf to blame."

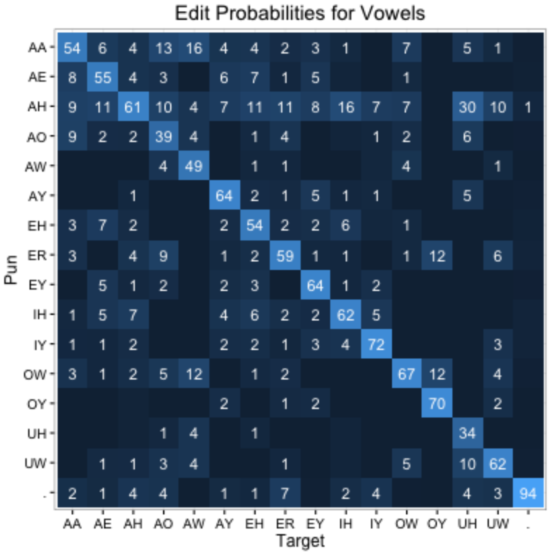

Figure 1: Edit probabilities for vowels based on the LM + PEM model.

oust unmarked. According to Zwicky and Zwicky (1986), if "marked ousts unmarked" we would expect to see that tense vowels oust lax vowels. Rather, what we find in this data is that the majority of vowels and diphthongs are ousted by AH (ə), widely considered an unmarked vowel. Puns demonstrating this phenomenon include

> "The pun is mightier than the sword"
>
> "He's an honest geologist, you can trust what he sediment"

(pun/pen and sediment/said he meant, respectively). We hypothesize that the low cost for substituting AH for other vowels is due in part to the fact paronomasic puns originally were a spoken phenomenon, and so the substitution possibilities for a given target vowel depend significantly on the variety of realizations of that vowel in speech. It is well attested cross-linguistically that vowels undergo reduction in unstressed positions (Crosswhite, 2004). In English running speech, this reduced form most closely resembles AH (Burzio, 2007). The data presented here suggests that punners take advantage of the commonality of running speech vowel reduction when considering target recoverability, resulting in the availability of AH as a replacement for most target vowels. Our model captures this fact by assigning low cost to such a substitution.

Our data provides other insights into the nature of vowel substitutions in puns. For instance, we see that IY (i) is less likely to change in a pun than other monophthongs, indicating a significant perceptual distance between IY and its neighbors. Most likely to change are the vowels AO (ɔ) and UH (ʊ). The violability of AO is likely due to the AO/AA merger present in many American English Dialects (Labov et al., 2006), and in fact we see targets with AO frequently mapping to puns with AA. The mutability of UH is also interesting: while it, like other monophthongs, is ousted by AH, it is also ousted by a closely articulated marked counterpart, UW (u). This seems to be the sole example in our data of marked vowels ousting an unmarked vowel to a significant degree.

Another interesting feature of this data is the substitutability of ER (ɝ) and OY (ɔɪ), as in puns like

> "The British used to dress their sandwiches with earl and vinegar"
>
> "In cooking class this week we're loining how to prepare tuna"

(earl/oil and loining/learning, respectively). These edits seem to indicate punners' awareness of rhoticity variation among English dialects (Labov, 1972).

Consonants. In Figure 2, we see several expected trends. D (d) ousting DH (ð), T (t) ousting TH (θ), and V (v) ousting W (w) are all as expected according to the "marked ousting unmarked" hypothesis of Zwicky and Zwicky (1986). Yet we also see S (s) ousting Z (z), which is an instance of the unmarked voiceless alveolar fricative ousting the voiced, as well as N (n) ousting NG (ŋ), an instance of the unmarked coronal ousting the marked velar. These oustings, like the case of AH ousting other vowels, are likely conditioned by segment frequency. For N ousting NG, syllable structure may play a role as well, as NG is restricted to codas whereas N is not.

An interesting feature of our consonant data is the extreme violability of interdentals TH and DH, which are more likely to map to T and D respectively than to retain their identity in a paronomasic pun. In addition to the "fit of whiskey" example mentioned earlier, we have

"Disgusting wind knocked over my trash cans"

(disgusting/this gusting). This phenomenon is known as "th-stopping" and is a common dialectal feature of many variants of English, from those of Philadelphia and New York to the Caribbean (Wells, 1982). This substitution supports the hypothesis that the substitution possibilities for a segment depend on the realizations of that segment which are commonly encountered in speech. Notably, T is significantly more likely to replace TH than is F (f), despite that the articulatory and acoustic similarity between TH and F is greater.

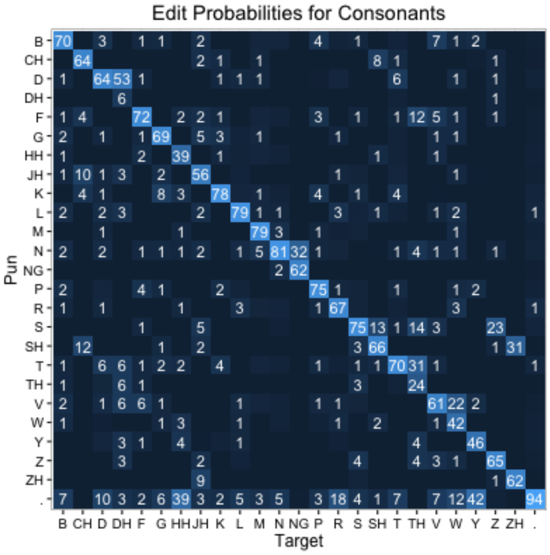

Figure 2: Edit probabilities for consonants based on the LM + PEM model.

5.2 Correlation with Human Ratings

Our phonetic edit model allows us to empirically verify an untested assumption with respect to phonological similarity from Fleischhacker (2002) "that degree of representation in the pun corpus correlates with pun goodness." In another paper, she repeats this assumption and adds the explanation "Truly funny puns are generally those in which the phonological relationship between pun and target is . . . subtle but quickly recognizable" (Fleischhacker, 2005). Hempelmann writes that this assumption is "unlikely" to be true.

We conducted a survey of native English speakers where respondents were asked to rate 17 puns on a five point scale: hilarious, funny, okay, bad, terrible. The puns were selected from the test set to have a variety of phonemic edit distances. Respondents also had the option to indicate that they did not understand the pun, in which case their answer was ignored. A phonetic edit score was calculated for each pun-target pair by averaging the log-likelihood value from our model over the phonemes in the pun. The order of the questions was randomized for each respondent. Advertising for the survey was done using /r/SampleSize, a Reddit forum for recruiting survey participants. The 435 respondents gave us 7,135 ratings in total.

The relationship between phonetic edit cost and goodness was measured using ordinal regression, with clustered standard errors to account for the fact that responses from the same person are not independent. We use the RMS package in R (Harrell Jr., 2015). The regression coefficient indicates that decreased phonetic edit cost is indeed associated with higher perceived goodness of the pun with $p < 0.0001$. For visualization purposes we mapped the categorical goodness ratings onto a numeric scale from 1-5 to create an average goodness rating for each pun. In Figure 3, we depict the phonetic edit cost vs. the average goodness rating for each of the 17 puns. The line shown in that figure is an outlier resistant linear regression.

The biggest outlier is

> "They say a Freudian slip is when you say one thing but really mean your mother."

The pun is on "your mother" with "another" as the target. This pun has the highest phonetic edit cost in our sample but it makes up for it with more interesting semantics than average.

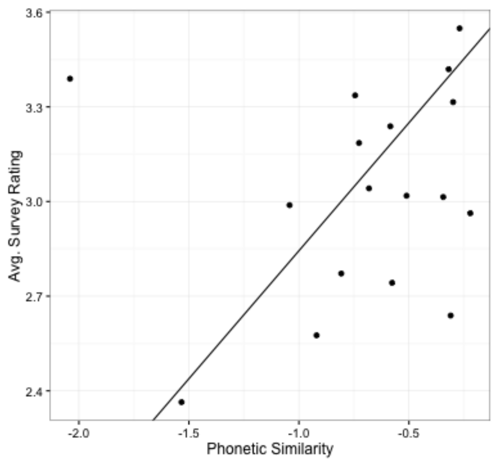

Figure 3: Relationship between the LM + PEM phonetic edit cost and goodness of the pun.

6 Conclusions and Future Work

The quality of our phonetic edit model is evident from its performance at the target recovery task, as well as the fact that it captures known linguistic phenomena such as vowel reduction and dialectal features. Furthermore, by collecting human ratings we are able to empirically verify the previously untested assumption that lower phonetic edit costs in puns correlate with pun goodness.

The strength of the model can be leveraged to improve the quality of pun generation and humor classification systems that have used weaker phonetic edit models (Binsted, 1996; Valitutti, 2011; Raz, 2012). Some pun generation systems are limited to exact homophones. In this work, we did not consider homographic puns. In principle, our algorithm can handle these by introducing an LM weight to control the balance of PEM/LM scores. Pun generation is much more complicated than target recovery as reflected in the complexity of proposed systems for humor generation. However, improved understanding of puns by way of progress in the target recovery task should also lead to corresponding improvements in the task of pun generation.

Our syllable extension to the PEM gave the best performance, but only by a small margin. Extending the edit model further is a fruitful area for future work but will likely require additional data.

In this work, we assume that the pun is given. Of interest for future work is joint recognition of the pun and its target. Preliminary experiments indicate that the unigram word probabilities are a somewhat strong feature for pun recognition but further work is needed. For contextually-integrated puns, identifying the pun is likely to be more difficult, and for some cases it would be useful to integrate image cues.

Acknowledgments

We thank Arjun Sondhi for his assistance in designing and analyzing the survey and Hope Boyarsky for her help assembling our pun corpus. We also would like to thank Nathan Loggins and the anonymous reviewers for their feedback on this work.

Abstract

We present a model of morphological segmentation that jointly learns to segment and restore orthographic changes, e.g., *funniest* ↦ *fun-y-est*. We term this form of analysis *canonical segmentation* and contrast it with the traditional *surface segmentation*, which segments a surface form into a sequence of substrings, e.g., *funniest* ↦ *funn-i-est*. We derive an importance sampling algorithm for approximate inference in the model and report experimental results on English, German and Indonesian.

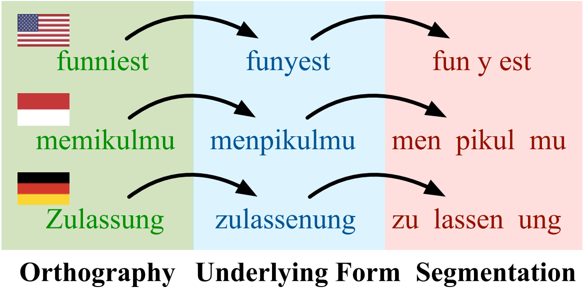

Figure 1: Examples of canonical segmentation for English (top), Indonesian (middle) and German (bottom).

1 Introduction

Morphological segmentation is useful for NLP applications, such as, automatic speech recognition (Afify et al., 2006), keyword spotting (Narasimhan et al., 2014), machine translation (Clifton and Sarkar, 2011) and parsing (Seeker and Çetinoğlu, 2015). Prior work cast the problem as *surface segmentation:* a word form w is segmented into a sequence of substrings whose concatenation is w. In this paper, we introduce the problem of *canonical segmentation:* w is analyzed as a sequence of *canonical morphemes*, based on a set of word forms that have been "canonically" annotated for supervised learning. Each canonical morpheme c corresponds to a *surface morph* s, defined as its orthographic manifestation, i.e., as the substring of w that is generated by applying editing operations like insertion and deletion. Consider the following example: *funniest* has a canonical segmentation *fun-y-est* with three morphs *funn-i-est*. Arriving at the canonical analysis requires two edit operations: delete *n* in *funn* and replace *i* with *y* in *i*. Figure 1 gives examples of orthography (i.e., the concatentation of surface morphs), underlying form (i.e., the concatentation of canonical morphemes) and canonical segmentation in three languages.

Canonical segmentation is motivated in the following three ways: (i) Computational morphology is the study of how words and their meanings are composed from smaller units. This goal is better supported by canonical morphemes than by surface morphemes because the smaller units are more accurately modeled. For *funniest*, composition can reason with canonical morphemes *fun* and *y*, whereas surface segmentation must work with *funn* and *i*. (ii) Morphological analysis is typically done with attribute-value pairs (AVP), e.g., [`lemma`=FUNNY, `degree`=SUPER]. While AVP is a good representation for *inflectional* morphology, it is not powerful enough for *derivational* morphology. If we represent the derivation of *funnier* as [`lemma`=FUN, `deriv-suffix`=-Y, `degree`=SUPER], then it is no longer clear in this fixed representation whether

Proceedings of NAACL-HLT 2016, pages 664–669,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

`degree` = SUPER applies to *fun* or *fun*+*y*.[1] Canonical segmentation is more flexible—allowing us to express derivational relations without committing to a fixed attribute-value structure, which are used to study inflection. This point is important due to the fundamental distinction between the creation of words through inflection vs. through derivation. Inflection alters words to express syntactic relations (e.g., tense) with no major change in meaning nor POS. For example, *perturbed* and *perturbs* are inflections of the verb *perturb*. On the other hand, derivation modifies words more drastically—often changing the meaning or POS. For example, the noun *perturbation* derives from the verb stem *perturb* and the suffix *ation* (Haspelmath and Sims, 2013). (iii) Most NLP systems take *word forms* as atomic building blocks. We propose *canonical morphemes*, an alternative representation that models the structure of a language's lexicon and supports applications that benefit from access to the internal structure of words. This includes access to internal *morphological* structure, e.g., canonical morphemes like *-y* and *-ly* are recognized (independent of their orthographic manifestation) as derivational suffixes that cause predictable modifications; as well as access to internal *semantic* structure, e.g., the canonical segmentations of *fun* and *funny* share the canonical morpheme *fun*).

The contributions of this paper are as follows. We present the challenging new task of canonical segmentation. We develop a feature-rich structured joint model for canonical segmentation, which accounts for orthographic variation and segment-level structure. We derive an efficient importance sampling algorithm for approximate inference. We present experiments on three languages: English, German and Indonesian.

2 Model, Inference and Training

Our goal is canonical segmentation: identifying both the canonical morphemes and the morphs (their orthographic manifestations) of a word. This task involves *segmenting* the input as well as accounting for *orthographic* changes occurring in the word formation processes. Let w be the surface form, u the orthographic underlying representation (UR) of w, and s a labeled segmentation of u. Note: all random variables are string-valued (Dreyer and Eisner, 2009). For example, consider the word *unhappiness*:

$$\underbrace{\textit{unhappiness}}_{w} \overset{\text{transduction}}{\mapsto} \underbrace{\textit{unhappyness}}_{u}$$

$$\overset{\text{segmentation}}{\mapsto} \underbrace{[\text{ prefix } \textit{un}][\text{stem } \textit{happy}][\text{suffix } \textit{ness}]}_{s}.$$

Note that our notion of an orthographic UR closely resembles the phonological concept of a UR (Kenstowicz, 1994) and, indeed, many orthographic variations are manifestations of phonology.

We model this process as a globally normalized log-linear model of the conditional distribution,

$$p(s,u \mid w)=\frac{1}{Z(w)}\exp\Big(\boldsymbol{\eta}^\top \boldsymbol{f}(s,u)+\boldsymbol{\omega}^\top \boldsymbol{g}(u,w)\Big),$$

where $\boldsymbol{\theta} = \{\boldsymbol{\eta}, \boldsymbol{\omega}\}$ are the model parameters, $\boldsymbol{f}$ and $\boldsymbol{g}$ are, respectively, feature functions of the segmentation-UR and UR-surface-form pairs and $Z(w) = \sum_{s',u'} \exp\left(\boldsymbol{\eta}^\top \boldsymbol{f}(s',u') + \boldsymbol{\omega}^\top \boldsymbol{g}(u',w)\right)$ is the partition function. We can view this model as a conjunction of a finite-state transduction factor $\boldsymbol{g}$ (Dreyer et al., 2008) and a semi-Markov segmentation factor $\boldsymbol{f}$ (Sarawagi and Cohen, 2004), relating it to previous semi-CRF models of segmentation.[2] To fit the model, we maximize the log-likelihood of the training data $\{(s_i, u_i, w_i)\}_{i=1}^N$, $\mathcal{L}(\boldsymbol{\theta}) = \sum_{i=1}^N \log p(s_i, u_i \mid w_i)$, with respect to the model parameters $\boldsymbol{\theta}$. Optimization is done with gradient-based methods—requiring the computation of $\log Z(w)$ and $\nabla \log Z(w)$, which is intractable.[3] Thus, we turn to sampling (Rubinstein and Kroese, 2011) and stochastic gradient methods.

Features Our model includes several simple feature templates. The transduction factor of the model is based on (Cotterell et al., 2014): we include features that fire on individual edit actions as well as conjunctions of edit actions and characters on the surrounding context. For the semi-Markov factor, we use the feature set of Cotterell et al. (2015a), which

[1] Note that *funnest* is a word of (colloquial) English.

[2] Our transduction factor maps surface forms w to UR strings u of bounded length by imposing an insertion limit k. Thus, $|u| \leq |w| + k$. Our experiments use $k = 5$.

[3] Since the semi-CRF features fire on substrings, we would need a dynamic programming state for each substring of each of the exponentially many settings of u.

includes indicator features on individual segments, conjunctions of segments and segment labels and conjunctions of segments and left and right context on the input string. We also include a feature that checks whether the segment is a word in ASPELL (or a monolingual corpus).

Importance Sampling To approximately compute the gradient for learning, we employ importance sampling (MacKay, 2003, pp. 361–364). Rather than considering all underlying orthographic forms u, we use samples taken from proposal distribution q—a distribution over Σ^*. In the following equations, we omit the dependence on w for notational brevity. Also, let $\boldsymbol{h}(s,u) = \boldsymbol{f}(s,u) + \boldsymbol{g}(u,w)$. We now provide the derivation of our importance sampling estimate for the gradient of log-partition function, including Rao-Blackwellization (Robert and Casella, 2013).

$$\begin{aligned}
\nabla \log Z &= \mathop{\mathbb{E}}_{(s,u)\sim p} [\boldsymbol{h}(s,u)] && (1)\\
&= \sum_{s,u} p(s,u)\boldsymbol{h}(s,u) && (2)\\
&= \sum_{s,u} p(s|u)p(u)\boldsymbol{h}(s,u) && (3)\\
&= \sum_{u} p(u) \sum_{s} p(s|u)\boldsymbol{h}(s,u) && (4)\\
&= \sum_{u} p(u) \mathop{\mathbb{E}}_{s\sim p(\cdot|u)} [\boldsymbol{h}(s,u)] && (5)\\
&= \mathop{\mathbb{E}}_{u\sim q} \left[\frac{p(u)}{q(u)} \mathop{\mathbb{E}}_{s\sim p(\cdot|u)} [\boldsymbol{h}(s,u)] \right]. && (6)
\end{aligned}$$

The expectation $\mathbb{E}_{s\sim p(\cdot|u)} [\boldsymbol{h}(s,u)]$ is efficiently computed with the semi-Markov generalization of the forward-backward algorithm (Sarawagi and Cohen, 2004). The algorithm runs in $\mathcal{O}(n^2 \cdot t^2)$ per sample where n is the length of the string to be segmented and t is the size of the label space. In our case, we have three labels: prefix, stem and suffix so $t = 3$.

So long as q has support everywhere p does (i.e., $p(u) > 0 \Rightarrow q(u) > 0$), the estimate is unbiased. Unfortunately, we can only efficiently compute $p(u) \propto \sum_s \exp(\boldsymbol{\theta}^\top \boldsymbol{h}(s,u))$ up to constant factor, $p(u) = \bar{p}(u)/Z_u$. Thus, we use the *indirect importance sampling estimator*,

$$\frac{1}{\sum_{i=1}^{m} \frac{\bar{p}(u^{(i)})}{q(u^{(i)})}} \sum_{i=1}^{m} \frac{\bar{p}(u^{(i)})}{q(u^{(i)})} \mathop{\mathbb{E}}_{s\sim p(\cdot|u^{(i)})} \left[\boldsymbol{h}(s,u^{(i)}) \right], \quad (7)$$

where $u^{(1)} \ldots u^{(m)} \overset{\text{i.i.d.}}{\sim} q$. The indirect estimator is biased, but statistically consistent.[4] We also note that the particular instantiation of the indirect estimator leverages an efficient dynamic program to compute the expected features under $p(\cdot|u^{(i)})$. This has the effect of decreasing the number of samples required to get a useful estimate of the gradient. Computing $\bar{p}(u^{(i)})$ is a side effect of the dynamic program, namely the normalization constant. As a proposal distribution q, we use the following locally normalized distribution,

$$q(u) = \frac{\exp(\boldsymbol{\omega}^\top \boldsymbol{g}(u,w))}{\sum_{u'} \exp(\boldsymbol{\omega}^\top \boldsymbol{g}(u',w))}. \quad (8)$$

3 Related Work

Most work on morphological segmentation has been unsupervised. The LINGUISTICA (Goldsmith, 2001) and MORFESSOR (Creutz and Lagus, 2002) models rely on the minimum description length principle (Cover and Thomas, 2012). In short, these methods seek to segment words while at the same time minimizing the number of unique morphs discovered, i.e., the complexity of the model. The MORFESSOR model has additionally been augmented to handle the semi-supervised scenario (Kohonen et al., 2010). Goldwater et al. (2009) proposed a Bayesian non-parametric approach to word and morphological segmentation. Poon et al. (2009) used contrastive estimation (Smith and Eisner, 2005) to learn a log-linear model for segmentation fully unsupervised.

Few supervised techniques have been applied to morphological segmentation. Ruokolainen et al. (2013) applied a linear-chain CRF, showing that with a minimal amount of labeled data the performance of standard unsupervised and semi-supervised baselines are surpassed. In follow-up work (Ruokolainen et al., 2014), they found that incorporating distributional character-level features acquired from large unlabeled corpora improved the earlier model. Cotterell et al. (2015a) showed that modeling morphotactics with a semi-CRF improves results further.

The previously described approaches only attempt to split words into a sequence of stem and affixes—making it difficult to restore the underlying structure

[4] Informally, the indirect importance sampling estimate converges to the *true* expectation as $m \to \infty$.

which has been "corrupted" by the orthographic process. Our approach, however, is capable of restoring the underlying morphemes, e.g., *stopping* ↦ *stop-ing*. We note two exceptions to the above statement. Both Dasgupta and Ng (2007) and Naradowsky and Goldwater (2009) incorporate basic, heuristic spelling rules into *unsupervised* induction algorithms. Relatedly, Cotterell et al. (2015b) induced a phonology in an unsupervised manner. In contrast, our model is fully supervised and supports rich features, which enable accurate prediction on new words.

4 Experiments

We provide canonical segmentation experiments in three languages: English, German and Indonesian.

4.1 Corpora

The English data was extracted from segmentations derived from CELEX (Baayen et al., 1993). The German data was extracted from DerivBase (Zeller et al., 2013), which provides a collection of derived forms and the transformation rules. We manipulated these rules to create canonical segmentations. Lastly, the Indonesian data was created from the output of the MORPHIND analyzer (Larasati et al., 2011), which we ran on an open-source corpus of Indonesian.[5] For each language we selected 10,000 forms at random from a uniform distribution over types to form our corpus. We sampled 5 splits of the data into 8000 training forms, 1000 development forms and 1000 test forms. We have released all train, development and test splits online with additional documentation about their construction.[6]

4.2 Models

We train two versions of our proposed model. First, we train a *pipeline model*, i.e., we train the transduction component and segmentation component independently and decode sequentially. This approach is faster both at train and at test but suffers from cascading errors. Second, we train a *joint model*, the transduction and the segmentation components are trained to work well together.

		Joint	Pipeline	SemiCRF	WFST
error	en	**0.27** (.02)	0.33 (.01)	0.33 (.01)	0.63 (.00)
	de	**0.41** (.03)	0.53 (.02)	0.65 (.01)	0.74 (.01)

	id	**0.15** (.02)	0.36 (.03)	0.49 (.02)	2.13 (.00)
F_1	en	**0.76** (.02)	0.70 (.02)	0.68 (.01)	0.53 (.02)
	de	**0.76** (.02)	0.71 (.01)	0.65 (.01)	0.59 (.02)
	id	**0.80** (.01)	0.75 (.01)	0.71 (.01)	0.62 (.02)

Table 1: Top: Error rate. Middle: Average edit distance. Bottom: Mean morpheme F_1 (higher better). Standard deviation in parentheses. Best result on each line in bold.

Baseline: Semi-CRF Segmenter The first baseline is a semi-CRF (Sarawagi and Cohen, 2004) that segments the orthographic form into morphs *without* canonicalization. Earlier work by Cotterell et al. (2015a) applied this model to *supervised* morphological segmentation. We use the feature set as Cotterell et al. (2015a), but we do not incorporate their augmented morphotactic state space.

Baseline: WFST Segmenter Our second baseline is a weighted finite-state transducer (Mohri, 1997) with a log-linear parameterization (Dreyer et al., 2008). We use the stochastic contextual edit model of Cotterell et al. (2014). We employ context n-gram features (up to 6-grams) on the input string to the left and right of the edit location in addition to 2-gram features on the lower string. The context features are then conjoined with the exact edit action. We refer the reader to Cotterell et al. (2014) for more details. The segmentation boundaries are marked as a distinguished symbol in the target string. This model is not entirely suited for the task as it makes it difficult to include the rich features we get through ASPELL.

Training and Decoding Details We train all models with AdaGrad (Duchi et al., 2011; Bottou, 2010). For the joint model, we take 10 samples ($m = 10$) for each gradient estimate. See Algorithm 3 of Bengio et al. (2003) for pseudocode for SGD with importance sampling. The pipeline and segmentation models use ordinary SGD. We use L_2 regularization with the regularization coefficient chosen by based on development set performance.

Exact decoding, $\text{argmax}_{s,u}\, p(s, u \mid w)$, is intractable. Thus, we use a sampling approximation:

[5] https://github.com/desmond86/Indonesian-English-Bilingual-Corpus

[6] http://ryancotterell.github.io/canonical-segmentation/

$\text{argmax}_{s,u^{(i)}}\, p(s, u^{(i)} \mid w)$ where $u^{(1)} \ldots u^{(m)} \overset{\text{i.i.d.}}{\sim} q$. We use $m = 1000$ in our experiments. Conditioned on each sample value for u, we use exact semi-CRF Viterbi decoding to select s.

4.3 Evaluation Measures

Evaluating morphological segmentation is tricky. The standard measure for the supervised task is border F_1, which measures how often the segmentation boundaries posited by the model are correct. However, this measure assumes that the concatenation of the segments is identical to the input string (i.e., surface segmentation) and is thus not applicable to canonical segmentation. On the other hand, the Morpho Challenge competition (Kurimo et al., 2010) uses a measure that samples a large number of word pairs from a linguistic gold standard. A form is considered correct if the gold standard contains at least one overlapping morph *and* the model posits at least one overlapping morph—this is problematic because for languages with multi-morphemic words (e.g., German), one should consider all morphs. Moreover, we can actually recover the linguistically annotated gold standard in contrast to unsupervised methods.

Instead, we report results under three measures: error rate, edit distance and morpheme F_1. Error rate is the proportion of analyses that are completely correct. Since error rate gives no partial credit, we also report edit distance between the predicted analysis and the gold standard, where both are encoded as strings using a distinguished boundary character at segment boundaries. Finally, morpheme F_1 (van den Bosch and Daelemans, 1999) considers overlap between the *set* of morphemes in the model's analysis and the set of morphemes in the gold standard. In this case, precision asks how often did the predicted segmentation contain morphemes in the gold standard and recall asks how often were the gold standard morphemes in the predicted segmentation.

4.4 Results and Error Analysis

Table 1 gives results for the three measures. Under error rate and morpheme F_1 our joint model performs the best on all three languages, followed by our pipeline model and then the two baselines. In fact, we observe that error rate and F_1 are quite correlated in general. Under edit distance, the joint model is the best model on German and Indonesian, but the pipeline model is superior on English. Error analysis indicates that the lower performance is due to spurious insertions. For example, our model incorrectly analyzes *ruby* (stone) as *ruble-y*, mistaking the *ruby* as an adjectival form of *ruble* (the Russian currency); the correct analysis is *ruby* $\mapsto$ *ruby*. We believe that a richer transduction component may fix some of these problems. Overall, our joint model performs well; it is on average within one edit operation of the gold segmentation on three languages.

Unsurprisingly, the WFST performs poorly because it cannot leverage segment-level features (e.g., ASPELL features), which are available to the other models. The performance of the semi-CRF is limited by the orthographic changes in the language, which it cannot model. German is rich in such changes, hence the semi-CRF performs poorly and gets more than half the test cases wrong.

5 Conclusion

We presented a joint model for the task of canonical morphological segmentation, which extends existing approaches with the ability to learn orthographic changes. We argue that canonical morphological segmentation provides a useful analysis of linguistic phenomena (e.g., derivational morphology) because the sequence of morphemes is canonical—making it evident, which words share morphemes. Our model outperforms two baselines on three languages.

Syntactic Parsing of Web Queries with Question Intent

Yuval Pinter[1], Roi Reichart[1,2], and Idan Szpektor[1]

Abstract

Accurate automatic processing of Web queries is important for high-quality information retrieval from the Web. While the syntactic structure of a large portion of these queries is trivial, the structure of queries with question intent is much richer. In this paper we therefore address the task of statistical syntactic parsing of such queries. We first show that the standard dependency grammar does not account for the full range of syntactic structures manifested by queries with question intent. To alleviate this issue we extend the dependency grammar to account for segments – independent syntactic units within a potentially larger syntactic structure. We then propose two distant supervision approaches for the task. Both algorithms do not require manually parsed queries for training. Instead, they are trained on millions of *(query, page title)* pairs from the *Community Question Answering (CQA)* domain, where the CQA page was clicked by the user who initiated the query in a search engine. Experiments on a new treebank[1] consisting of 5,000 Web queries from the CQA domain, manually parsed using the proposed grammar, show that our algorithms outperform alternative approaches trained on various sources: tens of thousands of manually parsed OntoNotes sentences, millions of unlabeled CQA queries and thousands of manually segmented CQA queries.

1 Introduction

As the World Wide Web grows in volume, it encompasses ever-increasing amounts of text. A major gateway to this invaluable resource is *Web queries* which users compose to guide a search engine in retrieving the information they desire to inspect. Automatic processing of Web queries is therefore of utmost importance.

Previous research (Bergsma and Wang, 2007; Barr et al., 2008) suggested that many Web queries are trivial in structure, usually embodying entity lookup, e.g. "*frozen*" or "*condos in NY*". However, with the increasing popularity of Community Question Answering (CQA) sites, such as Yahoo Answers, StackOverflow and social QA forums, more Web queries encompass information needs related to questions that these sites can answer. We found that this subcategory of queries, which we call *CQA queries* (following Liu et al. (2011; Carmel et al. (2014)), exhibits a wide range of structures. This suggests that the processing of such queries, which constitute $\sim$10% of all queries issued to search engines (White et al., 2015), may benefit from syntactic analysis (Tsur et al., 2016).

Recent progress in statistical parsing (Choi et al., 2015) has resulted in models that are both fast, parsing several hundred sentences per second, and accurate. These parsers, however, still suffer from the problem of domain adaptation (McClosky et al., 2010), excelling mostly when their training and test domains are similar. This problem is of particular importance in the heterogeneous Web (Petrov and McDonald, 2012) and is expected to worsen when addressing queries, due to their non-standard grammatical conventions.

Some recent work addresses the syntactic analysis of User Generated Content (UGC) (Petrov and McDonald, 2012; Eisenstein, 2013; Kong et al., 2014). Yet, these efforts generally focus on UGC aspects related to grammatical mistakes made by users (Foster et al., 2008) and to the unique writing conventions of specific Web platforms, such as Twitter (Foster et al., 2011; Kong et al., 2014). Our analysis of thousands of CQA queries, however, reveals that regardless of such issues, CQA queries are generated by a well-defined grammar that sometimes deviates from the one used to generate the standard written language of edited resources such as newspapers.

Consequently, this work has two main contributions. First, we extend the standard dependency grammar to de-

[1] This treebank has been released via Yahoo's Webscope program: `webscope.sandbox.yahoo.com`.

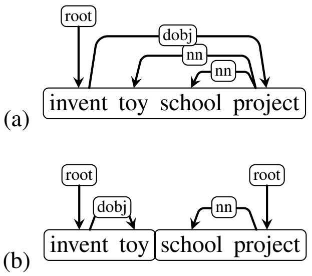

Figure 1: A two-segment query, parsed by an off-the shelf parser: (a) as is, producing an incorrect noun phrase ("toy school project"); (b) after correct segmentation.

scribe the syntax of queries with question intent. The extended grammar is driven by the concept of a *syntactic segment*: an independent syntactic unit within a potentially larger syntactic structure. A query may include several segments, potentially related to each other semantically but lacking an explicit syntactic connection. Hence, query analysis consists of the query's segments and their internal dependency structure, and may be complemented by the inter-segment semantic relationships. Therefore, we constructed a new query treebank consisting of 5,000 CQA queries, manually annotated according to our extended grammar. A comparison of direct application of an off-the-shelf parser (Clear (Choi and McCallum, 2013)) trained on edited text (OntoNotes 5 (Weischedel et al., 2013)) to a raw query with the application of the same parser to the gold-standard segments of that query is given in Fig. 1.

Second, we develop two CQA query parsing algorithms that can adapt any given off-the-shelf dependency parser trained on standard edited text to produce syntactic structures that conform to the extended grammar. Both our algorithms employ *distant supervision* in the form of a training set consisting of millions of *(query, title)* pairs. The *title* is the title of the Yahoo Answers question page that was clicked by the user who initiated the *query*. The alignment between the query and the title provides a valuable training signal for query segmentation and parsing, since the title is usually a grammatical question. Both algorithms employ an off-the-shelf parser, but differ on whether segmentation and parsing are performed in a pipeline or jointly.

We compared our algorithms to several alternatives: (a) Direct application of an off-the-shelf parser to queries; (b) A supervised variant of our pipeline algorithm where thousands of manually segmented queries replace the distant supervision source; and (c) A pipeline algorithm similar to ours where segmentation is based on the predictions of a query language model. We report results on two query treebank tasks: (a) Dependency parsing, reporting Unlabeled Attachment Score (UAS); and (b) Query segmentation, which reflects the core aspect of the extended grammar compared to the standard one.

In experiments on our new treebank, our joint model outperformed the alternatives on UAS for the full test set and for the subset of single-segment queries. Our pipeline model excelled both on UAS and on segmentation F1 for two large subsets that are automatically identifiable at test time: (a) Queries that consist mostly of content words (42.4% of the test set); and (b) Queries for which the confidence score of the off-the-shelf parser is at most 0.8 (30% of the test set). It also beat all other models on the subset of multi-segment queries.

2 Previous Work

The Web attracts considerable NLP research attention (e.g. Eisenstein (2013)). Here we focus on grammar and parsing of Web data in general and queries in particular.

Syntactic Query Analysis Web queries differ from standard sentences in a number of aspects: they tend to be shorter, not to follow standard grammatical conventions, and to convey more information than can be directly inferred from their words. Consequently, a number of works addressed their syntactic analysis. Allan and Raghavan (2002) use part-of-speech (POS) tag patterns in order to manually map very short queries into clarification questions, which are then presented to the user to help them clarify their intent. Barr et al. (2008) trained POS taggers for Web queries and used a set of rules to map the resulting tagged queries into one of seven syntactic categories, whose merit is tested in the context of information retrieval tasks. Manshadi and Li (2009) and Li (2010) addressed the task of semantic tagging and structural analysis of Web queries, focusing on noun phrase queries. Bendersky et al. (2010) used the POS tags of the top-retrieved documents to enhance the initial POS tagging of query terms. Bendersky et al. (2011) proposed a joint framework for annotating queries with POS tags and phrase chunks. Ganchev et al. (2012) trained a POS tagger on automatically tagged queries. The POS tags of the training queries are projected from sentences containing the query terms within Web pages retrieved for them. The retrieved sentences were POS tagged using an off-the-shelf tagger. These works, as opposed to ours, do not aim to produce a complete syntactic analysis of queries.

Syntactic Parsing of Web Data To the best of our knowledge, only a handful of works have aimed at building syntactic parsers for Web data. Petrov and McDonald (2012) conducted a shared task on parsing Web data from the Google Web Treebank, consisting of texts from the email, weblog, CQA, newsgroup, and review domains. The participating systems relied mostly on existing domain adaptation techniques to adapt parsers trained on existing treebanks of edited text to the Web. Foster et al.

(2011) took a similar approach for tweet parsing. Contrary to our approach, these works rely on existing grammatical frameworks, particularly phrase-structure and dependency grammars, and do not aim at adapting them to domains such as Web queries, where standard grammar does not properly describe the language. This may be the reason Web queries were not included in the shared task.

A work that is more related to ours is Kong et al. (2014), who addressed the task of tweet parsing. Like us, they adapt the grammatical annotation scheme to the target linguistic domain and produce a multi-rooted syntactic structure. However, CQA queries and tweets exhibit different syntactic properties: (1) tweets often consist of multiple sentences, while CQA queries are concise in nature and usually correspond to a phrase, a fragment of a sentence, or several of these concatenated; and (2) queries are generated in order to retrieve information from the Web. Tweets, on the other hand, usually aim to convey a short message. These differences lead us to take approaches substantially different from theirs.

3 CQA Query Grammar

3.1 Motivating Analysis

In this section we define the class of *CQA queries* and analyze their properties in comparison with other writing genres. This analysis will establish the motivation for the extension of standard dependency grammar so that it accounts for CQA queries (§3.2).

The data we analyzed consists of queries randomly sampled from the Yahoo Answers log. In cases where a searcher, after issuing a Web query on a search engine, viewed a question page on Yahoo Answers, a popular CQA site, this query is logged. From this log we sampled 100K queries for our analysis, as well as 5,000 additional queries for constructing a query treebank (see §3.3).

According to Barr et al. (2008), who analyzed queries from Yahoo's search engine, 69.8% of general Web queries are composed of a single noun phrase, leaving little room for a meaningful taxonomy. Focusing on CQA queries removes this bias and allows exploration of additional syntactic categories of queries. Especially, we would like to delve into the categories Barr et al. label as *word salad* (e.g. "*mp3s free*") and *other-query* (e.g. "*florida reading conference 2006*"), cited as composing 8.1% and 6.8% of all queries respectively and for which no analysis is offered.

To characterize the domain of CQA queries, we compare its properties to those of other Web domain samples: (a) 100K general Web queries; (b) 120K titles of questions posted on Yahoo Answers; and (c) 100K story bodies from Yahoo News. In our analysis, individual sentences were identified using the OpenNLP sentence splitting tool[2], POS-tagged by the Stanford parser (Klein and Manning, 2003)[3] and syntactically parsed using the Clear parser (Choi and McCallum, 2013)[4].

Table 1 presents four measures of syntactic complexity (four leftmost measure columns). The first column reports the average number of word tokens per parsed item. The second column contains the median and mean dependency tree depths, defined as the number of edges in the longest path from the root node to a leaf in the tree. The third and fourth columns present the fraction of dependency tree root edges that go to words POS-tagged as nouns or as verbs, respectively. We use these last two measures as proxies of the syntactic category of the input text, with noun roots often indicating simple noun phrases and verb roots often indicating more complex syntactic forms that include a verb argument structure[5]. Finally, the rightmost column of the table presents the average parser confidence per item provided by Clear, which we use as a proxy for parsing difficulty.

As the table shows, both CQA and general Web queries are harder to parse (according to parser confidence) compared to news article sentences and CQA question titles. Yet, CQA and general Web queries strongly differ with respect to their syntactic complexity. Indeed, CQA queries have substantially more tokens and deeper trees. Moreover, while 62.9% of the root nodes in general query parse trees govern a noun and 30.3% govern a verb, in CQA queries the respective figures are flipped: 32.2% and 62.7%, respectively.

3.2 Dependency Grammar Extension for Queries

Our analysis above reveals the special status of CQA queries. Like general Web queries, CQA queries are hard to parse. However, while the difficulty of parsing general Web queries may result from their short length and shallow syntactic structure, CQA queries are longer and seem to have a deeper syntactic structure.

Based on our manual inspection of thousands of the queries used in the above analysis, we propose an extension of the standard dependency grammar so that it accounts for CQA queries. Our reasoning is that the grammatical structure of CQA queries is a syntactic forest. The query's tokens are partitioned into one or more contiguous *syntactic segments*, each representing a maximal constituent unit syntactically independent of the other units. The final syntactic representation of the query consists of a set of trees produced according to the Stanford Dependency schema (De Marneffe and Manning, 2008),

[2] opennlp.apache.org

[3] Manual inspection revealed that this parser outperforms the Stanford tagger (Toutanova et al., 2003) on these sets.

[4] Version 2.0.1, parsing model 1.2. www.clearnlp.com

[5] We verified this hypothesis by manual inspection of the 1,000 development set queries (see §3.3).

Corpus	Average token count	Median (mean) tree depth	$root \rightarrow NN*$ edges (%)	$root \rightarrow VB*$ edges (%)	Average parser confidence
News article sentences	18.4	6 (6.5)	12.0	84.8	0.898
CQA question titles	10.5	4 (4.5)	10.0	86.9	0.991
CQA queries	6.4	4 (3.7)	32.2	62.7	0.809
General queries	4.5	3 (3.0)	62.9	30.3	0.752

Table 1: Syntactic properties of four types of Web domains. The four leftmost properties are proxies of syntactic complexity. The fifth property (parser confidence) is a proxy of parsing difficulty. The "$root \rightarrow NN*$ *edges*" and "$root \rightarrow VB*$ *edges*" columns present the fraction of edges from the root of the parse tree that go to words POS-tagged as nouns and verbs respectively.

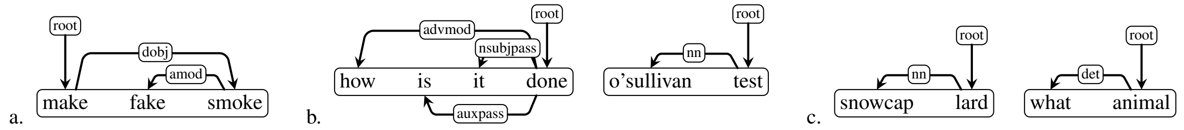

Figure 2: Queries segmented and parsed according to our extended dependency grammar.

one tree per segment. Based on this observation, CQA queries may consist of several syntactically independent segments, as opposed to grammatical sentences which consist of exactly one segment. Importantly, query segments are syntactically independent, although they tend to be semantically related.

Figure 2 provides examples of parsed queries. Query (a) consists of a single segment, a verb phrase rooted by the word *make*. Query (b) is composed of two segments that are syntactically independent, but semantically connected. Particularly, the first segment is an interrogative sentence rooted in the word *done* and the second is a noun phrase which specifies the pronoun *it* from the first segment. Finally, query (c) consists of two segments, each a noun phrase, presumably connected by an *is-made-of* semantic relation. As in query (b), the segments of this query are syntactically independent, but unlike query (b), their semantic connection is more loose. The existence of such loose connections motivates us to exclude semantic subcategorization from the syntactic layer.

We note that the notion of *segment* has another meaning, within the task of *query segmentation* (Bergsma and Wang, 2007; Guo et al., 2008; Tan and Peng, 2008; Mishra et al., 2011; Hagen et al., 2012). This task's goal is to identify words in the query that together form compound concepts or phrases, like "*Chicago Bulls*". As such, this task differs from ours as it defines segmentation in semantic rather than syntactic terms.

We also note that query segments are distinct from the concept of *fragments* in constituency parsing. Marcus et al. (1993) introduce fragments in order to overcome problems involving the attachment point of various modifying phrases, *e.g.* in the sentence '*In Asia, as [FRAG in Europe], a new order is taking shape*'. While proper treatment of such phrases often requires extra syntactic information, their syntactic connection to other parts of the sentence is present, unlike between query segments.

3.3 Query Treebank

Following our proposed grammar, we constructed a treebank by manually annotating 5,000 queries that landed on Yahoo Answers (see §3.1). These queries were randomly split into a 4,000-query test set and a 1,000-query development set. Four human annotators segmented both sets, and parsed the test set with unlabeled dependency trees (including POS tags). The annotators' sets did not overlap, yet cross-reviews were made in cases deemed difficult by them. On a validation set of 100 queries tagged by all annotators, the agreement scores measured were 0.97 for segmentation and 0.96 for dependency edges.

To evaluate how well out-of-the-box parsers conform with our grammar, we applied seven dependency parsers to the 4,000-query test set. We trained all parsers on the OntoNotes 5 training set [6] and applied them: (a) to each gold-standard segment of each query; and (b) to full, unsegmented, queries. For comparison we also recap the performance of the parsers on the OntoNotes 5 test set as reported in Choi et al. (2015). The same non-gold POS tags were provided to all parsers (see §6.2).

The results, presented in Table 2, establish the difficulty of our task: UAS differences between OntoNotes and full queries range from 13.4% to 18.6%. Moreover, injecting gold segmentation knowledge increases the performance of the parsers by 5.3-5.9%, highlighting the value of accurate segmentation in syntactic query analysis. Finally, the ranking of the parsers with respect to their accuracy on queries differs from their ranking with respect to accuracy on OntoNotes, raising Redshift to first place and dropping RBG to last place.

Since knowledge of segment boundaries consistently improves parsing quality in our analysis, we next present two distant supervision approaches that attempt to discover the segments of an input query and return a parse forest that adheres to the segment boundaries.

[6] This parser training convention was kept throughout the paper.

Parser	ON5	Segmented Queries	Full Queries
Redshift (Honnibal et al., 2013)	91.0	**82.5**	**76.6**
Mate (Bohnet and Nivre, 2012)	**91.6**	81.4	75.5
Clear (Choi and McCallum, 2013)	91.3	80.7	75.4
SNN (Chen and Manning, 2014)	88.2	80.7	74.8
GN13 (Goldberg and Nivre, 2013)	89.2	80.5	74.8
Turbo (Martins et al., 2013)	89.6	79.4	73.9
RBG (Lei et al., 2014)	91.4	78.5	72.8

Table 2: UAS of out-of-the-box parsers trained on OntoNotes 5. RBG is reported on its best-performing setting, *basic*.

	Question Title	Associated Query (After segmentation)	Segmentation Cue
1	How many crickets to feed 7 month old leopard gecko?	[leopard gecko] [7 month old] [how many to feed]	Reordering (x2)
2	Does any1 think that Heath Ledger is Cute?	[heath ledger] [cute]	Intruding BE
3	Does Beijing still have license plate restrictions?	[beijing] [license plate restrictions]	Intruding HAVE
4	Do you know the song “Little Sister” by Queens of the Stone Age?	[little sister] [queens]	Intruding IN
5	What came first the jedi or the sith?	[what came first jedi] [sith]	Intruding CC
6	What do you think of a double major in Finance and Marketing?	[double major] [finance] [marketing]	Intruding IN, CC

Table 3: Examples for title-query pairs with the resulting segmentation and the corresponding segmentation cues. Note that they do not necessarily produce correct data.

4 A Pipeline Segmentation-Parsing Model

As our first approach, we present a query segmentation algorithm which can be combined with an off-the-shelf parser in two ways in order to form a pipeline query parsing system: (a) first segmenting the query and then applying the parser to each of the segments; or (b) first parsing the query and then fixing the resulting dependency tree so that it conforms with the segmentation. In the second setup the parser's output is aligned against the segmentation such that dependency edges which cross segment boundaries are re-assigned to become *root* edges. In our experiments we found that, for all our tested pipeline models, the first setup performed slightly better. We therefore report results only for this setup.

Our segmentation algorithm is based on the observation that CQA queries are generated in order to express a searcher's need which is likely to be formulated as a question on the web page that they then visit, and that this paraphrasing can serve as a source for query segmentation cues. The algorithm therefore inspects at training time *(query,title)* pairs where *title* is the title of a Yahoo Answers question page that was clicked by the user who initiated *query*. A query for which a full word-wise alignment to the clicked question can be found is annotated with segmentation markers according to several cues, then added to the training set.

Segmentation Cues The following cues are used for detection of query segment boundaries:

- **Reordering**: a part of the query which appears in the title out of order relative to another part of the query is marked as a segmentation location on both ends (ex. #1 in Table 3). This rule accounted for about 32% of the segmentation cues.
- **Intruding word classes**: if between two words which appear adjacent in the query there are words of certain classes in the question title, the position between them is marked for segmentation. These classes include the verb BE and its conjugations (ex. #2), HAVE and its conjugations (ex. #3), prepositions (ex. #4, #6), and conjunctions (ex. #5, #6). In addition, any multi-word intruding sequence that contains a word of these classes in one of the last three positions is construed as a cue.

Training Set Generation We started with a query log for 60 million Yahoo Answers pages. We filtered out titles of more than 20 words, titles that do not start with a question word, and titles that do not have an associated query which after lowercasing and punctuation removal contains only words from the title (as well as possibly ‘*site:*’ terms or the word ‘*to*’). The remaining 7.5 million queries were automatically segmented according to the above cues. A sample of 100 queries was found to have a segmentation F1 score (defined in §6.2) of 64.5.

Model and Training We trained a linear chain CRF with pairwise potentials (Lafferty et al., 2001)[7] on the set of 7.5M automatically segmented queries. The model employs the following standard features: (a) unigram and bigram word features (±2 and ±1 windows around the represented word respectively); (b) unigram and bigram POS features (in a ±2 window); (c) unigram word+POS features (±1 window); and (d) distance of word from start and end of query, as well as each distance combined with word and/or POS.

[7] We used CRF++ (`crfpp.googlecode.com`)

Algorithm 1 Projection-based query parsing

```
 1: function FINDPROJECTIONBASEDSEGMENTPARSE-
    TREES(QUERY)
 2:     question ← Q2Q(query)
 3:     parse ← OffTheShelfParse(question)
 4:     for Node n in parse do
 5:         if n.text does not match token in query then
 6:             CollapseAllEdges(n, parse)
 7:             parse.remove(n)
 8:     segment-trees ← ∅
 9:     for Node r in parse.root.children do
10:         segment-trees.add(Tree(r))
        return segment-trees

 1: function COLLAPSEALLEDGES(N, PARSE)
 2:     in ← n.incomingEdge
 3:     for Edge out in n.outgoingEdges do
 4:         label ← GenerateLabel(in.type, out.type)
 5:         if n.POS is preposition or conjunction then
 6:             parse.addEdge(parse.root, out.target, 'root')
 7:         else
 8:             parse.addEdge(in.source, out.target, label)
```

5 A Joint Projection-based Model

An alternative distant supervision approach is to employ the *(query,title)* pair set in the training of a model that maps queries to natural language questions. These inferred questions are supposedly easier to parse as they follow standard grammatical conventions. A query parsing algorithm that employs such a mapping component has three steps: first, a grammatical question with a similar information need to that of the query is automatically inferred. Then, the inferred question is parsed by an off-the-shelf dependency parser, trained on a grammatical corpus. Finally, the question parse is projected onto the query, inducing the query's multi-rooted syntactic forest. Algorithm 1 presents pseudo-code for the projection-based query parsing algorithm.

The first step maps a given user query to a synthetic natural-language question. For this step we implemented the Query-to-Question (Q2Q) algorithm of Dror et al. (2013). Q2Q maps queries into valid CQA questions by instantiating templates that were extracted out of *(query,title)* pairs taken from the page view log of a CQA site. We trained the Q2Q algorithm on millions of *(query,title)* pairs taken from the Yahoo Answers log, where each *title* starts with a question word and query length ≥ 3.

Our algorithm obtains the top inferred Q2Q question and parses it using an off-the-shelf parser, trained on grammatical English sentences (lines 2-3 in Algorithm 1). It then projects the question parse tree onto the original query to generate its syntactic structure, in accordance with the extended dependency grammar (§3.2), as follows. First (lines 4-7), the algorithm traverses the question parse, removing all question tokens that do not appear in the query and reassigning the dependents of each removed token to be headed by its parent. In addition, as prepositions and conjunctions inserted by the Q2Q templates are strong signals of segmentation, parse subtrees governed by such nodes are also treated as separate segments. Following this phase, all remaining question tokens appear in the query. The algorithm is then left with a syntactic forest, since the root node may have multiple children, each one defining a query segment. Lines 8-10 extract these segments and their parse trees.

Figure 3 shows the projection process for two queries, the second of which demonstrates how an added preposition ('*on*') invokes segmentation. We emphasize that the only manually annotated data required for the training of our joint model is a treebank of standard edited text (OntoNotes 5), used for training the off-the-shelf parser.

Since we expect the projected query parse to produce trees for contiguous segments, we only accept the top Q2Q result where the query word order is maintained in the question, and use an off-the-shelf parser which produces projective trees. In addition, the projection algorithm may collapse several edges from the question tree into a single edge within a query segment tree, leaving the resulting label unspecified. In this work we evaluate unlabeled parse trees and therefore defer the treatment of this issue to future work (leaving $GenerateLabel()$ in line 4 of Algorithm 1 unspecified).

6 Experiments

6.1 Models

We evaluated the following models (summarized in Table 4) on our new query treebank (§3.3):

Distant Supervision Models Our proposed pipeline (§4) and joint (§5) models. Our pipeline model, denoted by *DistPipe*, performs query segmentation and then parses each segment. Our projection-based joint model, denoted by *Q2QProj*, parses an inferred question for the query and projects the parse tree on the query. Both models use the Clear parser for parsing. Importantly, both our models do not require any type of manually annotated queries (parsed or segmented) for training.

The Q2Q algorithm employed by our joint model returns a question for only 2954 of the 4000 test set queries. We thus reverted to the full-query parsing baseline when it returned no result.

Baselines The first natural baseline is the Clear parser, which is employed by our models. We note that while Clear is not constrained to output a single segment tree[8], in practice it generated a multi-segment structure for ∼2% of the development queries, compared to ∼25% of

[8] Personal communication with the authors.

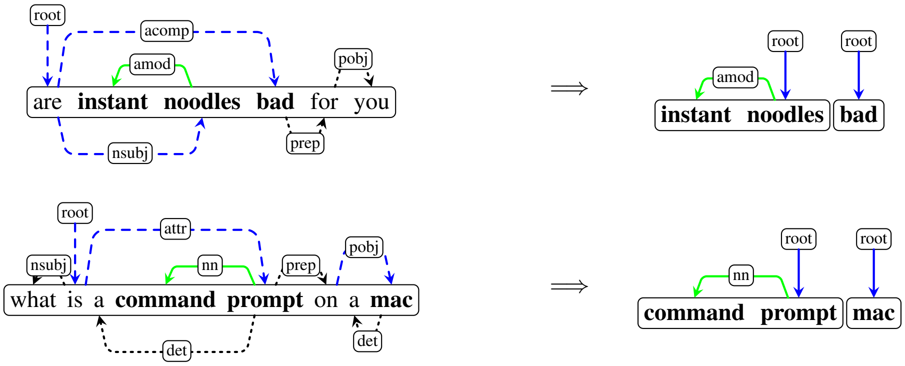

Figure 3: Question parse trees and their projections onto the queries they were generated for. Solid edges are preserved in the projection, dotted edges are removed, and dashed edges are collapsed (in both cases demonstrated, into root edges).

Group	Setup name	Segmentation	Process
Benchmark	*Gold*	gold	pipeline
Ensemble	*Ens*	CRF ensemble	pipeline
Supervised	*Sup*	supervised CRF	pipeline
Distant Supervision	*DistPipe*	distant CRF	pipeline
	Q2QProj	from question parse	projection
Baselines	*Lm*	NNLM	pipeline
	Clear	from parse	parser only

Table 4: The algorithms evaluated in this work.

the queries in the gold standard annotation, making it ill-qualified for multi-segment queries.

As a second baseline, denoted by *Lm*, we constructed a pipeline model identical to ours expect that segmentation is performed with a *Language model (LM)* based approach. For this aim we applied a Neural-Network language model (NNLM) (Mikolov, 2012) to each input query. For each word the language model computes its likelihood given the current model state, which is based on previous words. We then used the 1,000-query development set to find the optimal probability threshold for which words with estimated probability under the threshold are considered "surprising" and therefore mark the beginning of a new segment. We learned a language model[9] with 200 dimensions over 20M randomly sampled queries of length ≥ 3.

Supervised Models We further compare our distant supervision approach to an algorithm that does use manually annotated queries for training, denoted by *Sup*. For this aim we implemented a pipeline model identical to ours, except that the pairwise linear-chain CRF is trained on manually-annotated queries. The algorithm is trained and tested following a 5-fold cross-validation protocol over the 4,000-query test set.

Ensemble Model We also tested the complementary aspects of distant and manual supervision by constructing the same pipeline model, except that segmentation is based on both types of supervision sources. We experimented with various ensemble generation techniques, and the one that has shown to work best was a method that unifies the segmentation decisions of the distant-supervised and supervised CRFs: the model, denoted by *Ens*, considers a token to be a segment boundary if it is considered to be so by at least one of the CRFs.

Gold Segmentation An upper-bound benchmark to our pipeline approach. This is a pipeline model, denoted by *Gold*, that is identical to ours, except that the segmentation is taken from the gold standard.

6.2 Evaluation Tasks and Data Pre-Processing

We consider two evaluation tasks: (a) Dependency parsing, reporting Unlabeled Attachment Score (UAS); and (b) Query Segmentation, reporting the F1 score, where each segment is represented by its boundaries: in order for an observed segment to be considered correct, both of its ends must match those of a gold segment.

All tested algorithms, except for our joint model, directly segment and parse queries and hence require these queries to be POS-tagged. Thus, we POS-tagged the test-set queries with the OpenNLP[10] POS tagger which was adapted to queries using the self-training algorithm of Ganchev et al. (2012). Our self-training set consisted of 14M *(query,title)* pairs from the Yahoo Answers log. This

[9] NNLM implementation in `rnnlm.org` with default parameters.

[10] `opennlp.apache.org`

tagger reached 88.2% accuracy on our query treebank, compared to 81.3% of the off-the-shelf tagger[11].

Analyzing our development set we noticed that a very strong indicator that a query is a grammatical, and thus consists of a single segment, is when it starts with a WH-word or an auxiliary verb. Hence, in all pipeline models, except *Gold*, we do not segment such queries but rather directly apply the Clear parser to them. In postmortem analysis of the test set we found that this indicator was correct for 93.2% of the 1600 detected queries with 40% recall with respect to the single-segment queries subset.

6.3 Results

Tables 5 and 6 present the results of our experiments. The *All Queries* column in Table 5 reports the performance of the tested models on the full test set. Overall, methods based on distant and manual supervision are superior to the baseline methods in both measures. Interestingly, our *Q2QProj* model performs best in terms of UAS (77.1%) although its segmentation F1 is mediocre (63.5). In terms of UAS, the distant-supervised and supervised models approach the performance of the upper bound gold standard segmentation. For example, *Q2QProj* is outperformed by *Gold* by only 3.6%. The *Clear* parser baseline, which is not trained to identify multiple segments, lags 5.7-5.8 F1 points behind the models that employ CRF segmentation. This is translated to a difference in UAS of up to 1.7%. The *Lm* baseline, on the other hand, scores substantially lower than the other models in both measures. This may be an indication of the syntactic, rather than lexical, nature of our task.

In development set experiments we were able to characterize two subsets of queries on which our distant supervised pipeline model performs particularly well, outperforming even the supervised pipeline algorithm which requires thousands of manually annotated queries for training. One such set is the subset of queries that contain at most one word not tagged with what we define to be a *content word POS*, namely: noun, verb, adjective or adverb ('≤ 1 *ncw*' column in Table 5). Intuitively, this subset, which accounts for 42.4% of the test set, consists of queries that convey larger amounts of semantic content and are structured less coherently. On this subset, our *DistPipe* model outperforms the supervised *Sup* model by 4.1 segmentation F1 points, and by 1.7% in UAS.

The other subset, which accounts for 30% of the test set, includes those queries for which the confidence score of the Clear parser, when applied to the whole query, is at most 0.8 ($LowConf$ column in Table 5). This subset singles out cases deemed difficult by the parser, indicating queries with non-standard syntax. Indeed, the performance of all models substantially drops compared to the full set or the '≤ 1 *ncw*' set. Here again, *DistPipe* improves over *Sup* by 5.8 segmentation F1 points and 1.9% in UAS, with additional gain by the ensemble model *Ens*.

Q2QProj performs lower than the pipeline models on both subsets, suggesting that this approach does not work for difficult queries as well as it does for more simple queries. The decreased performance of the *Clear* baseline on both these subsets compared to the entire test set is not surprising, given their challenging syntactic properties.

Altogether, queries belonging to either of the two subsets (or both) account for 50.2% of the full set, emphasizing the benefit of developing more sophisticated ensemble approaches, based on the above characteristics of queries and the individual tested models.

Next, we turn to Table 6, which compares the performance of the various models on the test subsets that consist of single-segment or multi-segment queries only[12]. Our pipeline model, *DistPipe*, excels on the multi-segment subset, achieving a segmentation F1 of 42.2 and UAS of 67.5% compared to only 23.5 and 64.3% respectively of the fully supervised *Sup* model. Our joint model *Q2QProj* achieves a UAS score similar to the supervised model, though its segmentation performance is lower. The ensemble model *Ens* provides additional improvement, hinting that the *Sup* and *DistPipe* models may have learned somewhat different segmentation cues. The segmentation F1 of Clear is as low as 2.2, as its training set contains only single-segment sentences.

We note that the intersection between the multi-segment subset and the '≤ 1 *ncw*' subset is only 622 queries (63.4% of the multi-seg set, 36.7% of '≤ 1 *ncw*'), and with $LowConf$ it is only 524 queries (53.3% of the multi-seg set, 43.7% of $LowConf$). This demonstrates that our *Dist* model is of merit for a variety of query types.

On Single-segment queries, our joint model, *Q2QProj*, achieves the best UAS. This may be because it provides the parser with more context for telegraphic single-segment queries, so much so, that it even outperforms the *Gold* benchmark. Both the *Q2QProj* and *DistPipe* models over-segment (86.5 and 86.8 F1), compared to the near perfect single-segment detection of the supervised *Sup* model (96.2). Still, these differences are only mildly reflected in the UAS scores for single-segment queries.

6.4 Error Analysis

To better understand our distant-supervised signal, we applied the CRF tagger introduced in §4 (without additional filtering) to the test set and analyzed two cases: 100 *false positives* – single-segment queries which were incorrectly tagged with multiple segments, and 100 *false negatives* – multi-segment queries the tagger was wrong to tag as having a single segment.

[11] Several other taggers we experimented with gave similar accuracy figures: ClearNLP, the Stanford tagger and the Stanford parser.

[12] These subsets are extracted using the gold standard and are therefore not available to the models at inference time.

Test Set Setup	All Queries (N=4000)		≤ 1 *ncw* (N=1694)		*LowConf* (N=1199)	
	F1	UAS	F1	UAS	F1	UAS
Gold	100	80.7	100	81.9	100	73.5
Ens	**70.4**	76.4	**63.5**	**73.0**	**59.2**	**64.6**
Sup	70.3	76	59.1	71.1	52.8	62.4
DistPipe	70.3	76.3	63.2	72.8	58.6	64.3
Q2QProj	63.5	**77.1**	53.1	70.5	47.2	61.1
Lm	37.2	66.6	31.6	59.9	30.8	54.4
Clear	64.6	75.4	51.3	69.5	42.9	60.7

Table 5: Performance of the various models on various automatically-extractable subsets of the data. *All Queries* is our test set, the others are its subsets with: ≤ 1 *ncw* – at most one non-content word according to POS tags; *LowConf* – a Clear parser confidence score of at most 0.8. 'F1' denotes segmentation F1.

Test Set Setup	Multi-segment (N=984)		Single-segment (N=3016)	
	S. F1	UAS	S. F1	UAS
Gold	100	83.9	100	79.8
Ens	**46.6**	**68.7**	84.8	78.7
Sup	23.5	64.3	96.2	79.4
DistPipe	42.2	67.5	86.8	78.9
Q2QProj	21.2	64.3	86.5	**80.9**
Lm	29.6	60.4	41.6	68.4
Clear	2.2	60.5	**96.9**	79.8

Table 6: Performance on queries which have a single segment or multiple segments according to the gold standard.

Two types of queries cause most false positives cases. The first type, making up 65% of the errors, is a full (or nearly-full) question or sentence. In half of these cases, a word in the middle of the query, which often marks the beginning of a grammatical question, is incorrectly marked as a segment start. Such an example is "*[sherlock is the best show ever]*", where the underlined word is the incorrectly tagged segment start. The other main error is the segmentation of a query consisting of a single noun phrase (19% of the cases), for example "*[clothing product testing]*".

Our false negative analysis discovered four main types of errors, where a multi-segment query is not segmented. The most frequent one (35%) is cases where the tagger did not detect a syntactic cue for a segment start, *e.g.* in "*[grilling pork chops] [seasoning]*", where '*and*' is potentially missing. Another common mistake (24%) is a named entity which is added as its own segment for context (usually in the beginning or the end of the query). Such a query is "*[biotin] [mcg vs mg]*". The third type of errors (17%) is queries for which segmentation detection requires the understanding of the semantics behind the query. One example is "*[movies on youtube] [list]*", where '*youtube list*' was construed as a single noun phrase. The forth type (11%) contains a reference for a preferred content provider by the searcher on its own segment, such as "*[is illuminati good] [yahoo]*".

This analysis shows that the more frequent errors involve semantics and require either a different segmentation approach, or more semantic-oriented features.

7 Conclusions

We studied the syntactic properties of Web queries with question intent. We motivated the need to extend the dependency grammar framework so that it accounts for such queries, and constructed a new Query Treebank, annotated according to the extended grammar. We then developed distant-supervised algorithms that can parse queries according to our grammar. Our algorithms outperform strong baselines, including a supervised model trained on thousands of manually segmented queries.

In future work we would like to improve the query analysis performance of our algorithms. In addition, we plan to assess the contribution of query parsing to IR tasks such as document retrieval and query reformulation.

Acknowledgments

We thank: Bettina Bolla and Shir Givoni, for their annotation work on Query Treebank; Avihai Mejer, for implementing the Q2Q element of the projection algorithm; and Joel Tetreault, for providing the infrastructure for the experiments in Section 3.3.

Abstract

While neural networks have been successfully applied to many NLP tasks the resulting vector-based models are very difficult to interpret. For example it's not clear how they achieve *compositionality*, building sentence meaning from the meanings of words and phrases. In this paper we describe strategies for visualizing compositionality in neural models for NLP, inspired by similar work in computer vision. We first plot unit values to visualize compositionality of negation, intensification, and concessive clauses, allowing us to see well-known markedness asymmetries in negation. We then introduce methods for visualizing a unit's *salience*, the amount that it contributes to the final composed meaning from first-order derivatives. Our general-purpose methods may have wide applications for understanding compositionality and other semantic properties of deep networks.

1 Introduction

Neural models match or outperform the performance of other state-of-the-art systems on a variety of NLP tasks. Yet unlike traditional feature-based classifiers that assign and optimize weights to varieties of human interpretable features (parts-of-speech, named entities, word shapes, syntactic parse features etc) the behavior of deep learning models is much less easily interpreted. Deep learning models mainly operate on word embeddings (low-dimensional, continuous, real-valued vectors) through multi-layer neural architectures, each layer of which is characterized as an array of hidden neuron units. It is unclear how deep learning models deal with *composition*, implementing functions like negation or intensification, or combining meaning from different parts of the sentence, filtering away the informational chaff from the wheat, to build sentence meaning.

In this paper, we explore multiple strategies to interpret meaning composition in neural models. We employ traditional methods like representation plotting, and introduce simple strategies for measuring how much a neural unit contributes to meaning composition, its 'salience' or importance using first derivatives.

Visualization techniques/models represented in this work shed important light on how neural models work: For example, we illustrate that LSTM's success is due to its ability in maintaining a much sharper focus on the important key words than other models; Composition in multiple clauses works competitively, and that the models are able to capture negative asymmetry, an important property of semantic compositionally in natural language understanding; there is sharp dimensional locality, with certain dimensions marking negation and quantification in a manner that was surprisingly localist. Though our attempts only touch superficial points in neural models, and each method has its pros and cons, together they may offer some insights into the behaviors of neural models in language based tasks, marking one initial step toward understanding how they achieve meaning composition in natural language processing.

The next section describes some visualization models in vision and NLP that have inspired this work. We describe datasets and the adopted neural models in Section 3. Different visualization strategies and correspondent analytical results are presented

Proceedings of NAACL-HLT 2016, pages 681–691,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

separately in Section 4,5,6, followed by a brief conclusion.

2 A Brief Review of Neural Visualization

Similarity is commonly visualized graphically, generally by projecting the embedding space into two dimensions and observing that similar words tend to be clustered together (e.g., Elman (1989), Ji and Eisenstein (2014), Faruqui and Dyer (2014)). (Karpathy et al., 2015) attempts to interpret recurrent neural models from a statical point of view and does deeply touch compositionally of meanings. Other relevant attempts include (Fyshe et al., 2015; Faruqui et al., 2015).

Methods for interpreting and visualizing neural models have been much more significantly explored in vision, especially for Convolutional Neural Networks (CNNs or ConvNets) (Krizhevsky et al., 2012), multi-layer neural networks in which the original matrix of image pixels is convolved and pooled as it is passed on to hidden layers. ConvNet visualizing techniques consist mainly in mapping the different layers of the network (or other features like SIFT (Lowe, 2004) and HOG (Dalal and Triggs, 2005)) back to the initial image input, thus capturing the human-interpretable information they represent in the input, and how units in these layers contribute to any final decisions (Simonyan et al., 2013; Mahendran and Vedaldi, 2014; Nguyen et al., 2014; Szegedy et al., 2013; Girshick et al., 2014; Zeiler and Fergus, 2014). Such methods include:

(1) Inversion: Inverting the representations by training an additional model to project outputs from different neural levels back to the initial input images (Mahendran and Vedaldi, 2014; Vondrick et al., 2013; Weinzaepfel et al., 2011). The intuition behind reconstruction is that the pixels that are reconstructable from the current representations are the content of the representation. The inverting algorithms allow the current representation to align with corresponding parts of the original images.

(2) Back-propagation (Erhan et al., 2009; Simonyan et al., 2013) and Deconvolutional Networks (Zeiler and Fergus, 2014): Errors are back propagated from output layers to each intermediate layer and finally to the original image inputs. Deconvolutional Networks work in a similar way by projecting outputs back to initial inputs layer by layer, each layer associated with one supervised model for projecting upper ones to lower ones These strategies make it possible to spot active regions or ones that contribute the most to the final classification decision.

(3) Generation: This group of work generates images in a specific class from a sketch guided by already trained neural models (Szegedy et al., 2013; Nguyen et al., 2014). Models begin with an image whose pixels are randomly initialized and mutated at each step. The specific layers that are activated at different stages of image construction can help in interpretation.

While the above strategies inspire the work we present in this paper, there are fundamental differences between vision and NLP. In NLP words function as basic units, and hence (word) vectors rather than single pixels are the basic units. Sequences of words (e.g., phrases and sentences) are also presented in a more structured way than arrangements of pixels. In parallel to our research, independent researches (Karpathy et al., 2015) have been conducted to explore similar direction from an error-analysis point of view, by analyzing predictions and errors from a recurrent neural models. Other distantly relevant works include: Murphy et al. (2012; Fyshe et al. (2015) used an manual task to quantify the interpretability of semantic dimensions by presetting human users with a list of words and ask them to choose the one that does not belong to the list. Faruqui et al. (2015). Similar strategy is adopted in (Faruqui et al., 2015) by extracting top-ranked words in each vector dimension.

3 Datasets and Neural Models

We explored two datasets on which neural models are trained, one of which is of relatively small scale and the other of large scale.

3.1 Stanford Sentiment Treebank

Stanford Sentiment Treebank is a benchmark dataset widely used for neural model evaluations. The dataset contains gold-standard sentiment labels for every parse tree constituent, from sentences to phrases to individual words, for 215,154 phrases in 11,855 sentences. The task is to perform both fine-grained (very positive, positive, neutral, negative and very negative) and coarse-grained (positive vs negative) classification at both the phrase and sentence level. For more details about the dataset, please refer to Socher et al. (2013).

While many studies on this dataset use recursive parse-tree models, in this work we employ only standard sequence models (RNNs and LSTMs) since these are the most widely used current neural models, and sequential visualization is more straightforward. We therefore first transform each parse tree node to a sequence of tokens. The sequence is first mapped to a phrase/sentence representation and fed into a softmax classifier. Phrase/sentence representations are built with the following three models: *Standard Recurrent Sequence* with TANH activation functions, *LSTMs* and *Bidirectional LSTMs*. For details about the three models, please refer to Appendix.

Training AdaGrad with mini-batch was used for training, with parameters ($L2$ penalty, learning rate, mini batch size) tuned on the development set. The number of iterations is treated as a variable to tune and parameters are harvested based on the best performance on the dev set. The number of dimensions for the word and hidden layer are set to 60 with 0.1 dropout rate. Parameters are tuned on the dev set. The standard recurrent model achieves 0.429 (fine grained) and 0.850 (coarse grained) accuracy at the sentence level; LSTM achieves 0.469 and 0.870, and Bidirectional LSTM 0.488 and 0.878, respectively.

3.2 Sequence-to-Sequence Models

SEQ2SEQ are neural models aiming at generating a sequence of output texts given inputs. Theoretically, SEQ2SEQ models can be adapted to NLP tasks that can be formalized as predicting outputs given inputs and serve for different purposes due to different inputs and outputs, e.g., machine translation where inputs correspond to source sentences and outputs to target sentences (Sutskever et al., 2014; Luong et al., 2014); conversational response generation if inputs correspond to messages and outputs correspond to responses (Vinyals and Le, 2015; Li et al., 2015). SEQ2SEQ need to be trained on massive amount of data for implicitly semantic and syntactic relations between pairs to be learned.

SEQ2SEQ models map an input sequence to a vector representation using LSTM models and then sequentially predicts tokens based on the pre-obtained representation. The model defines a distribution over outputs (Y) and sequentially predicts tokens given inputs (X) using a softmax function.

$$
\begin{aligned}
P(Y|X) &= \prod_{t=1}^{n_y} p(y_t|x_1, x_2, ..., x_t, y_1, y_2, ..., y_{t-1}) \\
&= \prod_{t=1}^{n_y} \frac{\exp(f(h_{t-1}, e_{y_t}))}{\sum_{y'} \exp(f(h_{t-1}, e_{y'}))}
\end{aligned}
$$

where $f(h_{t-1}, e_{y_t})$ denotes the activation function between h_{t-1} and e_{y_t}, where h_{t-1} is the representation output from the LSTM at time $t-1$. For each time step in word prediction, SEQ2SEQ models combine the current token with previously built embeddings for next-step word prediction.

For easy visualization purposes, we turn to the most straightforward task—autoencoder— where inputs and outputs are identical. The goal of an autoencoder is to reconstruct inputs from the pre-obtained representation. We would like to see how individual input tokens affect the overall sentence representation and each of the tokens to predict in outputs. We trained the auto-encoder on a subset of WMT'14 corpus containing 4 million english sentences with an average length of 22.5 words. We followed training protocols described in (Sutskever et al., 2014).

4 Representation Plotting

We begin with simple plots of representations to shed light on local compositions using Stanford Sentiment Treebank.

Local Composition Figure 1 shows a 60d heatmap vector for the representation of selected words/phrases/sentences, with an emphasis on extent modifications (adverbial and adjectival) and negation. Embeddings for phrases or sentences are attained by composing word representations from the pretrained model.

The intensification part of Figure 1 shows suggestive patterns where values for a few dimensions are strengthened by modifiers like “a lot” (the red bar in the first example) “so much” (the red bar in the second example), and “incredibly”. Though the patterns for negations are not as clear, there is still a consistent reversal for some dimensions, visible as a shift between blue and red for dimensions boxed on the left.

We then visualize words and phrases using t-sne (Van der Maaten and Hinton, 2008) in Figure 2, de-

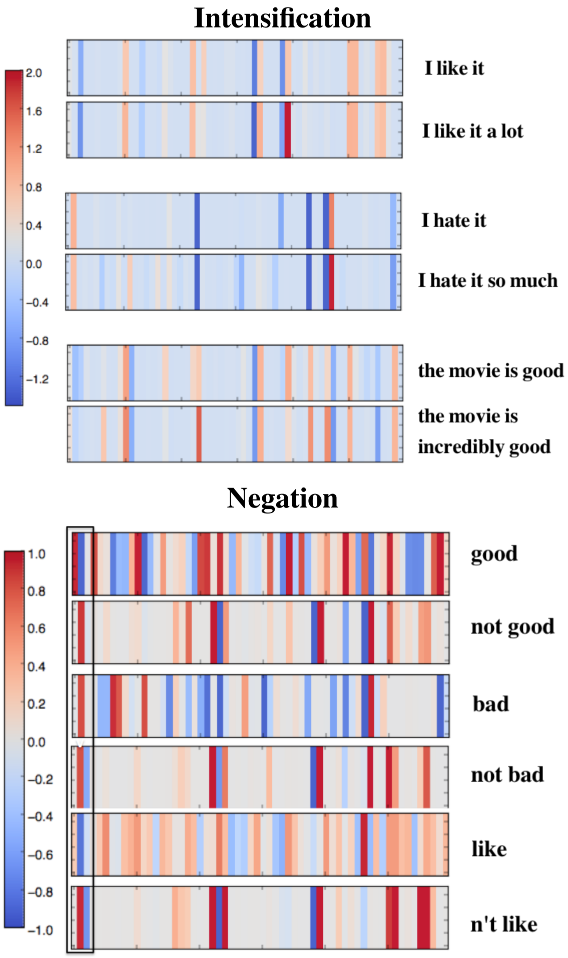

Figure 1: Visualizing intensification and negation. Each vertical bar shows the value of one dimension in the final sentence/phrase representation after compositions. Embeddings for phrases or sentences are attained by composing word representations from the pretrained model.

liberately adding in some random words for comparative purposes. As can be seen, neural models nicely learn the properties of local compositionally, clustering negation+positive words ('not nice', 'not good') together with negative words. Note also the asymmetry of negation: "not bad" is clustered more with the negative than the positive words (as shown both in Figure 1 and 2). This asymmetry has been widely discussed in linguistics, for example as arising from markedness, since 'good' is the unmarked direction of the scale (0; Horn, 1989; Fraenkel and Schul, 2008). This suggests that although the model does seem to focus on certain units for negation in Figure 1, the neural model is not just learning to apply a fixed transform for 'not' but is able to capture the subtle differences in the composition of different words.

Concessive Sentences In concessive sentences, two clauses have opposite polarities, usually related by a contrary-to-expectation implicature. We plot evolving representations over time for two concessives in Figure 3. The plots suggest:

1. For tasks like sentiment analysis whose goal is to predict a specific semantic dimension (as opposed to general tasks like language model word prediction), too large a dimensionality leads to many dimensions non-functional (with values close to 0), causing two sentences of opposite sentiment to differ only in a few dimensions. This may explain why more dimensions don't necessarily lead to better performance on such tasks (For example, as reported in (Socher et al., 2013), optimal performance is achieved when word dimensionality is set to between 25 and 35).

2. Both sentences contain two clauses connected by the conjunction "though". Such two-clause sentences might either work *collaboratively*— models would remember the word "though" and make the second clause share the same sentiment orientation as first—or *competitively*, with the stronger one dominating. The region within dotted line in Figure 3(a) favors the second assumption: the difference between the two sentences is diluted when the final words ("interesting" and "boring") appear.

Clause Composition In Figure 4 we explore this clause composition in more detail. Representations move closer to the negative sentiment region by adding negative clauses like "although it had bad acting" or "but it is too long" to the end of a simply positive "I like the movie". By contrast, adding a concessive clause to a negative clause does not move toward the positive; "I hate X but ..." is still very negative, not that different than "I hate X". This difference again suggests the model is able to capture negative asymmetry (0; Horn, 1989; Fraenkel and Schul, 2008).

5 First-Derivative Saliency

In this section, we describe another strategy which is is inspired by the back-propagation strategy in vision (Erhan et al., 2009; Simonyan et al., 2013). It measures how much each input unit contributes to

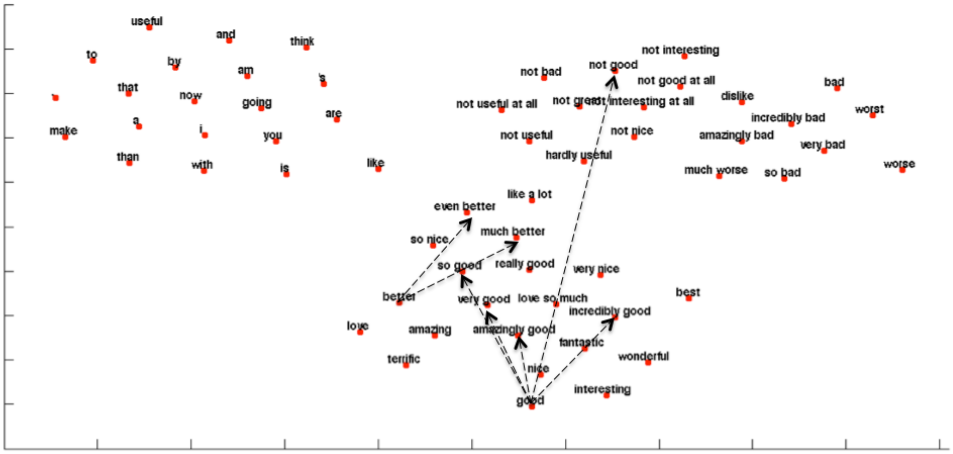

Figure 2: t-SNE Visualization on latent representations for modifications and negations.

the final decision, which can be approximated by first derivatives.

More formally, for a classification model, an input E is associated with a gold-standard class label c. (Depending on the NLP task, an input could be the embedding for a word or a sequence of words, while labels could be POS tags, sentiment labels, the next word index to predict etc.) Given embeddings E for input words with the associated gold class label c, the trained model associates the pair (E, c) with a score $S_c(E)$. The goal is to decide which units of E make the most significant contribution to $S_c(e)$, and thus the decision, the choice of class label c.

In the case of deep neural models, the class score $S_c(e)$ is a highly non-linear function. We approximate $S_c(e)$ with a linear function of e by computing the first-order Taylor expansion

$$S_c(e) \approx w(e)^T e + b \tag{1}$$

where $w(e)$ is the derivative of S_c with respect to the embedding e.

$$w(e) = \frac{\partial(S_c)}{\partial e} \mid_e \tag{2}$$

The magnitude (absolute value) of the derivative indicates the sensitiveness of the final decision to the change in one particular dimension, telling us how much one specific dimension of the word embedding contributes to the final decision. The saliency score is given by

$$S(e) = |w(e)| \tag{3}$$

5.1 Results on Stanford Sentiment Treebank

We first illustrate results on Stanford Treebank. We plot in Figures 5, 6 and 7 the saliency scores (the absolute value of the derivative of the loss function with respect to each dimension of all word inputs) for three sentences, applying the trained model to each sentence. Each row corresponds to saliency score for the correspondent word representation with each grid representing each dimension. The examples are based on the clear sentiment indicator "hate" that lends them all negative sentiment.

"I hate the movie" All three models assign high saliency to "hate" and dampen the influence of other tokens. LSTM offers a clearer focus on "hate" than the standard recurrent model, but the bi-directional LSTM shows the clearest focus, attaching almost zero emphasis on words other than "hate". This is presumably due to the gates structures in LSTMs and Bi-LSTMs that controls information flow, making these architectures better at filtering out less relevant information.

"I hate the movie that I saw last night" All three models assign the correct sentiment. The simple recurrent models again do poorly at filtering out irrelevant information, assigning too much salience to words unrelated to sentiment. However none of the models suffer from the gradient vanishing problems despite this sentence being longer; the salience of "hate" still stands out after 7-8 following convolutional operations.

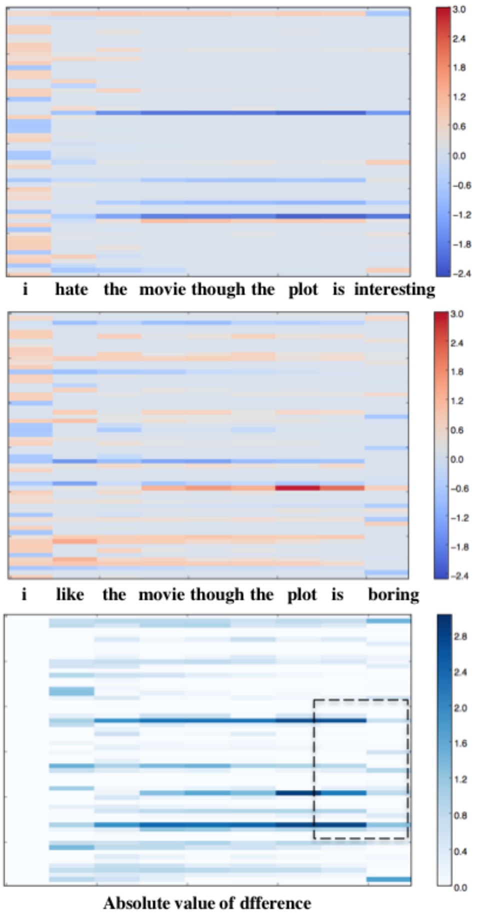

Figure 3: Representations over time from LSTMs. Each column corresponds to outputs from LSTM at each time-step (representations obtained after combining current word embedding with previous build embeddings). Each grid from the column corresponds to each dimension of current time-step representation. The last rows correspond to absolute differences for each time step between two sequences.

"I hate the movie though the plot is interesting" The simple recurrent model emphasizes only the second clause "the plot is interesting", assigning no credit to the first clause "I hate the movie". This might seem to be caused by a vanishing gradient, yet the model correctly classifies the sentence as very negative, suggesting that it is successfully incorporating information from the first negative clause. We separately tested the individual clause "though the plot is interesting". The standard recurrent model confidently labels it as positive. Thus despite the lower saliency scores for words in the first clause, the simple recurrent system manages to rely on that clause and downplay the information from the latter positive clause—despite the higher saliency scores of the later words. This illustrates a limitation of saliency visualization. first-order derivatives don't capture all the information we would like to visualize, perhaps because they are only a rough approximate to individual contributions and might not suffice to deal with highly non-linear cases. By contrast, the LSTM emphasizes the first clause, sharply dampening the influence from the second clause, while the Bi-LSTM focuses on both "hate the movie" and "plot is interesting".

5.2 Results on Sequence-to-Sequence Autoencoder

Figure 9 represents saliency heatmap for auto-encoder in terms of predicting correspondent token at each time step. We compute first-derivatives for each preceding word through back-propagation as decoding goes on. Each grid corresponds to magnitude of average saliency value for each 1000-dimensional word vector. The heatmaps give clear overview about the behavior of neural models during decoding. Observations can be summarized as follows:

1. For each time step of word prediction, SEQ2SEQ models manage to link word to predict back to correspondent region at the inputs (automatically learn alignments), e.g., input region centering around token "hate" exerts more impact when token "hate" is to be predicted, similar cases with tokens "movie", "plot" and "boring".

2. Neural decoding combines the previously built representation with the word predicted at the current step. As decoding proceeds, the influence of the initial input on decoding (i.e., tokens in source sentences) gradually diminishes as more previously-predicted words are encoded in the vector representations. Meanwhile, the influence of language model gradually dominates: when word "boring" is to be predicted, models attach more weight to earlier predicted tokens "plot" and "is" but less to correspondent regions in the inputs, i.e., the word "boring" in inputs.

6 Average and Variance

For settings where word embeddings are treated as parameters to optimize from scratch (as opposed to using pre-trained embeddings), we propose a second,

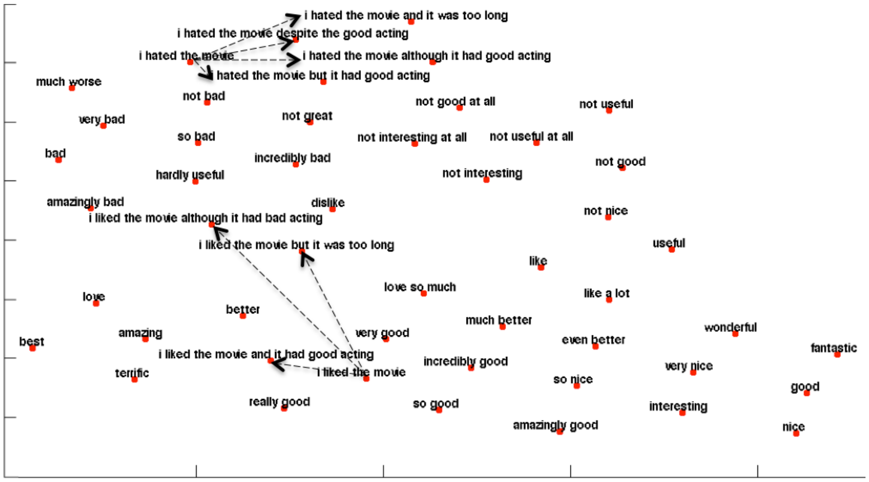

Figure 4: t-SNE Visualization for clause composition.

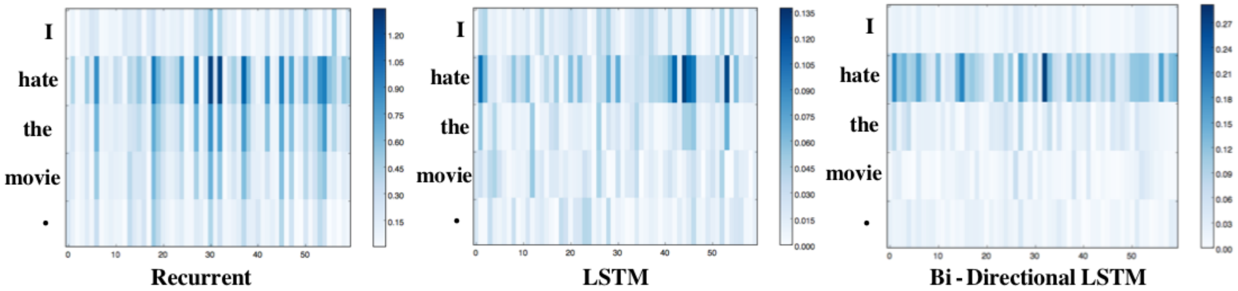

Figure 5: Saliency heatmap for for "I hate the movie ." Each row corresponds to saliency scores for the correspondent word representation with each grid representing each dimension.

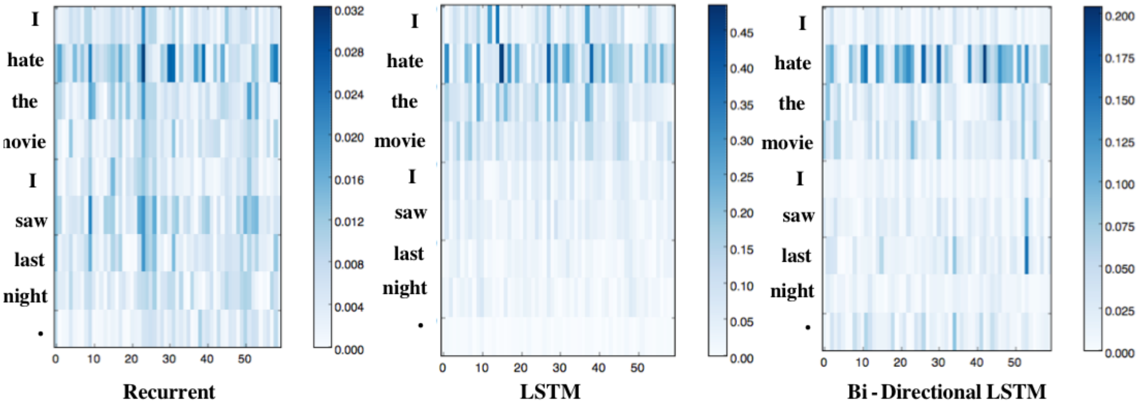

Figure 6: Saliency heatmap for "I hate the movie I saw last night ." .

surprisingly easy and direct way to visualize important indicators. We first compute the average of the word embeddings for all the words within the sentences. The measure of salience or influence for a word is its deviation from this average. The idea is that during training, models would learn to render indicators different from non-indicator words, enabling them to stand out even after many layers of computation.

Figure 8 shows a map of variance; each grid corresponds to the value of $||e_{i,j} - \frac{1}{N_S}\sum_{i' \in N_S} e_{i'j}||^2$ where $e_{i,j}$ denotes the value for j th dimension of word i and N denotes the number of token within the sentences.

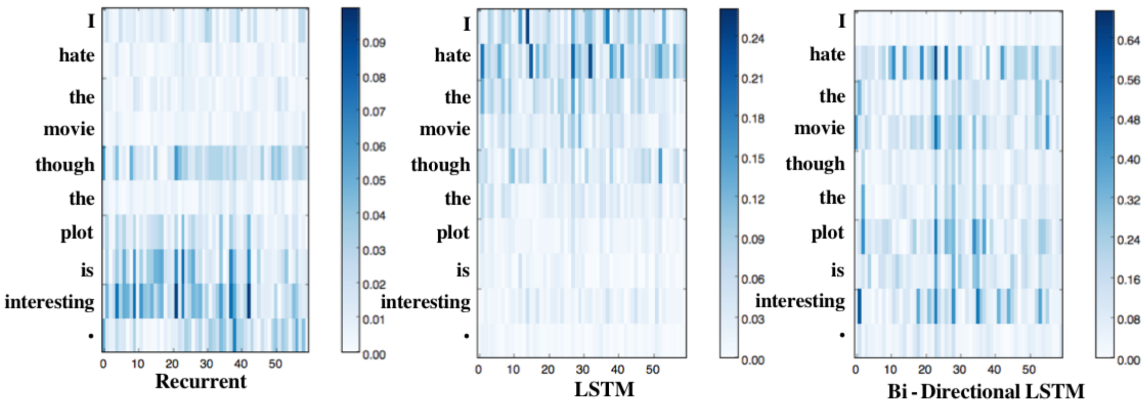

Figure 7: Saliency heatmap for “I hate the movie though the plot is interesting .” .

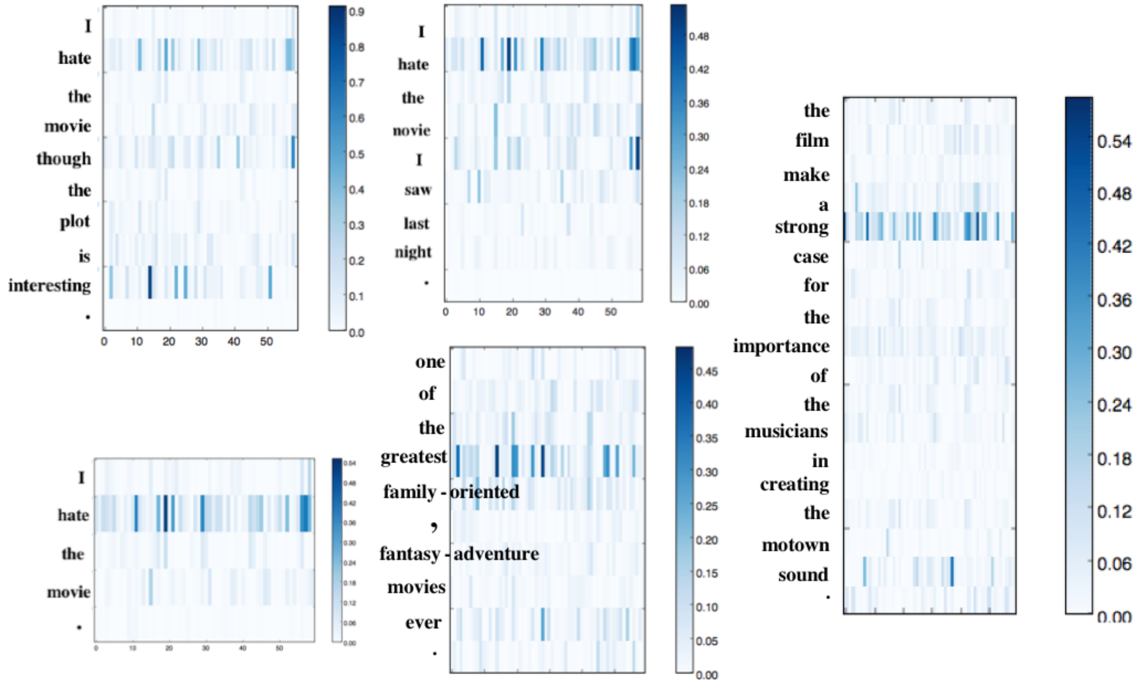

Figure 8: Variance visualization.

As the figure shows, the variance-based salience measure also does a good job of emphasizing the relevant sentiment words. The model does have shortcomings: (1) it can only be used in to scenarios where word embeddings are parameters to learn (2) it's clear how well the model is able to visualize local compositionality.

7 Conclusion

In this paper, we offer several methods to help visualize and interpret neural models, to understand how neural models are able to compose meanings, demonstrating asymmetries of negation and explain some aspects of the strong performance of LSTMs at these tasks.

Though our attempts only touch superficial points in neural models, and each method has its pros and cons, together they may offer some insights into the behaviors of neural models in language based tasks, marking one initial step toward understanding how they achieve meaning composition in natural language processing. Our future work includes using results of the visualization be used to perform error analysis, and understanding strengths limitations of

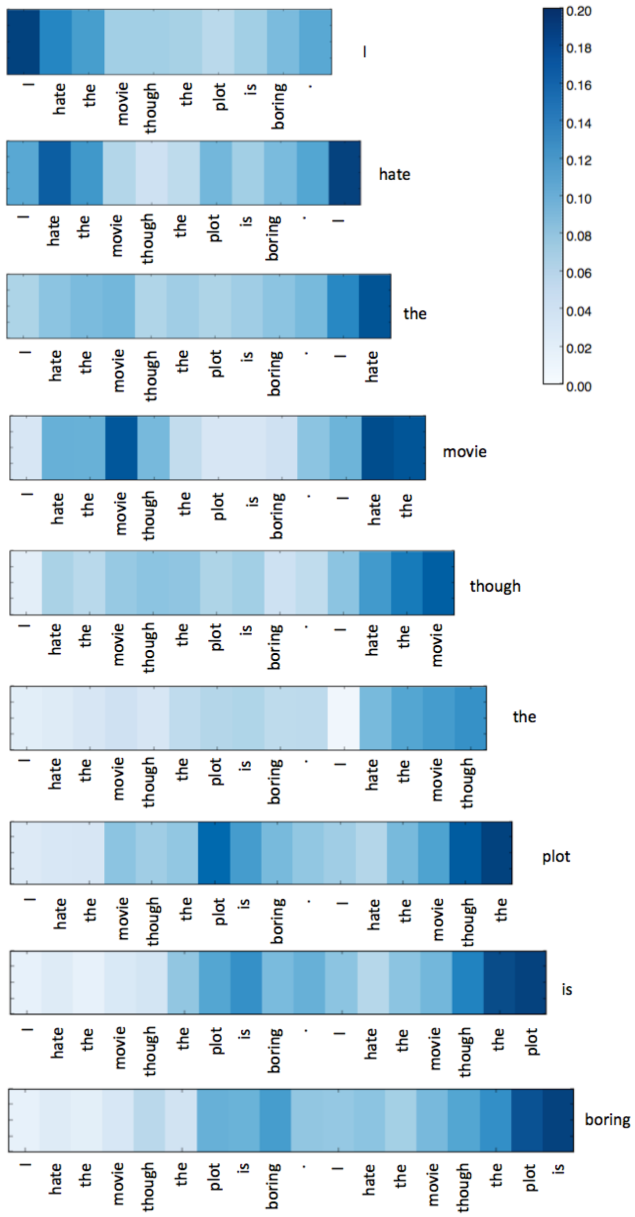

Figure 9: Saliency heatmap for SEQ2SEQ auto-encoder in terms of predicting correspondent token at each time step.

different neural models.

Appendix

Recurrent Models A recurrent network successively takes word w_t at step t, combines its vector representation e_t with previously built hidden vector h_{t-1} from time $t-1$, calculates the resulting current embedding h_t, and passes it to the next step. The embedding h_t for the current time t is thus:

$$h_t = f(W \cdot h_{t-1} + V \cdot e_t) \tag{4}$$

where W and V denote compositional matrices. If N_s denote the length of the sequence, h_{N_s} represents the whole sequence S. h_{N_s} is used as input a softmax function for classification tasks.

Multi-layer Recurrent Models Multi-layer recurrent models extend one-layer recurrent structure by operation on a deep neural architecture that enables more expressivity and flexibly. The model associates each time step for each layer with a hidden representation $h_{l,t}$, where $l \in [1, L]$ denotes the index of layer and t denote the index of time step. $h_{l,t}$ is given by:

$$h_{t,l} = f(W \cdot h_{t-1,l} + V \cdot h_{t,l-1}) \tag{5}$$

where $h_{t,0} = e_t$, which is the original word embedding input at current time step.

Long-short Term Memory LSTM model, first proposed in (Hochreiter and Schmidhuber, 1997), maps an input sequence to a fixed-sized vector by sequentially convoluting the current representation with the output representation of the previous step. LSTM associates each time epoch with an input, control and memory gate, and tries to minimize the impact of unrelated information. i_t, f_t and o_t denote to gate states at time t. h_t denotes the hidden vector outputted from LSTM model at time t and e_t denotes the word embedding input at time t. We have

$$\begin{aligned} i_t &= \sigma(W_i \cdot e_t + V_i \cdot h_{t-1}) \\ f_t &= \sigma(W_f \cdot e_t + V_f \cdot h_{t-1}) \\ o_t &= \sigma(W_o \cdot e_t + V_o \cdot h_{t-1}) \\ l_t &= \text{tanh}(W_l \cdot e_t + V_l \cdot h_{t-1}) \\ c_t &= f_t \cdot c_{t-1} + i_t \times l_t \\ h_t &= o_t \cdot m_t \end{aligned} \tag{6}$$

where σ denotes the sigmoid function. i_t, f_t and o_t are scalars within the range of [0,1]. × denotes pairwise dot.

A multi-layer LSTM models works in the same way as multi-layer recurrent models by enable multi-layer's compositions.

Bidirectional Models (Schuster and Paliwal, 1997) add bidirectionality to the recurrent framework where embeddings for each time are calculated both forwardly and backwardly:

$$\begin{aligned} h_t^{\rightarrow} &= f(W^{\rightarrow} \cdot h_{t-1}^{\rightarrow} + V^{\rightarrow} \cdot e_t) \\ h_t^{\leftarrow} &= f(W^{\leftarrow} \cdot h_{t+1}^{\leftarrow} + V^{\leftarrow} \cdot e_t) \end{aligned} \tag{7}$$

Normally, bidirectional models feed the concatenation vector calculated from both directions $[e_1^{\leftarrow}, e_{N_S}^{\rightarrow}]$ to the classifier. Bidirectional models can be similarly extended to both multi-layer neural model and LSTM version.

Bilingual Word Embeddings from Parallel and Non-parallel Corpora for Cross-Language Text Classification

Abstract

In many languages, sparse availability of resources causes numerous challenges for textual analysis tasks. Text classification is one of such standard tasks that is hindered due to limited availability of label information in low-resource languages. Transferring knowledge (i.e. label information) from high-resource to low-resource languages might improve text classification as compared to the other approaches like machine translation. We introduce BRAVE (*Bilingual paRAgraph VEctors*), a model to learn bilingual distributed representations (i.e. embeddings) of words without word alignments either from sentence-aligned parallel or label-aligned non-parallel document corpora to support cross-language text classification. Empirical analysis shows that classification models trained with our bilingual embeddings outperforms other state-of-the-art systems on three different cross-language text classification tasks.

1 Introduction

The availability of language-specific annotated resources is crucial for the efficiency of natural language processing tasks. Still, many languages lack rich annotated resources that support various tasks such as part-of-speech tagging, dependency parsing and text classification. While the growth of multilingual information on the web has provided an opportunity to build these missing annotated resources, but still lots of manual effort is required to achieve high quality resources for every language separately.

Another possibility is to utilize the unlabeled data present in those languages or transfer knowledge from annotation-rich languages. For the first alternative, recent advancements made in learning monolingual distributed representations of words (Mikolov et al., 2013a; Pennington et al., 2014; Levy and Goldberg, 2014) (i.e. monolingual word embeddings) capturing syntactic and semantic information in an unsupervised manner was useful in numerous NLP tasks (Collobert et al., 2011). However, this may not be sufficient for several other tasks such as cross-language information retrieval (Grefenstette, 2012), cross-language word semantic similarity (Vulić and Moens, 2014), cross-language text classification (CLTC, henceforth) (Klementiev et al., 2012; Xiao and Guo, 2013; Prettenhofer and Stein, 2010; Tang and Wan, 2014) and machine translation (Zhao et al., 2015) due to irregularities across languages. In these kind of scenarios, transfer of knowledge can be useful.

Several approaches (Hermann and Blunsom, 2014; Sarath Chandar et al., 2014; Gouws et al., 2015; Coulmance et al., 2015) tried to induce monolingual distributed representations into a language independent space (i.e. bilingual or multilingual word embeddings) by jointly training on pair of languages. Although the overall goal of these approaches is to capture linguistic regularities in words that share same semantic and syntactic space across languages, they differ in their implementation. One set of methods either perform offline alignment of trained monolingual embeddings or jointly-train both monolingual and cross-lingual objectives, while the other set uses only cross-lingual objective. Jointly-trained or offline alignment methods can be further divided based on the type of par-

allel corpus (e.g. word-aligned, sentence-aligned) they use for learning the cross-lingual objective. Table 1 summarizes different setups to learn bilingual or multilingual embeddings for the various tasks.

Methods in the Table 1 that use word-aligned parallel corpus as offline alignment (Mikolov et al., 2013b; Faruqui and Dyer, 2014) assume single correspondence between the words across languages and ignore polysemy. While, the jointly-train methods (Klementiev et al., 2012) that use word-alignment parallel corpus and consider polysemy perform computationally expensive operation of considering all possible interactions between the pairs of words in vocabulary of two different languages. Methods (Hermann and Blunsom, 2014; Sarath Chandar et al., 2014) that overcame the complexity issues of word-aligned models by using sentence-aligned parallel corpora limits themselves to only cross-lingual objective, thus making these approaches unable to explore monolingual corpora. Jointly-trained models (Gouws et al., 2015; Coulmance et al., 2015) overcame the issues of both word-aligned and purely cross-lingual objective models by using monolingual and sentence-aligned parallel corpora. Nonetheless, these approaches still have certain drawbacks such as usage of only bag-of-words from the parallel sentences ignoring order of words. Thus, they are missing to capture the non-compositional meaning of entire sentence. Also, learned bilingual embeddings were heavily biased towards the sampled sentence-aligned parallel corpora. It is also sometimes hard to acquire sentence-level parallel corpora for every language pair. To subdue this concern, few approaches (Rajendran et al., 2015) used pivot languages like English or comparable document-aligned corpora (Vulić and Moens, 2015) to learn bilingual embeddings specific to only one task.

This major downside can be observed in other aforementioned methods also, which are inflexible to handle different types of parallel corpora and have a tight-binding between cross-lingual objectives and the parallel corpora. For example, a method using sentence-level parallel corpora cannot be altered to leverage document-level parallel corpora (if available) that might have better performance for some tasks. Also, none of the approaches do leverage widely available label/class-aligned non-parallel documents (e.g. sentiment labels, multi-class datasets) across languages which share special semantics such as sentiment or correlation between concepts as opposed to parallel texts.

In this paper, we introduce BRAVE a jointly-trained flexible model that learns bilingual embeddings based on the availability of the type of corpora (e.g. sentence-aligned parallel or label/class-aligned non-parallel document) by just altering the cross-lingual objective. BRAVE leverages paragraph vector embeddings (Le and Mikolov, 2014) of the monolingual corpora to effectively conceal semantics of the text sequences across languages and build a cross-lingual objective. Method closely related to our approach is by Pham et al. (2015) who uses shared context sentence vector across languages to learn multilingual text sequences.

The main contributions of this paper are:

- We jointly train monolingual part of parallel corpora with the improved cross-lingual alignment function that extends beyond bag-of-word models.
- Introduced a novel approach to leverage non-parallel data sets such as label or class aligned documents in different languages for learning bilingual cues.
- Experimental evaluation on three different CLTC tasks, namely cross-language document classification, multi-label classification and cross-language sentiment classification using learned bilingual word embeddings.

2 Related Work

Most of the related work can be associated to the approaches that aim to learn latent topics across languages or distributed representations of the words and larger pieces of text for supporting various cross-lingual tasks.

2.1 Cross-Language Latent Topics

Various approaches have been proposed to identify latent topics in monolingual (Blei, 2012; Rus et al., 2013) and multilingual (Mimno et al., 2009; Fukumasu et al., 2012) scenarios for cross-language semantic word similarity and document comparison. Extraction of cross-language latent topics or concepts use context-insensitive (Zhang et al., 2010) and context-sensitive methods (Vulić and Moens, 2014) to build word co-occurrence statistics for document representations.

2.2 Distributed Representations

Continuous word representations (Bengio et al., 2003; Mikolov et al., 2013a; Pennington et al., 2014) was further extended to multilingual (Hermann and Blunsom, 2014; Kočiský et al., 2014; Coulmance et al., 2015), bilingual (Gouws et al., 2015; Vulić and Moens, 2015; Luong et al., 2015) and polylingual (Al-Rfou et al., 2013) settings by projecting multiple or pair of languages into the shared semantic space. Also, word representations were extended to meet larger textual units like phrases, sentences and documents either monolingual (Socher et al., 2012; Le and Mikolov, 2014) or bilingual (Pham et al., 2015). Some approaches fine tuned the embeddings for specific tasks such as cross-lingual sentiment analysis (Zhou et al., 2015b), cross-language POS tagging (Gouws and Søgaard, 2015), machine translation (Cho et al., 2014) etc.

3 BRAVE Model

In this section, we present the BRAVE model along with its variations whose aim is to learn bilingual embeddings that can generalize across different languages.

3.1 Bilingual Paragraph Vectors (BRAVE)

Most of the NLP tasks require fixed-length vectors. Tasks like CLTC also require fixed-length vectors to incorporate inherent semantics of sentences or documents. Distributed representation of sentences and documents i.e. paragraph vectors (Le and Mikolov, 2014) are designed to out-perform certain text classification tasks by overcoming constraints posed by the bag-of-words models.

Here, we leverage paragraph vectors distributed memory model (PV-DM) as the monolingual objective $\mathcal{M}(\cdot)$ and jointly optimize with bilingual regularization function $\varphi(\cdot)$ for learning bilingual embeddings similar to the earlier approaches (Gouws et al., 2015; Coulmance et al., 2015). Equation 1 shows the formulation of the overall objective function that is minimized.

$$\mathcal{L} = \min_{\theta^{l_1}, \theta^{l_2}} \sum_{l \epsilon \{l_1, l_2\}} \sum_{C^l} \mathcal{M}^l(w_t, h; \theta^l) + \frac{\lambda \varphi(\theta^{l_1}, \theta^{l_2})}{2} \tag{1}$$

Here, C^l represent the corpus of individual languages (i.e. l_1 or l_2). Given any sequence of words $(w_1^l, w_2^l ... w_T^l)$ in C^l, w_t is the predicted word in a context h constrained on paragraph p (i.e. sentence or document) and sequence of words.

Formally, the first term (i.e. $\mathcal{M}(\cdot)$) in the Equation 1 maximizes the average log probability based on word vector matrix W^l and a unique paragraph vector matrix P^l. Equation 2 represents the average log probability.

$$\mathcal{M}^l(w_t, h; \theta^l) = \frac{\sum_{t=k}^{T-k} y_{w_t}^l - log(\sum_i e^{y_i^l})}{T} \tag{2}$$

where each y_i^l is log-probability of predicted word i and is given by Equation 3.

$$y^l = b + Uh(w_{t-k}^l....w_{t+k}^l; W^l, P^l) \tag{3}$$

To optimize for efficiency, hierarchical softmax (Mnih and Hinton, 2009) is used in training with U and b as parameters. Binary Huffmann tree is utilized to represent hierarchial softmax (Mikolov et al., 2013a). Analogous to Pham et al., (2015), we also derive h by concatenating paragraph vector from P^l with the average of word vectors in W^l. This helps to fine tune both word and paragraph vectors independently.

Now, to capture the bilingual cues, the regularization function ($\varphi(\cdot)$) is learned in two different ways. In the first approach a sentence-aligned parallel corpora is used, while in the second approach a label-aligned document corpora.

3.2 BRAVE with Sentence-Aligned Parallel corpora (BRAVE-S)

To compute the bilingual regularization function $\varphi(\cdot)$, we slightly deviate from earlier approaches (Gouws et al., 2015). Instead of simply performing L$_2$-loss between the mean of word vectors in each sentence pair ($s_j^{l_1}$,$s_j^{l_2}$) of the sentence-aligned parallel corpus (PC) at each training step. We use the concept of elastic net regularization (Zou and Hastie, 2005) and employ linear combination of L$_2$-loss between *sentence paragraph vectors* $SP_j^{l_1}$ and $SP_j^{l_2} \in R^d$ precomputed from the monolingual term $\mathcal{M}(\cdot)$ with L$_2$-loss between the mean of word vectors observed in sentences. This induces a constraint on the usage of monolingual part of parallel training data to learn $\mathcal{M}(\cdot)$. At the same time, it has an advantage of using combination of paragraph and word vectors which combines compositional and non-compositional meanings of sentences.

Also, it eliminates the need for word-alignment and makes an assumption that each word observed in the sentence of language l_1 can potentially find its alignment in the sentence of language l_2. Theoretically, low value of $\varphi(\cdot)$ ensures that words across languages which are similar are embedded closer to each other. Equation 4 shows the regularization term.

$$\alpha||SP_j^{l_1} - SP_j^{l_2}||^2 + (1-\alpha)||\frac{1}{m}\sum_{w_i \epsilon s_j^{l_1}}^{m} W_i^{l_1} - \frac{1}{n}\sum_{w_k \epsilon s_j^{l_2}}^{n} W_k^{l_2}||^2 \tag{4}$$

Where $W_i^{l_1}$ and $W_k^{l_2}$ represent word embeddings obtained for the words w_i and w_k in each sentence (s_j) of length m and n in languages l_1 and l_2 respectively.

3.3 BRAVE with Non-Parallel Document Corpora (BRAVE-D)

Sometimes it is hard to acquire sentence-aligned parallel corpora for many languages. Availability of non-parallel corpora such as topic-aligned (e.g. Wikipedia) or label/class-aligned document corpora (e.g. sentiment analysis and multi-class classification data sets) in different languages can be leveraged to learn bilingual embeddings for performing CLTC. Earlier approaches like CL-LSI (Dumais et al., 1997) and CL-KCCA (Vinokourov et al., 2003) were used to learn bilingual document spaces for the tasks comparable to CLTC. Although these approaches provide decent results, they face serious scalability issues and are mostly limited to Wikipedia. Cross-lingual latent topic extraction models (Vulić and Moens, 2014) showed promising results for the tasks like word-level or phrase-level translations, but have certain drawbacks for CLTC tasks.

Here, we propose a two step approach to build bilingual embeddings with label/class-aligned document corpora.

- In the first step, we perform manifold alignment using Procrustes analysis (Wang and Mahadevan, 2008) between sets of documents belonging to same class/label in different languages. This will help to identify the closest alignment of a document in language l_1 with a document in another language l_2.

- In the second step, we use the pair of partially aligned documents belonging to same class or label in different languages to extract bilingual cues similar to the approach mentioned in § 3.2. Only difference being paragraph vector is learned for the entire document.

Step-1:
Let S^{l_1} and S^{l_2} be the sets containing languages l_1 and l_2 training documents associated to label or a class. Below, we provide the three step procedure to attain partial alignment between the documents present in these sets.

- Learning low-dimensional embeddings of the sets (S^{l_1}, S^{l_2}) is key for alignment. We use **document paragraph vectors** (Le and Mikolov, 2014) to learn low-dimensional embeddings of the documents in each language. Let X^{l_1} and X^{l_2} be the low-dimensional embeddings of S^{l_1} and S^{l_2} respectively.
- To find the optimal values of transformation, Procrustes superimposition is done by translating, rotating and scaling the objects (i.e. rows of X^{l_2} is transformed to make it similar to the rows of X^{l_1}). Transformation is achieved by
  - **Translation:** Taking mean of all the members of set to make centroids $(\sum_{i=1}^{|S^{l_1}|} \frac{X^{l_1}}{|S^{l_1}|}, \sum_{i=1}^{|S^{l_2}|} \frac{X^{l_2}}{|S^{l_2}|})$ lie at origin.
  - **Scaling and Rotation:** The rotation and scaling that maximizes the alignment is given by orthogonal matrix (Q) and scaling factor (k). They are obtained by minimizing orthogonal Procrustes problem (Schönemann, 1966) and is provided by Equation 5.

    $$\arg\min_{k,Q} ||X^{l_1} - X_*^{l_2}||_F \tag{5}$$

    where $X_*^{l_2}$ a matrix of transformed X^{l_2} values given by $kX^{l_2}Q$ and $||.||_F$ is the Frobenius norm constrained over $Q^TQ = I$.
- If $S_*^{l_2}$ represents the new document set obtained after identifying the close alignment among documents in S^{l_1} and S^{l_2} with cosine similarity between X^{l_1} and $X_*^{l_2}$, then the partially aligned corpora $\{S^{l_1}, S_*^{l_2}\}$ contains one-to-one correspondence between the two languages documents that are used to learn bilingual cues in the second step.

From perturbation theory of spectral spaces (Kostrykin et al., 2003) it can be understood that the difference between low-dimensional embedding subspaces (i.e. X^{l_1} and $X_*^{l_2}$) is always bounded, thus the new alignment obtained between document sets $\{S^{l_1}, S_*^{l_2}\}$ is insensitive to perturbations. Which also means that Procrustes analysis has provided best possible document alignments.

Step-2:
Now, document pairs ($d_j^{l_1}$,$d_j^{l_2}$) of the partially-aligned corpus (PAC) is used to compute bilingual regularization function $\varphi(\cdot)$. At each training step, L$_2$-loss of precomputed *document paragraph vectors* DP_j^{l1} and DP_j^{l2} $\in$ R^d obtained from the monolingual term $\mathcal{M}(\cdot)$ is combined with the L$_2$-loss between vector of words weighted by the probability of their occurrence in a particular label/class of entire **PAC**. Consideration of word probabilities will help to induce label/class specific information. Equation 6 provides the regularization term.

$$\begin{aligned}&\alpha||DP_j^{l_1} - DP_j^{l_2}||^2 \\ &+ (1-\alpha)|| \sum_{w_i \epsilon d_j^{l_1}}^{m} \frac{p_{w_i} W_i^{l_1}}{\sum_m p_{w_i}} - \sum_{w_k \epsilon d_j^{l_2}}^{n} \frac{q_{w_k} W_k^{l_2}}{\sum_n q_{w_k}}||^2\end{aligned} \tag{6}$$

Where w_i,w_k are words and their embeddings $W_i^{l_1}$,$W_k^{l_2}$ observed in each document (d_j) of length m and n in languages l_1 and l_2 respectively. While, p_{w_i} and q_{w_k} represents probability of occurrence of words w_i and w_k in a specific label/class of entire **PAC**. Figure- 1 shows overall goal of both the approaches.

4 Experiments

In this section, we report results on three different CLTC tasks to comprehend whether our learned bilingual embeddings are semantically useful across languages. First, cross-language document classification (CLDC) task proposed by Klementiev et al. (2012) using the subset of Reuters RCV1/RCV2 corpora (Lewis et al., 2004). Second, a multi-label CLDC task with more languages using TED corpus[1] of Hermann et al. (2014) . Subsequently, a cross-language sentiment classification (CLSC) proposed by Prettenhofer et al., (2010) on a multi-domain sentiment dataset.

[1] http://www.clg.ox.ac.uk/tedcorpus

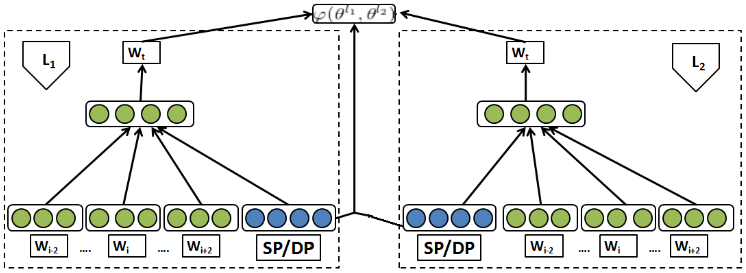

Figure 1: Bilingual word embeddings learned using sentence or document paragraph vectors (SP/DP) along with word vectors.

4.1 Parallel and Non-Parallel Corpora

For sentence-aligned parallel corpora, Europarl-v7 [2](EP) is used as both monolingual and parallel training data. While for label-aligned non-parallel document corpora, only training and testing collections of the cross-language multi-domain Amazon product reviews(CL-APR) (Prettenhofer and Stein, 2010) corpus with sentiment labels is used.

4.2 Implementation

Our implementation launches monolingual paragraph vector (Le and Mikolov, 2014) threads for each language along with bilingual regularization thread. Word and paragraph embeddings matrices are initialized with normal distribution ($\mu = 0$ and $\sigma^2 = 0.1$) for each language and all threads access them asynchronously. Following Pham et al. (2015) suggested combination (P=5*W) of paragraph and word embeddings, we chose paragraph embeddings with dimensionality of 200 and 640 when word embeddings are of 40 and 128 dimensions respectively. Asynchronous stochastic gradient descent (ASGD) is used to update parameters (i.e. P^l,W^l,U and b) and train the model.

For each training pair in parallel or non-parallel corpora, initially monolingual threads sample context h with window size of 8 from a random paragraph (i.e. sentence or document) in each language. Then the bilingual regularization thread along with monolingual threads make update to parameters asynchronously. Learning rate is set to 0.001 which decrease with the increase of epochs, while α is chosen to be 0.6 (can be fine tuned based on empirical analysis) to give more weight to paragraph vectors. All models are trained for 50 epochs.

4.3 Document Representation

Documents are represented with tf-idf weighted sum of embedding vectors of the words that are present in them.

4.4 Results

The experimental results for each of the CLTC tasks are presented separately.

4.4.1 Cross-language Document Classification (CLDC) - RCV1/RCV2

Goal of this task is to classify target language documents with the labeled examples from the source language. To achieve it, we used the subset of Reuters RCV1/RCV2 corpora as the training and evaluation sets and replicated the experimental setting of Klementiev et al. (2012). From the English, German, French and Spanish collection of the dataset, only those documents are selected which was labeled with a single topic (i.e. CCAT, ECAT, GCAT and MCAT). For the classification experiments, 1000 labeled documents from source language are selected to train a multi-class classifier using averaged perceptron (Freund and Schapire, 1999; Collins, 2002) and 5000 documents were used as the testing data.

English-German, English-French and English-Spanish portion of **EP** corpora (i.e. each with around 1.9M sentence-pairs) is used both as monolingual and parallel training data with **BRAVE-S** approach to build vocabulary of around 85k English, 144k German, 119k French and 118k Spanish. While training and testing collections belonging to all domains in English-German, English-French languages of **CL-APR** ((i.e. around 12,000 document-pairs)) was used both as monolingual and partially aligned data with **BRAVE-D** approach to build vocabulary of around 21k English, 22k German and

18k French. Further, documents in the training and testing data of RCV1/RCV2 corpora are represented as described in § 4.3 with the vocabulary built. Table 2 shows the comparison of our approaches with the existing systems.

4.4.2 Multi-label CLDC - TED Corpus

To understand the applicability of our approaches to wider range of languages[3] and class labels, we perform experiments with the subset of TED corpus (Hermann and Blunsom, 2014). Aim of this task is same as § 4.4.1, but experiments were conducted with larger variety of languages and class labels. TED Corpus contains English transcriptions and their sentence-aligned translations for 12 languages from the TED conference. Entire corpus is further classified into 15 topics (i.e. class labels) based on the most frequent keywords appearing in them.

To conduct our experiments, we follow the *single* mode setting of Hermann et al. (2014) (i.e. embeddings are learned only from a single language pair). Entire language pair (i.e. en→L2) training data of the TED corpus is used both as monolingual and parallel training data to learn bilingual word embeddings with dimensionality of 128 using **BRAVE-S** approach. Bilingual word embeddings of 128 dimensions learned with **EP** and **CL-APR** are also used for comparison. Documents in the training and testing data of TED corpus are represented as described in § 4.3 using each of these embeddings. A multi-class classifier using averaged perceptron is built using training documents in source language to be applied on target language testing data for predicting the class labels. Table 3 shows the cumulative F1-scores.

4.4.3 Cross-language Sentiment Classification (CLSC)

The objective of the third CLTC task is to identify sentiment polarity (e.g. positive or negative) of the data in target language by exploiting the labeled data in source language. We chose subset of publicly available Amazon product reviews (CL-APR) (Prettenhofer and Stein, 2010) dataset mainly English(E), German(G) and French(F) languages belonging to three different product categories (books(B), dvds(D) and music(M)) to conduct our experiments. For each language-category pair, corpus consists of training, testing sets comprising 1000 positive and 1000 negative reviews each with an additional unlabeled reviews varying from 9,000 to 170,000.

We constructed 12 different CLSC tasks using different languages (i.e. E,G and F) for three categories (i.e. B,D and M). For example, EFM refers English music reviews as source language and French music reviews as target language. Bilingual word embeddings with dimensionality of 128 learned with

[3] Our goal is not to evaluate shared multilingual semantic representation.

Table 4: Average classification accuracies and standard deviations for 12 CLSC tasks. Results of other baselines are adopted from CL-SCL (Prettenhofer and Stein, 2010), CL-SSMC (Xiao and Guo, 2002), CL-SLF (Zhou et al., 2015a), CL-DCI$_{100}$ (Esuli and Fernandez, 2015) and BSE (Tang and Wan, 2014)

BRAVE-S and **BRAVE-D** are used to represent each review as described in § 4.3. To have fair comparison with earlier approaches, sentiment classification model is then trained with libsvm[4] default parameter settings using source language training reviews[5] to classify target language test reviews. Table 4 shows the accuracy and standard deviation results after we randomly chose subset of target language testing documents and repeated the experiment for 10 times for all CLSC tasks.

5 Discussion

First CLTC task (i.e. CLDC) results presented in Table 2 shows that BRAVE-S was able to outperform most of the existing systems. Success of BRAVE-S can be attributed to its ability to incorporate both non-compositional and compositional meaning observed in entire sentence and the individual words respectively. Thus making it different from other models which use only bag-of-words (Gouws et al., 2015) or bi-grams (Hermann and Blunsom, 2014).

Similarly, second CLTC task (i.e. multi-label

[4] https://www.csie.ntu.edu.tw/ cjlin/libsvm/

[5] We do not use 100 labeled target language reviews in model training, as it was shown by earlier approaches that 100 labeled target language reviews does not have much impact.

Table 5: Nearest Neighbors for English Words in German and French.

CLDC) results presented in Table 3 shows that BRAVE-S learned with the training data of TED corpus outperformed *single mode* DOC/* embedding models (Hermann and Blunsom, 2014), BRAVE-S learned with **EP** and BRAVE-D. The BRAVE-S(TED) was able to capture better linguistic regularities across languages that is more specific to the corpus, than the general purpose bilingual embeddings learned with **EP**. Though in some cases, all our embedding models could not outperform machine translation baseline. This can be due to the asymmetry between languages induced by the language specific words which could not find its equivalents in English.

Also, it can be apprehended from the Table 2 and Table 3 that BRAVE-D results are not as expected. Though being a general approach like BRAVE-S which can capture both non-compositional and compositional meaning from larger pieces of texts, minimal overlap of vocabulary learned with BRAVE-D using cross-language sentiment label-aligned corpora with other domains (i.e. Reuters and TED) produce unfavorable results. Thus, we understand that the choice of label/class-aligned corpora is crucial.

Final CLTC task (i.e. CLSC) results presented in Table 4 shows that BRAVE-D outperforms other baseline approaches in most of the cases. As BRAVE-D learns bilingual word embeddings using **CL-APR**, it was able to inherently encompass sentiment label information effectively like earlier approaches (Tang and Wan, 2014; Zhou et al., 2015b) than the general purpose embeddings learned using BRAVE-S with **EP** and similar approaches (Meng et al., 2012). Thus making it more suitable for sentiment classification task. Also unlike CL-SSMC (Xiao and Guo, 2002) and CL-SLF (Zhou et al., 2015a), BRAVE-D is not highly parameter dependent where the results of the former approaches show big variance based on the parameter settings. To visualize the difference in embeddings learned with BRAVE-S and BRAVE-D, we selected sentiment words and identified cross-language nearest neighbors in Table 5. It can be observed that BRAVE-D was able to identify better sentiment (either positive or negative) word neighbors than BRAVE-S.

6 Conclusion and Future Work

In this paper, we presented an approach that leverages paragraph vectors to learn bilingual word embeddings with sentence-aligned parallel and label-aligned non-parallel corpora. Empirical analysis exhibited that embeddings learned from both of these types of corpora have shown good impact on CLTC tasks. In future, we aim to extend the approach to learn multilingual semantic spaces with more labels/classes.

Abstract

This paper addresses the problem of comment classification in community Question Answering. Following the state of the art, we approach the task with a global inference process to exploit the information of all comments in the answer-thread in the form of a fully connected graph. Our contribution comprises two novel joint learning models that are on-line and integrate inference within learning. The first one jointly learns two *node*- and *edge*-level MaxEnt classifiers with stochastic gradient descent and integrates the inference step with loopy belief propagation. The second model is an instance of fully connected pairwise CRFs (FCCRF). The FCCRF model significantly outperforms all other approaches and yields the best results on the task to date. Crucial elements for its success are the global normalization and an Ising-like edge potential.

1 Introduction

Online community fora have been gaining a lot of popularity in recent years. Many of them, such as Stack Exchange[1], are quite open, allowing anybody to ask and anybody to answer a question, which makes them very valuable sources of information. Yet, this same democratic nature resulted in some questions accumulating a large number of answers, many of which are of low quality. While nowadays online fora are typically searched using standard search engines that index entire threads, this is not optimal, as it can be very time-consuming for a user to go through and make sense of a long thread.

Q: *hello guys and gals..could anyone of u knows where to buy a good and originals RC helicopters and toy guns here in qatar..im longin for this toys but its nowhere to find.. thanks*

A$_1$ Go to Doha city center you may get it at 4 floor.
Local: Good, Human: Good

A$_2$ "Hobby Shop" in City center has these toys with original motors. They are super cool.. U will love that shop..and will definetly buy one :) Have fun :)
Local: Good, Human: Good

A$_3$ IM selling all my rc nitro helicopters. call me at 5285113.. (1)TREX 600 new/ (1) TREX500 (1) SHUTTLERG (1) FUTABA ... [truncated]
Local: Good, Human: Bad

A$_4$ Hobby Shop- City Centre
Local: Bad, Human: Good

A$_5$ OMG!! :— Guns and helicopters??!!
Local: Good, Human: Bad

A$_6$ Speed Marine- Salwa Road I think these guys r the best in town...
Local: Good, Human: Good

A$_7$ City center, i've seen wonderful collection.. Its some wer besides the kids fun place..
Local: Bad, Human: Good

A$_8$ try the shop in city center. they have many RC toys for sale there. and for the toy guns, in your talking baout airsoft i think its prohibited here. good luck
Local: Good, Human: Good

Thus, the creation of automatic systems for Community Question Answering (cQA), which could provide efficient and effective ways to find good answers in a forum, has received a lot of research attention recently (Duan et al., 2008; Li and Manandhar, 2011; dos Santos et al., 2015; Zhou et al., 2015a; Wang and Ittycheriah, 2015; Tan et al., 2015; Feng et al., 2015; Nicosia et al., 2015; Barrón-Cedeño et al., 2015; Joty et al., 2015). There have been also related shared tasks at SemEval-2015[2] and SemEval-2016[3] (Nakov et al., 2015; Nakov et al., 2016).

In this paper, we focus on the particular problem of classifying comments in the answer-thread of a given question as *good* or *bad* answers. Figure 1 presents an excerpt of a real example from the QatarLiving dataset from SemEval-2015 Task 3. There is a question on top (Q) followed by eight comments $(A_1, A_2, \cdots, A_8)$. According to the human annotations ('Human'), all comments but 3 and 5 are good answers to Q. The comments also contain the predictions of a *good-vs-bad* binary classifier trained with state-of-the-art features on this dataset (Nicosia et al., 2015); its errors are highlighted in red. Many comments are short, making it difficult for the classifier to make the right decisions, but some errors could be corrected using information in the other comments. For instance, comments 4 and 7 are similar to each other, but also to comments 2 and 8 ('Hobby shop', 'City Center', etc.). It seems reasonable to think that similar comments should have the same labels, so comments 2, 4, 7 and 8 should all be labeled consistently as *good* comments.

Indeed, recent work has shown the benefit of using varied thread-level information for answer classification, either by developing features modeling the thread structure and dialogue (Barrón-Cedeño et al., 2015), or by applying global inference mechanisms at the thread level using the predictions of local classifiers (Joty et al., 2015). We follow the second approach, assuming a graph representation of the answer-thread, where nodes are comments and edges represent pairwise (similarity) relations between them. Classification decisions are at the level of nodes and edges, and global inference is used to get the best label assignment to all comments.

Our main contribution is to propose online models for learning the decisions jointly, incorporating the inference inside the joint learning algorithm. Building on the ideas from papers coupling learning and inference for NLP structure prediction problems (Punyakanok et al., 2005; Carreras et al., 2005), we propose joint learning of two MaxEnt classifiers with stochastic gradient descent, integrating global inference based on loopy belief propagation. We also propose a joint model with global normalization, that is an instance of Fully Connected Conditional Random Fields (Murphy, 2012). We compare our joint models with the previous state of the art for the comment classification problem. We find that the coupled learning-and-inference model is not competitive, probably due to the label bias problem. On the contrary, the fully connected CRF model improves results significantly over all rivaling models, yielding the best results on the task to date.

In the remainder of this paper, after discussing related work in Section 2, we introduce our joint models in Section 3. We then describe our experimental settings in Section 4. The experiments and analysis of results are presented in Section 5. Finally, we summarize our contributions with future directions in Section 6.

2 Related Work

The idea of using global inference based on locally learned classifiers has been tried in various settings. In the family of graph-based inference, Pang and Lee (2004) used local classification scores with proximity information as edge weights in a graph-cut inference to collectively identify subjective sentences in a review. Thomas et al. (2006) used the same framework to classify congressional transcribed speeches. They applied a classifier to provide edge weights that reflect the degree of agreement between speakers. Burfoot et al. (2011) extended the framework by including other inference algorithms such as loopy belief propagation and mean-field.

"Learning and inference under structural and linguistic constraints" (Roth and Yih, 2004) is a framework to combine the predictions of local classifiers in a global decision process solved by Integer Linear Programming.

[2] http://alt.qcri.org/semeval2015/task3/

[3] http://alt.qcri.org/semeval2016/task3/

The framework has been applied to many NLP structure prediction problems, including shallow parsing (Punyakanok and Roth, 2000), semantic role labeling (Punyakanok et al., 2004), and joint learning of entities and relations (Roth and Yih, 2004). Further work explored the possibility of coupling learning and inference in the previous setting. For instance, Carreras et al. (2005) presented a model for parsing that jointly trains several local decisions with a perceptron-like algorithm that gets feedback after inference. Punyakanok et al. (2005) studied empirically and theoretically the cases in which this *inference-based learning* strategy is superior to the decoupled approach.

On the particular problem of comment classification in cQA, we find some work exploiting thread-level information. Hou et al. (2015) used features about the position of the comment in the thread. Barrón-Cedeño et al. (2015) developed more elaborated global features to model thread structure and the interaction among users. Other work exploited global inference algorithms at the thread-level. For instance, (Zhou et al., 2015c; Zhou et al., 2015b; Barrón-Cedeño et al., 2015) treated the task as sequential classification, using a variety of machine learning algorithms to label the sequence of time-sorted comments: LSTMs, CRFs, SVM^{hmm}, etc. Finally, Joty et al. (2015) showed that exploiting the pairwise relations between comments (at any distance) is more effective than the sequential information. Their results are the best on this task to date. In this paper, we assume the same setting (cf. Section 3) and we experiment with new models to do learning jointly with inference in the same manner as in (Punyakanok et al., 2005), and also using fully connected pairwise CRFs.

3 Our Model

Given a forum question Q and a thread of answers $T = \{A_1, A_2, \cdots, A_n\}$, the task is to classify each answer A_i in the thread into one of K possible classes based on its relevance to the question. We represent each thread as a fully-connected graph, where each node represents an answer in the thread.

Given this setting, there exist at least three fundamentally different approaches to learn classification functions.

First, the traditional approach of learning a local classifier ignoring the structure in the output and using it to predict the label of each node A_i separately. This approach only considers correlations between the label of A_i and features extracted from A_i.

The second approach, adopted by Joty et al. (2015), is to first learn two local classifiers separately: (*i*) a node-level classifier to predict the label for each individual node, and (*ii*) an edge-level classifier to predict whether the two nodes connected by an edge should have the same label or not (assuming a fully connected graph). The predictions of the local classifiers are then used in a global inference algorithm (e.g., graph-cut) to perform collective classification by maintaining structural constraints in the output. There are two issues with this model: (*i*) the local classifiers are trained separately; (*ii*) by decoupling learning from inference, this approach can lead to suboptimal solutions, as Punyakanok et al. (2005) pointed out.

The third approach, which we adopt in this paper, is to model the dependencies between the output variables while learning the classification functions jointly by optimizing a global performance criterion. The dependencies are captured using node-level and edge-level factors defined over a fully connected graph. The idea is that incorporating structural constraints in the form of all-pair relations during training can yield a better solution that directly optimizes an objective function for the target task.

Before we present our models in subsections 3.1 and 3.2, let us first introduce the notation that we will use. Each thread $T = \{A_1, A_2, \cdots, A_n\}$ is represented by a complete graph $G = (V, E)$. Each node $i \in V$ in the graph is associated with an input vector $\mathbf{x}_i$, which represents the features of an answer A_i, and an output variable $y_i \in \{1, 2, \cdots, K\}$, representing the class label. Similarly, each edge $(i, j) \in E$ is associated with an input feature vector $\phi(\mathbf{x}_i, \mathbf{x}_j)$, derived from the node-level features, and an output variable $y_{i,j} \in \{1, 2, \cdots, L\}$, representing the labels for the pair of nodes. We use $\psi_n(y_i|\mathbf{x}_i, \mathbf{v})$ and $\psi_e(y_{i,j}|\phi(\mathbf{x}_i, \mathbf{x}_j), \mathbf{w})$ to denote the node-level and the edge-level classification functions, respectively. We call ψ_n and ψ_e factors, which can be either normalized (e.g., probabilities) or unnormalized quantities. The model parameters $\theta = [\mathbf{v}, \mathbf{w}]$ are to be learned during training.

3.1 Joint Learning of Two Classifiers with Global Thread-Level Inference

Our aim is to train the local classifiers so that they produce correct global classification. To this end, in our first model we train the node- and the edge-level classifiers jointly based on global feedback provided by a global inference algorithm. The global feedback determines how much to adjust the local classifiers so that the classifiers and the inference together produce the desired result. We use log-linear models (aka maximum entropy) for both classifiers:

$$\psi_n(y_i = k|\mathbf{x_i}, \mathbf{v}) \quad = \quad \frac{\exp(\mathbf{v}_k^T \mathbf{x_i})}{\sum_{k'=1}^{K} \exp(\mathbf{v}_k^T \mathbf{x_i})} \qquad (1)$$

$$\psi_e(y_{i,j} = l|\phi(\mathbf{x_i}, \mathbf{x_j}), \mathbf{w}) = \frac{\exp(\mathbf{w}_l^T \phi(\mathbf{x_i}, \mathbf{x_j}))}{\sum_{l'=1}^{L} \exp(\mathbf{w}_{l'}^T \phi(\mathbf{x_i}, \mathbf{x_j}))} \quad (2)$$

The log likelihood (LL) for one data point $(\mathbf{x}, \mathbf{y})$ (i.e., a thread) can be written as follows:

$$f(\theta) = \sum_{i \in V} \sum_{k=1}^{K} y_i^k \left[\mathbf{v}_k^T \mathbf{x_i} - \log Z(\mathbf{v}, \mathbf{x_i})\right] +$$

$$\sum_{(i,j) \in E} \sum_{l=1}^{L} y_{i,j}^l \left[\mathbf{w}_l^T \phi(\mathbf{x_i}, \mathbf{x_j}) - \log Z(\mathbf{w}, \mathbf{x_i}, \mathbf{x_j})\right] \quad (3)$$

where y_i^k and $y_{i,j}^l$ are the gold labels for i-th node and (i, j)-th edge expressed in 1-of-K (or 1-of-L) encoding, respectively, and $Z(\cdot)$ terms are the local normalization constants.

We give a pseudocode in Algorithm 1 that trains this model in an online fashion using feedback from the loopy belief propagation (LBP) inference algorithm (to be described later in Section 3.1.1). Specifically, the marginals from the LBP are used in a stochastic gradient descent (SGD) algorithm, which has the following (minibatch) update rule:

$$\theta_{t+1} = \theta_t - \eta_t \frac{1}{N} f'(\theta_t) \qquad (4)$$

where θ_t and η_t are the model parameters and the learning rate at step t, respectively, and $\frac{1}{N} f'(\theta_t)$ is the mean gradient for the minibatch (a thread). For our maximum entropy models, the gradients become

$$f'(\mathbf{v}) \quad = \quad \sum_{i \in V} \left[\beta_n(y_i) - y_i\right] . \mathbf{x}_i \qquad (5)$$

$$f'(\mathbf{w}) \quad = \quad \sum_{(i,j) \in E} \left[\beta_e(y_{i,j}) - y_{i,j}\right] . \phi(\mathbf{x_i}, \mathbf{x_j}) \quad (6)$$

Algorithm 1: Joint learning of local classifiers with global thread-level inference

```
1. Initialize the model parameters $\mathbf{v}$ and $\mathbf{w}$;
2. repeat
    for each thread $G = (V, E)$ do
        a. Compute node and edge probabilities
           $\psi_n(y_i|\mathbf{x}_i, \mathbf{v})$ and $\psi_e(y_{i,j}|\phi(\mathbf{x}_i, \mathbf{x}_j), \mathbf{w})$;
        b. Infer node and edge marginals $\beta_n(y_i)$
           and $\beta_e(y_{i,j})$ using sum-product LBP;
        c. Update: $\mathbf{v} = \mathbf{v} - \frac{\eta}{|V|} f'(\mathbf{v})$;
        d. Update: $\mathbf{w} = \mathbf{w} - \frac{\eta}{|E|} f'(\mathbf{w})$;
    end
   until convergence;
```

In the above equations, β and y are the marginals and the gold labels, respectively.

Note that when applying the model to the test threads, we need to perform the same global inference to get the best label assignments.

3.1.1 Inference Using Belief Propagation

Belief Propagation or BP (Pearl, 1988) is a message passing algorithm for inference in probabilistic graphical models. It supports (*i*) *sum-product,* to compute the marginal distribution for each unobserved variable, i.e., $p(y_i|\mathbf{x}, \theta)$; and (*ii*) *max-product,* to compute the most likely label configuration, i.e., $\text{argmax}_\mathbf{y}\, p(\mathbf{y}|\mathbf{x}, \theta)$. We describe here the variant that operates on undirected graphs (aka Markov random fields) with pairwise factors, which uses the following equations:

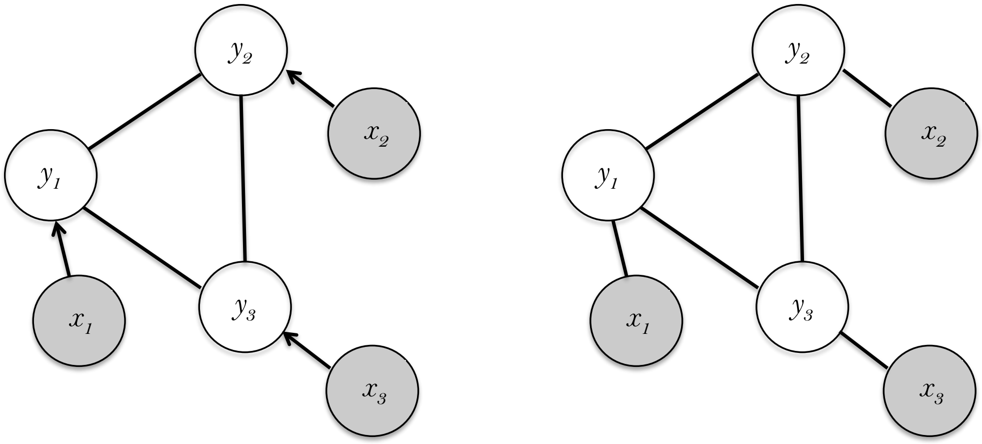
$$\mu_{i \to j}(y_j) \ = \sum_{y_i} \psi_n(y_i) \psi_e(y_{i,j}) \prod_{k \in N(i) \setminus j} \mu_{k \to i}(y_i) \qquad (7)$$

$$\beta_n(y_i) \quad \approx \quad \psi_n(y_i) \prod_{j \in N(i)} \mu_{j \to i}(y_i) \qquad (8)$$

where $\mu_{i \to j}$ is a message from node i to node j, $N(i)$ are the nodes neighbouring i, and $\psi_n(y_i)$ and $\psi_e(y_{i,j})$ are the node and the edge factors.

The algorithm proceeds by sending messages on each edge until the node beliefs $\beta_n(y_i)$ stabilize. The edge beliefs can be written as follows:

$$\beta_e(y_{i,j}) \approx \psi_e(y_{i,j}) \times \mu_{i \to j}(y_i) \times \mu_{j \to i}(y_j) \qquad (9)$$



(a) Locally normalized joint model

(b) Globally normalized joint model

Figure 2: Graphical representation of our two joint models: (a) a joint model with locally normalized factors; (b) a joint model with global normalization, i.e., a fully connected conditional random field.

The node and the edge marginals are then computed by normalizing the node and the edge beliefs, respectively. By replacing the summation with a $\max$ operation in Equation 7, we can get the most likely label configuration (i.e., argmax over labels).

BP is guaranteed to converge to an exact solution if the graph is a tree. However, exact inference is intractable for general graphs, i.e., graphs with loops. Despite this, it has been advocated by Pearl (1988) to use BP in loopy graphs as an approximation scheme; see also (Murphy, 2012), page 768. The algorithm is then called "loopy" BP, or LBP. Although LBP gives approximate solutions for general graphs, it often works well in practice (Murphy et al., 1999), outperforming other methods such as mean field (Weiss, 2001) and graph-cut (Burfoot et al., 2011).

It is important to mention that the approach presented above (i.e., subsection 3.1) is similar in spirit to the approach of Collins (2002), Carreras and Màrquez (2003) and Punyakanok et al. (2005). The main difference is that they use a Perceptron-like online algorithm, where the updates are done based on the best label configuration (i.e., $\operatorname{argmax}_{\mathbf{y}} p(\mathbf{y}|\mathbf{x}, \theta)$) rather than the marginals.

One can use graph-cut (applicable only for binary output variables) or max-product LBP for the decoding task. However, this yields a discontinuous estimate (even with averaged perceptron) for the gradient (see Section 5). For the same reason, we use sum-product LBP rather than max-product LBP.

3.2 A Joint Model with Global Normalization

Although the approach of updating the parameters of the local classifiers based on the global inference might seem like a natural extension to train the classifiers jointly, it suffers from at least two problems. First, since the node and the edge scores are normalized locally (see Equations 1 and 2), this approach leads to the so-called *label bias* problem, previously discussed by Lafferty et al. (2001). Namely, due to the local normalization, local features at any node do not influence states of other nodes in the graph. Second, the two classifiers use their own feature sets. However, the same feature sets that give optimal results locally (i.e., when trained on local objectives), may not work well when the models are trained jointly based on the global feedback. In order to address these issues, below we propose a different model.

In our second approach, we seek to build a joint model with global normalization. We define the following conditional joint distribution:

$$p(\mathbf{y}|\mathbf{v}, \mathbf{w}, \mathbf{x}) = \frac{1}{Z(\mathbf{v}, \mathbf{w}, \mathbf{x})} \prod_{i \in V} \psi_n(y_i|\mathbf{x}, \mathbf{v}) \cdot \prod_{(i,j) \in E} \psi_e(y_{i,j}|\mathbf{x}, \mathbf{w}) \qquad (10)$$

where ψ_n and ψ_e are the node and edge *factors*, and $Z(\cdot)$ is the global normalization constant that ensures a valid probability distribution.

This model is essentially a fully connected conditional random field or FCCRF (Murphy, 2012). Figure 2 shows the differences between the two models with the standard graphical model representation.[4] The global normalization allows CRFs to take long-range interactions into account. Similar to our previous model, we use a log-linear representation for the factors:

$$\psi_n(y_i|\mathbf{x},\mathbf{v}) = \exp(\mathbf{v}^T\phi(y_i,\mathbf{x})) \quad (11)$$

$$\psi_e(y_{i,j}|\mathbf{x},\mathbf{w}) = \exp(\mathbf{w}^T\phi(y_{i,j},\mathbf{x})) \quad (12)$$

where $\phi(\cdot)$ is a feature vector derived from the inputs and the labels. The LL for one data point becomes

$$f(\theta) = \sum_{i\in V}\mathbf{v}^T\phi(y_i,\mathbf{x}) + \sum_{(i,j)\in E}\mathbf{w}^T\phi(y_{i,j},\mathbf{x}) - \log Z(\mathbf{v},\mathbf{w},\mathbf{x}) \quad (13)$$

This objective is convex, so we can use gradient-based methods to find the global optimum. The gradients have the following form:

$$f'(\mathbf{v}) = \sum_{i\in V}\phi(y_i,\mathbf{x}) - \mathbb{E}[\phi(y_i,\mathbf{x})] \quad (14)$$

$$f'(\mathbf{w}) = \sum_{(i,j)\in E}\phi(y_{i,j},\mathbf{x}) - \mathbb{E}[\phi(y_{i,j},\mathbf{x})] \quad (15)$$

where $\mathbb{E}[\phi(.)]$ terms denote the expected feature vector. Traditionally, CRFs have been trained using offline methods like limited-memory BFGS. Online training of CRFs using SGD was proposed by Vishwanathan et al. (2006). To compare our two methods, we use SGD to train our CRF models. The pseudocode is very similar to Algorithm 1.

3.2.1 Modeling Edge Factors

One crucial aspect in the joint models described above is the modeling of edge factors. The traditional way is to define edge factors, where $y_{i,j}$ spans over all possible state transitions, that is K^2 different transitions, each of which is associated with a weight vector. This method has the advantage that it models transitions in a fine-grained way, but, in doing so, it also increases the number of model parameters, which may result in overfitting.

Alternatively, one can define *Ising-like* edge factors, where we only distinguish between two transitions: (*i*) *same*, when $y_i = y_j$ and (*ii*) *different*, when $y_i \neq y_j$. This modeling involves tying one set of parameters for all *same* transitions, and another set for all *different* transitions.

4 Experimental Setting

In this section, we describe our experimental setting. We first introduce the dataset we use, then we present the features and the models that we compare.

4.1 Datasets and Evaluation

We experimented with the dataset from SemEval-2015 Task 3 on Answer Selection for Community Question Answering (Nakov et al., 2015). The dataset contains question-answer threads from the Qatar Living forum.[5] Each thread consists of a question followed by one or more (up to 143) comments. The dataset is split into training, development and test sets, with 2,600, 300, and 329 questions, and 16,541, 1,645, and 1,976 answers, respectively.

Each comment in the dataset is annotated with one of the following labels, reflecting how well it answers the question: *Good*, *Potential*, *Bad*, *Dialogue*, *Not English*, and *Other*. At SemEval-2015 Task 3, the latter four classes were merged into *BAD* at testing time, and the evaluation measure uses a macro-averaged F_1 over the three classes: *Good*, *Potential*, and *BAD*. Unfortunately, the *Potential* class was both the smallest (covering about 10% of the data), and also the noisiest and the hardest to predict; yet, its impact was magnified by the macro-averaged F_1. Thus, subsequent work has further merged *Potential* under *BAD* (Barrón-Cedeño et al., 2015; Joty et al., 2015), and has used for evaluation F_1 with respect to the *Good* category (or just accuracy). For our experiments below, we also report F_1 for the *Good* class and the overall accuracy. We further perform statistical significance tests using an approximate randomization test based on accuracy.[6] We used SIGF V.2 (Padó, 2006) with 10,000 iterations.

[4] Edge level features and output variables are not shown in Figure 2 to avoid visual clutter.

[5] `http://www.qatarliving.com/forum`

[6] Significance tests operate on individual instances rather than individual classes; thus, they are not applicable for F_1.

4.2 Features

For comparison, we use the features from our previous work (Joty et al., 2015) to implement all classifiers in our models and baselines. There are two sets of features, corresponding to the two main classification problems in the models: node-level (i.e., classifying a comment as *good* or *bad*) and edge-level (i.e., classifying a pair of comments as having the *same* or *different* labels).

The features for node-level classification include three types of information: (*i*) a variety of textual similarity measures computed between the question and the comment, (*ii*) several boolean features capturing the presence of certain relevant words or patterns, e.g., URLs, emails, positive/negative words, acknowledgements, forum categories, presence of long words, etc., and (*iii*) a set of global features modeling dialogue and user interactions in the answer-thread. The features in the last two categories are manually engineered (Nicosia et al., 2015; Barrón-Cedeño et al., 2015).

The features we use for edge-level classification include (*i*) all features from the node classification problem coded as the absolute value of the difference between the two comments, (*ii*) a variety of text similarity features between the two comments, (*iii*) the *good/bad* predictions of the node-level classifier on the two comments involved in the edge decision. See (Joty et al., 2015) and (Barrón-Cedeño et al., 2015) for a detailed description of the features.

4.3 Methods Compared

We experimentally compare our above-described joint models to some baselines and to the state of the art for this problem. We briefly describe all models below, together with the names used in the tables of results.

Independent Comment Classification (ICC) These are binary classifiers to label thread comments independently into *good* and *bad* categories. The simplest baseline (Majority) classifies all examples with the most frequent category. We also train a MaxEnt classifier with stochastic gradient descent (SGD) and a voted perceptron (ICC$_{ME}$ and ICC$_{Perc}$, respectively).

Learning-and-Inference Models (LI) This is the approach presented by Joty et al. (2015), who report the best results on the task. The model is explained in Section 3. We experiment with MaxEnt classifiers trained on-line with SGD and two different inference strategies, graph-cut and loopy BP (LI$_{ME-GC}$ and LI$_{ME-LBP}$, in our notation).

Joint Learning and Inference Models These are our new models. First, we experiment with the model for joint learning of two classifiers coupled with thread-level inference (Section 3.1). We have two versions, one using MaxEnt classifiers and the other using averaged Perceptron. The inference algorithm is loopy BP in both cases. We call these methods Joint$_{ME-LBP}$ and Joint$_{Perc-LBP}$, respectively. Second, we experiment with the joint model with global normalization (cf. Section 3.2). We call it FCCRF, for fully connected CRF. We use the *Ising-like* edge factors defined in Section 3.2.1.

5 Evaluation

All results we report below are calculated in the test set, using parameters tuned on the development set.

Our main results are shown in Table 1, where we report accuracy (Acc) as well as precision (P), recall (R) and F$_1$-score (F$_1$) for the *good* class.

The models are organized in four blocks. On top, we see that the majority class baseline achieves accuracy of 50.5%, as the dataset is very well balanced between the classes.

In block II, we find the results for the local classifiers, ICC$_{ME}$ and ICC$_{Perc}$, which achieve very similar results. They are comparable to MaxEnt in Table 2, where we report the best published results on this dataset; yet, our classifiers are trained on-line.

Block III in the table reports results for models that train two local MaxEnt classifiers and then perform thread-level inference using either graph-cut (LI$_{ME-GC}$) or loopy BP (LI$_{ME-LBP}$).[7] This yields improvements over the ICC models with the thread-level inference in block II, which is consistent with the findings of (Joty et al., 2015); however, the difference in terms of accuracy is not statistically significant (p-value = 0.09).

[7] Given that MaxEnt and Perceptron perform comparably in this setting, we have just used MaxEnt as it provides directly the class probabilities needed for the thread-level inference.

	Model	*Learning*	*Inference*	P	R	F_1	Acc
I.	Majority	–	–	50.5	100.0	67.1	50.5
II.	ICC$_{ME}$	Local, SGD	–	75.1	85.8	80.1	78.5
	ICC$_{Perc}$	Local, Voted	–	76.6	82.4	79.4	78.4
III.	LI$_{ME-GC}$	Local, SGD	Graph-cut	**77.4**	83.6	80.4	79.4
	LI$_{ME-LBP}$	Local, SGD	LBP	76.4	84.6	80.3	79.1
IV.	Joint$_{ME-LBP}$	2 classifiers, Joint, SGD	LBP	76.1	84.4	80.0	78.7
	Joint$_{Perc-LBP}$	2 classifiers, Joint, AVG	LBP	77.1	74.5	75.8	76.0
	FCCRF	Joint, SGD	LBP	77.3	**86.2**	**81.5**	**80.5**

Table 1: Results of all compared models on the test set. The best results are boldfaced.

Model	P	R	F_1	Acc
MaxEnt classifier	75.7	84.3	79.8	78.4
Linear CRF	74.9	83.5	78.9	77.5
MaxEnt+ILP	77.0	83.5	80.2	79.1
MaxEnt+GraphCut	**78.3**	82.9	80.6	79.8
Our method (FCCRF)	77.3	**86.2**	**81.5**	**80.5**

Table 2: Comparison to the best published results on the same datasets, as reported in (Joty et al., 2015).

Comparing our LI$_{ME-GC}$ to MaxEnt+GraphCut in Table 2, we see that we are slightly worse: -0.2 in F_1-score, and -0.4 in accuracy. It turns out that this is due to our on-line MaxEnt classifier for the pairwise classification being slightly worse (-0.4 accuracy points absolute), which could explain the lower performance after the graph-cut inference.

Next, block IV shows that the fully connected CRF model (FCCRF) improves over the models in block III by more than one point absolute in both F_1 and accuracy. The improvement is statistically significant (p-value = 0.04); especially noticeable is the increase in recall (+2.6 points). This result is also an improvement over the state of the art, as Table 2 shows.

Again in block IV, we can see that the two models that perform joint training of two classifiers and then integrate inference in the training loop, Joint$_{ME-LBP}$ and Joint$_{Perc-LBP}$, do not work well and fall below the learning and inference models from block III. As we explained above, these models have two major disadvantages compared to FCCRF: (*i*) the local normalization of node and edge scores is prone to label bias issues; (*ii*) each of the two classifiers uses its own feature set, which might not be optimal when they are trained jointly based on the global feedback.

Notice that the version using Perceptron, Joint$_{Perc-LBP}$, works bad in this setting. Since updates are done after each thread-level inference, we could not use a voted perceptron, but an averaged one (Collins, 2002). Moreover, it did not yield probabilities but real-valued scores, which we had to remap to the [0;1] interval using a sigmoid.

5.1 CRF Variants Analysis

Table 3 compares different variants of CRF. The first two rows show the results for the commonly used linear-chain CRF (LCCRF) of order 1 and 2. We can see that these models fall two accuracy (and F_1) points below FCCRF, which indicates that the pairwise relations between non-consecutive comments provide additional relevant information for the task. The fourth row shows the results when we eliminate the edge-level features and we consider state transitions using the bias features only: the decrease in performance is tiny, which means that what matters is to model the interaction in the first place; the particular features used are less important. More noticeable is the effect of using Ising-like modeling of the edge factors in our FCCRF model. If we use finer-grained edge factors for each of the four combinations (Good-Good, Good-Bad, Bad-Good, and Bad-Bad), the performance decreases significantly, mostly due to a drop in recall (see ‘FCCRF (4C)’).

5.2 Error Analysis

Next, we get a closer look at the predictions made by our best Local (ICC$_{ME}$), Inference (LI$_{ME-GC}$), and Global (FCCRF) models. We focus on questions for which there are at least two comments. There were 280 such test questions (out of 329), with a total of 1,927 comments.

Model	P	R	F_1	Acc
LCCRF (ord=1)	76.1	83.2	79.4	78.3
LCCRF (ord=2)	76.8	82.1	79.3	78.4
FCCRF	77.3	**86.2**	**81.5**	**80.5**
FCCRF-noFeatures	77.2	86.0	81.4	80.1
FCCRF (4C)	**78.8**	79.7	79.3	79.0

Table 3: Results for different variants of the joint CRF model on the test set.

The Local, the Inference, and the Joint models made correct predictions for 78.7%, 79.1% and 80.4% of the comments, respectively. We can see that the Inference model behaves more like Local, and not so much like Joint. This is indeed further confirmed when we look at the agreement between each pair of models: Local vs. Inference has 6.0% disagreement, for Local vs. Joint it is 9.9%, and for Inference vs. Joint it is 8.8%.

Figure 3 compares the three models vs. the gold human labels on a particular test question (ID=Q2908; some long comments are truncated and the four omitted answers were classified correctly by all three classifiers). We can see that the Joint model is more robust than the Local one: while Joint corrects two of the three wrong classifications of Local, Inference makes two further errors instead.

6 Conclusion

We have proposed two learning methods for comment classification in community Question Answering. We depart from the state-of-the-art knowledge that exploiting the interrelations between all the comments in the answer-thread is beneficial for the task. Thus, we take as our baseline the learning and inference model from Joty et al. (2015), in which the answer-thread is modeled as a fully connected graph. Our contribution consists of moving the framework to on-line learning and proposing two models for coupling learning with inference.

Our first model learns jointly the two MaxEnt classifiers with SGD and incorporates the graph inference at every step with loopy belief propagation. This model, due to its local normalization, suffers from the label bias problem. The alternative we proposed is to use an instance of a Fully Connected CRF that operates on the same graph and considers the node and edge factors with a shared set of features. One of the main advantages is that the normalization is global. We experimented with the SemEval-2015 Task 3 dataset and we confirmed the advantage of the FCCRF model, which outperforms all baselines and achieves better results than the state of the art.

Q: *I have a female friend who is leaving for a teaching job in Qatar in January. What would be a useful portable gift to give her to take with her?*

Figure 3: Sample test question with a thread of comments and, for each comment, decisions by the local (Loc), the global inference (Inf), and the global joint (Jnt) classifiers, as well as by the human annotators.

In the near future, we plan to apply the FCCRF model to the full cQA task, i.e., finding good answers to newly-asked questions using previously-asked questions and their answer threads. In this setting, we want to experiment with (*i*) ranking comments (instead of classifying them), (*ii*) exploiting the similarities between the new question and the questions in the database and also the relations between comments across different answer-threads.

Acknowledgments

This research was performed by the Arabic Language Technologies (ALT) group at the Qatar Computing Research Institute (QCRI), HBKU, part of Qatar Foundation. It is part of the Interactive sYstems for Answer Search (IYAS) project, which is developed in collaboration with MIT-CSAIL.

Weak Semi-Markov CRFs for NP Chunking in Informal Text

Aldrian Obaja Muis and **Wei Lu**
Singapore University of Technology and Design
{aldrian_muis,luwei}@sutd.edu.sg

Abstract

This paper introduces a new annotated corpus based on an existing informal text corpus: the NUS SMS Corpus (Chen and Kan, 2013). The new corpus includes 76,490 noun phrases from 26,500 SMS messages, annotated by university students. We then explored several graphical models, including a novel variant of the semi-Markov conditional random fields (semi-CRF) for the task of noun phrase chunking. We demonstrated through empirical evaluations on the new dataset that the new variant yielded similar accuracy but ran in significantly lower running time compared to the conventional semi-CRF.

1 Introduction

Processing user-generated text data is getting more popular recently as a way to gather information, such as collecting facts about certain events (Ritter et al., 2015), gathering and identifying user profiles (Layton et al., 2010; Li et al., 2014; Spitters et al., 2015), or extracting information in open domain (Ritter et al., 2012; Mitchell et al., 2015).

Most recent work focus on the texts generated through Twitter, which, due to the design of Twitter, contain a lot of announcement-like messages mostly intended for general public. In contrast, SMS was designed as a way to communicate short personal messages to a known person, and hence SMS messages tend to be more conversational and more informal compared to tweets.

> *Hmm Dr teh says the research presentation should still prepare, butshe's not to sure whether they'd time to present*

Figure 1: Sample SMS, with NPs underlined

As conversational texts, SMS data often contains references to named entities such as people and locations relevant to certain events. Recognizing those references will be useful for further NLP tasks. One way to recognize those named entities is to first create a list of candidates, which can be further filtered to get the desired named entities. Nadeau (Nadeau and Sekine, 2007) lists several methods that work upon candidates for NER. As all named entities are nouns, recognizing noun phrases (NP) is therefore a task that can be potentially useful for further steps in the NLP pipeline to build upon. Figure 1 shows an example SMS message within which noun phrases are highlighted. As can be seen from this example, recognizing the NP information on such a dataset presents some additional challenges over conventional NP recognition tasks. Specifically, the texts are highly informal and noisy, with misspelling errors and without grammatical structures. The correct casing and punctuation information is often missing. The lack of spaces between adjacent words makes the detection of NP boundaries more challenging.

Furthermore, the lack of available annotated data for such informal datasets prevents researchers from understanding what effective models can be used to resolve the above issues. In this work, we focus on tackling these issues while making the following two main contributions:

- We build a new corpus of SMS data that is fully annotated with noun phrase information.
- We propose and build a new variant of semi-

Proceedings of NAACL-HLT 2016, pages 714–719,
San Diego, California, June 12-17, 2016.

Markov CRF (Sarawagi and Cohen, 2004) for the task of NP chunking on our corpus, which is faster and yields a performance similar to the conventional semi-Markov CRF models.

2 NP-annotated SMS Corpus

Our text corpus comes from the NUS SMS Corpus (Chen and Kan, 2013), containing 55,835 SMS messages from university students, mostly in English. We used the 2011 version of the corpus, containing 45,718 messages, as it is more relevant to modern phone models using full keyboard layout.

We note that there are a small portion of the messages written in non-English language, such as Tamil and Chinese. As we are focusing on English, we excluded messages written by non-native English speakers based on the metadata (21.3% of all messages). We also excluded messages which contain only one word (6.1%) and we remove duplicate messages (8.1%). [1]

We assigned the remaining 27,700 messages to 64 university students who conduct annotations, each annotating 500 with 100 messages co-annotated by two other annotators. After manual verification we excluded annotations with low quality from 3 students. We used the resulting 26,500 messages as our dataset. The students were asked to annotate the top-level noun phrases found in each message using the BRAT rapid annotation tool[2], where they were instructed to highlight character spans to be marked as noun phrases. The number of noun phrases per message can be found in Table 1.

Due to the noisy nature of SMS messages, there may not be proper capitalization or punctuation, and in some cases there might be missing spaces between words. Figure 1 shows a sample SMS message taken from the corpus. We can see that “Dr teh” is not properly capitalized and “she” in “butshe’s” is missing spaces around it. NPs which do not have clear boundaries (*improper* NPs) constitutes 4.0% of all NPs.

We then use this dataset to evaluate some models on base NP chunking task, where, given a text, the system should return a list of character spans denoting the noun phrases found in the text.

	#SMS	#NPs	#*improper*	#tokens
total	26,500	76,490	3,066 (4.0)	359,009
train	21,200	61,212	2,406 (3.9)	287,590
dev	2,650	7,617	338 (4.4)	35,470
test	2,650	7,661	322 (4.2)	35,949

Table 1: Number of messages, NPs, number of *improper* NPs (as percentage in brackets), which are NPs that end in a middle of a word, and number of tokens.

3 Models

In this paper, we will build our models based on a class of discriminative graphical models, namely conditional random fields (CRFs) (Lafferty et al., 2001), for extracting NPs. The edges in the graph represents the dependencies between states and the features are defined over each edge in the graph. Though CRFs are undirected graphical models, we can use directed acyclic graphs with a root, a leaf, and some inner nodes to represent label sequences[3]. A path in the graph from the root to the leaf represents one possible label assignment to the input. In the labeled instance, there will be only one single path from the root to the leaf, while for the unlabeled instance, the graph will compactly encode all possible label assignments. The learning procedure is essentially the process that tries to tune the feature weights such that the true structures get assigned higher weights as compared to all other alternative structures in the graph.

In general, a CRF tries to maximize the following objective function:

$$\mathcal{L}(\mathcal{T}) = \sum_{(\mathbf{x},\mathbf{y})\in\mathcal{T}} \left[\sum_{e\in\mathcal{E}(\mathbf{x},\mathbf{y})} \mathbf{w}^T\mathbf{f}(e) - \log Z_{\mathbf{w}}(\mathbf{x}) \right] - \lambda||\mathbf{w}||^2 \quad (1)$$

where $\mathcal{T}$ is the training set, $(\mathbf{x}, \mathbf{y})$ is a training instance consisting of the sentence $\mathbf{x}$ and the label sequence $\mathbf{y} \in \mathcal{Y}^n$ for a label set $\mathcal{Y}$, $\mathbf{w}$ is the feature weight vector, $\mathcal{E}(\mathbf{x}, \mathbf{y})$ is the set of edges which form the path in the labeled instance, $\mathbf{f}(e)$ is the feature vector of the edge e, $Z_{\mathbf{w}}(\mathbf{x})$ is the normaliza-

[1] We also manually excluded some messages (ID 1017-4016) which are mostly not written in English (4.0% of all messages).

[2] http://brat.nlplab.org

[3] Extension to directed hypergraphs is possible. See (Lu and Roth, 2015).

tion term which sums over all possible paths from the root to the leaf node, and λ is the regularization parameter.

The set of edges and features defined in each model affects the feature expectation and the normalization term. Computation of the normalization term, being the highest in time complexity, will determine the overall complexity of training the model. The set of edges and the normalization term in each model will be described in the following sections.

3.1 Linear CRF

A linear-chain CRF, or linear CRF is a standard version of CRF which was introduced in (Lafferty et al., 2001), where each word in the sentence is given a set of nodes representing the possible labels, and edges are present between any two nodes from adjacent words, forming a trellis graph. Here we consider only the first-order linear CRF.

The normalization term $Z_{\mathbf{w}}(\mathbf{x})$ is calculated as:

$$\sum_{i=1}^{n}\sum_{y\in\mathcal{Y}}\sum_{y'\in\mathcal{Y}}\mathbf{w}^T\mathbf{f}_{\mathbf{x}}(y',y,i) \tag{2}$$

where $\mathbf{f}_{\mathbf{x}}(y',y,i)$ represents the feature vector on the edge connecting state y' at position $i-1$ to state y at position i. The time complexity of the inference procedure for this model is $O(n\,|\mathcal{Y}|^2)$.

3.2 Semi-CRF

In semi-CRF (Sarawagi and Cohen, 2004), in addition to the edges defined in linear CRF, there are additional edges from a node to all nodes up to L next words away, representing a segment within which the words will be labeled with a single label.

The normalization term $Z_{\mathbf{w}}(\mathbf{x})$ is calculated as:

$$\sum_{i=1}^{n}\sum_{y\in\mathcal{Y}}\sum_{k=1}^{L}\sum_{y'\in\mathcal{Y}}\mathbf{w}^T\mathbf{g}_{\mathbf{x}}(y',y,i-k,i) \tag{3}$$

where $\mathbf{g}_{\mathbf{x}}(y',y,i-k,i)$ represents the feature vector on the edge connecting state y' at position $i-k$ to state y at position i. The time complexity for this model is $O(nL\,|\mathcal{Y}|^2)$.

3.3 Weak Semi-CRF

Note that in semi-CRF, each node is connected to $L \times |\mathcal{Y}|$ next nodes. Intuitively, the model tries to decide the next segment length and type at the same time. We propose a weaker variant that makes the two decisions separately by restricting each node to connect to either only the nodes of the same label up to L next words away, or to all the nodes only in the next word. We call this *Weak Semi-CRF*.

To implement this, we need to split the original nodes into Begin and End nodes, representing the start and end of a segment. The End nodes connect only to the very next Begin nodes of any label, while the Begin nodes connect only to the End nodes of same label up to next L words. The term $Z_{\mathbf{w}}(\mathbf{x})$ is:

$$\sum_{i=1}^{n}\sum_{y\in\mathcal{Y}}\left[\sum_{y'\in\mathcal{Y}}\mathbf{w}^T\mathbf{f}_{\mathbf{x}}(y',y,i)+\sum_{k=1}^{L}\mathbf{w}^T\mathbf{g}_{\mathbf{x}}(y,i-k,i)\right] \tag{4}$$

where $\mathbf{g}_{\mathbf{x}}(y,i-k,i)$ represents the feature vector on the edge connecting the Begin node with state y at position $i-k$ to the End node with the same state y at position i. Note that, different from the $\mathbf{g}_{\mathbf{x}}$ function defined in Equation (3), this new $\mathbf{g}_{\mathbf{x}}$ function is defined over a single (current) y label only, making the time complexity $O(n\,|\mathcal{Y}|^2 + nL\,|\mathcal{Y}|)$. Theoretically this model is slightly more efficient than the conventional semi-CRF model.

Unlike conventional (first-order) semi-Markov CRF, this new model does not allow us to capture the dependencies between one segment and its adjacent segment's label information. We argue that, however, such dependencies can be less crucial for our task. We will empirically assess this aspect through experiments. Figure 2 illustrates the differences among the three models.

4 Features

In linear CRF, the baseline feature set considers the previous word, current word, and the tag transition.

In semi-CRF, following (Sarawagi and Cohen, 2004) we put all words not part of a noun phrase in its own segment, and put each noun phrase in one segment, possibly spanning over multiple words. Here we set $L = 6$ and ignored NPs with more than six words during training, which is less than 0.5% of all NPs. For each segment, we defined the following features as the baseline: (1) indexed words inside current segment, running from the start and from the end of the segment, (2) the word before and after

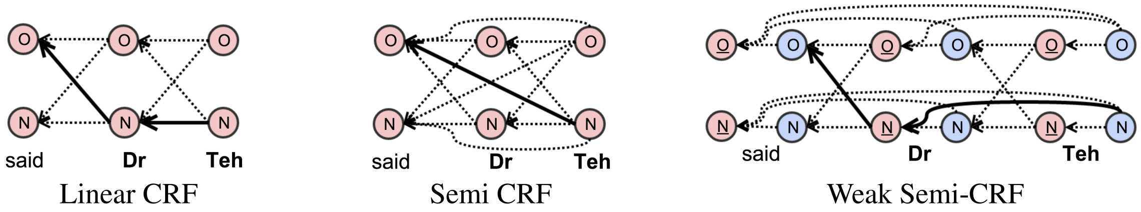

Figure 2: Graphical illustrations of the differences between three models. The bold arrows represent the path in each model to label "Dr Teh" as a noun phrase. For Linear CRF, this is a simplified diagram; in the implementation we used the "BIO" approach to represent text chunks. The underlined nodes in Weak Semi-CRF are the Begin nodes.

current segment, and (3) the labels of last segment and current segment.

In weak semi-CRF we use the same feature set as semi-CRF, adjusting the features accordingly where segment-specific features (1) are defined only in the Begin-End edges, and transition features (3) are defined only in the End-Begin edges.

For each model we then add the character prefixes and suffixes up to length 3 for each word (+a), Brown cluster (Brown et al., 1992) for current word (+b), and word shapes (+s). For Brown cluster features we used 100 clusters trained on the whole NUS SMS Corpus. The cluster information is then used directly as a feature.

Word shapes can be considered a generic representation of words that retains only the "shape" information, such as whether it starts with capital letter or whether it contains digits. The Brown clusters and word shapes features are applied to each of the word features described in each model.

5 Experiments

All models were built by us using Java, and were optimized with L-BFGS. Models are all tuned in the development set for optimal λ. The optimal λ values are noted in Table 2.

Since the models that we consider are all word-based [4], we tokenize the corpus using a regex-based tokenizer similar to the `wordpunct_tokenize` function in Python NLTK package. We also included some rules to consider special anonymization tokens in the SMS dataset (Chen and Kan, 2013).

	Linear CRF	Semi-CRF	Weak Semi-CRF
base	0.125	2.0	2.0
+s	0.25	1.0	2.0
+b	0.5	1.0	2.0
+b+s	0.5	2.0	2.0
+a	1.0	2.0	2.0
+a +s	2.0	1.0	2.0
+a+b	1.0	2.0	2.0
+a+b+s	2.0	2.0	2.0

Table 2: Tuned regularization parameter λ from the set $\{0.125, 0.25, 0.5, 1.0, 2.0\}$ for various feature sets. +a, +b, and +s refer to the affix, Brown cluster, and word shape features respectively.

The gold character spans are converted into word labels in BIO format, reducing or extending the character spans as necessary to the closest word boundaries. The converted annotations are regarded as gold word spans. Note that this conversion is lossy due to the presence of *improper* NPs, which makes it impossible for the converted format to represent the original gold standard.

We evaluated the models in the original character-level spans and also in the converted word-level spans, to see the impact of the lossy conversion on the scores. In character-level evaluation, the system output is converted back into character boundaries and compared with the original gold standard, while in the word-level evaluation, the system output is compared directly with the gold word spans. For this reason, we anticipate that the scores in word-level evaluation will be higher than in the character-level evaluation. The results are shown in Table 3. The scores for "Gold" in the character-level evaluation mark the upperbound of word-based models due to the presence of *improper* NPs.

The average time per training iteration on the base models is 1.311s, 2.072s, and 1.811s respectively for Linear CRF, Semi-CRF, and Weak Semi-CRF.

[4] We experimented with character-based models, but they do not perform well. We leave them for future investigations.

5.1 Discussion

First, we see that the two semi-CRF models perform better compared to the baseline linear CRF model, showing the benefit of using segment features over only single word features.

It is also interesting that, while being a weaker version of the semi-CRF, the weak semi-CRF can actually perform in the same level within 95% confidence interval as the conventional semi-CRF. This shows that some of the dependencies in the conventional semi-CRF do not really contribute to the strength of semi-CRF over standard linear CRF. As noted in Section 3.3, weak semi-CRF makes the decision on the segment type and length separately. This means there is enough information in the local features to decide the segment type and length separately, and so we can remove some combined features while retaining the same performance.

This result, coupled with the fact that the weak semi-CRF requires 12.5% less time than the conventional semi-CRF (1.811s vs 2.072s), shows the potentials of using this weak semi-CRF as an alternative of the conventional semi-CRF. With more label types (here only two), the difference will be larger, since the weak semi-CRF is linear in number of label types, while conventional semi-CRF is quadratic.

6 Related Work

Ritter et al. (2011) previously showed that off-the-shelf NP-chunker performs worse on informal text. Then they trained a linear-CRF model on additional in-domain data, reducing the error up to 22%. However no results on semi-CRF was given.

Semi-CRF has proven effective in chunking tasks. Other variants of semi-CRF models also exist. Nguyen et al. (2014) explored the use of higher-order dependencies to improve the performance of semi-CRF models on synthetic data and on handwriting recognition. They exploited the sparsity of label sequence in order to make the training efficient.

It is also known that feature selection is an important aspect when trying to use semi-CRF models to improve on the linear CRF. Andrew (2006) reported an error reduction of up to 25% when using features that are best exploited by semi-CRF.

7 Conclusion and Future Work

In this paper we present a new NP-annotated SMS corpus, together with a novel variant of the semi-CRF model, which runs in significantly lower time while maintaining similar accuracy on the NP chunking task on the new dataset. Future work includes the application of the weak semi-CRF model to other structured prediction problems, as well as performing investigations on handling other types of informal or noisy texts such as speech transcripts. We make the code and data available for download at http://statnlp.org/research/ie/.

What to talk about and how? Selective Generation using LSTMs with Coarse-to-Fine Alignment

Abstract

We propose an end-to-end, domain-independent neural encoder-aligner-decoder model for selective generation, i.e., the joint task of content selection and surface realization. Our model first encodes a full set of over-determined database event records via an LSTM-based recurrent neural network, then utilizes a novel coarse-to-fine aligner to identify the small subset of salient records to talk about, and finally employs a decoder to generate free-form descriptions of the aligned, selected records. Our model achieves the best selection and generation results reported to-date (with 59% relative improvement in generation) on the benchmark WEATHERGOV dataset, despite using no specialized features or linguistic resources. Using an improved k-nearest neighbor beam filter helps further. We also perform a series of ablations and visualizations to elucidate the contributions of our key model components. Lastly, we evaluate the generalizability of our model on the ROBOCUP dataset, and get results that are competitive with or better than the state-of-the-art, despite being severely data-starved.

1 Introduction

We consider the important task of producing a natural language description of a rich world state represented as an over-determined database of event records. This task, which we refer to as selective generation, is often formulated as two subproblems: *content selection*, which involves choosing a subset of relevant records to talk about from the exhaustive database, and *surface realization*, which is concerned with generating natural language descriptions for this subset. Learning to perform these tasks jointly is challenging due to the uncertainty in deciding which records are relevant, the complex dependencies between selected records, and the multiple ways in which these records can be described.

Previous work has made significant progress on this task (Chen and Mooney, 2008; Angeli et al., 2010; Kim and Mooney, 2010; Konstas and Lapata, 2012). However, most approaches solve the two content selection and surface realization subtasks separately, use manual domain-dependent resources (e.g., semantic parsers) and features, or employ template-based generation. This limits domain adaptability and reduces coherence. We take an alternative, neural encoder-aligner-decoder approach to free-form selective generation that jointly performs content selection and surface realization, without using any specialized features, resources, or generation templates. This enables our approach to generalize to new domains. Further, our memory-based model captures the long-range contextual dependencies among records and descriptions, which are integral to this task (Angeli et al., 2010).

We formulate our model as an encoder-aligner-decoder framework that uses recurrent neural networks with long short-term memory units (LSTM-RNNs) (Hochreiter and Schmidhuber, 1997) together with a coarse-to-fine aligner to select and "translate" the rich world state into a natural language description. Our model first encodes the full set of over-determined[1] event records using a bidirectional LSTM-RNN. A novel coarse-to-fine aligner then reasons over multiple abstractions of the input to decide which of the records to discuss. The model next employs an LSTM decoder to gen-

[1] By "over-determined", we mean that there are extraneous and redundant records present in the database.

Proceedings of NAACL-HLT 2016, pages 720–730,
San Diego, California, June 12-17, 2016.

erate natural language descriptions of the selected records.

The use of LSTMs, which have proven effective for similar long-range generation tasks (Sutskever et al., 2014; Vinyals et al., 2015b; Karpathy and Fei-Fei, 2015), allows our model to capture the long-range contextual dependencies that exist in selective generation. Further, the introduction of our proposed variation on alignment-based LSTMs (Bahdanau et al., 2014; Xu et al., 2015) enables our model to learn to perform content selection and surface realization jointly, by aligning each generated word to an event record during decoding. Our novel coarse-to-fine aligner avoids searching over the full set of over-determined records by employing two stages of increasing complexity: a pre-selector and a refiner acting on multiple abstractions (low- and high-level) of the record input. The end-to-end nature of our framework has the advantage that it can be trained directly on corpora of record sets paired with natural language descriptions, without the need for ground-truth content selection.

We evaluate our model on a benchmark weather forecasting dataset (WEATHERGOV) and achieve the best results reported to-date on content selection (12% relative improvement in F-1) and language generation (59% relative improvement in BLEU), despite using no domain-specific resources. We also perform a series of ablations and visualizations to elucidate the contributions of the primary model components, and also show improvements with a simple, k-nearest neighbor beam filter approach. Finally, we demonstrate the generalizability of our model by directly applying it to a benchmark sportscasting dataset (ROBOCUP), where we get results competitive with or better than state-of-the-art, despite being extremely data-starved.

2 Related Work

Selective generation is a task where a natural language description is produced for a salient subset of a rich world state represented as an over-determined database of event records. A good deal of attention in this area has been paid to the individual content selection and selective realization subproblems. With regards to the former, Barzilay and Lee (2004) model the content structure from unannotated documents and apply it to the application of text summarization. Barzilay and Lapata (2005) treat content selection as a collective classification problem and simultaneously optimize the local label assignment and their pairwise relations. Liang et al. (2009) address the related task of aligning a set of records to given textual description clauses. They propose a generative semi-Markov alignment model that jointly segments text sequences into utterances and associates each to the corresponding record.

Surface realization is often treated as a problem of producing text according to a given representation (Reiter et al., 2000). Walker et al. (2001) and Stent et al. (2004) design trainable sentence planners to generate sentences (and their combinations) for context planning and dialog, relying upon various linguistics features. Soricut and Marcu (2006) propose a language generation system that uses the WIDL-representation, a formalism used to compactly represent probability distributions over finite sets of strings. Wong and Mooney (2007) and Lu and Ng (2011) use synchronous context-free grammars to generate natural language sentences from formal meaning representations. Similarly, Belz (2008) employs probabilistic context-free grammars to perform surface realization. Other effective approaches include the use of tree conditional random fields (Lu et al., 2009) and template extraction within a log-linear framework (Angeli et al., 2010).

Recent work seeks to solve the full selective generation problem through a single framework. Chen and Mooney (2008) and Chen et al. (2010) learn alignments between comments and their corresponding event records using a translation model for parsing and generation. Kim and Mooney (2010) implement a two-stage framework that decides what to discuss using a combination of the methods of Lu et al. (2008) and Liang et al. (2009), and then produces the text based on the generation system of Wong and Mooney (2007).

Angeli et al. (2010) propose a unified concept-to-text model that treats joint content selection and surface realization as a sequence of local decisions represented by a log-linear model. Similar to other work, they train their model using external alignments from Liang et al. (2009). Generation then follows as inference over this model, where they first choose an event record, then the record's fields (i.e., attributes), and finally a set of templates that they then fill in with words for the selected fields. Their ability to model long-range dependencies relies on their choice of features for the log-linear model, while the template-based generation further employs some domain-specific features for fluent output.

Konstas and Lapata (2012) propose an alternative method that simultaneously optimizes the content selection and surface realization problems. They employ a probabilistic context-free grammar that specifies the structure of the event records, and then treat generation as finding the best derivation tree according to this grammar. However, their method still selects and orders records in a local fashion via a Markovized chaining of records. Konstas and Lapata (2013) improve upon this approach with global document representations. However, this approach also requires alignment during training, which they estimate using the method of Liang et al. (2009).

We treat the problem of selective generation as end-to-end learning via a recurrent neural network encoder-aligner-decoder model, which enables us to jointly learn content selection and surface realization directly from database-text pairs, without the need for an external aligner or ground-truth selection labels. The use of LSTM-RNNs enables our model to capture the long-range dependencies that exist among the records and natural language output. Additionally, the model does not rely on any manually-selected or domain-dependent features, templates, or parsers, and is thereby generalizable. The alignment-RNN approach has recently proven successful for generation-style tasks, e.g., machine translation (Bahdanau et al., 2014) and image captioning (Xu et al., 2015). Since selective generation requires identifying the small number of salient records among an over-determined database, we avoid performing exhaustive search over the full record set, and instead propose a novel coarse-to-fine aligner that divides the search complexity into pre-selection and refinement stages.

3 Task Definition

We consider the problem of generating a natural language description for a rich world state specified in terms of an over-determined set of records (database). This problem requires deciding which of the records to discuss (content selection) and how to discuss them (surface realization). Training data consists of *scenario* pairs $(r^{(i)}, x^{(i)})$ for $i = 1, 2, \ldots, n$, where $r^{(i)}$ is the complete set of records and $x^{(i)}$ is the natural language description (Fig. 1). At test time, only the records are given. We evaluate our model in the context of two publicly-available benchmark selective generation datasets.

$r_{1:N}$:

temperature(time=17-06, min=48, mean=53, max=61)
windSpeed(time=17-06, min=3, mean=6, max=11)
windDir(time=17-06, mode=SSW)
gust(time=17-06, min=0, mean=0, max=0)
skyCover(time=17-21, mode=0-25)
skyCover(time=02-06, mode=75-100)
precipChance(time=17-06, min=2, mean=14, max=20)
rainChance(time=17-06, mode=someChance)

$x_{1:N}$: "a 20 percent chance of showers after midnight. increasing clouds, with a low around 48 southwest wind between 5 and 10 mph"

(a) WEATHERGOV

$r_{1:N}$:

pass(arg1=purple6, arg2=purple3)
kick(arg1=purple3)
badPass(arg1=purple3, arg2=pink9)
turnover(arg1=purple3, arg2=pink9)

$x_{1:N}$: "purple3 made a bad pass that was picked off by pink9"

(b) ROBOCUP

Figure 1: Sample database-text pairs chosen from the (a) WEATHERGOV and (b) ROBOCUP datasets.

WEATHERGOV The weather forecasting dataset (see Fig. 1(a)) of Liang et al. (2009) consists of 29528 scenarios, each with 36 weather records (e.g., temperature, sky cover, etc.) paired with a natural language forecast (28.7 avg. word length).

ROBOCUP We evaluate our model's generalizability on the sportscasting dataset of Chen and Mooney (2008), which consists of only 1539 pairs of temporally ordered robot soccer events (e.g., pass, score) and commentary drawn from the four-game 2001–2004 RoboCup finals (see Fig. 1(b)). Each scenario contains an average of 2.4 event records and a 5.7 word natural language commentary.

4 The Model

We formulate selective generation as inference over a probabilistic model $P(x_{1:T}|r_{1:N})$, where

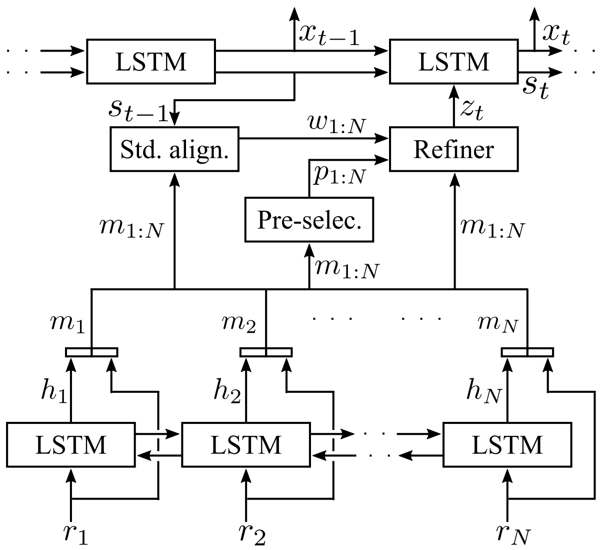

Figure 2: Our model architecture with a bidirectional LSTM encoder, coarse-to-fine aligner, and decoder.

$r_{1:N} = (r_1, r_2, \ldots, r_N)$ is the input set of over-determined event records,[2] $x_{1:T} = (x_1, x_2, \ldots, x_T)$ is the generated description with x_t being the word at time t and x_0 being a special start token:

$$x^*_{1:T} = \underset{x_{1:T}}{\arg\max}\, P(x_{1:T}|r_{1:N}) \tag{1a}$$

$$= \underset{x_{1:T}}{\arg\max} \prod_{t=1}^{T} P(x_t|x_{0:t-1}, r_{1:N}) \tag{1b}$$

The goal of inference is to generate a natural language description for a given set of records. An effective means of learning to perform this generation is to use an encoder-aligner-decoder architecture with a recurrent neural network, which has proven effective for related problems in machine translation (Bahdanau et al., 2014) and image captioning (Xu et al., 2015). We propose a variation on this general model with novel components that are well-suited to the selective generation problem.

Our model (Fig. 2) first encodes each input record r_j into a hidden state h_j with $j \in \{1, \ldots, N\}$ using a bidirectional recurrent neural network (RNN). Our novel coarse-to-fine aligner then acts on a concatenation m_j of each record and its hidden state as multi-level representation of the input to compute the selection decision z_t at each decoding step t. The model then employs an RNN decoder to arrive at the word likelihood $P(x_t|x_{0:t-1}, r_{1:N})$ as a function of the multi-level input and the hidden state of the decoder s_{t-1} at time step $t-1$. In order to model the long-range dependencies among the records and descriptions (which is integral to effectively performing selective generation (Angeli et al., 2010; Konstas and Lapata, 2012; Konstas and Lapata, 2013)), our model employs LSTM units as the nonlinear encoder and decoder functions.

Encoder Our LSTM-RNN encoder (Fig. 2) takes as input the set of event records represented as a sequence $r_{1:N} = (r_1, r_2, \ldots, r_N)$ and returns a sequence of hidden annotations $h_{1:N} = (h_1, h_2, \ldots, h_N)$, where the annotation h_j summarizes the record r_j. This results in a representation that models the dependencies that exist among the records in the database.We adopt an encoder architecture similar to that of Graves et al. (2013)

$$\begin{pmatrix} i^e_j \\ f^e_j \\ o^e_j \\ g^e_j \end{pmatrix} = \begin{pmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{pmatrix} T^e \begin{pmatrix} r_j \\ h_{j-1} \end{pmatrix} \tag{2a}$$

$$c^e_j = f^e_j \odot c^e_{j-1} + i^e_j \odot g^e_j \tag{2b}$$

$$h_j = o^e_j \odot \tanh(c^e_j) \tag{2c}$$

where T^e is an affine transformation, σ is the logistic sigmoid that restricts its input to $[0, 1]$, i^e_j, f^e_j, and o^e_j are the input, forget, and output gates of the LSTM, respectively, and c^e_j is the memory cell activation vector. The memory cell c^e_j summarizes the LSTM's previous memory c^e_{j-1} and the current input, which are modulated by the forget and input gates, respectively. Our encoder operates bidirectionally, encoding the records in both the forward and backward directions, which provides a better summary of the input records. In this way, the hidden annotations $h_j = (\overrightarrow{h}^\top_j; \overleftarrow{h}^\top_j)^\top$ concatenate forward $\overrightarrow{h}_j$ and backward $\overleftarrow{h}_j$ annotations, each determined using Equation (2c).

Coarse-to-Fine Aligner Having encoded the input records $r_{1:N}$ to arrive at the hidden annotations $h_{1:N}$, the model then seeks to select the content at each time step t that will be used for generation. Our

[2] These records may take the form of an unordered set or have a natural ordering (e.g., temporal in the case of ROBOCUP). In order to make our model generalizable, we treat the set as a sequence and use the order specified by the dataset. We note that it is possible that a different ordering will yield improved performance, since ordering has been shown to be important when operating on sets (Vinyals et al., 2015a).

model performs content selection using an extension of the alignment mechanism proposed by Bahdanau et al. (2014), which allows for selection and generation that is independent of the ordering of the input.

In selective generation, the given set of event records is over-determined with only a small subset of salient records being relevant to the output natural language description. Standard alignment mechanisms limit the accuracy of selection and generation by scanning the entire range of over-determined records. In order to better address the selective generation task, we propose a coarse-to-fine aligner that prevents the model from being distracted by non-salient records. [3] Our model aligns based on multiple abstractions of the input: both the original input record as well as the hidden annotations $m_j = (r_j^\top; h_j^\top)^\top$, an approach that has previously been shown to yield better results than aligning based only on the hidden state (Mei et al., 2015).

Our coarse-to-fine aligner avoids searching over the full set of over-determined records by using two stages of increasing complexity: a pre-selector and refiner (Fig. 2). The pre-selector first assigns to each record a probability p_j of being selected, while the standard aligner computes the alignment likelihood w_{tj} over all the records at each time step t during decoding. Next, the refiner produces the final selection decision by re-weighting the aligner weights w_{tj} with the pre-selector probabilities p_j:

$$p_j = \text{sigmoid}\left(q^\top \tanh(Pm_j)\right) \tag{3a}$$

$$\beta_{tj} = v^\top \text{tanh}(Ws_{t-1} + Um_j) \tag{3b}$$

$$w_{tj} = \exp(\beta_{tj}) / \sum_j \exp(\beta_{tj}) \tag{3c}$$

$$\alpha_{tj} = p_j w_{tj} / \sum_j p_j w_{tj} \tag{3d}$$

$$z_t = \sum_j \alpha_{tj} m_j \tag{3e}$$

where P, q, U, W, v are learned parameters. Ideally, the selection decision would be based on the highest-value alignment $z_t = m_k$ where $k = \arg\max_j \alpha_{tj}$. However, we use the weighted average (Eqn. 3e) as its soft approximation to maintain differentiability of the entire architecture.

The pre-selector assigns large values ($p_j > 0.5$) to a small subset of salient records and small values ($p_j < 0.5$) to the rest. This modulates the standard aligner, which then has to assign a large weight w_{tj} in order to select the j-th record at time t. In this way, the learned prior p_j makes it difficult for the alignment (attention) to be distracted by non-salient records. Further, we can relate the output of the pre-selector to the number of records that are selected. Specifically, the output p_j expresses the extent to which the j-th record should be selected. The summation $\sum_{j=1}^{N} p_j$ can then be regarded as a real-valued approximation to the total number of pre-selected records (denoted as γ), which we regularize towards, based on validation (see Eqn. 5).

Decoder Our architecture uses an LSTM decoder that takes as input the current context vector z_t, the last word x_{t-1}, and the LSTM's previous hidden state s_{t-1}. The decoder outputs the conditional probability distribution $P_{x,t} = P(x_t | x_{0:t-1}, r_{1:N})$ over the next word, represented as a deep output layer (Pascanu et al., 2014),

$$\begin{pmatrix} i_t^d \\ f_t^d \\ o_t^d \\ g_t^d \end{pmatrix} = \begin{pmatrix} \sigma \\ \sigma \\ \sigma \\ \tanh \end{pmatrix} T^d \begin{pmatrix} Ex_{t-1} \\ s_{t-1} \\ z_t \end{pmatrix} \tag{4a}$$

$$c_t^d = f_t^d \odot c_{t-1}^d + i_t^d \odot g_t^d \tag{4b}$$

$$s_t = o_t^d \odot \tanh(c_t^d) \tag{4c}$$

$$l_t = L_0(Ex_{t-1} + L_s s_t + L_z z_t) \tag{4d}$$

$$P_{x,t} = \text{softmax}\,(l_t) \tag{4e}$$

where E (an embedding matrix), L_0, L_s, and L_z are parameters to be learned.

Training and Inference We train the model using the database-record pairs $(r_{1:N}, x_{1:T})$ from the training corpora so as to maximize the likelihood of the ground-truth language description $x_{1:T}^*$ (Eqn. 1). Additionally, we introduce a regularization term $(\sum_{j=1}^{N} p_j - \gamma)^2$ that enables the model to influence the pre-selector weights based on the aforementioned relationship between the output of the pre-selector and the number of selected records. Moreover, we also introduce the term $(1.0 - \max(p_j))$, which accounts for the fact that at least one record should be pre-selected. Note that when γ is equal to N, the pre-selector is forced to select all the records

[3] Our coarse-to-fine nomenclature is based on the alignment inference at successively finer granularities.

($p_j = 1.0$ for all j), and the coarse-to-fine alignment reverts to the standard alignment introduced by Bahdanau et al. (2014). Together with the negative log-likelihood of the ground-truth description $x^*_{1:T}$, our loss function becomes

$$L = -\log P(x^*_{1:T}|r_{1:N}) + G \tag{5a}$$

$$= -\sum_{t=1}^{T} \log P(x^*_t|x_{0:t-1}, r_{1:N}) + G \tag{5b}$$

$$G = \left(\sum_{j=1}^{N} p_j - \gamma\right)^2 + \Big(1 - \max(p_j)\Big) \tag{5c}$$

Having trained the model, we generate the natural language description by finding the maximum a posteriori words under the learned model (Eqn. 1). [4] For inference, we perform greedy search starting with the first word x_1. Beam search offers a way to perform approximate joint inference — however, we empirically found that beam search does not perform any better than greedy search on the datasets that we consider, an observation that is shared with previous work (Angeli et al., 2010). We later discuss an alternative k-nearest neighbor-based beam filter (see Sec 6.2).

5 Experimental Setup

Datasets We analyze our model on the benchmark WEATHERGOV dataset, and use the data-starved ROBOCUP dataset to demonstrate the model's generalizability. Following Angeli et al. (2010), we use WEATHERGOV training, development, and test splits of size 25000, 1000, and 3528, respectively. For ROBOCUP, we follow the evaluation methodology of previous work (Chen and Mooney, 2008), performing three-fold cross-validation whereby we train on three games (approximately 1000 scenarios) and test on the fourth. Within each split, we hold out 10% of the training data as the development set to tune the early-stopping criterion and γ. We then report the standard average performance (weighted by the number of scenarios) over these four splits.

Dataset Processing In this section, we present the implementation details regarding our data preprocessing. We use WEATHERGOV as an example here, since it is our primary dataset, and the same recipe is followed for ROBOCUP.

For tokenization of the textual descriptions, we simply treat as token each string unit delimited by a space, which includes regular words ("sunny"), punctuation (","), and numerical values ("20"). A special token is added to represent the beginning and end of the entire textual description. This operation results in a vocabulary of size 338, and we did not filter out any rare tokens. Moreover, in this setup, numerical values are also generated as any other token during decoding period.

For event record representation, we represent each event as a fixed-length vector, concatenated by multiple "attribute (field) vectors". Each attribute vector represents either a 1) record type (e.g., "rainChance") with a one-hot vector, 2) record time slot (e.g., "06:00–21:00") with a one-hot vector, 3) record mode (e.g., "SSE") with a one-hot vector, or, 4) record value (e.g., "20") with a 0-1 vector. The 0-1 vector for record value is simply the signed binary representation of this number. We choose the usage of 0-1 binary representation vectors for numbers because it allows us to share binning-style information between nearby numbers (whereas a one-hot vector is sparse).

Training Details On WEATHERGOV, we lightly tune the number of hidden units and γ on the development set according to the generation metric (BLEU), and choose 500 units from $\{250, 500, 750\}$ and $\gamma = 8.5$ from $\{6.5, 7.5, 8.5, 10.5, 12.5\}$. For ROBOCUP, we only tune γ on the development set and choose $\gamma = 5.0$ from the set $\{1.0, 2.0, \ldots, 6.0\}$. However, we do not retune the number of hidden units on ROBOCUP. For each iteration, we randomly sample a mini-batch of 100 scenarios during back-propagation and use Adam (Kingma and Ba, 2015) for optimization. Training typically converges within 30 epochs. We select the model according to the BLEU score on the development set.[5]

Evaluation Metrics We consider two metrics as a means of evaluating the effectiveness of our model on the two selective generation subproblems. For content selection, we use the F-1 score of the set of

[4] Numerical values are also generated exactly as any other token in the vocabulary.

[5] We implement our model in Theano (Bergstra et al., 2010; Bastien et al., 2012) and will make the code publicly available.

Table 1: Primary WeatherGov results

Method	F-1	sBLEU	cBLEU
KL12	–	33.70	–
KL13	–	36.54	–
ALK10	65.40	38.40	51.50
Our model	**73.21**	**61.01**	**70.39**

selected records as defined by the harmonic mean of precision and recall with respect to the ground-truth selection record set. We define the set of selected records as consisting of the record with the largest selection weight α_{ti} computed by our aligner at each decoding step t.

We evaluate the quality of surface realization using the BLEU score[6] (a 4-gram matching-based precision) (Papineni et al., 2001) of the generated description with respect to the human-created reference. To be comparable to previous results on WeatherGov, we also consider a modified BLEU score (cBLEU) that does not penalize numerical deviations of at most five (Angeli et al., 2010) (i.e., to not penalize "low around 58" compared to a reference "low around 60"). On RoboCup, we also evaluate the BLEU score in the case that ground-truth content selection is known (sBLEU$_{\mathrm{G}}$), to be comparable to previous work.

6 Results and Analysis

We analyze the effectiveness of our model on the benchmark WeatherGov (as primary) and RoboCup (as generalization) datasets. We also present several ablations to illustrate the contributions of the primary model components.

6.1 Primary Results (WeatherGov)

We report the performance of content selection and surface realization using F-1 and two BLEU scores (standard sBLEU and the customized cBLEU of Angeli et al. (2010)), respectively (Sec. 5). Table 1 compares our test results against previous methods that include KL12 (Konstas and Lapata, 2012), KL13 (Konstas and Lapata, 2013), and ALK10 (Angeli et al., 2010). Our method achieves the best results reported to-date on all three metrics, with relative improvements of 11.94% (F-1), 58.88% (sBLEU), and 36.68% (cBLEU) over the previous state-of-the-art.

6.2 Beam Filter with k-Nearest Neighbors

We perform greedy search as an approximation to full inference over the set of decision variables (Eqn. 1). We considered beam search as an alternative, but as with previous work on this dataset (Angeli et al., 2010), we found that greedy search still yields better BLEU performance (Table 2).

Table 2: Effect of beam width

Beam width M	1	2	5	10
dev sBLEU	65.58	64.70	57.02	47.07
dev cBLEU	75.78	74.91	65.83	54.19

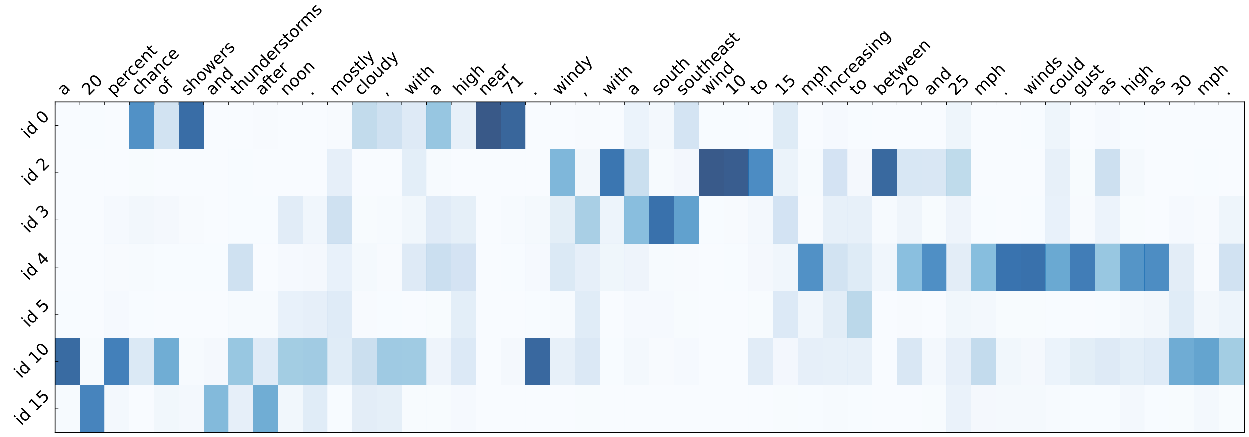
As an alternative, we consider a beam filter based on a k-nearest neighborhood. First, we generate the M-best description candidates (i.e., a beam width of M) for a given input record set (database) using standard beam search. Next, we find the K nearest neighbor database-description pairs from the training data, based on the cosine similarity of each neighbor database with the given input record. We then compute the BLEU score for each of the M description candidates relative to the K nearest neighbor descriptions (as references) and select the candidate with the highest BLEU score. We tune K and M on the development set and report the results in Table 3. Table 4 presents the test results with this tuned setting ($M = 2$, $K = 1$), where we achieve BLEU scores better than our primary greedy results.

Table 3: k-NN beam filter (dev set)

sBLEU	$M = 2$	$M = 5$	$M = 10$
$K = 1$	**65.99**	65.88	65.65
$K = 2$	65.89	65.98	65.83
$K = 5$	65.64	65.45	65.41
$K = 10$	65.91	65.89	65.12

cBLEU	$M = 2$	$M = 5$	$M = 10$
$K = 1$	**76.21**	76.13	75.98
$K = 2$	75.99	76.03	75.82
$K = 5$	75.90	75.63	75.41
$K = 10$	75.95	75.87	75.23

[6] We compute BLEU using the publicly available evaluation provided by Angeli et al. (2010).



Record details:
id-0: temperature(time=06-21, min=52, mean=63, max=71); id-2: windSpeed(time=06-21, min=8, mean=17, max=23);
id-3: windDir(time=06-21, mode=SSE); id-4: gust(time=06-21, min=0, mean=10, max=30);
id-5: skyCover(time=6-21, mode=50-75); id-10: precipChance(time=06-21, min=19, mean=32, max=73);
id-15: thunderChance(time=13-21, mode=SChc)

	Primary	k-NN ($M = 2$, $K = 1$)
sBLEU	61.01	**61.76**
cBLEU	70.39	**71.23**

6.3 Ablation Analysis (WEATHERGOV)

Next, we present several ablations to analyze the contribution of our model components.[7]

Aligner Ablation First, we evaluate the contribution of our proposed coarse-to-fine aligner by comparing our model with the basic encoder-aligner-decoder model introduced by Bahdanau et al. (2014) (which we originally started with). Table 5 reports the results demonstrating that our two-level aligner yields superior F-1 and BLEU scores relative to a standard aligner.[8]

Table 5: Coarse-to-fine aligner ablation (dev set)

Aligner	F-1	sBLEU	cBLEU
Basic	60.35	63.54	74.90
Coarse-to-fine	76.28	65.58	75.78

Encoder Ablation Next, we consider the effectiveness of the encoder. Table 6 compares the results with and without the encoder on the development set, and demonstrates that there is a significant gain from encoding the event records using the LSTM-RNN. We attribute this improvement to the LSTM-RNN's ability to capture the relationships that exist among the records, which is known to be essential to selective generation (Barzilay and Lapata, 2005; Angeli et al., 2010).

Table 6: Encoder ablation (dev set)

Encoder	F-1	sBLEU	cBLEU
With	76.28	65.58	75.78
Without	57.45	56.47	68.63

6.4 Qualitative Analysis (WEATHERGOV)

Output Examples Fig. 3 shows an example record set with its output description and record-word alignment heat map. As shown, our model learns to align records with their corresponding words (e.g., windDir and "southeast," temperature and "71," windSpeed and "wind 10," and gust and "winds could gust as high as 30 mph"). It also learns the subset of salient records to talk about (matching the ground-truth description perfectly for this example, i.e., a standard BLEU of 100.00). We also see some word-level mismatch, e.g., "cloudy" mis-

[7] These results are based on our primary model of Sec. 6.1 and on the development set.

[8] The same improvement trends hold on the test set. Moreover, our two-level aligner (and the basic aligner) model is substantially better than having no aligner at all, i.e., a simple encoder-decoder model of Sutskever et al. (2014).

aligns to id-0 temp and id-10 precipChance, which we attribute to the high correlation between these types of records ("garbage collection" in Liang et al. (2009)).

Word Embeddings (Trained & Pretrained) Training our decoder has the effect of learning embeddings for the words in the training set (via the embedding matrix E in Eqn. 4). Here, we explore the extent to which these learned embeddings capture semantic relationships among the training words. Table 7 presents nearest neighbor words for some of the common words from the WEATHERGOV dataset (according to cosine similarity in the embedding space).

Table 7: Nearest neighbor word for example words

Word	Nearest neighbor
gusts	gust
clear	sunny
isolated	scattered
southeast	northeast
storms	winds
decreasing	falling

We also consider different ways of using pre-trained word embeddings (Mikolov et al., 2013) to bootstrap the quality of our learned embeddings. One approach initializes our embedding matrix with the pre-trained vectors and then refines the embedding based on our training corpus. The second concatenates our learned embedding matrix with the pre-trained vectors in an effort to simultaneously exploit general similarities as well as those learned for the domain. As shown previously for other tasks (Vinyals et al., 2014; Vinyals et al., 2015b), we find that the use of pre-trained embeddings results in negligible improvements (on the development set).

6.5 Out-of-Domain Results (ROBOCUP)

We use the ROBOCUP dataset to evaluate the domain-independence of our model. The dataset is severely data-starved with only 1000 (approx.) training pairs, which is much smaller than is typically necessary to train RNNs. This results in higher variance in the trained model distributions, and we thus adopt the standard denoising method of ensembles (Sutskever et al., 2014; Vinyals et al., 2015b; Zaremba et al., 2014).[9]

Table 8: ROBOCUP results

Method	F-1	sBLEU	sBLEU$_G$
CM08	72.00	–	28.70
LJK09	75.70	–	–
CKM10	79.30	–	–
ALK10	79.90	–	28.80
KL12	–	24.88	**30.90**
Our model	**81.58**	**25.28**	29.40

Following previous work, we perform two experiments on the ROBOCUP dataset (Table 8), the first considering full selective generation and the second assuming ground-truth content selection at test time. On the former, we obtain a standard BLEU score (sBLEU) of 25.28, which exceeds the best score of 24.88 (Konstas and Lapata, 2012). Additionally, we achieve an selection F-1 score of 81.58, which is also the best result reported to-date. In the case of assumed (known) ground-truth content selection, our model attains an sBLEU$_G$ score of 29.40, which is competitive with the state-of-the-art.[10]

7 Conclusion

We presented an encoder-aligner-decoder model for selective generation that does not use any specialized features, linguistic resources, or generation templates. Our model employs a bidirectional LSTM-RNN model with a novel coarse-to-fine aligner that jointly learns content selection and surface realization. We evaluate our model on the benchmark WEATHERGOV dataset and achieve state-of-the-art selection and generation results. We achieve further improvements via a k-nearest neighbor beam filter. We also present several model ablations and visualizations to elucidate the effects of the primary components of our model. Moreover, our model generalizes to a different, data-starved domain (ROBOCUP), where it achieves results competitive with or better than the state-of-the-art.

Acknowledgments

We thank Gabor Angeli, David Chen, Ioannis Konstas, and the reviewers for their helpful comments.

[9] We use an ensemble of five randomly initialized models.

[10] The Chen and Mooney (2008) sBLEU$_G$ result is from Angeli et al. (2010).

Abstract

Language generation from purely semantic representations is a challenging task. This paper addresses generating English from the Abstract Meaning Representation (AMR), consisting of re-entrant graphs whose nodes are concepts and edges are relations. The new method is trained statistically from AMR-annotated English and consists of two major steps: (i) generating an appropriate spanning tree for the AMR, and (ii) applying tree-to-string transducers to generate English. The method relies on discriminative learning and an argument realization model to overcome data sparsity. Initial tests on held-out data show good promise despite the complexity of the task. The system is available open-source as part of JAMR at:
`http://github.com/jflanigan/jamr`

1 Introduction

We consider natural language generation from the Abstract Meaning Representation (AMR; Banarescu et al., 2013). AMR encodes the meaning of a sentence as a rooted, directed, acyclic graph, where concepts are nodes, and edges are relationships among the concepts.

Because AMR models propositional meaning[1] while abstracting away from surface syntactic realizations, and is designed with human annotation in mind, it suggests a separation of (i) engineering the application-specific propositions that need to be communicated about from (ii) general-purpose realization details, modeled by a generator shareable across many applications. The latter is our focus here.

Because any AMR graph has numerous valid realizations, and leaves underspecified many important details—including tense, number, definiteness, whether a concept should be referred to nominally or verbally, and more—transforming an AMR graph into an English sentence is a nontrivial problem.

To our knowledge, our system is the first for generating English from AMR. The approach is a statistical natural language generation (NLG) system, trained discriminatively using sentences in the AMR bank (Banarescu et al., 2013). It first transforms the graph into a tree, then decodes into a string using a weighted tree-to-string transducer and a language model (Graehl and Knight, 2004). The decoder bears a strong similarity to state-of-the-art machine translation systems (Koehn et al., 2007; Dyer et al., 2010), but with a rule extraction approach tailored to the NLG problem.

2 Overview

Generation of English from AMR graphs is accomplished as follows: the input graph is converted to a tree, which is input into the weighted intersection of a tree-to-string transducer (§4) with a language model. The output English sentence is the (approximately) highest-scoring sentence according to a feature-rich discriminatively trained linear model. After discussing notation (§3), we describe our approach in §4. The transducer's rules are extracted from the limited AMR corpus and learned general-

[1] In essence, AMR handles semantic roles, entity types, within-sentence coreference, discourse connectives, modality, negation, and some other phenomena.

Proceedings of NAACL-HLT 2016, pages 731–739,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

izations; they are of four types: **basic rules** (§5), **synthetic rules** created using a specialized model (§6), **abstract rules** (§7), and a small number of **handwritten rules** (§8).

3 Notation and Definitions

AMR graphs are directed, weakly connected graphs with node labels from the set of **concepts** L_N and edge labels from the set of **relations** L_E.

AMR graphs are transformed to eliminate cycles (details in §4); we refer to the resulting tree as a **transducer input representation (TI representation)**. For a node n with label $\mathcal{C}$ and outgoing edges $n \xrightarrow{L_1} n_1, \ldots, n \xrightarrow{L_m} n_m$ sorted lexicographically by L_i (each an element of L_E), the TI representation of the tree rooted at n is denoted:[2]

$$(X\ \mathcal{C}\ (L_1\ T_1) \ldots (L_m\ T_m)) \tag{1}$$

where each T_i is the TI representation of the tree rooted at n_i. See Fig. 1 for an example. A LISP-like textual formatting of the TI representation in Fig. 1 is:

$$(X\ \textit{want-01}\ (\textit{ARG0}\ (X\ \textit{boy}))\ (\textit{ARG1}\ (X\ \textit{ride-01}\ (\textit{ARG0}\ (X\ \textit{bicycle}\ (\textit{mod}\ (X\ \textit{red})))))))$$

To ease notation, we use the function $sort[]$ to lexicographically sort edge labels in a TI representation. Using this function, an equivalent way of representing the TI representation in Eq. 1, if the L_i are unsorted, is:

$$(\mathrm{X}\ \mathcal{C}\ sort[(L_1\ T_1) \ldots (L_m\ T_m)])$$

The TI representation is converted into a word sequence using a tree-to-string transducer. The tree transducer formalism we use is one-state extended linear, non-deleting tree-to-string (**1-xRLNs**) transducers (Huang et al., 2006; Graehl and Knight, 2004).[3]

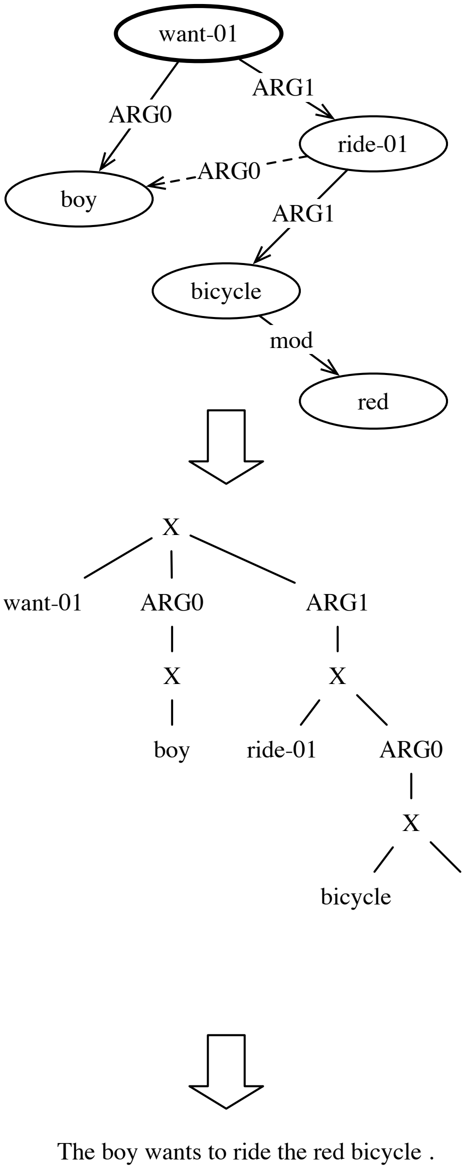

Figure 1: The generation pipeline. An AMR graph (top), with a deleted re-entrancy (dashed), is converted into a transducer input representation (TI representation, middle), which is transduced to a string using a tree-to-string transducer (bottom).

Definition 1. *(From Huang et al., 2006.) A* ***1-xRLNs transducer*** *is a tuple* $(N, \Sigma, W, \mathcal{R})$ *where* N *is the set of nonterminals (relation labels and* X*),* Σ *is the input alphabet (concept labels),* W *is the output alphabet (words), and* $\mathcal{R}$ *is the set of rules. A rule in* $\mathcal{R}$ *is a tuple* (t, s, ϕ) *where:*

1. *t is the LHS tree, whose internal nodes are labeled by nonterminal symbols, and whose frontier nodes are labeled terminals from Σ or variables from a set $\mathcal{X} = \{X_1, X_2, \ldots\}$;*

[2] If there are duplicate child edge labels, then the conversion process is ambiguous and any of the conversions can be used. The ordering ambiguity will be handled later in the tree-transducer rules.

[3] Multiple states would be useful for modeling dependencies in the output, but we do not use them here.

2. *$s \in (\mathcal{X} \cup W)^*$ is the RHS string;*

3. *ϕ is a mapping from $\mathcal{X}$ to nonterminals N.*

A rule is a **purely lexical rule** if it has no variables.

As an example, the tree-to-string transducer rules which produce the output sentence from the TI representation in Fig. 1 are:

$$\begin{gathered}(X \textit{ want-01 } (\textit{ARG0 } X_1)\ (\textit{ARG1 } X_2)) \rightarrow \\ \text{The } X_1 \text{ wants to } X_2 \text{ .} \\ (X \textit{ ride-01 } (\textit{ARG1 } X_1)) \rightarrow \text{ride the } X_1 \\ (X \textit{ bicycle } (\textit{mod } X_1)) \rightarrow X_1 \text{ bicycle} \\ (X \textit{ red}) \rightarrow \text{red} \\ (X \textit{ boy}) \rightarrow \text{boy} \end{gathered} \tag{2}$$

Here, all X_i are mapped by a trivial ϕ to the nonterminal X.

The output string of the transducer is the target projection of the derivation, defined as follows:

Definition 2. *(From Huang et al., 2006.) A* ***derivation*** *d, its* ***source and target projections****, denoted $\mathcal{S}(d)$ and $\mathcal{E}(d)$ respectively, are recursively defined as follows:*

1. *If $r = (t, s, \phi)$ is a purely lexical rule, then $d = r$ is a derivation, where $\mathcal{S}(d) = t$ and $\mathcal{E}(d) = s$;*

2. *If $r = (t, s, \phi)$ is a rule, and d_i is a (sub)-derivation with the root symbol of its source projection maching the corresponding substition node in r, i.e., root$(\mathcal{S}(d_i)) = \phi(x_i)$, then $d = r(d_1, \ldots, d_m)$ is also a derivation, where $\mathcal{S}(d) = [x_i \mapsto \mathcal{S}(d_i)]t$ and $\mathcal{E}(d) = [x_i \mapsto \mathcal{E}(d_i)]s$.*

The notation $[x_i \mapsto y_i]t$ is shorthand for the result of substituting y_i for each x_i in t, where x_i ranges over all variables in t.

The set of all derivations of a target string e with a transducer T is denoted

$$\mathcal{D}(e, T) = \{d \mid \mathcal{E}(d) = e\}$$

where d is a derivation in T.

We use a shorthand notation for the transducer rules that will be useful when discussing rule extraction and synthetic rules. Let f_i be a TI representation. The TI representation has the form

$$f_i = (X\ \mathcal{C}\ (L_1\ T_1) \ldots (L_m\ T_m))$$

where $L_i \in L_E$ and $T_1, \ldots, T_m$ are TI representations.[4] Let $A_1, \ldots A_n \in L_E$. We use

$$(f_i, A_1, \ldots, A_n) \rightarrow r \tag{3}$$

as shorthand for the rule:

$$\begin{gathered}(X\ \mathcal{C}\ \textit{sort}[(L_1\ T_1)\ \ldots\ (L_m\ T_m) \\ (A_1\ X_1)\ \ldots\ (A_n\ X_n)]) \rightarrow r\end{gathered} \tag{4}$$

Note r must contain the variables $X_1 \ldots X_n$. In (3) and (4), argument slots with relation labels A_i have been added as children to the root node of the TI representation f_i.

For example, the shorthand for the transducer rules in (2) is:

$$\begin{gathered}((X \textit{ want-01}), \textit{ARG0}, \textit{ARG1}) \rightarrow \\ \text{The } X_1 \text{ wants to } X_2 \text{ .} \\ ((X \textit{ ride-01}), \textit{ARG1}) \rightarrow \text{ride the } X_1 \\ ((X \textit{ bicycle}), \textit{mod}) \rightarrow X_1 \text{ bicycle} \\ ((X \textit{ red})) \rightarrow \text{red}\end{gathered} \tag{5}$$

4 Generation

To generate a sentence e from an input AMR graph G, a spanning tree G' of G is computed, then transformed into a string using a tree-to-string transducer.

Spanning tree. The choice of the graph G's spanning tree G' could have a big effect on the output, since the transducer's output will always be a projective reordering of the tree's leaves. Our spanning tree results from a breadth-first-search traversal, visiting child nodes in lexicographic order of the relation label (inverse relations are visited last). The edges traversed are included in the tree. This simple heuristic is a baseline which can potentially be improved in future work.

Decoding. Let $T = (N, \Sigma, W, \mathcal{R})$ be a tree-to-string transducer. The output sentence is the highest scoring transduction of G':

$$e = \mathcal{E}\left(\underset{d \in \mathcal{D}(G', T)}{\arg\max}\ \textit{score}(d; \boldsymbol{\theta})\right) \tag{6}$$

[4] If f_i is just a single concept with no children, then $m = 0$ and $f_i = (X\ \mathcal{C})$.

Eq. 6 is solved approximately using the cdec decoder for machine translation (Dyer et al., 2010). The score of the transduction is a linear function (with coefficients $\boldsymbol{\theta}$) of a vector of features including the output sequence's language model log-probability and features associated with the rules in the derivation (denoted $\mathbf{f}$; Table 1):

$$score(d;\boldsymbol{\theta}) = \theta_{LM}\log(p_{LM}(\mathcal{E}(d))) + \sum_{r\in d}\boldsymbol{\theta}^\top\mathbf{f}(r)$$

The feature weights are trained on a development dataset using MERT (Och, 2003).

In the next four sections, we describe the rules extracted and generalized from the training corpus.

5 Inducing Basic Rules

The basic rules, denoted $\mathcal{R}_B$, are extracted from the training AMR data using an algorithm similar to extracting tree transucers from tree-string aligned parallel corpora (Galley et al., 2004). Informally, the rules are extracted from a sentence $\boldsymbol{w} = \langle w_1, \ldots, w_n\rangle$ with AMR graph G as follows:

1. The AMR graph and the sentence are aligned; we use the JAMR aligner from Flanigan et al. (2014), which aligns non-overlapping subgraphs of the graph to spans of words. The subgraphs that JAMR aligns are called **fragments**. In JAMR's aligner, all fragments are trees.

2. G is replaced by its spanning tree by deleting relations that use a variable in the AMR annotation.

3. In the spanning tree, for each node i, we keep track of the word indices $b(i)$ and $e(i)$ in the original sentence that trap all of i's descendants. (This is calculated using a simple bottom-up propagation from the leaves to the root.)

4. For each aligned fragment i, a rule is extracted by taking the subsequence $\langle w_{b(i)} \ldots w_{e(i)}\rangle$ and "punching out" the spans of the child nodes (and their descendants) and replacing them with argument slots.

See Fig. 2 for examples.

More formally, assume the nodes in G are numbered $1, \ldots, N$ and the fragments are numbered $1, \ldots, F$. Let $\text{nodes} : \{1, \ldots, F\} \to 2^{\{1,\ldots,N\}}$ and $\text{root} : \{1, \ldots, F\} \to \{1, \ldots, N\}$ be functions that return the nodes in a fragment and the root of a fragment, respectively, and let $\text{children} : \{1, \ldots, N\} \to 2^{\{1,\ldots,N\}}$ return the child nodes of a node. We consider a node aligned if it belongs to an aligned fragment. Let the span of an aligned node i be denoted by endpoints a_i and a'_i; for unaligned nodes, $a_i = \infty$ and $a'_i = -\infty$ (depicted with superscripts in Fig. 2). The node alignments are propagated by defining $b(\cdot)$ and $e(\cdot)$ recursively, bottom up:

$$b(i) = \min(a_j, \min_{j\in\text{children}(i)} b(j))$$

$$e(i) = \max(a'_j, \max_{j\in\text{children}(i)} e(j))$$

Also define functions $\tilde{b}$ and $\tilde{e}$, from fragment indices to integers, as:

$$\tilde{b}(i) = b(\text{root}(i))$$

$$\tilde{e}(i) = e(\text{root}(i))$$

For fragment i, let $C_i = \text{children}(\text{root}(i)) - \text{nodes}(i)$, which is the children of the fragment's root concept that are not included in the fragment. Let f_i be the TI representation for fragment i.[5] If C_i is empty, then the rule extracted for fragment i is:

$$r_i : (f_i) \to w_{\tilde{b}(i):\tilde{e}(i)} \tag{7}$$

Otherwise, let $m = |C_i|$, and denote the edge labels from $\text{root}(i)$ to elements of C_i as $A_1(i) \ldots A_m(i)$. For $j \in \{1, \ldots, m\}$, let k_j select the elements c_{k_j} of C_i in ascending order of $b(k_j)$. Then the rule extracted for fragment i is:

$$\begin{aligned} r_i : (f_i, A_{k_1}(i), \ldots A_{k_m}(i)) \to \\ w_{\tilde{b}(i):\tilde{b}(k_1)}\, X_1\, w_{\tilde{e}(k_1):\tilde{b}(k_2)}\, X_2 \ldots \\ \ldots w_{\tilde{e}(k_{m-1}):\tilde{b}(k_m)} X_m\, w_{\tilde{e}(k_m):\tilde{e}(i)} \end{aligned} \tag{8}$$

A rule is only extracted if the fragment i is aligned and the child spans do not overlap. Fig. 2 gives an example of a tree annotated with alignments, b and e, and the extracted rules.

[5] I.e., the nodes in fragment i, with the edges between them, represented as a TI representation.

Name	**Description**
Rule	1 for every rule
Basic	1 for basic rules, else 0
Synthetic	1 for synthetic rules, else 0
Abstract	1 for abstract rules, else 0
Handwritten	1 for handwritten rules, else 0
Rule given concept	log(number of times rule extracted / number of times concept observed in training data) (only for basic rules, 0 otherwise)
… without sense	same as above, but with sense tags for concepts removed
Synthetic score	model score for the synthetic rule (only for synthetic rules, 0 otherwise)
Word count	number of words in the rule
Stop word count	number of words not in a stop word list
Bad stop word	number of words in a list of meaning-changing stop words, such as "all, can, could, only, so, too, until, very"
Negation word	number of words in "no, not, n't"

Table 1: Rule features in the transducer. There is also an indicator feature for every handwritten rule.

6 Modeling Synthetic Rules

The synthetic rules, denoted $\mathcal{R}_S(G)$, are created to generalize the basic rules and overcome data sparseness resulting from our relatively small training dataset. Our synthetic rule model considers an AMR graph G and generates a set of rules for each node in G. S synthetic rule's LHS is a TI representation f with argument slots $A_1 \dots A_m$ (this is the same form as the LHS for basic rules). For each node in G, one or more LHS are created (we will discuss this further below), and for each LHS, a set of k-best synthetic rules are produced. The simplest case of a LHS is just a concept and argument slots corresponding to each of its children.

For a given LHS, the synthetic rule model creates a RHS by concatenating together a string in W^* (called a **concept realization** and corresponding to the concept fragment) with strings in $W^*\mathcal{X}W^*$ (called an **argument realization** and corresponding to the argument slots). See the top of Fig. 3 for a synthetic rule with concept and argument realizations highlighted.

Synthetic rules have the form:

$$\begin{aligned} &r : (f, A_1, \dots A_m) \rightarrow \\ &\mathbf{l}_{k_1} X_{k_1} \mathbf{r}_{k_1} \dots \mathbf{l}_{k_c} X_{k_c} \mathbf{r}_{k_c} \; \mathbf{c} \\ &\quad \mathbf{l}_{k_{c+1}} X_{k_{c+1}} \mathbf{r}_{k_{c+1}} \dots \mathbf{l}_{k_m} X_{k_m} \mathbf{r}_{k_m} \end{aligned} \tag{9}$$

where:

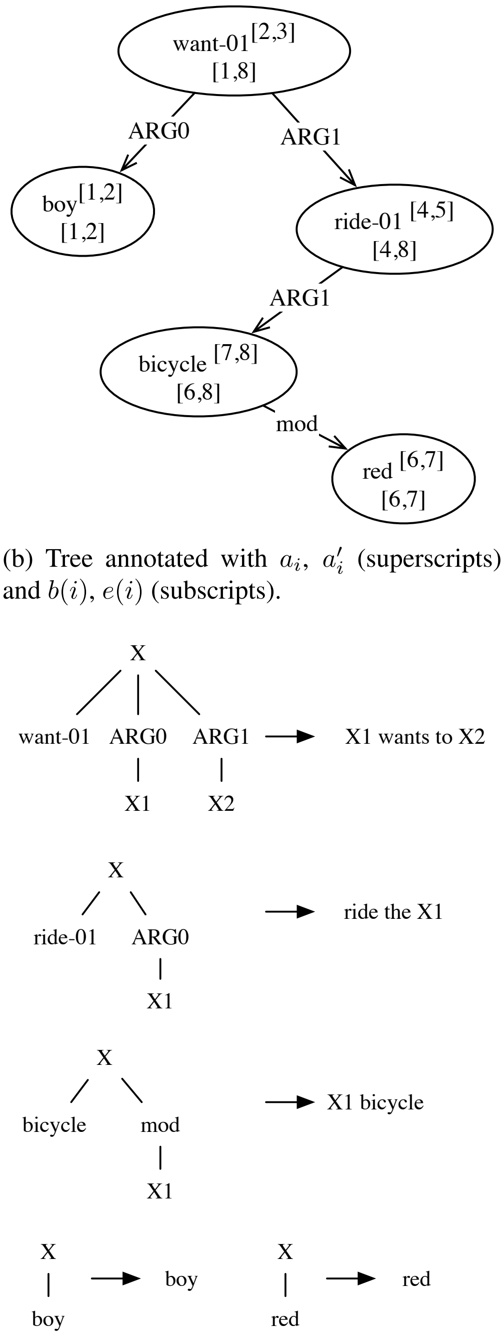
- f is a TI representation.
- Each $A_i \in L_E$.
- $\langle k_1, \dots, k_m \rangle$ is a permutation of $\langle 1, \dots, m \rangle$
- $\mathbf{c} \in W^*$ is the **realization** of TI representation f.
- Each $\mathbf{l}_i, \mathbf{r}_i \in W^*$ and $X_i \in \mathcal{X}$. Let $R_i = \langle \mathbf{l}_i, \mathbf{r}_i \rangle$ denote the **realization of argument** i.
- $c \in [0, m]$ is the position of $\mathbf{c}$ among the realizations of the arguments.

Let $\mathcal{F}$ be the space of all possible TI representations. Synthetic rules make use of three lookup tables (which are partial functions) to provide candidate realizations for concepts and arguments: a table for concept realizations $lex : \mathcal{F} \rightarrow 2^{W^*}$, a table for argument realizations when the argument is on the left $left_{lex} : \mathcal{F} \times L_E \rightarrow 2^{W^*}$, and a table for argument realizations when the argument is on the right $right_{lex} : \mathcal{F} \times L_E \rightarrow 2^{W^*}$. These tables are constructed during basic rule extraction, the details of which are discussed below .

Synthetic rules are selected using a linear model with features $\mathbf{g}$ and coefficients $\boldsymbol{\phi}$, which scores each RHS for a given LHS. For LHS = $(f, A_1, \dots A_m)$, the RHS is specified completely by $\mathbf{c}, c, R_1, \dots, R_m$ and a permutation $k_1, \dots, k_m$. For each node in G, and for each TI representation f in the domain of lex that matches the node, a LHS is created, and a set of K synthetic rules is produced for each $\mathbf{c} \in lex(f)$. The rules produced are the

$_0$ The $_1$ ((boy) $_2$ wants $_3$ to $_4$ (ride $_5$ the $_6$ ((red) $_7$ bicycle))) $_8$

(a) Sentence annotated with indexes, and bracketed according to $b(i)$ and $e(i)$ from the graph in (b).



(b) Tree annotated with a_i, a'_i (superscripts) and $b(i)$, $e(i)$ (subscripts).

(c) Extracted rules.

Figure 2: Example rule extraction from an AMR-annotated sentence.

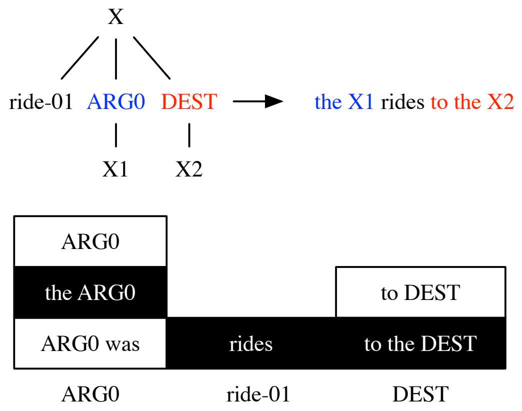


Figure 3: Synthetic rule generation for the rule shown at top. In the rule RHS, the realization for ARG0 is blue, the realization for DEST is red, and the realization for ride-01 is black. For a fixed permutation of the concept and arguments, choosing the argument realizations can be seen as a sequence labeling problem (bottom). The highlighted sequence corresponds to the rule at top.

K-best solutions to:

$$\begin{aligned}\arg\max_{c,k_1\ldots k_m,R_1,\ldots,R_m} \Big(&\sum_{i=1}^{c} \boldsymbol{\psi}^\top \mathbf{g}(R_{k_i}, A_{k_i}, \mathbf{c}, i, c) \\ &+ \boldsymbol{\psi}^\top \mathbf{g}(\langle\epsilon,\epsilon\rangle, *, \mathbf{c}, c+1, c) \\ &+ \sum_{i=c+1}^{m} \boldsymbol{\psi}^\top \mathbf{g}(R_{k_i}, A_{k_i}, \mathbf{c}, i+1, c)\Big) \end{aligned} \tag{10}$$

where the max is over $c \in 0\ldots m$, $k_1,\ldots,k_m$ is any permutation of $1,\ldots,m$, and $R_i \in \mathit{left}_{\mathit{lex}}(A_i)$ for $i < c$ and $R_i \in \mathit{right}_{\mathit{lex}}(A_i)$ for $i > c$. $*$ is used to denote the concept position. ϵ is the empty string.

The best solution to Eq. 10 is found exactly by brute force search over concept position $c \in [0, m+1]$ and the permutation $k_1,\ldots,k_m$. With fixed concept position and permutation, each R_i for the $\arg\max$ is found independently. To obtain the exact K-best solutions, we use dynamic programming with a K-best semiring (Goodman, 1999) to keep track of the K best sequences for each concept position and permutation, and take the best K sequences over all values of c and k..

The synthetic rule model's parameters are estimated using basic rules extracted from the training data. Basic rules are put into the form of Eq. 9 by

Feature name	**Value**

$\mathbf{c}$ + A_i + side + “dist”	$\lvert c - i\rvert$
$\mathbf{c}$ + POS + A_i + side + “dist”	$\lvert c - i\rvert$

Table 2: Synthetic rule model features. POS is the most common part-of-speech tag sequence for $\mathbf{c}$, “dist” is the string “dist”, and side is “L” if $i < c$, “R” otherwise. $+$ denotes string concatenation.

segmenting the RHS into the form

$$\mathbf{l}_1 X_1 \mathbf{r}_1 \ \ldots\ \mathbf{c}\ \ldots\ \mathbf{l}_m X_m \mathbf{r}_m \qquad (11)$$

by choosing $\mathbf{c}, \mathbf{l}_i, \mathbf{r}_i \in W^*$ for $i \in \{1, \ldots, m\}$. An example segmentation is the rule RHS in Fig. 3.

Segmenting the RHS of the basic rules into the form of Eq. 11 is done as follows: $\mathbf{c}$ is the aligned span for f. For the argument realizations, arguments to the left of $\mathbf{c}$ pick up words to their right, and arguments to the right pick up words to their left. Specifically, for $i < c$ (R_i to the left of $\mathbf{c}$ but not next to $\mathbf{c}$), $\mathbf{l}_i$ is empty and $\mathbf{r}_i$ contains all words between a_i and a_{i+1}. For $i = c$ (R_i directly to the left of $\mathbf{c}$), $\mathbf{l}_i$ is empty and $\mathbf{r}_i$ contains all words between a_c and $\mathbf{c}$. For $i > c{+}1$, $\mathbf{l}_i$ contains all words between a_{i-1} and a_i, and for $i = c + 1$, $\mathbf{l}_i$ contains all words between $\mathbf{c}$ and a_i.

The tables for lex, $left_{lex}$, and $right_{lex}$ are populated using the segmented basic rules. For each basic rule extracted from the training corpus and segmented according to the previous paragraph, $f \to \mathbf{c}$ is added to lex, and $A_{k_i} \to \langle \mathbf{l}_i, \mathbf{r}_i \rangle$ is added to $left_{lex}$ for $i \leq c$ and $right_{lex}$ for $i > c$. The permutation k_i is known during extraction in Eq. 8.

The parameters $\boldsymbol{\psi}$ are trained using AdaGrad (Duchi et al., 2011) with the perceptron loss function (Rosenblatt, 1957; Collins, 2002) for 10 iterations over the basic rules. The features $\mathbf{g}$ are listed in Table 2.

Split	Sentences	Tokens
Train	10,000	210,000
Dev.	1,400	29,000
Test	1,400	30,000
MT09	204	5,000

Table 3: Train/dev./test/MT09 split.

7 Abstract Rules

Like the synthetic rules, the abstract rules $\mathcal{R}_A(G)$ generalize the basic rules. However, abstract rules are much simpler generalizations which use part-of-speech (POS) tags to generalize. Abstract rules make use of a **POS abstract rule table**, which is a table listing every combination of the POS of the concept realization, the child arguments' labels, and rule RHS with the concept realization removed and replaced with $*$. This table is populated from the basic rules extracted from the training corpus. An example entry in the table is:

$$(\mathrm{VBD}, \mathrm{ARG0}, \mathrm{DEST}) \rightarrow$$
$$X_1 \ \langle * \rangle \ \text{to the}\ X_2$$

For the LHS $(f, A_1, \ldots A_m)$, an abstract rule is created for each member of $\mathbf{c} \in lex(f)$ and the most common POS tag p for $\mathbf{c}$ by looking up p, $A_1, \ldots A_m$ in the POS abstract rule table, finding the common RHS, and filling in the concept position with $\mathbf{c}$. The set of all such rules is returned.

8 Handwritten Rules

We have handwritten rules for dates, conjunctions, multiple sentences, and the concept have-org-role-91. We also create pass-through rules for concepts by removing sense tags and quotes (for string literals).

9 Experiments

We evaluate on the AMR Annotation Release version 1.0 (LDC2014T12) dataset. We follow the recommended train/dev./test splits, except that we remove MT09 data (204 sentences) from the training data and use it as another test set. Statistics for this dataset and splits are given in Table 3. We use a 5-gram language model trained with KenLM (Heafield et al., 2013) on Gigaword (LDC2011T07), and use 100-best synthetic rules.

We evaluate with the Bleu scoring metric (Papineni et al., 2002) (Table 4). We report single ref-

Rules	Test	MT09
Full	22.1	21.2
Full – basic	22.1	20.9
Full – synthetic	9.1	7.8
Full – abstract	22.0	21.2
Full – handwritten	21.9	20.5

Table 4: Uncased Bleu scores with various types of rules removed from the full system.

erence Bleu for the LCD2014T12 test set, and four-reference Bleu for the MT09 set. We report ablation experiments for different sources of rules. When ablating handwritten rules, we do not ablate pass-through rules.

The full system achieves 22.1 Bleu on the test set, and 21.2 on MT09. Removing the synthetic rules drops the results to 9.1 Bleu on test and 7.8 on MT09. Removing the basic and abstract rules has little impact on the results. This may be because the synthetic rule model already contains much of the information in the basic and abstract rules. Removing the handwritten rules has a slightly larger effect, demonstrating the value of handwritten rules in this statistical system.

10 Related Work

There is a large body of work for statistical and non-statistical NLG from a variety of input representations. Statistical NLG systems have been built for input representations such as HPSG (Nakanishi et al., 2005), LFG (Cahill and Van Genabith, 2006; Hogan et al., 2007), and CCG (White et al., 2007), as well as surface and deep syntax (Belz et al., 2011). The deep syntax representations in Bohnet et al. (2010) and Belz et al. (2011) share similarities with AMR: the representations are graphs with re-entrancies, and have an concept inventory from PropBank (Palmer et al., 2005).

The Nitrogen and Halogen systems (Langkilde and Knight, 1998; Langkilde, 2000) used an input representation that was a precursor to the modern version of AMR, which was also called AMR, although it was not the same representation as Banarescu et al. (2013).

Techniques from statistical machine translation have been applied to the problem of NLG (Wong and Mooney, 2006), and many grammar-based approaches can be formulated as weighted tree-to-string transducers. Jones et al. (2012) developed technology for generation and translation with synchronous hyperedge replacement (SHRG) grammars applied to the GeoQuery corpus (Wong and Mooney, 2006), which in principle could be applied to AMR generation.

11 Conclusion

We have presented a two-stage method for natural language generation from AMR, setting a baseline for future work. We have also demonstrated the importance of modeling argument realization for good performance. Our feature-based, tree-transducer approach can be easily extended with rules and features from other sources, allowing future improvements.

Abstract

We present a corpus of 2,380 natural language queries paired with machine readable formulae that can be executed against world wide geographic data of the OpenStreetMap (OSM) database. We use the corpus to learn an accurate semantic parser that builds the basis of a natural language interface to OSM. Furthermore, we use response-based learning on parser feedback to adapt a statistical machine translation system for multilingual database access to OSM. Our framework allows to map fuzzy natural language expressions such as "nearby", "north of", or "in walking distance" to spatial polygons on an interactive map. Furthermore, it combines syntactic complexity and compositionality with a reasonable lexical variability of queries, making it an interesting new publicly available dataset for research on semantic parsing.

1 Introduction

OpenStreetMap[1] (OSM) is a community-built database of geographic data, containing user-contributed local and up-to-date information about landmarks all over the world. Currently, the database contains over 3 billion data objects and is continuously growing with contributions from over 2 million registered users. While the main API is optimized for editing map data, there exists an API that allow to filter map data based on search criteria such as location, type of objects, or features with which objects are tagged. However, issuing a query that is executable against the OSM database still requires detailed knowledge of database internals, something that cannot be expected from a layman user.

The goal of our work is the development of an interface to OSM that lets a user ask a question in natural language, which is then parsed into a database query that is executable against a web-based filtering tool and returns OSM data on an interactive map. For example, we want a user without detailed knowledge of OSM to be able to ask questions that embrace the "fuzziness" of natural language, for example, "*What are the locations, names and telephone numbers of hotels in Paris with wheelchair access that are close to the station Gare du Nord?*". To find such information one would have to issue a query that requires detailed knowledge of the database and the query language: "*area[name='Paris']→.a;node(area.a) [name='Gare du Nord']→.b;node(around.b:1000) [tourism='hotel'][wheelchair='yes'];out;*". Additionally, we present an adaptation of a statistical machine translation (SMT) system for multilingual access to OSM by response-based learning from parser executability of translated queries.

As a starting point for our natural language interface we built a corpus of 2,380 natural language queries paired with machine readable language (MRL) formulae that we used to extract a semantic parser. We chose to manually creating a corpus of MRLs from which structure and weights of a semantic parser can be learned for three reasons:

Online availability: We want to be able to present the OSM community with a set of sample questions that can be executed and whose database

[1] http://www.openstreetmap.org

Proceedings of NAACL-HLT 2016, pages 740–750,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

query representation can be inspected. We hope it will be inspiring and helpful for OSM users and developers to see how complex geographical facts can be issued as simple natural language queries that are parsed into executable filters on OSM objects.

Accuracy: For an online natural language interface, high accuracy of semantic parsing is crucial. So far, semi-automatic methods of constructing semantic parsers without bootstrapping from MRLs could not reach the accuracy of semantic parsers extracted from manually created MRLs (Wang et al., 2015). The semantic parser we extracted by simple monolingual machine translation (Andreas et al., 2013) achieves a F1 score of 77.3% for answer retrieval on our data.

Complexity: Our corpus adds a new and complex domain for research on semantic parsing: Compared to existing corpora such as GEOQUERY (Wong and Mooney, 2006) or FREE917 (Cai and Yates, 2013), our corpus combines the compositionality and syntactic complexity of the former corpus with a lexical variation that constitutes a healthy middle ground between closed and open domains.

Our contributions in this paper are threefold: First, we introduce OSM as a new knowledge base that has not, to the best of our knowledge, been used for question answering, and offer a new corpus to the research community. Second, we show that a parser read off the corpus achieves promising parsing accuracy and can be used to adapt SMT to multilingual database access. Third, our work builds the basis of a natural language interface to OSM that will be enabling for interesting directions of future research, e.g., response-based learning to improve semantic parsing and multilingual database access.

2 Related Work

The common approach to semantic parsing is a manual annotation of a corpus with natural language utterances and machine readable formulae which are then used to learn the structure and weights of a semantic parser. Corpora that have been used for training and testing a number of semantic parsers are GEOQUERY (Zelle and Mooney, 1996; Kate et al., 2005) and FREE917 (Cai and Yates, 2013). While GEOQUERY queries are restricted to the closed domain of US geography, the structural complexity of the questions is higher than for FREE917, which focuses on open domain queries. Seminal work on building semantic parsers from the GEOQUERY meaning representations are Zettlemoyer and Collins (2005) or Wong and Mooney (2006). Later approaches try to learn semantic parsers from question-answer pairs only, for example, Liang et al. (2009) for GEOQUERY, or Kwiatkowski et al. (2013) or Berant et al. (2013) for FREE917. Newer research attempts to close the gap between lexical variability and structural complexity (Vlachos and Clark, 2014; Artzi et al., 2015; Pasupat and Liang, 2015), however, answer retrieval accuracy is low if semantic parsers cannot be bootstrapped from a corpus of queries and MRLs (Wang et al., 2015; Pasupat and Liang, 2015).

# users	2,389,374
# objects	3,464,399,738
# nodes	3,139,787,926
# ways	320,775,580
# relations	3,836,232
# tags	1,259,132,137
# distinct tags	76,204,309
# distinct keys	57,159

Table 1: Statistics of OSM as of December 14th, 2015

Our approach treats semantic parsing as a monolingual machine translation problem in which natural language is translated into the machine readable language. This approach is convenient because one can make use of the efficient and robust decoders that are freely available for SMT. Despite the simplicity of the approach, Andreas et al. (2013) have shown that highly accurate semantic parsers can be trained from annotated data.

OSM has previously been used by Boye et al. (2014) for pedestrian routing using a dialogue system, however, no details on semantic parsing and no resource are provided.

Our SMT tuning experiment builds on the work of Riezler et al. (2014) and Haas and Riezler (2015) who applied response-based learning for SMT to the GEOQUERY and FREE917 domains, respectively.

The way consists of several nodes that together span the outline of the relevant building. Clicking on the way gives all the key-value pairs registered for this way in the database.

3 OpenStreetMap

OpenStreetMap is a freely available map of the world, annotated by volunteers and editable by anyone. Entered GPS points, referred to as *nodes*, constitute the basis of the database and currently amount to over 3 billion examples (see Figure 1 for more statistics on the OSM database). Nodes can be given tags which are key-value pairs, such as "*amenity=restaurant*", "*highway=living_street*" or "*abandoned:tourism=theme_park*". In total there are over 76 million distinct tags which are based on 57,159 unique keys. Nodes may be grouped together to form *ways*. Ways can be given their own set of tags and are for example used to display roads or building outlines. Both nodes and ways may be joined to be part of a *relation* which is used to model the interdependence of several objects. A relation can for example be employed to delineate bus lines or to define administrative boundaries. As relations can also be part of other relations, one can even express hierarchical structures.

The Overpass API[2] can be used to query the database made up of the aforementioned nodes, ways and relations. It can efficiently extract the correct subset of database objects that satisfy the entered constraints. The following constraints are most relevant for our corpus creation later on:

- The simplest constraints require the database objects to have certain keys or key-value pairs. For example to search for hotels, one would use "*node[tourism='hotel'];out;*".
- Overpass can find ways and relations that form a filled polygon. Based on this, Overpass is able to search for database objects in only the specified *area*, such as a town or country. To search for hotels in Paris, the corresponding Overpass would be: "*area[name='Paris']→.a; node(area.a)[tourism='hotel'];out;*".
- The operator called *around* allows the user to search for a database object in a certain radius around another object. For hotels in a radius of 1,000 metres around Gare du Nord in Paris, the Overpass query would be: "*area[name='Paris']→.a; node(area.a)[name='Gare du Nord']→.b; node(around.b:1000)[tourism='hotel'];out;*".

Further tools related to OSM are Overpass turbo[3], a web interface that allows users to run Overpass queries, and the Overpass turbo Query Wizard, which supports querying by predefined human readable shorthands to executable Overpass queries. A screenshot of the map and an example database entry for an Overpass query is shown in Figure 1.

4 Query Creation

Since even the Overpass Query Wizard requires users to be familiar with the tag set of OSM key-value pairs, it unusable for users with only casual or no knowledge of OSM's internal structure. Nonetheless, we could use parts of the user query log to formulate natural language questions. For example users would enter the query "*(node["abandoned:tourism"="theme_park"]; way["abandoned:tourism"="theme_park"]; rela-*

[2] http://wiki.openstreetmap.org/wiki/Overpass_API

[3] http://overpass-turbo.eu/

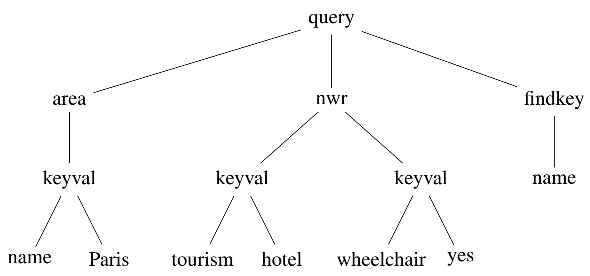

Figure 2: The question “*Which hotels in Paris have wheelchair access?*” with MRL “*query(area(keyval(name,'Paris')), nwr(keyval(tourism,'hotel'),keyval(wheelchair,'yes')), findkey(name))*” can be presented as a tree. A preorder traversal gives: “*query@3 area@1 keyval@2 name@0 Paris@s nwr@2 keyval@2 tourism@0 hotel@s keyval@2 wheelchair@0 yes@s findkey@1 name@0*”

tion[”abandoned:tourism”=”theme_park”];);out;” which we then extended to “When did the abandoned theme parks close?” and added the corresponding MRL “*query(nwr(keyval('abandoned:tourism','theme_park')),qtype(findkey('end_date')))*”. Additionally we often had to provide a reference point for the queries, as users usually searched their current map cut-out and while all abandoned theme parks in the world is a short list, all restaurants for example would be too many to realistically handle. Thus we fell back to 3 chosen cities in those cases, Heidelberg, Paris and Edinburgh. In sum, most of the queries are based on OSM user queries that were issued to the Overpass turbo Query Wizard and shared among users; others were written by the first author with an utilization of the underlying Overpass API in mind.

5 Machine Readable Language (MRL)

Our corpus creation process was guided by the goal to pair a diverse range of questions with machine readable language (MRL) formulae. These should include the most important OSM tags so that the parser is able to learn a mapping between these tags and the different corresponding natural language expressions.

To answer concise questions without including superfluous details, the MRL needs to be able to extract more specific information instead of a list of all database objects as in the underlying Overpass result. The MRL thus wraps around Overpass and contains additional indicators about what information should be returned from a database object, for example just its GPS coordinates, or a website address, or the number of returned objects.

Given the above consideration, we define our MRL as a variable free language that focuses on practicality and speed, akin in style to the GEOQUERY MRL language. It is unambiguously defined via a context-free grammar (CFG) so that one can always ascertain whether or not a formula is valid. While the written form of the MRL is a bracket structure, this structure can easily be encoded as a tree by taking a pre-order traversal which makes it easy and efficient to work with. An example CFG tree for a MRL is given in Figure 2. In the following, we list the operators of our MRL.

Query Operator. A single database query is encoded in the operator **query()** which will hold the Overpass query as well as further specifications about what kind of answer should be retrieved. A few operators are directly derived from Overpass, merely re-written as a tree structure. As such OSM key-value pairs are encoded using the operator **keyval()** which takes 2 arguments, the first being the *key* and the second the *value*. The area operator from Overpass directly translates to the operator **area()**. Nodes, ways and relations are grouped together under the **nwr()** operator which will supply the union of the query run with the 3 types in turn. This is necessary because often buildings, e.g. schools, may be represented as any of the 3 types depending on how specific the annotator wanted to be. Both *area()* and *nwr()* then take one ore more **keyval()** arguments. If *area()* and *nwr()* appear as siblings in the tree (for an example see Figure 2), then only the objects that lie within *area()* will be searched to determine if they fulfil the *nwr()* constraints.

Meta Operators. In order to add specificity beyond the lists returned by Overpass, each MRL formula needs one or more of the following meta parameters to be valid; the meta parameters in turn are held by the operator **qtype()**. The operator **latlong()** retrieves the geographical coordinates of the database objects. For a node this is simply its recorded GPS point. In the case of ways and relations the centre of the associated nodes is calcu-

</node>
```

Figure 3: Mapping of natural language question to MRL (via semantic parsing) and to structured database query, returning a set of database objects (via Overpass API) which may be represented as XML documents, from which the correct answer is retrieved.

lated. **findkey()** searches for a specific key (such as *name* or *website*) in the database objects of the retrieved set and returns its value. **count()** simply counts the number of elements in the retrieved set. **least()** checks for the existence of at least x elements in the returned set, whereas x is defined in a second meta function **topx()** which returns the top x elements of a set. *topx()* may also be used in conjunction with *latlong()* and *findkey()*.

Additionally the user can ask for the distance between two points of interests. This operator, **dist()** needs to be supplied with two separate *query()* operators using the *latlong()* meta operator, and can return the value in either kilometres or miles (*unit(mi/km)*). In conjunction with that the user can inquire if the point of interest is still within walking distance (*for("walk")*), or if a car is recommended (*for("car")*).

Fuzzy Language Operators. Fuzzy terms such as "nearby", "within walking distance" and "closest" can be modelled by making use of the *around* operator from Overpass. **around()** searches for points of interest (supplied via **search()**) in the vicinity of another (supplied using **center()**). If only the x closest points are to be returned, *topx()* can be added. The radius is defined via *dist()*. This information can occur either explicitly (*"No further than 200m away"*), or implicitly (*"Give me a cinema with a car park close by"* implies that the car park should be in walking distance). For the implicit case 4 options are available: walking distance, within town distance, out of town distance, and day trip distance. Choosing the appropriate distance in the implicit case is of particular difficulty because often a term such as "*close by*" implies a different distance depending on the surrounding context. For example, "*a close by airport*" may imply day trip distance, while "*a close by restaurant*" at most implies a just out of town distance (see also Minock and Mollevik (2013)).

Another set of fuzzy terms are the cardinal directions, either within an *area()* operator ("*Where are hotels in the north of Paris?*"), or beyond an *nwr()* operator ("*Where are hotels north of Gare du Nord in Paris?*"). The correct operator, **north()**, **east()**, **south()** or **west()**, follows after *query()*, if present.

Further Operators. Some further operators were needed to model the MRL formula for complex questions. **and()** is used when the user asks for two different nuggets of information (*"Where is the closest bakery and the closest butcher?"* or *"Give me the website and name of ..."*). **or()** is used to create unions, as for example, needed in a sentence such as *"Give me the closest bar or restaurant."* "*" can be used as a wild card in a value position, e.g. *['historic'=*]* will returned any historic objects, be it a castle, a monument or something else. **nodup()** returns a set with no duplicates. This is, for example, needed in *"Which cuisines are there?"*.

Figure 5: Corpus statistics of the corpora NLMAPS, GEOQUERY, FREE917. NT stands for non-terminal and FRES is the Flesch Reading Ease Score (Flesch, 1974).

The complete pipeline process leading from natural language question to an appropriate answer can be seen in Figure 3. The natural language question is first translated by the semantic parser into a MRL, from which the Overpass query is deterministically extracted, while keeping a list of the relevant further indicators. These indicators then operate on the database objects returned by the Overpass query to form the answer.

6 Corpus Statistics

Our corpus, called NLMAPS, is more than twice as large as GEOQUERY or FREE917. In the following, we present a comparison of the lexical and syntactic complexity of the three corpora. All statistics reported in Figure 5 are normalized by the number of sentences.

Lexically, NLMAPS is more diverse than GEOQUERY, as can be seen by the average number of types, but less so compared to FREE917 due to the fact that the OSM database is still a somewhat more closed domain compared to Freebase. Syntactically however, NLMAPS is with 3 more words on average per sentence more complex than GEOQUERY and FREE917, which have nearly identical sentence length. As a further test, we ran the Stanford Parser (Klein and Manning, 2003) on the queries to generate syntactic parse trees. We then counted the number of non-terminals required to produce the parse tree. This result reaffirms what the simpler sentence length already reported: the language in NLMAPS is more complex than in the other two corpora, which have identical complexity.

In Figure 4 we report the number of operators and values needed to construct the different gold formulae. While there are a few questions that need a formula shorter than 10, the vast majority needs a length of around 15, followed by a long tail of sizes with decreasing frequency of up to 36. The fact that many of the gold formulae are in fact longer than the average sentence length shows that the questions are far from trivial and require elaborate database queries to be answered. The last measure we report is the Flesch Reading Ease Score (Flesch, 1974) which is usually used to asses the text difficulty for readers. In this score, a lower number indicates a harder text. NLMAPS receives the lowest number, indicating it as the most complex corpus.

Overall we can infer that NLMAPS provides a good balance between lexical diversity as well as stability for a machine learning algorithm to learn. With regards to syntactic complexity, NLMAPS easily supersedes the other two corpora. We conclude this section with a few example sentences:

```
What are the websites and
names of the museums or art
centers in walking distance of
the Eiffel Tower?
```

```
What are the opening times of
the Sainsbury's Local closest
to the Edinburgh Waverley in
Edinburgh?
```

```
What are the peaks in the
north of Languedoc-Roussillon
called and how high are they?
```

7 Semantic Parsing

We treat semantic parsing as an SMT problem, using our own implementation of the framework in-

		Precision	Recall	F1
1	+intersect +stem +cdec	84.69	62.42	71.87
2	+intersect +stem +cdec +sparse	84.40	65.8	73.95^{1}
3	+intersect +stem +cdec +pass +cfg	**89.45**	65.19	75.41^{1}
4	+intersect +stem +cdec +sparse +pass +cfg	89.04	**68.3**	$\mathbf{77.3}^{1,2,3}$

Table 2: Semantic Parsing results on NLMAPS (split 1500/880 for train/test set) using different settings. Tuning was carried out on the training set. In the case of MERT tuning, the results are averaged over 3 runs due to the randomness MERT introduces. Best results are indicated in **bold face**. Statistical significance in terms of F1 of system differences at $p < 0.05$ are indicated by experiment number in superscript.

troduced by Andreas et al. (2013) who have shown that this approach achieves state-of-the-art performance on GEOQUERY. In this framework it is crucial that the MRL can be represented as a tree. A pre-order tree traversal can give a unique string in which each node is a word (i.e. surrounded by white space). Once the MRL has been converted into such a structure (for an example see Figure 2), a word aligner, here GIZA++ (Och and Ney, 2003), can be used to generate word-to-word alignments in both translation directions which can then be combined with various heuristics (Koehn, 2010, Chapter 4.5.3). From the next step onwards we use the freely available SMT framework CDEC (Dyer et al., 2010). After building a language model for the target (MRL) side, SCFG grammars for hierarchical phrases for tuning and testing were extracted. Experiments in n-gram order showed that 5-gram models are sufficient for language modelling.

At test time, a critical issue is the fact that monolingual SMT does not ensure that the translations are valid MRL formulae. Thus a k-best list (sorted from most probable to least) is generated which needs to be traversed until a valid formula is found. Experimentation with the k-best list size showed that 100 is a good trade-off between speed and performance. A bigger size of k might enable us to find a valid (and correct) formula further down the k-best, however, we verified experimentally that in most cases no option in the extended k-best list contained a valid formula either.

Once a valid formula is found, it is executed against a database and the resulting answer is compared to the answer the gold formula provides. Only exact matches are considered correct. We report *Precision*, *Recall* and *F1-score* to evaluate the semantic parser.[4]

Table 2 shows experimental results for different settings of semantic parsing on NLMAPS. Statistical significance of system differences in terms of F1 was assessed by an Approximate Randomization test (Noreen, 1989). For the word-alignment step, we found that the choice of the strategy for combining word alignments from both translation directions is crucial to the semantic parser's performance. The *intersect* strategy performs significantly better than any other, suggesting that high precision alignments are very important when using a monolingual SMT approach for semantic parsing. Further, stemming the words on the NL side is also always significantly better than not doing so. In a next step we compare the use of dense features (Dyer et al., 2010) in conjunction with the tuning algorithm MERT (Och, 2003) and additional sparse features (Simianer et al., 2012). As MERT cannot handle such a large amount of features, we paired the sparse features with the tuning algorithm MIRA (Crammer and Singer, 2003). Because MERT suffers from optimizer instability (Clark et al., 2011) due to random initialization, the experiments 1 & 3 in Table 2 report the average result based on 3 different MERT runs. Another variation we tested is the use of the NLMAPS CFG to check whether or not a translation is a valid MRL, instead of a quicker check that only ensures that a translation can be parsed as a tree. This variation is indicated with "+*cfg*". Lastly, while the system was able to directly learn the mapping of named entities previously seen dur-

[4] *Recall* is defined as the percentage of correct answers out of all examples, *Precision* the percentage of correct answers out of all examples with an answer, and *F1-score* the harmonic mean between the two aforementioned.

ing training, this is not possible for new named entities. These unknown named entities will automatically be passed through by the SMT system but they will be missing the marker of where in the tree they belong. As named entities always have to be in a value position in the corresponding MRL and values are always leave nodes, this can easily be rectified by appending the marker for a leave node to passed through words ("+*pass*"). Of course, when stemming is used, one has to also keep track of the unstemmed form. The decision of which route to go with named entities is left up to the SMT system.

Overall, the modules tested in Table 2 add up to a total F1 score of 77.3%. Given the complexity of our corpus and the simplicity of the semantic parser, this is a promising result.

8 Multilingual Parsing

Riezler et al. (2014) and Haas and Riezler (2015) have shown how to use semantic parsers for GEOQUERY and FREE917, respectively, to adapt an SMT system for multilingual database access. In this section we show that our semantic parser can be used for response-based learning of an SMT system to allow multilingual natural language queries to OSM, here German. To this end, a SMT system first translates the question from German to English and then the translation is passed to the semantic parser to answer the question. The SMT system uses the feedback from the parser, i.e. the knowledge whether or not the question could be parsed to the correct answer, to improve translations.

More formally, assume an SMT system with a joint feature representation $\phi(x, y)$ for input sentences x and output translations $y \in Y(x)$, that uses a linear scoring function to predict the most likely translation $\hat{y} = \arg\max_{y \in Y(x)} w^\top \phi(x, y)$. We define a cost function $\mathrm{c}(y^{(i)}, y) = (1 - \mathrm{BLEU}(y^{(i)}, y))$ based on sentence-wise BLEU (Nakov et al., 2012) and a binary feedback function $\mathrm{e}(y) \in \{1, 0\}$. The binary function evaluates to 1 if and only if a natural language's semantic parse receives the same answer as the corresponding gold parse. Training is performed by moving w closer to a *hope* translation y^+ while pushing it away from a *fear* translation y^-. Both y^+ and y^- have a high model score. y^+ incorporates the *hope* for a best translation to have a low cost and positive feedback. y^- is *feared* due to a high cost and negative feedback, thus we define:

$$y^+ = \arg\max_{y \in Y(x^{(i)}):\mathrm{e}(y)=1} \Big(\mathrm{s}(x^{(i)}, y; w) - \mathrm{c}(y^{(i)}, y)\Big),$$

$$y^- = \arg\max_{y \in Y(x^{(i)}):\mathrm{e}(y)=0} \Big(\mathrm{s}(x^{(i)}, y; w) + \mathrm{c}(y^{(i)}, y)\Big).$$

The algorithm, called REBOL (Riezler et al., 2014), proceeds by iterating over the training data, predicting the top translation $\hat{y}$, and receiving feedback for this translation from a semantic parser. If the feedback is positive, $\hat{y}$ is set equal to y^+, otherwise to y^-. The algorithm then searches the k-best list for the missing y^- or y^+, respectively, and performs an update that adds the feature vector of y^+ onto w, and subtracts the feature vector of y^-.

For our experiment, the NLMAPS questions were translated by the first author into German. As parser we chose to use number 3 (+intersect +stem +cdec +pass +cfg) from Table 2, deciding against the use of sparse features due speed reasons. The CDEC (Dyer et al., 2010) decoder was used for machine translation from German to English. Here we employ its standard features plus additional sparse features[5] and the COMMON CRAWL[6] (Smith et al., 2013) corpus to built the baseline SMT system.

REBOL is compared to a baseline system without discriminative training (CDEC) and to a stochastic (sub)gradient descent variant of RAMPION (Gimpel and Smith, 2012). Both baseline systems do not make use of the feedback from the semantic parser. While both REBOL and RAMPION assume the availability of both a reference translation and a gold parse, response-based learning can also succeed without any access to reference translations or even to gold standard parses. Riezler et al. (2014) introduced an algorithm, called EXEC, that only relies on task-based feedback and omits the cost function based on sentence-wise BLEU. Collecting real world data for this algorithm is realistic for an online interface to OSM since it only requires a user to pose a question and then indicate if it was answered to their satisfaction.

method	P	R	F1	BLEU
1cdec	67.8	24.89	36.41	38.3
2Exec	75.2	31.36	44.27^{1}	40.85^{1}
3Rampion	78.21	38.75	$51.82^{1,2}$	$51.82^{1,2}$
4Rebol	80.76	41.02	**54.41**^{1,2,3}	**51.88**^{1,2}

Table 3: SMT results on NLmaps, reporting Precision (P), Recall (R) and their harmonic mean (F1). Best results are indicated in **bold face**. Statistical significance of result differences at $p < 0.05$ are indicated by algorithm number in superscript.

While we do report BLEU (Papineni et al., 2002), the primary goal in our work is to achieve highest possible F1 score. This is vital because our ultimate aim is to give users asking German questions the correct answer, whereas the English translation from which BLEU is be calculated is only an intermediate result that is irrelevant for the task goal.

To test significance of F1 and BLEU, we again use Approximate Randomization. Before training, we split of 200 sentences from the training set to use as held out data (dev set). Rampion, Rebol and Exec ran for 50 epochs and then the dev set was used to pinpoint the best epoch for each algorithm. In the case of Rampion, the best epoch equalled the epoch in which the dev set achieved the highest BLEU score (epoch 20). For Rebol and Exec, on the other hand, this decision was made by the highest F1 score on the dev set (epoch 40 and 6 respectively). The learning rate for both algorithms was set on a per feature basis using Adadelta (Zeiler, 2012).

As shown in Table 3, Rebol can significantly improve in terms of F1 and BLEU over the cdec baseline. It is also significantly better than Rampion in terms of F1 while being able to keep up in BLEU. Should reference translations not be available, Exec shows that it can still significantly outperform the cdec baseline, it however cannot keep up with Rebol or Rampion which have a more detailed supervision signal available to them.

9 Conclusion

We presented an approach to query the OSM database for complex geographical facts via natural language questions. The key technology is a semantic parser that is trained in supervised fashion from a large set of questions annotated with executable MRLs. Our corpus is larger than previous annotated question-answer corpora, while including a wide variety of challenging questions.

Terms such as "*nearby*", "*in the south of*", "*within x miles*" are particularly well-suited for a natural language query interface that allows to map the fuzziness of natural language to flexible spatial polygons. Our corpus is publicly available[7] and a website where users can query OSM using natural language is under development[8]. This in turn will give us new and more realistic data which we can use to extend the corpus and to improve the semantic parser.

An online version of our natural language interface to OSM will be enabling for various interesting directions of future research: Besides the possibility to gain new and more realistic data which we can use to extend the corpus, the semantic parser can be improved itself by response-based learning, where supervision signals can be extracted from the executed parses of new user queries against the database (Kwiatowski et al. (2013), Berant et al. (2013), Goldwasser and Roth (2013), *inter alia*). In a similar way, multilingual database access can be enhanced by adapting an SMT system by response-based learning, using executability of a parse of a translated query as supervision signal (Riezler et al., 2014). Both cases of response-based learning only require a user who issues a query and gives feedback on whether the proposed OSM object was the intended answer. Such an interactive scenario enables further research on alternative algorithms for learning from partial feedback (Szepesvári, 2009; Bubeck and Cesa-Bianchi, 2012).

Acknowledgments

We would like to thank the OSM developers Roland Olbricht and Martin Raifer for their support and for contributing a dataset of shared user queries. The research reported in this paper was supported in part by DFG grant RI-2221/2-1 "Grounding Statistical Machine Translation in Perception and Action".

Abstract

We propose a framework for devising empirically testable algorithms for bridging the communication gap between humans and robots. We instantiate our framework in the context of a problem setting in which humans give instructions to robots using unrestricted natural language commands, with instruction sequences being subservient to building complex goal configurations in a blocks world. We show how one can collect meaningful training data and we propose three neural architectures for interpreting contextually grounded natural language commands. The proposed architectures allow us to correctly understand/ground the blocks that the robot should move when instructed by a human who uses unrestricted language. The architectures have more difficulty in correctly understanding/grounding the spatial relations required to place blocks correctly, especially when the blocks are not easily identifiable.

1 Motivation

Much of the progress in Natural Language Processing can be attributed to defining problems of broad interest (e.g. parsing and machine translation); collecting or creating publicly available corpora that encode meaningful ⟨input, output⟩ samples (e.g. Penn TreeBank and LDC Parallel Corpora); and devising simple, objective and computable evaluation metrics to automatically assess the performance of algorithms designed to solve the problems of interest, independent of the approach or technology used (e.g. ParseEval and Bleu).

As robots become increasingly ubiquituous, we need to learn to interact with them intelligently, in the same manner we interact with members of our own species. To make rapid progress in this area, we propose to use an intellectual framework that has the same ingredients that have transformed our field: appealing science problem definitions; publicly available datasets; and easily computable, objective evaluation metrics.

In this paper, we study the problem of Human-Robot Natural Language Communication in a setting inspired by a traditional AI problem – blocks world (Winograd, 1972). After reviewing previous work (Section 2), we propose a novel Human-Robot Communication Problem that is testable empirically (Section 3.1) and we describe the publicly available datasets (Section 3.2) and evaluation metric that we devised to support our research (Section 6). We then introduce a set of algorithms for solving our problem and we evaluate their performance both objectively and subjectively (Sections 4–8).

2 Previous work

Most research on Human-Robot Interaction (Klingspor et al., 1997; Thompson et al., 1993; Mavridis, 2015) bridges the gap between natural language commands and the physical world via a set of pre-defined templates characterized by a small vocabulary and grammar. Progress on language in this area has largely focused on grounding visual attributes (Kollar et al., 2013; Matuszek et al., 2014) and on learning spatial relations and actions for small vocabularies with hard-coded abstract concepts (Steels and Vogt, 1997; Roy, 2002;

Proceedings of NAACL-HLT 2016, pages 751–761,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

Guadarrama et al., 2013). Language is sometimes grounded into simple actions (MacMahon et al., 2006; Yu and Siskind, 2013) but the data, while multimodal, is relatively formulaic, the vocabularies are small, and the grammar is constrained. Although robots have significantly increased their autonomy and ability to plan, that has not resulted, to date, in more flexible human-robot communication protocols that would enable robots to understand free-er form language and/or acquire simple and complex concepts via human-robot interactions.

Recently the connection between less formulaic language and simple actions has been explored successfully in the context of simulated worlds (Branavan et al., 2009; Goldwasser and Roth, 2011; Branavan et al., 2011; Artzi and Zettlemoyer, 2013; Andreas and Klein, 2015) and videos (Malmaud et al., 2015; Venugopalan et al., 2015). However, to our knowledge, there is no body of work that focuses on understanding the relation between natural language and complex actions and goals or on explaining flexibly the actions taken by a robot in natural language utterances. As observed by Klingspor (1997), there is a big gap between the formulaic interactions that are typical of state-of-the-art human-robot communications and human-human interactions, which are more abstract.

3 A Framework for Human-Robot Natural Language Communication Research

3.1 Problem Definition

Problem-Solution Sequences. In order to build models that understand the ambiguous and complex language used by people when communicating to solve a task, we adopt the Problem-Solution Sequence (PSS) framework proposed by Bisk et al. (2016). Problem-Solution Sequences provide high and low level descriptions of actions in service of a goal; more specifically, they are sequences of images that encode what a robot might see as it goes about accomplishing a goal. In this paper, we work with PSSs specific to a simple world that has blocks placed on a table and a robot that can visually inspect the table and manipulate the blocks on it.

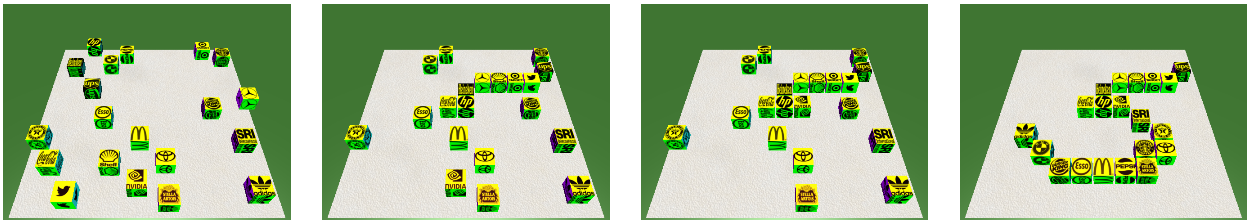
Figure 1 shows four intermediate block configurations of a PSS the robot observes as it transforms the initial state block configuration (random) into the final one (the number five). The PSS makes explicit the natural language instructions that a human may give to a robot in order to transform the configuration in an Image$_i$ into the configuration in an Image$_j$ - the two configurations may correspond to one robot action (for adjacent states in the sequence) or to a sequence of robot actions (for non-adjacent states). To account for language variance, each simple action or sequence of actions is associated with a set of alternative natural language instructions. For example, nine descriptions of the same action ($t_8 \rightarrow t_9$) from Figure 1 are shown in Table 1.

1 coca cola , hp , nvidia .
2 nvidia , to the right of hp
3 place the nvidia block east of the hp block .
4 move the nvidia block to the right of the hp block
5 place the nvidia block to the east of the hp block .
6 move the nvidia block directly to the right of the hp block .
7 move the nvidia block just to the right of the hp block in line with the mercedes block .
8 put the nvidia block on the right end of the row of blocks that includes the coca cola and hp blocks .
9 put the nvidia block on the same row as the coca cola block , in the first open space to the right of the coca cola block .

Table 1: Examples of the type of natural language instructions seen in our corpus that verbalize the action needed to transition from t_8 to t_9 in Figure 1.

We see some structural similarity between the utterances, but they require different amounts of inference to understand, use different (potentially synonymous) language, and choose different blocks as contextual anchors for proper interpretation. Despite this, they each describe the action with equal precision. The natural language instructions encode implicitly partial or full descriptions of the world ("in line with" or "first open space").

Simple Instruction/Command Understanding. The problem definition we focus on in this paper is that of simple instruction/command understanding: given a state of the world, Image$_i$, and a human-like natural language command, C, we would like to infer the target world, Image$_{i+1}$, that a robot should construct if it understood C. If we assume, for simplicity, that only one block can be moved at a time, command understanding has a straightforward se-



t_0: Initial state t_8 t_9 t_{20}: Final drawing

Figure 1: Above are four states in a 20-action sequence for drawing the digit 5. The world state can be encoded for the learner as IDs and locations or raw images. Annotations are provided between every adjacent state (See Table 1) or between sequences (e.g. $t_8 \rightarrow t_{20}$: *Create a four-line diagonal which moves to the southeast. Starting with Heineken ...*) to describe multi-action plans.

mantics: understanding a command amounts to inferring that the block at location $(x, y, z)_S$ needs to be moved and the location $(x, y, z)_T$ where the block needs to be moved. The rest of the blocks are not affected by the move.

3.2 Data

We follow Bisk et al. (2016)'s methodology and collect PSSs specific to both goal oriented and random actions.[1] Our discussion focuses primarily on the goal oriented data, wherein blocks are used to draw configurations/scenes that look like the digits zero through nine. To create these abstract drawings in a diverse and natural manner, configurations are derived from actual hand-written digits in the MNIST corpus (LeCun et al., 1998). These digits provide an easily recognizable target goal when arranging blocks. To create a sequence of actions that draws out these digits, the MNIST images were sharpened and down-sampled until each had at most 20 active pixels which could be replaced with blocks. The blocks were either decorated with brands (as shown above) or with the numbers one through twenty.

These block configurations were placed into a virtual world and scrambled until the board's initial state was unrecognizable. This was achieved by randomly relocating adjacent blocks to new locations in the world. Once every block had been placed at a new location, the world appears random (for example, Image$_0$ in Figure 1), but when these random actions are played in reverse, the sequence of moves recreates the digit in a deliberate and ordered manner. Each of these actions are then shown to Amazon Mechanical Turkers. To ensure that our robot learns to understand human-like commands, turkers were asked to provide instructions they would give to another person in order to transform a block configuration corresponding to a first image (t_i) into a second block configuration corresponding to an image (t_{i+1}). Each image pair was presented to three turkers, each of whom had to provide three different instructions for achieving the same goal.

A total of 100 digits sequences were annotated (10 drawings for every digits). The sequences were split so that half were decorated with numbers and half with logos. The sides of every block have a different color and a logo or number is overlayed on every side. Eight sequences for every digit are included in Training, one for development and two for testing. Overall, the training data has 11,871 commands, while the development and test corpora each have 1,719 and 3,177 commands, respectively.

For each learning example, we thus have access to an input that consists of an Image$_i$ (what the robot sees), the (x, y, z) coordinates of each block in Image$_i$ (a discrete representation of the world corresponding to the image), and a natural language command that a robot needs to understand in order to operate on the world in Image$_i$. The output consists of an Image$_{i+1}$ (what the robot should build) and the (x, y, z) coordinates of each block in Image$_{i+1}$.

The training/development/test sections of the data contain ∼177K/31K/48K tokens for the decorated blocks. The overall lexical type and token counts for our data are presented in Table 2. To compute statistics all text was lower-cased and tokenized using Stanford's CoreNLP (Manning et al., 2014). For the MNIST configurations, digits 0-9 are present in the test data as drawn with both logos and numbered blocks. In contrast, only half the digits appear with

	MNIST		Blank	
	Types	Tokens	Types	Tokens
Train	1,506	177K	961	58K
Dev	583	31K	444	8K
Test	645	48K	575	17K
Total	1,359 / 257K		1,172 / 84K	

Table 2: Type and token counts for the Logo and Number decorated block data sets (left) and the Blank blocks (right).

	# of Commands	
Command Length (l)	MNIST	Random
$1 \leq l \leq 5$	81	0
$5 < l \leq 10$	3,817	61
$10 < l \leq 20$	5,752	995
$20 < l \leq 40$	2,028	1,329
$40 < l \leq 80$	192	107

Table 3: A breakdown of the number of commands in the training data by the number of tokens per sentence.

a given decoration in the development data.

Perhaps because annotators were not constrained or told they were giving instructions to a robot, the breadth of constructions and variance in command length is substantial. For example, the length of the commands varies wildly. Table 3 shows the number of training commands in a given length range. Some commands span multiple sentences. The average command length is 15 tokens with a standard deviation of 8.

The free form nature of the language and task allows for both utilitarian descriptions as well as more flowery instructions which utilize the full three-dimensional world:

> *take a plunger . plunge the top of the adidas block . lift it into the air , and place it directly to the left of the burgerking block , making sure the right edge of the adidas block and the left edge of the burgerking block are touching . remove the plunger .*

Random Blank Blocks. In both Table 2 and 3 we also present statistics on a second much more challenging dataset of blank blocks used to build random configurations. For this data, blocks were randomly placed alongside each other, on top of one another, or randomly scattered in the space. Additionally, these blocks have no identifying labels so they are more difficult to describe, making the grounding problem difficult. This leads to more interesting language with more spatial cues and counting (e.g. *third block from the top...*). This manifests as much longer descriptions averaging 23.5 words with a standard deviation of 9 words. We see this length bias in Table 3. Finally, this data also presents the challenge of stack creation in the third-dimension. As capturing the language and phenomena of this data is largely out of the scope of our current work, we present baseline results to demonstrate its difficulty in the hope of motivating future research. The complete blank blocks corpus consists of 2,493 training commands, 360 for development and 720 for testing or a total of ∼58K/8K/17K tokens.

4 Learning Problems of Interest

Implicitly encoded in our data are three tasks with varying amounts of abstraction and context-specific language: Entity grounding, Spatial Relation grounding, and Planning.

Entity Grounding. As one would expect based on Gricean maxims, there are many ways an object might be referred to in everyday speech. These are context specific and depend on the perceived ambiguity of a scene. For example, the decoration of blocks with logos allows for easy indexing ("nvidia block") which uniquely identifies the referent. If a human feels the brand is not sufficiently recognizable they may choose to describe *Texaco* as "the star block", or *Mercedes* as "three lines in a circle". In these cases, the speaker is appealing to more basic geometric knowledge in lieu of brand recognition.

The introduction of numbered blocks complicates the grounding as many actions also contain measures of how far to move a block:

put block 10 four spaces below block 9 .

In this case, the user has decided to denote the block IDs with the numerals 0-9, but distances by spelling out the number. As is to be expected, most strategies do not hold across users, and an individual user may be very inconsistent:

move block seven two spaces to the right of block 6

This inconsistency, while difficult for a learner, introduces no actual ambiguity for a fluent speaker.

Finally, blank block descriptions use lots of spacial references the involve often complicated recursive structure:

> *Move the block that is to the* [*left of* [*the block closest to* [*the right side of the table*]]] *so that it is on top of the block that is at the* [*top of the* [*group of blocks* [*closest to the* [*left side of the table*]]]].

It follows that an important subtask for our models/algorithms is to correctly ground the entities referenced in naturally occurring commands. In general this may require a thorough understanding of syntax and scoping.

Spatial Relation Grounding. Another subtask is that of understanding spacial relations. Again, we are presented with lots of linguistic ambiguity which can be resolved by the shared context and references of the speaker and listener. For example, the first command in Table 1 is simply a list of three brands:

coca cola, hp, nvidia.

This statement on its own is meaningless, but in the context of an image that contains the first two brands in sequence from left to right, the list implies that the final logo should be appended to the existing line.

Naturally occurring commands also assume basic knowledge of physics. The final description in Table 1, asks that we place a block in the "first open space to the right ...". Implicit in this statement is a shared understanding that two blocks cannot occupy the same space. This implies that a human or robot knows to search for the open space, which may be arbitrarily far away. Knowledge of physics or basic geometric shapes appears to be common in the instructions and injecting this knowledge into our models may be helpful.

> *use block 2 as a bridge to complete the diagonal line formed by blocks 17 , 8 , 6 , 4 and 1 .*

Finally, when analyzing the data, we found that command givers would often create an ad hoc grid to assist in specifying where a block should be placed. This was particularly common when placing the first block ($t_0 \rightarrow t_1$) to start the drawing. This initial block may need to be placed in a position that is not near any existing blocks. Common solutions include specifying midpoints between blocks to center a conversation:

> *place the adidas block in the column between the columns that contain the mercedes and esso blocks , but two block spaces below either .*

Often the referenced blocks may be very far apart but appear opposite one another and equidistant from a useful reference point in space.

Plan Recognition. The third problem of interest is plan recognition. The annotation of sequences of actions shows that natural commands are also used in a manner that assumes the ability to plan and execute individual and complex actions:

> *slide the adidas block 2 blocks straight up . then slide it 6 block spaces to the left .*

The models we introduce in this paper have difficulty dealing with these kind of commands.

5 Models

In order to correctly interpret commands in context, we need models that ground entities and understand spatial relations, shapes, and the compositionality of language. This is a large and fertile space for exploration. In contrast with previous work which attempts to produce deep semantic interpretations of commands (Kim and Mooney, 2012; Dukes, 2014), in this paper we explore the degree to which we can solve our communication problem using semantic free models. We are quick to note though that our framework can also assess the performance of semantic-heavy approaches.

We outline here three basic neural models that provide a set of reasonable baselines for other researchers interested in solving this problem. Each approach assumes less knowledge injection than the previous. As discussed in Section 3.1, in all three models, the eventual output is a tuple specifying where to find the block to move and where to move it: $(x, y, z)_S$ and $(x, y, z)_T$. For each model presented below we will try both simple feed-forward and recurrent neural network architectures for encoding the input utterance.

5.1 Model Architecture

The goal of our models is to convert an utterance and world state into a location prediction in the world. We tackle this problem by breaking the problem into four steps: Encoding, Representation, Grounding, Prediction. Components of this pipeline

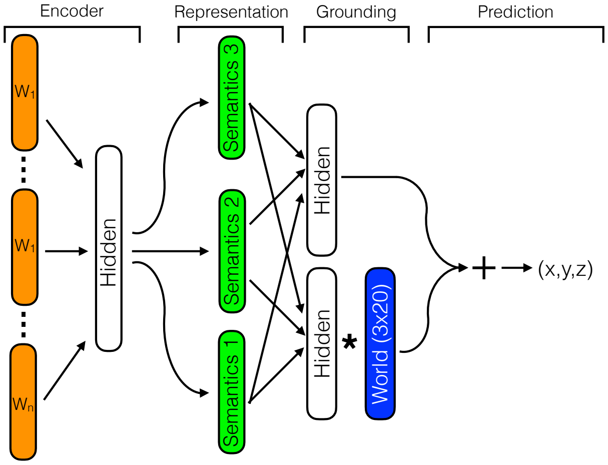

Figure 2: Our models all follow the above architecture. 1-Hot word vectors (orange) are fed as input to a Feed-Forward or Recurrent Neural Network for encoding. A semantic representation is extracted (green), which in conjunction with knowledge of the world (blue) is grounded to predict an action.

can be trained independently (Sections 5.2 and 5.3) or jointly as a single End-to-End model (Section 5.4). This division of labor also allows for differing amounts of human intervention both during training and in the interpretation of actions and bears some resemblance to (Andreas et al., 2016). Specifically, we will first present results where the model predicts a fixed semantic interpretation of actions which are easily human interpretable (Encoder + Representation). In this setting, the experimenter/human then must convert the semantics to actions in the world. Second, we remove the human interpreter and train a model for Grounding and Predicting from our semantic representation. Finally, we maintain our architecture but remove the human entirely, forcing the model to both converge to and interpret its own internal semantic representation.

The model architecture, regardless of how it is trained, at least implicitly, encodes our beliefs about the best way to solve the learning problem: performing single actions requires identifying anchors in the world that can be used as spacial referents from which a target location can be offset.

5.2 Discrete Predictions of a Fixed Semantics

Our first model assumes a setup with very simple semantics. Despite all blocks existing in a real-valued world, we will assume that a final location is parameterized by knowledge of a reference block and the direction from the reference to the target position.

Move the Adidas block to the right of the BMW.

For example, in the simple command above, we can distill three pieces of relevant information:

`Source:`	Adidas
`Reference:`	BMW
`Direction:`	right (*east*)

By assuming a grid world, BMW can be converted to its location in the world $(x, y, z)_{\text{BMW}}$, which we shift *east* by changing the y component to yield: $(x, y + \delta, z)$. In practice we define a set of nine relative positions:

NW (x-δ, y+δ, z)	N (x, y+δ, z)	NE (x+δ, y+δ, z)
NW (x-δ, y, z)	TOP (x, y, z+δ)	E (x+δ, y, z)
SW (x-δ, y-δ, z)	S (x, y-δ, z)	SE (x+δ, y-δ, z)

First our model produces an encoding of the sentence. We present two approaches:

Feed-Forward Neural Network (FFN): This model produces a sentence encoding by concatenating one-hot word vectors as input to a hidden layer. We pad sentences so all inputs are the same length.

Recurrent Neural Network (RNN): In contrast, the RNN encoder consumes the full sentence, each word passing through a hidden layer one at a time, before returning a final representation.

Additionally, in both encoding approaches, words which only occur a single time during training are replaced with an `UNK` token.

We use a single hidden layer architecture with a softmax for prediction and and train with cross entropy loss. We train a separate model for each prediction (The Encoder and Representation stages of Figure 2). Once three versions of the model have been used to predict the Source, Reference and Direction, this triple is used to compute both the source $(x, y, z)_S$ and target $(x, y, z)_T$ locations. The former is computed via a simple look-up table, while the latter amends the reference look-up with the appropriate offset from the aforementioned grid.

When the model predicts a reference block which is not on the board (not all configurations use all 20 blocks) we set the reference location to the center of the board and then apply the relative position transformation to this hallucinated block location.

5.3 Continuous Valued Predictions From a Semantic Triple

At this point, we have constructed a model for predicting a specific semantic triple, but rely on the human to convert its output to physical locations given the current state of the world. To address this, we train a simple architecture which is shown the world and automatically learn direction offsets (the Grounding and Prediction stages of Figure 2).

The model takes knowledge of the Source, Reference and Direction and passes them to two hidden layers. One is multiplied by the world (a 3 × 20 matrix of coordinates) and then both are summed to produce a final (x, y, z) prediction. The world matrix columns are the locations of each block, with a fixed ordering. If any block is missing from the configuration the matrix is padded with [-1,-1,-1]. This component of the network is then trained with a mean-square error regression loss.

Running this model on the predicted representation of Section 5.2 creates a simple pipeline from Sentence and World representations to location predictions, with no human intervention. We are particularly interested in this model's performance because its intermediary representation is forced to conform to the simple, interpretable semantics we chose for this domain and task.

5.4 End-to-End Model

Finally, we present a single model which takes as input the sentence and world as before and predicts either the location of the block to move or its final location. This corresponds to training the neural architecture (Figure 2). We train the model twice, once to predict the source location $(x, y, z)_S$ and a second time to predict the target location $(x, y, z)_T$. While the model architecture implicitly assumes the presence of an internal semantics we do not train it directly, but rather rely on the model to discover one based solely on its prediction error in the world. This approach is likely to allow for easier future extensions that encode finer-grained direction information and scaling (see analysis in Section 8).

6 Evaluation Metric

In our formulation, understanding a command C in the context of a world configuration Image$_i$ amounts to inferring the block $(x, y, z)_S$ that needs to be moved and the target location $(x, y, z)_T$ where the block needs to be moved to. Given that we control the manner in which the data is generated, we always have access to the gold interpretation of command C. Therefore, it is trivial to measure the performance of various command understanding algorithms by tracking two metrics: (i) we measure our ability to identify the block to be moved (and reference/direction information when available) using standard accuracy figures; (ii) and we measure our ability to select and place the block to be moved by measuring the distance between our predicted locations and the gold locations.

The first evaluation is presented in Table 4 under the `S`, `R`, and `D` columns. The distance errors are computed in terms of block lengths and we present the mean and median errors both for the source block's initial and final location.

7 Baselines and Human Performance

Since the gold annotations make explicit only the block to move and its target location, the Fixed Semantics models do not have gold training data for predicting the reference block used for anchoring or the direction to offset. To remedy this, we use a simple string matching heuristic that chooses a reference block during training and that computes a "gold" direction from its location. The reference is chosen as the closest block mentioned in the sentence, other than the source.

Oracle. To evaluate the strength of this heuristic, we perform an oracle evaluation (Table 4): we assume perfect knowledge of the source block that is moved; we apply our string matching heuristic to choose a reference block; and then assume perfect knowledge of the quadrant in which we place the block that is moved. For the blank blocks, our string matching heuristic fails, so we simply use the closest block to the target location to the reference location. This, unsurprisingly, leads to higher error.

Human Performance. We randomly sampled 50 utterances from each dataset to evaluate human performance. The participants in our experiment were not affiliated with the project and were not provided any guidance about the task; for example, they were

		MNIST Patterns with labeled blocks							Random Patterns with blank blocks						
		Source		Target					Source		Target				
		Med	Mean	Med	Mean	S	R	D	Med	Mean	Med	Mean	S	R	D
	Human Performance	0.00	0.00	0.21	0.53	100			0.00	0.30	0.37	1.39	93		
	Oracle	–	–	0.00	0.45	100	100	100	–	–	1.00	1.09	100	100	100

	End-to-End	0.03	0.19	0.53	1.05				**3.29**	**3.47**	**3.60**	**3.70**			
	Center Baseline	–	–	3.46	3.43	100			–	–	4.09	4.06	100		
	Random Baseline	6.37	6.49	6.12	6.21	5	5	11	4.90	4.97	5.51	5.44	10	11	12

Table 4: Model error when trained on only the subset of the data with decorated blocks or blank blocks. Where appropriate S, R, and D are the model's predictive accuracy at identifying the Source, Reference and Direction. All models are evaluated on the Median and Mean prediction error the source block and its final target location. Distances are presented in block-lengths.

not told about the high-level goal of drawing a number. Despite this, Table 4 shows human performance is very similar to Oracle performance. Although humans did not place blocks in line "perfectly", they were comparable to or outperformed the oracle.

Baselines. Finally, Table 4 also shows the results obtained by two baseline models. One (Center) has perfect knowledge of the source block to move, but always places it in the center of the table. The second baseline (Random), chooses random values for the source, reference, and direction. As expected, the performance of these baselines is abysmal.

8 Results

The results in Table 4 show that there is a massive difference in performance between block configurations that use blocks marked with identifiers (logos and digits) and those without. When the blocks are marked with clearly identifiable logos, all models outperform our baselines by a wide margin. However, when blocks are blank the situation is flipped.

The results in Table 4 also highlight a noticeable gap in performance between the simplest Discrete model and the two location predicting models. The comparable performance of the Continuous and End-to-End models on labeled blocks seems to imply that the End-to-End model is capturing/discovering similar anchoring information without being explicitly told to do so. On the blank block data, the End-to-End model performs best by learning its own more appropriate representation.

Parameters. Where appropriate, we used 256 unit hidden-layers, 0.5 dropout, and the Adam optimizer with a learning rate of 0.001. With the exception of the FFN Discrete Predictions model, SGD parameter grid-search did not yield an improvement.

8.1 Subjective Error Analysis

In Table 5, we collected 50 of our models worst errors on the decorated blocks data and categorized them into five classes of error. Eliminating most of these errors require more knowledge or a richer representation than currently afforded by our simple semantic triples. This is often due to the use of multiple reference blocks, but grammatical ambiguity and a knowledge of some basic geometric primitives also account for many of the mistakes.

8.2 Future Work on Blank Blocks

One of the most jarring results we present is the the clear performance gap between easily grounded blocks (MNIST data) and the Blank blocks (Random) which require a much richer understanding of the world. We do not believe this is due to additional complexity in the types of relations present in the data, but rather the difficulty in grounding the references. When analyzing the data we see that much of the data still follow a very simple (Source, Ref-

Error Type	Count	Example
Multi-Relation Actions	20	Place block 20 parallel with the 8 block and slightly to the right of the 6 block. Place block 15 on the same vertical column as blocks 16 and 17, and two rows above blocks 11 and 3.
Geometric Understanding	10	Continue the diagonal row of 20, 19 and 15 downward with 13. Put block 12 in the column between the columns with blocks 4 and 13, and on the same row as the lowest block on the board.
Grammatical Ambiguity	10	19 moved from behind the 8 to under the 18th block. Burger King tile should be directly above the Coca Cola tile. Move Coca Cola.
Grounding Names	5	Put the block that looks like a taurus symbol just above the bird.
Understanding Distance	5	move the texaco block 5 block lengths above the BMW block

Table 5: We performed a subjective error analysis of the results of our Fixed Semantics model using the RNN encoder. Example sentences and the frequency of each type of error are reported above from the worst 50 errors on the development data.

Scene	**Utterance**
	Move the block that is currently located closest to the top left corner to the bottom left of the table, slightly higher than the block in the bottom right corner.
Error:	`7.29 Block lengths`
	Move the block closest to the top left corner so it is above half a block length to the right of the blocks near the lower left corner of the table.
Error:	`0.94 Block lengths`

Table 6: Above are two commands and the worlds they apply to. Below we see the prediction error of our best model.

erence, Direction) paradigm, but automatically extracting that semantics is now more difficult and the purview for future work with scene understanding.

To remove the possibility that this performance difference is due to sparsity, we down-sampled the training data from the decorated blocks to match that of the blank ones. We found the development errors grew (Average 0.27 and 1.35 on source and target, respectively) but were still substantially lower than those observed with blank block data.

Because extracting the semantics for training is so difficult, a particularly nice result is that while the End-to-End model was slightly weaker than the others on the MNIST based data, it actually performs best in this domain, where we cannot provide an explicit training signal for the representation.

The nature of the language in the blank blocks differs quite dramatically due to this grounding difficulty. Table 6 shows the two sentences we perform best (and worst) on in the development data and that make use of a reference and direction.

9 Conclusion

We showed how human-robot communication can be attacked within an empirical framework that supports alternative models to be evaluated and compared using objective metrics. We introduced a set of simple algorithms for human-robot, in-context command/instruction understanding that should serve as strong baselines for future research in this field. The datasets present unique and important challenges for NLU, in which the interpretation of the language has varying amounts of dependence on the world in which it is uttered. The datasets we created in support of this work are made publicly available and should support the development of increasingly sophisticated models and algorithms for solving the problem defined in this paper, as well as additional problems that concern human-robot communication.

Abstract

In this paper, we examine the impact of employing contextual, structural information from a tree-structured document set to derive a language model. Our results show that this information significantly improves the accuracy of the resultant model.

1 Introduction

Conventional Language Models (LMs) are based on n-grams, and thus rely upon a limited number of preceding words to assign a probability to the next word in a document. Recently, Mikolov *et al.* (2010) proposed a Recurrent Neural Network (RNN) LM which uses a vector representation of all the preceding words in a sentence as the context for language modeling. This model, which theoretically can utilize an infinite context window within a sentence, yields an LM with lower perplexity than that of n-gram-based LMs. However, the model does not leverage the wider contextual information provided by words in other sentences in a document or in related documents.

Several researchers have explored extending the contextual information of an RNN-based LM. Mikolov and Zweig (2012) proposed a context-dependent RNN LM that employs Latent Dirichlet Allocation for modeling a long span of context. Wang and Cho (2015) offered a bag-of-words representation of preceding sentences as the context for the RNN LM. Ji *et al.* (2015) used a Document-Context LM (DCLM) to leverage both intra- and inter-sentence context.

These works focused on contextual information at the document level for LM, but did not consider information at the inter-document level. Many document sets on the Internet are structured, which means there are connections between different documents. This phenomenon is prominent in social media, where all the posts are directly linked to several other posts. We posit that these related documents could hold important information about a particular post, including the topic and language use, and propose an RNN-based LM architecture that utilizes both intra- and inter-document contextual information. Our approach, which was tested on the social media dataset `reddit`, yielded promising results, which significantly improve on the state of the art.

2 Dataset

We used pre-collected `reddit` data,[1] which as of December, 2015, consists of approximately 1.7 billion comments in JSON format. A comment thread starts with a "topic", which might be a link or an image. The users then begin to comment on the topic, or reply to previous comments. Over time, this process creates a tree-structured document repository (Figure 1), where a level indicator is assigned to each comment, e.g., a response to the root topic is assigned level 1, and the reply to a level n comment is assigned level $n + 1$. We parsed the raw data in JSON format into a tree structure, removing threads that have less than three comments, contain deleted comments, or do not have comments above

Figure 1: reddit example

Table 1: Dataset statistics

	# of threads	# of posts	# of sentences	# of tokens
training	1500	14592	40709	648624
testing	500	5007	13612	217164
validation	100	968	2762	44575

level 2. We randomly selected 2100 threads that fit these criteria. The data were then split into training/testing/validation sets. Table 1 displays some statistics of our dataset.

3 Baseline Neural Language Models

Our inter-document contextual language model scaffolds on the RNN LM (Mikolov et al., 2010) and DCLMs (Ji et al., 2015), as described below.

RNN-LSTM. Given a sentence $\{x_t\}_{t\in[1,\dots,N]}$, where x_t is the vector representation of the t-th word in the sentence, and N is the length of the sentence, Mikolov *et al.*'s (2010) RNN LM can be defined as:

$$\boldsymbol{h}_t = \boldsymbol{f}(\boldsymbol{h}_{t-1}, \boldsymbol{x}_t) \tag{1}$$

$$\boldsymbol{y}_t \sim \text{softmax}\left(\boldsymbol{W}_o \boldsymbol{h}_{t-1} + \boldsymbol{b}_o\right) \tag{2}$$

where $\boldsymbol{h}_t$ is the hidden unit at word t, and $\boldsymbol{y}_t$ is the prediction of the t-th word given the previous hidden unit $\boldsymbol{h}_{t-1}$. The function $\boldsymbol{f}$ in Equation 1 can be any non-linear function. Following the approach in (Sundermeyer et al., 2012) and (Ji et al., 2015), we make use of Long Short-Term Memory (LSTM) units (Hochreiter and Schmidhuber, 1997) rather than the simple hidden units used in the original RNN LM. In our work, the word representation $\boldsymbol{x}_t$ is obtained from the one-hot representation using an affine transformation, as follows:

$$\boldsymbol{x}_t = \boldsymbol{W}_p \boldsymbol{o}_t + \boldsymbol{b}_p \tag{3}$$

where $\boldsymbol{o}_t$ is the one-hot representation, $\boldsymbol{W}_p$ is the projection matrix, and $\boldsymbol{b}_p$ is a bias term.

Document Context LMs (DCLMs). We re-implemented two of Ji *et al.*'s (2015) DCLMs as our baselines,[2] viz Context-to-context (Figure 2a) and Context-to-output (Figure 2b). These models extend the RNN-LSTM model by leveraging information from preceding sentences.

The context-to-context model (ccDCLM) concatenates the final hidden unit of the previous sentence with the word vectors of the current sentence. Thus, Equation 1 becomes:

$$\boldsymbol{h}_t^i = \boldsymbol{f}(\boldsymbol{h}_{t-1}^i, \boldsymbol{x}'_{i,t}) \tag{4}$$

$$\boldsymbol{x}'_{i,t} = \text{concat}\left(\boldsymbol{x}_{i,t}, \boldsymbol{h}_{N_{i-1}}^{i-1}\right) \tag{5}$$

where N_{i-1} is the length of the previous sentence in the document, $\boldsymbol{x}_{i,t}$ is the vector representation of the t-th word in the i-th sentence, $\boldsymbol{x}'_{i,t}$ is the concatenation of the vector representation $\boldsymbol{x}_{i,t}$ and the previous sentence's final hidden unit $\boldsymbol{h}_{N_{i-1}}^{i-1}$.

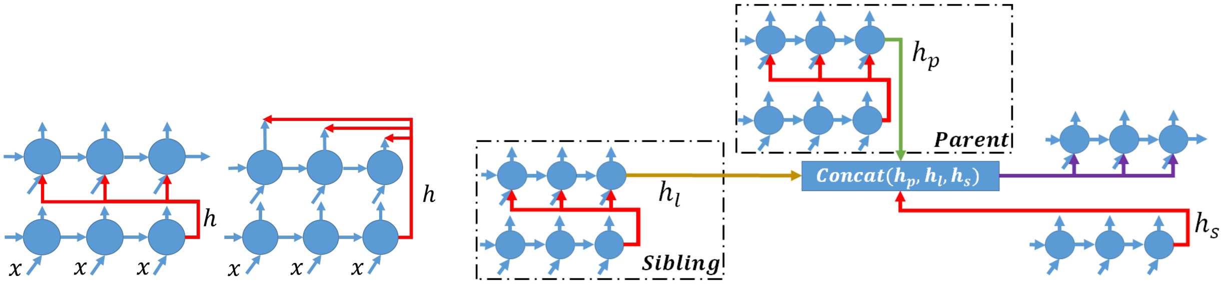
The context-to-output model (coDCLM) applies the additional information directly to the word-decoding phase. Thus, Equation 2 becomes:

$$\boldsymbol{y}_{i,t} \sim \text{softmax}\left(\boldsymbol{W}_o \boldsymbol{h}_{t-1}^i + \boldsymbol{W}'_o \boldsymbol{h}_{N_{i-1}}^{i-1} + \boldsymbol{b}_o\right) \tag{6}$$

4 Inter-document Context Language Model

We now extend the DCLM by leveraging the information at the inter-document level, taking advantage of the structure of the repository — a tree in reddit. Specifically, by harnessing the information in documents related to a target document, i.e., its siblings and parent, the LM is expected to contain additional relevant information, and hence lower perplexity. Formally, let's call the sentence-level context vector h_s, the parent document context

[2] Ji *et al.*'s three options performed similarly.



(a) ccDCLM (b) coDCLM (c) Our model (PS-ccDCLM)

Figure 2: Contextual language models; see Sections 3 and 4 for detailed descriptions.

vector h_p, the sibling context vector h_l, and the overall context vector h_c. Our framework is defined as:

$$\begin{aligned} \boldsymbol{h}_c &= \boldsymbol{g}_h(\boldsymbol{h}_s, \boldsymbol{h}_l, \boldsymbol{h}_p) && (7) \\ \boldsymbol{x}'_{i,t} &= \boldsymbol{g}_i(\boldsymbol{x}_{i,t}, \boldsymbol{h}_c) && (8) \\ \boldsymbol{h}_t &= \boldsymbol{f}(\boldsymbol{h}_{t-1}, \boldsymbol{x}'_t) && (9) \\ \boldsymbol{y}_t &\sim \text{softmax}\left(\boldsymbol{g}_o(\boldsymbol{h}_{t-1}, \boldsymbol{x}'_t, \boldsymbol{h}_c)\right) && (10) \end{aligned}$$

We use the last hidden vector of the RNNs as the representation of the parent post, the older-sibling, and the previous sentence. The definition of the context function ($\boldsymbol{g}_h$), the input function ($\boldsymbol{g}_i$), and the word-decoding function ($\boldsymbol{g}_o$) yields different configurations.

We also explored two strategies of training the models: *Disconnected (disC)* and *Fully Connected (fulC)*. In the disC-trained models, the error signal within a time step (i.e. a post or sentence) only affects the parameters in that time step. This is in contrast to the fulC-trained models, where the error signal is propagated to the previous time steps, hence influencing parameters in those time steps too.

4.1 Analysis of our modelling approach

In this section, we empirically analyze different training and modelling decisions within our framework, namely DC vs FC training, as well as contextual information from parent vs sibling.

The Setup. For our analysis, we employed a subset of the data described in Table 1 which contains 450 threads split into training/testing/validation sets with 300/100/50 threads respectively. The hidden-vector and word-vector dimensions were set to 50 and 70, respectively. The models were implemented in Theano (Bastien et al., 2012; Bergstra et al., 2010), and trained with RMSProp (Tieleman and Hinton, 2012).

Table 2: disC/fulC-trained models vs the baselines.

Model	Training	Perplexity
6-gram	na	205
RNN-LSTM	na	182
ccDCLM	disC	185
coDCLM	disC	181
ccDCLM	fulC	176
coDCLM	fulC	172

disC vs fulC. We first compared the disC and fulC strategies, at the sentence level only, in order to select the best strategy in a known setting. To this effect, we re-implemented Ji *et al.*'s (2015) DCLMs with the disC strategy, noting that Ji *et al.*'s original sentence-based models are fulC-trained. The results of this experiment appear in Table 2 which further compares these models with the following baselines: (1) vanila RNN-LSTM, and (2) a 6-gram LM with Kneser-Ney smoothing[3] (Kneser and Ney, 1995). The disC-trained models showed no improvement over the RNN-LSTM, and lagged behind their fulC-trained counterparts. The lower performance of the disC-trained models may be due to not fully leveraging the contextual information; disC-training lose information, as the error signal from the current time step is not used to calibrate the parameters of previous time steps. Therefore, we make use of fulC strategy to train our models in the rest of this paper.

Parent vs Sibling Context. The inter-document information in `reddit`'s case may come from a parent post, sibling posts or both. We tested our models with different combinations of inter-document con-

[3] Tested with the SRILM toolkit (Stolcke et al., 2011).

text information to reflect these options. At present, we consider only the closest older-sibling of a post, as it is deemed the most related; different combinations of sibling posts are left for future work. We tested the following three context-to-context configurations: parent only (P-ccDCLM), sibling only (S-ccDCLM), and parent and sibling (PS-ccDCLM), which define the context function as Equation 11, 12 and 13 respectively. The three configurations use the same word-decoding function (Equation 15) and the same input function (Equation 14).

$$\boldsymbol{h}_c = \text{concat}\left(\boldsymbol{h}_s, \boldsymbol{h}_p\right) \quad (11)$$

$$\boldsymbol{h}_c = \text{concat}\left(\boldsymbol{h}_s, \boldsymbol{h}_l\right) \quad (12)$$

$$\boldsymbol{h}_c = \text{concat}\left(\boldsymbol{h}_s, \boldsymbol{h}_l, \boldsymbol{h}_p\right) \quad (13)$$

$$\boldsymbol{x}'_{i,t} = \text{concat}\left(\boldsymbol{x}_{i,t}, \boldsymbol{h}_c\right) \quad (14)$$

$$\boldsymbol{y}_{i,t} \sim \text{softmax}\left(\boldsymbol{W}_o \boldsymbol{h}_{t-1} + \boldsymbol{b}_o\right) \quad (15)$$

The results of this experiment appear in the first three rows of Table 3, which shows that the best-performing model is PS-ccDCLM.

As discussed by Ji *et al.* (2015), the coDCLM makes the hidden units of the previous sentence have no effect on the hidden units of the current sentence. While this configuration might have some advantages (Ji et al., 2015), applying it directly to a larger context may lead to complications. Suppose we use the last hidden unit of the previous document as the context for the next document. With the context-to-output approach, the last hidden unit summarizes only the information in the last sentence of the previous document, and doesn't reflect the entire document. We address this problem by not using the context-to-output approach in isolation. Instead, we use the context-to-output approach in tandem with the context-to-context approach of ccDCLM. This approach was tested in an additional parent-sibling configuration (PS-ccoDCLM), as an alternative to the best performing context-to-context configuration. The PS-ccoDCLM is similar to the PS-ccDCLM except for the decoding equation, which is changed into Equation 16.

$$\boldsymbol{y}_{i,t} \sim \text{softmax}\left(\boldsymbol{W}_o \boldsymbol{h}^i_{t-1} + \boldsymbol{W}'_o \boldsymbol{h}_c + \boldsymbol{b}_o\right) \quad (16)$$

Based on the results of these trials, we chose the best-performing PS-ccDCLM (Figure 2c) as our final system.

Table 3: Comparing models incorporating parent (P) and/or sibling (S) contextual information.

Systems	Perplexity

PS-ccoDCLM	175

Table 4: Results on the entire dataset.

Systems	Perplexity
6-gram	209
RNN-LSTM	184
ccDCLM	168
coDCLM	176
PS-ccDCLM	**159**

4.2 Results

The model perplexity obtained by the baselines and our best-performing model for the test set (Table 1) is shown in Table 4 — our system (PS-ccDCLM) statistically significantly outperforms the best baseline (ccDCLM), with $\alpha = 0.01$, using the Friedman test. The inter-sentence contextual information under the context-to-context regime (ccDCLM) decreases model perplexity by 9% compared to the original RNN-LSTM, while the inter-document contextual information (PS-ccDCLM) reduces perplexity by a further 5% compared to ccDCLM.

5 Discussion and Future Work

Our results show that including inter-document contextual information yields additional improvements to those obtained from inter-sentence information. However, as expected, the former are smaller than the latter, as sentences in the same post are more related than sentences in different posts. At present, we rely on the final hidden-vector of the sentences and the posts for contextual information. In the future, we propose to explore other options, such as additional models to combine the contextual information from all siblings in the tree structure, and extending our model to structures beyond trees.

Ultradense Word Embeddings by Orthogonal Transformation

Sascha Rothe and **Sebastian Ebert** and **Hinrich Schütze**
Center for Information and Language Processing
LMU Munich, Germany
{sascha|ebert}@cis.lmu.de

Abstract

Embeddings are *generic* representations that are useful for many NLP tasks. In this paper, we introduce DENSIFIER, a method that learns an *orthogonal transformation* of the embedding space that focuses the information relevant for a task in an *ultradense subspace* of a dimensionality that is smaller by a factor of 100 than the original space. We show that ultradense embeddings generated by DENSIFIER reach state of the art on a lexicon creation task in which words are annotated with three types of lexical information – sentiment, concreteness and frequency. On the SemEval2015 10B sentiment analysis task we show that no information is lost when the ultradense subspace is used, but training is an order of magnitude *more efficient* due to the compactness of the ultradense space.

1 Introduction

Embeddings are useful for many tasks, including word similarity (e.g., Pennington et al. (2014)), named entity recognition (NER) (e.g., Collobert et al. (2011)) and sentiment analysis (e.g., Kim (2014), Kalchbrenner et al. (2014), Severyn and Moschitti (2015)). Embeddings are generic representations, containing different types of information about a word. Statistical models can be trained to make best use of these generic representations for a specific application like NER or sentiment analysis (Ebert et al., 2015).

Our hypothesis in this paper is that the information useful for any given task is contained in an *ultradense subspace* E_u. We propose the new method DENSIFIER to identify E_u. Given a set of word embeddings, DENSIFIER learns an *orthogonal transformation* of the original space E_o on a task-specific training set. The orthogonality of the transformation can be considered a hard regularizer.

The benefit of the proposed method is that embeddings are most useful if learned on unlabeled corpora and performance-enhanced on a broad array of tasks. This means we should try to keep all information offered by them. Orthogonal transformations "reorder" the space without adding or removing information and preserve the bilinear form, i.e., Euclidean distance and cosine. The transformed embeddings concentrate all information relevant for the task in E_u.

The benefits of E_u compared to E_o are (i) *high-quality* and (ii) *efficient* representations. (i) DENSIFIER moves non-task-related information outside of E_u, i.e., into the orthogonal complement of E_u. As a result, E_u provides *higher-quality representations* for the task than E_o; e.g., noise that could result in overfitting is reduced in E_u compared to E_o. (ii) E_u has a *dimensionality smaller by a factor of 100* in our experiments. As a result, training statistical models on these embeddings is much faster. These models also have many fewer parameters, thus again helping to prevent overfitting, especially for complex, deep neural networks.

We show the benefits of ultradense representations in two text polarity classification tasks (SemEval2015 Task 10B, Czech movie reviews).

In the most extreme form, ultradense representations – i.e., E_u – have a single dimension. We exploit this for creating lexicons in which words are

Proceedings of NAACL-HLT 2016, pages 767–777,
San Diego, California, June 12-17, 2016.

annotated with lexical information, e.g., with sentiment. Specifically, we create high-coverage lexicons with up to 3 million words (i) for three lexical properties: for *sentiment*, *concreteness* and *frequency*; (ii) for five languages: *Czech*, *English*, *French*, *German* and *Spanish*; (iii) for two domains, *Twitter* and *News*, in a domain adaptation setup.

The main advantages of this method of lexicon creation are: (i) We need a training lexicon of only a few hundred words, thus making our method effective for new domains and languages and requiring only a minimal manual annotation effort. (ii) The method is applicable to any set of embeddings, including phrase and sentence embeddings. Assuming the availability of a small hand-labeled lexicon, DENSIFIER automatically creates a domain dependent lexicon based on a set of embeddings learned on a large corpus of the domain. (iii) While the input lexicon is *discrete* – e.g., positive (+1) and negative (-1) sentiment – the output lexicon is *continuous* and this more fine-grained assessment is potentially more informative than a simple binary distinction.

We show that lexicons created by DENSIFIER beat the state of the art on SemEval2015 Task 10E (determining association strength).

One of our goals is to make embeddings more interpretable. The work on sentiment, concreteness and frequency we present in this paper is a first step towards a *general decomposition of embedding spaces into meaningful, dense subspaces*. This would lead to cleaner and more easily interpretable representations – as well as representations that are more effective and efficient.

2 Model

Let $Q \in \mathbb{R}^{d \times d}$ be an orthogonal matrix that transforms the original word embedding space into a space in which certain types of information are represented by a small number of dimensions. Concretely, we learn Q such that the dimensions $D^s \subset \{1, \ldots, d\}$ of the resulting space correspond to a word's sentiment information and the $\{1, \ldots, d\} \backslash D^s$ remaining dimensions correspond to non-sentiment information. Analogously, the sets of dimensions D^c and D^f correspond to a word's concreteness information and frequency information, respectively. In this paper, we assume that these properties do not correlate and therefore the ultradense subspaces do not overlap, e.g., $D^s \cap D^c = \emptyset$. However, this might not be true for other settings, e.g., sentiment and semantic information.

If $e_w \in E_o \subset \mathbb{R}^d$ is the original embedding of word w, the transformed representation is Qe_w. We use $*$ as a placeholder for s, c and f and call $d^* = |D^*|$ the dimensionality of the ultradense subspace of $*$. For each ultradense subspace, we create $P^* \in \mathbb{R}^{d^* \times d}$, an identity matrix for the dimensions in $D^* \subset \{1, \ldots, d\}$. Thus, the ultradense representation $u^*_w \in E_u \subset \mathbb{R}^{d^*}$ of e_w is defined as:

$$u^*_w := P^* Q e_w \qquad (1)$$

2.1 Separating Words of Different Groups

We assume to have a lexicon resource l in which each word w is annotated for a certain information as either $l^*(w) = +1$ (positive, concrete, frequent) or $l^*(w) = -1$ (negative, abstract, infrequent). Let $L^*_{\not\sim}$ be a set of word index pairs (v, w) for which $l^*(v) \neq l^*(w)$ holds. We want to maximize:

$$\sum_{(v,w) \in L^*_{\not\sim}} \|u^*_v - u^*_w\| \qquad (2)$$

Thus, our objective is given by:

$$\underset{Q}{\operatorname{argmax}} \sum_{(v,w) \in L^*_{\not\sim}} \|P^* Q (e_w - e_v)\| \qquad (3)$$

or, equivalently, by:

$$\underset{Q}{\operatorname{argmin}} \sum_{(v,w) \in L^*_{\not\sim}} -\|P^* Q (e_w - e_v)\| \qquad (4)$$

subject to Q being an orthogonal matrix.

2.2 Aligning Words of the Same Group

Another goal is to minimize the distance of two words of the same group. Let $L^*_{\sim}$ be a set of word index pairs (v, w) for which $l^*(v) = l^*(w)$ holds. In contrast to Eq. 3, we now want to minimize each distance. Thus, the objective is given by:

$$\underset{Q}{\operatorname{argmin}} \sum_{(v,w) \in L^*_{\sim}} \|P^* Q (e_w - e_v)\| \qquad (5)$$

subject to Q being an orthogonal matrix.

The intuition behind the two objectives is graphically depicted in Figure 1.

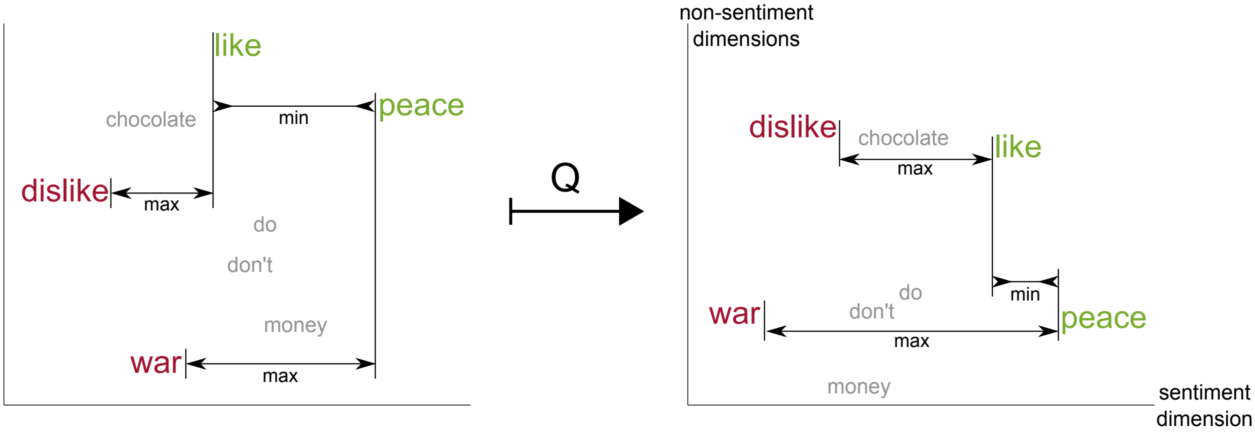

Figure 1: The original word embedding space (left) and the transformed embedding space (right). The training objective for Q is to *minimize* the distances in the sentiment dimension between words of the same group (e.g., positive/green: "like" & "peace") and to *maximize* the distances between words of different groups (e.g., negative/red & positive/green: "war" & "peace"; not necessarily antonyms).

2.3 Training

We combine the two objectives in Eqs. 3/5 for each subspace, i.e., for sentiment, concreteness and frequency, and weight them with α^* and $1-\alpha^*$. Hence, there is one hyperparameter α^* for each subspace. We then perform stochastic gradient descent (SGD). Batch size is 100 and starting learning rate is 5, multiplied by .99 in each iteration.

2.4 Orthogonalization

Each step of SGD updates Q. The updated matrix Q' is in general no longer orthogonal. We therefore reorthogonalize Q' in each step based on singular value decomposition:

$$Q' = USV^T$$

where S is a diagonal matrix, and U and V are orthogonal matrices. The matrix

$$Q := UV^T$$

is the nearest orthogonal matrix to Q' in both the 2-norm and the Frobenius norm (Fan and Hoffman, 1955). (Formalizing our regularization directly as projected gradient descent would be desirable. However, gradient descent includes an additive operation and orthogonal matrices are not closed under summation.)

SGD for this problem is sensitive to the learning rate. If the learning rate is too large, a large jump results and the reorthogonalized matrix Q basically is a random new point in the parameter space. If the learning rate is too small, then learning can take long. We found that our training regime of starting at a high learning rate (5) and multiplying by .99 in each iteration is effective. Typically, the cost initially stays about constant (random jumps in parameter space), then cost steeply declines in a small number of about 50 iterations (sweet spot); the curve flattens after that. Training Q took less than 5 minutes per experiment for all experiments in this paper.

3 Lexicon Creation

For lexicon creation, the input is a set of *embeddings* and a lexicon *resource* l, in which words are annotated for a lexical information such as sentiment, concreteness or frequency. DENSIFIER is then trained to produce a *one-dimensional ultradense subspace*. The output is an *output lexicon*. It consists of all words covered by the embedding set, each associated with its one-dimensional ultradense subspace representation (which is simply a real number), an indicator of the word's strength for that information.

The embeddings and lexicon resources used in this paper cover five languages and three domains (Table 1). The Google News embeddings for English[1] and the FrWac embeddings for French[2] are

Table 1: Results for lexicon creation. #tokens: size of embedding training corpus (in billion). #types: size of output lexicon (in million). For each resource, we give its size ("#words") and the size of the intersection of resource and embedding set ("∩"). Kendall's τ is computed on "∩".

publicly available. We use word2vec to train 400-dimensional embeddings for English on a 2013 Twitter corpus of size 5.4 $\times 10^9$. For Czech, German and Spanish, we train embeddings on web data of sizes 3.3, 8.0 and 3.8 $\times 10^9$, respectively. We use the following lexicon resources for sentiment: SubLex 1.0 (Veselovská and Bojar, 2013) for Czech; WHM for English [the combination of MPQA (Wilson et al., 2005), Opinion Lexicon (Hu and Liu, 2004) and NRC Emotion lexicons (Mohammad and Turney, 2013)]; FEEL (Abdaoui et al., 2014) for French; German Polarity Clues (Waltinger, 2010) for German; and the sentiment lexicon of Pérez-Rosas et al. (2012) for Spanish. For concreteness, we use BWK, a lexicon of 40,000 English words (Brysbaert et al., 2014). For frequency, we exploit the fact that word2vec stores words in frequency order; thus, the ranking provided by word2vec is our lexicon resource for frequency.

For a resource/embedding-set pair (l, E), we intersect the vocabulary of l with the top 80,000 words of E to filter out noisy, infrequent words that tend to have low quality embeddings and we do not want them to introduce noise when training the transformation matrix.

For the sentiment and concreteness resources, $l^*(w) \in \{-1, 1\}$ for all words w covered. We create a resource l^f for frequency by setting $l^f(w) = 1$ for the 2000 most frequent words and $l^f(w) = -1$ for words at ranks 20000-22000. 1000 words randomly selected from the 5000 most frequent are the test set.[3] We designate three sets of dimensions D^s, D^c and D^f to represent sentiment, concreteness and frequency, respectively, and arbitrarily set (i) $D^c = \{11\}$ for English and $D^c = \emptyset$ for the other languages since we do not have concreteness resources for them, (ii) $D^s = \{1\}$ and (iii) $D^f = \{21\}$. Referring to the lines in Table 1, we then learn six orthogonal transformation matrices Q: for CZ-web (1), DE-web (2), ES-web (3), FR-web (4, 9), EN-twitter (5) and EN-news (6, 7, 8).

4 Evaluation

4.1 Top-Ranked Words

Table 2 shows the top 10 positive/negative words (i.e., most extreme values on dimension D^s) when we apply the transformation to the corpora EN-twitter, EN-news and DE-web and the top 10 concrete/abstract words (i.e., most extreme values on dimension D^c) for EN-news. For EN-twitter (leftmost double column), the selected words look promising: they contain highly domain-specific words such as hashtags (e.g., #happy). This is surprising because there is not a single hashtag in the lexicon resource WHM that DENSIFIER was trained on. Results for the other three double columns show likewise extreme examples for the corresponding information and language. This initial evaluation indicates that our method effectively learns high quality lexicons for new domains. Figure 3 depicts values for selected words for the three properties. Illustrative examples are "brother" / "brotherhood" for concreteness and "hate" / "love" for sentiment.

[3] The main result of the frequency experiment below is that τ is low even in a setup that is optimistic due to train/test overlap; presumably it would be even lower without overlap.

EN-twitter		EN-news		EN-news		DE-web	
positive	negative	positive	negative	concrete	abstract	positive	negative
#blessed	rape	expertise	angry	tree	fundamental	herzlichen	gesperrt
inspiration	racist	delighted	delays	truck	obvious	kenntnisse	droht
blessed	horrible	honored	worse	kitchen	legitimate	hervorragende	verurteilt
inspiring	nasty	thank	anger	dog	reasonable	ideale	gefahr
foundation	jealousy	wonderful	foul	bike	optimistic	bestens	falsche
provide	murder	commitment	blamed	bat	satisfied	glückwunsch	streit
wishes	waste	affordable	blame	garden	surprising	optimale	angst
dedicated	mess	passion	complained	homer	honest	anregungen	krankheit
offers	disgusting	exciting	bad	bed	regard	freuen	falschen
#happy	spam	flexibility	deaths	gallon	extraordinary	kompetenzen	verdacht

Table 2: Top 10 words in the output lexicons for the domains Twitter and News (English) and Web (German).

4.2 Quality of Predictions

Table 1 presents experimental results. In each case, we split the resource into train/test, except for Twitter where we used the trial data of SemEval2015 Task 10E for test. We train DENSIFIER on train and compute Kendall's τ on test. The size of the lexicon resource has no big effect; e.g., results for Spanish (small resource; line 3) and French (large resource; line 4) are about the same. See Section 5.2 for a more detailed analysis of the effect of resource size.

The quality of the output lexicon depends strongly on the quality of the underlying word embeddings; e.g., results for French (small embedding training corpus; line 4) are worse than results for English (large embedding training corpus; line 6) even though the lexicon resources have comparable size.

In contrast to sentiment/concreteness, τ values for frequency are low (lines 8-9). For the other three languages we obtain $\tau \in [.34, .46]$ for frequency (not shown). This suggests that word embeddings represent sentiment and concreteness much better than frequency. The reason for this likely is the learning objective of word embeddings: modeling the context. Infrequent words can occur in frequent contexts. Thus, the frequency information in a single word embedding is limited. In contrast negative words are likely to occur in negative contexts.

The nine output lexicons in Table 1 – each a list of words annotated with predicted strength on one of three properties – are available at `www.cis.lmu.de/~sascha/Ultradense/`.

		τ

7	Sentiment140	.508†	.538†
8	DENSIFIER, trial only	.627†	

Table 3: Results for Lexicon Creation. The first column gives the correlation with the entire test lexicon of SemEval2015 10E, the last column only on the intersection of our output lexicon and Sentiment140. Of the 1315 words of task 10E, 985 and 1308 are covered by DENSIFIER and Sentiment140, respectively. †: significantly worse than the best (bold) result in the same column ($\alpha = .05$, Fisher z-transformation).

4.3 Determining Association Strength

We also evaluate lexicon creation on SemEval2015 Task 10E. As before, the task is to predict the sentiment score of words/phrases. We use the trial data of the task to tune the hyperparameter, $\alpha^s = .4$. Out-of-vocabulary words were predicted as neutral (7/1315). Table 3 shows that the lexicon computed by DENSIFIER (line 5, Table 1) has a τ of .654 (line 6, column *all*), significantly better than all other systems, including the winner of SemEval 2015 ($\tau = .626$, line 1). DENSIFIER also beats Sentiment140 (Mohammad et al., 2013), a widely used semi-automatic sentiment lexicon. The last column is τ on the intersection of DENSIFIER and Sentiment140. It shows that DENSIFIER again performs significantly better than Sentiment140.

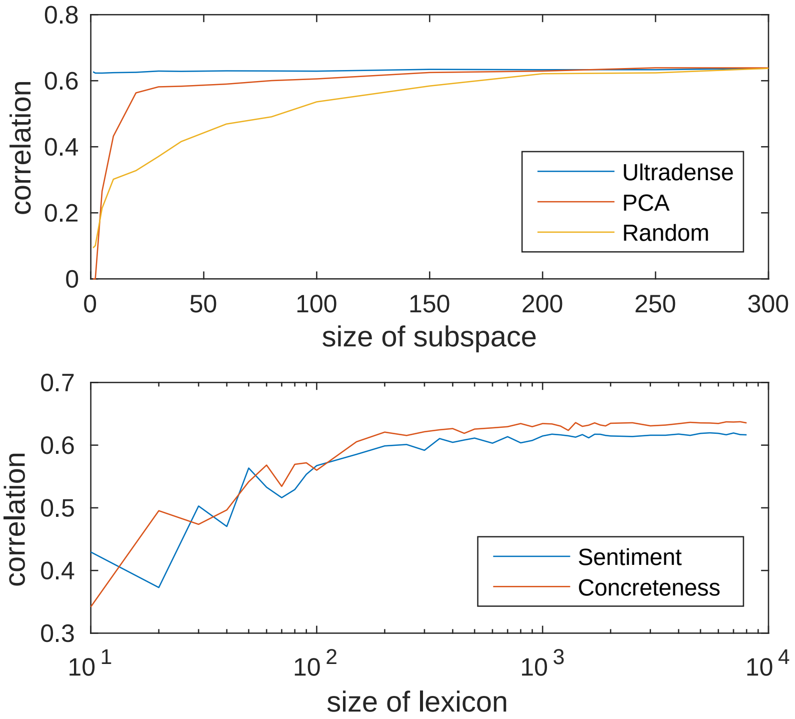

Figure 2: Kendall's τ versus subspace size (top) and training resource size (bottom). See lines 6 & 8, Table 1, for train/test split.

4.4 Text Polarity Classification

We now show that ultradense embeddings decrease model training times without any noticeable decrease in performance compared to the original embeddings. We evaluate on SemEval2015 Task 10B, classification of Twitter tweets as positive, negative or neutral. We reimplement the linguistically-informed convolutional neural network (lingCNN) of Ebert et al. (2015) that has close to state-of-the-art performance on the task. We do not use sentence-based features to focus on the evaluation of the embeddings. We initialize the first layer of lingCNN, the embedding layer, in three different ways: (i) 400-dimensional Twitter embeddings (Section 3); (ii) 40-dimensional ultradense embeddings derived from (i); (iii) 4-dimensional ultradense embeddings derived from (i). The objective weighting is $\alpha^s = .4$, optimized on the development set.

The embedding layer converts a sentence into a matrix of word embeddings. We also add linguistic features for words, such as sentiment lexicon scores. The combination of embeddings and linguistic features is the input for a convolution layer with filters spanning 2-5 words (100 filters each). This is followed by a max pooling layer, a rectifier nonlinearity (Nair and Hinton, 2010) and a fully connected softmax layer predicting the final label. The model is trained with SGD using AdaGrad (Duchi et al., 2011) and ℓ_2 regularization ($\lambda = 5 \times 10^{-5}$). Learning rate is 0.01. Mini-batch size is 100.

We follow the official guidelines and use the SemEval2013 training and development sets as training set, the SemEval2013 test set as development set and the SemEval2015 test set to report final scores (Nakov et al., 2013; Rosenthal et al., 2015). We report macro F_1 of positive and negative classes (the official SemEval evaluation metric) and accuracy over the three classes. Table 4 shows that 40-dimensional ultradense embeddings perform almost as well as the full 400-dimensional embeddings (no significant difference according to sign test). Training time is shorter by a factor of 21 (85/4 examples/second). The 4-dimensional ultradense embeddings lead to only a small loss of 1.5% even though the size of the embeddings is smaller by a factor of 100 (again not a significant drop). Training time is shorter by a factor of 44 (178/4).

We perform the same experiment on CSFD, a

Table 4: Performance on Text Polarity Classification

Czech movie review dataset (Habernal et al., 2013), to show the benefits of ultradense embeddings for a low-resource language where only one rather small lexicon is available. As original word embeddings we train new 400 dimensional embeddings on a large Twitter corpus (3.3 $\times 10^9$ tokens). We use DENSIFIER to create 40 and 4 dimensional embeddings out of these embeddings and SubLex 1.0 (Veselovská and Bojar, 2013). Word polarity features are also taken from SubLex. A simple binary negation indicator is implemented by searching for all tokens beginning with "ne". Since that includes superlative forms having the prefix "nej", we remove them with the exception of common negated words, such as "nejsi" – "you are not". We randomly split the 91,000 dataset instances into 90% train and 10% test and report accuracy and macro F_1 score over all three classes.

Table 4 shows that what we found for English is also true for Czech. There is only a small performance drop when using ultradense embeddings (not significant for 40 dimensional embeddings) while the speed improvement is substantial.

5 Parameter Analysis

In this section, we analyze two parameters: size of ultradense subspace and size of lexicon resource. We leave an evaluation of another parameter, the size of the embedding training corpus, for future work, but empirical results suggest that this corpus should ideally have a size of several billion tokens.

5.1 Size of Subspace

With the exception of the two text polarity classification experiments, all our subspaces have dimensionality $d^* = 1$. The question arises: does a one-dimensional space perhaps have too low a capacity to encode all relevant information and could we further improve our results by increasing the dimensionality of the subspace to values $d^* > 1$? The lexicon resources that we train and test on are all binary; thus, if we use values $d^* > 1$, then we need to map the subspace embeddings to a one-dimensional scale for evaluation. We do this by training, on the train part of the resource, a linear transformation from the ultradense subspace to the one-dimensional scale (e.g., to the sentiment scale).

Figure 2 compares different values of d^s for three different types of subspaces in this setup, i.e., the setup in which the subspace representations are mapped via linear transformation to a one-dimensional sentiment value: (i) *Random*: we take the first d^s dimensions of the original embeddings; (ii) *PCA*: we compute a PCA and take the first d^s principal components; (iii) *Ultradense* subspace of dimensionality d^s. We use the word embeddings and lexicon resources of line 6 in Table 1. For random, the performance starts dropping when the subspace is smaller than 200 dimensions. For PCA, the performance is relatively stable until the subspace becomes smaller than 100. In contrast, ultradense subspaces have almost identical performance for all values of d^s, even for $d^s = 1$. This suggests that a single dimension is sufficient to encode all sentiment information needed for sentiment lexicon creation. However, for other sentiment tasks more dimensions may be needed, e.g., for modeling different emotional dimensions of polarity: fear, sadness, anger etc.

An alternative approach to create a low-dimensional space is to simply train low-dimensional word2vec embeddings. The following experiment suggests that this does not work very well. We used word2vec to train 60-dimensional twitter embeddings with the same settings as on line 5 in Table 1. While the correlation for 400-dimensional embeddings shown in Table 1 is .661, the correlation of 60-dimensional embeddings is only .568. Thus, even though we show that the information in 400-dimensional embeddings that is relevant for sentiment can be condensed into a single dimension, hundreds of dimensions seem to be needed if we use word2vec to collect sentiment information. If we run word2vec with a small dimensionality, only a subset of available sentiment information is "harvested" from the corpus.

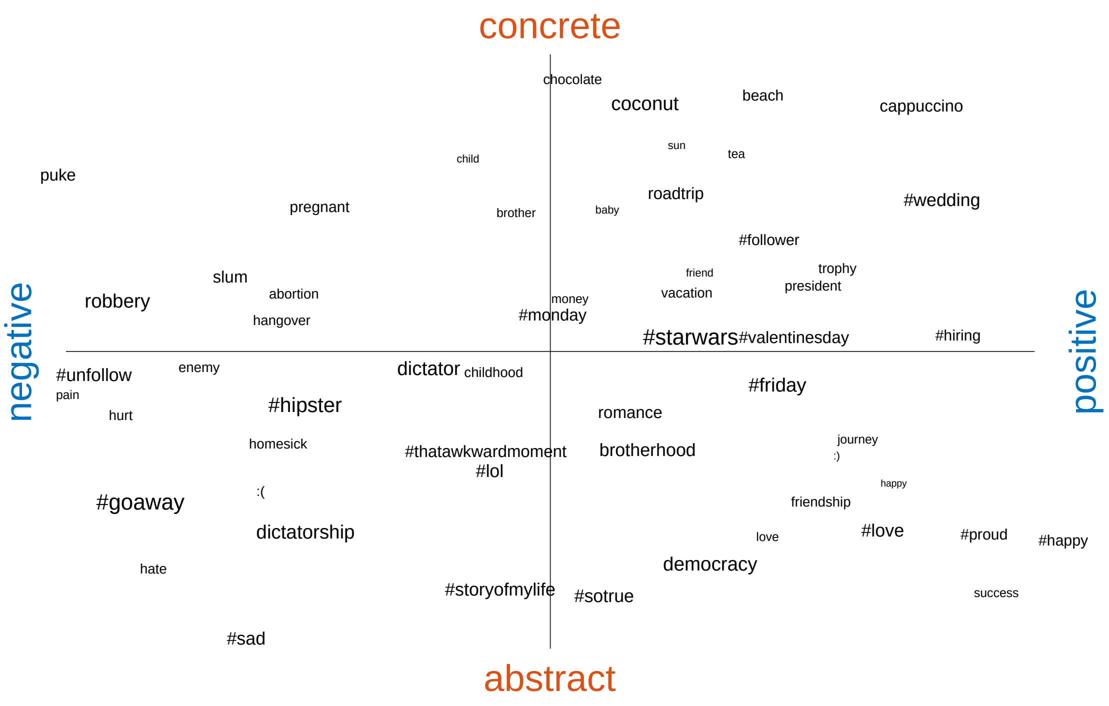

Figure 3: Illustration of EN-twitter output lexicon: DENSIFIER values are x coordinate (sentiment), y coordinate (concreteness) and font size (frequency)

5.2 Size of Training Resource

Next, we analyze what size of training resource is required to learn a good transformation Q. Labeled resources covering many words may not be available or suffer from lack of quality. We use the settings of lines 6 (sentiment) and 7 (concreteness) in Table 1. Figure 2 shows that a small training resource of 300 entries is sufficient for high performance. This suggests that DENSIFIER can create a high quality output lexicon for a new language by hand-labeling only 300 words; and that a small, high-quality resource may be preferable to a large lower-quality resource (semi-automatic or out of domain).

To provide further evidence for this, we train DENSIFIER on only the trial data of SemEval2015 task 10E. To convert the continuous trial data to binary -1 / 1 labels, we discard all words with sentiment values between -0.5 and 0.5 and round the remaining values, giving us 39 positive and 38 negative training words. The resulting lexicon has $\tau =$ .627 (Table 3, line 8).[4] This is worse than $\tau =$ .654 (line 6) for the setup in which we used several large resources, but still better than all previous work. This indicates that DENSIFIER is especially suited for languages or domains for which little training data is available.

6 Related Work

To the best of our knowledge, this paper is the first to train an orthogonal transformation to reorder word embedding dimensions into ultradense subspaces. However, there is much prior work on postprocessing word embeddings.

Faruqui et al. (2015) perform postprocessing based on a semantic lexicon with the goal of fine-tuning word embeddings. Their transformation is not orthogonal and therefore does not preserve distances. They show that their approach optimizes word embeddings for a given application, i.e., word similarity, but also that it worsens them for other applications like detecting syntactic relations. Faruqui et al. (2015)'s approach also does not have the bene-

[4] Here, we tune α^s on train (equals trial data of SemEval2015 task 10E). This seems to work due to the different objectives for training (maximize/minimize difference) and development (correlation).

fit of ultradense embeddings, in particular the benefit of increased efficiency.

In a tensor framework, Rothe and Schütze (2015) transform the word embeddings to sense (synset) embeddings. In their work, all embeddings live in the same space whereas we explicitly want to change the embedding space to create ultradense embeddings with several desirable properties.

Xing et al. (2015) restricted the work of Mikolov et al. (2013) to an orthogonal transformation to ensure that normalized embeddings stay normalized. This transformation is learned between two embedding spaces of different languages to exploit similarities. They normalized word embeddings in a first step, something that did not improve our results.

As a reviewer pointed out, our method is also related to Oriented PCA (Diamantaras and Kung, 1996). However in contrast to PCA a solution for Oriented PCA is not orthogonal.

Sentiment lexicons are often created semi-automatically, e.g., by extending manually labeled seed sets of sentiment words or adding for each word its syno-/antonyms. Alternatively, words frequently cooccurring with a seed set of manually labeled sentiment words are added (Turney, 2002; Kiritchenko et al., 2014). Heerschop et al. (2011) used WordNet together with a PageRank-based algorithm to propagate the sentiment of the seed set to unknown words. Scheible (2010) presented a semi-automatic approach based on machine translation of sentiment lexicons. The winning system of SemEval2015 10E (Amir et al., 2015) was based on structured skip-gram embeddings with 600 dimensions and support vector regression with RBF kernels. Hamdan et al. (2015), the second ranked team, used the average of six sentiment lexicons as a final sentiment score, a method that cannot be applied to low resource languages. We showed that the lexicons created by DENSIFIER achieve better performance than other semi-automatically created lexicons.

Tang et al. (2014b) train sentiment specific embeddings by extending Collobert & Weston's model and Tang et al. (2014a)'s skip-gram model. The first model automatically labels tweets as positive/negative based on emoticons, a process that cannot be easily transferred to other domains like news. The second uses the Urban Dictionary to expand a small list of 350 sentiment seeds. In our work, we showed that a training resource of about the same size is sufficient without an additional dictionary. DENSIFIER differs from this work in that it does not need a text corpus, but can transform existing, publicly available word embeddings. DENSIFIER is independent of the embedding learning algorithm and therefore extensible to other word embedding models like GloVe (Pennington et al., 2014), to phrase embeddings (Yu and Dredze, 2015) and even to sentence embeddings (Kiros et al., 2015).

7 Conclusion

We have introduced DENSIFIER, a method that is trained to focus embeddings used for an application to an ultradense subspace that contains the information relevant for the application. In experiments on SemEval, we demonstrate two benefits of the ultradense subspace. (i) Information is preserved even if we focus on a subspace that is smaller by a factor of 100 than the original space. This means that unnecessary noisy information is removed from the embeddings and robust learning without overfitting is better supported. (ii) Since the subspace is 100 times smaller, models that use the embeddings as their input representation can be trained more efficiently and have a much smaller number of parameters. The subspace can be learned with just $80-300$ training examples, achieving state-of-the-art results on lexicon creation.

We have shown in this paper that up to three orthogonal ultradense subspaces can be created. Many training datasets can be restructured as sets of similar/dissimilar pairs. For instance, in part-of-speech tasks verb/verb pairs would be similar, verb/noun pairs dissimilar. Hence, our objective is widely applicable. In future work, we will explore the possibility of factoring all information present in an embedding into a dozen or so orthogonal subspaces. This factorization would not change the information embeddings contain, but it would make them more compact for any given application, more meaningful and more interpretable.

The nine large DENSIFIER lexicons shown in Table 1 are publicly available.[5]

Abstract

We examine different features and classifiers for the categorization of opinion words into actor and speaker view. To our knowledge, this is the first comprehensive work to address sentiment views on the word level taking into consideration opinion verbs, nouns and adjectives. We consider many high-level features requiring only few labeled training data. A detailed feature analysis produces linguistic insights into the nature of sentiment views. We also examine how far global constraints between different opinion words help to increase classification performance. Finally, we show that our (prior) word-level annotation correlates with contextual sentiment views.

1 Introduction

While there has been much research in sentiment analysis on the tasks of subjectivity detection and polarity classification, there has been less work on other types of categorizations that can be imposed upon subjective expressions.

In this paper, we focus on the *views* that an opinion expression evokes. By views, we understand the perspective of the holder of some opinion. We distinguish between the two most common types: expressions conveying sentiment of the entities participating in the event denoted by the opinion word, referred to as **actor views** (e.g. *disappointed* in (1) or *praised* in (2)), and expressions conveying sentiment of the speaker of the utterance, referred to as **speaker views** (e.g. *excelled* in (3) or *wasted* in (4)).

(1) Party members were **disappointed**$_{actor}$ at the election outcome.
(2) All representatives **praised**$_{actor}$ the final agreement.
(3) Sarah **excelled**$_{speaker}$ in virtually every subject.
(4) The government **wasted**$_{speaker}$ a lot of money.

The distinction between those categories is relevant for related tasks in sentiment analysis, most importantly, opinion holder and target extraction. This has already been demonstrated for verbs (Wiegand and Ruppenhofer, 2015). For example, even though the noun *Peter* has the same grammatical relation to the opinion verb in (5) & (6), in the former sentence it is a holder but in the latter it is a target. Similar cases can be observed for opinion nouns (7) & (8) and opinion adjectives (9) & (10). Only the knowledge of sentiment views helps us to assign opinion roles correctly.

(5) [Peter]$_{Holder}$ **criticizes**$^{verb}_{actor}$ Mary.
(6) [Peter]$_{Target}$ **cheated**$^{verb}_{speaker}$ in the exam.
(7) [Peter's]$_{Holder}$ **belief**$^{noun}_{actor}$ is that all people should be treated equally.
(8) [Peter's]$_{Target}$ **misbehaviour**$^{noun}_{speaker}$ is unbearable.
(9) [Peter]$_{Holder}$ is **disappointed**$^{adj}_{actor}$.
(10) [Peter]$_{Target}$ is **intelligent**$^{adj}_{speaker}$.

While the distinction of sentiment views is not new, we put a different emphasis on this task. Our focus is on the prior meaning that opinion words evoke. Hence we consider this as a **word-level** task. Every opinion word from a sentiment lexicon is to be categorized as conveying either an actor or a speaker view. Our aim is to find comprehensive methods to automatically categorize opinion words of various parts of speech (verbs, nouns, adjectives). The resulting lexical resources are indispensable for open-domain categorization. Previous work focused on contextual classification of sentiment views (Johans-

Proceedings of NAACL-HLT 2016, pages 778–788,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

son and Moschitti, 2013). Wiegand and Ruppenhofer (2015) showed that while prior lexical knowledge of sentiment views is effective in transferring opinion role extractors to other domains, this does not apply to contextual classifiers.

In this work, we focus on linguistic properties for predicting sentiment views. We examine in how far morphological information can be used. Distributional and syntactic information is also considered. In terms of lexical resources, we examine WordNet and FrameNet. We show that information from a sentiment lexicon can give some additional clues.

In order to combine the different features to predict the sentiment views evoked by opinion words we employ supervised classification. As a classifier, we use Markov Logic Networks (Richardson and Matthew, 2006) since they do not only allow us to define features for instances (i.e. opinion words) but also to formulate global constraints between different instances. The latter cannot be expressed by traditional classifiers (e.g. SVM). We examine two types of constraints: consistency between instances that are distributionally similar and consistency between morphologically related instances.

Finally, we also examine the relationship between prior lexical information (i.e. our approach) and contextual annotation in the MPQA corpus.

2 Related Work

The annotation scheme of the MPQA corpus (Wiebe et al., 2005) was the first work to address the distinction between different sentiment views. The two sentiment views are referred to as *direct subjectivity* (=actor view) and *expressive subjectivity* (=speaker view). In subsequent research, some approaches have been proposed to distinguish these two categories in the MPQA corpus. The most extensive work is Johansson and Moschitti (2013). Since MPQA provides annotation regarding sentiment in context, sentiment views are exclusively considered in *contextual* classification. The fact that it is the opinion words that convey those views, as we do in this paper, is not addressed. Unlike in this paper, the focus of Johansson and Moschitti (2013) is also on optimizing a machine-learning classifier, in particular to model the interaction between different subjective phrases within the same sentence.

	Actor View		Speaker View	
Part of Speech	**Freq**	**Perc**	**Freq**	**Perc**
adjective	223	8.9	2279	91.1
noun	487	29.1	1189	70.9
verb	618	52.6	557	47.4

Table 1: Distribution of the different sentiment views.

Some of the lexical resources we examine, i.e. WordNet (§4.1) and FrameNet (§4.2), have also been employed in Breck et al. (2007) who, like Johansson and Moschitti (2013), also deal with contextual (sentiment) classification. However, the authors do not examine in how far these individual resources separate speaker and actor views.

Maks and Vossen (2012b) link sentiment views to opinion words as part of a lexicon model for sentiment analysis. Maks and Vossen (2012a) also examine a corpus-driven method to induce opinion words for the different sentiment views. The authors, however, conclude that their approach, which sees news articles as a source for actor views and news comments as a source for speaker views, is not sufficiently effective.

The work most closely related to our research is Wiegand and Ruppenhofer (2015). Opinion words are categorized according to their sentiment view. Our work substantially goes beyond that previous research: Firstly, Wiegand and Ruppenhofer (2015) only consider distributional similarity for inducing opinion views. In this work, we consider various linguistic features and also compare this with distributional information. Secondly, Wiegand and Ruppenhofer (2015) only consider opinion verbs, while we also consider opinion nouns and opinion adjectives.

Wiegand and Ruppenhofer (2015) distinguish between two types of actor views, *agent views* and *patient views*. The former take their opinion holder as an agent and their target as a patient (typical verbs are *criticize*, *love*, *believe*), while the latter align their roles inversely (typical verbs are *disappoint*, *please*, *interest*). Since this distinction between actor views does not exist among nouns or adjectives, we consider one merged (actor-view) category for all three parts of speech in this paper.

3 Data

We manually annotated all verbs, nouns and adjectives contained in the Subjectivity Lexicon (Wilson et al., 2005) for view type. The dataset comprises 2502 adjectives, 1676 nouns and 1175 verbs. Since our new dataset[1] is an extension of the dataset from Wiegand and Ruppenhofer (2015), we adhere to the annotation process proposed in that paper. That is, the basis of the annotation were online dictionaries (e.g. *Macmillan Dictionary*) which provide both a word definition and example sentences. Each word is either labeled as primarily conveying an actor or a speaker view. (Our categorization is binary.) On a subset of 250 words for each part of speech, we computed an interannotation agreement (Cohen's κ) of 61.9, 71.9 and 60.1 for verbs, nouns and adjectives, respectively. This agreement can be considered substantial (Landis and Koch, 1977). Table 1 shows the distribution of the different sentiment views among the different parts of speech.

The expressions comprising our gold standard do not represent anywhere near the full set of English subjective words with these parts of speech. Otherwise, an automatic categorization would not be necessary in the presence of our gold standard. The classification approach that we propose in this paper, which works well with few labeled training data, would also be helpful for categorizing sentiment views on much larger sets of subjective expressions.

4 Feature Design

4.1 WordNet

WordNet (Miller et al., 1990) is the largest lexical ontology for the English language. It is organized in synsets. However, we want to assign categories to words. Due to the lack of robust word sense disambiguation, in order to use this resource, we consider the union of synsets in which a word with the same part of speech to be categorized is contained.

4.1.1 Gloss Information (GLOSS)

One common way to harness WordNet is by taking into account its glosses. A gloss represents some explanatory text for each synset, usually some definition of the concept. We use the words from those glosses as features in a supervised classifier. We assume that opinion words conveying the same sentiment view also contain similar glosses.

Glosses are a special type of feature. It is basically a bag-of-words feature set, i.e. a *low-level* feature set, which is known to be sparse yet effective when sufficient training data are used. All the other features presented in this paper are *high-level* features, i.e. more frequently occurring features already being effective if only few labeled data are used. Glosses are one of the most frequently used features for lexicon induction tasks in sentiment analysis (Esuli and Sebastiani, 2005; Andreevskaia and Bergler, 2006; Gyamfi et al., 2009; Choi and Wiebe, 2014; Kang et al., 2014). We will consider them as a baseline, showing that our proposed high-level features are more suitable for our task.

4.1.2 Lexicographer Files (LEX)

Lexicographer files organize the synset inventory of WordNet into a coarse-grained set of semantic categories. In total, there are 45 categories for the three parts of speech we consider.[2] The advantage of such a coarse-grained inventory is that it should require only few labeled training data in supervised classification.

4.2 FrameNet (FN)

FrameNet (Baker et al., 1998) is a semantic resource that has been found useful for subtasks of sentiment analysis related to ours, i.e. opinion holder/target extraction (Bethard et al., 2004; Kim and Hovy, 2006). It includes a large set of more than $1,200$ semantic frames that comprise words with similar semantic behaviour. As a feature we use the frame-membership of the opinion words, assuming that different frames are associated with different sentiment views. We use FrameNet version 1.5.

4.3 Subcategorization Frames (SUB)

Subcategorization frames could also be predictive. For example, actor views demand the presence of an

[1] available at: `www.coli.uni-saarland.de/~miwieg/naacl_2016_views_data.tgz`

[2] For adjectives there exist only two categories. These are too general for our task. Instead we use the lexicographer files of all nouns and verbs occurring in the glosses of those adjectives.

Type	Affixes Used
Sentiment	*-able*, *dis-*, *mis-*, *over-*, *under-*, *-(i)sm*
Neutral	adj → noun: *-cy*, *-ity*, *-ness*; adj/noun → verb: *-ize*; verb → adj: *-ed*, *-ing*; verb → noun: *-ion*, *-ing*

Table 2: Affixes used as features.

explicit entity that utters some opinion, i.e. the opinion holder. For a speaker view, this entity remains implicit. This should be reflected in the argument valence of the respective opinion words. We employ the subcategorization frames encoded in *COMLEX* (Grishman et al., 1994) for verbs and adjectives, and *NOMLEX* (Macleod et al., 1998) for nouns.

4.4 Morphological Information (MORPH)

As morphological information, we consider derivational affixes. Table 2 lists our choice of prefixes and suffixes. We only included affixes that occurred at least 10 times in our dataset.

We distinguish between sentiment and neutral affixes. The *sentiment affixes* are affixes which, due to their meaning, suggest a sentiment view. For example, *mis-* as in *misinterpret* indicates that the speaker believes that a given interpretation is incorrect. *-able* as in *admirable* has the meaning of *capable of* which corresponds to an evaluation of the speaker. We could only find sentiment affixes for speaker views.

The *neutral affixes* that we use specify which kinds of bases they can combine with. For example, the noun suffix *-ness* as in *foolishness* indicates that the word originates from an adjective (i.e. *foolish*). Even though this knowledge is syntactic, it may give us some clue as to what sentiment view an opinion word conveys. Table 1 shows that adjectives predominantly carry speaker views. Therefore, a noun ending in *-ness* (thus originating from an adjective) may be similarly likely to convey a speaker view.

4.5 Context Patterns (PATT)

Wiegand and Ruppenhofer (2015) proposed patterns for actor-view and speaker-view verbs. For actor views (PATT_actor), they rely on *prototypical opinion holders (protoOHs)*, i.e. common nouns, such as *opponents* or *critics*, that act like opinion holders (Wiegand and Klakow, 2011). If a verb often co-occurs with an opinion holder – Wiegand and Ruppenhofer (2015) take protoOHs as a proxy – then this is a good indicator of being an actor view (speaker views, per definition, do not have any opinion holder as their dependent). ProtoOHs can similarly be used to extract actor-view nouns and adjectives. For speaker views (PATT_speaker), Wiegand and Ruppenhofer introduced *reproach patterns*, e.g. *blamed for X* as in (11). These patterns can also be applied to nouns (12) but not to adjectives. For the latter, we did not find any pattern. The patterns were applied to the North American News Text Corpus (LDC95T21).

(11) The UN was **blamed for** *misinterpreting*$_{verb}$ climate data.

(12) The UN was **blamed for** the *misinterpretation*$_{noun}$ of climate data.

4.6 Polarity Information (POLAR)

We also investigate in how far polarity information correlates with sentiment views. This information is obtained from the Subjectivity Lexicon (Wilson et al., 2005). Each opinion word is assigned a polarity type, i.e. *positive*, *negative* or *neutral*.

5 Markov Logic Networks and Global Constraints

Markov Logic Networks (MLNs) are a supervised classifier combining first-order logic with probabilities. MLNs are a set of pairs (F_i, w_i) where F_i is a first-order logic formula and w_i a real valued weight associated with F_i. They build a template for constructing a Markov network given a set of constants C. The probability distribution that is estimated is a log-linear model

$$P(X = x) = \frac{1}{Z} exp\left(\sum_{i=1}^{k} w_i n_i(x)\right) \qquad (1)$$

where $n_i(x)$ is the number of groundings in F_i in x and Z is a normalization constant. As an implementation, we use *thebeast* (Riedel, 2008).

We employ MLNs since they allow us (in addition to including ordinary features, i.e. §4.1-§4.6) to formulate constraints holding between individual instances. Such *global constraints* have been effectively exploited with MLNs in related tasks, such as semantic-role labeling (Meza-Ruiz and Riedel, 2009), anaphora resolution (Hou et al., 2013), question answering (Khot et al., 2015) and discourse-based sentiment analysis (Zirn et al., 2011). We formulate three such constraints. Two of them are

Abbrev.	Constraint as Logic Formula
w2v	$\forall x[\forall y[\forall z[\forall u[[Opin.Word(x) \wedge Opin.Word(y) \wedge Word2Vec\text{-}Similar(x,y) \wedge ViewOf(z,x) \wedge ViewOf(u,y)] \rightarrow (z == u)]]]]$
lin	$\forall x[\forall y[\forall z[\forall u[[Opin.Word(x) \wedge Opin.Word(y) \wedge DekangLin\text{-}Similar(x,y) \wedge ViewOf(z,x) \wedge ViewOf(u,y)] \rightarrow (z == u)]]]]$
morph	$\forall x[\forall y[\forall z[\forall u[[Opin.Word(x) \wedge Opin.Word(y) \wedge MorphRelated(x,y) \wedge ViewOf(z,x) \wedge ViewOf(u,y)] \rightarrow (z == u)]]]]$

Table 3: Global constraints enforcing sentiment view consistency as incorporated in MLNs.

based on the two most effective types of word similarities from Wiegand and Ruppenhofer (2015). The first word similarity measures the cosine of word vectors representing opinion words produced by *Word2Vec*-embeddings (Mikolov et al., 2013). The second word similarity is represented by the metric of Lin (1998), which exploits the rich set of dependency-relation labels in the context of distributional similarity.[3] The third type of consistency considers morphological relatedness by which we understand two words deriving from two different parts of speech but belonging to the same lexical root and therefore carrying similar meaning (e.g. *happiness.noun* and *happy.adj*). We obtain that type of relatedness from WordNet (Miller et al., 1990).

Table 3 lists our constraints. They state that if for two opinion words some similarity or morphological relatedness holds, then these words should convey the same sentiment view. For the two types of word-similarity consistencies we considered the top 3 most similar words for each noun, and the top 5 most similar words for each verb and adjective. These values were determined empirically. For the generation of word vectors, we used 200 dimensions along the default configuration of *Word2Vec*. Word similarity and word vectors were generated from the North American News Text Corpus.

6 Experiments

For our evaluation of supervised classification, we focus on a setting in which only few labeled training data are available. We sampled from our gold standard 20% of the labeled training data. The remaining 80% are used as test data. This process was repeated five times. We report performance averaged over these five (test) samples. We focus on small training sizes since we think that for the given lexicon induction task, we should pursue an approach that requires little human annotation. Moreover, we show that our approach yields good results despite the absence of large amounts of training data.

6.1 High-Precision Features

Before we evaluate supervised classification, we look for each part of speech at the 10 features with the highest precision (for each of the two views) as displayed in Table 4. This provides a good overview of the quality of different features. Since we do not have an equal class distribution, we also list a baseline-precision that always predicts the sentiment view under consideration. Since this is just an exploratory experiment, we measure precision on the entire dataset. We exclude the WordNet glosses (§4.1.1) from our analysis as we found individual words from glosses too difficult to interpret.

Table 4 shows that features from all feature groups (§4.1-§4.6) achieve a high precision. Subcategorization features (§4.3) are very predictive for verbs conveying actor views. The frame types that are predictive mostly have in common that one of their arguments is some proposition (13)-(17). This is also true for adjectives (18).

(13) PP-HOW-TO-INF: They $\underline{\text{agree}}_{actor}$ [with him]$_{PP}$ [how to solve the problem]$_{HOW\text{-}TO\text{-}INF}$.

(14) NP-TOBE: They $\underline{\text{believe}}_{actor}$ [him]$_{NP}$ [to be honest]$_{TOBE}$.

(15) NP-ADJP-PRED: They $\underline{\text{consider}}_{actor}$ [him]$_{NP}$ [foolish]$_{ADJP\text{-}PRED}$.

(16) NP-TO-INF: He $\underline{\text{allowed}}_{actor}$ [her]$_{NP}$ [to go]$_{TO\text{-}INF}$.

(17) S: They $\underline{\text{thought}}_{actor}$ [he was always late]$_{S}$.

(18) THAT-S-ADJ: They were $\underline{\text{aware}}_{actor}$ [that he was sick]$_{THAT\text{-}S\text{-}ADJ}$.

FrameNet-frames (§4.2) achieve high precision; but the only frame with good coverage is *Stimulus-focus* for adjectives conveying a speaker view.

There are fewer lexicographer files (§4.1.2) than FrameNet-frames in Table 4, but some of them have high coverage, most notably *LEX_person* for speaker-view nouns and *LEX_feeling* for actor-view nouns. Given the strength of *LEX_person*, we conclude that most opinion nouns denoting persons tend to be speaker views (e.g. *idiot* or *loser*). There are also several predictive lexicographer files whose label seems fairly unintuitive, e.g. *LEX_weather* for

[3] WordNet is not a good option for measuring similarity, as many synonyms of the same synset have different sentiment views, e.g. *comment.noun* (actor) vs. *gossip.noun* (speaker).

Table 4: High-precision features (*minimal frequency* > 10).

speaker-view verbs or *LEX_animal* for speaker-view nouns. These are not errors, however. They actually concern words that convey opinions in metaphorical usage. For instance, *cloud* (a typical weather verb) conveys a speaker view if it is used metaphorically as in *The stroke clouded memories of her youth.* Nouns denoting animals, such as *bull* and *dragon*, convey a speaker view if they are meant to describe a human being (*She is a real dragon!*). Other noun classes follow this pattern, e.g. *body (parts)* with terms such as *backbone* or *bum*.

Simple morphological features (§4.4) also seem to be meaningful. In particular, the noun suffix *-ity* (occurring 132 times in our set of opinion nouns) is indicative of speaker views. The relevant nouns are derived from adjectives (Table 2) and the set of adjectives predominantly conveys speaker views (Table 1).

Even plain polarity information (§4.6) has some significance. *Neutral* sentiment verbs often convey an actor view, such as *opinion*, *utterance* or *view*.

The fact that the pattern-feature (§4.5) also appears on the list of actor-view nouns and adjectives suggests that it is not only effective for verbs as shown in Wiegand and Ruppenhofer (2015) but also for nouns and adjectives.

Classifier(s)	**Description**
graph	graph-based induction approach as proposed in Wiegand and Ruppenhofer (2015)
mln_{local}	Markov Logic Networks with only local features, i.e. features from §4
svm	Support Vector Machines using exactly the same features as mln_{local}
mln_{w2v}, mln_{lin}, mln_{morph}	Markov Logic Networks with global constraints from Table 3
mln+graph	Markov Logic Networks that uses the output of *graph* as a further feature

Table 5: Description of the different classifiers.

Finally, we performed an ablation experiment in which we trained a classifier with all of these features in MLNs and compared it to another classifier in which each of the feature groups (*POLAR*, *LEX*, *MORPH* etc.) was removed, one by one. We computed statistical significance (t-test), testing whether the classifier trained on a feature set in which one feature group was removed performs significantly worse than a classifier with all features. We found that, at a significance level $p < 0.05$, this is always the case, with the exception of *LEX* (here, the significance level is $p = 0.0552$). This is proof that features from most feature groups contain information that is to some extent complementary.

6.2 Classification

Table 5 lists the different types of classifiers we consider. As one baseline, we consider the graph-based approach *graph* from Wiegand and Ruppenhofer (2015) which starts with the seeds gained by the surface patterns (§4.5)[4] and then runs label propagation (Talukdar et al., 2008) based on a distributional similarity graph (using the metric by Lin (1998)). *graph* is the only classifier not depending on manually labeled training data. So far, it has only been examined on verbs. As a further baseline, we consider our features from §4 on an SVM. (We use SVM^{light} (Joachims, 1999).) It should be considered as a state-of-the-art classifier that, unlike *mln*, cannot incorporate global constraints (Table 3).

Table 6 shows the results. Both *graph* and *svm* are significantly outperformed. *graph* performs better on verbs (in terms of F-score) than on nouns and adjectives. It is also for these parts of speech that the global constraints *w2v* and *lin* notably improve the performance of *mln*. Global constraints have a lesser impact on verbs. However, a combination of global constraints is effective, as well as a combination of *graph* and *mln*. The best overall results are obtained by the combination of *mln* with global constraints and *graph*. These results suggest that our new features (including global constraints) are useful and complementary to previous work, i.e. *graph*.

Figure 1 compares the feature derived from WordNet glosses (§4.1.1), a standard feature for lexicon induction, with the remaining features we use on a learning curve. This feature performs poorly if only few labeled training data are used. Our proposed feature set is consistently better. The combination of glosses and our proposed features is only helpful if many labeled training instances are used ($> 60\%$).

6.3 Prior Labels and Context Labels

So far, we have considered sentiment views as prior information of words. Now we relate those labels to sentiment views annotated in context. For that, we consider the view annotation in the MPQA corpus.

Table 7 shows that prior labels of opinion words largely coincide with the respective context labels. This proves that it is a valid approach to compile lexicons with sentiment views, which can subsequently be used in contextual sentiment-view classification.

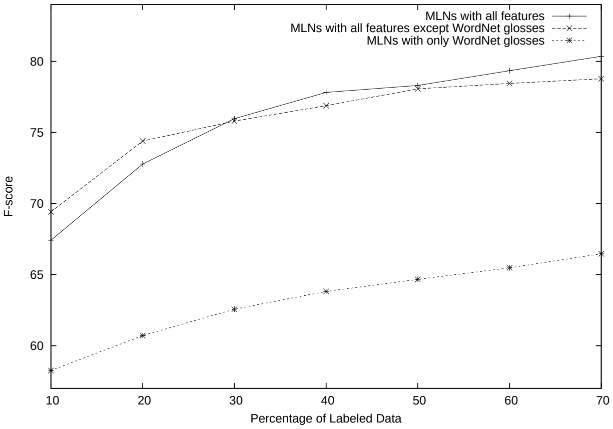

Figure 1: WordNet gloss feature vs. the remaining features *(results averaged over all three parts of speech).*

	context					
	verbs		**nouns**		**adjectives**	
prior	actor	speaker	actor	speaker	actor	speaker
actor	**2926**	834	**1671**	802	**269**	81
speaker	119	**810**	151	**2150**	354	**3489**

Table 7: Comparison of prior labels and context labels.

However, in Table 7, we still observe mismatches between prior and contextual labels. This mostly concerns actor-view words in speaker-view contexts. We examine this mismatch more closely on nouns *(highlighted in gray)* where this confusion is greatest. In MPQA, most subjective expressions that are annotated are sequences of tokens rather than individual words. We found that the largest set of disagreements derives from the nature of MPQA's contextual annotation. The annotators were asked to label spans that expressed opinions that are salient in the document context. Often these are larger spans composed of multiple smaller subjective expressions. The component expressions were not kept track of because the opinion expressed by the larger span was more salient on the document level.

For example, the annotation of the subjective phrase *this must be a* ***warning*** as a speaker view (containing the actor noun *warning*), in our opinion is primarily triggered by the epistemic modal verb *must*, which signals that the speaker feels compelled to come to the conclusion that *this is a warn-*

[4] Since the surface patterns for speaker views from Wiegand and Ruppenhofer (2015) cannot be applied to adjectives (§4.5), we instead used the effective suffix feature MORPH_-*able* (Table 4) for generating speaker-view seeds of opinion adjectives.

ing. The actor view of *warning* is not invalidated by this: it is just backgrounded relative to the speaker view introduced by the modal verb, which, going in parallel with its greater prominence, is also the syntactic governor of the verb phrase *be a warning*, of which the actor view *warning* is part. Our evaluation scheme might thus detect a match between our prior annotation for the modal *must* and the MPQA's larger phrase. But since the less prominent actor view was not picked up by the MPQA annotators, our prior annotation has no counterpart. Copula constructions similarly represent instances, where the speaker performs a speech act (e.g. a warning) by using the copular construction (e.g. *This is a warning*). Here, the speaker is identical to the actor of the warning. Practically, it makes no difference whether we call such a case speaker or actor view, as long as we can recognize that the actor is the speaker.

In order to show that the annotation of MPQA focuses on the more salient opinions and thus sentiment views as conveyed by less prominent expressions are not considered (and largely account for the mismatches in Table 7), we designed a supervised classifier whose features indicate whether a mention of an actor-view expression in a subjective phrase is salient. The features are displayed in Table 8.

The key salience features regarding speaker views, i.e. *modal* and *copular*, were already discussed above. Features indicating the salience of the actor-view word address the subcategorization frame of the word. Cases in which there is a person as some subcategorized argument (*personArg*) often imply an opinion holder. The presence of an (explicit) opinion holder indicates an actor view. A proposition as argument of an opinion word is typically the proposition of some opinion holder (*propArg*) and not of the speaker of the utterance.

For this experiment we take the detection of subjective phrases as given. (Only the information regarding contextual sentiment views is withheld.) This allows us to define features that explicitly look into the entire text span constituting the subjective phrase in which each opinion word is contained. The two length features (*shortPhrase* and *longPhrase*) make use of this information. If a phrase is long, chances are high that there are other more salient opinion words contained than the one under consideration. In short subjective phrases, the presence of other salient words in it is unlikely. This is supported by the fact that the average length of subjective phrases with a speaker view (in which an actor-view opinion noun occurs) are 5.4 tokens while actor-view phrases (that include an actor-view noun) only have an average length of 2.3 tokens.

The majority features (*majActor* and *majSpeaker*) also exploit the information of the entire subjective phrase. We argue that the sentiment view of the phrase is likely to coincide with the view of the majority of the opinion words contained in that phrase.

Table 9 shows how these features separate the mentions of an actor-view opinion noun into contextual actor views and speaker views. We report classification using an SVM (10-fold cross-validation). With only those few features, we largely outperform the baseline always classifying an instance as an actor view (i.e. the majority class). Table 10 displays the precision of each individual feature, supporting that these features are effective. These experiments show that there is indeed a systematic relationship between salience and contextual sentiment views.

Abbreviation	**Features Indicating Contextual ACTOR View**
personArg	a person is argument of opinion word; persons may indicate opinion holders; (explicit) opinion holders indicate absence of speaker view (***his** warning of a catastrophe*)
propArg	a proposition is argument of the opinion word (*warning **that this fish is not fit to eat***); propositions are typically arguments of actor-views words
lightVerb	opinion word is governed by light verb (*they **issued/gave** a warning*), light verbs indicate the presence of an actor outside of the maximal phrase of a subjective noun
shortPhrase	opinion word is part of short subjective phrase ($<$ 3 tokens); short phrases make embedding of another more salient (speaker-view) word unlikely
majActor	majority of other opinion words in subjective phrase are actor-view words
Abbreviation	**Features Indicating Contextual SPEAKER View**
copula	opinion word is part of copula construction (*this **is a warning***) – see discussion in §6.3
modal	opinion word is in modal scope (*this **must** be a warning*) – see discussion in §6.3
emphasis	opinion word is accompanied by emphatic cue, e.g. *!*, quotation (*they gave him a **"**warning**"***), (rhetoric) question; emphases typically originate from speaker
precededByAs	preceded by *as* (*this was regarded* [***as** an urgent warning*]$_{as\text{-}phrase}$), *as*-phrase typically occurs as an argument of categorization predicates *regard*, *view*, *see*, *consider* etc. – with these predicates an *as*-phrase often conveys a speaker view, especially since the predicates often have no explicit holder
longPhrase	opinion word is part of long subjective phrase ($>$ 4 tokens); long phrases make embedding of another more salient (speaker-view) word likely
majSpeaker	majority of other opinion words in subjective phrase are speaker-view words

7 Conclusion

We examined different types of features and classifiers for the categorization of sentiment views that opinion words convey. We found that many features are effective for this task. A detailed feature analysis provided linguistic insights into the nature of sentiment views. As a classifier, MLNs performed best. This classifier has the advantage that global constraints can be incorporated, which raises classification performance on nouns and adjectives. Our approach outperforms a previously proposed graph-based approach evaluated on opinion verbs. We also demonstrated that prior sentiment views correlate with contextual sentiment views on MPQA.

Abstract

This paper presents a clustering approach that simultaneously identifies product features and groups them into aspect categories from online reviews. Unlike prior approaches that first extract features and then group them into categories, the proposed approach combines feature and aspect discovery instead of chaining them. In addition, prior work on feature extraction tends to require seed terms and focus on identifying explicit features, while the proposed approach extracts both *explicit* and *implicit* features, and does not require seed terms. We evaluate this approach on reviews from three domains. The results show that it outperforms several state-of-the-art methods on both tasks across all three domains.

1 Introduction

If you are thinking of buying a TV for watching football, you might go to websites such as Amazon to read customer reviews on TV products. However, there are many products and each of them may have hundreds of reviews. It would be helpful to have an aspect-based sentiment summarization for each product. Based on other customers' opinions on multiple aspects such as size, picture quality, motion-smoothing, and sound quality, you might be able to make the decision without going through all the reviews. To support such summarization, it is essential to have an algorithm that extracts product features and aspects from reviews.

Features are components and attributes of a product. A feature can be directly mentioned as an opinion target (i.e., explicit feature) or implied by opinion words (i.e., implicit feature). Different feature expressions may be used to describe the same *aspect* of a product. Aspect can be represented as a group of features. Consider the following review sentences, in which we denote **explicit** and *implicit* features in boldface and italics, respectively.

1. This phone has great **display** and perfect **size**. It's very *fast* with all great **features**.
2. Good **features** for an *inexpensive* android. The **screen** is *big* and *vibrant*. Great **speed** makes *smooth* viewing of tv programs or sports.
3. The phone runs *fast* and *smooth*, and has great **price**.

In review 1, *display* is an explicit feature, and opinion word "fast" implies implicit feature *speed*. The task is to identify both explicit and implicit features, and group them into aspects, e.g., {speed, fast, smooth}, {size, big}, {price, inexpensive}.

Many existing studies (Hu and Liu, 2004; Su et al., 2006; Qiu et al., 2009; Hai et al., 2012; Xu et al., 2013) have focused on extracting features without grouping them into aspects. Some methods have been proposed to group features given that feature expressions have been identified beforehand (Zhai et al., 2010; Moghaddam and Ester, 2011; Zhao et al., 2014), or can be learned from semi-structured Pros and Cons reviews (Guo et al., 2009; Yu et al., 2011). In recent years, topic models have been widely studied for their use in aspect discovery with the advantage that they extract features and group them simultaneously. However, researchers have found some

Proceedings of NAACL-HLT 2016, pages 789–799,
San Diego, California, June 12-17, 2016.

limitations of such methods, e.g., the produced topics may not be coherent or directly interpretable as aspects (Chen et al., 2013; Bancken et al., 2014), the extracted aspects are not fine-grained (Zhang and Liu, 2014), and it is ineffective when dealing with aspect sparsity (Xu et al., 2014).

In this paper, we present a clustering algorithm that extracts features and groups them into aspects from product reviews. Our work differs from prior studies in three ways. First, it identifies both features and aspects simultaneously. Existing clustering-based solutions (Su et al., 2008; Lu et al., 2009; Bancken et al., 2014) take a two-step approach that first identifies features and then employs standard clustering algorithms (e.g., k-means) to group features into aspects. We propose that these two steps can be combined into a single clustering process, in which different words describing the same aspect can be automatically grouped into one cluster, and features and aspects can be identified at the same time. Second, both explicit and implicit features are extracted and grouped into aspects. While most existing methods deal with explicit features (e.g., "speed", "size"), much less effort has been made to identify implicit features implied by opinion words (e.g., "fast", "big"), which is challenging because many general opinion words such as "good" or "great" do not indicate product features, therefore they should not be identified as features or grouped into aspects. Third, it is unsupervised and does not require seed terms, hand-crafted patterns, or any other labeling efforts.

Specifically, the algorithm takes a set of reviews on a product (e.g., TV, cell phone) as input and produces aspect clusters as output. It first uses a part-of-speech tagger to identify nouns/noun phrases, verbs and adjectives as candidates. Instead of applying the clustering algorithm to all the candidates, only the frequent ones are clustered to generate *seed clusters*, and then the remaining candidates are placed into the closest seed clusters. This does not only speed up the algorithm, but it also reduces the noise that might be introduced by infrequent terms in the clustering process. We propose a novel *domain-specific similarity measure* incorporating both statistical association and semantic similarity between a pair of candidates, which recognizes features referring to the same aspects in a particular domain. To further improve the quality of clusters, several problem-specific *merging constraints* are used to prevent the clusters referring to different aspects from being merged during the clustering process. The algorithm stops when it cannot find another pair of clusters satisfying these constraints.

This algorithm is evaluated on reviews from three domains: cell phone, TV and GPS. Its effectiveness is demonstrated through comparison with several state-of-the-art methods on both tasks of feature extraction and aspect discovery. Experimental results show that our method consistently yields better results than these existing methods on both tasks across all the domains.

2 Related Work

Feature and aspect extraction is a core component of aspect-based opinion mining systems. Zhang and Liu (2014) provide a broad overview of the tasks and the current state-of-the-art techniques.

Feature identification has been explored in many studies. Most methods focus on explicit features, including unsupervised methods that utilize association rules (Hu and Liu, 2004; Liu et al., 2005), dependency relations (Qiu et al., 2009; Xu et al., 2013), or statistical associations (Hai et al., 2012) between features and opinion words, and supervised ones that treat it as a sequence labeling problem and apply Hidden Markov Model (HMM) or Conditional Random Fields (CRF) (Jin et al., 2009; Yang and Cardie, 2013) to it. A few methods have been proposed to identify implicit features, e.g., using co-occurrence associations between implicit and explicit features (Su et al., 2006; Hai et al., 2011; Zhang and Zhu, 2013), or leveraging lexical relations of words in dictionaries (Fei et al., 2012). Many of these techniques require seed terms, hand-crafted rules/patterns, or other annotation efforts.

Some studies have focused on grouping features and assumed that features have been extracted beforehand or can be extracted from semi-structured Pros and Cons reviews. Methods including similarity matching (Carenini et al., 2005), topic modeling (Guo et al., 2009; Moghaddam and Ester, 2011), Expectation-Maximization (EM) based semi-supervised learning (Zhai et al., 2010; Zhai et al., 2011), and synonym clustering (Yu et al., 2011) have been explored in this context.

To extract features and aspects at the same time, topic model-based approaches have been explored by a large number of studies in recent years. Standard topic modeling methods such as pLSA (Hofmann, 2001) and LDA (Blei et al., 2003) are extended to suit the peculiarities of the problem, e.g., capturing local topics corresponding to ratable aspects (Titov and McDonald, 2008a; Titov and McDonald, 2008b; Brody and Elhadad, 2010), jointly extracting both topic/aspect and sentiment (Lin and He, 2009; Jo and Oh, 2011; Kim et al., 2013; Wang and Ester, 2014), incorporating prior knowledge to generate coherent aspects (Mukherjee and Liu, 2012; Chen et al., 2013; Chen et al., 2014), etc.

Very limited research has focused on exploring clustering-based solutions. Su et al. (2008) presented a clustering method that utilizes the mutual reinforcement associations between features and opinion words. It employs standard clustering algorithms such as k-means to iteratively group feature words and opinion words separately. The similarity between two feature words (or two opinion words) is determined by a linear combination of their intra-similarity and inter-similarity. Intra-similarity is the traditional similarity, and inter-similarity is calculated based on the degree of association between feature words and opinion words. To calculate the inter-similarity, a feature word (or an opinion word) is represented as a vector where each element is the co-occurrence frequency between that word and opinion words (or feature words) in sentences. Then the similarity between two items is calculated by cosine similarity of two vectors. In each iteration, the clustering results of one type of data items (feature words or opinion words) are used to update the pairwise similarity of the other type of items. After clustering, the strongest links between features and opinion words form the aspect groups. Mauge et al. (2012) first trained a maximum-entropy classifier to predict the probability that two feature expressions are synonyms, then construct a graph based on the prediction results and employ greedy agglomerative clustering to partition the graph to clusters. Bancken et al. (2014) used k-medoids clustering algorithm with a WordNet-based similarity metric to cluster semantically similar aspect mentions.

These existing clustering methods take two steps. In the first step, features are extracted based on association rules or dependency patterns, and in the second step features are grouped into aspects using clustering algorithms. In contrast, our method extracts features and groups them at the same time. Moreover, most of these methods extract and group only explicit features, while our method deals with both explicit and implicit features. The method proposed in (Su et al., 2008) also handles implicit features (opinion words), but their similarity measure largely depends on co-occurrence between features and opinion words, which may not be efficient in identifying features that are semantically similar but rarely co-occur in reviews.

3 The Proposed Approach

Let $X = \{x_1, x_2, ..., x_n\}$ be a set of candidate features extracted from reviews of a given product (e.g., TV, cell phone). Specifically, by using a part-of-speech tagger[1], nouns (e.g., "battery") and two consecutive nouns (e.g., "battery life") are identified as candidates of *explicit* features, and adjectives and verbs are identified as candidates of *implicit* features. Stop words are removed from X. The algorithm aims to group similar candidate terms so that the terms referring to the same aspect are put into one cluster. At last, the important aspects are selected from the resulting clusters, and the candidates contained in these aspects are identified as features.

3.1 A Clustering Framework

Algorithm 1 illustrates the clustering process. The algorithm takes as input a set X that contains n candidate terms, a natural number k indicating the number of aspects, a natural number s ($0 < s \leq n$) indicating the number of candidates that will be grouped first to generate the *seed clusters*, and a real number δ indicating the upper bound of the distance between two mergeable clusters. Instead of applying the *agglomerative clustering* to all the candidates, it first selects a set $X' \subseteq X$ of s candidates that appear most frequently in the corpus for clustering. The reasons for this are two-fold. First, the frequently mentioned terms are more likely the actual features of customers' interests. By clustering these terms first, we can generate high quality seed clusters.

[1] http://nlp.stanford.edu/software/tagger.shtml

Second, as the clustering algorithm requires pairwise distances between candidates/clusters, it could be very time-consuming if there are a large number of candidates. We can speed up the process by clustering only the most frequent ones.

Algorithm 1: Clustering for Aspect Discovery

```
Input: $X = \{x_1, ..., x_n\}$, $k$, $s$, $\delta$
Output: $\{A_j\}_{j=1}^k$
Select the top $s$ most frequent candidates from $X$: $X' = \{x'_1, ..., x'_s\}$;
Set $C_1 \leftarrow \{x'_1\}, ..., C_s \leftarrow \{x'_s\}$;
Set $\Theta \leftarrow \{C_1, ..., C_s\}$;
while there exist a pair of mergeable clusters from $\Theta$ do
    Select a pair of closest clusters $C_l$ and $C_m$ such that VIOLATE-CONSTRAINTS($C_l$, $C_m$, $\delta$) is false;
    $C_m \leftarrow C_l \cup C_m$;
    $\Theta \leftarrow \Theta - \{C_l\}$;
for $x_i \in X - X'$ do
    Select the closest clusters $C_d$ from $\Theta$ such that VIOLATE-CONSTRAINTS($\{x_i\}$, $C_d$, $\delta$) is false;
    if there exist such cluster $C_d$ then
        $C_d \leftarrow C_d \cup \{x_i\}$;
$\{A_j\}_{j=1}^k \leftarrow$ SELECT($\Theta$, $k$);
```

The clustering starts with every frequent term x'_i in its own cluster C_i, and Θ is the set of all clusters. In each iteration, a pair of clusters C_l and C_m that are most likely composed of features referring to the same aspect are merged into one. Both a similarity measure and a set of constraints are used to select such pair of clusters. We propose a *domain-specific similarity measure* that determines how similar the members in two clusters are regarding the particular domain/product. Moreover, we add a set of *merging constraints* to further ensure that the terms from different aspects would not be merged. The clustering process stops when it cannot find another pair of clusters that satisfy the constraints. We call the obtained clusters in Θ the *seed clusters*. Next, the algorithm assigns each of the remaining candidate $x_i \in X - X'$ to its closest seed cluster that satisfies the merging constraints. At last, k clusters are selected from Θ as aspects[2]. Based on the idea that the frequent clusters are usually the important aspects of customers' interests, we select the top k clusters having the highest sum of members' frequencies of occurrence. From the k aspects, the nouns and noun phrases (e.g., "speed", "size") are recognized as explicit features, and the adjectives and verbs (e.g., "fast", "big"), are recognized as implicit features.

3.2 Domain-specific Similarity

The similarity measure aims to identify terms referring to the same aspect of a product. Prior studies (Zhai et al., 2010; Zhai et al., 2011) have shown that general semantic similarities learned from thesaurus dictionaries (e.g., WordNet) do not perform well in grouping features, mainly because the similarities between words/phrases are domain dependent. For example, "ice cream sandwich" and "operating system" are not relevant in general, but they refer to the same aspect in *cell phone* reviews[3]; "smooth" and "speed" are more similar in *cell phone* domain than they are in *hair dryer* domain. Methods based on distributional information in a domain-specific corpus are usually used to determine the domain-dependent similarities between words/phrases. However, relying completely on the corpus may not be sufficient either. For example, people usually use "inexpensive" or "great price" instead of "inexpensive price"; similarly, they use "running fast" or "great speed" instead of "fast speed". Though "inexpensive" and "price" or "fast" and "speed" refer to the same aspect, we may not find they are similar based on their context or co-occurrences in the corpus.

We propose to estimate the domain-specific similarities between candidates by incorporating both general semantic similarity and corpus-based statistical association. Formally, let G be a $n \times n$ similarity matrix, where G_{ij} is the *general semantic similarity* between candidates x_i and x_j, $G_{ij} \in [0, 1]$, $G_{ij} = 1$ when $i = j$, and $G_{ij} = G_{ji}$. We use UMBC Semantic Similarity Service[4] to get G. It combines both WordNet knowledge and statistics

[2] If k is larger than the number of clusters obtained, all the clusters are selected as aspects.

[3] *Ice Cream Sandwich* is a version of the Android mobile operating system.

[4] http://swoogle.umbc.edu/SimService/index.html

from a large web corpus to compute the semantic similarity between words/phrases (Han et al., 2013).

Let T be a $n \times n$ association matrix, where T_{ij} is the pairwise *statistical association* between x_i and x_j in the domain-specific corpus, $T_{ij} \in [0,1]$, $T_{ij} = 1$ when $i = j$, and $T_{ij} = T_{ji}$. We use normalized pointwise mutual information (NPMI) (Bouma, 2009) as the measure of association to get T, that is,

$$NPMI(x_i, x_j) = \frac{\log \frac{Nf(x_i,x_j)}{f(x_i)f(x_j)}}{-\log \frac{f(x_i,x_j)}{N}},$$

where $f(x_i)$ (or $f(x_j)$) is the number of documents where x_i (or x_j) appears, $f(x_i, x_j)$ is the number of documents where x_i and x_j co-occur in a sentence, and N is the total number of documents in the domain-specific corpus. NPMI is the normalization of pointwise mutual information (PMI), which has the pleasant property $NPMI(x_i, x_j) \in [-1, 1]$ (Bouma, 2009). The values of NPMI are rescaled to the range of $[0, 1]$, because we want $T_{ij} \in [0, 1]$.

A candidate x_i can be represented by the i-th row in G or T, i.e., the row vector $g_{i:}$ or $t_{i:}$, which tells us what x_i is about in terms of its general semantic similarities or statistical associations to other terms. The cosine similarity between two vectors $\vec{u}$ and $\vec{v}$ can be calculated as:

$$cosine(\vec{u}, \vec{v}) = \frac{\vec{u} \cdot \vec{v}}{\parallel \vec{u} \parallel \parallel \vec{v} \parallel} = \frac{\sum_{i=1}^{n} u_i v_i}{\sqrt{\sum_{i=1}^{n} u_i^2}\sqrt{\sum_{i=1}^{n} v_i^2}}.$$

By calculating the cosine similarity between two vectors of x_i and x_j ($i \neq j$), we get the following similarity metrics:

$$\begin{aligned}
&sim_g(x_i, x_j) = cosine(g_{i:}, g_{j:}),\\
&sim_t(x_i, x_j) = cosine(t_{i:}, t_{j:}),\\
&sim_{gt}(x_i, x_j) = max(cosine(g_{i:}, t_{j:}), cosine(t_{i:}, g_{j:})).
\end{aligned}$$

$sim_g(x_i, x_j)$ provides the comparison between $g_{i:}$ and $g_{j:}$. Similar row vectors in G indicate similar semantic meanings of two terms (e.g., "price" and "inexpensive"). $sim_t(x_i, x_j)$ provides the comparison between $t_{i:}$ and $t_{j:}$. Similar row vectors in T indicate similar context of two terms in the domain, and terms that occur in the same contexts tend to have similar meanings (Harris, 1954) (e.g., "ice cream sandwich" and "operating system"). $sim_{gt}(x_i, x_j)$ provides the comparison between the row vector in G and the row vector in T of two terms. $sim_{gt}(x_i, x_j)$ is designed to get high value when the terms strongly associated with x_i (or x_j) are semantically similar to x_j (or x_i). By this measure, the domain-dependent synonyms such as "smooth" and "speed" (in *cell phone* domain) can be identified because the word "smooth" frequently co-occurs with some other words (e.g., "fast", "run") that are synonymous with the word "speed".

Because $G_{ij} \in [0, 1]$ and $T_{ij} \in [0, 1]$, the values of $sim_g(x_i, x_j)$, $sim_t(x_i, x_j)$, and $sim_{gt}(x_i, x_j)$ range from 0 to 1. In addition, $sim_g(x_i, x_j) = sim_g(x_j, x_i)$, $sim_t(x_i, x_j) = sim_t(x_j, x_i)$ and $sim_{gt}(x_i, x_j) = sim_{gt}(x_j, x_i)$. When $i = j$, we set all the similarity metrics between x_i and x_j to 1. Finally, the domain-specific similarity between x_i and x_j ($i \neq j$) is defined as the weighted sum of the above three similarity metrics: $sim(x_i, x_j) = w_g sim_g(x_i, x_j) + w_t sim_t(x_i, x_j) + w_{gt} sim_{gt}(x_i, x_j)$, where w_g, w_t and w_{gt} denote the relative weight of importance of the three similarity metrics, respectively. The values of the weight ranges from 0 to 1, and $w_g + w_t + w_{gt} = 1$.

Based on the domain-specific similarities between candidates, we now define the distance measures of clustering as:

$$\begin{aligned}
&dist_{avg}(C_l, C_m) = \frac{\sum_{x_{i'} \in C_l} \sum_{x_{j'} \in C_m} (1 - sim(x_{i'}, x_{j'}))}{|C_l| \times |C_m|},\\
&r(C_l) = argmax_{x_{i'} \in C_l} f(x_{i'}),\\
&dist_{rep}(C_l, C_m) = 1 - sim(r(C_l), r(C_m)),
\end{aligned}$$

where $dist_{avg}(C_l, C_m)$ is the average of candidate distances between clusters C_l and C_m, $r(C_l)$ is the most frequent member (i.e., *representative term*) in cluster C_l, and $dist_{rep}(C_l, C_m)$ is the distance between the representative terms of two clusters. The two clusters describing the same aspect should be close to each other in terms of both average distance and representative distance, thus the final distance is defined as the maximum of these two:

$$dist(C_l, C_m) = max(dist_{avg}(C_l, C_m), dist_{rep}(C_l, C_m)).$$

3.3 Merging Constraints

Prior studies (Wagstaff et al., 2001) have explored the idea of incorporating background knowledge as constraints on the clustering process to further improve the performance. Two types of constraints are usually considered: must-link constraints specifying that two objects (e.g., words) must be placed in the same cluster, and cannot-link constraints specifying that two objects cannot be placed in the same cluster. We also add problem-specific constraints that specify which clusters cannot be merged together, but instead of manually creating the cannot-links between specific words, our cannot-link constraints are automatically calculated during the clustering process.

Specifically, two clusters cannot be merged if they violate any of the three merging constraints: (1) The distance between two clusters must be less than a given value δ (see Algorithm 1). (2) There must be at least one noun or noun phrase (candidate of explicit feature) existing in one of the two clusters. Because we assume an aspect should contain at least one explicit feature, and we would not get an aspect by merging two non-aspect clusters. (3) The sum of frequencies of the candidates from two clusters co-occurring in the same sentences must be higher than the sum of frequencies of them co-occurring in the same documents but different sentences. The idea is that people tend to talk about different aspects of a product in different sentences in a review, and talk about the same aspect in a small window (e.g., the same sentence).

4 Experiments

In this section, we evaluate the effectiveness of the proposed approach on feature extraction and aspect discovery. Table 1 describes the datasets from three different domains that were used in the experiments. The cell phone reviews were collected from the online shop of a cell phone company, and the GPS and TV reviews were collected from Amazon.

Three human annotators manually annotate the datasets to create gold standards of features and aspects. These annotators first identify feature expressions from reviews independently. The expressions that were agreed by at least two annotators were selected as features. Then the authors manually specified a set of aspects based on these features, and asked three annotators to label each feature with an aspect category. The average inter-annotator agreement on aspect annotation was $\kappa = 0.687$ ($stddev = 0.154$) according to Cohen's Kappa statistic. To obtain the gold standard annotation of aspects, the annotators discussed to reach an agreement when there was a disagreement on the aspect category of a feature. *We are making the datasets and annotations publicly available*[5].

Table 1 shows the number of reviews, aspects, unique explicit/implicit features manually identified by annotators, and candidates of explicit (i.e., noun and noun phrase) and implicit (i.e., adjective and verb) features extracted from the datasets in three domains.

	Cell phone	GPS	TV
# Reviews	500	500	500
# Aspects	46	37	34
# Features (expl.)	419	637	485
# Features (impl.)	339	492	277
# Candidates (expl.)	1,248	2,078	2,333
# Candidates (impl.)	1,115	1,779	1,690

Table 1: Data sets and gold standards.

We use "CAFE" (**C**lustering for **A**spect and **F**eature **E**xtraction) to denote the proposed method. We assume the number of aspects k is specified by the users, and set $k = 50$ throughout all the experiments. We use $s = 500$, $\delta = 0.8$, $w_g = w_t = 0.2, w_{gt} = 0.6$ as the default setting of CAFE, and study the effect of parameters in Section "Influence of Parameters". In addition, we evaluate each individual similarity metric – "CAFE-g", "CAFE-t" and "CAFE-gt" denote the variations of "CAFE" that use $sim_g(x_i, x_j)$, $sim_t(x_i, x_j)$, and $sim_{gt}(x_i, x_j)$ as the similarity measure, respectively. We empirically set $\delta = 0.4$ for "CAFE-g", $\delta = 0.84$ for "CAFE-t" and $\delta = 0.88$ for "CAFE-gt".

4.1 Evaluations on Feature Extraction

We compared CAFE against the following two state-of-the-art methods on feature extraction:

- **PROP**: A double propagation approach (Qiu et al., 2009) that extracts features using hand-crafted rules based on dependency relations between features and opinion words.
- **LRTBOOT**: A bootstrapping approach (Hai et al., 2012) that extracts features by mining pairwise feature-feature, feature-opinion, opinion-opinion associations between terms in the corpus, where the association is measured by the likelihood ratio tests (LRT).

Both methods require seeds terms. We ranked the feature candidates by descending document fre-

(a) Cell Phone

(b) GPS

(c) TV

Figure 1: Precision-recall curves at various parameter settings for three feature extraction methods.

quency and manually selected the top 10 genuine features as seeds for them. According to the study (Hai et al., 2012), the performance for LRTBOOT remained almost constant when increasing the seeds from 1 to 50. Three association thresholds need to be specified for LRTBOOT. Following the original study in which the experiments were conducted on cell-phone reviews, we set $ffth = 21.0$, $ooth = 12.0$, and performed grid search for the value of $foth$. The best results were achieved at $foth = 9.0$ for cell-phone reviews, and at $foth = 12.0$ for GPS and TV reviews.

The results were evaluated by precision $= \frac{N_{agree}}{N_{result}}$, recall $= \frac{N_{agree}}{N_{gold}}$, and F-score $= \frac{2\times\text{precision}\times\text{recall}}{\text{precision}+\text{recall}}$, where N_{result} and N_{gold} are the number of features in the result and the gold standard, respectively, and N_{agree} is the number of features that are agreed by both sides. Because PROP and LRTBOOT extract only explicit features, the evaluation was conducted on the quality of explicit features. The performance of identifying implicit features will be examined by evaluation on aspect discovery, because implicit features have to be merged into aspects to be detected.

Table 2 shows the best results (in terms of F-score) of feature extraction by different methods. Both PROP and LRTBOOT obtain high recall and relatively low precision. CAFE greatly improves precision, with a relatively small loss of recall, resulting in 21.68% and 9.36% improvement in macro-averaged F-score over PROP and LRTBOOT, respectively. We also plot precision-recall curves at various parameter settings for CAFE and LRTBOOT in Figure 1. For CAFE, we kept $s = 500$, $w_g = w_t = 0.2, w_{gt} = 0.6$, and increased δ from 0.64 to 0.96. For LRTBOOT, we kept $ffth = 21.0$, $ooth = 12.0$, and increased $foth$ from 6.0 to 30.0. For PROP, only one precision-recall point was obtained. From Figure 1, we see that the curve of CAFE lies well above those of LRTBOOT and PROP across three datasets. Though LRTBOOT achieved similar precision as CAFE did at the recall rate of approximately 0.37 for GPS reviews and at the recall rate of approximately 0.49 for TV reviews, it performed worse than CAFE at increasing recall levels for both datasets.

The key difference between CAFE and the baselines is that CAFE groups terms into clusters and identifies the terms in the selected aspect clusters as features, while both baselines enlarge a feature seed set by mining syntactical or statistical associations between features and opinion words. The results suggest that features can be more precisely identified via aspect clustering. Generally, CAFE is superior to its variations, and CAFE-g outperforms CAFE-gt and CAFE-t.

4.2 Evaluations on Aspect Discovery

For comparison with CAFE on aspect discovery, we implemented the following three methods:

- **MuReinf**: A clustering method (Su et al., 2008) that utilizes the mutual reinforcement association between features and opinion words to iteratively group them into clusters. Similar to the proposed method, it is unsupervised, clustering-based, and handling implicit features.

- **L-EM**: A semi-supervised learning method (Zhai et al., 2011) that adapts the Naive Bayesian-based EM algorithm to group synonym features into categories. Because semi-supervised learning needs some labeled examples, the proposed method first automatically generates some labeled examples (i.e., the groups of synonym feature expressions) based on features sharing common words and lexical similarity.
- **L-LDA**: A baseline method (Zhai et al., 2011) that is based on LDA. The same labeled examples generated by L-EM are used as seeds for each topic in topic modeling.

These three methods require features to be extracted beforehand, and focus on grouping features into aspects. Both LRTBOOT and CAFE are used to provide the input features to them. We set $\alpha = 0.6$ for MuReinf, because their study (Su et al., 2008) showed that the method achieved best results at $\alpha > 0.5$. All three methods utilize dictionary-based semantic similarity to some extent. Since CAFE uses the UMBC Semantic Similarity Service, we use the same service to provide the semantic similarity for all the methods.

	Cell-phone	GPS	TV	macro-average
LRTBOOT + MuReinf	0.7182	0.8031	0.7747	0.7653
LRTBOOT + L-EM	0.6633	0.6893	0.7138	0.6888
LRTBOOT + L-LDA	0.7653	0.7198	0.7664	0.7505
CAFE + MuReinf	0.7973	0.8212	**0.8334**	0.8173
CAFE + L-EM	0.7581	0.7772	0.7879	0.7744
CAFE + L-LDA	0.7904	0.8144	0.8247	0.8098
CAFE	0.8041	**0.8238**	0.8326	**0.8202**
CAFE-g	0.7382	0.7534	0.8205	0.7707
CAFE-t	0.7868	0.8050	0.7965	0.7961
CAFE-gt	**0.8073**	0.7716	0.7906	0.7898

Table 3: Rand Index of aspect identification.

The results were evaluated using Rand Index (Rand, 1971), a standard measure of the similarity between the clustering results and a gold standard. Given a set of n objects and two partitions of them, the Rand Index is defined as $\frac{2(a+b)}{n \times (n-1)}$. The idea is that the agreements/disagreements between two partitions are checked on $n \times (n-1)$ pairs of objects. Among all the pairs, there are a pairs belonging to the same cluster in both partitions, and b pairs belonging to different clusters in both partitions. In this study, the gold standard and the aspect clusters may not share the exact same set of features due to the noise in feature extraction, therefore we consider n the number of expressions in the union of two sets.

Table 3 shows the Rand Index achieved by different methods. Among the methods that generate partitions of the same features provided by CAFE, CAFE achieves the best macro-averaged Rand Index, followed by CAFE + MuReinf, CAFE + L-LDA, and CAFE + L-EM. CAFE outperforms the variations using the single similarity metric, i.e., CAFE-g, CAFE-t and CAFE-gt. The results imply the effectiveness of our domain-specific similarity measure in identifying synonym features in a particular domain. Using the input features from LRTBOOT, the performance of MuReinf, L-EM and L-LDA decrease on all three domains, compared with using the input features from CAFE. The decrease is more significant for L-EM and L-LDA than for MuReinf, which suggest that the semi-supervised methods L-EM and L-LDA are more dependent on the quality of input features.

Table 4 illustrates a sample of the discovered aspects and features by CAFE. The algorithm identifies the important *aspects* in general sense as well as the important aspects that are not so obvious thus could be easily missed by human judges, e.g., *suction cup* for GPS and *glare* for TV. In addition, both explicit and implicit features are identified and grouped into the aspects, e.g., *expensive* and *price*, *big* and *size*, *sensitive* and *signal*, etc.

4.3 Influence of Parameters

We varied the value of δ (distance *upper bound*), s (the number of frequent candidates selected to generate seed clusters) and w_{gt} (the weight of sim_{gt}) to see how they impact the results of CAFE, for both feature extraction (in terms of F-Score) and aspect discovery (in terms of Rand Index). Both F-score and Rand Index increases rapidly at first and then slowly decreases as we increase δ from 0.64 to 0.96 (see the left subplot in Figure 2). Because more clusters are allowed to be merged as we increase δ, which is good at first but then it introduces more noise than benefit. Based on the experiments on

Table 4: Examples of discovered aspects and features by the proposed approach CAFE. Explicit and implicit features are denoted in boldface and italics, respectively. The first term in each cluster is the representative term of that aspect.

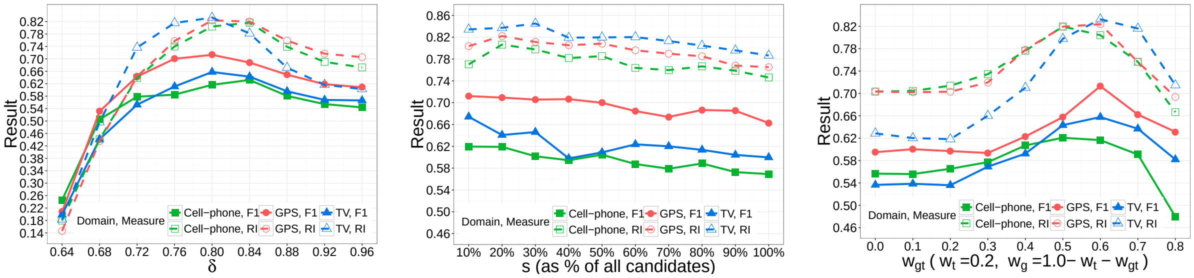

Figure 2: CAFE parameter tuning: feature quality in terms of F-score (F1) and aspect quality in terms of Rand Index (RI). The default setting is $s = 500$, $\delta = 0.8$, $w_g = w_t = 0.2$, $w_{gt} = 0.6$. We keep other parameters as the default setting when we tune an individual parameter.

three domains, the best results can be achieved when δ is set to a value between 0.76 and 0.84. The middle subplot illustrates the impact of s, which shows that CAFE generates better results by first clustering the top 10%-30% most frequent candidates. Infrequent words/phrases are usually more noisy, and the results could be affected more seriously if the noises are included in the clusters in the early stage of clustering. Experiments were also conducted to study the impact of the three similarity metrics. Due to the space limit, we only display the impact of w_{gt} and w_g given $w_t = 0.2$. As we can see from the right subplot in Figure 2, setting w_{gt} or w_g to zero evidently decreases the performance, indicating both similarity metrics are useful. The best F-score and Rand Index can be achieved when we set w_{gt} to 0.5 or 0.6 across all three domains.

5 Conclusion

In this paper, we proposed a clustering approach that simultaneously extracts features and aspects of a given product from reviews. Our approach groups the feature candidates into clusters based on their domain-specific similarities and merging constraints, then selects the important aspects and identifies features from these aspects. This approach has the following advantages: (1) It identifies both aspects and features simultaneously. The evaluation shows its accuracy on both tasks outperforms the competitors. (2) Both explicit and implicit features can be identified and grouped into aspects. The mappings of implicit features into explicit features are accomplished naturally during the clustering process. (3) It does not require labeled data or seed words, which makes it easier to apply and broader in application. In our future work, instead of selecting aspects based on frequency, we will leverage domain knowledge to improve the selection.

Abstract

We present an approach to the new task of opinion holder and target extraction on opinion compounds. Opinion compounds (e.g. *user rating* or *victim support*) are noun compounds whose head is an opinion noun. We do not only examine features known to be effective for noun compound analysis, such as paraphrases and semantic classes of heads and modifiers, but also propose novel features tailored to this new task. Among them, we examine paraphrases that jointly consider holders and targets, a verb detour in which noun heads are replaced by related verbs, a global head constraint allowing inferencing between different compounds, and the categorization of the sentiment view that the head conveys.

1 Introduction

One of the key subtasks in sentiment analysis is opinion role extraction. It can be divided into the extraction of *opinion holders (OH)*, i.e. entities expressing an opinion, and the extraction of *opinion targets (OT)*, i.e. entities or propositions at which sentiment is directed. This task is vital for various applications involving sentiment analysis, e.g. opinion summarization or opinion question answering.

Opinion role extraction is commonly regarded as a task in lexical semantics. An opinion is evoked by some opinion word, e.g. *criticized* in (1), *skeptical* in (2) or *intentions* in (3), and its opinion roles are usually realized as syntactic dependents. Opinion words come in many shapes, the most frequent types being opinion verbs (1), opinion adjectives (2) and opinion nouns (3). These types of opinion words have extensively been studied in various sentiment-related corpora, such as MPQA (Wiebe et al., 2005).

(1) [Peter $_{OH}$] **criticized**$_{verb}$ [Mary $_{OT}$].
(2) [Mary $_{OH}$] was **skeptical**$_{adj}$ [about the plan $_{OT}$].
(3) [Peter $_{OH}$] had firm **intentions**$_{noun}$ [to quit his job $_{OT}$].

In this work, we examine opinion roles that are realized in opinion compounds. We define an opinion compound (Table 1) as a noun compound, i.e. a sequence of two nouns, where the second noun, i.e. the *head*, is an opinion expression. The first noun, i.e. the *modifier*, can represent an opinion holder (4)-(5), an opinion target (6)-(7) or neither (8)-(9). Our aim is to automatically classify the modifier into these categories. This task is challenging as, unlike with opinion roles expressed in the syntax (1)-(3), the immediate context of compounds does not contain explicit cues as to the relation between head and modifier. Moreover, due to the high productivity of compounding, this task cannot be solved by compiling a (finite) compound lexicon that encodes for each compound the category of its modifier.

(4) [user $_{OH}$] **rating** *(i.e. user rates something)*
(5) [consumer $_{OH}$] **uncertainty** *(i.e. consumers are uncertain)*
(6) [victim $_{OT}$] **support** *(i.e. support for victims)*
(7) [test $_{OT}$] **anxiety** *(i.e. having anxiety towards test taking)*
(8) spring **upswing** *(i.e. economic upswing in spring)*
(9) phone **harassment** *(i.e. harassment inflicted via phone)*

Notice that we focus exclusively on opinion role extraction. We do not try to detect the polarity associated with the compound. Neither do we consider implicature-related information about effects (Deng and Wiebe, 2014), but only inherent sentiment.

We study opinion role extraction on opinion compounds in German. German is known for its frequent

use of noun compounds. In the STEPS-corpus, the benchmark dataset for German opinion role extraction (Ruppenhofer et al., 2014), almost every other sentence contains an opinion compound.

Compounds can also be commonly found in other key languages, such as English. Since the methods we apply to this task and the issues that they address are not language specific, our approach can be replicated on other languages.

Apart from examining traditional features from noun compound analysis, in this paper, we also introduce novel features specially designed for the analysis of opinion compounds.

We also created a new gold standard for this task (see also §3). The STEPS-corpus, as such, is fairly small and only contains about 200 unique compounds. We considered this amount insufficient for producing a gold standard. Also, none of the existing datasets on noun compounds (Lauer, 1995; Barker and Szpakowicz, 1998; Nastase and Szpakowicz, 2003; Girju et al., 2009; Kim and Baldwin, 2005; Tratz and Hovy, 2010; Dima et al., 2014) contain any information regarding opinion roles.

2 Related Work

With regard to opinion role extraction, many features for supervised learning have been explored. They typically address the relationship between opinion word and opinion role on the basis of surface patterns (Choi et al., 2005), part-of-speech information (Wiegand and Klakow, 2010), syntactic information (Kessler and Nicolov, 2009; Jakob and Gurevych, 2010) or semantic role labeling (Johansson and Moschitti, 2013; Deng and Wiebe, 2015). The majority of those features cannot be applied to our task since for opinion compounds, there is no context between opinion role and opinion word.

In the area of noun compound analysis, there are two predominant approaches. On the one hand, lexical resources, such as WordNet (Miller et al., 1990), are employed in order to assign semantic categories to head and modifier and infer from those labels the underlying relation (Rosario and Hearst, 2001; Kim and Baldwin, 2005; Girju et al., 2005; Girju et al., 2009). On the other hand, paraphrases that contain co-occurrences of head and modifier are exploited (Girju et al., 2009; Nakov and Hearst, 2013). In order to increase coverage, paraphrases can be automatically acquired (Butnariu and Veale, 2008; Kim and Nakov, 2011). Cross-lingual information has also been harnessed for this task (Girju, 2007).

3 Data & Annotation

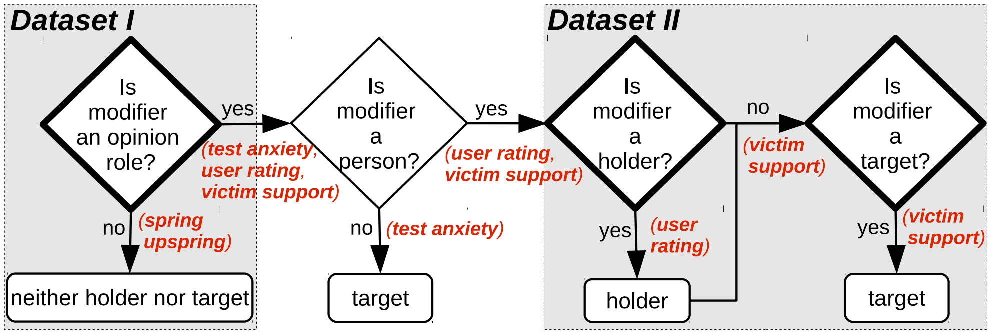
We created a new dataset[1] by retrieving opinion compounds from the ***deWaC***-corpus (Baroni et al., 2009) comprising 1.7 billion words. (Word embeddings (§5.2 & §5.6) and word similarity graphs (§5.7 & §6.4) were also created from this corpus.)

In German, noun compounds are typically realized as single tokens. In order to obtain a set of opinion compounds, we extracted all noun compounds from *deWaC* whose second morpheme is an opinion noun. Morphological analysis was carried out using *morphisto* (Zielinski and Simon, 2009).[2] As opinion nouns, we used the nouns from the **PolArt sentiment lexicon** (Klenner et al., 2009). Unfortunately, this lexicon is lacking in *neutral* opinion nouns, such as *Meinung (opinion)* or *Erwartung (expectation)* which frequently occur in compounds, e.g. *Expertenmeinung (expert opinion)* or *Kundenerwartungen (customer expectations)*. Therefore, we translated the 235 neutral opinion nouns from the (English) Subjectivity Lexicon (Wilson et al., 2005) into German.

From the opinion compounds extracted from *deWaC*, we created two manually annotated datasets (Table 2). We use more than one dataset as we consider our task as a multi-stage task as shown in Figure 1. We believe that this is necessary as differ-

[1] available at: `www.coli.uni-saarland.de/~miwieg/naacl_2016_op_compounds_data.tgz`

[2] *The data release provides more details regarding the gold standard, e.g. how compound instances were sampled.*



Example opinion compounds are listed in brackets.

Each question (indicated by a rhombus) can be modeled with one binary supervised classifier. We build 3 classifiers, thus excluding the second question because of its simplicity.

Figure 1: Generic pipeline for processing opinion compounds.

ent types of knowledge are required for the different steps. In the first step (**Dataset I**), the compounds containing some opinion role (4)-(7) are separated from those not containing any role at all (8)-(9). At this stage, holders are not distinguished from targets. This is done in the second step which exclusively focuses on opinion roles. This step is further divided into two substeps. First, one checks whether the modifier denotes a person. A modifier representing an opinion role but not denoting a person (e.g. *test anxiety*) can only be a target. Since this is a simple classification step (provided a lexical resource is available which tells persons apart from non-persons, e.g. WordNet), we have no dataset for it. The greater challenge lies in all those compounds whose modifier is a person and for which we already know that it is either holder or target (e.g. *user rating* or *victim support*). Only for those cases do we produce another dataset (**Dataset II**). Note that in this dataset the two roles are not completely disjoint. In 3% of the compounds, the modifier represents both holder and target. Prominent examples are reciprocal relationships, e.g. *Geschwisterneid (sibling jealousy).*

On a sample of 200 compounds extracted from each of the two datasets we measured inter-annotation agreement. On the first dataset, we obtained Cohen's $\kappa = 0.60$, while on the second, we obtained $\kappa = 0.60$ for holders and $\kappa = 0.62$ for targets, respectively. These scores can be interpreted as substantial agreement (Landis and Koch, 1977).

4 Classifiers and the Three Different Tasks

We solve the given task as a supervised classification problem. As a classifier, we employ Markov Logic Networks (MLNs). We use this classifier because it allows us to integrate all of our features, including global constraints (see discussion in §5.5).

We consider **3 different tasks** (bold rhombuses in Figure 1): the detection of opinion **roles** (Dataset I), the detection of opinion **holders** (Dataset II) and the detection of opinion **targets** (Dataset II). Each task is modeled as a binary classifier. Even though the latter two tasks use the same dataset, we cannot train just one single binary classifier as there are compounds whose modifiers represent both holder and target, e.g. *Geschwisterneid (sibling jealousy).*[3]

5 Feature Design

Our core **global features**, which are used for all three tasks (§4), include the two predominant approaches for compound analysis, i.e. (plain) paraphrases (§5.1) and semantic knowledge (§5.4). We extend the paraphrase approach with two major innovations. First, we examine a verb detour (§5.2) by which we gain important information regarding the syntactic relationship between the modifier and the head of the compound. Secondly, we show that joint paraphrases (§5.3) considering both holder and

[3] For the holder-detection task, the modifier of such compounds are considered a holder, while for the target-detection task, they are considered a target. For the holder-detection task, we have the two classes *holder* and *no holder*, while for the target-detection task, the classes are *target* and *no target*.

Global Features	
features used on all three tasks (i.e. Datasets I and II)	PARA (§5.1-5.3), SEM (§5.4), HEAD (§5.5)
Local Features	
feature used only on task *Role* (i.e. Dataset I)	SUBJ (§5.6)
feature used only on task *Holder* and task *Target* (i.e. Dataset II)	VIEW (§5.7)

Table 3: Division of global and local features.

target are better than paraphrases focusing on only one role. We argue that for our task, (syntactic) ambiguity rather than lack of coverage is the pressing problem. Therefore, we do not focus on paraphrase acquisition but introduce new disambiguation features. Beside the extensions to paraphrases mentioned above, we introduce a global head constraint (§5.5) as an additional global feature. As a **local feature** for the initial role classification, we perform subjectivity detection on the compound (§5.6). And finally, we use the sentiment view that the head of the compound evokes (§5.7) as a local feature in the holder and target classification tasks.

Table 3 lists which feature is used in which task. If a feature is restricted to a specific task (i.e. it is a local feature), then this is motivated below in the relevant subsection introducing the respective feature.

5.1 Plain Paraphrases (PARA$_{plain}$)

An established method for computing the relation expressed by a compound is to consider paraphrases, that is, co-occurrences of the head and modifier as individual constituents accompanied by some predictive context. For example, the compound *Expertenauffassung (expert view)* can be paraphrased by *Auffassung unter Experten (view among experts).* The preposition *unter (among)* is an explicit lexical clue for the (implicit) relation holding between head and modifier in the compound. As paraphrases we manually collected 18 frequent dependency relations that typically hold between an opinion noun and its opinion holder (10) or its opinion target (11).[4] *(The data release provides more information including a full list of all paraphrases.)* For each compound, we check in *deWaC* whether head and modifier can be observed in any of those relations.

(10) objp$_{unter(among)}$(<opinion noun>, <holder>): Auffassung unter Experten (view among experts)

(11) objp$_{auf(towards)}$(<opinion noun>, <target>): Hass auf Christen (hatred towards Christians)

We consider each of those selected dependency relations as an individual feature, i.e. we do not explicitly group the chosen relations to *holder* and *target*. Assuming that the predictiveness of the different relations varies, this encoding allows a supervised classifier to appropriately weight each relation.

5.2 Verb Detour Paraphrases (PARA$_{verb}$)

Some of the paraphrases from §5.1 are ambiguous. This particularly concerns *objp*$_{von(of)}$ which occurs with approx. 40% of the compounds of our dataset. On the first reading illustrated by (12)a), we observe a modifier being a holder, while, on the second reading shown by (13)a), the modifier is a target.

For heads being deverbal nouns (e.g. *comment* or *assessment*), this ambiguity can often be resolved by considering morphologically related verbs. In (12)b) and (13)b), the two modifiers no longer share the same dependency relation to the opinion word. Opinion holders tend to occur in subject position (12)b) while targets occur in object position (13)b). Wiegand and Klakow (2012) identify these dependency relations for the two different opinion roles as the most frequent ones. So for deverbal nouns, which make up 57% of the heads of our compounds, we add a feature that checks in *deWaC* whether the modifier is more often observed as a subject or an object of a verb related to the head. (Wiegand and Klakow (2012) actually consider semantic roles, i.e. *agent* and *patient*, instead of dependency relations. Due to the lack of robust semantic role-labeling for German, we use dependency relations as a proxy. That is, we identify agents with the dependency relation *subj* and patients with the relation *obj*.)

(12) *paraphrases for* Leserkommentar (reader comments):
   a) Kommentar$_{noun}$ [von Lesern $_{objp_{von}}$]
      (comment$_{noun}$ [of readers $_{objp_{of}}$]).
   b) Leser$_{subj}$ kommentieren$_{verb}$ ein Ereignis.
      (Readers$_{subj}$ comment$_{verb}$ on an event.)

(13) *paraphrases for* Schülerbeurteilung (student assessment):
   a) Beurteilung$_{noun}$ [von Schülern $_{objp_{von}}$]
      (assessment$_{noun}$ [of students $_{objp_{of}}$])
   b) Lehrer beurteilen$_{verb}$ Schüler$_{obj}$.
      (Teachers assess$_{verb}$ students$_{obj}$.)

Even though the disambiguation of deverbal noun compounds with the help of verb relations has been

[4] We obtain dependency parses by *ParZu* (Sennrich et al., 2009).

examined before (Lapata, 2002), it has not been exploited for an actual application, such as opinion role extraction. Neither has it been compared against plain paraphrases, which use the head noun of the compound directly (§5.1).

Our use of verb semantics for compound analysis is also different from its predominant use in previous work (Kim and Baldwin, 2006; Nakov and Hearst, 2013) where noun compounds are considered whose parts represent arguments of an abstract verbal relation (e.g. *malaria mosquito* are arguments of relation *'mosquito **causes** malaria'*). Thus, the aim has been to predict verbs for those compounds that match those abstract relations (e.g. *to cause*). We are looking for different verbs, namely those that are the morphological basis for the head noun.

For this verb detour, we produce a mapping from nouns (i.e. the heads of our opinion compounds) to verbs by combining distributional and string similarity. We extracted the verbs most similar to each of these nouns (we use top 100). For that we induce vector representations of all head nouns of our gold standard and all existing German verbs using the embedding toolkit *Word2Vec* (Mikolov et al., 2013).[5] For each noun, we select the verb with the highest cosine-similarity that has at least a *Levenshtein (string) similarity* (Levenshtein, 1966) of 3. This high threshold ensures that nouns which are not deverbal nouns are not mapped to any verb. Against a manual mapping, our automatic method produced an F-score of 76.1 (at a precision of 77.1).

5.3 Joint Paraphrases (PARA$_{joint}$)

Another way of reducing the ambiguity of paraphrases is to employ paraphrases that jointly consider opinion holder and target (Table 4). We assume that the presence of one ambiguous dependency relation is less problematic in the presence of another less ambiguous relation. The ambiguity can be resolved by method of elimination. For instance, even though *objp*$_{von/of}$*(Widerstand/resistance, Bauern/farmers)* is ambiguous, in the first example of Table 4, it can only represent a holder, since the second relation *objp*$_{gegen/against}$*(Widerstand/resistance, Gesetz/regulation)* implies a target.

We also use paraphrases in which the compound itself occurs (second and third pattern type of Table 4). Since, in the first example of the second pattern type, only the relation *objp*$_{mit/with}$*(Zufriedenheit/satisfaction, Unternehmen/company)* is indicative of a target, the modifier is likely to be a holder. (The example of the third pattern type follows an analogous pattern to extract a target.) The second example (of the second pattern type) *Sprengstoffanschlag (bomb attack)* illustrates that paraphrases can also be used to infer the absence of opinion roles. *Sprengstoff (explosive)* cannot be a target because of the other target relation that is present. It cannot be a holder either as it is not a person.

The fourth pattern type in Table 4 considers patterns involving possessive pronouns. They typically represent holders, so the remaining dependency relation can only represent a target.

Similar to §5.1, we encode the joint-paraphrase patterns by their individual dependency relations. That is, the first example in Table 4 would be represented as the feature $objp^{\textbf{modifier}}_{von}\_objp_{gegen}$.

5.4 Semantic Knowledge (SEM)

We use GermaNet (Hamp and Feldweg, 1997), the German version of WordNet, to look up the hypernyms of each modifier and each head. The hypernymy relation is the most frequently used semantic relation employed for noun compound analysis (Girju et al., 2005; Nastase et al., 2006; Girju et al., 2009; Tratz and Hovy, 2010). Hypernyms allow some generalization over the lexical units representing the heads and modifiers of our compounds. By manual inspection, we found that there are several hypernyms that correlate with a category we want to predict. For example, heads having the hypernym *politische Handlung (political act)* typically indicate holders as in *Arbeiterunruhe (worker unrest)* or *Studentenrebellion (student rebellion)*. Hypernyms may also serve as negative cues. For example, heads having the hypernym *Verbrechen (crime)* are typically contained in compounds whose modifiers represent neither a holder nor a target, such as *Steuervergehen (tax offense)* or *Autodiebstahl (car theft)*.

[5] We used the `cbow`-model with 200 dimensions. All remaining parameters are set to their respective default values.

Pattern Type	Example Compound	Label	Example Sentence
<head> <holder> <target>	Bauern**widerstand** (farmer **resistance**)	holder	**Widerstand** [von Bauern $_{objp_{von}}$] [gegen das Gesetz $_{objp_{gegen}}$] (**resistance** [of farmers $_{objp_{of}}$] [against the regulation $_{objp_{against}}$])
	Schüler**beurteilung** (student **assessment**)	target	**Beurteilung** [der Lehrer $_{gmod}$] [von Schülern $_{objp_{von}}$] ([teachers' $_{possessive}$] **assessment** [of students $_{objp_{of}}$])
<compound> <target>	Mitarbeiter**zufriedenheit** (staff **satisfaction**)	holder	Mitarbeiter**zufriedenheit** [mit dem Unternehmen $_{objp_{mit}}$] (staff **satisfaction** [with their company$_{objp_{with}}$])
	Sprengstoff**anschlag** (bomb **attack**)	no role	Sprengstoff**anschlag** [auf Touristen $_{objp_{auf}}$] (bomb **attack** [on tourists $_{objp_{on}}$])
<compound> <holder>	Prüfungs**angst** (test **anxiety**)	target	Prüfungs**angst** [unter Schülern $_{objp_{unter}}$] (test **anxiety** [among students $_{objp_{among}}$])
<possessive> <head> <target>	Kinder**freundlichkeit** (child **friendliness**)	target	[seine $_{possessive}$] **Freundlichkeit** [gegenüber Kindern $_{objp_{gegenueber}}$] ([his $_{possessive}$] **friendliness** [towards children $_{objp_{towards}}$])

Table 4: Illustration of patterns for joint paraphrases.

Head	Preference	Examples
Haltung (attitude)	holder	Arbeitgeberhaltung (employer attitude), Autorenhaltung (author attitude), Konsumentenhaltung (consumer attitude), Verbraucherhaltung (customer attitude), Zuschauerhaltung (viewer attitude)
Verehrung (worship)	target	Ahnenverehrung (ancestor worship), Heldenverehrung (hero worship), Ikonenverehrung (icon worship), Kaiserverehrung (emperor worship), Märtyrerverehrung (martyr worship)
Attentat (attack)	no role	Bombenattentat (bombing attack), Flugzeugattentat (aircraft attack), Selbstmordattentat (suicide attack), Sprengstoffattentat (explosive attack), Säureattentat (acid attack)

Table 5: Illustration of selectional preferences of heads of opinion compounds.

5.5 Head Constraint (HEAD)

We observed that many heads have a strong selectional preference as to what type they select as a modifier. This is illustrated in Table 5. There are heads that prefer opinion holders as modifiers (e.g. *Haltung (attitude)*), heads that prefer targets (e.g. *Verehrung (worship)*) or heads that prefer no role (e.g. *Attentat (attack)*). This is further substantiated by Table 6 showing the high average role-purity of compound groups sharing the same head. Purity is measured by the proportion of the most frequent role occurring within each group of compounds sharing the same head.[6] Given this selectional preference, we formulate a *global head constraint* (Table 7) that if two compounds have the same head, their modifiers should convey the same opinion role.

In order to implement this constraint in a supervised classifier we employ Markov Logic Networks (MLNs), which combine first-order logic with probabilities. As a tool, we use *thebeast* (Riedel, 2008). MLNs have been effectively used in various related NLP tasks, such as discourse-based sentiment analysis (Zirn et al., 2011), semantic-role labeling (Meza-Ruiz and Riedel, 2009), anaphora resolution (Hou et al., 2013) or question answering (Khot et al., 2015).

Dataset I	88.86	Dataset II	91.36

Table 6: Role-purity of compounds with the same head.

MLNs are a set of pairs (F_i, w_i) where F_i is a first-order logic formula and w_i an associated real-valued weight. They build a template for constructing a Markov network given a set of constants C. The probability distribution that is estimated is a log-linear model

$$P(X = x) = \frac{1}{Z} exp\left(\sum_{i=1}^{k} w_i n_i(x)\right) \tag{1}$$

where $n_i(x)$ is the number of groundings in F_i in x and Z is some normalization constant.

5.6 Subjectivity Disambiguation (SUBJ)

Many opinion words are known to be ambiguous. Some of their senses convey subjectivity while others do not (Akkaya et al., 2009). 13% of the compounds in Dataset I (Figure 1) are not subjective due to an ambiguous head. The modifier of such compounds neither represents a holder or a target. Examples are *Luftdruck (air pressure)* or *Strömungswiderstand (flow resistance)*. Dataset II exclusively contains compounds whose modifiers are holders or targets. By definition, all those compounds are subjective. So a subjectivity feature may only be useful for the *role*-detection task, which uses Dataset I.

[6] On average, a head occurs in 5 different compounds on Dataset I, and in 4 different compounds on Dataset II.

$$\forall c_1[\forall c_2[\forall h[\forall r_1[\forall r_2[[isCompound(c_1) \land isCompound(c_2) \land isHeadOf(h, c_1) \land isHeadOf(h, c_2) \land isRoleOfModifierOf(r_1, c_1) \land isRoleOfModifierOf(r_2, c_2)] \rightarrow (r_1 == r_2)]]]]]$$

Table 7: Head constraint as logic formula.

For a feature indicating the subjectivity of a compound, we cannot look up the compounds in a sentiment lexicon since they are rarely included. Instead, we compute the 100 most similar German nouns for every compound and use as a feature the proportion of opinion nouns (according to the PolArt sentiment lexicon) on that list. Opinion nouns on that similarity list are less likely to be compounds and therefore more likely to be found in a sentiment lexicon. As in §5.2, similarity is measured by the cosine between two *Word2Vec*-vector embeddings. As a result, we find, for example, for *Luftdruck (air pressure)*, other non-subjective terms, such as *Temperatur (temperature)* or *Luftfeuchtigkeit (humidity)*, while for the subjective compound *Hexenglaube (witch belief)*, we find the subjective expressions *Aberglaube (superstition)* or *Häresie (heresy)*.

5.7 Sentiment Views (VIEW)

Our final feature considers the sentiment view (Wiegand and Ruppenhofer, 2015) that an opinion noun, in our case the head of the compound, conveys. We distinguish between *speaker views*, expressions conveying sentiment of the speaker of the utterance (e.g. *mistake*, *finesse*, *noise*), and *actor views*, expressions conveying sentiment of the entities participating in the event denoted by the opinion noun (e.g. *support*, *criticism*, *rating*). Nouns conveying speaker views have an implicit opinion holder (i.e. the speaker). Therefore, if such a noun is the head of an opinion compound, the modifier cannot be a holder but only a target, e.g. *Arztfehler (doctor's mistake)*, *Kinderlärm (children's noise)* or *Neonazipropaganda (neonazi propaganda)*. Only heads conveying an actor view can take modifiers to represent a holder *(Nutzerwertung/user rating)* or a target *(Opferunterstützung/victim support)*. Sentiment views may be helpful on Dataset II (Figure 1), where we have to decide between holders and targets. 40.3% of those heads convey a speaker view.

So far, the detection of sentiment views on a *lexical* level has only been examined for opinion verbs. Wiegand and Ruppenhofer (2015) propose a bootstrapping approach in which seed verbs for the different sentiment views are automatically extracted.[7] Then, a label propagation algorithm (Talukdar et al., 2008) is run on a word-similarity graph generated from the opinion verbs. Thus labels from the seeds can be expanded to the remaining opinion verbs. The nodes in the graph correspond to the opinion verbs. The best performing graph is based on the similarity metric introduced in Lin (1998).

A critical step is the seed generation. Wiegand and Ruppenhofer (2015) extract seeds representing actor views by looking for opinion words frequently co-occurring with *prototypical opinion holders (protoOHs)*. These are common nouns, such as *opponents* or *critics*, that typically act as opinion holders (Wiegand and Klakow, 2011). By definition, such explicit opinion holders indicate an actor view. Seeds for speaker-view verbs are obtained by extracting verbs co-occurring with *reproach-patterns*, such as *obji(beschuldigt/blamed for, <verb>)* (14) that matches in (15).

(14) *Pattern*: obji(*beschuldigt/blamed for*, <**speaker-view verb**>)

(15) Die UNO wurde *beschuldigt*, [die Klimadaten **fehlgedeutet**$_{verb}$ zu haben $_{obji}$]. (The UN was *blamed for* **misinterpreting**$_{verb}$ climate data.)

(16) *Pattern*: objg(*beschuldigt/blamed for*, <**speaker-view noun**>)

(17) Die UNO wurde [der **Fehldeutung**$_{noun}$ $_{objg}$] von Klimadaten *beschuldigt*. (The UN was *blamed for* the **misinterpretation**$_{noun}$ of climate data.)

This bootstrapping approach can be immediately applied to our setting. In the word-similarity graph, the opinion verbs are replaced by opinion nouns. With protoOHs, not only actor-view verbs but also actor-view nouns can be extracted. Similarly, the reproach-patterns work for both verbs (15) and nouns (17). (Only the dependency relation changes from *obji* (14) to *objg* (16).) ProtoOHs and reproach patterns are simply translated from English to German.

[7] Wiegand and Ruppenhofer (2015) consider two types of actor views, *agent view* and *patient view*. The former take their opinion holder as an agent (typical verbs are *criticize* or *support*), while the latter align holders to patients (typical verbs are *disappoint* or *please*). Since this distinction of actor views does not exist among nouns, we combine them into a single category in this paper.

6 Experiments

We consider one binary MLN classifier for each of our three tasks (§4). Most of our features are frequently occurring features (e.g. paraphrases (§5.1), subjectivity feature (§5.6), sentiment views (§5.7)). Supervised classifiers only require few training data in order to assign appropriate weights to such features. Therefore, we sample 20% of the instances for each task of the respective dataset as training data. We test on the remaining 80% of the dataset. This procedure is repeated 5 times. The 5 training samples within each task are disjoint. We report macro-average F-score averaged over the 5 test samples.

We will first evaluate global features and then proceed to the local features. A division of our feature set into these groups was presented in Table 3.

6.1 Evaluation of Global Features

Table 8 compares the features that can be applied on all three tasks. On average, PARA (§5.1-§5.3) is slightly better than SEM (§5.4). Since their combination always results in a significant improvement, we conclude that these features contain complementary information. In the majority of cases, HEAD (§5.5) also yields significant improvement.

Table 9 compares the different subtypes of paraphrases (§5.1-§5.3). For all tasks, notable improvements are obtained by adding the other types of paraphrases to the plain paraphrases. While the joint paraphrases improve the plain paraphrases on all tasks, for the verb detour, improvements can be observed only for the extraction of holders and targets. However, this improvement is significantly better than that of the joint paraphrases. In summary, in order to obtain best possible results on all three types of classifications, we need all types of paraphrases.

	Tasks		
Features	**Role**	**Holder**	**Target**
SEM	54.75	58.82	58.10
SEM+HEAD	56.33°	60.88°	60.33°
PARA	62.62	57.01	57.46
PARA+HEAD	63.82*†	59.07*	60.64*
PARA+SEM	63.92†	60.28	62.20‡
PARA+SEM+HEAD	**65.26***†‡	**61.58***†	**63.27**°‡

statistical significance testing (paired t-test): °: better than w/o **+HEAD** ($p < 0.1$); *: better than w/o **+HEAD** ($p < 0.05$); †: better than **SEM+HEAD** ($p < 0.05$); ‡: better than **PARA+HEAD** ($p < 0.05$)

Table 8: F-scores of features applicable to all tasks.

	Tasks		
Features	**Role**	**Holder**	**Target**
PARA$_{plain}$	58.34	52.55	51.64
PARA$_{plain+joint}$	62.34*	54.87*	54.96*
PARA$_{plain+verb}$	58.85	**57.51***†	**58.43***†
PARA$_{plain+joint+verb}$	**62.62***	57.01*†	57.46*†

statistical significance testing (paired t-test, significance level $p < 0.05$) *: better than **PARA**$_{plain}$; †: better than **PARA**$_{plain+joint}$

Table 9: F-scores of paraphrase features.

6.2 Evaluation of the Local Feature for Role Detection

Table 10 examines the impact of the subjectivity feature (§5.6). We closely compare this feature with the head constraint since we found both features only working in combination with other features. In terms of statistical significance, the head constraint is more effective than the subjectivity feature.

6.3 Evaluation of the Local Feature for the Detection of Holders and Targets

Table 11 examines the impact of the sentiment-view feature (§5.7). We evaluate two variants of this feature. **VIEW**$_{gold}$ is a manual view annotation of all opinion head nouns. It should be considered an upper bound. The second variant, **VIEW**$_{boot}$, employs the views as produced automatically by the bootstrapping approach outlined in §5.7.[8]

Table 11 shows that this feature has a notable impact on both PARA$_{plain}$ (i.e. the simplest feature set) and SEM+PARA+HEAD (i.e. the most complex feature set). This underlines that sentiment views are an important aspect for opinion role extraction.

[8] Note that unlike Wiegand and Ruppenhofer (2015) we manually removed incorrect seeds from the set of automatically generated seeds (this affects less than 9% of the seeds).

Features	**SEM**		**PARA**		**PARA+SEM**	
		+HEAD		**+HEAD**		**+HEAD**
	54.75	56.33†	62.62	63.82‡	63.92	65.26‡

each training/test instance represents the set of all sentences in which head and modifier of a specific compound co-occur

Table 12: Features for distant supervision (baseline) classifier.

6.4 Comparison against Baselines

Table 13 compares the best result from our previous experiments against **3 baselines**. The first is a **majority classifier** predicting the majority class.

The second baseline is a classifier inspired by **distant supervision** (Mintz et al., 2009). As in our paraphrase features, this classifier considers the context in which modifier and head of a compound occur as separate constituents. The difference is, however, that we consider every such co-occurrence (within the same sentence) as a context that conveys the same relation as the one that is (implicitly) conveyed by the compound. Even though such an assumption is naive, it has been shown to produce quite reasonable performance in relation extraction (Mintz et al., 2009). The advantage of such an approach is that a *generic* relation extraction/opinion role extraction classifier can be trained on the resulting data. Unlike our proposed method, it does not require features tailored to the specific task (e.g. *manually* written paraphrases). Since the resulting feature set (see also Table 12) is fairly high-dimensional, we employ a support vector machine. As an implementation, we use SVM^{light} (Joachims, 1999).

		Tasks		
Features		**Role**	**Holder**	**Target**
BASELINES	Majority	34.70	35.49	36.71
	Distant Superv.	54.85	47.71	45.72
	Distributional	58.15	52.91	52.72
our approach *(best feature sets)*		**66.42***	**64.71***	**66.50***

*: better than all baselines according to statistical significance testing (paired t-test, significance level at $p < 0.05$)

Table 13: Comparison of our approach against baselines; *evaluation measure: F-score.*

The third baseline is a **distributional approach** in which label propagation is performed on a word-similarity graph for compounds. The fundamental difference between that baseline and our proposed approach is that no relationship between head and modifier is modeled but just the contexts of the compounds themselves. We use the same (distributional) similarity metric to form the word-similarity graph and the same label propagation algorithm for this task as we did for bootstrapping sentiment views in §5.7. The only difference is that the nodes in the graph are opinion compounds instead of opinion nouns. The training data for the second and third baseline are the same compounds as in our previous experiments.

Table 13 shows that our proposed method substantially outperforms the baselines.

7 Conclusion

We presented an approach to the new task of opinion role extraction on opinion compounds. We produced a gold standard and proposed a method for classification. We did not only consider established features for noun compound analysis, i.e. paraphrases and semantic classes of heads and modifiers, but also proposed useful new features tailored to our task. We examined paraphrases that jointly consider holders and targets, a verb detour in which noun heads are replaced by related verbs, a global head constraint, and an auxiliary classification categorizing the sentiment view of the head of the compound. None of these features is language-specific.

Capturing Reliable Fine-Grained Sentiment Associations by Crowdsourcing and Best–Worst Scaling

Svetlana Kiritchenko and **Saif M. Mohammad**
National Research Council Canada
{svetlana.kiritchenko,saif.mohammad}@nrc-cnrc.gc.ca

Abstract

Access to word–sentiment associations is useful for many applications, including sentiment analysis, stance detection, and linguistic analysis. However, manually assigning fine-grained sentiment association scores to words has many challenges with respect to keeping annotations consistent. We apply the annotation technique of Best–Worst Scaling to obtain real-valued sentiment association scores for words and phrases in three different domains: general English, English Twitter, and Arabic Twitter. We show that on all three domains the ranking of words by sentiment remains remarkably consistent even when the annotation process is repeated with a different set of annotators. We also, for the first time, determine the minimum difference in sentiment association that is perceptible to native speakers of a language.

1 Introduction

Word–sentiment associations, commonly captured in sentiment lexicons, are useful in automatic sentiment prediction (Pontiki et al., 2014; Rosenthal et al., 2014), stance detection (Mohammad et al., 2016a; Mohammad et al., 2016b), literary analysis (Hartner, 2013; Kleres, 2011; Mohammad, 2012), detecting personality traits (Grijalva et al., 2015; Mohammad and Kiritchenko, 2015), and other applications. Manually created sentiment lexicons are especially useful because they tend to be more accurate than automatically generated lexicons; they can be used to automatically generate large-scale lexicons (Tang et al., 2014; Esuli and Sebastiani, 2006); they can be used to evaluate different methods of automatically creating sentiment lexicons; and they can be used for linguistic analyses such as examining how sentiment is composed in phrases and sentences.

The sentiment of a phrase can differ significantly from the sentiment of its constituent words. Sentiment composition is the determining of sentiment of a multi-word linguistic unit, such as a phrase or a sentence, from its constituents. Lexicons that include sentiment associations for phrases as well as for their constituent words are useful in studying sentiment composition. We refer to them as *sentiment composition lexicons (SCLs)*. We created SCLs for three domains, and all three were used in recent SemEval shared tasks. We refer to the lexicon created for the English Twitter domain as the *SemEval-2015 English Twitter Sentiment Lexicon*; for the general English domain as the *SemEval-2016 General English Sentiment Modifiers Lexicon*; and for the Arabic Twitter domain as the *SemEval-2016 Arabic Twitter Sentiment Lexicon*. Note that the English Twitter lexicon was first described in (Kiritchenko et al., 2014), whereas the other two are novel contributions presented in this paper.

Most existing manually created sentiment lexicons tend to provide only lists of positive and negative words with very coarse levels of sentiment (Stone et al., 1966; Hu and Liu, 2004; Wilson et al., 2005; Mohammad and Turney, 2013). The coarse-grained distinctions may be less useful in downstream applications than having access to fine-grained (real-valued) sentiment association scores. Only a small number of manual lexicons

Proceedings of NAACL-HLT 2016, pages 811–817,
San Diego, California, June 12-17, 2016.

capture sentiment associations at a fine-grained level (Bradley and Lang, 1999; Warriner et al., 2013). This is not surprising because obtaining real-valued sentiment annotations has several challenges. Respondents are faced with a higher cognitive load when asked for real-valued sentiment scores for terms as opposed to simply classifying terms as either positive or negative. Besides, it is difficult for an annotator to remain consistent with his/her annotations. Further, the same sentiment association may map to different sentiment scores in the minds of different annotators; for example, one annotator may assign a score of 0.6 and another 0.8 for the same degree of positive association. One could overcome these problems by providing annotators with pairs of terms and asking which is more positive (a comparative approach), however that requires a much larger set of annotations (order N^2, where N is the number of terms to be annotated). Best–Worst Scaling (BWS) is an annotation technique, commonly used in marketing research (Louviere and Woodworth, 1990), that exploits the comparative approach to annotation while keeping the number of required annotations small.

In this work, we investigate the applicability and reliability of the Best–Worst Scaling annotation technique in capturing word–sentiment associations via crowdsourcing. Our main contributions are as follows:

1. We create fine-grained sentiment composition lexicons for Arabic Twitter and general English (in addition to our earlier work on English Twitter) using Best–Worst Scaling. The lexicons include entries for single words as well as multi-word phrases. The sentiment scores are real values between -1 (most negative) and +1 (most positive).

2. We show that the annotations on all three domains are reliable; re-doing the annotation with different sets of annotators produces a very similar order of terms—an average Spearman rank correlation of 0.98. Furthermore, we show that reliable rankings can be obtained with just two or three annotations per BWS question. (Warriner et al. (2013) and Graham et al. (2015) have shown that conventional rating-scale methods require a much higher number of responses (15 to 20)).

3. We examine the relationship between 'difference in the sentiment scores between two terms' and 'agreement amongst annotators' when asked which term is more positive. We show that agreement grows rapidly and reaches 90% when the difference in sentiment scores is about 0.4 (20% of interval between -1 and 1).

4. We calculate the minimum difference in sentiment scores of two terms that is perceptible to native speakers of a language. For sentiment scores between -1 (most negative) and 1 (most positive), we show that the perceptible difference is about 0.08 for English and Arabic speakers. Knowing the least perceptible difference helps researchers better understand sentiment composition. For example, consider the task of determining whether an adjective significantly impacts the sentiment of the noun it qualifies. This can be accomplished by determining whether the difference in sentiment scores between the combined phrase and the constituent noun alone is greater than the least perceptible difference.

The data and code created as part of this project (the lexicons, the annotation questionnaire, and the code to generate BWS questions) are made available.[1]

2 Capturing Fine-Grained Sentiment Associations By Manual Annotation

We now describe how we created three lexicons, through manual annotation, that each provide real-valued sentiment association scores.

2.1 Best–Worst Scaling Method of Annotation

Best–Worst Scaling (BWS), also sometimes referred to as Maximum Difference Scaling (MaxDiff), is an annotation scheme that exploits the comparative approach to annotation (Louviere and Woodworth, 1990; Cohen, 2003; Louviere et al., 2015). Annotators are given four items (4-tuple) and asked which item is the Best (highest in terms of the property of interest) and which is the Worst (least in terms of the property of interest). These annotations can then be easily converted into real-valued scores of association between the items and the property, which eventually allows for creating a ranked list of items as per their association with the property of interest.

[1] www.saifmohammad.com/WebPages/BestWorst.html

Given n terms to be annotated, the first step is to randomly sample this set (with replacement) to obtain sets of four terms each, *4-tuples*, that satisfy the following criteria:

1. no two 4-tuples have the same four terms;
2. no two terms within a 4-tuple are identical;
3. each term in the term list appears approximately in the same number of 4-tuples;
4. each pair of terms appears approximately in the same number of 4-tuples.

In practice, around $1.5 \times n$ to $2 \times n$ BWS questions, where n is the number of items, are sufficient to obtain reliable scores. We annotated terms for the three lexicons separately, and generated $2 \times n$ 4-tuples for each set.

Next, the sets of 4-tuples were annotated through a crowdsourcing platform, CrowdFlower. The annotators were presented with four terms at a time, and asked which term is the most positive (or least negative) and which is the most negative (or least positive). Below is an example annotation question.[2] (The Arabic data was annotated through a similar questionnaire in Arabic.)

Focus terms:
1. th*nks 2. doesn't work 3. w00t 4. #theworst

Q1: Identify the term that is associated with the most amount of positive sentiment (or least amount of negative sentiment) – **the most positive term**:
1. th*nks 2. doesn't work 3. w00t 4. #theworst

Q2: Identify the term that is associated with the most amount of negative sentiment (or least amount of positive sentiment) – **the most negative term**:
1. th*nks 2. doesn't work 3. w00t 4. #theworst

Each 4-tuple was annotated by ten respondents.

The responses were then translated into real-valued scores and also a ranking of terms by sentiment for all the terms through a simple counting procedure: For each term, its score is calculated as the percentage of times the term was chosen as the most positive minus the percentage of times the term was chosen as the most negative (Orme, 2009; Flynn and Marley, 2014). The scores range from -1 (the most negative) to 1 (the most positive).

2.2 Lexicons Created With Best–Worst Scaling

SemEval-2015 English Twitter Lexicon: This lexicon is comprised of 1,515 high-frequency English single words and simple negated expressions commonly found in tweets. The set includes regular English words as well as some misspelled words (e.g., *parlament*), creatively-spelled words (e.g., *happeee*), hashtagged words (e.g., *#loveumom*), and emoticons.

SemEval-2016 Arabic Twitter Lexicon: This lexicon was created in a similar manner as the English Twitter Lexicon but using Arabic words and negated expressions commonly found in Arabic tweets. It has 1,367 terms.

SemEval-2016 General English Sentiment Modifiers Lexicon aka Sentiment Composition Lexicon for Negators, Modals, and Degree Adverbs (SCL-NMA): This lexicon consists of all 1,621 positive and negative single words from Osgood's seminal study on word meaning (Osgood et al., 1957) available in General Inquirer (Stone et al., 1966). In addition, it includes 1,586 high-frequency phrases formed by the Osgood words in combination with simple negators such as *no*, *don't*, and *never*, modals such as *can*, *might*, and *should*, or degree adverbs such as *very* and *fairly*. More details on the lexicon creation and an analysis of the effect of different modifiers on sentiment can be found in (Kiritchenko and Mohammad, 2016).

Table 1 shows example entries from each lexicon. The complete lists of modifiers used in the three lexicons are available online.[3] Details on the use of these lexicons in SemEval shared tasks can be found in (Rosenthal et al., 2015; Kiritchenko et al., 2016).

3 Quality of Annotations

3.1 Agreement and Reproducibility

Let *majority answer* refer to the option chosen most often for a BWS question. The percentage of responses that matched the majority answer were as follows: 82% for the English Twitter Lexicon, 80% for the Arabic Twitter Lexicon, and 80% for the General English Lexicon.

[2] The full sets of instructions for both English and Arabic datasets are available at:
http://www.saifmohammad.com/WebPages/BestWorst.html

[3] www.saifmohammad.com/WebPages/SCL.html#ETSL
www.saifmohammad.com/WebPages/SCL.html#ATSL
www.saifmohammad.com/WebPages/SCL.html#NMA

Table 1: Example entries from the three lexicons.

Lexicon, Term	Sentiment
SemEval-2015 English Twitter Lexicon	
yummm	0.813
cant waitttt	0.656
#feelingsorryformyself	-0.547
:'(	-0.563
SemEval-2016 Arabic Twitter Lexicon	
#السعادة_الزوجية (marital happiness)	0.800
#يقين (certainty)	0.675
لا امكن (not possible)	-0.400
ارهاب (terrorism)	-0.925
SemEval-2016 General English Lexicon	
would be very easy	0.431
did not harm	0.194
increasingly difficult	-0.583
severe	-0.833

Annotations are reliable if similar results are obtained from repeated trials. To test the reliability of our annotations, we randomly divided the sets of ten responses to each question into two halves and compared the rankings obtained from these two groups of responses. The Spearman rank correlation coefficient between the two sets of rankings produced for each of the three lexicons was found to be at least 0.98. (The Pearson correlation coefficient between the two sets of sentiment scores for each lexicon was also at least 0.98.) Thus, even though annotators might disagree about answers to individual questions, the aggregated scores produced by applying the counting procedure on the BWS annotations are remarkably reliable at ranking terms.

Number of annotations needed: Even though we obtained ten annotations per BWS question, we wanted to determine the least number of annotations needed to obtain reliable sentiment scores. For every k (where k ranges from 1 to 10), we made the following calculations: for each BWS question, we randomly selected k annotations and calculated sentiment scores based on the selected subset of annotations. We will refer to these sets of scores for the different values of k as S_1, S_2, and so on until S_{10}. This process was repeated ten times for each k. The average Spearman rank correlation coefficient between S_1 and S_{10} was 0.96, between S_2 and S_{10} was 0.98, and S_3 and S_{10} was 0.99. This shows that as few as two or three annotations per BWS question are sufficient to obtain reliable sentiment scores. Note that with $2 \times n$ BWS questions (for n terms), each term occurs in eight 4-tuples on average, and so even just one annotation per BWS question means that each term is assessed eight times.

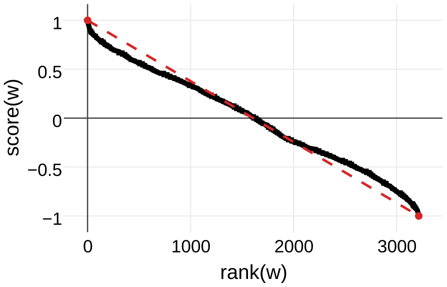

Figure 1: Rank vs. sentiment scores in SCL-NMA.

3.2 Distribution of Sentiment Scores

Figure 1 gives an overview of the sentiment scores in SCL-NMA. Each term in the lexicon is shown as a dot in the corresponding plot. The x-axis is the rank of each term in the lexicon when the terms are ordered from most positive to least positive. The y-axis is the real-valued sentiment score obtained from the BWS annotations. Observe that the lexicon has entries for the full range of sentiment scores (-1 to 1); that is, there are no significant gaps—ranges of sentiment scores for which the lexicon does not include any terms. The dashed red line indicates a uniform spread of scores, i.e., the same number of terms are expected to fall into each same-size interval of scores. Observe that the lexicon has slightly fewer terms in the intervals with very high and very low sentiment scores. Similar figures (not shown here) were obtained for the other two lexicons.

3.3 Perception of Sentiment Difference

The created lexicons capture sentiment associations at a fine level of granularity. Thus, these annotations can help answer key questions such as: (1) If native speakers of a language are given two terms and asked which is more positive, how does human agreement vary with respect to the amount of difference in sentiment between the two focus terms? It is expected that the greater the difference in sentiment, the higher the agreement, but the exact shape of this increase in agreement has not been shown till now. (2) What least amount of difference in sentiment is perceptible to native speakers of a language?

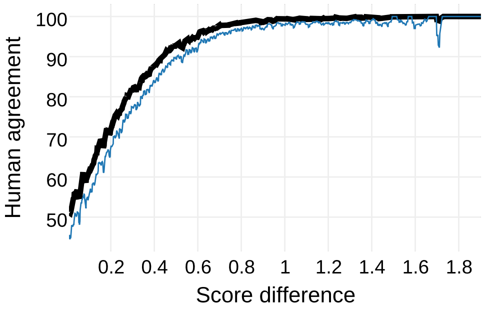

Figure 2: SCL-NMA: Human agreement on annotating term w_1 as more positive than term w_2 for pairs with difference in scores d = $score(w_1)$ - $score(w_2)$. The x-axis represents d. The y-axis plots the avg. percentage of human annotations that judge term w_1 as more positive than term w_2 (thick line) and the corresponding 99.9%-confidence lower bound (thin blue line).

Agreement vs. Sentiment Difference: For each word pair w_1 and w_2 such that $score(w_1) - score(w_2) \geq 0$, we count the number of BWS annotations from which we can infer that w_1 is more positive than w_2 and divide this number by the total number of BWS annotations from which we can infer either that w_1 is more positive than w_2 or that w_2 is more positive than w_1. (We can infer that w_1 is more positive than w_2 if in a 4-tuple that has both w_1 and w_2 the annotator selected w_1 as the most positive or w_2 as the least positive. The case for w_2 being more positive than w_1 is similar.) This ratio is the human agreement for w_1 being more positive than w_2, and we expect that it is correlated with the sentiment difference $d = score(w_1) - score(w_2)$. To get more reliable estimates, we average the human agreement for all pairs of terms whose sentiment differs by $d \pm 0.01$. Figure 2 shows the resulting average human agreement on SCL-NMA. Similar figures (not shown here) were obtained for the English and Arabic Twitter data. Observe that the agreement grows rapidly with the increase in score differences. Given two terms with sentiment differences of 0.4 or higher, more than 90% of the annotators correctly identify the more positive term.

Least Difference in Sentiment that is Perceptible to Native Speakers: In psychophysics, there is a notion of *least perceptible difference* (aka *just-noticeable difference*)—the amount by which something that can be measured (e.g., weight or sound intensity) needs to be changed in order for the difference to be noticeable by a human (Fechner, 1966). Analogously, we can measure the least perceptible difference in sentiment. If two words have close to identical sentiment associations, then it is expected that native speakers will choose each of the words about the same number of times when forced to pick a word that is more positive. However, as the difference in sentiment starts getting larger, the frequency with which the two terms are chosen as most positive begins to diverge. At one point, the frequencies diverge so much that we can say with high confidence that the two terms do not have the same sentiment associations. The average of this minimum difference in sentiment score is the least perceptible difference for sentiment. To determine the least perceptible difference, we first obtain the 99.9%-confidence lower bounds on the human agreement (see the thin blue line in Figure 2). The least perceptible difference is the point starting at which the lower bound consistently exceeds 50% threshold (i.e., the point starting at which we observe with 99.9% confidence that the human agreement is higher than chance). The least perceptible difference when calculated from SCL-NMA is 0.069, from the English Twitter Lexicon is 0.080, and from the Arabic Twitter Lexicon is 0.087. Observe, that the estimates are very close to each other despite being calculated from three completely independent datasets. Kiritchenko and Mohammad (2016) use the least perceptible difference to determine whether a modifier significantly impacts the sentiment of the word it composes with.

4 Conclusions

We obtained real-valued sentiment association scores for single words and multi-word phrases in three domains (general English, English Twitter, and Arabic Twitter) by manual annotation and Best–Worst Scaling. Best–Worst Scaling exploits the comparative approach to annotation while keeping the number of annotations small. Notably, we showed that the procedure when repeated produces remarkably consistent rankings of terms by sentiment. This reliability allowed us to determine the value of the psycho-linguistic concept—least perceptible difference in sentiment. We hope these findings will encourage further use of Best–Worst Scaling in linguistic annotation.

Abstract

In recent years many knowledge bases (KBs) have been constructed, yet there is not yet a verb resource that maps to these growing KB resources. A resource that maps verbs in different languages to KB relations would be useful for extracting facts from text into the KBs, and to aid alignment and integration of knowledge across different KBs and languages. Such a multi-lingual verb resource would also be useful for tasks such as machine translation and machine reading. In this paper, we present a scalable approach to automatically construct such a verb resource using a very large web text corpus as a kind of interlingua to relate verb phrases to KB relations. Given a text corpus in any language and any KB, it can produce a mapping of that language's verb phrases to the KB relations. Experiments with the English NELL KB and ClueWeb corpus show that the learned English verb-to-relation mapping is effective for extracting relation instances from English text. When applied to a Portuguese NELL KB and a Portuguese text corpus, the same method automatically constructs a verb resource in Portuguese that is effective for extracting relation instances from Portuguese text.

1 Introduction

In recent years a variety of large knowledge bases (KBs) have been constructed e.g., Freebase (Bollacker et al., 2008), DBpedia (Auer et al., 2007), NELL (Carlson et al., 2010), and Yago (Suchanek et al., 2007). These KBs consist of (1) an ontology that defines a set of categories (e.g., *SportsTeam, City*), (2) another part of the ontology that defines relations with these categories as argument types (e.g., ***teamPlaysInCity****(SportsTeam, City)*), (3) KB entities which instantiate these categories (e.g., *Steelers* ∈ *SportsTeam*), and (4) KB entity pairs which instantiate these relations (e.g., (*Steelers*, *Pittsburgh*) ∈ ***teamPlaysInCity***). The KB ontology also specifies constraints (e.g., mutual exclusion, subset) among KB categories and relations.

Despite recent progress in KB construction, there is not yet a verb resource that maps to these KBs: one that contains verb phrases[1] that identify KB relations. Such a verb resource can be useful to aid KB relation extraction. A distribution of verb phrases associated with any given KB relation is also a KB-independent representation of that relation's semantics which can form the basis of aligning ontologies across arbitrary KBs (Wijaya et al., 2013). Given a KB and verb resources in different languages that map to the KB, we can also begin to align knowledge expressed in different languages.

We introduce here an approach to mapping verb phrases to KB relations using a very large ClueWeb corpus (Callan et al., 2009) as a kind of interlingua. Our approach grounds each KB relation instance (e.g., ***teamPlaysInCity****(Steelers, Pittsburgh)*) in mentions of its argument pair in this text, then represents the relation in terms of the verb phrases that connect these paired mentions (see Fig. 1). For a high coverage mapping, we train on both labelled and unlabelled data using expectation maximization (EM). We introduce argument type checking during

[1] In this paper we use the term "verb phrase" and "verb" interchangeably; both referring to either verb or verb+preposition

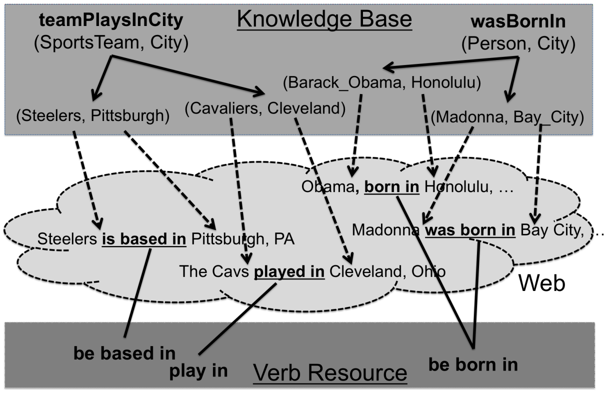

Figure 1: Mapping verb phrases to relations in KB through Web-text as interlingua. Each relation instance is grounded by its mentions in the Web-text. The verbs that co-occur with mentions of the relation's instances are mapped to that relation.

the EM process to ensure only verbs whose argument types match the relation's argument types are mapped to the relation. We also incorporate constraints defined in the KB ontology to find a verb to relation mapping consistent with these constraints.

Our contributions are: (1) We propose a scalable EM-based method that automatically maps verb phrases to KB relations by using the mentions of the verb phrases with the relation instances in a very large unlabeled text corpus. (2) We demonstrate the effectiveness of the resource for extracting relation instances in NELL KB. Specifically, it improves the recall of both the supervised- and the unsupervised- verb-to-relation mapping; demonstrating the benefit of semi-supervised learning on unlabeled Web-scale text. (3) We demonstrate the flexibility of the method, which is both KB- and language-independent, by using the same method for constructing English verb resource to automatically construct a Portuguese verb resource. (4) We make our verb resources publicly available [2].

2 Method

2.1 Terminology

We define a NELL KB to be a 6-tuple $(C, I_C, R, I_R, Subset, Mutex)$. C is the set of categories e.g., *SportsTeam* i.e., $c_j \in C = \{c_1, ..., c_{|C|}\}$. I_C is the set of category instances which are entity-category pairs e.g., (*Cleveland*, *City*) i.e., I_C = $\{(e_m, c_j) \mid e_m \in c_j,\ c_j \in C\}$.

R is the set of relations e.g., ***teamPlaysInCity*** i.e., $r_i \in R = \{r_1, ..., r_{|R|}\}$. We also define f_{type} to be a function that when applied to a relation r_i returns the argument type signature of the relation $f_{type}(r_i) = (c_j, c_k)$ for some $c_j, c_k \in C$ e.g., f_{type}(***teamPlaysInCity***) = *(SportsTeam, City)*.

I_R is the set of relation instances which are entity-relation-entity triples e.g., *(Cavaliers, **teamPlaysInCity**, Cleveland)* i.e., I_R = $\{(e_m, r_i, e_n) \mid (e_m, e_n) \in r_i,\ r_i \in R,\ e_m \in c_j,\ e_n \in c_k,\ f_{type}(r_i) = (c_j, c_k)\}$; $I_R = I_{r_1} \cup I_{r_2} \cup ...\ I_{r_{|R|}}$.

$Subset$ is the set of all subset constraints among relations in R i.e., $Subset = \{(i, k) : I_{r_i} \subseteq I_{r_k}\}$. For example $\{$*(person, **ceoOf**, company)*$\} \subseteq \{$*(person, **worksFor**, company)*$\}$.

$Mutex$ is the set of all mutual exclusion constraints among relations in R i.e., $Mutex = \{(i, k) : I_{r_i} \cap I_{r_k} = \phi\}$. For example $\{$*(drug, **hasSideEffect**, physiologicalCondition)*$\} \cap \{$*(drug, **possiblyTreats**, physiologicalCondition)*$\}$ = ϕ.

Each KB entity e_m can be referred to by one or more noun phrases (NPs). For example, the entity *Cavaliers*, can be referred to in text using either the NP *"Cleveland Cavaliers"* or the NP *"The Cavs"*[3]. We define $N_{en}(e_m)$ to be the set of English NPs corresponding to entity e_m.

We define SVO to be the English Subject-Verb-Object (SVO) interlingua[4] consisting of tuples of the form (np_s, v_p, np_o, w), where np_s and np_o are noun phrases (NP) corresponding to subject and object, respectively, v_p is a verb phrase that connects them, and w is the count of the tuple.

2.2 Data Construction

We construct a dataset D for mapping English verbs to NELL KB relations. First, we convert each tuple in SVO to its equivalent entity pair tuple(s) in $SVO' = \{(e_m, v_p, e_n, w) \mid np_s \in N_{en}(e_m),\ np_o \in N_{en}(e_n),\ (np_s,\ v_p,\ np_o,\ w) \in SVO\}$. Then, we construct D from SVO' as a collection of labeled and unlabeled instances.

[2] http://www.cs.cmu.edu/%7Edwijaya/mapping.html

[3] defined by the ***canReferTo*** relation in NELL KB

[4] We use 600 million SVO triples collected from the entire ClueWeb (Callan et al., 2009) of about 230 billion tokens with some filtering described in Section 3.1.

The set of labeled instances is $D^\ell = \{(\mathbf{y}_{(e_m,e_n)}, \mathbf{v}_{(e_m,e_n)})\}$ where $\mathbf{y}_{(e_m,e_n)} \in \{0,1\}^{|R|}$ is a bit vector of label assignment, each bit representing whether the instance belongs to a particular relation i.e., $y^i_{(e_m,e_n)} = 1 \iff (e_m, e_n) \in r_i$ and 0 otherwise. $\mathbf{v}_{(e_m,e_n)} \in \mathbb{R}^{|V|}$ is a $|V|$-dimensional vector of verb phrase counts that connect e_m and e_n in SVO' (V is the set of all verb phrases) i.e., $v^p_{(e_m,e_n)}$ is the number of times the verb phrase v_p connects e_m and e_n in SVO'.

The collection of unlabeled instances is constructed from entity pairs in SVO' whose label assignment $\mathbf{y}$ are unknown (its bits are all zero) i.e., $D^u = \{(\mathbf{y}_{(e_m,e_n)}, \mathbf{v}_{(e_m,e_n)}) \mid (e_m, *, e_n, *) \in SVO', (e_m, *, e_n) \notin I_R\}$.

An instance in our dataset $d_{(e_m,e_n)} \in D$ is therefore either a labeled or unlabeled tuple i.e., $d_{(e_m,e_n)} = (\mathbf{y}_{(e_m,e_n)}, \mathbf{v}_{(e_m,e_n)})$.

We let $f_{type}(d_{(e_m,e_n)})$ return the argument type of the instance i.e., $f_{type}(d_{(e_m,e_n)}) = (c_j, c_k)$ where (e_m, c_j) and $(e_n, c_k) \in I_C$.

We let $f_{verb}(d_{(e_m,e_n)})$ return the set of all verb phrases that co-occur with the instance in SVO' i.e., $f_{verb}(d_{(e_m,e_n)}) = \{v_p \mid (e_m, v_p, e_n, *) \in SVO'\}$.

When applied to a relation r_i, we let $f_{verb}(r_i)$ return the set of all verb phrases that co-occur with instances in D whose types match that of the relation i.e., $f_{verb}(r_i) = \{v_p \mid \exists\ d_{(e_m,e_n)} \in D,\ v_p \in f_{verb}(d_{(e_m,e_n)}),\ f_{type}(d_{(e_m,e_n)}) = f_{type}(r_i)\}$.

2.3 Model

We train a Naive Bayes classifier on our dataset. Given as input a collection D^ℓ of labeled instances and D^u of unlabeled instances, it outputs a classifier, $\hat{\theta}$, that takes an unlabeled instance and predicts its label assignment i.e., for each unlabeled instance $d_{(e_m,e_n)} \in D^u$ the classifier predicts the label assignment $\mathbf{y}_{(e_m,e_n)}$ using $\mathbf{v}_{(e_m,e_n)}$ as features:

$$\begin{aligned} P(y^i_{(e_m,e_n)} = 1 \mid d_{(e_m,e_n)};\ \hat{\theta}) &= \frac{P(r_i|\hat{\theta}) P(d_{(e_m,e_n)} \mid r_i; \hat{\theta})}{P(d_{(e_m,e_n)}|\hat{\theta})} \\ &= \frac{P(r_i|\hat{\theta}) \prod_{p=1}^{|V|} P(v_p|r_i;\hat{\theta})^{v^p_{(e_m,e_n)}}}{\sum_{k=1}^{|R|} P(r_k|\hat{\theta}) \prod_{p=1}^{|V|} P(v_p|r_k;\hat{\theta})^{v^p_{(e_m,e_n)}}} \end{aligned} \quad (1)$$

If the task is to classify the unlabeled instance into a single relation, only the bit of the relation with the highest posterior probability is set i.e, $y^k_{(e_m,e_n)} = 1$ where $k = \arg\max_i P(y^i_{(e_m,e_n)} = 1 \mid d_{(e_m,e_n)}; \hat{\theta})$.

2.3.1 Parameter Estimation

To estimate model parameters (the relation prior probabilities $\hat{\theta}_{r_i} \equiv P(r_i|\hat{\theta})$ and probabilities of a verb given a relation $\hat{\theta}_{v_p|r_i} \equiv P(v_p|r_i;\hat{\theta})$) from both labeled and unlabeled data, we use an Expectation Maximization (EM) algorithm (Nigam et al., 2006). The estimates are computed by calculating a maximum a posteriori estimate of θ, i.e. $\hat{\theta} = \arg\max_\theta \mathcal{L}(\theta|D) = \arg\max_\theta\ log(P(D \mid \theta)P(\theta))$.

The first term, $P(D \mid \theta)$ is calculated by the product of all the instance likelihoods:

$$\begin{aligned} &P\left(D \mid \theta\right) \\ &= \prod_{d_{(e_m,e_n)} \in D^u} \sum_{i=1}^{|R|} P(r_i|\theta) P(d_{(e_m,e_n)}|r_i;\theta) \\ &\times \prod_{d_{(e_m,e_n)} \in D^\ell} \sum_{\{i|y^i_{(e_m,e_n)}=1\}} P(r_i|\theta) P(d_{(e_m,e_n)}|r_i;\theta) \end{aligned} \quad (2)$$

The second term, $P(\theta)$, the prior distribution over parameters is represented by Dirichlet priors: $P(\theta) \propto \prod_{i=1}^{|R|}((\theta_{r_i})^{\alpha_1 - 1} \prod_{p=1}^{|V|}(\theta_{v_p|r_i})^{\alpha_2 - 1})$ where α_1 and α_2 are parameters that effect the strength of the priors. In this paper we set $\alpha_1 = 2$ and $\alpha_2 = 1 + \sigma(P^e(v_p|r_i))$, where $P^e(v_p|r_i)$ is the initial bias of the verb-to-relation mapping. Thus, in this paper we define $P(\theta)$ as:

$$P(\theta) = \prod_{i=1}^{|R|}(P(r_i|\theta) \prod_{p=1}^{|V|}(P(v_p|r_i;\theta)^{\sigma(P^e(v_p|r_i))}) \quad (3)$$

We can see from this that $\sigma(P^e(v_p|r_i))$ is a conjugate prior on $P(v_p|r_i;\theta)$ with σ as the confidence parameter. This conjugate prior allows incorporation of any existing knowledge (Section 2.3.2) we may have about the verb-to-relation mapping.

From Equation 2, we see that $log\ P(D|\theta)$ contains a log of sums, which makes a maximization by partial derivatives computationally intractable. Using EM, we instead maximize the *expected* log likelihood of the data with respect to the posterior distribution of the y labels given by: $\arg\max_\theta E_{(\mathbf{y}|D;\theta)}[log\ P(D|\theta)]$.

In the E-step, we use the current estimates of the parameters $\hat{\theta}^t$ to compute $\hat{\mathbf{y}}^t = E[\mathbf{y}|D; \hat{\theta}^t]$ the expected label assignments according to the current model. In practice it corresponds to calculating the posterior distribution over the y labels for unlabeled instances $P(y^i_{(e_m,e_n)} = 1 \mid d_{(e_m,e_n)}; \hat{\theta}^t)$ (Equation 1) and using the estimates to compute its expected label assignment $\hat{\mathbf{y}}^t_{(e_m,e_n)}$.

In the M-step, we calculate a new maximum a posteriori estimate for $\hat{\theta}^{(t+1)}$ which maximizes the expected log likelihood of the complete data, $\mathcal{L}_c(\theta|D; \hat{\mathbf{y}}^t) = log(P(\theta^t)) +\ \hat{\mathbf{y}}^t\ [log\ P(D|\theta^t)]$:

$$\begin{aligned}\mathcal{L}_c(\theta|D;\hat{\mathbf{y}}^{\mathbf{t}}) &= log(P(\theta^t)) \\ &+ \sum_{d_{(e_m,e_n)}\in D} \sum_{i=1}^{|R|} y^{ti}_{(e_m,e_n)}\ log\ P(r_i|\theta)P(d_{(e_m,e_n)}|r_i;\theta)\end{aligned} \tag{4}$$

$\mathcal{L}_c(\theta|D; \mathbf{y})$ bounds $\mathcal{L}(\theta|D)$ from below (by application of Jensen's inequality $E[log(X)] \leq log(EX)$). The EM algorithm produces parameter estimates $\hat{\theta}$ that correspond to a local maximum of $\mathcal{L}_c(\theta|D; \mathbf{y})$. The relation prior probabilities are thus estimated using current label assignments as:

$$P(r_i|\hat{\theta}^{(t+1)}) = \frac{1 + \sum_{d_{(e_m,e_n)}\in D} y^{ti}_{(e_m,e_n)}}{|R| + |D|} \tag{5}$$

The verb-to-relation mapping probabilities are estimated in the same manner:

$$\begin{aligned}&P(v_p \mid r_i;\ \hat{\theta}^{(t+1)}) = \\ &\frac{\sigma_i^{(t+1)}\ (P^e(v_p \mid r_i))\ +\ \sum_{d_{(e_m,e_n)}\in D} v^p_{(e_m,e_n)}\ y^{ti}_{(e_m,e_n)}}{\sigma_i^{(t+1)}\ + \sum_{s=1}^{|V|} \sum_{d_{(e_m,e_n)}\in D} v^s_{(e_m,e_n)}\ y^{ti}_{(e_m,e_n)}}\end{aligned} \tag{6}$$

We start with $\sigma = |V|$ and gradually reduce the impact of prior by decaying σ with a decay parameter of 0.8 at each iteration in the manner of (Lu and Zhai, 2008)). This will allow the EM to gradually pick up more verbs from the data to map to relations.

EM iteratively computes parameters θ^1, ..., θ^t using the above E-step and M-step update rule at each iteration t, halting when there is no further improvement in the value of $\mathcal{L}_c(\theta|D; \mathbf{y})$.

2.3.2 Prior Knowledge

In our prior $P(\theta)$, we incorporate knowledge about verb-to-relation mappings from the text patterns learned by NELL to extract relations. This is our way of *aligning* our verb-to-relation mappings with NELL's current extractions. Coupled Pattern Learner (CPL) (Carlson et al., 2010) is a component in NELL that learns these contextual patterns for extracting instances of relations and categories.

We consider only CPL's extraction patterns that contain verb phrases. Given a set E_{r_i} of CPL's extraction patterns for a relation r_i, and E_{r_i,v_p} as the set of extraction patterns in E_{r_i} that contains the verb phrase v_p, we compute $P^e(v_p \mid r_i) = \frac{\mid E_{r_i,v_p} \mid}{\mid E_{r_i} \mid}$ and use them as priors in our classifier (Equation 3).[5]

2.3.3 Argument Type Checking

Although some verbs are ambiguous (e.g., the verb "play" may express several relations: ***musicianPlaysMusicalInstrument***, ***athletePlaysSport***, ***actorPlaysMovie***, etc), knowing the types of the verbs' arguments can help disambiguate the verbs (e.g., the verb "play" that takes a *musicalInstrument* type as object is more likely to express the ***musicianPlaysMusicalInstrument*** relation). Therefore, we incorporate argument type checking in our EM process to ensure that it maps verbs to relations whose argument types match:

- In the E-Step, we make sure that unlabeled instances are only labeled with relations that have the same argument types as the instance *and* that share some verbs with the instance. In other words, in the E-step we compute $P(y^i_{(e_m,e_n)} = 1 \mid d_{(e_m,e_n)})$ if $f_{type}(r_i) = f_{type}(d_{(e_m,e_n)})$ *and* $\big(f_{(verb)}(r_i) \cup \{v_p|E_{r_i,v_p} \neq \emptyset\}\big) \cap f_{(verb)}(d_{(e_m,e_n)}) \neq \emptyset$.

- In the M-step, we make sure that verbs are only mapped to relations whose argument types match at least one of the instances that co-occur with the verbs in SVO'. In other words, in the M-step we compute $P(v_p \mid r_i)$ if $v_p \in f_{verb}(r_i)$ or $E_{r_i,v_p} \neq \emptyset$.

[5] We manually add a few verb phrases for relations whose E_r is an empty set when possible, to set the EM process on these relations with good initial guesses of the parameters. In average, each relation has about 6 verb patterns in total as priors.

2.3.4 Incorporating Constraints

In the E-step, for each unlabeled instance, given the probabilities over relation labels $P(y^i_{(e_m,e_n)} = 1 \mid d_{(e_m,e_n)}; \hat{\theta}^t)$, and $Subset$ and $Mutex$ constraints[6], similar to (Dalvi et al., 2015), we use a Mixed-Integer Program (MIP) to produce its bit vector of label assignment as output: $\hat{\mathbf{y}}^t_{(e_m,e_n)}$.

The constraints among relations are incorporated as constraints on bits in this bit vector. For example, if for an unlabeled instance (*Jeff Bezos*, *Amazon*), a bit corresponding to the relation ***ceoOf*** is set then the bit corresponding to the relation ***worksFor*** should also be set due to the subset constraint: ***ceoOf*** $\subseteq$ ***worksFor***. For the same instance, the bit corresponding to ***competesWith*** should not be set due to the mutual exclusion constraint ***ceoOf*** $\cap$ ***competesWith*** = ϕ. The MIP formulation for each unlabeled instance thus tries to maximize the sum of probabilities of selected relation labels after penalizing for violation of constraints (Equation 7), where ζ_{ik} are slack variables for $Subset$ constraints and δ_{ik} are slack variables for $Mutex$ constraints:

$$\begin{aligned}
&\underset{\mathbf{y}_{(e_m,e_n)},\zeta_{ik},\delta_{ik}}{\text{maximize}} \left(\sum_{i=1}^{|R|} y^i_{(e_m,e_n)} \times \; P(y^i_{(e_m,e_n)} = 1|d_{(e_m,e_n)}; \hat{\theta}^t) \right.\\
&\qquad \left. - \sum_{(i,k)\in Subset} \zeta_{ik} - \sum_{(i,k)\in Mutex} \delta_{ik} \right)\\
&\qquad \text{subject to,}\\
&\qquad y^i_{(e_m,e_n)} \leq \; y^k_{(e_m,e_n)} + \zeta_{ik}, \forall (i,k) \in Subset\\
&\qquad y^i_{(e_m,e_n)} + y^k_{(e_m,e_n)} \leq 1 + \delta_{ik}, \forall (i,k) \in Mutex\\
&\qquad \zeta_{ik}, \delta_{ik} \geq 0, y^i_{(e_m,e_n)} \in \{0,1\}, \forall i,k \qquad (7)
\end{aligned}$$

Our algorithm that includes argument type checking and constraints is summarized in Algorithm 1.

2.4 Portuguese Verb Mapping

To map Portuguese verbs to relations in Portuguese NELL, which is an automatically and independently constructed KB separate from English NELL, we use the Portuguese NELL and Portuguese text corpus SVO_{pt}[7] and construct a dataset D_{pt}. Given D_{pt}, we follow the same approach as before to find a mapping of Portuguese verbs to relations. Since Portuguese NELL is newly constructed, it contains fewer facts (category and relation instances) than English NELL, and hence its dataset D^{ℓ}_{pt} has fewer labeled instances (see Table 1).

Algorithm 1 The EM Algorithm for Verb-to-Relation Mapping

```
Input: $D = D^{\ell} \cup D^u$ and an initial naive Bayes classifier $\theta^1$ from
    labeled documents $D^{\ell}$ only (using Equations 5 and 6)
Output: $\theta^T$ that include verbs to relations mappings given by
    $P(v_p|r_i;\theta^T)$
for $t$ = 1 ... $T$ do
    E-Step:
    for $d_{(e_m,e_n)} \in D^u$ do
        Compute $P(y^i_{(e_m,e_n)} = 1|d_{(e_m,e_n)};\theta^t)$ $\forall r_i \in R$ that
        satisfy argument types checking (Equation 1)
        Find a consistent label assignment $\mathbf{y}^t_{(e_m,e_n)}$ by solving
        MIP (Equation 7)
    end for
    M-step: Recompute model parameters $\theta^{t+1}$ based on current
    label assignments (Equation 5 and 6) respecting argument type
    checking
    if convergence ($\mathcal{L}_c(\theta^{t+1})$, $\mathcal{L}_c(\theta^t)$) then
        break
    end if
end for
return $\theta^T$
```

	English NELL	Portuguese NELL	Portuguese NELL^{+en}
$\vert R\vert$	317	302	302
$\vert I_R\vert$	135,267	5,675	12,444
$\vert D^{\ell}\vert$	85,192	2,595	5,412
$\vert D^u\vert$	240,490	595,274	1,186,329

Table 1: Statistics of KB facts and dataset constructed

Adding more relation instances to Portuguese NELL can result in more labeled instances in the dataset D_{pt}, a more productive EM, and a better verb-to-relation mapping. Since each category and each relation in Portuguese NELL ontology has a one-to-one mapping in English NELL ontology, we can add relation instances to Portuguese NELL from the corresponding English NELL relations.

English NELL however, has only English noun phrases (NPs) to refer to entities in its relation instances. To add more labeled instances in D_{pt} using English relation instances, we need to find instantiations of these English relation instances in Portuguese SVO_{pt}, which translates to finding Portuguese NPs that refer to English NELL entities. For example, Portuguese NP: “Artria torcica interna” for English NELL entity: *internal mammary artery*.

To automatically translate English NELL enti-

[6] The $Subset$ and $Mutex$ constraints are obtained as part of the NELL KB ontology, which is publicly available at the NELL Read The Web project website: http://rtw.ml.cmu.edu/resources/.

[7] We obtain the Portuguese SVO from the NELL-Portuguese team at Federal University of Sao Carlos.

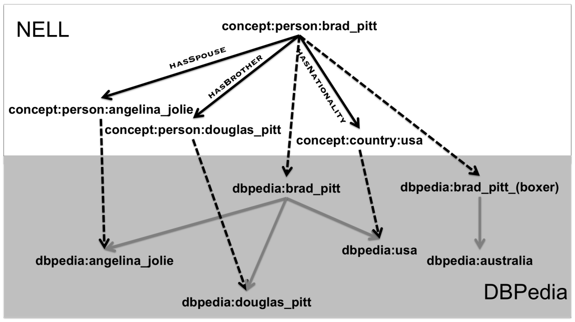

Figure 2: Mapping NELL entity *Brad Pitt* to DBPedia.

ties to Portuguese NPs, we use DBPedia (Auer et al., 2007) which has structured information about Wikipedia pages in many languages. The idea is to map each English NELL entity e_m to its corresponding English DBPedia page and therefore its Portuguese DBPedia page[8]. We use the structured information of the Portuguese page in DBPedia: its title and label as the set of Portuguese NPs corresponding to the English entity, $N_{pt}(e_m)$.

More specifically, for each English NELL entity e_m with English NPs that can refer to it, $N_{en}(e_m)$, we find *candidate* English DBPedia pages that can refer to the entity. We do this by computing Jaccard similarities (Jaccard, 1912; Chapman, 2009) of the entity's NPs with titles and labels of English DBPedia pages. We select pages with Jaccard similarities of more than 0.6 as candidates e.g., for English NELL entity *Brad Pitt* we find candidate English pages: `http://dbpedia.org/page/Brad_Pitt` (*Brad Pitt,* the US actor) and `http://dbpedia.org/page/Brad_Pitt_(boxer)` (*Brad Pit,* the Australian boxer).

Then, we construct a graph containing nodes that are: (1) the NELL entity that we want to map to DBPedia, (2) its candidate DBPedia pages, (3) other entities that have relations to the entity in NELL KB, and (4) the candidate DBPedia pages of these other entities (see Fig. 2 for the NELL entity *Brad Pitt*).

We add as edges to this graph: (1) the can-refer-to edges between entities in NELL and their candidate pages in DBPedia (dashed edges in Fig. 2), (2) the relation edges between the entities in NELL KB (black edges), and (3) the hyperlink edges between the pages in DBPedia (gray edges). In this graph we want to use the knowledge that NELL has already learned about the entity to narrow its candidates down to the page that the entity refers to. The idea is that relatedness among the entities in NELL implies relatedness among the DBPedia pages that refer to the entities. We use Personalized Page Rank (Page et al., 1999) to rank candidate DBPedia pages in this graph and pick the top ranked page as the page that can refer to the NELL entity.

For example, to find the DBPedia page that can refer to our NELL entity *Brad Pitt*, we use NELL's knowledge about this entity to rank its candidate pages. As seen in Fig. 2, DBPedia page of *Brad Pitt*, the US actor (*dbpedia:brad_pitt*) is highly connected to other pages (*dbpedia:angelina_jolie*, *dbpedia:douglas_pitt*, *dbpedia:usa*) that are in turn connected to the NELL entity *Brad Pitt*. *dbpedia:brad_pitt* is thus ranked highest and picked as the page that can refer to the NELL entity *Brad Pitt*.

Once we have an English DBPedia page that can refer to the NELL entity e_m, we can obtain the corresponding Portuguese page from DBPedia. The title and label of the Portuguese page becomes the set of Portuguese NPs that can refer to the NELL entity i.e., $N_{pt}(e_m)$ (see Table 2 for examples). Using $N_{pt}(e_m)$ we find instantiations of English relation instances in SVO_{pt} to add as labeled instances in D_{pt}. Portuguese NELL enriched with English NELL (i.e., Portuguese NELL^{+en}) has more than double the amount of relation instances, labeled and unlabeled instances (Table 1) than Portuguese NELL. In the experiments, we observe that this translates to a better verb-to-relation mapping.

Mapping NELL to DBPedia is also useful because it can align existing knowledge and add new knowledge to NELL. For example, by mapping to DBPedia, we can resolve abbreviations (e.g., the NELL entity: *COO* as "Chief Operations Officer" in English or "Diretor de Operaçőes" in Portuguese), or resolve a person entity (e.g., the NELL entity: *Utamaro* as "Kitagawa Utamaro", the virtual artist).

3 Experiments

3.1 Pre-processing

For better coverage of verbs, we lemmatize verbs in the English SVO (using Stanford CoreNLP (Man-

[8] Almost every DBPedia English page has a corresponding Portuguese page

English NELL entity	Portuguese NPs
Amazonian Brown Brocket	“Veado-Roxo”, “Fuboca”
COO	“Diretor de Operações”
Utamaro	“Kitagawa Utamaro”
Notopteridae	“Peixe-faca”
1967 Arab Israeli War	“Guerra dos Seis Dias”, “Guerra de 1967”
Food Products	“Produtos Alimenticios”, “Alimento”, “Comida”, ...

Table 2: Example Portuguese NPs learned for NELL entities

ning et al., 2014)). We lemmatize verbs in Portuguese SVO_{pt} (using LemPORT (Rodrigues et al., 2014)) and expand contracted prepositions.

For better precision and to make our method scale to a large text corpus, we focus on mapping verbs that are important for a relation based on how often the verbs co-occur with entity pairs that match the relation's argument type. For each argument type in the English SVO we consider only the top 50 verbs (in terms of *tf-idf* scores) for mapping. We use *tf-idf* scores to adjust for the fact that some verbs appear more frequently in general. For each of these verbs, we also use only the top 50 entity pairs that co-occur with the verb in the SVO (in terms of co-occurrence counts) to construct our dataset D.

For Portuguese verb-to-relation mapping, since SVO_{pt} is much smaller than the English SVO (i.e., it contains only about 22 million entity pair-verb triples compared to the 600 million triples in the English SVO), we use all the Portuguese entity pairs and verbs for mapping. To adjust for the fact that some verbs appear more frequently in general, we use *tf-idf* scores instead of co-occurrence counts for the values of $\mathbf{v}_{(e_m,e_n)}$ in the M-step (Equation 6).

3.2 Evaluation

We set aside 10% of D^ℓ for testing. Given a test instance $t_{(e_m,e_n)}$ and the trained model, we can predict the label assignment $\mathbf{y}_{(e_m,e_n)}$ using Eq. 1. This simulates the task of relation extraction where we predict relation(s) that exist between the entity pair in $t_{(e_m,e_n)}$.

We compare predicted labels of these test instances to the actual labels and measure precision, recall and F1 values of the prediction. We evaluate NELL relations that have more than one labeled instances in D^ℓ (constructed using the method described in section 2.2). For experiments on the English NELL, we evaluate 77 relations, with an average of 23 (and a median of 11) *training* instances per relations. For experiments on the Portuguese NELL^{+en}, which is Portuguese NELL enriched with relation instances from English NELL, we evaluate 85 relations, with an average of 31 (and a median of 10) *training* instances per relations. We compare the prediction produced by our approach: **EM** with that of other systems: **CPL**, **DIRT**, and **NB**.

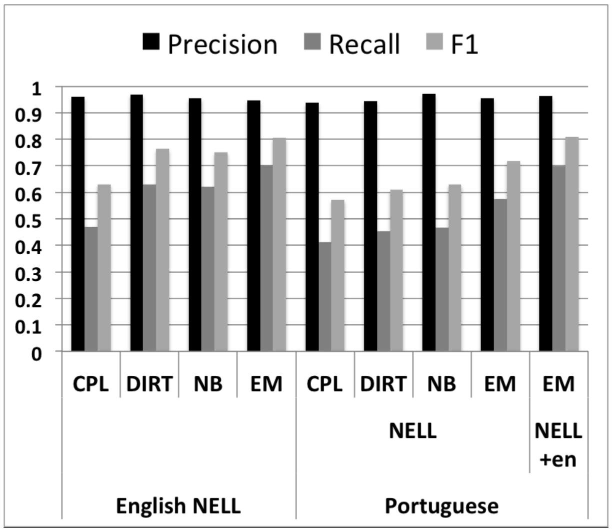

Figure 3: Performance on leaf relations.

In **CPL**, we obtain verb-to-relation mapping weights from NELL's CPL patterns and hand-labeled verb phrases (see Section 2.3.2). In **DIRT**, we obtain verb-to-relation mapping weights in an unsupervised manner (Lin and Pantel, 2001) based on their mutual information over labeled training instances. In Naive Bayes (**NB**) we learn the verb-to-relation mapping weights from labeled training instances. In contrast to the other systems, **EM** allows learning from both labeled and unlabeled instances.

To make other systems comparable to our proposed method, For **NB** and **DIRT** we add **CPL** weights as priors to their verb-to-relation mapping weights. For all these other systems, we also incorporate type-checking during prediction in that unlabeled instances are only labeled with relations that have the same argument types as the instance.

We show the micro-averaged performance of the systems on *leaf* relations of English NELL and Portuguese NELL (Fig. 3), where we do not incorporate constraints and classify each test instance into a single relation. We observe in both English and

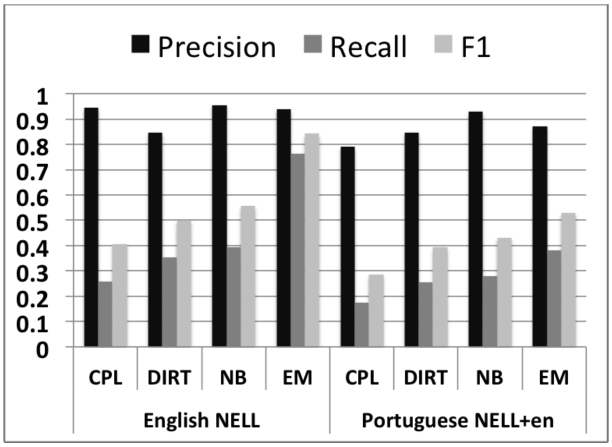

Figure 4: Performance on all relations.

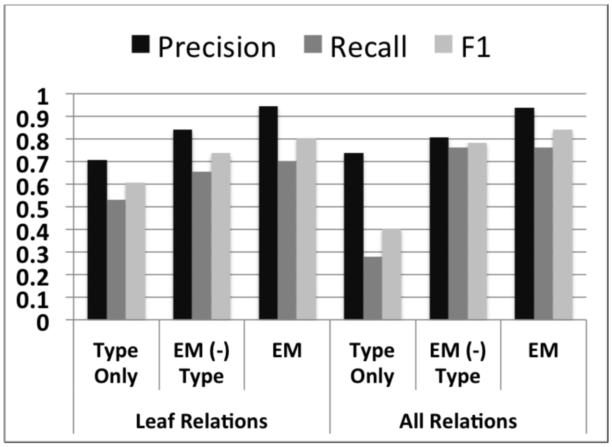

Figure 5: Performance on English NELL relations with and without type-checking.

Portuguese NELL that the verb-to-relation mapping obtained by **EM** results in predictions that have a much higher recall and comparable precision.

In Figure 3, we also observe a gain in performance when we run **EM** on Portuguese NELL^{+en} which is Portuguese NELL enriched with relation instances from English NELL obtained using our DBPedia linking in section 2.4. More labeled instances results in higher recall and precision. This shows the usefulness of aligning and merging knowledge from many different KBs to improve verb-to-relation mapping and relation extraction in general.

We show the micro-averaged performance of the systems on *all* relations of English NELL and Portuguese NELL (Fig. 4). Here, we incorporate hierarchical and mutual exclusive constraints between relations in our **EM**, allowing a test instance to be classified into more than one relation while respecting these constraints. Like before, we observe that the verb-to-relation mapping obtained by **EM** results in predictions with a much higher recall and comparable precision to other systems which do not incorporate constraints between relations.

In the experiments we also observe that **NB** performs comparably or better than **DIRT**. We hypothesize that it is because **NB** obtains its verb-to-relation mapping in a supervised manner while **DIRT** obtains its mapping in an unsupervised manner.

We also conduct experiments to investigate how much influence type-checking has on prediction. We show performance over instances whose types alone are not enough to disambiguate their assignments (i.e., when more than one relation shares their argument type signatures) to see the merits of verb-to-relation mapping on prediction (Fig. 5). We observe that verbs learned by **EM** results in a better prediction even when used without type-checking (**EM** (-) **Type**) than using type-checking alone (by picking majority class among relations that have the correct type) (**Type Only**). Adding type checking improves performance even further (**EM**). This shows how verbs learning is complementary to type-checking.

Relation	Verbs	Proposed New Instances
bookWriter	a_1 be written by a_2, a_2 write a_1	(*Dracula*, *Bram Stoker*), (*Divine Comedy*, *Dante*)
city-Also-KnownAs	a_1 be known as a_2, a_2 be known as a_1, a_2 be renamed a_1,	(*Amman*, *Philadelphia*), (*Chennai*, *Madras*), (*Southport*, *Smithville*)
liderDe-Organizacao	a_1 fundador a_2, a_1 ceo de/em a_2	(*Jimmy Wales*, *Wikipedia*), (*Chad Hurley*, *Youtube*)
pessoa-Acusada-DoCrime	a_1 ser condenar aa_2, a_1 ser acusar de a_2, a_1 ser prender por a_2	(*Pedrinho Matador*, *Homicidios*), (*Omid Tahvili*, *Trafico de Drogaso*)

Table 3: Some relations' verbs and proposed new instances

The results of our experiments also highlight the merit of learning from a large, though unlabeled corpus to improve the coverage of verb-to-relation mapping and hence the recall of predictions. We also observe the usefulness of incorporating constraints and for merging knowledge from multiple KBs to improve performance. Another advantage of **EM** is that it produces relation labels for unlabeled data not yet in NELL KB. We show some of these new proposed relation instances as well as some of the verb-to-relation mapping obtained by **EM** (Table 3).

EM learns in average 177 English verbs and 3310 Portuguese verbs per relation; and propose in average 1695 new instances per relation for English NELL, and 6426 new instances per relation for Portuguese NELL. It learns less English verbs than Portuguese due to the filtering of English data (Section 3.1) and a high degree of inflection in Portuguese verbs. The smaller size of Portuguese KB also means more of its proposed instances are new.

4 Related Work

Existing verb resources are limited in their ability to map to KBs. Some existing resources classify verbs into semantic classes either manually (e.g. WordNet (Miller et al., 1990)) or automatically (e.g. DIRT (Lin and Pantel, 2001)). However, these classes are not directly mapped to KB relations. Other resources provide relations between verbs and their arguments in terms of semantic roles (e.g. PropBank (Kingsbury and Palmer, 2002), VerbNet (Kipper et al., 2000), FrameNet (Ruppenhofer et al., 2006)). However, it is not directly clear how the verbs map to relations in specific KBs.

Most existing verb resources are also manually constructed and not scalable. A verb resource that maps to KBs should grow in coverage with the KBs, possibly by leveraging large corpora such as the Web for high coverage mapping. One system that leverages Web-text as an interlingua is (Wijaya et al., 2013). However, they use it to map KBs to KBs, and obtain a verb-to-relation mapping only indirectly. They also compute heuristic confidences in verb-to-relation mappings from label propagation scores, which are not probabilities. In contrast, we map verbs directly to relations, and obtain $P(v_p|r_i)$ as an integral part of our EM process.

In terms of systems that learn mappings of textual patterns to KB relations, CPL (Carlson et al., 2010) is one system that is most similar to our proposed approach in that it also learns text patterns for KB relations in a semi-supervised manner and uses constraints in KB ontology to couple the learning to produce extractors consistent with these constraints. However, CPL uses a combination of heuristics in its learning, while we use EM. In our experiments, we use CPL patterns that contain verbs as priors and show that our approach outperforms CPL in terms of effectiveness for extracting relation instances.

In terms of the relation extraction, there are distantly-supervised methods that can produce verb groupings as a by product of relation extraction. One state-of-the-art uses matrix factorization and universal schemas to extract relations (Riedel et al., 2013). In this work, they populate a database of a universal schema (which involves surface form predicates and relations from pre-existing KBs such as Freebase) by using matrix factorization models that learn latent feature vectors for relations and entity tuples. One can envision obtaining a verb grouping for a particular relation by predicting verb surface forms that occur between entity tuples that are instances of the relation. However, unlike our proposed method that learns mapping between typed-verbs to relations, they do not incorporate argument types in their learning, preferring to learn latent entity representation from data. Although this improves relation extraction, they observe that it hurts performance of surface form prediction because a single surface pattern (like “visit”) can have multiple argument types (person-visit-location, person-visit-person, etc). Unlike our method, it is not clear in their method how argument types of surface patterns can be dealt with. Furthermore, it is not clear how useful prior constraints between relations (subset, mutex, etc.) can be incorporated in their method.

5 Conclusion

In this paper, we introduce an EM-based approach with argument type checking and ontological constraints to automatically map verb phrases to KB relations. We demonstrate that our verb resource is effective for extracting KB relation instances while improving recall; highlighting the value of learning from large scale unlabeled Web text. We also show the flexibility of our method. Being KB-, and language-independent, our method is able to construct a verb resource for any language, given a KB and a text corpus in that language. We illustrate this by building a verb resource in Portuguese and in English which are both effective for extracting KB relations. Future work will explore the use of our multilingual verb resource for relation extraction by reading natural language text in multiple languages.

Abstract

We address relation classification in the context of slot filling, the task of finding and evaluating fillers like “Steve Jobs” for the slot X in “X founded Apple”. We propose a convolutional neural network which splits the input sentence into three parts according to the relation arguments and compare it to state-of-the-art and traditional approaches of relation classification. Finally, we combine different methods and show that the combination is better than individual approaches. We also analyze the effect of genre differences on performance.

1 Introduction

Structured knowledge about the world is useful for many natural language processing (NLP) tasks, such as disambiguation, question answering or semantic search. However, the extraction of structured information from natural language text is challenging because one relation can be expressed in many different ways. The TAC Slot Filling (SF) Shared Task defines slot filling as extracting fillers for a set of predefined relations (“slots”) from a large corpus of text data. Exemplary relations are the city of birth of a person or the employees or founders of a company. Participants are provided with an evaluation corpus and a query file consisting of pairs of entities and slots. For each entity slot pair (e.g. “Apple” and “founded_by”), the systems have to return the second argument (“filler”) of the relation (e.g. “Steve Jobs”) as well as a supporting sentence from the evaluation corpus. The key challenge in slot filling is relation classification: given a sentence s of the evaluation corpus containing the name of a queried entity (e.g., “Apple”) and a filler candidate (e.g., “Steve Jobs”), we need to decide whether s expresses the relation (“founded_by”, in this case). We will refer to the mentions of the two arguments of the relation as *name* and *filler*. Performance on relation classification is crucial for slot filling since its effectiveness directly depends on it.

In this paper, we investigate three complementary approaches to relation classification.

The first approach is pattern matching, a leading approach in the TAC evaluations. Fillers are validated based on patterns. In this work, we consider patterns learned with distant supervision and patterns extracted from Universal Schema relations.

The second approach is support vector machines. We evaluate two different feature sets: a bag-of-word feature set (BOW) and more sophisticated skip n-gram features.

Our third approach is a convolutional neural network (CNN). CNNs have been applied to NLP tasks like sentiment analysis, part-of-speech tagging and semantic role labeling. They can recognize phrase patterns independent of their position in the sentence. Furthermore, they make use of word embeddings that directly reflect word similarity (Mikolov et al., 2013). Hence, we expect them to be robust models for the task of classifying filler candidates and to generalize well to unseen test data. In this work, we train different variants of CNNs: As a baseline, we reimplement the recently developed piecewise CNN (Zeng et al., 2015). Then, we extend this model by splitting the contexts not only for

Proceedings of NAACL-HLT 2016, pages 828–838,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

pooling but also for convolution (contextwise CNN).

Currently, there is no benchmark for slot filling. Therefore, it is not possible to directly compare results that were submitted to the Shared Task to new results. Comparable manual annotations for new results, for instance, cannot be easily obtained. There are also many different system components, such as document retrieval from the evaluation corpus and coreference resolution, that affect Shared Task performance and that are quite different in nature from relation classification. Even in the subtask of relation classification, it is not possible to directly use existing relation classification benchmarks (e.g. Riedel et al. (2013), Hendrickx et al. (2010)) since data and relations can be quite different. Many benchmark relations, for instance, correspond to Freebase relations but not all slots are modeled in Freebase and some slots even comprise more than one Freebase relation. While most relation classification benchmarks either use newswire or web data, the SF task includes documents from both domains (and discussion fora). Another difference to traditional relation classification benchmarks arises from the pipeline aspect of slot filling. Depending on the previous steps, the input for the relation classification models can be incomplete, noisy, include coreferent mentions, etc.

The official SF Shared Task evaluations only assess whole systems (with potential subsequent faults in their pipelines (Pink et al., 2014)). Thus, we expect component wise comparisons to be a valuable addition to the Shared Task: With comparisons of single components, teams would be able to improve their modules more specifically. To start with one of the most important components, we have created a benchmark for slot filling relation classification, based on 2012 – 2014 TAC Shared Task data. It will be described below and published along with this paper.[1] In addition to presenting model results on this benchmark dataset, we also show that these results correlate with end-to-end SF results. Hence, optimizing a model on this dataset will also help improving results in the end-to-end setting.

In our experiments, we found that our models suffer from large genre differences in the TAC data. Hence, the SF Shared Task is a task that conflates an investigation of domain (or genre) adaptation with the one of slot filling. We argue that both problems are important NLP problems and provide datasets and results for both within and across genres. We hope that this new resource will encourage others to test their models on our dataset and that this will help promote research on slot filling.

In summary, our contributions are as follows. (i) We investigate the complementary strengths and weaknesses of different approaches to relation classification and show that their combination can better deal with a diverse set of problems that slot filling poses than each of the approaches individually. (ii) We propose to split the context at the relation arguments before passing it to the CNN in order to better deal with the special characteristics of a sentence in relation classification. This outperforms the state-of-the-art piecewise CNN. (iii) We analyze the effect of genre on slot filling and show that it is an important conflating variable that needs to be carefully examined in research on slot filling. (iv) We provide a benchmark for slot filling relation classification that will facilitate direct comparisons of models in the future and show that results on this dataset are correlated with end-to-end system results.

Section 2 gives an overview of related work. Section 3 discusses the challenges that slot filling systems face. In Section 4, we describe our slot filling models. Section 5 presents experimental setup and results. Section 6 analyzes the results. We present our conclusions in Section 7 and describe the resources we publish in Section 8.

2 Related Work

Slot filling. The participants of the SF Shared Task (Surdeanu, 2013) are provided with a large text corpus. For evaluation, they get a collection of queries and need to provide fillers for predefined relations and an offset of a context which can serve as a justification. Most participants apply pipeline based systems. Pink et al. (2014) analyzed sources of recall losses in these pipelines. The results of the systems show the difficulty of the task: In the 2014 evaluation, the top-ranked system had an F_1 of .37 (Angeli et al., 2014a). To train their models, most groups use distant supervision (Mintz et al., 2009). The top-ranked systems apply machine learning based ap-

[1] http://cistern.cis.lmu.de

proaches rather than manually developed patterns or models (Surdeanu and Ji, 2014). The methods for extracting and scoring candidates range from pattern based approaches (Gonzàlez et al., 2012; Liu and Zhao, 2012; Li et al., 2012; Qiu et al., 2012; Roth et al., 2014) over rule based systems (Varma et al., 2012) to classifiers (Malon et al., 2012; Roth et al., 2013). The top ranked system from 2013 used SVMs and patterns for evaluating filler candidates (Roth et al., 2013); their results suggest that n-gram based features are sufficient to build reliable classifiers for the relation classification module. They also show that SVMs outperform patterns.

CNNs for relation classification. Zeng et al. (2014) and Dos Santos et al. (2015) apply CNNs to the relation classification SemEval Shared Task data from 2010 and show that CNNs outperform other models. We train CNNs on noisy distant supervised data since (in contrast to the SemEval Shared Task) clean training sets are not available. Malon et al. (2012) describe a CNN for slot filling that is based on the output of a parser. We plan to explore parsing for creating a more linguistically motivated input representation in the future.

Baseline models. In this paper, we will compare our methods against traditional relation classification models: Mintz++ (Mintz et al., 2009; Surdeanu et al., 2012) and MIMLRE (Surdeanu et al., 2012). Mintz++ is a model based on the Mintz features (lexical and syntactic features for relation extraction). It was developed by Surdeanu et al. (2012) and used as a baseline model by them. MIMLRE is a graphical model designed to cope with multiple instances and multiple labels in distant supervised data. It is trained with Expectation Maximization.

Another baseline model which we use in this work is a piecewise convolutional neural network (Zeng et al., 2015). This recently published network is designed especially for the relation classification task which allows to split the context into three parts around the two relation arguments. While it uses the whole context for convolution, it performs max pooling over the three parts individually. In contrast, we propose to split the context even earlier and apply the convolutional filters to each part separately.

Genre dependency. There are many studies showing the genre dependency of machine learning models. In 2012, the SANCL Shared Task focused on evaluating models on web data that have been trained on news data (Petrov and McDonald, 2012). The results show that POS tagging performance can decline a lot when the genre is changed. For other NLP tasks like machine translation or sentiment analysis, this is also a well-known challenge and domain adaptation has been extensively studied (Glorot et al., 2011; Foster and Kuhn, 2007). We do not investigate domain adaptation per se, but show that the genre composition of the slot filling source corpus poses challenges to genre independent models.

3 Challenges of Slot Filling

Slot filling includes NLP challenges of various natures. Given a large evaluation corpus, systems first need to find documents relevant to the entity of the query. This involves challenges like alternate names for the same entity, misspellings of names and ambiguous names (different entities with the same name). Then for each relevant document, sentences with mentions of the entity need to be extracted, as well as possible fillers for the given slot. In most cases, coreference resolution and named entity recognition tools are used for these tasks. Finally, the systems need to decide which filler candidate to output as the solution for the given slot. This step can be reduced to relation classification. It is one of the most crucial parts of the whole pipeline since it directly influences the quality of the final output. The most important challenges for relation classification for slot filling are little or noisy (distant supervised) training data, data from different domains and test sentences which have been extracted with a pipeline of different NLP components. Thus, their quality directly depends on the performance of the whole pipeline. If, for example, sentence splitting fails, the input can be incomplete or too long. If coreference resolution or named entity recognition fails, the relation arguments can be wrong or incomplete.

4 Models for Relation Classification

Patterns. The first approach we evaluate for relation classification is pattern matching. For a given sentence, the pattern matcher classifies the relation as correct if one of the patterns matches; otherwise the candidate is rejected. In particular, we apply two different pattern sets: The first set consists of patterns learned using distant supervision (*PATdist*). They have been used in the SF challenge by the top-ranked system in the 2013 Shared Task (Roth et al., 2013). The second set contains patterns from universal schema relations for the SF task (*PATuschema*). Universal schema relations are extracted based on matrix factorization (Riedel et al., 2013). In this work, we apply the universal schema patterns extracted for slot filling by Roth et al. (2014).

Support vector machines (SVMs). Our second approach is support vector machines. We evaluate two different feature sets: bag-of-word features (*SVMbow*) and skip n-gram features (*SVMskip*). Based on the results of Roth et al. (2013), we will not use additional syntactic or semantic features for our classifiers. For SVMbow, the representation of a sentence consists of a flag and four bag-of-word vectors. Let m_1 and m_2 be the mentions of name and filler (or filler and name) in the sentence, with m_1 occurring before m_2. The binary flag indicates in which order name and filler occur. The four BOW vectors contain the words in the sentence to the left of m_1, between m_1 and m_2, to the right of m_2 and all words of the sentence. For SVMskip, we use the previously described BOW features and additionally a feature vector which contains skip n-gram features. They wildcard tokens in the middle of the n-gram (cf. Roth et al. (2013)). In particular, we use skip 3-grams, skip 4-grams and skip 5-grams. A possible skip 4-gram of the context ", founder and director of", for example, would be the string "founder of", a pattern that could not have been directly extracted from this context otherwise. We train one linear SVM (Fan et al., 2008) for each relation and feature set and tune parameter C on dev.

Convolutional neural networks (CNNs). CNNs are increasingly applied in NLP (Collobert et al., 2011; Kalchbrenner et al., 2014). They extract n-gram based features independent of the position in the sentence and create (sub-)sentence representations. The two most important aspects that make this possible are convolution and pooling. Max pooling (Collobert et al., 2011) detects the globally most relevant features obtained by local convolution.

Another promising aspect of CNNs for relation classification is that they use an embedding based input representation. With word embeddings, similar words are represented by similar vectors and, thus, we can recognize (near-)synonyms – synonyms of relation triggers as well as of other important context words. If the CNN has learned, for example, that the context "is based in" triggers the relation location_of_headquarters and that "based" has a similar vector representation as "located", it may recognize the context "is located in" correctly as another trigger for the same relation even if it has never seen it during training. In the following paragraphs, we describe the different variants of CNNs which we evaluate in this paper. For each variant, we train one binary CNN per slot and optimize the number of filters ($\in \{300, 1000, 3000\}$), the size of the hidden layer ($\in \{100, 300, 1000\}$) and the filter width ($\in \{3, 5\}$) on dev. We use word2vec (Mikolov et al., 2013) to pre-train word embeddings (dimensionality $d = 50$) on a May-2014 English Wikipedia corpus.

Piecewise CNN. Our baseline CNN is the model developed by Zeng et al. (2015). It represents the input sentence by a matrix of word vectors, applies several filters for convolution and then divides the resulting n-gram representation into left, middle and right context based on the positions m_1 and m_2 of name and filler (see SVM description). For each of the three parts, one max value is extracted by pooling. The results are passed to a softmax classifier.

Contextwise CNN. In contrast to the piecewise CNN, we propose to split the context before convolution as shown in Figure 1. Hence, similar to our BOW vectors for the SVM, we split the original context words into left, middle and right context. Then, we apply convolution and pooling to each of the contexts separately. In contrast to the piecewise CNN, there is no convolution across relation arguments. Thus, the network learns to focus on the context words and cannot be distracted by the presence of (always present) relation arguments. The filter weights W are shared for the three contexts. Our intuition is that the most important sequence features we want to extract by convolution can appear in two or three of the regions. Weight sharing also reduces the number of parameters and increases robustness. We also found in initial experiments that sharing filter weights across left, middle, right outperformed not sharing weights. The results of convolution are pooled using k-max pooling (Kalchbrenner et al.,

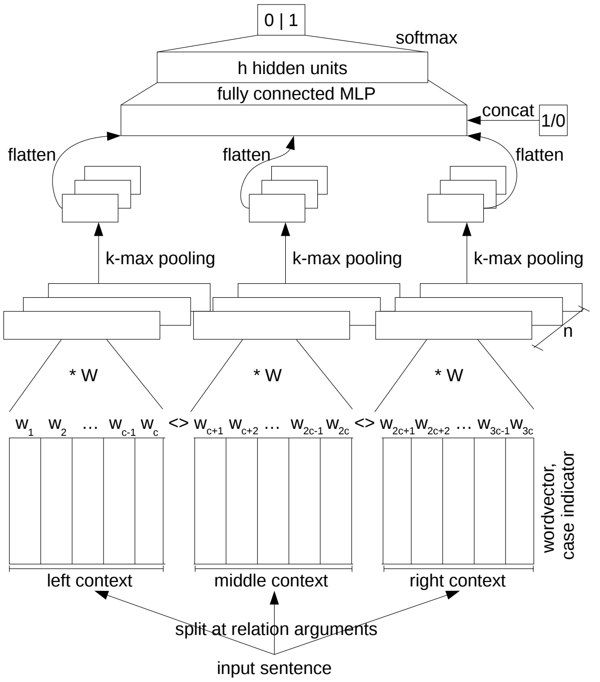

Figure 1: Contextwise CNN for relation classification

2014): only the $k = 3$ maximum values of each filter application are kept. The pooling results are then concatenated to a single vector and extended by a flag indicating whether the name or the filler appeared first in the sentence.

In initial experiments, we found that a fully connected hidden layer after convolution and pooling leads to a more powerful model. It connects the representations of the three contexts and, thus, can draw conclusions based on cooccurring patterns across contexts. Therefore, the result vector after convolution and pooling is fed into a fully connected hidden layer. A softmax layer makes the final decision.

For a fair comparison of models, we also add a hidden layer to the piecewise CNN and apply k-max pooling there as well. Thus, the number of parameters to learn is the same for both models. We call this model *CNNpieceExt*. The key difference between CNNpieceExt and CNNcontext is the time when the context is split into three parts: before or after convolution. This affects the windows of words to which the convolutional filters are applied.

Model combination (CMB). To combine a set M of models for classification, we perform a simple linear combination of the scores of the models:

$$q_{\text{CMB}} = \sum_{m=1...M} \alpha_m q_m$$

where q_m is the score of model m and α_m is its weight (optimized on dev using grid search). All weights sum to 1.

For a comparison of different combination possibilities, see, for example, (Viswanathan et al., 2015).

5 Experiments and Results

5.1 Training Data

We used distant supervision for generating training data. We created a set of (subject, relation, object) tuples by querying Freebase (Bollacker et al., 2008) for relations that correspond to the slot relations. Then we scanned the following corpora for sentences containing both arguments of a relation in the tuple set: (i) the TAC source corpus (TAC, 2014), (ii) a snapshot of Wikipedia (May 2014), (iii) the Freebase description fields, (iv) a subset of Clueweb[2], (v) a New York Times corpus (LDC2008T19). The resulting sentences are positive training examples. Based on the tuple set, we selected negative examples by scanning the corpora for sentences that (i) contain a mention of a name occurring in a tuple, (ii) do not contain the correct filler, (iii) contain a mention different from the correct filler, but with the same named entity type (based on CoreNLP NER (Manning et al., 2014)). All negative examples for date slots, for instance, are sentences containing an incorrect date.

This procedure gave us a large but noisy training set for most slots. In order to reduce incorrect labels, we applied a self-training procedure: We trained SVMs on the SF dataset created by Angeli et al. (2014b). With the resulting SVMs, we predicted labels for our training set. If the predicted label did not match the distant supervised label, we deleted the corresponding training example (Min et al., 2012). This procedure was conducted in several iterations on different chunks of the training set. Finally, the SF dataset and the filtered training examples were merged. (We do not use the SF dataset directly because (i) it provides few examples per slot

[2] `http://lemurproject.org/clueweb12`

(min: 1, max: 4960) and (ii) it consists of examples for which the classifiers of Angeli et al. (2014b) were indecisive, i.e., presumably contexts that are hard to classify.) Since their contexts are similar, we also merged city, state-or-province and country slots to one location slot.

5.2 Evaluation Data

One of the main challenges in building and evaluating relation classification models for SF is the shortage of training and evaluation data. Each group has their own datasets and comparisons across groups are difficult. Therefore, we have developed a script that creates a clean dataset based on manually annotated system outputs from previous Shared Task evaluations. In the future, it can be used by all participants to evaluate components of their slot filling systems.[3] The script only extracts sentences that contain mentions of both name and filler. It conducts a heuristic check based on NER tags to determine whether the name in the sentence is a valid mention of the query name or is referring to another entity. In the latter case, the example is filtered out. One difficulty is that many published offsets are incorrect. We tried to match these using heuristics. In general, we apply filters that ensure high quality of the resulting evaluation data even if that means that a considerable part of the TAC system output is discarded. In total, we extracted 39,386 high-quality evaluation instances out of the 59,755 system output instances published by TAC and annotated as either completely correct or completely incorrect.

A table in the supplementary material[4] gives statistics: the number of positive and negative examples per slot and year (without duplicates). For 2013, the most examples were extracted. The lower number for 2014 is probably due to the newly introduced inference across documents. This limits the number of sentences with mentions of both name and filler. The average ratio of positive to negative examples is 1:4. The number of positive examples per slot and year ranges from 0 (org:member_of, 2014) to 581 (per:title, 2013), the number of negative examples from 5 (org:website, 2014) to 1886 (per:title, 2013).

In contrast to other relation classification benchmarks, this dataset is not based on a knowledge base (such as Freebase) and unrelated text (such as web documents) but directly on the SF assessments. Thus, it includes exactly the SF relations and addresses the challenges of the end-to-end task: noisy data, possibly incomplete extractions of sentences and data from different domains.

We use the data from 2012/2013 as development and the data from 2014 as evaluation set.

5.3 Experiments

We evaluate the models described in Section 4, select the best models and combine them.

Experiments with patterns. First, we compare the performance of PATdist and PATuschema on our dataset. We evaluate the pattern matchers on all slots presented in Table 1 and calculate their average F_1 scores on dev. PATdist achieves a score of .35, PATuschema of .33. Since it performs better, we use PATdist in the following experiments.

Experiments with SVMs. Second, we train and evaluate SVMbow and SVMskip. Average F_1 of SVMskip and SVMbow are .62 and .59, respectively. Thus, we use SVMskip. We expected that SVMskip beats SVMbow due to its richer feature set, but SVMbow performs surprisingly well.

Experiments with CNNs. Finally, we compare the performance of CNNpiece, CNNpieceExt and CNNcontext. While the baseline network CNNpiece (Zeng et al., 2015) achieves F_1 of .52 on dev, CNNpieceExt has an F_1 score of .55 and CNNcontext an F_1 of .60. The difference of CNNpiece and CNNpieceExt is due to the additional hidden layer and k-max pooling. The considerable difference in performance of CNNpieceExt and CNNcontext shows that splitting the context for convolution has a positive effect on the performance of the network.

Overall results. Table 1 shows the slot wise results of the best patterns (PATdist), SVMs (SVMskip) and CNNs (CNNcontext). Furthermore, it provides a comparison with two baseline models: Mintz++ and MIMLRE. SVM and CNN clearly outperform these baselines. They also outperform PAT for almost all slots. The difference between dev and eval results varies a lot among the slots. We suspect that this is a result of genre differences in the data and analyze this in Section 6.4.

Table 1: Performance on Slot Filling benchmark dataset (dev: data from 2012/2013, eval: from 2014). CMB denotes the combination of PATdist, SVMskip and CNNcontext.

Slot wise results of the other models (PATuschema, SVMbow, CNNpiece, CNNpieceExt) can be found in the supplementary material.

Comparing PAT, SVM and CNN,[5] different patterns emerge for different slots. Each is best on a subset of the slots (see bold numbers). This indicates that relation classification for slot filling is not a uniform problem: each slot has special properties and the three approaches are good at modeling a different subset of these properties. Given the big differences, we expect to gain performance by combining the three approaches. Indeed, CMB (PATdist + SVMskip + CNNcontext), the combination of the three best performing models, obtains the best results in average (in bold).

Section 6.3 shows that the performance on our dataset is highly correlated with SF end-to-end performance. Thus, our results indicate that a combination of different models ist the most promising approach to getting good performance on slot filling.

6 Analysis

6.1 Contribution of Each Model

To see how much each model contributes to CMB, we count how often each weight between 0.0 and 1.0 is selected for the linear interpolation. The results are plotted as a histogram (Figure 2). A weight of 0.0 means that the corresponding model does not contribute to CMB. We see that all three models contribute to CMB for most of the slots. The CNN, for instance, is included in the combination for 14 of 24 slots.

6.2 Comparison of CNN to Traditional Models

Our motivation for using a CNN is that convolution and max pooling can recognize important n-grams independent of their position in the sentence. To in-

[5] In prior experiments, we also compared with recurrent neural networks. RNN performance was comparable to CNNs, but required much more training time and parameter tuning. Therefore, we focus on CNNs in this paper. See also Vu et al. (2016).

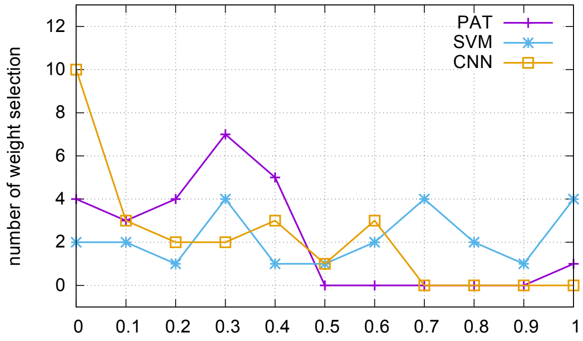

Figure 2: # times each weight is selected in CMB

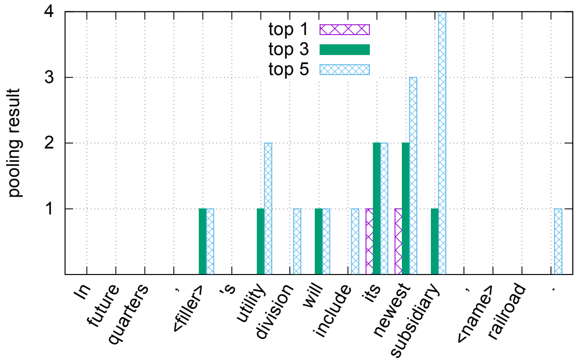

Figure 3: Analysis of convolution and pooling

vestigate this effect, we select for each CNN the top five kernels whose activations are the most correlated with the final score of the positive class. Then we calculate which n-grams are selected by these kernels in the max pooling step. This corresponds to those n-grams which are recognized by the kernel to be the most informative for the given slot. Figure 3 shows the result for an example sentence expressing the slot relation org:parents. The height of a bar is the number of times that the 3-gram around the corresponding word was selected by k-max pooling; e.g., the bar above "newest" corresponds to the trigram "its newest subsidiary". The figure shows that the convolutional filters are able to learn phrases that trigger a relation, e.g., "its subsidiary". In contrast to patterns, they do not rely on exact matches. The first reason is embeddings. They generalize similar words and phrases by assigning similar word vectors to them. For PAT and SVM, this type of generalization is more difficult. The second type of generalization that the CNN learns concerns insertions, similar to skip n-gram features. The recognition of important phrases in convolution is robust against insertions. An example is "newest" in Figure 3, a word that is not important for the slot.

A direct comparison of results with PAT shows that the CNN has better eval scores for about 67% of the slots (see Table 1). Our reasoning above can explain this. Compared to the SVM, the CNN generalizes better to unseen data in only 42% of all cases. The fact that this does not happen in more cases shows the power of the skip n-gram features of the SVM: they also provide a kind of generalization against insertions. The SVM might also need less data to train than the CNN. Nevertheless, the final scores show that the CNN performs almost as well as the SVM in average (.60 vs .62 on dev, .46 vs .48 on eval) and contributes to a better combination score.

6.3 Correlation with End-to-end Results

In this section, we show that using the dataset we provide with this paper allows tuning classification models for the end-to-end SF task. For each model and each possible combination of models, we calculate average results on our evaluation set as well as final F_1 scores when running the whole slot filling pipeline with our in-house system. The best results of our slot filling system are an F_1 of .29 on the 2013 queries and of .25 on the 2014 queries. We calculate Pearson's correlation coefficient to assess correlation of relation classification and end-to-end performances for the n different system configurations (i.e., model combinations). The correlation of the results on our eval dataset with the SF results on 2013 queries is .89, the correlation with the SF results on 2014 queries is .82. This confirms that good results on the dataset we propose lead to good results on the slot filling end-to-end task.

6.4 Effect of Genre and Time

The TAC source corpus consists of about 1M news documents, 1M web documents and 100K documents from discussion forums (TAC, 2014). The distribution of these different genres in the extracted assessment data is as shown in Table 2.

The proportion of non-news more than doubled from 12.5% to 26.6%. Thus, when using 2012/2013 as the development and 2014 as the test set, we are faced with a domain adaptation problem.

	2012/3	2014
news	87.5%	73.4%
web + forums	12.5%	26.6%

Table 2: Distribution of genres

In this section, we show the effect of domain differences on our models in more detail. For our genre analysis, we retrain our models on genre specific training sets WEB and NEWS$_\subset$ and show within-genre as well as cross-genre evaluations. To avoid performance differences due to different training set sizes, we reduced the news training set to the same size as the web training set. We refer to this subset as NEWS$_\subset$.

Cross-genre evaluation. Table 3 shows results of testing models trained on genre-specific data: on data of the same genre and on data of the other genre. We present results only for a subset of relations in this paper, however, the numbers for the other slots follow the same trends.

Models trained on news (left part) show clearly higher performance in the within-genre evaluation than cross-genre. For models trained on web (right part), this is different. We suspect that the reason is that web data is much noiser and thus less predictable, even for models trained on web. For all evaluations, the differences among dev and eval are quite large. Especially for slot filling on web (bottom part of Table 3), the results on dev do not seem much related to the results on eval. This domain effect increases the difficulties of training robust relation classification models for slot filling. It can also explain why optimizing models for unseen data (with unknown genre distributions) as in Table 1 is challenging. Since slot filling by itself is a challenging task, even in the absence of domain differences, we will distribute two splits: a split by year and a split by genre. For training and tuning models for the slot filling research challenge, the year split can be used to cover the challenge of mixing different genres. For experiments on domain adaptation or genre-specific effects, our genre split can be used.

7 Conclusion

In this paper, we presented different approaches to slot filling relation classification: patterns, support vector machines and convolutional neural networks. We investigated their complementary strengths and weaknesses and showed that their combination can better deal with a diverse set of problems that slot filling poses than each of the approaches individually. We proposed a contextwise CNN which outperforms the recent state-of-the-art piecewise CNN. Furthermore, we analyzed the effect of genre on slot filling and showed that it needs to be carefully examined in research on slot filling. Finally, we provided a benchmark for slot filling relation classification that will facilitate direct comparisons of approaches in the future.

Abstract

Representation and learning of commonsense knowledge is one of the foundational problems in the quest to enable deep language understanding. This issue is particularly challenging for understanding casual and correlational relationships between events. While this topic has received a lot of interest in the NLP community, research has been hindered by the lack of a proper evaluation framework. This paper attempts to address this problem with a new framework for evaluating story understanding and script learning: the 'Story Cloze Test'. This test requires a system to choose the correct ending to a four-sentence story. We created a new corpus of 50k five-sentence commonsense stories, ROCStories, to enable this evaluation. This corpus is unique in two ways: (1) it captures a rich set of causal and temporal commonsense relations between daily events, and (2) it is a high quality collection of everyday life stories that can also be used for story generation. Experimental evaluation shows that a host of baselines and state-of-the-art models based on shallow language understanding struggle to achieve a high score on the Story Cloze Test. We discuss these implications for script and story learning, and offer suggestions for deeper language understanding.

1 Introduction

Story understanding is an extremely challenging task in natural language understanding with a long-running history in AI (Charniak, 1972; Winograd, 1972; Turner, 1994; Schubert and Hwang, 2000). Recently, there has been a renewed interest in story and narrative understanding based on progress made in core NLP tasks. This ranges from generic story telling models to building systems which can compose meaningful stories in collaboration with humans (Swanson and Gordon, 2008). Perhaps the biggest challenge of story understanding (and story generation) is having commonsense knowledge for the interpretation of narrative events. The question is how to provide commonsense knowledge regarding daily events to machines.

A large body of work in story understanding has focused on learning scripts (Schank and Abelson, 1977). Scripts represent structured knowledge about stereotypical event sequences together with their participants. It is evident that various NLP applications (text summarization, co-reference resolution, question answering, etc.) can hugely benefit from the rich inferential capabilities that structured knowledge about events can provide. Given that developing hand-built scripts is extremely time-consuming, there is a serious need for automatically induced scripts. Most relevant to this issue is work on unsupervised learning of 'narrative chains' (Chambers and Jurafsky, 2008) and event schemas (Chambers and Jurafsky, 2009; Balasubramanian et al., 2013; Cheung et al., 2013; Nguyen et al., 2015). The first requirement of any learner is to decide on a corpus to drive the learning process. We are foremost interested in a resource that is full of temporal and causal relations between events because causality is a central component of coherency. Personal stories from daily weblogs are good sources of commonsense causal information (Gordon and Swan-

Proceedings of NAACL-HLT 2016, pages 839–849,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

son, 2009; Manshadi et al., 2008), but teasing out useful information from noisy blog entries is a problem of its own. Consider the following snippet from ICWSM 2011 Spinn3r Dataset of Weblog entries (Burton et al., 2009):

> "I had an interesting day in the studio today. It was so interesting that I took pictures along the way to describe it to you. Sometimes I like to read an autobiography/biography to discover how someone got from there to here.....how they started, how they traveled in mind and spirit, what made them who they are now. Well, today, my work was a little like that."

This text is full of discourse complexities. A host of challenging language understanding tasks are required to get at the commonsense knowledge embedded within such text snippets. What is needed is a simplified version of these narratives. This paper introduces a new corpus of such short commonsense stories. With careful prompt design and multiple phases of quality control, we collected 50k high quality five-sentence stories that are full of stereotypical causal and temporal relations between events. The corpus not only serves as a resource for learning commonsense narrative schemas, but is also suitable for training story generation models. We describe this corpus in detail in Section 3.

This new corpus also addresses a problem facing script learning over the past few years. Despite the attention scripts have received, progress has been inhibited by the lack of a systematic evaluation framework. A commonly used evaluation is the 'Narrative Cloze Test' (Chambers and Jurafsky, 2008) in which a system predicts a held-out event (a verb and its arguments) given a set of observed events. For example, the following is one such test with a missing event: $\{$X threw, pulled X, told X, ???, X completed$\}$[1]. As is often the case, several works now optimize to this specific test, achieving higher scores with shallow techniques. This is problematic because the models often are not learning commonsense knowledge, but rather how to beat the shallow test.

This paper thus introduces a new evaluation framework called the Story Cloze Test. Instead of predicting an event, the system is tasked with choosing an entire sentence to complete the given story. We collected 3,742 doubly verified Story Cloze Test cases. The test is described in detail in Section 4.

Finally, this paper proposes several models, including the most recent state-of-the-art approaches for the narrative cloze test, for tackling the Story Cloze Test. The results strongly suggest that achieving better than random or constant-choose performance requires richer semantic representation of events together with deeper levels of modeling the semantic space of stories. We believe that switching to the Story Cloze Test as the empirical evaluation framework for story understanding and script learning can help direct the field to a new direction of deeper language understanding.

2 Related Work

Several lines of research have recently focused on learning narrative/event representations. Chambers and Jurafsky first proposed narrative chains (Chambers and Jurafsky, 2008) as a partially ordered set of narrative events that share a common actor called the 'protagonist'. A narrative event is a tuple of an event (a verb) and its participants represented as typed dependencies. Several expansions have since been proposed, including narrative schemas (Chambers and Jurafsky, 2009), script sequences (Regneri et al., 2010), and relgrams (Balasubramanian et al., 2013). Formal probabilistic models have also been proposed to learn event schemas and frames (Cheung et al., 2013; Bamman et al., 2013; Chambers, 2013; Nguyen et al., 2015). These are trained on smaller corpora and focus less on large-scale learning. A major shortcoming so far is that these models are mainly trained on news articles. Little knowledge about everyday life events are learned.

Several groups have directly addressed script learning by focusing exclusively on the narrative cloze test. Jans et al. (Jans et al., 2012) redefined the test to be a text ordered sequence of events, whereas the original did not rely on text order (Chambers and Jurafsky, 2008). Since then, others have shown language-modeling techniques perform well (Pichotta and Mooney, 2014a; Rudinger et al., 2015). This paper shows that these approaches struggle on the richer Story Cloze evaluation.

There has also been renewed attention toward natural language comprehension and commonsense

[1] Narrative cloze tests were not meant to be human solvable.

reasoning (Levesque, 2011; Roemmele et al., 2011; Bowman et al., 2015). There are a few recent frameworks for evaluating language comprehension (Hermann et al., 2015; Weston et al., 2015), including the MCTest (Richardson et al., 2013) as a notable one. Their framework also involves story comprehension, however, their stories are mostly fictional, on average 212 words, and geared toward children in grades 1-4. Some progress has been made in story understanding by limiting the task to the specific domains and question types. This includes research on understanding newswire involving terrorism scripts (Mueller, 2002), stories about people in a restaurant where a reasonable number of questions about time and space can be answered (Mueller, 2007), and generating stories from fairy tales (McIntyre and Lapata, 2009). Finally, there is a rich body of work on story plot generation and creative or artistic story telling (Méndez et al., 2014; Riedl and León, 2008). This paper is unique to these in its corpus of short, simple stories with a wide variety of commonsense events. We show these to be useful for learning, but also for enabling a rich evaluation framework for narrative understanding.

3 A Corpus of Short Commonsense Stories

We aimed to build a corpus with two goals in mind:

1. The corpus contains a *variety* of commonsense causal and temporal relations between everyday events. This enables learning narrative structure across a range of events, as opposed to a single domain or genre.

2. The corpus is a high quality collection of nonfictional daily short life stories, which can be used for training rich coherent story-telling models.

In order to narrow down our focus, we carefully define a narrative or story as follows: 'A narrative or story is anything which is told in the form of a causally (logically) linked set of events involving some shared characters'. The classic definition of a story requires having a plot, (e.g., a character following a goal and facing obstacles), however, here we are not concerned with how entertaining or dramatic the stories are. Instead, we are concerned with the essence of actually being a logically meaningful story. We follow the notion of 'storiness' (Forster, 1927; Bailey, 1999), which is described as "the expectations and questions that a reader may have as the story develops", where expectations are 'common-sense logical inferences' made by the imagined reader of the story.

We propose to satisfy our two goals by asking hundreds of workers on Amazon Mechanical Turk (AMT) to write novel five-sentence stories. The five-sentence length gives enough context to the story without allowing room for sidetracks about less important or irrelevant information in the story. In this Section we describe the details about how we collected this corpus, and provide statistical analysis.

3.1 Data Collection Methodology

Crowdsourcing this corpus makes the data collection scalable and adds to the diversity of stories. We tested numerous pilots with varying prompts and instructions. We manually checked the submitted stories in each pilot and counted the number of submissions which did not have our desired level of coherency or were specifically fictional or offensive. Three people participated in this task and they iterated over the ratings until everyone agreed with the next pilot's prompt design. We achieved the best results when we let the workers write about anything they have in mind, as opposed to mandating a prespecified topic. The final crowdsourcing prompt can be found in supplementary material.

The key property that we had enforced in our final prompt was the following: the story should read like a coherent story, with a specific *beginning* and *ending*, where *something happens* in between. This constraint resulted in many causal and temporal links between events. Table 1 shows the examples we provided to the workers for instructing them about the constraints. We set a limit of 70 characters to the length of each sentence. This prevented multi-part sentences that include unnecessary details. The workers were also asked to provide a title that best describes their story. Last but not least, we instructed the workers not to use quotations in their sentences and avoid using slang or informal language.

Collecting high quality stories with these constraints gives us a rich collection of commonsense stories which are full of stereotypical inter-event re-

✗	The little puppy thought he was a great basketball player. He challenged the kitten to a friendly game. The kitten agreed. Kitten started to practice really hard. Eventually the kitten beat the puppy by 40 points.
✓	Bill thought he was a great basketball player. He challenged Sam to a friendly game. Sam agreed. Sam started to practice really hard. Eventually Sam beat Bill by 40 points.
✗	I am happy with my life. I have been kind. I have been successful. I work out. Why not be happy when you can?
✗	The city is full of people and offers a lot of things to do. One of my favorite things is going to the outdoor concerts. I also like visiting the different restaurants and museums. There is always something exciting to do in the city.
✓	The Smith family went to the family beach house every summer. They loved the beach house a lot. Unfortunately there was a bad hurricane once. Their beach house was washed away. Now they lament the loss of their beach house every summer.
✗	Miley was in middle school. ~~She lived in an apartment~~. Once Miley made a mistake and cheated in one of her exams. She tried to hide the truth from her parents. After her parents found out, they grounded her for a month.
✓	Miley was in middle school. She usually got good grades in school . Once Miley made a mistake and cheated in one of her exams. She tried to hide the truth from her parents. After her parents found out, they grounded her for a month.

Table 1: Examples of good and bad stories provided to the crowd-sourced workers. Each row emphasizes one of the three properties that each story should satisfy: (1) being realistic, (2) having clear beginning and ending, and (3) not stating anything irrelevant to the story.

X *challenge* Y – Y *agree* play —— Y *practice* —— Y *beat* X

Figure 1: An example narrative chain with characters X and Y.

lations. For example, from the good story in first row of Table 1, one can extract the narrative chain represented in Figure 1. Developing a better semantic representation for narrative chains which can capture rich inter-event relations in these stories is a topic of future work.

Quality Control: One issue with crowdsourcing is how to instruct non-expert workers. This task is a type of creative writing, and is trickier than classification and tagging tasks. In order to ensure we get qualified workers, we designed a qualification test on AMT in which the workers had to judge whether or not a given story (total five stories) is an acceptable one. We used five carefully selected stories to be a part of the qualification test. This not only eliminates any potential spammers on AMT, but also provides us with a pool of creative story writers. Furthermore, we qualitatively browsed through the submissions and gave the workers detailed feedback before approving their submissions. We often bonused our top workers, encouraging them to write new stories on a daily basis.

Statistics: Figure 2 shows the distribution of number of tokens of different sentence positions. The first sentence tends to be shorter, as it usually introduces characters or sets the scene, and the fifth sentence is longer, providing more detailed conclusions to the story. Table 2 summarizes the statistics of our crowdsourcing effort. Figure 3 shows the distribution of the most frequent 50 events in the corpus. Here we count event as any hyponym of ‘event’ or ‘process’ in WordNet (Miller., 1995). The top two events, ‘go’ and ‘get’, each comprise less than 2% of all the events, which illustrates the rich diversity of the corpus.

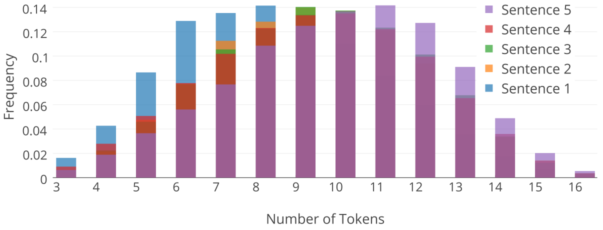

Figure 2: Number of tokens in each sentence position.

# submitted stories	49,895
# approved stories	**49,255**
# workers participated	932
Average # stories by one worker	52.84
Max # stories written by one worker	3,057
Average work time among workers (minute)	4.80
Median work time among workers (minute)	2.16
Average payment per story (cents)	26

Table 2: Crowdsourcing worker statistics.

Figure 4 visualizes the n-gram distribution of our story titles, where each radial path indicates an n-

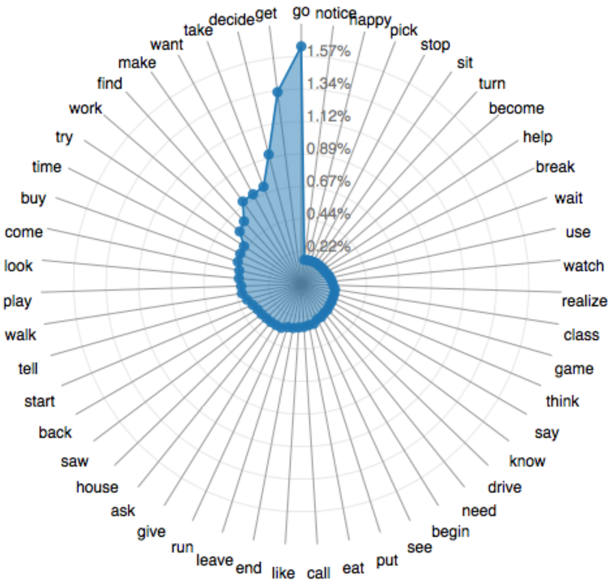

Figure 3: Distribution of top 50 events in our corpus.

gram sequence. For this analysis we set n=5, where the mean number of tokens in titles is 9.8 and median is 10. The 'end' token distinguishes the actual ending of a title from five-gram cut-off. This figure demonstrates the range of topics that our workers have written about. The full circle reflects on 100% of the title n-grams and the n-gram paths in the faded 3/4 of the circle comprise less than 0.1% of the n-grams. This further demonstrates that the range of topics covered by our corpus is quite diverse. A full dynamic visualization of these n-grams can be found here: `http://goo.gl/Qhg60B`.

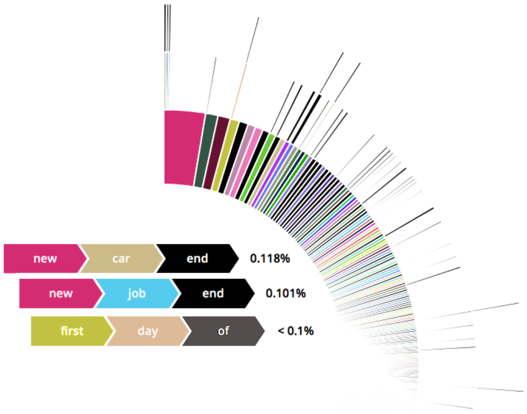

Figure 4: N-gram distribution of story titles.

3.2 Corpus Release

The corpus is publicly available to the community and can be accessed through `http://cs.rochester.edu/nlp/rocstories`, which will be grown even further over the coming years. Given the quality control pipeline and the creativity required from workers, data collection goes slowly.

We are also making available semantic parses of these stories. Since these stories are not newswire, off-the-shelf syntactic and shallow semantic parsers for event extraction often fail on the language. To address this issue, we customized search parameters and added a few lexical entries[2] to TRIPS broad-coverage semantic parser[3], optimizing its performance on our corpus. TRIPS parser (Allen et al., 2008) produces state-of-the-art logical forms for input stories, providing sense disambiguated and ontology-typed rich deep structures which enables event extraction together with semantic roles and coreference chains throughout the five sentences.

3.3 Temporal Analysis

Being able to temporally order events in the stories is a pre-requisite for complete narrative understanding. Temporal analysis of the events in our short commonsensical stories is an important topic of further research on its own. In this Section, we summarize two of our analyses regarding the nature of temporal ordering of events in our corpus.

Shuffling Experiment: An open question in any text genre is how text order is related to temporal order. Do the sentences follow the real-world temporal order of events? This experiment shuffles the stories and asks AMT workers to arrange them back to a coherent story. This can shed light on the correlation between the original position of the sentences and the position when another human rearranges them in a commonsensically meaningful way. We set up this experiment as follows: we sampled two sets of 50 stories from our corpus: *Good-Stories*$_{50}$ and *Random-Stories*$_{50}$. *Good-Stories*$_{50}$[4] is sampled from a set of stories written by top workers

[2] For example, new informal verbs such as 'vape' or 'vlog' have been added to the lexicon of this semantic parser.

[4] This set can be found here: `https://goo.gl/VTnJ9s`

	Good-Stories$_{50}$	*Random-Stories*$_{50}$
% perfectly ordered, taking majority ordering for each of the 50 stories	100	86
% all sentences perfectly ordered, out of 250 orderings	95.2	82.4
% $\leq$ 1 sentences misplaced, rest flow correctly, out of 250 orderings	98.0	96.0
% correct placements of each position, 1 to 5	**98.8**, 97.6, 96, 96, **98.8**	**95.6**, 86, 86.8, 91.2, **96.8**

Table 3: Results from the human temporal shuffling experiment.

who have shown shown consistent quality throughout their submissions. *Random-Stories*$_{50}$[5] is a random sampling from all the stories in the corpus. Then we randomly shuffled the sentences in each story and asked five crowd workers on AMT to rearrange the sentences.

Table 3 summarizes the results of this experiment. The first row shows the result of ordering if we take the absolute majority ordering of the five crowd workers as the final ordering. The second row shows the result of ordering if we consider each of the 250 (50 stories x 5 workers ordering each one) ordering cases independently. As shown, the good stories are perfectly ordered with very high accuracy. It is important to note that this specific set rarely had any linguistic adverbials such as 'first', 'then', etc. to help human infer the ordering, so the main factors at play are the following: (1) the commonsensical temporal and causal relation between events (narrative schemas), e.g., human knows that first someone loses a phone then starts searching; (2) the natural way of narrating a story which starts with introducing the characters and concludes the story at the end. The role of the latter factor is quantified in the misplacement rate of each position reported in Table 3, where the first and last sentences are more often correctly placed than others. The high precision of ordering in sentences 2 up to 4 further verifies the richness of our corpus in terms of logical relation between events.

TimeML Annotation: TimeML-driven analysis of these stories can give us finer-grained insight about temporal aspect of the events in this corpus. We performed a simplified TimeML-driven (Pustejovsky et al., 2003) expert annotation of a sample of 20 stories[6]. Among all the temporal links (TLINK) annotated, 62% were 'before' and 10% were 'simultaneous'. We were interested to know if the actual text order mirrors real-world order of events. We found that sentence order matches TimeML order 55% of the time. A more comprehensive study of temporal and causal aspects of these stories requires defining a specific semantic annotation framework which covers not only temporal but also causal relations between commonsense events. This is captured in a recent work which introduces a Causal and Temporal Relation Scheme (CaTeRS) for semantic annotation of event structures (Mostafazadeh et al., 2016).

4 A New Evaluation Framework

As described earlier in the introduction, the common evaluation framework for script learning is the 'Narrative Cloze Test' (Chambers and Jurafsky, 2008), where a system generates a ranked list of guesses for a missing event, given some observed events. The original goal of this test was to provide a comparative measure to evaluate narrative knowledge. However, gradually, the community started optimizing towards the performance on the test itself, achieving higher scores without demonstrating narrative knowledge learning. For instance, generating the ranked list according to the event's corpus frequency (e.g., always predicting 'X said') was shown to be an extremely strong baseline (Pichotta and Mooney, 2014b). Originally, narrative cloze test chains were extracted by hand and verified as gold chains. However, the cloze test chains used in all of the most recent works are not human verified as gold.

It is evident that there is a need for a more systematic automatic evaluation framework which is more in line with the original deeper script/story understanding goals. It is important to note that reordering of temporally shuffled stories (Section 3.3) can serve as a framework to evaluate a system's story understanding. However, reordering can be achieved to a degree by using various surface features such as adverbials, so this cannot be a foolproof story understanding evaluation framework. Our ROCStories corpus enables a brand new framework for evaluating story understanding, called the *'Story Cloze*

[5] This set can be found here: `https://goo.gl/pgm2KR`

[6] The annotation is available: `http://goo.gl/7qdNsb`

Test'.

4.1 Story Cloze Test

The cloze task (Taylor, 1953) is used to evaluate a human (or a system) for language understanding by deleting a random word from a sentence and having a human fill in the blank. We introduce 'Story Cloze Test', in which a system is given a four-sentence 'context' and two alternative endings to the story, called 'right ending' and 'wrong ending'. Hence, in this test the fifth sentence is blank. Then the system's task is to choose the right ending. The 'right ending' can be viewed as 'entailing' hypothesis in a classic Recognizing Textual Entailment (RTE) framework (Giampiccolo et al., 2007), and 'wrong' ending can be seen as the 'contradicting' hypothesis. Table 4 shows three example Story Cloze Test cases.

Story Cloze Test will serve as a generic story understanding evaluation framework, also applicable to evaluation of story generation models (for instance by computing the log-likelihoods assigned to the two ending alternatives by the story generation model), which does not necessarily imply requirement for explicit narrative knowledge learning. However, it is safe to say that any model that performs well on Story Cloze Test is demonstrating some level of deeper story understanding.

4.2 Data Collection Methodology

We randomly sampled 13,500 stories from ROCStories Corpus and presented only the first four sentences of each to AMT workers. For each story, a worker was asked to write a 'right ending' and a 'wrong ending'. The workers were prompted to satisfy two conditions: (1) the sentence should follow up the story by sharing at least one of the characters of the story, and (2) the sentence should be entirely realistic and sensible when read in isolation. These conditions make sure that the Story Cloze Test cases are not trivial. More details on this setup is described in the supplementary material.

Quality Control: The accuracy of the Story Cloze Test can play a crucial role in directing the research community in the right trajectory. We implemented the following two-step quality control:

1. Qualification Test: We designed a qualification test for this task, where the workers had to choose whether or not a given 'right ending' and 'wrong ending' satisfy our constraints. At this stage we collected 13,500 cloze test cases.

2. Human Verification: In order to further validate the cloze test cases, we compiled the 13,500 Story Cloze Test cases into $2 \times 13,500 = 27,000$ full five-sentence stories. Then for each story we asked three crowd workers to verify whether or not the given sequence of five sentences makes sense as a meaningful and coherent story, rating within {-1, 0, 1}. Then we filtered cloze test cases which had 'right ending' with all ratings 1 and 'wrong ending' with all ratings 0. This process ensures that there are no boundary cases of 'right ending' and 'wrong ending'. This resulted in final 3,742 test cases, which was randomly divided into validation and test Story Cloze Test sets. We also made sure to remove the original stories used in the validation and test set from our ROCStories Corpus.

Statistics: Table 5 summarizes the statistics of our crowdsourcing effort. The Story Cloze Test sets can also be accessed through our website.

5 Story Cloze Test Models

In this Section we demonstrate that Story Cloze Test cannot be easily tackled by using shallow techniques, without actually understanding the underlying narrative. Following other natural language inference frameworks such as RTE, we evaluate system performance according to basic accuracy measure, which is defined as $\frac{\#correct}{\#test\ cases}$. We present the following baselines and models for tackling Story Cloze Test. All of the models are tested on the validation and test Story Cloze sets, where only the validation set could be used for any tuning purposes.

1. Frequency: Ideally, the Story Cloze Test cases should not be answerable without the context. For example, if for some context the two alternatives are 'He was mad after he won'[7] and 'He was cheerful after he won', the first alternative is simply less probable in real world than the other one. This baseline chooses the alternative with higher

[7] Given our prompt that the 'wrong ending' sentences should make sense in isolation, such cases should be rare in our dataset.

Context	Right Ending	Wrong Ending
Tom and Sheryl have been together for two years. One day, they went to a carnival together. He won her several stuffed bears, and bought her funnel cakes. When they reached the Ferris wheel, he got down on one knee.	Tom asked Sheryl to marry him.	He wiped mud off of his boot.
Karen was assigned a roommate her first year of college. Her roommate asked her to go to a nearby city for a concert. Karen agreed happily. The show was absolutely exhilarating.	Karen became good friends with her roommate.	Karen hated her roommate.
Jim got his first credit card in college. He didn't have a job so he bought everything on his card. After he graduated he amounted a $10,000 debt. Jim realized that he was foolish to spend so much money.	Jim decided to devise a plan for repayment.	Jim decided to open another credit card.

Table 4: Three example Story Cloze Test cases, completed by our crowd workers.

# cases collected	13,500
# workers participated	282
Average # cases written by one worker	47.8
Max # cases written by one worker	1461
Average payment per test case (cents)	10
Size of the final set (verified by human)	**3,744**

Table 5: Statistics for crowd-sourcing Story Cloze Test instances.

search engine[8] hits of the main event (verb) together with its semantic roles (e.g., 'I*poison*flowers' vs 'I*nourish*flowers'). We extract the main verb and its corresponding roles using TRIPS semantic parser.

2. N-gram Overlap: Simply chooses the alternative which shares more n-grams with the context. We compute Smoothed-BLEU (Lin and Och, 2004) score for measuring up to four-gram overlap of an alternative and the context.

3. GenSim: Average Word2Vec: Choose the hypothesis with closer average word2vec (Mikolov et al., 2013) embedding to the average word2vec embedding of the context. This is basically an enhanced word overlap baseline, which accounts for semantic similarity.

4. Sentiment-Full: Choose the hypothesis that matches the average sentiment of the context. We use the state-of-the-art sentiment analysis model (Manning et al., 2014) which assigns a numerical value from 1 to 5 to a sentence.

5. Sentiment-Last: Choose the hypothesis that matches the sentiment of the last context sentence.

6. Skip-thoughts Model: This model uses Skip-thoughts' Sentence2Vec embedding (Kiros et al., 2015) which models the semantic space of novels. This model is trained on the 'BookCorpus' (Zhu et al., 2015) (containing 16 different genres) of over 11,000 books. We use the skip-thoughts embedding of the alternatives and contexts for making decision the same way as with GenSim model.

7. Narrative Chains-AP: Implements the standard approach to learning chains of narrative events based on Chambers and Jurafsky (2008). An event is represented as a verb and a typed dependency (e.g., the *subject* of *runs*). We computed the PMI between all event pairs in the Associate Press (AP) portion of the English Gigaword Corpus that occur at least 2 times. We run coreference over the given story, and choose the hypothesis whose coreferring entity has the highest average PMI score with the entity's chain in the story. If no entity corefers in both hypotheses, it randomly chooses one of the hypotheses.

8. Narrative Chains-Stories: The same model as above, but trained on ROCStories.

9. Deep Structured Semantic Model (DSSM): This model (Huang et al., 2013) is trained to project the four-sentences context and the fifth sentence into the same vector space. It consists of two separate deep neural networks for learning jointly the embedding of the four-sentences context and the fifth sentence, respectively. As suggested in Huang et al. (2013), the input of the DSSM is based on context-dependent characters, e.g., the distribution count of letter-trigrams in the context and in the fifth sentence, respectively. The hyper parameters of the DSSM is determined on the validation set, while the

	Constant-choose-first	Frequency	N-gram-overlap	GenSim	Sentiment-Full	Sentiment-Last	Skip-thoughts	Narrative-Chains-AP	Narrative-Chains-Stories	DSSM	Human
Validation Set	0.514	0.506	0.477	0.545	0.489	0.514	0.536	0.472	0.510	0.604	1.0
Test Set	0.513	0.520	0.494	0.539	0.492	0.522	0.552	0.478	0.494	**0.585**	1.0

Table 6: The accuracy of various models on The Story Cloze validation and test sets.

model's parameters are trained on the ROCStories corpus. In our experiment, each of the two neural networks in the DSSM has two layers: the dimension of the hidden layer is 1000, and the dimension of the embedding vector is 300. At runtime, this model picks the candidate with the largest cosine similarity between its vector representation and the context's vector representation.

The results of evaluating these models on the Story Cloze validation and test sets are shown in Table 6. The constant-choose-first (51%) and human performance (100%) is also provided for comparison. Note that these sets were doubly verified by human, hence it does not have any boundary cases, resulting in 100% human performance. The DSSM model achieves the highest accuracy, but only 7.2 points higher than constant-choose-first. Error analysis on the narrative chains model shows why this and other event-based language models are not sufficient for the task: often, the final sentences of our stories contain complex events beyond the main verb, such as 'Bill was highly unprepared' or 'He had to go to a homeless shelter'. Event language models only look at the verb and syntactic relation like 'was-object' and 'go-to'. In that sense, going to a homeless shelter is the same as going to the beach. This suggests the requirement of having richer semantic representation for events in narratives. Our proposed Story Cloze Test offers a new challenge to the community.

6 Discussion

There are three core contributions in this paper: (1) a new corpus of commonsense stories, called ROCStories, (2) a new evaluation framework to evaluate script/story learners, called Story Cloze Test, and (3) a host of first approaches to tackle this new test framework. ROCStories Corpus is the first crowdsourced corpus of its kind for the community. We have released about 50k stories, as well as validation and test sets for Story Cloze Test. This dataset will eventually grow to 100k stories, which will be released through our website. In order to continue making meaningful progress on this task, although it is possible to keep increasing the size of the training data, we expect the community to develop models that will learn to generalize to unseen commonsense concepts and situations.

The Story Cloze Test proved to be a challenge to all of the models we tested. We believe it will serve as an effective evaluation for both story understanding and script knowledge learners. We encourage the community to benchmark their progress by reporting their results on Story Cloze test set. Compared to the previous Narrative Cloze Test, we found that one of the early models for that task actually performs worse than random guessing. We can conclude that Narrative Cloze test spurred interest in script learning, however, it ultimately does not evaluate deeper knowledge and language understanding.

Acknowledgments

We would like to thank the amazing crowd workers whose endless hours of daily story writing made this research possible. We thank William de Beaumont and Choh Man Teng for their work on TRIPS parser. We thank Alyson Grealish for her great help in the quality control of our corpus. This work was supported in part by Grant W911NF-15-1-0542 with the US Defense Advanced Research Projects Agency (DARPA), the Army Research Office (ARO) and the Office of Naval Research (ONR). Our data collection effort was sponsored by Nuance Foundation.

Dynamic Entity Representation with Max-pooling Improves Machine Reading

Sosuke Kobayashi and **Ran Tian** and **Naoaki Okazaki** and **Kentaro Inui**
Tohoku University, Japan
{sosuke.k, tianran, okazaki, inui}@ecei.tohoku.ac.jp

Abstract

We propose a novel neural network model for machine reading, *DER Network*, which explicitly implements a reader building dynamic meaning representations for entities by gathering and accumulating information around the entities as it reads a document. Evaluated on a recent large scale dataset (Hermann et al., 2015), our model exhibits better results than previous research, and we find that max-pooling is suited for modeling the accumulation of information on entities. Further analysis suggests that our model can put together multiple pieces of information encoded in different sentences to answer complicated questions. Our code for the model is available at https://github.com/soskek/der-network

1 Introduction

Machine reading systems (Poon et al., 2010; Richardson et al., 2013) can be tested on their ability to answer queries about contents of documents that they read, thus a central problem is how the information of documents should be organized in the system and retrieved by the queries. Recently, large scale datasets of document-query-answer triples have been constructed from online newspaper articles and their summaries (Hermann et al., 2015), by replacing named entities in the summaries with placeholders to form Cloze (Taylor, 1953) style questions (Figure 1). These datasets have enabled training and testing of complicated neural network models of hypothesized machine readers (Hermann et al., 2015; Hill et al., 2015).

Query

" **[X]** " star *@entity0* presents a young child with a bionic arm

Answer *@entity2*

Figure 1: A document-query-answer triple constructed from a news article and its bullet point summary. An entity in the summary (*Robert Downey Jr.*) is replaced by the placeholder **[X]** to form a query. All entities are anonymized to exclude world knowledge and focus on reading comprehension.

In this paper, we hypothesize that a reader without world knowledge can only understand a named entity by dynamically constructing its meaning from the contexts. For example, in Figure 1, a reader reading the sentence "*Robert Downey Jr. may be Iron Man …* " can only understand "*Robert Downey Jr.*" as something that "*may be Iron Man*" at this stage, given that it does not know Robert Downey Jr. *a priori*. Information about this entity can only

Proceedings of NAACL-HLT 2016, pages 850–855,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

be accumulated by its subsequent occurrence, such as "*Downey recently presented a robotic arm* ...". Thus, named entities basically serve as anchors to link multiple pieces of information encoded in different sentences. This insight has been reflected by the anonymization process in construction of the dataset, in which coreferent entities (e.g. "*Robert Downey Jr.*" and "*Downey*") are replaced by randomly permuted abstract entity markers (e.g. "*@entity0*"), in order to prevent additional world knowledge from being attached to the surface form of the entities (Hermann et al., 2015). We, however, take it as a strong motivation to implement a reader that dynamically builds meaning representations for each entity, by gathering and accumulating information on that entity as it reads a document (Section 2).

Evaluation of our model, *DER Network*, exhibits better results than previous research (Section 3). In particular, we find that max-pooling of entity representations, which is intended to model the accumulation of information on entities, can drastically improve performance. Further analysis suggests that max-pooling can help our model draw multiple pieces of information from different sentences.

2 Model

Following Hermann et al. (2015), our model estimates the conditional probability $p(e|D,q)$, where q is a query and D is a document. A candidate answer for the query is denoted by e, which in this paper is any named entity. Our model can be factorized as:

$$p(e|D,q) \propto \exp(\boldsymbol{v}(e;D,q)^{\mathrm{T}}\boldsymbol{u}(q)) \qquad (1)$$

in which $\boldsymbol{u}(q)$ is the learned meaning for the query and $\boldsymbol{v}(e;D,q)$ the dynamically constructed meaning for an entity, depending on the document D and the query q. We note that (1) is in contrast to the factorization used by Hermann et al. (2015):

$$p(a|D,q) \propto \exp(\boldsymbol{v}(a)^{\mathrm{T}}\boldsymbol{u}(D,q)) \qquad (2)$$

in which a vector $\boldsymbol{u}(D,q)$ is learned to represent the status of a reader after reading a document and a query, and this vector is used to retrieve an answer by coupling with the answer vector $\boldsymbol{v}(a)$.[1]

Factorization (2) relies on the hypothesis that there exists a fixed vector for each candidate answer representing its meaning. However, as we argued in Section 1, an entity surface does not possess meaning; rather, it serves as an anchor to link pieces of information about it. Therefore, we hypothesize that the meaning representation $\boldsymbol{v}(e;D,q)$ of an entity e should be dynamically constructed from its surrounding contexts, and the meanings are "accumulated" through the reader reading the document D. We explain the construction of $\boldsymbol{v}(e;D,q)$ in Section 2.1, and propose a max-pooling process for modeling information accumulation in Section 2.2.

2.1 Dynamic Entity Representation

For any entity e, we take its context c as any sentence that includes a token of e. Then, we use bidirectional single-layer LSTMs (Hochreiter and Schmidhuber, 1997; Graves et al., 2005) to encode c into vectors. LSTM is a neural cell that outputs a vector $\boldsymbol{h}_{c,t}$ for each token t in the sentence c; taking the word vector $\boldsymbol{x}_{c,t}$ of the token as input, each $\boldsymbol{h}_{c,t}$ is calculated recurrently from its precedent vector $\boldsymbol{h}_{c,t-1}$ or $\boldsymbol{h}_{c,t+1}$, depending on the direction of the encoding. Formally, we write forward and backward LSTMs as:

$$\overrightarrow{\boldsymbol{h}}_{c,t} = \overrightarrow{LSTM}(\boldsymbol{x}_{c,t}, \overrightarrow{\boldsymbol{h}}_{c,t-1}) \quad \text{(forward)} \qquad (3)$$

$$\overleftarrow{\boldsymbol{h}}_{c,t} = \overleftarrow{LSTM}(\boldsymbol{x}_{c,t}, \overleftarrow{\boldsymbol{h}}_{c,t+1}) \quad \text{(backward)} \qquad (4)$$

Then, denoting the length of the sentence c as T and the index of the entity e token as τ, we define the dynamic entity representation $\boldsymbol{d}_{e,c}$ as the concatenation of the vectors $[\overrightarrow{\boldsymbol{h}}_{c,T}, \overleftarrow{\boldsymbol{h}}_{c,1}, \overrightarrow{\boldsymbol{h}}_{c,\tau}, \overleftarrow{\boldsymbol{h}}_{c,\tau}]$ encoded by a feed-forward layer (Figure 2):

$$\boldsymbol{d}_{e,c} = \tanh(W_{hd}[\overrightarrow{\boldsymbol{h}}_{c,T}, \overleftarrow{\boldsymbol{h}}_{c,1}, \overrightarrow{\boldsymbol{h}}_{c,\tau}, \overleftarrow{\boldsymbol{h}}_{c,\tau}]+\boldsymbol{b}_d)$$

in which W_{hd} and $\boldsymbol{b}_d$ respectively stand for the learned weight matrix and bias vector of that feed-forward layer. Index hd denotes that W_{hd} is a matrix mapping $\boldsymbol{h}$-vectors to $\boldsymbol{d}$-vectors. Index d shows that $\boldsymbol{b}_d$ has the same dimension as $\boldsymbol{d}$-vectors. We use this convention throughout this paper.

Having $\boldsymbol{d}_{e,c}$ as the dynamic representation of an entity e occurring in context c, we define vector

[1] Hermann et al. (2015) models $p(a|D,q)$ for every word token a in a document. While the approach could be more general because it has the potential to answer other types of questions given appropriate training data, our approach is arguably suitable for the specific task and natural for testing our hypothesis.

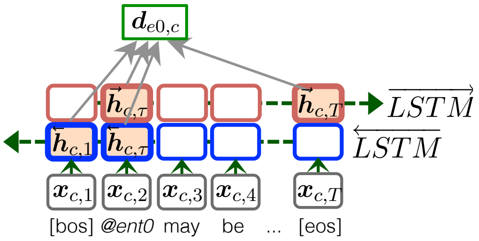

Figure 2: Dynamic entity representation $\boldsymbol{d}_{e,c}$ encodes LSTM outputs, modeling surrounding context.

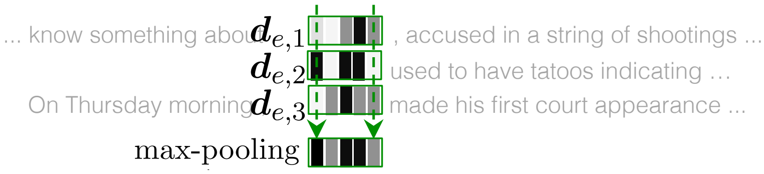

Figure 3: Max-pooling takes the max value of each dimension of dynamic entity representations, modeling accumulation of context information. It is then fed to $\boldsymbol{x}_{c,\tau}$ as input to LSTMs.

$\boldsymbol{v}(e;D,q)$ for each entity as a weighted sum [2]:

$$\boldsymbol{v}(e;D,q) = W_{dv}\big[\sum_{c\in D} s_{e,c}(q)\boldsymbol{d}_{e,c}\big] + \boldsymbol{b}_v \tag{5}$$

in which $s_{e,c}(q)$ is calculated by the attention mechanism (Bahdanau et al., 2015), modeling the degree to which our reader should attend to a particular occurrence of an entity, given the query q. More precisely, $s_{e,c}(q)$ is defined as the following:

$$s_{e,c}(q) = \frac{\exp(s'_{e,c}(q))}{\sum_{c'}\exp(s'_{e,c'}(q))} \tag{6}$$

$$s'_{e,c'}(q) = \boldsymbol{m}^{\mathrm{T}}\tanh(W_{dm}\boldsymbol{d}_{e,c'} + \boldsymbol{q}) + b_s \tag{7}$$

where $s_{e,c}(q)$ is calculated by taking the softmax of $s'_{e,c'}(q)$, which is calculated from the dynamic entity representation $\boldsymbol{d}_{e,c'}$ and the query vector $\boldsymbol{q}$. The vector $\boldsymbol{m}$, matrix W_{dm}, and the bias b_s in (7) are learned parameters in the attention mechanism. Vector $\boldsymbol{m}$ is used here to map a vector value to a scalar.

The query vector[3] $\boldsymbol{u}(q)$ is constructed similarly as dynamic entity representations, using bidirectional LSTMs[4] to encode the query and then encoding the output vectors. More precisely, if we denote the length of the query as T and the index of the placeholder as τ, the query vector is calculated as:

$$\boldsymbol{u}(q) = W_{hq}[\vec{\boldsymbol{h}}_{q,T}, \overleftarrow{\boldsymbol{h}}_{q,1}, \vec{\boldsymbol{h}}_{q,\tau}, \overleftarrow{\boldsymbol{h}}_{q,\tau}] + \boldsymbol{b}_q \tag{8}$$

Then, $\boldsymbol{v}(e;D,q)$ and $\boldsymbol{u}(q)$ are used in (1) to calculate probability $p(e|D,q)$.

2.2 Max-pooling

We expect the dynamic entity representation to capture information about an entity mentioned in a sentence. However, as an entity occurs multiple times in a document, information is accumulated as subsequent occurrences of the entity draw information from previous mentions. For example, in Figure 1, the first sentence mentioning "*Robert Downey Jr.*" relates *Downey* to *Iron Man*, whereas a subsequent mention of "*Downey*" also relates him to a robotic arm. Both of the two pieces of information are necessary to answer the query "*Iron Man star [X] presents ... with a bionic arm*". Therefore, the dynamic entity representations as constructed individually from single sentences may not provide enough information for our reader model. We thus propose the use of max-pooling to model information accumulation of dynamic entity representations.

More precisely, for each entity e, max-pooling takes the max value of each dimension of the vectors $\boldsymbol{d}_{e,c'}$ from all preceding contexts c' (Figure 3). Then, in a subsequent sentence c where the entity occurs again at index τ, we use the vector

$$\boldsymbol{x}_{c,\tau} = W_{dx}\ \underset{c'\prec c}{\text{max-pooling}}(\boldsymbol{d}_{e,c'}) + \boldsymbol{b}_x$$

as input for the LSTMs in (3) and (4) for encoding the context. This vector $\boldsymbol{x}_{c,\tau}$ draws information from preceding contexts, and is regarded as the meaning of the entity e that the reader understands so far, before reading the sentence c. It is used in place of a vector previously randomly initialized as a notion of e, in the construction of the new dynamic entity representation $\boldsymbol{d}_{e,c}$.

[2] Following a heuristic used in Hill et al. (2015), we add a secondary bias $\boldsymbol{b}'_v$ to $\boldsymbol{v}(e;D,q)$ if the entity e already appears in the query q.

[3] $\boldsymbol{u}(q)$ and another query vector $\boldsymbol{q}$, are calculated respectively, in the same way (8) with unshared model parameters, while sharing the parameters is also promising.

[4] The parameters of the bi-LSTM for queries are not shared with the ones for entity contexts.

3 Evaluation

We use the CNN-QA dataset (Hermann et al., 2015) for evaluating our model's ability to answer questions about named entities. The dataset consists of (D, q, e)-triples, where the document D is taken from online news articles, and the query q is formed by hiding a named entity e in a summarizing bullet point of the document (Figure 1). The training set has 90k articles and 380k queries, and both validation and test sets have 1k articles and 3k queries. An average article has about 25 entities and 700 word tokens. One trains a machine reading system on the data by maximizing likelihood of correct answers. We use `Chainer`[5] (Tokui et al., 2015) to implement our model[6].

Experimental Settings Named entities in CNN-QA are already recognized. For preprocessing, we segment sentences at punctuation marks ".", "!", and "?".[7] We train our model[8] with hyper-parameters lightly tuned on the validation set[9], and we conduct ablation test on several techniques that improve our basic model.

Results As shown in Table 1, Max-pooling described in Section 2.2 drastically improves performance, showing the effect of accumulating information on entities. Another technique, called "Byway", is based on the observation that the attention mechanism (5) must always promote some entity occurrences (since all weights sum to 1), which could be difficult if the entity does not answer the query. To counter this, we make an artificial occurrence for each entity with no contexts, which serves as a byway to attend when no other occurrences can be reasonably related to the query. This simple trick shows clear effects, suggesting that the attention mechanism plays a key role in our model. Combining these two techniques helps more. Further, we note that initializing our model with pre-trained word vectors[10] is helpful, though world knowledge of entities has been prevented by the anonymization process. This suggests that pre-trained word vectors may still bring extra linguistic knowledge encoded in ordinary words. Finally, we note that our model, full *DER Network*, shows the best results compared to several previous reader models (Hermann et al., 2015; Hill et al., 2015), endorsing our approach as promising. The 99% confidence intervals of the results of full DER Network and the one initialized by word2vec on the test set were $[0.700, 0.740]$ and $[0.708, 0.749]$, respectively (measured by bootstrap tests).

Models	**Valid**	**Test**

[5] `http://chainer.org/`

[6] The implementation is available at `https://github.com/soskek/der-network`.

[7] Text in CNN-QA are tokenized without any sentence segmentations.

[8] Training process takes roughly a week (3-5 passes of the training data) on a 6-core 2.4GHz Xeon CPU.

[9] Vector dimension: 300, Dropout: 0.3, Batch: 50, Optimization: RMSProp with momentum (Tieleman and Hinton, 2012; Graves, 2013) (momentum: 0.9, decay: 0.95), Learning rate: 1e-4 divided by 2.0 per epoch, Gradient clipping factor: 10. We initialize word vectors by uniform distribution [-0.05, 0.05], and other matrix parameters by Gaussians of mean 0 and variance 2/(# rows + # columns).

[10] We use GoogleNews vectors from `http://code.google.com/p/word2vec/` (Mikolov et al., 2013).

Analysis In the example shown in Figure 4, our basic model missed by paying little attention to the second and third sentences, probably because it does not mention @*entity0* (*Downey*). In contrast, max-pooling of @*entity2* (*Iron Man*) draws attention to the second and third sentences because *Iron Man* is said related to *Downey* in the first sentence. This helps *Iron Man* surpass @*entity26* (*Transformers*), which is the name of a different movie series in which robots appear but *Downey* doesn't. Quantitatively, in the 479 samples in test set correctly answered by max-pooling but missed by basic model, the average occurrences of answer entities (8.0) is higher than the one (7.2) in the 1782 samples correctly answered by both models. This suggests that max-pooling especially helps samples with more entity mentions.

4 Discussion

It is actually a surprise for us that deep learning models, despite their vast amount of parameters, seem able to learn as intended by the designers. This also indicates a potential that additional linguistic intuitions modeled by deep learning methods can improve performances, as in the other work using max-pooling (LeCun et al., 1998; Socher et al., 2011; Le et al., 2012; Collobert et al., 2011; Kalchbrenner et al., 2014), attention (Bahdanau et al., 2015; Luong et al., 2015; Xu et al., 2015; Rush et al., 2015), etc. In this work, we have focused on modeling a reader that dynamically builds meanings for entities. We believe the methodology can be inspiring to other problems as well.

Abstract

We address the problem of automatically finding the parameters of a statistical machine translation system that maximize BLEU scores while ensuring that decoding speed exceeds a minimum value. We propose the use of Bayesian Optimization to efficiently tune the speed-related decoding parameters by easily incorporating speed as a noisy constraint function. The obtained parameter values are guaranteed to satisfy the speed constraint with an associated confidence margin. Across three language pairs and two speed constraint values, we report overall optimization time reduction compared to grid and random search. We also show that Bayesian Optimization can decouple speed and BLEU measurements, resulting in a further reduction of overall optimization time as speed is measured over a small subset of sentences.

1 Introduction

Research in Statistical Machine Translation (SMT) aims to improve translation quality, typically measured by BLEU scores (Papineni et al., 2001), over a baseline system. Given a task defined by a language pair and its corpora, the quality of a system is assessed by contrasting choices made in rule/phrase extraction criteria, feature functions, decoding algorithms and parameter optimization techniques.

Some of these choices result in systems with significant differences in performance. For example, in phrase-based translation (PBMT) (Koehn et al., 2003), decoder parameters such as pruning thresholds and reordering constraints can have a dramatic impact on both BLEU and decoding speed. However, unlike feature weights, which can be optimized by MERT (Och and Ney, 2004), it is difficult to optimize decoder parameters either for speed or for BLEU.

We are interested in the problem of automatically finding the decoder parameters and feature weights that yield the best BLEU at a specified minimum decoding speed. This is potentially very expensive because each change in a decoder parameter requires re-decoding to assess both BLEU and translation speed. This is under-studied in the literature, despite its importance for real-life commercial SMT engines whose speed and latency can be as significant for user satisfaction as overall translation quality.

We propose to use Bayesian Optimization (Brochu et al., 2010b; Shahriari et al., 2015) for this constrained optimization task. By using prior knowledge of the function to be optimized and by exploring the most uncertain and the most promising regions of the parameter space, Bayesian Optimization (BO) is able to quickly find optimal parameter values. It is particularly well-suited to optimize expensive and non-differentiable functions such as the BLEU score of a decoder on a tuning set. The BO framework can also incorporate noisy constraints, such as decoder speed measurements, yielding parameters that satisfy these constraints with quantifiable confidence values.

For a set of fixed feature weights, we use BO to optimize phrase-based decoder parameters for speed and BLEU. We show across 3 different language

[*] This work was done during an internship of the first author at SDL Research, Cambridge.

Proceedings of NAACL-HLT 2016, pages 856–865,
San Diego, California, June 12-17, 2016.

pairs that BO can find fast configurations with high BLEU scores much more efficiently than other tuning techniques such as grid or random search. We also show that BLEU and decoding speed can be treated as decoupled measurements by BO. This results in a further reduction of overall optimization time, since speed can be measured over a smaller set of sentences than is needed for BLEU.

Finally, we discuss the effects of feature weights reoptimization after speed tuning, where we show that further improvements in BLEU can be obtained. Although our analysis is done on a phrase-based system with standard decoder parameters (decoding stack size, distortion limit, and maximum number of translations per source phrase), BO could be applied to other decoding paradigms and parameters.

The paper is organized as follows. Section 2 gives a brief overview of Bayesian Optimization and describes how it can be applied to our problem, Section 3 reports our speed-constrained tuning experiments, Section 4 reviews related work, and Section 5 concludes.

2 Bayesian Optimization

We are interested in finding a global maximizer of an objective function f:

$$\theta_\star = \arg\max_{\theta \in \Theta} f(\theta) \tag{1}$$

where θ is a parameter vector from a search space Θ. It is assumed that f has no simple closed form but can be evaluated at an arbitrary θ point. In this paper, we take f as the BLEU score produced by an SMT system on a tuning set, and θ will be the PBMT decoder parameters.

Bayesian Optimization is a powerful framework to efficiently address this problem. It works by defining a prior model over f and evaluating it sequentially. Evaluation points are chosen to maximize the utility of the measurement, as estimated by an acquisition function that trades off exploration of uncertain regions in Θ versus exploitation of regions that are promising, based on function evaluations over all x points gathered so far. BO is particularly well-suited when f is non-convex, non-differentiable and costly to evaluate (Shahriari et al., 2015).

2.1 Prior Model

The first step in performing BO is to define the prior model over the function of interest. While a number of different approaches exist in the literature, in this work we follow the concepts presented in Snoek et al. (2012) and implemented in the Spearmint[1] toolkit, which we detail in this Section.

The prior over f is defined as a Gaussian Process (GP) (Rasmussen and Williams, 2006):

$$f \sim \mathcal{GP}(m(\theta), k(\theta, \theta')) \tag{2}$$

where m and k are the mean and kernel (or covariance) functions. The mean function is fixed to the zero constant function, as usual in GP models. This is not a large restriction because the *posterior* over f will have non-zero mean in general. We use the Matèrn52 kernel, which makes little assumptions about the function smoothness.

The observations, BLEU scores in our work, are assumed to have additive Gaussian noise over f evaluations. In theory we do not expect variations in BLEU for a fixed set of decoding parameters but in practice assuming some degree of noise helps to make the posterior calculation more stable.

2.2 Adding Constraints

The optimization problem of Equation 1 can be extended to incorporate an added constraint on some measurement $c(\theta)$:

$$\theta_\star = \arg\max_{\theta \in \Theta} f(\theta) \quad \text{s.t. } c(\theta) > t \tag{3}$$

In our setup, $c(\theta)$ is the decoding speed of a configuration θ, and t is the minimum speed we wish the decoder to run at. This formulation assumes c is deterministic given a set of parameters θ. However, as we show in Section 3.2, speed measurements are inherently noisy, returning different values when using the same decoder parameters.

So, we follow Gelbart et al. (2014) and redefine Equation 3 by assuming a probabilistic model p over $c(\theta)$:

$$\theta_\star = \arg\max_{\theta \in \Theta} f(\theta) \quad \text{s.t. } p(c(\theta) > t) \geq 1 - \delta \tag{4}$$

where δ is a user-defined tolerance value. For our problem, the formulation above states that we wish

[1] https://github.com/HIPS/Spearmint

to optimize the BLEU score for decoders that run at speeds faster than t with probability $1 - \delta$. Like f, c is also assumed to have a GP prior with zero mean, Matèrn52 kernel and additive Gaussian noise.

2.3 Acquisition Function

The prior model combined with observations gives rise to a posterior distribution over f. The posterior mean gives information about potential optima in Θ, in other words, regions we would like to *exploit*. The posterior variance encodes the uncertainty in unknown regions of Θ, i.e., regions we would like to *explore*. This exploration/exploitation trade-off is a fundamental aspect not only in BO but many other global optimization methods.

Acquisition functions are heuristics that use information from the posterior to suggest new evaluation points. They naturally encode the exploration/exploitation trade-off by taking into account the full posterior information. A suggestion is obtained by maximizing this function, which can be done using standard optimization techniques since they are much cheaper to evaluate compared to the original objective function.

Most acquisition functions used in the literature are based on improving the best evaluation obtained so far. However, it has been shown that this approach has some pathologies in the presence of constrained functions (Gelbart et al., 2014). Here we employ Predictive Entropy Search with Constraints (PESC) (Hernández-Lobato et al., 2015), which aims to maximize the information about the global optimum $\theta_\star$. This acquisition function has been empirically shown to obtain better results when dealing with constraints and it can easily take advantage of a scenario known as *decoupled constraints* (Gelbart et al., 2014), where the objective (BLEU) and the constraint (speed) values can come from different sets of measurements. This is explained in the next Section.

Algorithm 1 summarizes the BO procedure under constraints. It starts with a set $\mathcal{D}_0$ of data points (selected at random, for instance), where each data point is a (θ, f, c) triple made of parameter values, one function evaluation (BLEU) and one constraint evaluation (decoding speed). Initial posteriors over the objective and the constraint are calculated[2]. At every iteration, the algorithm selects a new evaluation point by maximizing the acquisition function α, measures the objective and constraint values on this point and updates the respective posterior distributions. It repeats this process until it reaches a maximum number of iterations N, and returns the best set of parameters obtained so far that is valid according to the constraint.

Algorithm 1 Constrained Bayesian Optimization

```
Input max. number of iterations $N$, acquisition
    function $\alpha$, initial evaluations $\mathcal{D}_0$, min. con-
    straint value $t$, tolerance $\delta$
 1: $\Theta = \emptyset$
 2: for $i = 1, \dots, N$ do
 3:   select new $\theta_i$ by maximizing $\alpha$:
          $\theta_i = \arg\max_\theta \; \alpha(\theta, p(f|\mathcal{D}_{i-1}), p(c|\mathcal{D}_{i-1}))$
 4:   $\Theta = \Theta \cup \theta_i$
 5:   query objective $f(\theta_i)$
 6:   query constraint $c(\theta_i)$
 7:   augment data $\mathcal{D}_i = \mathcal{D}_i \cup (\theta, f, c)_i$
 8:   update objective posterior $p(f|\mathcal{D}_i)$
 9:   update constraint posterior $p(c|\mathcal{D}_i)$
10: end for
11: return $\theta_\star$ as per Equation 4
```

2.4 Decoupling Constraints

Translation speed can be measured on a much smaller tuning set than is required for reliable BLEU scores. In speed-constrained BLEU tuning, we can decouple the constraint by measuring speed on a small set of sentences, while still measuring BLEU on the full tuning set. In this scenario, BO could spend more time querying values for the speed constraint (as they are cheaper to obtain) and less time querying the BLEU objective.

We use PESC as the acquisition function because it can easily handle decoupled constraints (Gelbart, 2015, Sec. 4.3). Effectively, we modify Algorithm 1 to update *either* the objective *or* the constraint posterior at each iteration, according to what is obtained by maximizing PESC at line 3. This kind of decoupling is not allowed by standard acquisition functions used in BO.

[2] Note that the objective posterior $p(f|\mathcal{D})$ does not depend on the constraint measurements, and the constraint posterior $p(c|\mathcal{D})$ does not depend on the objective measurements.

The decoupled scenario makes good use of heterogeneous computing resources. For example, we are interested in measuring decoding speed on a specific machine that will be deployed. But translating the tuning set to measure BLEU can be parallelized over whatever computing is available.

3 Speed Tuning Experiments

We report translation results in three language pairs, chosen for the different challenges they pose for SMT systems: Spanish-to-English, English-to-German and Chinese-to-English. For each language pair, we use generic parallel data extracted from the web. The data sizes are 1.7, 1.1 and 0.3 billion words, respectively.

For Spanish-to-English and English-to-German we use mixed-domain tuning/test sets, which have about 1K sentences each and were created to evenly represent different domains, including world news, health, sport, science and others. For Chinese-to-English we use in-domain sets (2K sentences) created by randomly extracting unique parallel sentences from in-house parallel text collections; this in-domain data leads to higher BLEU scores than in the other tasks, as will be reported later. In all cases we have one reference translation.

We use an in-house implementation of a phrase-based decoder with lexicalized reordering model (Galley and Manning, 2008). The system uses 21 features, whose weights are optimized for BLEU via MERT (Och and Ney, 2004) at very slow decoder parameter settings in order to minimize search errors in tuning. The feature weights remain fixed during the speed tuning process.

3.1 Decoder Parameters

We tune three standard decoder parameters $\theta = (d, s, n)$ that directly affect the translation speed. We describe them next.

d**:** distortion limit. The maximum number of source words that may be skipped by the decoder as it generates phrases left-to-right on the target side.

s**:** stack size. The maximum number of hypotheses allowed to survive histogram pruning in each decoding stack.

n**:** number of translations. The maximum number of alternative translations per source phrase considered in decoding.

3.2 Measuring Decoding Speed

To get a better understanding of the speed measurements we decode the English-German tuning set 100 times with a slow decoder parameter setting, *i.e.* $\theta = (5, 100, 100)$, and repeat for a fast setting with $\theta = (0, 1, 1)$. We collect speed measurements in number of translated words per minute (wpm)[3].

The plots in Figure 1 show histograms containing the measurements obtained for both slow and fast settings. While both fit in a Gaussian distribution, the speed ranges approximately from 750 to 950 wpm in the slow setting and from 90K to 120K wpm in the fast setting. This means that speed measurements exhibit heteroscedasticity: they follow Gaussian distributions with different variances that *depend on* the decoder parameter values. This is a problem for our BO setting because the GP we use to model the constraint assumes homoscedasticity, or constant noise over the support set Θ.

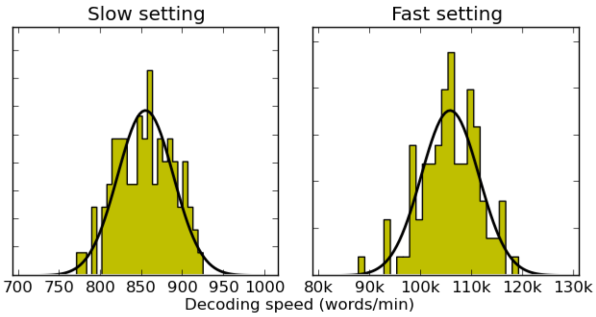

Figure 1: Histograms of speed measurements. The solid line shows a Gaussian fit with the empirical mean and variance. Note the difference in scale between the two settings, showing the heteroscedasticity.

A simple way to reduce the effect of heteroscedasticity is to take the logarithm of the speed measurements, which is also a standard practice when modeling non-negative measures in a GP (Gelbart et al., 2014). Table 1 shows the values for mean and standard deviation before and after the log transformation. Using the logarithm keeps the GP inference

[3] Measured on an Intel Xeon E5-2450 at 2.10GHz.

	Slow setting		Fast setting	
	Mean	Std	Mean	Std
speed	854.23	33.88	105.7k	5.6k
log speed	6.75	0.0398	11.57	0.0541

Table 1: Speed means and standard deviations in words per minute before and after the logarithmic transformation.

formulas tractable so we use this solution in our experiments.

3.3 BO Details and Baselines

All BO experiments use Spearmint (Snoek et al., 2012) with default values unless explicitly stated otherwise. We set the minimum and maximum values for d, s and n as $[0, 10]$, $[1, 500]$ and $[1, 100]$, respectively. We model d in linear scale but s and n in logarithmic scale for both BO and the baselines. This scaling is based on the intuition that optimal values for s and n will be in the lower interval values, which was confirmed in preliminary experiments on all three datasets.

We run two sets of experiments, using 2000wpm and 5000wpm as minimum speed constraints. In addition, we use the following BO settings:

Standard (BO-S): in this setting each BO iteration performs a full decoding of the tuning set in order to obtain both the BLEU score and the decoding speed jointly. We use $\delta = 0.01$ as the constraint tolerance described in Section 2.2.

Decoupled (BO-D): here we decouple the objective and the constraint as explained in Section 2.4. We still decode the full tuning set to get BLEU scores, but speed measurements are taken from a smaller subset of 50 sentences. Since speed measurements are faster in this case, we enforce BO to query for speed more often by modeling the task duration as described by Snoek et al. (2012). We use a higher constraint tolerance ($\delta = 0.05$), as we found that BO otherwise focused on the speed constraints at the expense of optimizing BLEU.

We compare these settings against two baselines: grid search and random search (Bergstra and Bengio, 2012). Grid search and random search seek parameter values in a similar way: a set of parameter values is provided; the decoder runs over the tuning set for all these values; the parameter value that yields the highest BLEU at a speed above the constraint is returned. For grid search, parameter values are chosen to cover the allowed value range in even splits given a budget of a permitted maximum number of decodings. For random search, parameters are chosen from a uniform distribution over the ranges specified above. BO-S, grid search and random search use a maximum budget of 125 decodings. BO-D is allowed a larger budget of 250 iterations, as the speed measurements can be done quickly. This is not a bias in favour of BO-D, as the overall objective is to find the best, fast decoder in as little CPU time as possible.

3.4 Results

Our results using the 2000wpm speed constraint are shown in Figure 2. The solid lines in the figure show the tuning set BLEU score obtained from the current best parameters θ, as suggested by BO-S, as a function of CPU time (in logarithmic scale). Given that $\delta = 0.01$, we have a 99% confidence under the GP model that the speed constraint is met.

Figure 2 also shows the best BLEU scores of fast systems found by grid and random search at increasing budgets of 8, 27, and 125 decodings of the tuning set[4]. These results are represented by squares/circles of different sizes in the plot: the larger the square/circle, the larger the budget. For grid and random search we report only the single highest BLEU score found amongst the sufficiently fast systems; the CPU times reported are the total time spent decoding the batch. For BO, the CPU times include both decoding time and the time spent evaluating the acquisition function for the next decoder parameters to evaluate (see Section 3.5).

In terms of CPU time, BO-S finds optimal parameters in less time than either grid search or random search. For example, in Spanish-to-English, BO-S takes ∼70 min (9 iterations) to achieve 36.6 BLEU score. Comparing to the baselines using a budget of 27 decodings, random search and grid search need ∼160 min and ∼6 hours, respectively, to achieve 36.5 BLEU. Note that, for a given budget, grid search proves always slower than random search because it always considers parameters val-

[4] For grid search, these correspond to 2, 3 and 5 possible values per parameter.

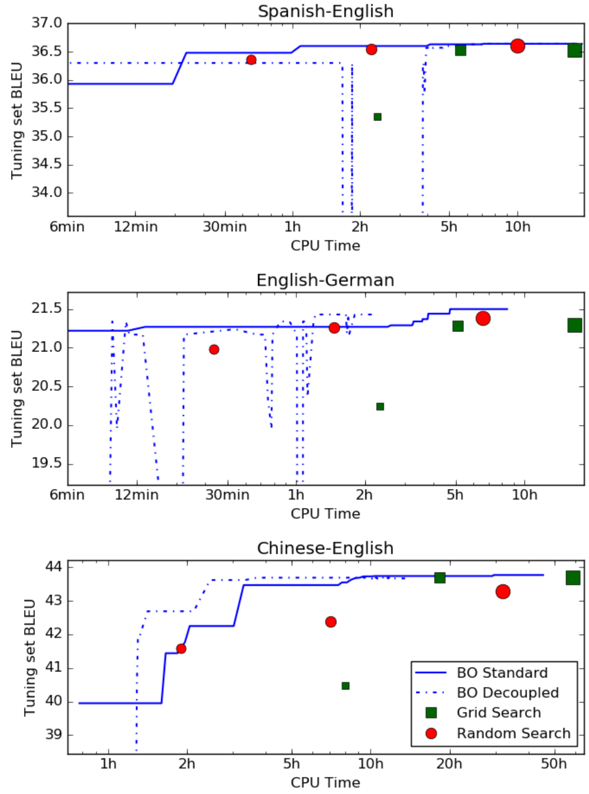

Figure 2: BLEU scores at 2000wpm. Squares and circles with increasing sizes correspond to searches with increasing evaluation budgets (8, 27, 125). For example: in Spanish-English, a random search with a budget of 125 evaluations required 10 CPU hours to run, and the highest BLEU score found among the sufficiently fast (>=2000wpm) systems was 36.2. For BO-D and BO-S, BLEU scores are plotted only if the speed is above 2000wpm and for BO-S only if the full dev set is decoded.

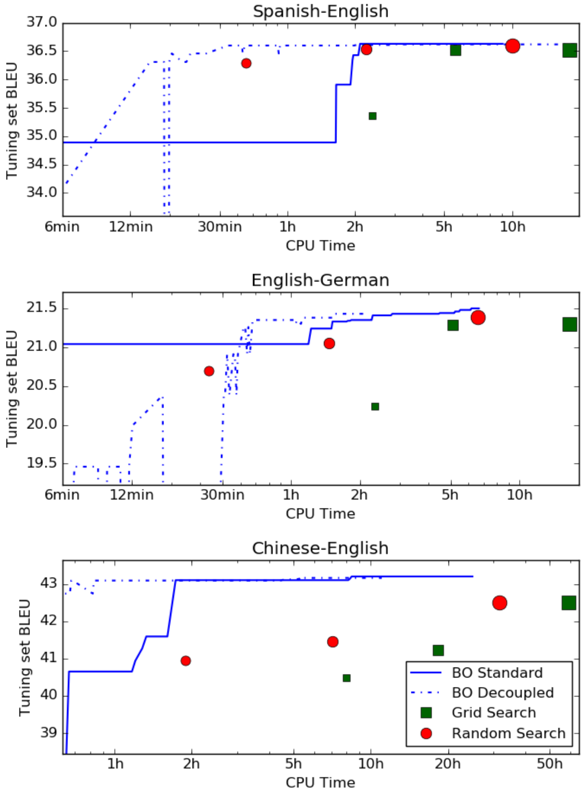

Figure 3: BLEU scores at 5000wpm. Squares and circles with increasing sizes correspond to baselines with increasing evaluation budgets (8, 27, 125).

ues at the high end of the ranges (which are the slowest decoding settings).

In terms of translation quality, we find that BO-S reaches the best BLEU scores across all language pairs, although all approaches eventually achieve similar scores, except in Chinese-to-English where random search is unable to match the BO-S BLEU score even after 125 decodings.

The dotted lines show the results obtained by the decoupled BO-D approach. BO-D does manage to find good BLEU scores, but it proceeds somewhat erratically. As the figure shows, BO-D spends a good deal of time testing systems at parameter values that are too slow. There are also negative excursions in the BLEU score, which we observed were due to updates of the posterior constraint model. For each new iteration, the confidence on the best parameter values may decrease, and if the confidence drops below $1 - \delta$, then BO suggests parameter values which are more likely to satisfy the speed constraint; this potentially hurts BLEU by decoding too fast. Interestingly, this instability is not seen on the Chinese-to-English pair. We speculate this is due to the larger tuning set for this language pair. Because the task time difference between BLEU and speed measurements is higher compared to the other language pairs, BO-D tends to query speed more in this case, resulting in a better posterior for the constraint.

Our results using the stricter 5000 wpm speed constraint are shown in Figure 3. As in the 2000wpm case, BO-S tends to find better parameter values faster than any of the baselines. One exception is found in Spanish-to-English after ∼40 min, when random search finds a better BLEU after 8 iterations when compared to BO-S. However, later BO-S catches up and finds parameters that yield the same score. In Chinese-to-English BO is able to find parameters that yield significantly better BLEU scores than any of the baselines. It appears that the harsher the speed constraint, the more difficult the optimization task, and the more chances BO will beat the baselines.

Interestingly, the decoupled BO-D approach is more stable than in the less strict 2000wpm case. After some initial oscillations in BLEU for English-to-German, BO-D curves climb to optimal parameters in much less CPU time than BO-S. This is clearly seen in Spanish-to-English and Chinese-to-English. We conclude that the harsher the speed constraint, the more benefit in allowing BO to query for speed separately from BLEU.

Tables 2 and 3 report the final parameters θ found by each method after spending the maximum allowed budget, and the BLEU and speed measured (average of 3 runs) when translating the tuning and test using θ. These show how different each language pair behaves when optimizing for speed and BLEU. For Spanish-to-English and English-to-German it is possible to find fast decoding configurations (well above 5K wpm) that nearly match the BLEU score of the slow system used for MERT tuning, *i.e.* $\theta_{MERT} = (10, 1000, 500)$. In contrast, significant degradation in BLEU is observed at 5000wpm for Chinese-to-English, a language pair with complicated reordering requirements – notice that all methods consistently keep a very high distortion limit for this language pair. However, both BO-S and BO-D strategies yield better performance on test (at least +0.5BLEU improvement) than the grid and random search baselines.

Only BO is able to find optimal parameters across all tasks faster. The optimum parameters yield similar performance on the tuning and test sets, allowing for the speed variations discussed in Section 3.2. All the optimization procedures guarantee that the constraint is always satisfied over the tuning set. However, this strict guarantee does not necessarily extend to other data in the same way that there might be variations in BLEU score. This can be seen in the Chinese-English experiments. Future work could focus on improving the generalization of the confidence over constraints.

	Tuning		Test		θ

3.5 BO Time Analysis

The complexity of GP-based BO is $O(n^3)$, n being the number of GP observations, or function evaluations (Rasmussen and Williams, 2006). As the objective function f is expected to be expensive, this

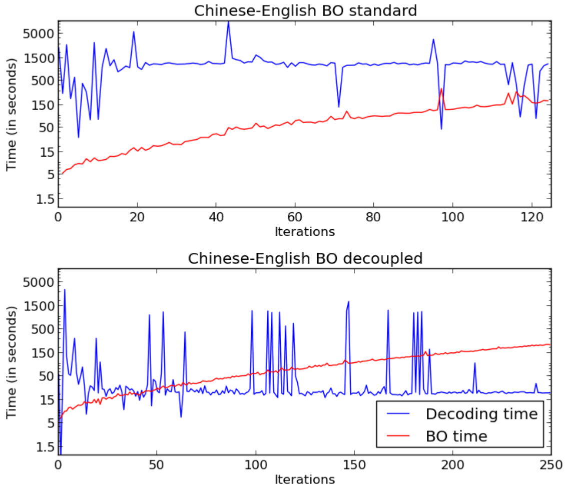

Figure 4: Time spent at each iteration in decoding and in BO (Chinese-to-English, 2000 wpm). BO-S (top), BO-D (bottom)

should not be an issue for low budgets. However, as the number of iterations grows there might reach a point at the time spent on the GP calculations surpasses the time spent evaluating the function.

This is investigated in Figure 4, where the time spent in decoding versus BO (in logarithmic scale) for Chinese-to-English using the 2K wpm constraint is reported, as a function of the optimization iteration. For BO-S (top), decoding time is generally constant but can peak upwards or downwards depending on the chosen parameters. For BO-D (bottom), most of the decoding runs are faster (when BO is querying for speed), and shoot up significantly only when the full tuning set is decoded (when BO is querying for BLEU). For both cases, BO time increases with the number of iterations, becoming nearly as expensive as decoding when a high maximum budget is considered. As shown in the previous section, this was no problem for our speed-tuning experiments because optimal parameters could be found with few iterations, but more complex settings (for example, with more decoder parameters) might require more iterations to find good solutions. For these cases the time spent in BO could be significant.

3.6 Reoptimizing Feature Weights

We have used BO to optimize decoder parameters for feature weights that had been tuned for BLEU using MERT. However, there is no reason to believe that the best feature weights for a slow setting are also the best weights at the fast settings we desire.

	Tuning		Test		θ		
	BLEU	speed	BLEU	speed	d	s	n
MERT	44.3	–	42.5	51	10	1K	500
BO-S	43.8	2.0K	41.9	1.9K	10	25	100
MERT-flat	43.8	2.0K	41.4	1.9K	10	25	100
MERT-opt	**44.3**	**2.0K**	**42.4**	**1.9K**	10	25	100

Table 4: Chinese-to-English results of re-running MERT using parameters that satisfy the 2K wpm speed constraint.

To assess this we now fix the decoder parameters θ and re-run MERT on Chinese-to-English with 2000 wpm using the fast settings found by BO-S: $\theta_{BO} = (10, 25, 100)$ in Table 2. We run MERT starting from flat weights (MERT-flat) and from the optimal weights (MERT-opt), previously tuned for the MERT baseline with θ_{MERT}. Table 4 reports the results.

We find that MERT-opt is able to recover from the BLEU drops observed during speed-constrained tuning and close the gap with the slow baseline (from 41.9 to 42.4 BLEU at 1.8 Kwpm, versus 42.5 for MERT at only 51wpm). Note that this performance is not achieved using MERT-flat, so rather than tune from flat parameters in a fixed fast setting, we conclude that it is better to: (1) use MERT to find feature weights in slow settings; (2) optimize decoder parameters for speed; (3) run MERT again with the fast decoder parameters from the feature weights found at the slow settings. As noted earlier, this may reduce the impact of search errors encountered in MERT when decoding at fast settings. However, this final application MERT is unconstrained and there is no guarantee that it will yield a decoder configuration that satisfies the constraints. This must be verified through subsequent testing.

Ideally, one should *jointly* optimize decoder parameters, feature weights and all decisions involved in building an SMT system, but this can be very challenging to do using only BO. We note anecdotally that we have attempted to replicate the feature weight tuning procedure of Miao et al. (2014) but obtained mixed results on our test sets. Effective ways to combine BO with well-established feature tuning algorithms such as MERT could be a promising research direction.

4 Related Work

Bayesian Optimization has been previously used for hyperparameter optimization in machine learning systems (Snoek et al., 2012; Bergstra et al., 2011), automatic algorithm configuration (Hutter et al., 2011) and for applications in which system tuning involves human feedback (Brochu et al., 2010a). Recently, it has also been used successfully in several NLP applications. Wang et al. (2015) use BO to tune sentiment analysis and question answering systems. They introduce a multi-stage approach where hyperparameters are optimized using small datasets and then used as starting points for subsequent BO stages using increasing amounts of data. Yogatama et al. (2015) employ BO to optimize text representations in a set of classification tasks. They find that there is no representation that is optimal for all tasks, which further justifies an automatic tuning approach. Wang et al. (2014) use a model based on optimistic optimization to tune parameters of a term extraction system. In SMT, Miao et al. (2014) use BO for feature weight tuning and report better results in some language pairs when compared to traditional tuning algorithms.

Our approach is heavily based on the work of Gelbart et al. (2014) and Hernández-Lobato et al. (2015) which uses BO in the presence of unknown constraints. They set speed and memory constraints on neural network trainings and report better results compared to those of naive models which explicitly put high costs on regions that violate constraints. A different approach based on augmented Lagrangians is proposed by Gramacy et al. (2014). The authors apply BO in a water decontamination setting where the goal is to find the optimal pump positioning subject to restrictions on water and contaminant flows. All these previous work in constrained BO use GPs as the prior model.

Optimizing decoding parameters for speed is an understudied problem in the MT literature. Chung and Galley (2012) propose direct search methods to optimize feature weights and decoder parameters jointly but aiming at the traditional goal of maximizing translation quality. To enable search parameter optimization they enforce a deterministic time penalty on BLEU scores, which is not ideal due to the stochastic nature of time measurements shown on Section 3.2 (this issue is also cited by the authors in their manuscript). It would be interesting to incorporate their approach into BO for optimizing translation quality under speed constraints.

5 Conclusion

We have shown that Bayesian Optimisation performs well for translation speed tuning experiments and is particularly suited for low budgets and for tight constraints. There is much room for improvement. For better modeling of the speed constraint and possibly better generalization in speed measurements across tuning and test sets, one possibility would be to use randomized sets of sentences. Warped GPs (Snelson et al., 2003) could be a more accurate model as they can learn transformations for heteroscedastic data without relying on a fixed transformation, as we do with log speed measurements.

Modelling of the objective function could also be improved. In our experiments we used a GP with a Matèrn52 kernel, but this assumes f is doubly-differentiable and exhibits Lipschitz-continuity (Brochu et al., 2010b). Since that does not hold for the BLEU score, using alternative smoother metrics such as linear corpus BLEU (Tromble et al., 2008) or expected BLEU (Rosti et al., 2010) could yield better results. Other recent developments in Bayesian Optimisation could be applied to our settings, like multi-task optimization (Swersky et al., 2013) or freeze-thaw optimization (Swersky et al., 2014).

In our application we treat Bayesian Optimisation as a sequential model. Parallel approaches do exist (Snoek et al., 2012; González et al., 2015), but we find it easy enough to harness parallel computation in decoding tuning sets and by decoupling BLEU measurements from speed measurements. However for more complex optimisation scenarios or for problems that require lengthy searches, parallelization might be needed to keep the computations required for optimisation in line with what is needed to measure translation speed and quality.

Abstract

We propose multi-way, multilingual neural machine translation. The proposed approach enables a single neural translation model to translate between multiple languages, with a number of parameters that grows only linearly with the number of languages. This is made possible by having a single attention mechanism that is shared across all language pairs. We train the proposed multi-way, multilingual model on ten language pairs from WMT'15 simultaneously and observe clear performance improvements over models trained on only one language pair. In particular, we observe that the proposed model significantly improves the translation quality of low-resource language pairs.

1 Introduction

Neural Machine Translation It has been shown that a deep (recurrent) neural network can successfully learn a complex mapping between variable-length input and output sequences on its own. Some of the earlier successes in this task have, for instance, been handwriting recognition (Bottou et al., 1997; Graves et al., 2009) and speech recognition (Graves et al., 2006; Chorowski et al., 2015). More recently, a general framework of encoder-decoder networks has been found to be effective at learning this kind of sequence-to-sequence mapping by using two recurrent neural networks (Cho et al., 2014b; Sutskever et al., 2014).

A basic encoder-decoder network consists of two recurrent networks. The first network, called an encoder, maps an input sequence of variable length into a point in a continuous vector space, resulting in a fixed-dimensional context vector. The other recurrent neural network, called a decoder, then generates a target sequence again of variable length starting from the context vector. This approach however has been found to be inefficient in (Cho et al., 2014a) when handling long sentences, due to the difficulty in learning a complex mapping between an arbitrary long sentence and a single fixed-dimensional vector.

In (Bahdanau et al., 2014), a remedy to this issue was proposed by incorporating an *attention mechanism* to the basic encoder-decoder network. The attention mechanism in the encoder-decoder network frees the network from having to map a sequence of arbitrary length to a single, fixed-dimensional vector. Since this attention mechanism was introduced to the encoder-decoder network for machine translation, neural machine translation, which is purely based on neural networks to perform full end-to-end translation, has become competitive with the existing phrase-based statistical machine translation in many language pairs (Jean et al., 2015; Gulcehre et al., 2015; Luong et al., 2015b).

Multilingual Neural Machine Translation Existing machine translation systems, mostly based on a phrase-based system or its variants, work by directly mapping a symbol or a subsequence of symbols in a source language to its corresponding symbol or subsequence in a target language. This kind of mapping is strictly specific to a given language *pair*, and it is not trivial to extend this mapping to work on multiple pairs of languages.

A system based on neural machine translation, on the other hand, can be decomposed into two mod-

Proceedings of NAACL-HLT 2016, pages 866–875,
San Diego, California, June 12-17, 2016.

ules. The encoder maps a source sentence into a continuous representation, either a fixed-dimensional vector in the case of the basic encoder-decoder network or a set of vectors in the case of attention-based encoder-decoder network. The decoder then generates a target translation based on this source representation. This makes it possible conceptually to build a system that maps a source sentence in any language to a common continuous representation space and decodes the representation into any of the target languages, allowing us to make a *multilingual machine translation* system.

This possibility is straightforward to implement and has been validated in the case of basic encoder-decoder networks (Luong et al., 2015a). It is however not so, in the case of the attention-based encoder-decoder network, as the attention mechanism, or originally called the alignment function in (Bahdanau et al., 2014), is conceptually language pair-specific. In (Dong et al., 2015), the authors cleverly avoided this issue of language pair-specific attention mechanism by considering only a one-to-many translation, where each target language decoder embedded its own attention mechanism. Also, we notice that both of these works have only evaluated their models on relatively small-scale tasks, making it difficult to assess whether multilingual neural machine translation can scale beyond low-resource language translation.

Multi-Way, Multilingual Neural Machine Translation In this paper, we first step back from the currently available multilingual neural translation systems proposed in (Luong et al., 2015a; Dong et al., 2015) and ask the question of whether the attention mechanism can be shared across multiple language pairs. As an answer to this question, we propose an attention-based encoder-decoder network that admits a shared attention mechanism with multiple encoders and decoders. We use this model for all the experiments, which suggests that it is indeed possible to share an attention mechanism across multiple language pairs.

The next question we ask is the following: in which scenario would the proposed multi-way, multilingual neural translation have an advantage over the existing, single-pair model? Specifically, we consider a case of the translation between a low-resource language pair. The experiments show that the proposed multi-way, multilingual model generalizes better than the single-pair translation model, when the amount of available parallel corpus is small. Furthermore, we validate that this is not only due to the increased amount of target-side, monolingual corpus.

Finally, we train a single model with the proposed architecture on all the language pairs from the WMT'15; English, French, Czech, German, Russian and Finnish. The experiments show that it is indeed possible to train a single attention-based network to perform multi-way translation.

2 Background: Attention-based Neural Machine Translation

The attention-based neural machine translation was proposed in (Bahdanau et al., 2014). It was motivated from the observation in (Cho et al., 2014a) that a basic encoder-decoder translation model from (Cho et al., 2014b; Sutskever et al., 2014) suffers from translating a long source sentence efficiently. This is largely due to the fact that the encoder of this basic approach needs to compress a whole source sentence into a single vector. Here we describe the attention-based neural machine translation.

Neural machine translation aims at building a single neural network that takes as input a source sequence $X = (x_1, \dots, x_{T_x})$ and generates a corresponding translation $Y = \left(y_1, \dots, y_{T_y}\right)$. Each symbol in both source and target sentences, x_t or y_t, is an integer index of the symbol in a vocabulary.

The encoder of the attention-based model encodes a source sentence into a set of context vectors $C = \{\mathbf{h}_1, \mathbf{h}_2, \dots, \mathbf{h}_{T_x}\}$, whose size varies w.r.t. the length of the source sentence. This context set is constructed by a bidirectional recurrent neural network (RNN) which consists of a forward RNN and reverse RNN. The forward RNN reads the source sentence from the first token until the last one, resulting in the forward context vectors $\left\{\overrightarrow{\mathbf{h}}_1, \dots, \overrightarrow{\mathbf{h}}_{T_x}\right\}$, where

$$\overrightarrow{\mathbf{h}}_t = \overrightarrow{\Psi}_{\text{enc}}\left(\overrightarrow{\mathbf{h}}_{t-1}, \mathbf{E}_x\left[x_t\right]\right),$$

and $\mathbf{E}_x \in \mathbb{R}^{|V_x| \times d}$ is an embedding matrix containing row vectors of the source symbols. The reverse RNN in an opposite direction, resulting in $\left\{\overleftarrow{\mathbf{h}}_1, \ldots, \overleftarrow{\mathbf{h}}_{T_x}\right\}$, where

$$\overleftarrow{\mathbf{h}}_t = \overleftarrow{\Psi}_{\text{enc}}\left(\overleftarrow{\mathbf{h}}_{t+1}, \mathbf{E}_x\left[x_t\right]\right).$$

$\overrightarrow{\Psi}_{\text{enc}}$ and $\overleftarrow{\Psi}_{\text{enc}}$ are recurrent activation functions such as long short-term memory units (LSTM, (Hochreiter and Schmidhuber, 1997)) or gated recurrent units (GRU, (Cho et al., 2014b)). At each position in the source sentence, the forward and reverse context vectors are concatenated to form a full context vector, i.e.,

$$\mathbf{h}_t = \left[\overrightarrow{\mathbf{h}}_t; \overleftarrow{\mathbf{h}}_t\right]. \tag{1}$$

The decoder, which is implemented as an RNN as well, generates one symbol at a time, the translation of the source sentence, based on the context set returned by the encoder. At each time step t in the decoder, a time-dependent context vector $\mathbf{c}_t$ is computed based on the previous hidden state of the decoder $\mathbf{z}_{t-1}$, the previously decoded symbol $\tilde{y}_{t-1}$ and the whole context set C.

This starts by computing the relevance score of each context vector as

$$e_{t,i} = f_{\text{score}}(\mathbf{h}_i, \mathbf{z}_{t-1}, \mathbf{E}_y\left[\tilde{y}_{t-1}\right]), \tag{2}$$

for all $i = 1, \ldots, T_x$. f$_{\text{score}}$ can be implemented in various ways (Luong et al., 2015b), but in this work, we use a simple single-layer feedforward network. This relevance score measures how relevant the i-th context vector of the source sentence is in deciding the next symbol in the translation. These relevance scores are further normalized:

$$\alpha_{t,i} = \frac{\exp(e_{t,i})}{\sum_{j=1}^{T_x}\exp(e_{t,j})}, \tag{3}$$

and we call $\alpha_{t,i}$ the attention weight.

The time-dependent context vector $\mathbf{c}_t$ is then the weighted sum of the context vectors with their weights being the attention weights from above:

$$\mathbf{c}_t = \sum_{i=1}^{T_x} \alpha_{t,i}\mathbf{h}_i. \tag{4}$$

With this time-dependent context vector $\mathbf{c}_t$, the previous hidden state $\mathbf{z}_{t-1}$ and the previously decoded symbol $\tilde{y}_{t-1}$, the decoder's hidden state is updated by

$$\mathbf{z}_t = \Psi_{\text{dec}}\left(\mathbf{z}_{t-1}, \mathbf{E}_y\left[\tilde{y}_{t-1}\right], \mathbf{c}_t\right), \tag{5}$$

where Ψ_{dec} is a recurrent activation function.

The initial hidden state $\mathbf{z}_0$ of the decoder is initialized based on the last hidden state of the reverse RNN:

$$\mathbf{z}_0 = f_{\text{init}}\left(\overleftarrow{\mathbf{h}}_{T_x}\right), \tag{6}$$

where f_{init} is a feedforward network with one or two hidden layers.

The probability distribution for the next target symbol is computed by

$$p(y_t = k|\tilde{y}_{<t}, X) \propto e^{g_k(\mathbf{z}_t, \mathbf{c}_t, \mathbf{E}[\tilde{y}_{t-1}])}, \tag{7}$$

where g_k is a parametric function that returns the unnormalized probability for the next target symbol being k.

Training this attention-based model is done by maximizing the conditional log-likelihood

$$\mathcal{L}(\boldsymbol{\theta}) = \frac{1}{N}\sum_{n=1}^{N}\sum_{t=1}^{T_y}\log p(y_t = y_t^{(n)}|y_{<t}^{(n)}, X^{(n)}), \tag{8}$$

where the log probability inside the inner summation is from Eq. (7). It is important to note that the ground-truth target symbols $y_t^{(n)}$ are used during training. The entire model is differentiable, and the gradient of the log-likelihood function with respect to all the parameters $\boldsymbol{\theta}$ can be computed efficiently by backpropagation. This makes it straightforward to use stochastic gradient descent or its variants to train the whole model jointly to maximize the translation performance.

3 Multi-Way, Multilingual Translation

In this section, we discuss issues and our solutions in extending the conventional *single-pair* attention-based neural machine translation into *multi-way, multilingual* model.

Problem Definition We assume $N > 1$ source languages $\left\{X^1, X^2, \ldots, X^N\right\}$ and $M > 1$ target languages $\left\{Y^1, Y^2, \ldots, Y^M\right\}$, and the availability of $L \leq M \times N$ *bilingual* parallel corpora $\{D_1, \ldots, D_L\}$, each of which is a set of sentence pairs of one source and one target language. We use $s(D_l)$ and $t(D_l)$ to indicate the source and target languages of the l-th parallel corpus.

For each parallel corpus l, we can directly use the log-likelihood function from Eq. (8) to define a pair-specific log-likelihood $\mathcal{L}^{s(D_l),t(D_l)}$. Then, the goal of multi-way, multilingual neural machine translation is to build a model that maximizes the joint log-likelihood function $\mathcal{L}(\boldsymbol{\theta}) = \frac{1}{L}\sum_{l=1}^{L}\mathcal{L}^{s(D_l),t(D_l)}(\boldsymbol{\theta})$. Once the training is over, the model can do translation from any of the source languages to any of the target languages included in the parallel training corpora.

3.1 Existing Approaches

Neural Machine Translation without Attention In (Luong et al., 2015a), the authors extended the basic encoder-decoder network for multitask neural machine translation. As they extended the basic encoder-decoder network, their model effectively becomes a set of encoders and decoders, where each of the encoder projects a source sentence into a common vector space. The point in the common space is then decoded into different languages.

The major difference between (Luong et al., 2015a) and our work is that we extend the attention-based encoder-decoder instead of the basic model. This is an important contribution, as the attention-based neural machine translation has become *de facto* standard in neural translation literatures recently (Jean et al., 2014; Jean et al., 2015; Luong et al., 2015b; Sennrich et al., 2015b; Sennrich et al., 2015a), by opposition to the basic encoder-decoder.

There are two minor differences as well. First, they do not consider multilinguality in depth. The authors of (Luong et al., 2015a) tried only a single language pair, English and German, in their model. Second, they only report translation perplexity, which is not a widely used metric for measuring translation quality. To more easily compare with other machine translation approaches it would be important to evaluate metrics such as BLEU, which counts the number of matched n-grams between the generated and reference translations.

One-to-Many Neural Machine Translation The authors of (Dong et al., 2015) earlier proposed a multilingual translation model based on the *attention-based neural machine translation*. Unlike this paper, they only tried it on one-to-many translation, similarly to earlier work by (Collobert et al., 2011) where one-to-many natural language processing was done. In this setting, it is trivial to extend the single-pair attention-based model into multilingual translation by simply having a single encoder for a source language and pairs of a decoder and attention mechanism (Eq. (2)) for each target language. We will shortly discuss more on why, with the attention mechanism, one-to-many translation is trivial, while multi-way translation is not.

3.2 Challenges

A quick look at neural machine translation seems to suggest a straightforward path toward incorporating multiple languages in both source and target sides. As described earlier already in the introduction, the basic idea is simple. We assign a separate encoder to each source language and a separate decoder to each target language. The encoder will project a source sentence in its own language into a common, language-agnostic space, from which the decoder will generate a translation in its own language.

Unlike training multiple single-pair neural translation models, in this case, the encoders and decoders are shared across multiple pairs. This is computationally beneficial, as the number of parameters grows only linearly with respect to the number of languages ($O(L)$), in contrary to training separate single-pair models, in which case the number of parameters grows quadratically ($O(L^2)$.)

The attention mechanism, which was initially called a soft-alignment model in (Bahdanau et al., 2014), aligns a (potentially non-contiguous) source phrase to a target word. This alignment process is largely specific to a language pair, and it is not clear whether an alignment mechanism for one language pair can also work for another pair.

The most naive solution to this issue is to have $O(L^2)$ attention mechanisms that are *not* shared across multiple language pairs. Each attention mechanism takes care of a single pair of source and

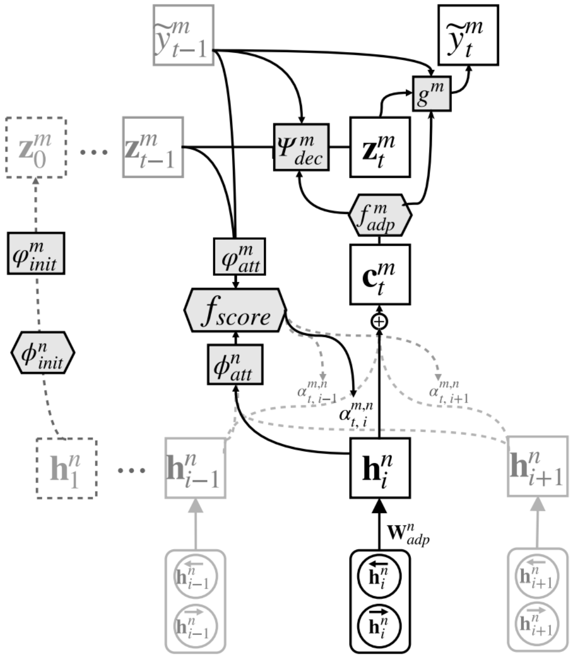

Figure 1: One step of the proposed multi-way. multilingual Neural Machine Translation model, for the n-th encoder and the m-th decoder at time step t. Shaded boxes are parametric functions and square boxes represent intermediate variables of the model. Initializer network is also illustrated as the left-most network with dashed boxes. Notice, all the shared components are drawn with diamond boxes. See Sec. 4 for details.

target languages. This is the approach employed in (Dong et al., 2015), where each decoder had its own attention mechanism.

There are two issues with this naive approach. First, unlike what has been hoped initially with multilingual neural machine translation, the number of parameters again grows quadratically w.r.t. the number of languages. Second and more importantly, having separate attention mechanisms makes it less likely for the model to fully benefit from having multiple tasks (Caruana, 1997), especially for transfer learning towards resource-poor languages.

In short, the major challenge in building a multi-way, multilingual neural machine translation is in avoiding independent (i.e., quadratically many) attention mechanisms. There are two questions behind this challenge. The first one is whether it is even possible to share a single attention mechanism across multiple language pairs. The second question immediately follows: how can we build a neural translation model to share a single attention mechanism for all the language pairs in consideration?

4 Multi-Way, Multilingual Model

We describe in this section, the proposed *multi-way, multilingual attention-based neural machine translation*. The proposed model consists of N encoders $\{\Psi^n_{\text{enc}}\}^N_{n=1}$ (see Eq. (1)), M decoders $\{(\Psi^m_{\text{dec}}, g^m, f^m_{\text{init}})\}^M_{m=1}$ (see Eqs. (5)–(7)) and a shared attention mechanism f_{score} (see Eq. (2) in the single language pair case).

Encoders Similarly to (Luong et al., 2015b), we have one encoder per source language, meaning that a single encoder is shared for translating the language to multiple target languages. In order to handle different source languages better, we may use for each source language a different type of encoder, for instance, of different size (in terms of the number of recurrent units) or of different architecture (convolutional instead of recurrent.)[1] This allows us to efficiently incorporate varying types of languages in the proposed multilingual translation model.

This however implies that the dimensionality of the context vectors in Eq. (1) may differ across source languages. Therefore, we add to the original bidirectional encoder from Sec. 2, a linear transformation layer consisting of a weight matrix $\mathbf{W}^n_{\text{adp}}$ and a bias vector $\mathbf{b}^n_{\text{adp}}$, which is used to project each context vector into a common dimensional space:

$$\mathbf{h}^n_t = \mathbf{W}^n_{\text{adp}}\left[\overrightarrow{\mathbf{h}}_t; \overleftarrow{\mathbf{h}}_t\right] + \mathbf{b}^n_{\text{adp}}, \tag{9}$$

where $\mathbf{W}^n_{\text{adp}} \in \mathbb{R}^{d\times(\dim \overrightarrow{\mathbf{h}}_t + \dim \overleftarrow{\mathbf{h}}_t)}$ and $\mathbf{b}^n_{\text{adp}} \in \mathbb{R}^d$.

In addition, each encoder exposes two transformation functions ϕ^n_{att} and ϕ^n_{init}. The first transformer ϕ^n_{att} transforms a context vector to be compatible with a shared attention mechanism:

$$\tilde{\mathbf{h}}^n_t = \phi^n_{\text{att}}(\mathbf{h}^n_t). \tag{10}$$

This transformer can be implemented as any type of parametric function, and in this paper, we simply apply an element-wise $\tanh$ to $\mathbf{h}^n_t$.

[1] For the pairs without enough parallel data, one may also consider using smaller encoders to prevent over-fitting.

The second transformer ϕ^n_{init} transforms the first context vector $\mathbf{h}^n_1$ to be compatible with the initializer of the decoder's hidden state (see Eq. (6)):

$$\hat{\mathbf{h}}^n_1 = \phi^n_{\text{init}}(\mathbf{h}^n_1). \tag{11}$$

Similarly to ϕ^n_{att}, it can be implemented as any type of parametric function. In this paper, we use a feedforward network with a single hidden layer and share one network ϕ_{init} for all encoder-decoder pairs.

Decoders We first start with an initialization of the decoder's hidden state. Each decoder has its own parametric function φ^m_{init} that maps the last context vector $\hat{\mathbf{h}}^n_{T_x}$ of the source encoder from Eq. (11) into the initial hidden state:

$$\mathbf{z}^m_0 = \varphi^m_{\text{init}}(\hat{\mathbf{h}}^n_{T_x}) = \varphi^m_{\text{init}}(\phi^n_{\text{init}}(\mathbf{h}^n_1))$$

φ^m_{init} can be any parametric function, and in this paper, we used a feedforward network with a single $\tanh$ hidden layer.

Each decoder exposes a parametric function φ^m_{att} that transforms its hidden state and the previously decoded symbol to be compatible with a shared attention mechanism. This transformer is a parametric function that takes as input the previous hidden state $\mathbf{z}^m_{t-1}$ and the previous symbol $\tilde{y}^m_{t-1}$ and returns a vector for the attention mechanism:

$$\tilde{\mathbf{z}}^m_{t-1} = \varphi^m_{\text{att}}\left(\mathbf{z}^m_{t-1}, \mathbf{E}^m_y\left[\tilde{y}^m_{t-1}\right]\right) \tag{12}$$

which replaces $\mathbf{z}_{t-1}$ in Eq. 2. In this paper, we use a feedforward network with a single $\tanh$ hidden layer for each φ^m_{att}.

Given the previous hidden state $\mathbf{z}^m_{t-1}$, previously decoded symbol $\tilde{y}^m_{t-1}$ and the time-dependent context vector $\mathbf{c}^m_t$, which we will discuss shortly, the decoder updates its hidden state:

$$\mathbf{z}_t = \Psi_{\text{dec}}\left(\mathbf{z}^m_{t-1}, \mathbf{E}^m_y\left[\tilde{y}^m_{t-1}\right], f^m_{\text{adp}}(\mathbf{c}^m_t)\right),$$

where f^m_{adp} affine-transforms the time-dependent context vector to be of the same dimensionality as the decoder. We share a single affine-transformation layer f^m_{adp}, for all the decoders in this paper.

Once the hidden state is updated, the probability distribution over the next symbol is computed exactly as for the pair-specific model (see Eq. (7).)

	# Symbols		# Sentence
	# En	Other	Pairs
En-Fr	1.022b	2.213b	38.85m
En-Cs	186.57m	185.58m	12.12m
En-Ru	50.62m	55.76m	2.32m
En-De	111.77m	117.41m	4.15m
En-Fi	52.76m	43.67m	2.03m

Table 1: Statistics of the parallel corpora from WMT'15. Symbols are BPE-based sub-words.

Attention Mechanism Unlike the encoders and decoders of which there is an instance for each language, there is only a single attention mechanism, shared across all the language pairs. This shared mechanism uses the *attention-specific* vectors $\tilde{\mathbf{h}}^n_t$ and $\tilde{\mathbf{z}}^m_{t-1}$ from the encoder and decoder, respectively.

The relevance score of each context vector $\mathbf{h}^n_t$ is computed based on the decoder's previous hidden state $\mathbf{z}^m_{t-1}$ and previous symbol $\tilde{y}^m_{t-1}$:

$$e^{m,n}_{t,i} = f_{\text{score}}\left(\tilde{\mathbf{h}}^n_t, \tilde{\mathbf{z}}^m_{t-1}, \tilde{y}^m_{t-1}\right)$$

These scores are normalized according to Eq. (3) to become the attention weights $\alpha^{m,n}_{t,i}$.

With these attention weights, the time-dependent context vector is computed as the weighted sum of the *original* context vectors: $\mathbf{c}^{m,n}_t = \sum_{i=1}^{T_x} \alpha^{m,n}_{t,i} \mathbf{h}^n_i$.

See Fig. 1 for the illustration.

5 Experiment Settings

5.1 Datasets

We evaluate the proposed multi-way, multilingual translation model on all the pairs available from WMT'15–English (En) ↔ French (Fr), Czech (Cs), German (De), Russian (Ru) and Finnish (Fi)–, totalling ten directed pairs. For each pair, we concatenate all the available parallel corpora from WMT'15 and use it as a training set. We use newstest-2013 as a development set and newstest-2015 as a test set, in all the pairs other than Fi-En. In the case of Fi-En, we use newsdev-2015 and newstest-2015 as a development set and test set, respectively.

Data Preprocessing Each training corpus is tokenized using the tokenizer script from the Moses decoder.[2] The tokenized training corpus is cleaned fol-

[2] `https://github.com/moses-smt/mosesdecoder/blob/master/scripts/tokenizer/tokenizer.perl`

lowing the procedure in (Jean et al., 2015). Instead of using space-separated tokens, or words, we use sub-word units extracted by byte pair encoding, as recently proposed in (Sennrich et al., 2015b). For each and every language, we include 30k sub-word symbols in a vocabulary. See Table 1 for the statistics of the final, preprocessed training corpora.

Evaluation Metric We mainly use BLEU as an evaluation metric using the multi-bleu script from Moses.[3] BLEU is computed on the tokenized text after merging the BPE-based sub-word symbols. We further look at the average log-probability assigned to reference translations by the trained model as an additional evaluation metric, as a way to measure the model's density estimation performance free from any error caused by approximate decoding.

5.2 Two Scenarios

Low-Resource Translation First, we investigate the effect of the proposed multi-way, multilingual model on low-resource language-pair translation. Among the six languages from WMT'15, we choose En, De and Fi as source languages, and En and De as target languages. We control the amount of the parallel corpus of each pair out of three to be 5%, 10%, 20% and 40% of the original corpus. In other words, we train four models with different sizes of parallel corpus for each language pair (En-De, De-En, Fi-En.)

As a baseline, we train a single-pair model for each multi-way, multilingual model. We further finetune the single-pair model to incorporate the target-side monolingual corpus consisting of all the target side text from the other language pairs (e.g., when a single-pair model was trained on Fi-En, the target-side monolingual corpus consists of the target sides from De-En.) This is done by the recently proposed deep fusion (Gulcehre et al., 2015). The latter is included to tell whether any improvement from the multilingual model is simply due to the increased amount of target-side monolingual corpus.

Large-scale Translation We train one multi-way, multilingual model that has six encoders and six decoders, corresponding to the six languages from WMT'15; En, Fr, De, Cs, Ru, Fi → En, Fr, De, Cs, Ru, Fi. We use the full corpora for all of them.

	Size	Single	Single+DF	Multi

Table 2: BLEU scores where the target pair's parallel corpus is constrained to be 5%, 10%, 20% and 40% of the original size. We report the BLEU scores on the development and test sets (separated by /) by the single-pair model (Single), the single-pair model with monolingual corpus (Single+DF) and the proposed multi-way, multilingual model (Multi).

5.3 Model Architecture

Each symbol, either source or target, is projected on a 620-dimensional space. The encoder is a bidirectional recurrent neural network with 1,000 gated recurrent units (GRU) in each direction, and the decoder is a recurrent neural network with also 1,000 GRU's. The decoder's output function g_k from Eq. (7) is a feedforward network with 1,000 $\tanh$ hidden units. The dimensionalities of the context vector $\mathbf{h}_t^n$ in Eq. (9), the attention-specific context vector $\tilde{\mathbf{h}}_t^n$ in Eq. (10) and the attention-specific decoder hidden state $\tilde{\mathbf{h}}_{t-1}^m$ in Eq. (12) are all set to 1,200.

We use the same type of encoder for every source language, and the same type of decoder for every target language. The only difference between the single-pair models and the proposed multilingual ones is the numbers of encoders N and decoders M. We leave those multilingual translation specific components, such as the ones in Eqs. (9)–(12), in the single-pair models in order to keep the number of shared parameters constant.

5.4 Training

Basic Settings We train each model using stochastic gradient descent (SGD) with Adam (Kingma and

Table 3: (a) BLEU scores and (b) average log-probabilities for all the five languages from WMT'15.

Ba, 2015) as an adaptive learning rate algorithm. We use the initial learning rate of $2 \cdot 10^{-4}$ and leave all the other hyperparameters as suggested in (Kingma and Ba, 2015). Each SGD update is computed using a minibatch of 80 examples, unless the model is parallelized over two GPUs, in which case we use a minibatch of 60 examples. We only use sentences of length up to 50 symbols during training. We clip the norm of the gradient to be no more than 1 (Pascanu et al., 2012). All training runs are early-stopped based on BLEU on the development set. As we observed in preliminary experiments better scores on the development set when finetuning the shared parameters and output layers of the decoders in the case of multilingual models, we do this for all the multilingual models. During finetuning, we clip the norm of the gradient to be no more than 5. [4]

Schedule As we have access only to bilingual corpora, each sentence pair updates only a subset of the parameters. Excessive updates based on a single language pair may bias the model away from the other pairs. To avoid it, we cycle through all the language pairs, one pair at a time, in Fi⇆En, De⇆En, Fr⇆En, Cs⇆En, Ru⇆En order. [5] Initial experiments on random scheduling across pairs and increasing the number of consecutive updates for a pair did not give better results and left as a future work.

Model Parallelism The size of the multilingual model grows linearly w.r.t. the number of languages. We observed that a single model that handles six source and six target languages does not fit in a single GPU[6] during training. We address this by distributing computational paths according to different translation pairs over multiple GPUs, following (Ding et al., 2014). The shared parameters, mainly related to the attention mechanism, is duplicated on both GPUs.

In more detail, we distribute language pairs across multiple GPUs such that those pairs in each GPU shares either an encoder or decoder. This allows us to avoid synchronizing a large subset of the parameters across multiple GPUs. Only the shared attention mechanism, which has substantially less parameters, is duplicated on all the GPUs. Before each update, we build a minibatch to contain an approximately equal number of examples per GPU in order to minimize any discrepancy in computation among multiple GPUs. Each GPU then computes the gradient w.r.t. the parameters on its own board and updates the local parameters. The gradients w.r.t. the attention mechanism are synchronized using direct memory access (DMA). In this way, we achieve near-linear speed-up.

6 Results and Analysis

Low-Resource Translation It is clear from Table 2 that the proposed model (Multi) outperforms the single-pair one (Single) in all the cases. This is true even when the single-pair model is strengthened with a target-side monolingual corpus (Single+DF). This suggests that the benefit of generalization from having multiple languages goes beyond that of simply having more target-side monolingual corpus. The performance gap grows as the size of target parallel corpus decreases.

[4] All the training details as well as the code is available at `http://github.com/nyu-dl/dl4mt-multi`.

[5] ⇆ indicates simultaneous updates on two GPUs.

[6] NVidia Titan X with 12GB on-board memory

Further, directly adding monolingual data from all languages during training, e.g. like an auto-encoder, En→ En, De→ De etc. is straightforward. In fact, experiments based on the autoencoder reconstruction criterion resulted in rapid memorization, copying source tokens without capturing semantics, resulting in worse performance. Exploring ways to leverage unlabeled data and regularizing the monolingual paths in the multi-way, multilingual architecture, is therefore left as a future work.

Large-Scale Translation In Table 3, we observe that the proposed multilingual model outperforms or is comparable to the single-pair models for the majority of the all ten pairs/directions considered. This happens in terms of both BLEU and average log-probability. This is encouraging, considering that there are twice more parameters in the whole set of single-pair models than in the multilingual model.

Note that, the numbers are below state-of-the-art neural MT systems, which use large vocabularies, unknown replacements techniques and ensembling. We mainly focused on comparing the proposed model against single-pair models without these techniques in order to carefully control and analyze the effect of having multiple languages. It is indeed required in the future to analyze the consequence of having both multiple languages and other such techniques in a single model.

It is worthwhile to notice that the benefit is more apparent when the model translates from a foreign language to English. This may be due to the fact that all of the parallel corpora include English as either a source or target language, leading to a better parameter estimation of the English decoder. In the future, a strategy of using a pseudo-parallel corpus to increase the amount of training examples for the decoders of other languages (Sennrich et al., 2015a) should be investigated to confirm this conjecture.

7 Conclusion

In this paper, we proposed multi-way, multilingual attention-based neural machine translation. The proposed approach allows us to build a single neural network that can handle multiple source and target languages simultaneously. The proposed model is a step forward from the recent works on multilingual neural translation, in the sense that we support attention mechanism, compared to (Luong et al., 2015a) and multi-way translation, compared to (Dong et al., 2015). Furthermore, we evaluate the proposed model on large-scale experiments, using the full set of parallel corpora from WMT'15.

We empirically evaluate the proposed model in large-scale experiments using all five languages from WMT'15 with the full set of parallel corpora and also in the settings with artificially controlled amount of the target parallel corpus. In both of the settings, we observed the benefits of the proposed multilingual neural translation model over having a set of single-pair models. The improvement was especially clear in the cases of translating low-resource language pairs.

We observed the larger improvements when translating to English. We conjecture that this is due to a higher availability of English in most parallel corpora, leading to a better parameter estimation of the English decoder. More research on this phenomenon in the future will result in further improvements from using the proposed model. Also, all the other techniques proposed recently, such as ensembling and large vocabulary tricks, need to be tried together with the proposed multilingual model to improve the translation quality even further. Finally, an interesting future work is to use the proposed model to translate between a language pair not included in a set of training corpus.

Abstract

Neural encoder-decoder models of machine translation have achieved impressive results, rivalling traditional translation models. However their modelling formulation is overly simplistic, and omits several key inductive biases built into traditional models. In this paper we extend the attentional neural translation model to include structural biases from word based alignment models, including positional bias, Markov conditioning, fertility and agreement over translation directions. We show improvements over a baseline attentional model and standard phrase-based model over several language pairs, evaluating on difficult languages in a low resource setting.

1 Introduction

Recently, models of end-to-end machine translation based on neural network classification have been shown to produce excellent translations, rivalling or in some cases surpassing traditional statistical machine translation systems (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015). This is despite the neural approaches using an overall simpler model, with fewer assumptions about the learning and prediction problem.

Broadly, neural approaches are based around the notion of an *encoder-decoder* (Sutskever et al., 2014), in which the source language is *encoded* into a distributed representation, followed by a *decoding* step which generates the target translation. We focus on the *attentional model* of translation (Bahdanau et al., 2015) which uses a dynamic representation of the source sentence while allowing the decoder to *attend* to different parts of the source as it generates the target sentence. The attentional model raises intriguing opportunities, given the correspondence between the notions of attention and alignment in traditional word-based machine translation models (Brown et al., 1993).

In this paper we map modelling biases from word based translation models into the attentional model, such that known linguistic elements of translation can be better captured. We incorporate *absolute positional bias* whereby word order tends to be similar between the source sentence and its translation (e.g., IBM Model 2 and (Dyer et al., 2013)), *fertility* whereby each instance of a source word type tends to be translated into a consistent number of target tokens (e.g., IBM Models 3, 4, 5), *relative position bias* whereby prior preferences for monotonic alignments/attention can be encouraged (e.g., IBM Model 4, 5 and HMM-based Alignment (Vogel et al., 1996)), and *alignment consistency* whereby the attention in *both* translation directions are encouraged to agree (e.g. symmetrisation heuristics (Och and Ney, 2003) or joint modelling (Liang et al., 2006; Ganchev et al., 2008)).

We provide an empirical analysis of incorporating the above structural biases into the attentional model, considering low resource translation scenario over four language-pairs. Our results demonstrate consistent improvements over vanilla encoder-

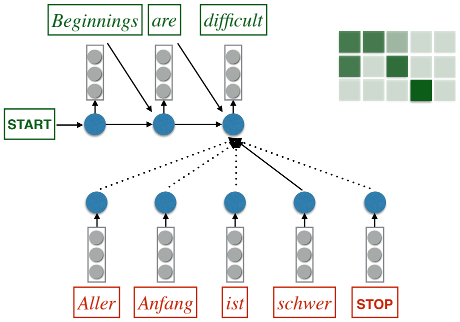

Figure 1: Attentional model of translation (Bahdanau et al., 2015). The encoder is shown below the decoder, and the edges connecting the two corresponding to the attention mechanism. Heavy edges denote a higher attention weight, and these values are also displayed in matrix form, with one row for each target word.

decoder and attentional model in terms of the perplexity and BLEU score, e.g. up to 3.5 BLEU points when re-ranking the candidate translations generated by a state-of-the-art phrase based model.

2 The attentional model of translation

We start by reviewing the attentional model of translation (Bahdanau et al., 2015), as illustrated in Fig. 1, before presenting our extensions in §3.

Encoder The encoding of the source sentence is formulated using a pair of RNNs (denoted *bi-RNN*) one operating left-to-right over the input sequence and another operating right-to-left,

$$\boldsymbol{h}_i^{\rightarrow} = \mathrm{RNN}(\boldsymbol{h}_{i-1}^{\rightarrow}, \boldsymbol{r}_{s_i}^{(\mathrm{s})})$$
$$\boldsymbol{h}_i^{\leftarrow} = \mathrm{RNN}(\boldsymbol{h}_{i+1}^{\rightarrow}, \boldsymbol{r}_{s_i}^{(\mathrm{s})})$$

where $\boldsymbol{h}_i^{\rightarrow}$ and $\boldsymbol{h}_i^{\leftarrow}$ are the RNN hidden states. The left-to-right RNN function is defined as

$$\boldsymbol{h}_i^{\rightarrow} = \tanh\left(\boldsymbol{W}_{si}^{\rightarrow}\boldsymbol{r}_{s_i}^{(\mathrm{s})} + \boldsymbol{W}_{sh}^{\rightarrow}\boldsymbol{h}_{i-1}^{\rightarrow} + \boldsymbol{b}_s^{\rightarrow}\right) \quad (1)$$

where $\boldsymbol{h}_0^{\rightarrow} \in \mathbb{R}^H$ is a learned parameter vector, as are $\mathbf{R}^{(\mathrm{s})} \in \mathbb{R}^{V_S \times E}$, $\boldsymbol{W}_{si}^{\rightarrow} \in \mathbb{R}^{H \times E}$, $\boldsymbol{W}_{sh}^{\rightarrow} \in \mathbb{R}^{H \times H}$ and $\boldsymbol{b}_s^{\rightarrow} \in \mathbb{R}^H$, with H the number of hidden units, V_S the size of the source vocabulary and E the word embedding dimensionality.[1] Each source word is then represented as a pair of hidden states, one from each RNN, $\boldsymbol{e}_i = \begin{bmatrix} \boldsymbol{h}_i^{\rightarrow} \\ \boldsymbol{h}_i^{\leftarrow} \end{bmatrix}$. This encodes not only the word but also its left and right context, which can provide important evidence for its translation.

A crucial question is how this dynamic sized matrix $\mathbf{E} = [\boldsymbol{e}_1, \boldsymbol{e}_2, \ldots, \boldsymbol{e}_I] \in \mathbb{R}^{I \times H}$ can be used in the decoder to generate the target sentence. As with Sutskever's encoder-decoder, the target sentence is created left-to-right using an RNN, while the encoded source is used to bias the process as an auxiliary input. The mechanism for this bias is by attentional vectors, i.e. vectors of scores over each source sentence location, which are used to aggregate the dynamic source encoding into a fixed length vector.

Decoder The decoder operates as a standard RNN over the translation $\boldsymbol{t}$, formulated as follows

$$\boldsymbol{g}_j = \tanh\left(\mathbf{W}^{(\mathrm{th})}\boldsymbol{g}_{j-1} + \mathbf{W}^{(\mathrm{ti})}\boldsymbol{r}_{t_{j-1}}^{(\mathrm{t})} + \mathbf{W}^{(\mathrm{ta})}\boldsymbol{c}_j\right) \quad (2)$$
$$\boldsymbol{u}_j = \tanh\left(\boldsymbol{g}_j + \mathbf{W}^{(\mathrm{uc})}\boldsymbol{c}_j + \mathbf{W}^{(\mathrm{ui})}\boldsymbol{r}_{t_{j-1}}^{(\mathrm{t})}\right) \quad (3)$$
$$t_j \sim \mathrm{softmax}\left(\mathbf{W}^{(\mathrm{ou})}\boldsymbol{u}_j + \boldsymbol{b}^{(\mathrm{to})}\right) \quad (4)$$

where the decoder RNN is defined analogously to Eq 1 but with an additional input, the source attention component $\boldsymbol{c}_j \in \mathbb{R}^{2H}$ and weighting matrix $\mathbf{W}^{(\mathrm{ta})} \in \mathbb{R}^{H \times 2H}$. The hidden state of the recurrence is then passed through a single hidden layer[2] (Eq 3) in combination with the source attention and target word using weighting matrices $\mathbf{W}^{(\mathrm{uc})} \in \mathbb{R}^{H \times 2H}$ and $\mathbf{W}^{(\mathrm{ui})} \in \mathbb{R}^{H \times E}$. In Eq 4 this vector is transformed to be target vocabulary sized, using weight matrix $\mathbf{W}^{(\mathrm{ou})} \in \mathbb{R}^{V_T \times H}$ and bias $\boldsymbol{b}^{(\mathrm{to})} \in \mathbb{R}^{V_T}$, after which a softmax is taken, and the resulting normalised vector used as the parameters of a Categorical distribution in generating the next target word.

The presentation above assumes a simple RNN is used to define the recurrence over hidden states, however we can easily use alternative formulations of recurrent networks including multiple-layer RNNs, gated recurrent units (GRU; Cho et al. (2014)), or long short-term memory (LSTM; Hochreiter and Schmidhuber (1997)) units. These more advanced methods allow for more efficient learning of more complex concepts, particularly

[1] Similarly, $\boldsymbol{h}_0^{\leftarrow} \in \mathbb{R}^H, \boldsymbol{W}_{si}^{\leftarrow} \in \mathbb{R}^{H \times E}, \boldsymbol{W}_{sh}^{\leftarrow} \in \mathbb{R}^{H \times H}, \boldsymbol{b}_s^{\leftarrow} \in \mathbb{R}^H$ are the parameters of the right-to-left RNN. Note that we use a long short term memory unit (Hochreiter and Schmidhuber, 1997) in place of the RNN, shown here for simplicity of exposition.

[2] In Bahdanau et al. (2015) they use a max-out layer for this final step, however we found this to be a needless complication, and instead use a standard hidden layer with tanh activation.

long distance effects. Empirically we found LSTMs to be the best performing, and therefore use these units herein.

The last key detail is the attentional component $\boldsymbol{c}_j$ in Eqs 2 and 3, which is defined as follows

$$\begin{aligned} f_{ji} &= \boldsymbol{v}^\top \tanh\left(\mathbf{W}^{(\mathrm{ae})}\boldsymbol{e}_i + \mathbf{W}^{(\mathrm{ah})}\boldsymbol{g}_{j-1}\right) \qquad (5) \\ \boldsymbol{\alpha}_j &= \mathrm{softmax}\left(\boldsymbol{f}_j\right) \\ \boldsymbol{c}_j &= \sum_i \alpha_{ji}\boldsymbol{e}_i \end{aligned}$$

with the scalars f_{ji} denoting the compatibility between the target hidden state $\boldsymbol{g}_{j-1}$ and the source encoding $\boldsymbol{e}_i$. This is defined as a neural network with one hidden layer of size A and a single output, parameterised by $\mathbf{W}^{(\mathrm{ae})} \in \mathbb{R}^{A\times 2H}$, $\mathbf{W}^{(\mathrm{ah})} \in \mathbb{R}^{A\times H}$ and $\boldsymbol{v} \in \mathbb{R}^A$. The softmax then normalises the scalar compatibility values such that for a given target word j, the values of α_j can be interpreted as alignment probabilities to each source location. Finally, these alignments are used to to reweight the source components E to produce a fixed length context representation.

Training of this model is done by minimising the cross-entropy of the target sentence, measured word-by-word as for a language model. We use standard stochastic gradient optimisation using the back-propagation technique for computation of partial derivatives according to the chain rule.

3 Incorporating Structural Biases

The attentional model, as described above, provides a powerful and elegant model of translation in which alignments between source and target words are learned through the implicit conditioning context afforded by the attention mechanism. Despite its elegance, the attentional model omits several key components of a traditional alignment models such as the IBM models (Brown et al., 1993) and Vogel's hidden Markov Model (Vogel et al., 1996) as implemented in the GIZA++ toolkit (Och and Ney, 2003). Combining the strengths of this highly successful body of research into a neural model of machine translation holds potential to further improve modelling accuracy of neural techniques. Below we outline methods for incorporating these factors as structural biases into the attentional model.

3.1 Position bias

First we consider position bias, based on the observation that a word at a given relative position in the source tends to align to a word at a similar relative position in the target, $\frac{i}{I} \approx \frac{j}{J}$ (Dyer et al., 2013). Related, the IBM model 2 learns discrete mappings between positions i and j conditioned on sentence lengths I and J.

We include a position bias through redefining the pre-normalised attention scalars f_{ji} in Eq 5 as:

$$\begin{aligned} f_{ji} = \boldsymbol{v}^\top \tanh\big(&\mathbf{W}^{(\mathrm{ae})}\boldsymbol{e}_i + \mathbf{W}^{(\mathrm{ah})}\boldsymbol{g}_{j-1} + \\ &\mathbf{W}^{(\mathrm{ap})}\psi(j,i,I)\big) \qquad (6) \end{aligned}$$

where the new component in the input is a simple feature function of the positions in the source and target sentences and the source length,

$$\psi(j,i,I) = \Big[\log(1+j), \log(1+i), \log(1+I)\Big]^\top$$

and $\mathbf{W}^{(\mathrm{ap})} \in \mathbb{R}^{A\times 3}$. We exclude the target length J as this is unknown during decoding, as a partial translation can have several (infinite) different lengths. The use of the $\log(1+\cdot)$ function is to avoid numerical instabilities from widely varying sentence lengths. The non-linearity in Eq 6 allows for complex functions of these inputs to be learned, such as relative positions and approximate distance from the diagonal, as well as their interactions with the other inputs (e.g., to learn that some words are exceptional cases where a diagonal bias should not apply).

3.2 Markov condition

The HMM model of translation (Vogel et al., 1996) is based on a Markov condition over alignment random variables, to allow the model to learn local effects such as when $i \leftarrow j$ is aligned then it is likely that $i+1 \leftarrow j+1$ or $i \leftarrow j+1$. These correspond to local diagonal alignments or one-to-many alignments, respectively. In general, there are many correlations between the alignments of a word and the alignments of the preceding word.

Markov conditioning can also be incorporated in a similar manner to positional bias, by augmenting the attentional input from Eqs 5 and 6 to include:

$$f_{ji} = \boldsymbol{v}^\top \tanh\left(\ldots + \mathbf{W}^{(\mathrm{am})}\xi_1(\boldsymbol{\alpha}_{j-1}; i)\right) \qquad (7)$$

where ... abbreviates the $\boldsymbol{e}_i$, $\boldsymbol{g}_{j-1}$ and ψ components from Eq 6, and $\xi_1(\boldsymbol{\alpha}_{j-1})$ provides a fixed dimensional representation of the attention state for the preceding word. It is not immediately obvious how to incorporate the previous attention vector as $\boldsymbol{\alpha}$ is dynamically sized to match the source sentence length, thus using it directly would not generalise over sentences of different lengths. For this reason, we make a simplification by just considering local moves offset by $\pm k$ positions, that is,

$$\xi_1(\boldsymbol{\alpha}_{j-1}; i) = \left[\alpha_{j-1,i-k}, .., \alpha_{j-1,i}, .., \alpha_{j-1,i+k}\right]^\top$$

with $\mathbf{W}^{(\text{am})} \in \mathbb{R}^{A\times(2k+1)}$. Our approach is likely to capture the most important alignments patterns forming the backbone of the alignment HMM, namely monotone, 1-to-many, and local inversions.

3.3 Fertility

Fertility is the propensity for a word to be translated as a consistent number of words in the other language, e.g., *Iseseisvusdeklaratsioon* (Et) translates as 3-4 words in English, namely *(the) Declaration of Independence*. Fertility is a central component in the IBM models 3–5 (Brown et al., 1993). Incorporating fertility into the attentional model is a little more involved, and we present two techniques for doing so.

Local fertility First we consider a feature-based technique, which includes the following features

$$\xi_2(\boldsymbol{\alpha}_{<j}; i) = \left[\sum_{j'<j} \alpha_{j',i-k}, .., \sum_{j'<j} \alpha_{j',i}, .., \sum_{j'<j} \alpha_{j',i+1}\right]^\top$$

and the corresponding feature weights, i.e., $\mathbf{W}^{(\text{af})} \in \mathbb{R}^{A\times(2k+1)}$. These sums represent the total alignment score for the surrounding source words, similar to fertility in a traditional latent variable model, which is the sum over binary alignment random variables. A word which already has several alignments can be excluded from participating in more alignments, thus combating the garbage collection problem. Conversely words that tend to need high fertility can be learned through the interactions between these features and the word and context embeddings in Eq 7.

Global fertility A second, more explicit, technique for incorporating fertility is to include this as a modelling constraint. Initially we considered a soft constraint based on the approach in (Xu et al., 2015), where an image captioning model was biased to attend to every pixel in the image exactly once. In our setting, the same idea can be applied through adding a regularisation term to the training objective of the form $\sum_i \left(1 - \sum_j \alpha_{j,i}\right)^2$. However this method is overly restrictive: enforcing that every word is used exactly once is not appropriate in translation where some words are likely to be dropped (e.g., determiners and other function words), while others might need to be translated several times to produce a phrase in the target language.[3] For this reason we develop an alternative method, based around a contextual fertility model, $p(f_i|\boldsymbol{s}, i) = \mathcal{N}\left(\mu(e_i), \sigma^2(e_i)\right)$ which scores the fertility of source word i, defined as $f_i = \sum_j \alpha_{j,i}$, using a normal distribution[4] parameterised by μ and σ^2, both positive scalar valued non-linear functions of the source word encoding e_i. This is incorporated into the training objective as an additional additive term, $\sum_i \log p(f_i|\boldsymbol{s}, i)$, for each training sentence.

This formulation allows for greater consistency in translation, through e.g., learning which words tend to be omitted from translation, or translate as several words. Compared to the fertility model in IBM 3–5 (Brown et al., 1993), ours uses many fewer parameters through working over vector embeddings, and moreover, the BiRNN encoding of the source means that we learn context-dependent fertilities, which can be useful for dealing with fixed syntactic patterns or multi-word expressions.

3.4 Bilingual Symmetry

So far we have considered a conditional model of the target given the source, modelling $p(\boldsymbol{t}|\boldsymbol{s})$. However it is well established for latent variable translation models that the alignments improve if $p(\boldsymbol{s}|\boldsymbol{t})$ is

[3] Modern decoders (Koehn et al., 2003) often impose the restriction of each word being translated exactly once, however this is tempered by their use of phrases as translation units rather than words, which allow for higher fertility within phrases.

[4] The normal distribution is deficient, as it has support for all scalar values, despite f_i being bounded above and below ($0 \leq f_i \leq J$). This could be corrected by using a truncated normal, or various other choices of distribution.

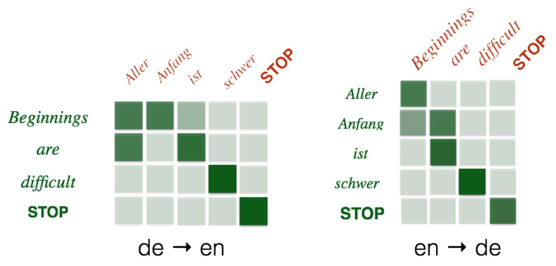

Figure 2: Symmetric training with trace bonus, computed as matrix multiplication, $-\operatorname{tr}(\boldsymbol{\alpha}^{s\leftarrow t}\boldsymbol{\alpha}^{s\rightarrow t\top})$. Dark shading indicates higher values.

also modelled and the inferences of both directional models are combined – evidenced by the symmetrisation heuristics used in most decoders (Koehn et al., 2005), and also by explicit joint agreement training objectives (Liang et al., 2006; Ganchev et al., 2008). The rationale is that both models make somewhat independent errors, so an ensemble stands to gain from variance reduction.

We propose a method for joint training of two directional models as pictured in Figure 2. Training twinned models involves optimising $\mathcal{L} = -\log p(\boldsymbol{t}|\boldsymbol{s}) - \log p(\boldsymbol{s}|\boldsymbol{t}) + \gamma B$ where, as before, we consider only a single sentence pair, for simplicity of notation. This corresponds to a pseudo-likelihood objective, with the B linking the two models.[5] The B component considers the alignment (attention) matrices, $\boldsymbol{\alpha}^{s\rightarrow t} \in \mathbb{R}^{J\times I}$ and $\boldsymbol{\alpha}^{t\leftarrow s} \in \mathbb{R}^{I\times J}$, and attempts to make these close to one another for both translation directions (see Fig. 2). To achieve this, we use a 'trace bonus', inspired by (Levinboim et al., 2015), formulated as

$$B = -\operatorname{tr}(\boldsymbol{\alpha}^{s\leftarrow t\,\top}\boldsymbol{\alpha}^{s\rightarrow t}) = \sum_j \sum_i \alpha_{i,j}^{s\leftarrow t}\alpha_{j,i}^{s\rightarrow t}\,.$$

As the alignment cells are normalised using the $\mathrm{softmax}$ and thus take values in [0,1], the trace term is bounded above by $\min(I, J)$ which occurs when the two alignment matrices are transposes of each other, representing perfect one-to-one alignments in both directions

Table 1: Statistics of the training sets, showing in each cell the count for the source language (left) and target language (right).

4 Experiments

Datasets. We conducted our experiments with four language pairs, translating between English ↔ Romanian, Estonian, Russian and Chinese. These languages were chosen to represent a range of translation difficulties, including languages with significant morphological complexity (Estonian, Russian). We focus on a (simulated) low resource setting, where only a limited amount of training data is available. This serves to demonstrate the robustness and generalisation of our model on sparse data – something that has not yet been established for neural models with millions of parameters with vast potential for over-fitting.

Table 1 shows the statistics of the training sets.[6] For Chinese-English, the data comes from the BTEC corpus, where the number of training sentence pairs is 44,016. We used 'devset1_2' and 'devset_3' as the development and test sets, respectively, and in both cases used only the first reference for evaluation. For Romanian and Estonian, the data come from the Europarl corpus (Koehn, 2005), where we used 100K sentence pairs for training, and 3K for development and 2K for testing.[7] The Russian-English data was taken from a web derived corpus (Antonova and Misyurev, 2011). The dataset is split into three parts using the same technique as for the Europarl sets. During the preprocessing stage we lower-cased and tokenized the data, and excluded sentences longer than 30 words. For the Europarl

[5] We could share some parameters, e.g., the word embedding matrices, however we found this didn't make much difference versus using disjoint parameter sets. We set $\gamma = 1$ herein.

[6] For all datasets words were thresholded for training frequency ≥ 5, with uncommon training and unseen testing words replaced by an $\langle$unk$\rangle$ symbol.

[7] The first 100K sentence pairs were used for training, while the development and test were drawn from the last 100K sentence pairs, taking the first 2K for testing and the last 3K for development.

data, we also removed sentences containing headings and other meeting formalities.[8]

Models and Baselines. We have implemented our neural translation model with linguistic features in C++ using the CNN library.[9] We compared our proposed model against our implementations of the attentional model (Bahdanau et al., 2015) and encoder-decoder architecture (Sutskever et al., 2014). As the baseline, we used a state-of-the-art phrase-based statistical machine translation model built using Moses (Koehn et al., 2007) with the standard features: relative-frequency and lexical translation model probabilities in both directions; distortion model; language model and word count. We used KenLM (Heafield, 2011) to create 3-gram language models with Kneser-Ney smoothing on the target side of the bilingual training corpora.

Evaluation Measures. Following previous work (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015; Neubig et al., 2015), we evaluated all neural models using test set perplexities and translation results, as well as in an additional re-ranking setting, using BLEU (Papineni et al., 2002) measure. We applied bootstrap resampling (Koehn, 2004) to measure statistical significance, $p < 0.05$, of our models compared to a baseline. For re-ranking, we generated 100-best translations using the baseline phrase-based model, to which we added log probability features from our neural models alongside all the features of the underlying phrase-based model. We trained the re-ranking models using MERT (Och, 2003) on development sets with 100-best translations.

4.1 Analysis of Alignment Biases

We start by investigating the effect of various linguistic constraints, described in Section 3, on the attentional model. Table 2 presents the perplexity of trained models for Chinese→English translation. For comparison, we report the results of an encoder-decoder-based neural translation model (Sutskever et al., 2014) as the baseline. All other results are for the attentional model with a single-layer LSTM as encoder and two-layer LSTM as decoder, using 512 embedding, 512 hidden, and 256 alignment dimensions. For each model, we also report the number of its parameters. Models are trained end-to-end using stochastic gradient descent (SGD), allowing up to 20 epochs. We use a held-out development set for regularisation by early stopping, which terminated the training after 5-10 epochs for most cases.

configuration	**test**	**#param (M)**
Sutskever encdec	5.35	8.7
Attentional	4.77	15.0
+align	4.56	15.0
+align+glofer	5.20	15.5
+align+glofer-pre	4.31	15.5
+align+sym	4.44	30.1
+align+sym+glofer-pre	4.43	31.2

Table 2: Perplexity results for attentional model variants evaluated on BTEC zh→en, and number of model parameters (in millions).

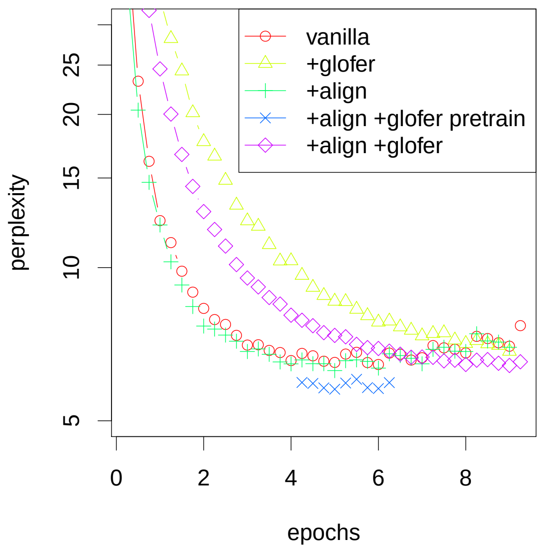

Figure 3: Perplexity with training epochs on ro-en translation, comparing several model variants.

As expected, the vanilla attentional model greatly improves over encoder-decoder (perplexity of 4.77 vs. 5.35), clearly making good use of the additional context. Adding the combined positional bias, local fertility, and Markov structure (denoted by +align) further decreases the perplexity to 4.56. Adding the global fertility (+glofer) is detrimental, however, increases perplexity to 5.20. Interestingly, global fertility helps to reduce the perplexity (to 4.31) when used with the pre-training setting (+align+glofer-

[8] E.g., *(The sitting was closed at 10.20pm)*.

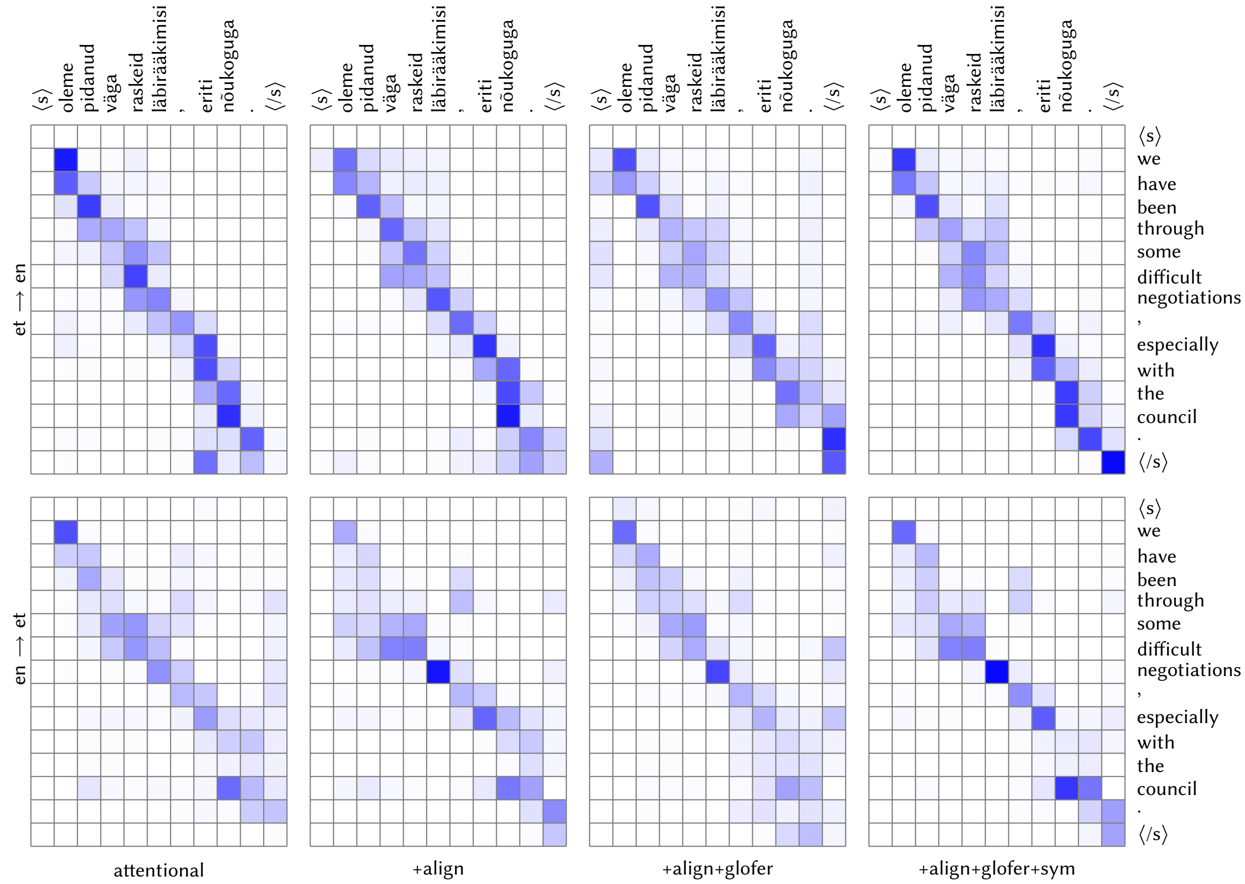

Figure 4: Example development sentence, showing the inferred attention matrix for various models for Et ↔ En. Rows correspond to the translation direction and columns correspond to different models: attentional, with alignment features (+align), global fertility (+glofer), and symmetric joint training (+sym). Darker shades denote higher values and white denotes zero.

pre). In this case, it is refining an already excellent model from which reliable global fertility estimates can be obtained. This finding is consistent with the other languages, see Figure 3 which shows typical learning curves of different variants of the attentional model. Note that when global fertility is added to the vanilla attentional model with alignment features, it significantly slows down training as it limits exploration in early training iterations, however it does bring a sizeable win when used to fine-tune a pre-trained model. Finally, the bilingual symmetry also helps to reduce the perplexity scores when used with the alignment features, however, does not combine well with global fertility (+align+sym+glofer-pre). This is perhaps an unsurprising result as both methods impose a often-times similar regularising effect over the attention matrix.

Figure 4 illustrates the different attention matrices inferred by the various model variants. Note the difference between the base attentional model and its variant with alignment features ('+align'), where more weight is assigned to diagonal and 1-to-many alignments. Global fertility pushes more attention to the sentinel symbols ⟨s⟩ and ⟨/s⟩. Determiners and prepositions in English show much lower fertility than nouns, while Estonian nouns have even higher fertility. This accords with Estonian morphology, wherein nouns are inflected with rich case marking, e.g., *nõukoguga* has the cogitative *-ga* suffix, meaning 'with', and thus translates as several English words (*with the council*). The right-most column corresponds to joint symmetric training, with many more confident attention values especially for consistent 1-to-many alignments (*difficult* in English and *raskeid* in Estonian, an adjective in partitive case meaning *some difficult*).

4.2 Experimental Results

The perplexity results of the neural models for the two translation directions across the four language pairs are presented in Table 3. In all cases, our work achieves lower perplexities compared to the vanilla attentional model and the encoder-decoder architecture, owing to the linguistic constraints. We also obtained similar patterns of improvements when decoding, using a greedy decoding strategy, as shown in Table 4. The exception was for en→ru, where the addition of the global fertility (in addition to the other aligment features) was detrimental, resulting in a decrease in BLEU score (5.94→5.26). This may be due to highly noisy nature of the web text corpus of Russian-English language pair, compared to the much cleaner sources for the other language pairs.

Greedy decoding does not appear to be competitive for neural models trained on small parallel corpora, not reaching the level of a phrase-based baseline (see Table 5). Despite this, however, these models still provide substantial gains when used for reranking (as shown in Table 5) for translating into English from the other four languages. We compare reranking settings using the log probabilities produced by our model as additional features[10] vs. using log probabilities from the vanilla attentional model and the encoder-decoder. The re-rankers based on our model are significantly better than the rest for Chinese and Estonian, and on par with the other for Russian and Romanian→English. In all cases our model has performance at least 1 BLEU point better than the baseline phrase-based system. It is worth noting that for Chinese-English, our re-ranker leads to a substantial increase of almost 3 BLEU points.

5 Related Work

Kalchbrenner and Blunsom (2013) were the first to propose a full neural model of translation, using a convolutional network as the source encoder, followed by an RNN decoder to generate the target translation. This was extended in Sutskever et al. (2014), who replaced the source encoder with an RNN using a Long Short-Term Memory (LSTM) and leveraged the last hidden RNN states as source context for generating the output. Inspired by this, Bahdanau et al. (2015) introduced the notion of "attention" to the model, whereby the source context can dynamically change during the decoding process to attend to the most relevant parts of the source sentence. Further, Luong et al. (2015) refined the attention mechanism to be more local, by constraining attention to a text span, whose words' representations are averaged.

Similar in spirit to our work, recent research has proposed different ways of leveraging the attention history to incorporate alignment structural biases. (Luong et al., 2015) made use of the attention vector of the previous position when generating the attention vector for the next position. Feng et al. (2016)

[10] We include two features: the normalised log-probability of the translation, evaluated in both translation directions.

added another recurrent structure for the attention mechanism to enhance its memorization capabilities and capture long-range dependencies between the attention vectors. Tu et al. (2016) proposed a coverage vector to keep track of the attention history, hence refining future attentions. Finally, Cheng et al. (2015) proposed a similar agreement-based joint training for bidirectional attention-based neural machine translation, and showed significant improvements in BLEU for the large data French↔English translation.

6 Conclusion

We have shown that the attentional model of translation does not capture many well known properties of traditional word-based translation models, and proposed several ways of imposing these as structural biases on the model. We show improvements across several challenging language pairs in a low-resource setting, as well as in perplexity, translation and reranking evaluations. In future work we intend to investigate the model performance on larger-scale datasets, and incorporate further linguistic information, such as morphological representations.

Multilingual Relation Extraction using Compositional Universal Schema

Abstract

Universal schema builds a knowledge base (KB) of entities and relations by jointly embedding all relation types from input KBs as well as textual patterns observed in raw text. In most previous applications of universal schema, each textual pattern is represented as a single embedding, preventing generalization to unseen patterns. Recent work employs a neural network to capture patterns' compositional semantics, providing generalization to all possible input text. In response, this paper introduces significant further improvements to the coverage and flexibility of universal schema relation extraction: predictions for entities unseen in training and multilingual transfer learning to domains with no annotation. We evaluate our model through extensive experiments on the English and Spanish TAC KBP benchmark, outperforming the top system from TAC 2013 slot-filling using no handwritten patterns or additional annotation. We also consider a multilingual setting in which English training data entities overlap with the seed KB, but Spanish text does not. Despite having no annotation for Spanish data, we train an accurate predictor, with additional improvements obtained by tying word embeddings across languages. Furthermore, we find that multilingual training improves English relation extraction accuracy. Our approach is thus suited to broad-coverage automated knowledge base construction in a variety of languages and domains.

1 Introduction

The goal of automatic knowledge base construction (AKBC) is to build a structured knowledge base (KB) of facts using a noisy corpus of raw text evidence, and perhaps an initial seed KB to be augmented (Carlson et al., 2010; Suchanek et al., 2007; Bollacker et al., 2008). AKBC supports downstream reasoning at a high level about extracted entities and their relations, and thus has broad-reaching applications to a variety of domains.

One challenge in AKBC is aligning knowledge from a structured KB with a text corpus in order to perform supervised learning through *distant supervision*. *Universal schema* (Riedel et al., 2013) along with its extensions (Yao et al., 2013; Gardner et al., 2014; Neelakantan et al., 2015; Rocktaschel et al., 2015), avoids alignment by jointly embedding KB relations, entities, and surface text patterns. This propagates information between KB annotation and corresponding textual evidence.

The above applications of universal schema express each text relation as a distinct item to be embedded. This harms its ability to generalize to inputs not precisely seen at training time. Recently, Toutanova et al. (2015) addressed this issue by embedding text patterns using a deep sentence encoder, which captures the compositional semantics of textual relations and allows for prediction on inputs never seen before.

This paper further expands the coverage abilities of universal schema relation extraction by introducing techniques for forming predictions for new entities unseen in training and even for new domains with no associated annotation. In the extreme example of domain adaptation to a completely new language, we may have limited linguistic resources or labeled data such as treebanks, and only rarely a KB with adequate coverage. Our method performs multilingual transfer learning, providing a predictive model for a language with no coverage in an existing KB, by leveraging common representations for shared entities across text corpora. As depicted in Figure 1, we simply require that one language have an available KB of seed facts. We can further improve our models by tying a small set of word embeddings across languages using only simple knowledge about word-level translations, learning to embed semantically similar textual patterns from different languages into the same latent space.

In extensive experiments on the TAC Knowledge Base Population (KBP) slot-filling benchmark we outperform the top 2013 system with an F1 score of 40.7 and perform relation extraction in Spanish with no labeled data or direct overlap between the Spanish training corpus and

Proceedings of NAACL-HLT 2016, pages 886–896,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

the training KB, demonstrating that our approach is well-suited for broad-coverage AKBC in low-resource languages and domains. Interestingly, joint training with Spanish improves English accuracy.

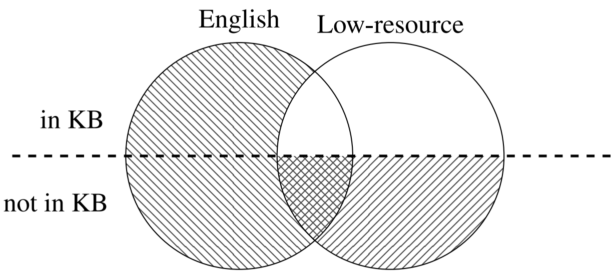

Figure 1: Splitting the entities in a multilingual AKBC training set into parts. We only require that entities in the two corpora overlap. Remarkably, we can train a model for the low-resource language even if entities in the low-resource language do not occur in the KB.

2 Background

AKBC extracts unary attributes of the form (*subject*, *attribute*), typed binary relations of the form (*subject*, *relation*, *object*), or higher-order relations. We refer to subjects and objects as *entities*. This work focuses solely on extracting binary relations, though many of our techniques generalize naturally to unary prediction. Generally, for example in Freebase (Bollacker et al., 2008), higher-order relations are expressed in terms of collections of binary relations.

We now describe prior work on approaches to AKBC. They all aim to predict (*s, r, o*) triples, but differ in terms of: (1) input data leveraged, (2) types of annotation required, (3) definition of relation label schema, and (4) whether they are capable of predicting relations for entities unseen in the training data. Note that all of these methods require pre-processing to detect entities, which may result in additional KB construction errors.

2.1 Relation Extraction as Link Prediction

A knowledge base is naturally described as a graph, in which entities are nodes and relations are labeled edges (Suchanek et al., 2007; Bollacker et al., 2008). In the case of *knowledge graph completion*, the task is akin to link prediction, assuming an initial set of (*s, r, o*) triples. See Nickel et al. (2015) for a review. No accompanying text data is necessary, since links can be predicted using properties of the graph, such as transitivity. In order to generalize well, prediction is often posed as low-rank matrix or tensor factorization. A variety of model variants have been suggested, where the probability of a given edge existing depends on a multi-linear form (Nickel et al., 2011; García-Durán et al., 2015; Yang et al., 2015; Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015), or non-linear interactions between s, r, and o (Socher et al., 2013). Other approaches model the compositionality of multi-hop paths, typically for question answering (Bordes et al., 2014; Gu et al., 2015; Neelakantan et al., 2015).

2.2 Relation Extraction as Sentence Classification

Here, the training data consist of (1) a text corpus, and (2) a KB of seed facts with provenance, i.e. supporting evidence, in the corpus. Given individual an individual sentence, and pre-specified entities, a classifier predicts whether the sentence expresses a relation from a target schema. To train such a classifier, KB facts need to be aligned with supporting evidence in the text, but this is often challenging. For example, not all sentences containing Barack and Michelle Obama state that they are married. A variety of one-shot and iterative methods have addressed the alignment problem (Bunescu and Mooney, 2007; Mintz et al., 2009; Riedel et al., 2010; Yao et al., 2010; Hoffmann et al., 2011; Surdeanu et al., 2012; Min et al., 2013; Zeng et al., 2015). An additional degree of freedom in these approaches is whether they classify individual sentences or predicting at the corpus level by aggregating information from all sentences containing a given pair of entities before prediction. The former approach is often preferable in practice, due to the simplicity of independently classifying individual sentences and the ease of associating each prediction with a provenance. Prior work has applied deep learning to small-scale relation extraction problems, where functional relationships are detected between common nouns (Li et al., 2015; dos Santos et al., 2015). Xu et al. (2015) apply an LSTM to a parse path, while Zeng et al. (2015) use a CNN on the raw text, with a special temporal pooling operation to separately embed the text around each entity.

2.3 Open-Domain Relation Extraction

In the previous two approaches, prediction is carried out with respect to a fixed schema R of possible relations r. This may overlook salient relations that are expressed in the text but do not occur in the schema. In response, *open-domain* information extraction (OpenIE) lets the text speak for itself: R contains all possible patterns of text occurring between entities s and o (Banko et al., 2007; Etzioni et al., 2008; Yates and Etzioni, 2007). These are obtained by filtering and normalizing the raw text. The approach offers impressive coverage, avoids issues of distant supervision, and provides a useful exploratory tool. On the other hand, OpenIE predictions are difficult to use in downstream tasks that expect information from a fixed schema.

Table 1 provides examples of OpenIE patterns. The examples in row two and three illustrate relational contexts for which similarity is difficult to be captured by an OpenIE approach because of their syntactically complex constructions. This motivates the technique in Section 3.2, which uses a deep architecture applied to raw tokens, instead of rigid rules for normalizing text to obtain patterns.

Sentence (context tokens italicized)	OpenIE pattern
Khan *'s younger sister,* **Annapurna Devi**, who later married Shankar, developed into an equally accomplished master of the surbahar, but custom prevented her from performing in public.	*arg1*'s * sister *arg2*
A professor emeritus at Yale, **Mandelbrot** *was born in Poland but as a child moved with his family to* **Paris** where he was educated.	*arg1* * moved with * family to *arg2*
Kissel *was born in Provo, Utah, but her family also lived in* **Reno**.	*arg1* * lived in *arg2*

Table 1: Examples of sentences expressing relations. Context tokens (italicized) consist of the text occurring between entities (bold) in a sentence. OpenIE patterns are obtained by normalizing the context tokens using hand-coded rules. The top example expresses the per:siblings relation and the bottom two examples both express the per:cities_of_residence relation.

2.4 Universal Schema

When applying Universal Schema (Riedel et al., 2013) (USchema) to relation extraction, we combine the OpenIE and link-prediction perspectives. By jointly modeling both OpenIE patterns and the elements of a target schema, the method captures broader relational structure than multi-class classification approaches that just model the target schema. Furthermore, the method avoids the distant supervision alignment difficulties of Section 2.2.

Riedel et al. (2013) augment a knowledge graph from a seed KB with additional edges corresponding to OpenIE patterns observed in the corpus. Even if the user does not seek to predict these new edges, a joint model over all edges can exploit regularities of the OpenIE edges to improve modeling of the labels from the target schema.

The data still consist of (s, r, o) triples, which can be predicted using link-prediction techniques such as low-rank factorization. Riedel et al. (2013) explore a variety of approximations to the 3-mode (s, r, o) tensor. One such probabilistic model is:

$$\mathbb{P}\left((s, r, o)\right) = \sigma\left(u_{s,o}^{\top} v_r\right), \qquad (1)$$

where $\sigma()$ is a sigmoid function, $u_{s,o}$ is an embedding of the entity pair (s, o), and v_r is an embedding of the relation r, which may be an OpenIE pattern or a relation from the target schema. All of the exposition and results in this paper use this factorization, though many of the techniques we present later could be applied easily to the other factorizations described in Riedel et al. (2013). Note that learning unique embeddings for OpenIE relations does not guarantee that similar patterns, such as the final two in Table 1, will be embedded similarly.

As with most of the techniques in Section 2.1, the data only consist of positive examples of edges. The absence of an annotated edge does not imply that the edge is false. In fact, we seek to predict some of these missing edges as true. Riedel et al. (2013) employ the Bayesian Personalized Ranking (BPR) approach of Rendle et al. (2009), which does not explicitly model unobserved edges as negative, but instead seeks to rank the probability of observed triples above unobserved triples.

Recently, Toutanova et al. (2015) extended USchema to not learn individual pattern embeddings v_r, but instead to embed text patterns using a deep architecture applied to word tokens. This shares statistical strength between OpenIE patterns with similar words. We leverage this approach in Section 3.2. Additional work has modeled the regularities of multi-hop paths through knowledge graph augmented with text patterns (Lao et al., 2011; Lao et al., 2012; Gardner et al., 2014; Neelakantan et al., 2015).

2.5 Multilingual Embeddings

Much work has been done on multilingual word embeddings. Most of this work uses aligned sentences from the Europarl dataset (Koehn, 2005) to align word embeddings across languages (Gouws et al., 2015; Luong et al., 2015; Hermann and Blunsom, 2014). Others (Mikolov et al., 2013; Faruqui et al., 2014) align separate single-language embedding models using a word-level dictionary. Mikolov et al. (2013) use translation pairs to learn a linear transform from one embedding space to another.

However, very little work exists on multilingual relation extraction. Faruqui and Kumar (2015) perform multilingual OpenIE relation extraction by projecting all languages to English using Google translate. However, as explained in Section 2.3 the OpenIE paradigm is not amenable to prediction within a fixed schema. Further, their approach does not generalize to low-resource languages where translation is unavailable – while we use translation dictionaries to improve our results, our experiments demonstrate that our method is effective even without this resource.

3 Methods

3.1 Universal Schema as Sentence Classifier

Similar to many link prediction approaches, (Riedel et al., 2013) perform transductive learning, where a model is learned jointly over train and test data. Predictions are made by using the model to identify edges that were unobserved in the test data but likely to be true. The approach is vulnerable to the *cold start* problem in collab-

Figure 2: Universal Schema jointly embeds KB and textual relations from Spanish and English, learning dense representations for entity pairs and relations using matrix factorization. Cells with a 1 indicate triples observed during training (left). The bold score represents a test-time prediction by the model (right). Using transitivity through KB/English overlap and English/Spanish overlap, our model can predict that a text pattern in Spanish evidences a KB relation despite no overlap between Spanish/KB entity pairs. At train time we use BPR loss to maximize the inner product of entity pairs with KB relations and text patterns encoded using a bidirectional LSTM. At test time we score compatibility between embedded KB relations and encoded textual patterns using cosine similarity. In our Spanish model we treat embeddings for a small set of English/Spanish translation pairs as a single word, e.g. casado and married.

	per:spouse	...	per:born_in	...	arg1 ´s wife arg2	...	arg1 was born in arg 2	...	arg1 es la esposa de arg2	...	arg1 nació en arg2	...
Barack Obama/ Michelle Obama	1				1

María Múnera/ Juan M Santos	**.93**											
...												
Barack Obama/ Hawaii			1				1					
María Múnera/ Colombia												1
...												

orative filtering (Schein et al., 2002): it is unclear how to form predictions for unseen entity pairs, without refactorizing the entire matrix or applying heuristics.

In response, this paper re-purposes USchema as a means to train a sentence-level relation classifier, like those in Section 2.2. This allows us to avoid errors from aligning distant supervision to the corpus, but is more deployable for real world applications. It also provides opportunities in Section 3.4 to improve multilingual AKBC.

We produce predictions using a very simple approach: (1) scan the corpus and extract a large quantity of triplets (s, r_{text}, o), where r_{text} is an OpenIE pattern. For each triplet, if the similarity between the embedding of r_{text} and the embedding of a target relation r_{schema} is above some threshold, we predict the triplet $(s, r_{\text{schema}}, o)$, and its provenance is the input sentence containing (s, r_{text}, o). We refer to this technique as *pattern scoring*. In our experiments, we use the cosine distance between the vectors (Figure 2). In Section 7.3, we discuss details for how to make this distance well-defined.

3.2 Using a Compositional Sentence Encoder to Predict Unseen Text Patterns

The pattern scoring approach is subject to an additional cold start problem: input data may contain patterns unseen in training. This section describes a method for using USchema to train a relation classifier that can take arbitrary context tokens (Section 2.3) as input.

Fortunately, the cold start problem for context tokens is more benign than that of entities since we can exploit statistical regularities of text: similar sequences of context tokens should be embedded similarly. Therefore, following Toutanova et al. (2015), we embed raw context tokens compositionally using a deep architecture. Unlike Riedel et al. (2013), this requires no manual rules to map text to OpenIE patterns and can embed any possible input string. The modified USchema likelihood is:

$$\mathbb{P}\left((s, r, o)\right) = \sigma\left(u_{s,o}^{\top}\text{Encoder}(r)\right). \tag{2}$$

Here, if r is raw text, then Encoder(r) is parameterized by a deep architecture. If r is from the target schema, Encoder(r) is a produced by a lookup table (as in traditional USchema). Though such an encoder increases the computational cost of test-time prediction over straightforward pattern matching, evaluating a deep architecture can be done in large batches in parallel on a GPU.

Both convolutional networks (CNNs) and recurrent networks (RNNs) are reasonable encoder architectures, and we consider both in our experiments. CNNs have been useful in a variety of NLP applications (Collobert et al., 2011; Kalchbrenner et al., 2014; Kim, 2014). Unlike Toutanova et al. (2015), we also consider RNNs, specifically Long-Short Term Memory Networks

(LSTMs) (Hochreiter and Schmidhuber, 1997). LSTMs have proven successful in a variety of tasks requiring encoding sentences as vectors (Sutskever et al., 2014; Vinyals et al., 2014). In our experiments, LSTMs outperform CNNs.

There are two key differences between our sentence encoder and that of Toutanova et al. (2015). First, we use the encoder at test time, since we process the context tokens for held-out data. On the other hand, Toutanova et al. (2015) adopt the transductive approach where the encoder is only used to help train better representations for the relations in the target schema; it is ignored when forming predictions. Second, we apply the encoder to the raw text between entities, while Toutanova et al. (2015) first perform syntactic dependency parsing on the data and then apply an encoder to the path between the two entities in the parse tree. We avoid parsing, since we seek to perform multilingual AKBC, and many languages lack linguistic resources such as treebanks. Even parsing non-newswire English text, such as tweets, is extremely challenging.

3.3 Modeling Frequent Text Patterns

Despite the coverage advantages of using a deep sentence encoder, separately embedding each OpenIE pattern, as in Riedel et al. (2013), has key advantages. In practice, we have found that many high-precision patterns occur quite frequently. For these, there is sufficient data to model them with independent embeddings per pattern, which imposes minimal inductive bias on the relationship between patterns. Furthermore, some discriminative phrases are idiomatic, i.e.. their meaning is not constructed compositionally from their constituents. For these, a sentence encoder may be inappropriate.

Therefore, pattern embeddings and deep token-based encoders have very different strengths and weaknesses. One values specificity, and models the head of the text distribution well, while the other has high coverage and captures the tail. In experimental results, we demonstrate that an ensemble of both models performs substantially better than either in isolation.

3.4 Multilingual Relation Extraction with Zero Annotation

The models described in previous two sections provide broad-coverage relation extraction that can generalize to all possible input entities and text patterns, while avoiding error-prone alignment of distant supervision to a corpus. Next, we describe techniques for an even more challenging generalization task: relation classification for input sentences in completely different languages.

Training a sentence-level relation classifier, either using the alignment-based techniques of Section 2.2, or the alignment-free method of Section 3.1, requires an available KB of seed facts that have supporting evidence in the corpus. Unfortunately, available KBs have low overlap with corpora in many languages, since KBs have cultural and geographical biases. In response, we perform multilingual relation extraction by jointly modeling a high-resource language, such as English, and an alternative language with no KB annotation. This approach provides transfer learning of a predictive model to the alternative language, and generalizes naturally to modeling more languages.

Extending the training technique of Section 3.1 to corpora in multiple languages can be achieved by factorizing a matrix that mixes data from a KB and from the two corpora. In Figure 1 we split the entities of a multilingual training corpus into sets depending on whether they have annotation in a KB and what corpora they appear in. We can perform transfer learning of a relation extractor to the low-resource language if there are entity pairs occurring in the two corpora, even if there is no KB annotation for these pairs. Note that we do not use the entity pair embeddings at test time: They are used only to bridge the languages during training. To form predictions in the low-resource language, we can simply apply the pattern scoring approach of Section 3.1.

In Section 5, we demonstrate that jointly learning models for English and Spanish, with no annotation for the Spanish data, provides fairly accurate Spanish AKBC, and even improves the performance of the English model. Note that we are not performing *zero-shot* learning of a Spanish model (Larochelle et al., 2008). The relations in the target schema are language-independent concepts, and we have supervision for these in English.

3.5 Tied Sentence Encoders

The sentence encoder approach of Section 3.2 is complementary to our multilingual modeling technique: we simply use a separate encoder for each language. This approach is sub-optimal, however, because each sentence encoder will have a separate matrix of word embeddings for its vocabulary, despite the fact that there may be considerable shared structure between the languages. In response, we propose a straightforward method for tying the parameters of the sentence encoders across languages.

Drawing on the dictionary-based techniques described in Section 2.5, we first obtain a list of word-word translation pairs between the languages using a translation dictionary. The first layer of our deep text encoder consists of a word embedding lookup table. For the aligned word types, we use a single cross-lingual embedding. Details of our approach are described in Appendix 7.5.

4 Task and System Description

We focus on the TAC KBP slot-filling task. Much related work on embedding knowledge bases evaluates on the FB15k dataset (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015; Yang et al., 2015; Toutanova et al., 2015). Here, relation extraction is posed as link prediction on a subset of Freebase. This task does not capture the particular difficulties we address: (1) evaluation on entities and text unseen during training, and (2) zero-annotation learning of a predictor for a low-resource language.

Also, note both Toutanova et al. (2015) and Riedel et al. (2013) explore the pros and cons of learning embeddings for entity pairs vs. separate embeddings for each entity. As this is orthogonal to our contributions, we only consider entity pair embeddings, which performed best in both works when given sufficient data.

4.1 TAC Slot-Filling Benchmark

The aim of the TAC benchmark is to improve both coverage and quality of relation extraction evaluation compared to just checking the extracted facts against a knowledge base, which can be incomplete and where the provenances are not verified. In the slot-filling task, each system is given a set of paired query entities and relations or 'slots' to fill, and the goal is to correctly fill as many slots as possible along with provenance from the corpus. For example, given the query entity/relation pair (*Barack Obama, per:spouse*), the system should return the entity *Michelle Obama* along with sentence(s) whose text expresses that relation. The answers returned by all participating teams, along with a human search (with timeout), are judged manually for correctness, i.e. whether the provenance specified by the system indeed expresses the relation in question.

In addition to verifying our models on the 2013 and 2014 English slot-filling task, we evaluate our Spanish models on the 2012 TAC Spanish slot-filling evaluation. Because this TAC track was never officially run, the coverage of facts in the available annotation is very small, resulting in many correct predictions being marked incorrectly as precision errors. In response, we manually annotated all results returned by the models considered in Table 4. Precision and recall are calculated with respect to the union of the TAC annotation and our new labeling[1].

4.2 Retrieval Pipeline

Our retrieval pipeline first generates all valid slot filler candidates for each query entity and slot, based on entities extracted from the corpus using FACTORIE (McCallum et al., 2009) to perform tokenization, segmentation, and entity extraction. We perform entity linking by heuristically linking all entity mentions from our text corpora to a Freebase entity using anchor text in Wikipedia. Making use of the fact that most Freebase entries contain a link to the corresponding Wikipedia page, we link all entity mentions from our text corpora to a Freebase entity by the following process: First, a set of candidate entities is obtained by following frequent link anchor text statistics. We then select that candidate entity for which the cosine similarity between the respective Wikipedia and the sentence context of the mention is highest, and link to that entity if a threshold is exceeded.

An entity pair qualifies as a candidate prediction if it meets the type criteria for the slot.[2] The TAC 2013 English and Spanish newswire corpora each contain about 1 million newswire documents from 2009–2012. The document retrieval and entity matching components of our relation extraction pipeline are based on RelationFactory (Roth et al., 2014), the top-ranked system of the 2013 English slot-filling task. We also use the English distantly supervised training data from this system, which aligns the TAC 2012 corpus to Freebase. More details on alignment are described in Appendix 7.4.

As discussed in Section 3.3, models using a deep sentence encoder and using a pattern lookup table have complementary strengths and weaknesses. In response, we present results where we ensemble the outputs of the two models by simply taking the union of their individual outputs. Slightly higher results might be obtained through more sophisticated ensembling schemes.

4.3 Model Details

All models are implemented in Torch (code publicly available[3]). Models are tuned to maximize F1 on the 2012 TAC KBP slot-filling evaluation. We additionally tune the thresholds of our pattern scorer on a per-relation basis to maximize F1 using 2012 TAC slot-filling for English and the 2012 Spanish slot-filling development set for Spanish. As in Riedel et al. (2013), we train using the BPR loss of Rendle et al. (2009). Our CNN is implemented as described in Toutanova et al. (2015), using width-3 convolutions, followed by tanh and max pool layers. The LSTM uses a bi-directional architecture where the forward and backward representations of each hidden state are averaged, followed by max pooling over time. See Section 7.2

We also report results including an alternate names (AN) heuristic, which uses automatically-extracted rules to detect the TAC 'alternate name' relation. To achieve this, we collect frequent Wikipedia link anchor texts for

[1] Following Surdeanu et al. (2012) we remove facts about undiscovered entities to correct for recall.

[2] Due to the difficulty of retrieval and entity detection, the maximum recall for predictions is limited. For this reason, Surdeanu et al. (2012) restrict the evaluation to answer candidates returned by their system and effectively rescaling recall. We do not perform such a re-scaling in our English results in order to compare to other reported results. Our Spanish numbers are rescaled. All scores reflect the 'anydoc' (relaxed) scoring to mitigate penalizing effects for systems not included in the evaluation pool.

Model	Recall	Precision	F1
CNN	31.6	36.8	34.1
LSTM	32.2	39.6	**35.5**
USchema	29.4	42.6	34.8
USchema+LSTM	34.4	41.9	37.7
USchema+LSTM+Es	38.1	40.2	**39.2**
USchema+LSTM+AN	36.7	43.1	39.7
USchema+LSTM+Es+AN	40.2	41.2	**40.7**
Roth et al. (2014)	35.8	45.7	40.2

Table 2: Precision, recall and F1 on the English TAC 2013 slot-filling task. AN refers to alternative names heuristic and Es refers to the addition of Spanish text at train time. LSTM+USchema ensemble outperforms any single model, including the highly-tuned top 2013 system of Roth et al. (2014), despite using no handwritten patterns.

Model	Recall	Precision	F1
CNN	28.1	29.0	28.5
LSTM	27.3	32.9	**29.8**
USchema	24.3	35.5	28.8
USchema+LSTM	34.1	29.3	31.5
USchema+LSTM+Es	34.4	31.0	**32.6**

Table 3: Precision, recall and F1 on the English TAC 2014 slot-filling task. Es refers to the addition of Spanish text at train time. The AN heuristic is ineffective on 2014 adding only 0.2 to F1. Our system would rank 4/18 in the official TAC 2014 competition behind systems that use hand-written patterns and active learning despite our system using neither of these additional annotations (Surdeanu and Ji., 2014).

each query entity. If a high probability anchor text co-occurs with the canonical name of the query in the same document, we return the anchor text as a slot filler.

5 Experimental Results

In experiments on the English and Spanish TAC KBC slot-filling tasks, we find that both USchema and LSTM models outperform the CNN across languages, and that the LSTM tends to perform slightly better than USchema as the only model. Ensembling the LSTM and USchema models further increases final F1 scores in all experiments, suggesting that the two different types of model compliment each other well. Indeed, in Section 5.3 we present quantitative and qualitative analysis of our results which further confirms this hypothesis: the LSTM and USchema models each perform better on different pattern lengths and are characterized by different precision-recall tradeoffs.

Model	Recall	Precision	F1
LSTM	9.3	12.5	10.7
LSTM+Dict	14.7	15.7	15.2
USchema	15.2	17.5	16.3
USchema+LSTM	21.7	14.5	17.3
USchema+LSTM+Dict	26.9	15.9	**20.0**

Table 4: Zero-annotation transfer learning F1 scores on 2012 Spanish TAC KBP slot-filling task. Adding a translation dictionary improves all encoder-based models. Ensembling LSTM and USchema models performs the best.

5.1 English TAC Slot-filling Results

Tables 2 and 3 present the performance of our models on the 2013 and 2014 English TAC slot-filling tasks. Ensembling the LSTM and USchema models improves F1 by 2.2 points for 2013 and 1.7 points for 2014 over the strongest single model on both evaluations, LSTM. Adding the alternative names (AN) heuristic described in Section 4.3 increases F1 by an additional 2 points on 2013, resulting in an F1 score that is competitive with the state-of-the-art. We also demonstrate the effect of jointly learning English and Spanish models on English slot-filling performance. Adding Spanish data improves our F1 scores by 1.5 points on 2013 and 1.1 on 2014 over using English alone. This places are system higher than the top performer at the 2013 TAC slot-filling task even though our system uses no hand-written rules.

The state of the art systems on this task all rely on matching handwritten patterns to find additional answers while our models use only automatically generated, indirect supervision; even our AN heuristics (Section 4.2) are automatically generated. The top two 2014 systems were Angeli et al. (2014) and RPI Blender (Surdeanu and Ji., 2014) who achieved F1 scores of 39.5 and 36.4 respectively. Both of these systems used additional active learning annotation. The third place team (Lin et al., 2014) relied on highly tuned patterns and rules and achieved an F1 score of 34.4.

Our model performs substantially better on 2013 than 2014 for two reasons. First, our RelationFactory (Roth et al., 2014) retrieval pipeline was a top retrieval pipeline on the 2013 task, but was outperformed on the 2014 task which introduced new challenges such as confusable entities. Second, improved training using active learning gave the top 2014 systems a boost in performance. No 2013 systems, including ours, use active learning. Bentor et al. (2014), the 4th place team in the 2014 evaluation, used the same retrieval pipeline (Roth et al., 2014) as our model and achieved an F1 score of 32.1.

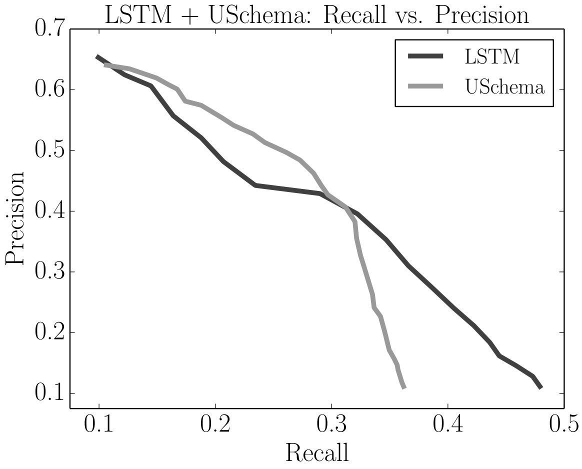

Figure 3: Precision-Recall curves for USchema and LSTM on 2013 TAC slot-filling. USchema achieves higher precision values whereas LSTM has higher recall.

5.2 Spanish TAC Slot-filling Results

Table 4 presents 2012 Spanish TAC slot-filling results for our multilingual relation extractors trained using zero-annotation transfer learning. Tying word embeddings between the two languages results in substantial improvements for the LSTM. We see that ensembling the non-dictionary LSTM with USchema gives a slight boost over USchema alone, but ensembling the dictionary-tied LSTM with USchema provides a significant increase of nearly 4 F1 points over the highest-scoring single model, USchema. Clearly, grounding the Spanish data using a translation dictionary provides much better Spanish word representations. These improvements are complementary to the baseline USchema model, and yield impressive results when ensembled.

In addition to embedding semantically similar phrases from English and Spanish to have high similarity, our models also learn high-quality multilingual word embeddings. In Table 5 we compare Spanish nearest neighbors of English query words learned by the LSTM with dictionary ties versus the LSTM with no ties, using no unsupervised pre-training for the embeddings. Both approaches jointly embed Spanish and English word types, using shared entity embeddings, but the dictionary-tied model learns qualitatively better multilingual embeddings.

5.3 USchema vs LSTM

We further analyze differences between USchema and LSTM in order to better understand why ensembling the models results in the best performing system. Figure 3 depicts precision-recall curves for the two models on the 2013 slot-filling task. As observed in earlier results, the LSTM achieves higher recall at the loss of

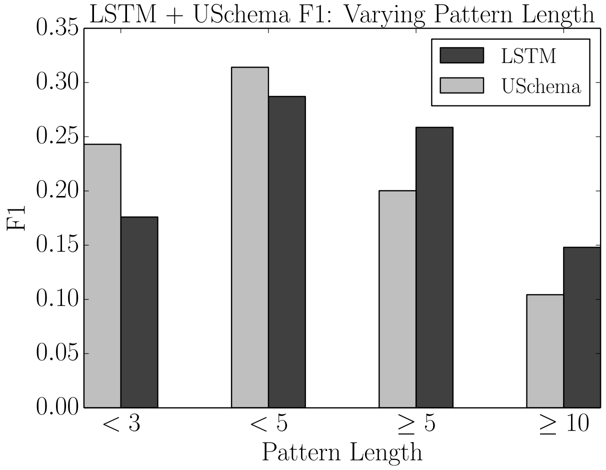

Figure 4: F1 achieved by USchema vs. LSTM models for varying pattern token lengths on 2013 TAC slot-filling. LSTM performs better on longer patterns whereas USchema performs better on shorter patterns.

some precision, whereas USchema can make more precise predictions at a lower threshold for recall. In Figure 4 we observe evidence for these different precision-recall trade-offs: USchema scores higher in terms of F1 on shorter patterns whereas the LSTM scores higher on longer patterns. As one would expect, USchema successfully matches more short patterns than the LSTM, making more precise predictions at the cost of being unable to predict on patterns unseen during training. The LSTM can predict using any text between entities observed at test time, gaining recall at the loss of precision. Combining the two models makes the most of their strengths and weaknesses, leading to the highest overall F1.

Qualitative analysis of our English models also suggests that our encoder-based models (LSTM) extract relations based on a wide range of semantically similar patterns that the pattern-matching model (USchema) is unable to score due to a lack of exact string match in the test data. For example, Table 6 lists three examples of the *per:children* relation that the LSTM finds which USchema does not, as well as three patterns that USchema does find. Though the LSTM patterns are all semantically and syntactically similar, they each contain different specific noun phrases, e.g. *Lori*, *four children*, *toddler daughter*, *Lee and Albert*, etc. Because these specific nouns weren't seen during training, USchema fails to find these patterns whereas the LSTM learns to ignore the specific nouns in favor of the overall pattern, that of a parent-child relationship in an obituary. USchema is limited to finding the relations represented by patterns observed during training, which limits the patterns matched at test-time to short and common patterns; all the USchema patterns matched at test time were similar to those listed in Table 6: variants of *'s son, '*.

LSTM
McGregor *is survived by his wife, Lori, and four children, daughters Jordan,* **Taylor** and Landri, and a son, Logan.
In addition to his wife, **Mays** *is survived by a toddler daughter and a son,* **Billy Mays Jr.**, who is in his 20s.

USchema
Dio *'s son,* **Dan Padavona**, cautioned the memorial crowd to be screened regularly by a doctor and take care of themselves, something he said his father did not do.
But **Marshall** *'s son,* **Philip**, told a different story.
"I'd rather have Sully doing this than some stranger, or some hotshot trying to be the next Billy Mays," said the guy who actually is the next **Billy Mays**, *his son* **Billy Mays III**.

Table 6: Examples of the *per:children* relation discovered by the LSTM and Universal Schema. Entities are bold and patterns italicized. The LSTM models a richer set of patterns

6 Conclusion

By jointly embedding English and Spanish corpora along with a KB, we can train an accurate Spanish relation extraction model using no direct annotation for relations in the Spanish data. This approach has the added benefit of providing significant accuracy improvements for the English model, outperforming the top system on the 2013 TAC KBC slot filling task, without using the hand-coded rules or additional annotations of alternative systems. By using deep sentence encoders, we can perform prediction for arbitrary input text and for entities unseen in training. Sentence encoders also provides opportunities to improve cross-lingual transfer learning by sharing word embeddings across languages. In future work we will apply this model to many more languages and domains besides newswire text. We would also like to avoid the entity detection problem by using a deep architecture to both identify entity mentions and identify relations between them.

Abstract

Can crowdsourced annotation of training data boost performance for relation extraction over methods based solely on distant supervision? While crowdsourcing has been shown effective for many NLP tasks, previous researchers found only minimal improvement when applying the method to relation extraction. This paper demonstrates that a much larger boost is possible, e.g., raising F1 from 0.40 to 0.60. Furthermore, the gains are due to a simple, generalizable technique, *Gated Instruction*, which combines an interactive tutorial, feedback to correct errors during training, and improved screening.

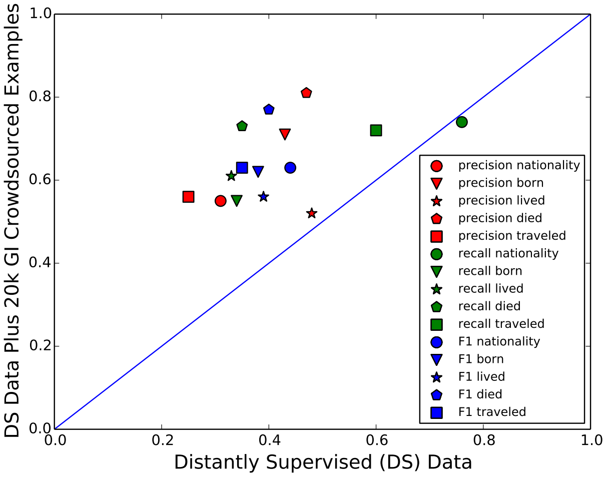

Figure 1: Adding 20K crowdsourced instances, acquired using Gated Instruction, to 700K examples from distant supervision raises precision, recall, and F1 for nearly all relations and raises overall F1 from 0.40 to 0.60 with MIML-RE learning.

1 Introduction

Relation extraction (RE) is the task of identifying instances of relations, such as *nationality (person, country)* or *place_of_birth (person, location)*, in passages of natural text. Since RE enables a broad range of applications — including question answering and knowledge base population — it has attracted attention from many researchers. Many approaches to RE use supervised machine learning, e.g., (Soderland et al., 1995; Califf and Mooney, 1997; Lafferty et al., 2001), but these methods require a large, human-annotated training corpus that may be unavailable.

In response, researchers developed methods for *distant supervision* (DS) in which a knowledge base such as Wikipedia or Freebase is used to automatically tag training examples from a text corpus (Wu and Weld, 2007; Mintz et al., 2009). Indeed, virtually all entries to recent TAC KBP relation extraction competitions use distant supervision (Ji and Grishman, 2011). However, distant supervision provides noisy training data with many false positives, and this limits the precision of the resulting extractors (see Section 2). A natural assumption is that human-annotated training data, either alone or in conjunction with distant supervision, would give better precision. In particular, Snow et al. (2008) showed that, for many NLP tasks, crowdsourced data is as good as or better than that annotated by experts.

It is quite surprising, therefore, that researchers who have applied crowdsourced annotation to relation extraction argue the *opposite*, that crowdsourcing provides only minor improvement:

Proceedings of NAACL-HLT 2016, pages 897–906,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

- Zhang et al. (2012) conclude that "Human feedback has relatively small impact on precision and recall." Instead, they advise applying distant supervision to vastly more data.
- Pershina et al. (2014) assert "Simply taking the union of the hand-labeled data and the corpus labeled by distant supervision is not effective since hand-labeled data will be swamped by a larger amount of distantly labeled data." Instead, they introduce a complex feature-creation approach which improves the F1-score of MIML-RE, a state-of-the-art extractor (Surdeanu et al., 2012), just 4%, from 0.28 to 0.32 on a set of 41 TAC KBP relations.
- Angeli et al. (2014) explored a novel active learning method to control crowdsourcing, but found no improvement from adding the crowdsourced training to distant supervision using the default settings of MIML-RE, and only a 0.04 improvement in F1 when they initialized MIML-RE using the crowdsourced training.

This paper reports quite a different result, showing up to a 0.20 boost to F1. By carefully designing a quality-controlled crowdsourcing workflow that uses *Gated Instruction* (GI), we are able to create much more accurate annotations than those produced by previous crowdsourcing methods. GI (summarized in Figure 2) includes an interactive tutorial to train workers, providing immediate feedback to correct mistakes during training. Workers are then screened by their accuracy on gold-standard questions while doing the annotation. We show that GI generates much better training data than crowdsourcing used by other researchers, and that this leads to dramatically improved extractors.

Adding GI-crowdsourced annotations of the example sentences selected by Angeli et al.'s active learning method provides a much larger boost to the performance of the learned extractors than when their traditional crowdsourcing methods are used. In fact, the improvement due to our crowdsourcing method substantially outweighs the benefits of Angeli et al.'s active learning strategy as well. In total, this paper makes the following contributions:

- We present the design of the Gated Instruction crowdsourcing workflow with worker training and screening that ensures high-precision annotations for relation extraction training data in the presence of unreliable workers.
- We demonstrate that Gated Instruction increases the annotation quality of crowdsourced training data, raising precision from 0.50 to 0.77 and recall from 0.70 to 0.78, compared to Angeli et al.'s crowdsourced tagging of the same sentences. We make the data available for future research (Section 4.1).
- Augmenting distant supervision with 10K of Angeli et al.'s training examples annotated using Gated Instruction boosts F1 from 0.40 to 0.47, compared to 0.43, the result from using Angeli et al.'s crowdsourced annotations.
- We demonstrate that improved crowdsourcing has a greater effect than Angeli et al.'s active learning approach. Adding 10K *randomly selected* sentences, labeled using Gated Instruction, to distantly supervised data raises F1 by 6 points, compared to the 3 point gain from adding Angeli et al.'s crowdsourced labels on their active-learning sample.
- In contradiction to Zhang et al.'s prior claims, we show that increasing amounts of crowdsourced data can dramatically improve extractor performance. When we augmented distant supervision with 20K instances using Gated Instruction, we show that F1 is raised from 0.40 to 0.60.
- Gated Instruction may also reduce the cost of crowdsourcing. We show that with the high quality Gated Instruction annotations, a single annotation is more effective than majority vote over multiple annotators.

Our results provide a clear lesson for future researchers hoping to use crowdsourced data for NLP tasks. Extreme care must be exercised in the details of the workflow design to ensure quality data and useful results.

2 Background and Related Work

Distant supervision (DS) is a method for training extractors that obviates the need for human-labeled training data by heuristically matching facts from a background knowledge base (KB) to a large textual corpus. Originally developed to extract biological relations (Craven and Kumlien, 1999), DS was later extended to extract relations from Wikipedia infoboxes (Wu and Weld, 2007) and Freebase (Mintz et al., 2009). Specifically, distant supervision uses the KB to find pairs of entities E_1 and E_2 for which a relation R holds. Distant supervision then makes that assumption that any sentence that contains a mention of both E_1 and E_2 is a positive training instance for $R(E_1, E_2)$.

Unfortunately, this assumption leads to a large proportion of false positive training instances. For example, Freebase asserts that Nicolas Sarkozy was born in Paris, but nearly all sentences in a news corpus that mention Sarkozy and Paris do not give evidence for a *place_of_birth* relation. To address this shortcoming, there have been attempts to model the relation dependencies as multi-instance multiclass (Bunescu and Mooney, 2007; Riedel et al., 2010) leading to state-of-the art extraction learners MultiR (Hoffmann et al., 2011) and MIML-RE (Surdeanu et al., 2012).

Additionally, other techniques developed to study the relation extraction problem have achieved certain success, including universal schemas (Riedel et al., 2013), and deep learning (Nguyen and Grishman, 2014). Despite these technical innovations, the best systems at the TAC-KBP evaluation[1] still require substantial human effort, typically handwritten extraction rules (Surdeanu and Ji, 2014).

Recently researchers have explored the idea of augmenting distant supervision with a small amount of crowdsourced annotated data in an effort to improve relation extraction performance (Angeli et al., 2014; Zhang et al., 2012; Pershina et al., 2014).

Zhang et al. (2012) studied how the size of the crowdsourcing training corpus and distant supervision corpus affect the performance of the relation extractor. They considered the 20 TAC KBP relations that had a corresponding Freebase relation. They added up to 20K instances of crowd data to 1.8M DS instances using sparse logistic regression, tuning the relative weight of crowdsourced and DS training. However, they saw only a marginal improvement from F1 0.20 to 0.22 when adding crowdsourced training to DS training, and conclude that human feedback has little impact.

Angeli et al. (2014) also investigated methods for infusing distant supervision with crowdsourced annotations in the Stanford TAC-KBP system. They experimented with several methods, including adding a random sample of annotated sentences to the training mix, and using active learning to select which sentences should be annotated by humans. Their best results were what they termed "Sample JS," training a committee of MIML-RE classifiers and then sampling the sentences to be crowdsourced weighted by the divergence of classifications.

Surprisingly, they found that the simple approach of just adding crowdsourced data to the training mix *hurt* extractor performance slightly. They conclude that the most important use for crowdsourced annotations is as a way to *initialize* MIML-RE, mitigating the problem of local minima during learning. When they initialized MIML-RE with 10K Sample JS crowdsourced instances and then trained on a combination of Sample JS crowdsourced and DS instances, this raised F1 from 0.34 to 0.38.

Pershina et al. (2014) also exploited a small set of highly informative hand-labeled training data to improve distant supervision. Rather than crowdsourcing, they used the set of 2,500 labeled instances from the KBP 2012 assessment data. They state that "Simply taking the union of the hand-labeled data and the corpus labeled by distant supervision is not effective since hand-labeled data will be swamped by a larger amount of distantly labeled data." Instead they use the hand-annotated data to learn *guidelines* that are included in a graphical prediction model that extends MIML-RE, trained using distant supervision. This raised F1 from 0.28 to 0.32 over a comparison system without the learned guidelines.

Gormley et al. (2010) filtered crowdsourced workers by agreement with gold questions and by noting which workers took fewer than three seconds per question. They reported good inter-annotator agreement, but did not build a relation extractor from their data.

Both Zhang et al. and Angeli et al. used traditional methods to ensure the quality of their crowdsourced data. Zhang et al. replicated each question three times and included a gold question (i.e., one with a known answer) in each set of five questions. They only used answers from workers who answered at least 80% of the gold-standard questions correctly.

[1] http://www.nist.gov/tac/

Angeli et al. included two gold-standard questions in every set of 15. They discarded sets in which both controls were answered incorrectly, and additionally discarded all submissions from workers who failed the controls on more than one third of their submissions. They collected five annotations for each example, and used the majority vote as the ground truth in their training. They did not report the resulting quality of their crowdsourced annotations, but did release their data, allowing us to measure its precision and recall (see Section 4.1).

We argue that all these systems would have gotten better performance by focusing attention on the quality of their crowdsourced annotation. We demonstrate that by improving the crowdsourcing workflow, we achieve a higher F1 score, both with the crowdsourced training alone and in combination with distant supervision.

Our work adds to the existing large body of work that shows that crowdsourcing can be and is an effective and efficient method for training machine learning algorithms. Snow et al. (2008) showed that multiple workers can simulate an expert worker in a variety of natural language tasks. Many researchers (e.g., (Dawid and Skene, 1979; Whitehill et al., 2009)) have designed methods to aggregate crowd labels in order to reduce noise, and Sheng et al. (2008) showed that paying multiple crowd workers to relabel examples, as opposed to labeling new ones, can increase the accuracy of a classifier.

The effectiveness of crowdsourcing is dependent on a number of human factors. Several researchers have studied how worker retention is affected by payment schemes (Mao et al., 2013), recruitment techniques (Ipeirotis and Gabrilovich, 2014), or attention diversions (Dai et al., 2015). Ipeirotis and Gabrilovich show that volunteer workers may provide higher quality work. By contrast, we show that paid workers, too, can produce high quality work through careful attention to worker training and testing.

3 Gated Instruction Crowdsourcing

We used Amazon Mechanical Turk for our crowdsourcing, but designed our own website to implement the Gated Instruction (GI) protocol, rather than use the platform Amazon provides directly. This allowed us greater control over the UI and the worker experience. The primary benefit of GI is worker training, which is necessary across platforms, so we expect to see comparable results on other platforms, such as CrowdFlower.

Gated Instruction Crowdsourcing Protocol

Phase I: Interactive tutorial

1. Give a clear definition of each relation and tagging criteria.
2. Worker annotates practice sentences that illustrate each relation.
3. Give immediate feedback after each practice sentence.

Phase II: Screening questions

1. Worker annotates representative set of 5 gold questions.
2. Give feedback to worker on each question.
3. Eliminate workers who fail a majority of these questions.

Phase III: Batches of questions (with continued screening)

1. Include gold questions without feedback.
2. Sets of 5 gold questions in batches (20 questions) with exponentially decreasing frequency.
3. Eliminate workers with accuracy lower than 80% on last 10 gold questions.

General Principles

1. Accept only workers with AMT reputation above threshold.
2. Provide a link to definitions of relations during the task.
3. Worker may not proceed before correcting mistakes shown in feedback.
4. Give feedback on how much earned so far and performance on gold questions after each batch.
5. Remind of a bonus from completing all 10 batches.

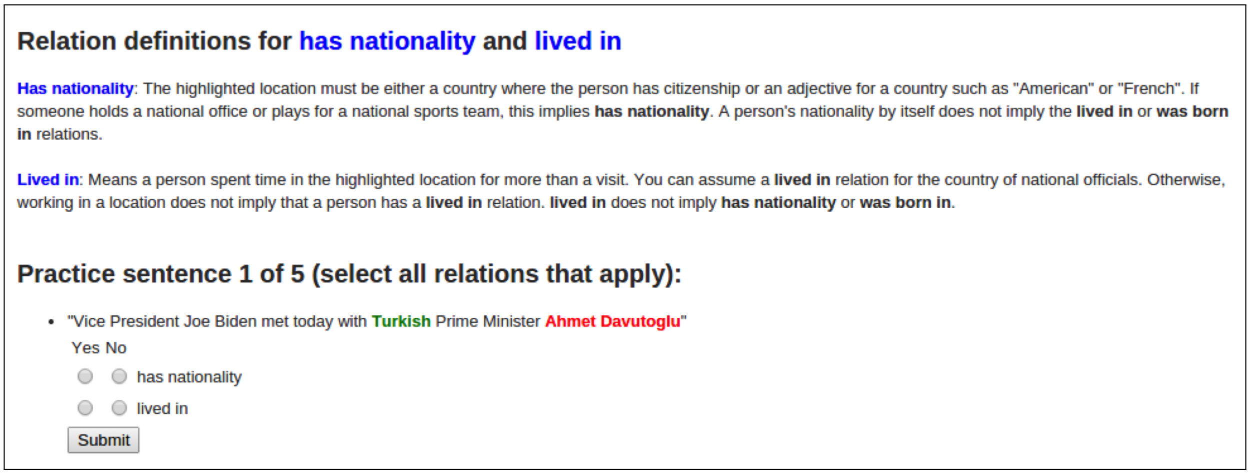
Figure 2: Architecture of the Gated Instruction protocol.

The ideas behind Gated Instruction are summarized in Figure 2. The workflow proceeds in three phases: tutorial, weed-out, and work (described below) with a focus on well-known user interface principles (rapid feedback and availability of extra help). While conceptually simple, we show this approach has a much bigger effect on the resulting learned NLP system than a more complex graphical model.

3.1 Interactive Tutorial Design

The most important step in crowdsourcing is ensuring that workers understand the task. To this end we required workers to complete an interactive tutorial to learn the criteria for the relations to be annotated.

Since we wanted to test our extractor against official answers for the TAC-KBP Slot Filling evaluation, our tutorial taught workers to follow the official KBP guidelines. These guidelines require tagging only relations directly stated in the sentence, and discourage plausible inferences. For example, if a sentence states only that a person works in a city, then annotating a *place_of_residence* relation with



Relation definitions for has nationality and lived in

Has nationality: The highlighted location must be either a country where the person has citizenship or an adjective for a country such as "American" or "French". If someone holds a national office or plays for a national sports team, this implies **has nationality**. A person's nationality by itself does not imply the **lived in** or **was born in** relations.

Lived in: Means a person spent time in the highlighted location for more than a visit. You can assume a **lived in** relation for the country of national officials. Otherwise, working in a location does not imply that a person has a **lived in** relation. **lived in** does not imply **has nationality** or **was born in**.

Practice sentence 1 of 5 (select all relations that apply):

- "Vice President Joe Biden met today with **Turkish** Prime Minister **Ahmet Davutoglu**"

Yes No
○ ○ has nationality
○ ○ lived in

Figure 3: Tutorial page that teaches guidelines for *nationality* and *lived_in*. The worker answers practice sentences with immediate feedback that teach each relation.

that city is counted as an error, even if it is probable that the person lives there.

Figure 3 shows a page from the tutorial that explains annotation guidelines for *nationality* and *lived_in* (i.e., *place_of_residence*). This figure shows the first page of the tutorial — as more relations are taught, those relations are added to the question. The real questions are asked in the same format later on for consistency. The worker can click on a link to see the relation definitions at any time during the tutorial or while doing the actual task. If workers make a mistake during the tutorial, they are given immediate feedback along with an explanation for the correct answer. The workers cannot proceed without correcting all errors on all problems in the tutorial.

3.2 Adaptive Worker Screening

After examining worker mistakes in a preliminary experiment, we manually selected a set of gold questions (i.e., questions with unambiguous, known answers) that workers are likely to get wrong if they don't clearly understand the annotation criteria. The gold questions are grouped into sets of 5 questions that represent all relations being annotated. The first 5 questions (the screening phase) are used to eliminate spammers and careless workers early on. These questions look no different from normal questions, but we give feedback to workers with the right answers if workers give wrong answers to any of these questions. If a worker fails a majority of such questions, the worker is disqualified from the task.

We then place additional sets of gold questions among real test questions without feedback in order to spot-check workers' responses. In our experience, workers who start out with high accuracy maintain that accuracy throughout the entire session. Therefore, we place the gold questions in exponentially decreasing frequency among the batches of 20 questions (5 gold questions in batches 2, 4, 8, etc.), and allow only workers who maintain at least 80% accuracy on the most recent 10 gold questions to continue with the task. Our task was not large enough to attract problems of collusion, but more lucrative or long-running tasks may require continual generation of new gold questions in order to combat sharing of answers among workers (Oleson et al., 2011). Techniques such as expectation maximization (Dawid and Skene, 1979) can be used to produce new gold questions based on worker answers.

3.3 Motivational Feedback

We want workers to stay motivated, so our crowdsourcing system also provides feedback to workers. In particular, workers receive adaptive per-batch message feedback at the end of each batch of questions (every 20 questions) about how well they did on the gold questions in the past batches, how much they have earned so far, and a reminder of the bonus for finishing all 10 batches. We paid workers $0.50 for each batch of 20 questions with a bonus of $1.00 for finishing 10 batches.

4 Experimental Results

In this section, we address the following questions:

- Does Gated Instruction produce training data with higher precision and recall than other research in crowdsourcing for relation extraction?
- Does higher quality crowdsourced training data result in higher extractor performance when adding crowdsourcing to distant supervision?
- How does the boost in extractor performance on random training instances labeled with Gated Instruction compare to that with instances labeled using traditional crowdsourcing techniques selected with active learning?
- How does extractor performance increase with larger amounts of Gated Instruction training data?
- What's the most cost-effective way to aggregate worker votes? Are multiple annotations needed, given high quality crowdsourcing?

4.1 Quality of Gated Instruction Training

We took the best training set of 10,000 instances from Angeli et al.'s 2014 system that selected training instances using active learning (their Sample JS data). In order to focus on the effect of crowdsourcing, we restricted our attention to four distinct relations between *person* and *location* that were used by previous researchers: *nationality*, *place_of_birth*, *place_of_residence*, and *place_of_death*[2]. We then sent these sentences to crowdsourced workers using the Gated Instruction protocol.

To evaluate the crowdsourced training data quality, we hand-tagged the crowdsourced annotations from both our Gated Instruction system and Angeli et al.'s work on 200 random instances. Annotations were considered correct if they followed the TAC-KBP annotation guidelines. Two authors tagged the sample with 87% agreement and then reconciled opinions to agree on consensus labels.

The training precision, recall, and F1 are shown in Figure 4. In this and all other experiments, aggregate statistics are macro-averaged across relations. We also include the training quality from Zhang et al., although this is on a different set of sentences and only for *place_of_birth*, *place_of_residence*, and *place_of_death*.

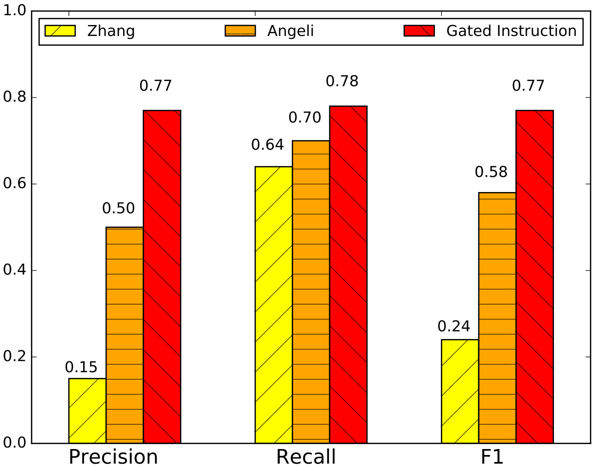


Figure 4: The training data produced by Gated Instruction has much higher precision and somewhat higher recall than that of Angeli et al. or Zhang et al.

Our Gated Instruction protocol gives higher F1 for the training set of each of the four relations we compared with Angeli's crowdsourcing on the same sentences. Our overall F1 was 0.77, compared to 0.58 for Angeli et al. and 0.24 for Zhang et al. The difference in precision is most dramatic, with our system achieving 0.77 compared to 0.50 and 0.15.

Worker agreement with GI was surprisingly high. Two workers agreed on between 78% to 97% of the instances, depending on the relation. The average agreement was 88%. The data is available for research purposes.[3]

4.2 Integrating Crowdsourced Data with the Relation Extraction Pipeline

The pipeline of our relation extraction system is as follows. First we collected sentences of training data from the TAC-KBP newswire corpus that contain a person and a location according to the Stanford NER tagger (Finkel et al., 2005). We represent them using the features described by Mintz et al. (2009). These features include NER tags of the two arguments, the dependency path between two designated arguments, the sequence of tokens between the ar-

[2] We collapsed the KBP relations *per:city_of_**, *per:stateorprovince_of_**, and *per:country_of_** into a single relation *place_of_**.

[3] `https://www.cs.washington.edu/ai/gated_instructions/naacl_data.zip`

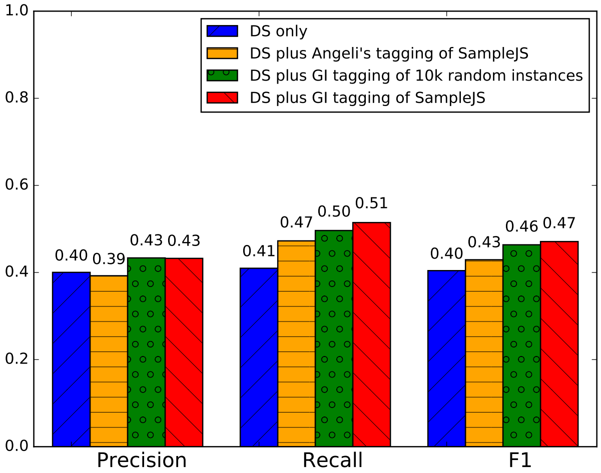

Figure 5: Adding 10K instances with Gated Instruction to 700K DS instances boosts F1 more than that of the original Sample JS annotations. Furthermore, GI applied to 10K randomly-selected instances outperforms active learning with traditional annotation.

guments, and the order of the arguments in the sentence.

We then split the data into 700K used for distant supervision and much smaller sets for crowdsourcing and for a held-out test set. For the experiments presented, unless otherwise noted, we used a variant of majority vote to create a training set. We obtained annotations from two workers for each example sentence and kept the instances where both agreed as our training data.

Finally, we ran a learning algorithm on the distant supervision training data, the crowdsourced training data, and a combination of the two. The results were evaluated on the hand-labeled test set.

4.3 Effect of Data Quality on Extractor Performance

We now study how the higher quality training data from our crowdsourcing protocol affects extractor performance, when it is added to a large amount of distantly-supervised data.

We compared adding the 10K crowdsourced instances from the previous experiment to 700K instances from distant supervision, where the crowdsourced data had tags from either Gated Instruction or the original crowdsourcing from Angeli et al. We compare only with Angeli et al. as we did not have annotations from Zhang et al. for the same training sentences.

We experimented using three learning algorithms: logistic regression, MultiR, and MIML-RE. We found that logistic regression gives the best results when applied to the crowdsourced training alone. With logistic regression, training on the 10K Sample JS instances gave F1 of 0.31 with Angeli et al.'s crowdsourced labels and 0.40 with Gated Instruction. Logistic regression is not a good fit for distant supervision — we had F1 of 0.34 from logistic regression trained on DS only.

MultiR and MIML-RE gave the best results for *combining* crowdsourcing with distant supervision. Each of these multi-instance multi-class learners had similar results, so we present results only for MIML-RE in the remainder of our experiments, as it is the learning algorithm used by other researchers.

We included no special mechanisms to prevent distant supervision data from swamping the smaller amount of crowdsourced data. MIML-RE has a built-in mechanism to combine supervised and distant supervision. It automatically builds a classifier from the supervised instances, uses this to initialize the distant supervision instance labels, and locks the supervised labels. With MultiR, we put the crowdsourced instances in separate singleton "bags" of training instances, since MultiR always takes at least one instance in each bag as truth.

As Angeli et al. found, it is important to use the crowdsourced training to initialize MIML-RE. With the default initialization, Angeli et al. report no gain in F1. We found a small gain in F1 even with the default initialization, but larger gains with crowdsourced initialization, which we use for the following experiments.

To see how much of the boost over distant supervision comes from the active learning that went into Angeli et al.'s sample JS training, we also used Gated Instruction on a *randomly selected* set of 10K newswire instances from the TAC KBP 2010 corpus (LDC2010E12) that contained at least one NER tag for *person* and one for *location*.

As Figure 5 shows, adding the Sample JS training with Gated Instruction crowdsourcing had a positive impact on performance, increasing precision from 0.40 to 0.43, recall from 0.41 to 0.51, and F1 from 0.40 to 0.47. With the original crowdsourced tag-

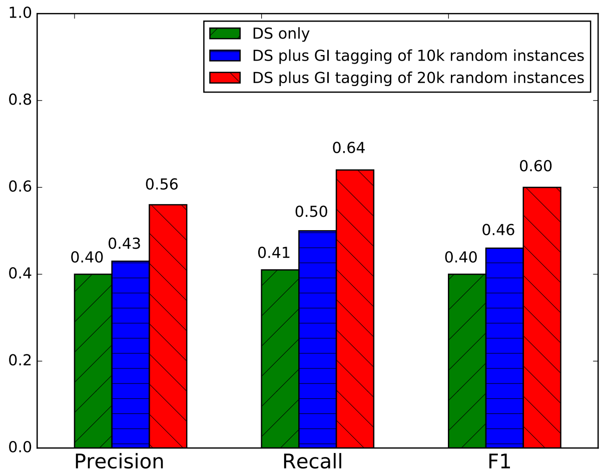

Figure 6: Adding 20K instances with Gated Instruction to DS gives a large boost to both precision and recall, raising F1 from 0.40 to 0.60.

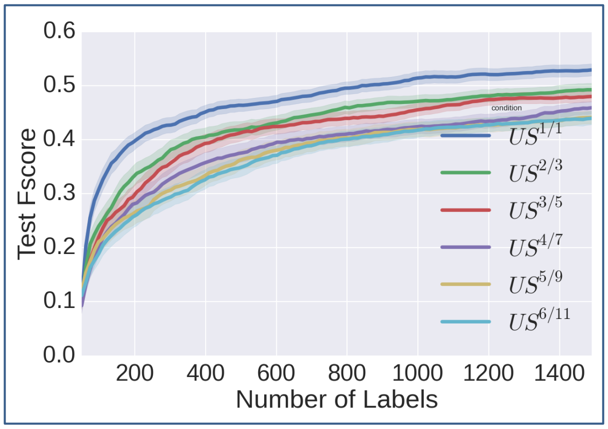

Figure 7: With high quality crowdsourcing, the simple policy of requesting a single annotation performs better than majority-vote of 3, 5, 7, 9, or 11 annotations (holding the annotation budget constant), since the increase in the *number* of data points outweighs the reduction in noise.

ging from Angeli et al., adding the crowdsourced instances actually caused a small *drop* in precision, a smaller gain in recall than Gated Instruction, and F1 of 0.43 — substantially less than achieved with labels from Gated Instruction.

Furthermore, in an apples-to-oranges comparison, we found that our improved crowdsourcing protocol had a much bigger impact than Angeli et al.'s active learning mechanism. Adding 10K *randomly* selected newswire instances tagged with Gated Instruction gave higher precision (0.43), recall (0.51), and F1 (0.46) than adding instances selected by active learning (Sample JS) when labeled using Angeli et al.'s protocol. In fact Gated Instruction gave double the improvement (6 points gain in F1 vs. 3). Of course, both of these numbers are small — bigger gains come from using the techniques together, and especially from using more crowdsourced data.

4.4 Effect of Data Quantity on Extractor Performance

Zhang et al. reported negligible improvement in F1 from adding 20K instances with their crowdsourcing to distant supervision, and Angeli et al. reported a gain of 0.04 F1 from adding 10K instances with active learning and their crowdsourcing.

As Figure 6 shows, Gated Instruction can raise F1 from 0.40 to 0.60 over distant supervision alone from adding 20K random newswire instances. This experiment uses all five relations that we crowdsourced, adding *travel_to* to the relations from Figure 5 that we had in common with Angeli et al. The results for DS only and 10K random instances are not significantly different from those in Figure 5 in which *travel_to* was omitted.

4.5 Comparison between Ways to Aggregate Annotations

In this section we explore the cost-effectiveness of alternate methods of creating training from Gated Instruction annotations. We compare a policy of using the majority vote of two out of three, or three out of five workers, and so forth, as opposed to soliciting a single annotation for each training sentence (unilabeling). Lin et al. (2014) show that in many settings, unilabeling is better because some classifiers are able to learn more accurately with a larger, noisier training set than a smaller, cleaner one.

With a given budget, single annotation gives three times as many training instances as the policy that uses three votes and five times as many as the policy that requires five votes, and so forth. Is the quality of data produced by Gated Instruction high enough to rely on just one annotation per instance?

We randomly select 2K examples from the 20K newswire instances and use Gated Instruction to acquire labels from 10 workers for each sentence. Figure 7 shows that when training a logistic regression classifier with high quality crowdsourcing data, a single annotation is, indeed, more cost effective than using a simple majority of three, five, or more annotations (given a fixed budget). The learning curves in Figure 7 use uncertainty sampling (US) to select examples from the 2000 available with the curves labeled US 1/1 for single votes, US 2/3 for two out of three, and so forth.

This is not to say that a single vote is always the best policy. It is another example of the impact of GI's high quality annotation. In the same domain of relation extraction, Lin et al. (2016) also show that with a more intelligent and dynamic relabeling policy, relabeling certain examples can still help.

5 Conclusion

This paper describes the design of Gated Instruction, a crowdsourcing protocol that produces high quality training data. GI uses an interactive tutorial to teach the annotation task, provides feedback during training so workers understand their errors, refuses to let workers annotate new sentences until they have demonstrated competence, and adaptively screens low-accuracy workers with a schedule of test questions. While we demonstrate GI for the task of relation extraction, the method is general and may improve annotation for many other NLP tasks.

Higher quality training data produces higher extractor performance for a variety of learning algorithms: logistic regression, MultiR, and MIML-RE. Contrary to past claims, augmenting distant supervision with a relatively small amount of high-quality crowdsourced training data gives a sizeable boost in performance. Adding 10K instances that Angeli et al. selected by active learning, annotated with Gated Instruction, raised F1 from 0.40 to 0.47 — substantially higher than the 0.43 F1 provided by Angeli et al.'s annotations. We also find that Gated Instruction is more effective than a complicated active learning strategy. Adding 10K randomly selected instances raises F1 to 0.46, and adding 20K random instances gave F1 of 0.60.

Our experimental results yield two main takeaway messages. First, we show that in contrast to prior work, adding crowdsourced training data substantially improves the performance of the resulting extractor as long as care is taken to ensure high quality crowdsourced annotations. We haven't yet experimented beyond person-location relations, but we believe that Gated Instruction is generalizable, particularly where there are clear criteria to be taught. We believe that Gated Instruction can greatly improve training data for other NLP tasks beside relation extraction as well.

Second, we provide practical and easily instituted guidelines for a novel crowdsourcing protocol, Gated Instruction, as an effective method for acquiring high-quality training data. It's important to break complex annotation guidelines into small, digestible chunks and to use tests (gates) to ensure that the worker reads and understands each chunk of the instructions before work begins. Without these extra checks, many poor workers pass subsequent gold tests by accident, polluting results.

Acknowledgment

This work was supported by NSF grant IIS-1420667, ONR grant N00014-15-1-2774, DARPA contract FA8750-13-2-0019, the WRF/Cable Professorship, and a gift from Google. We are very grateful to Chris Re and Ce Zhang who generously supplied their annotated data. Likewise, Masha Pershina and Ralph Grishman allowed us an early look at their paper and gave us their data. Similarly, Gabor Angeli and Chris Manning not only provided their data, but provided many insights about the best ways to combine crowd and distantly supervised annotations. Without this cooperation it would have been impossible to have done our work. We appreciate Natalie Hawkins, who helped prepare the data used in our study. We further thank Shih-Wen Huang and Congle Zhang for their suggestions on the design of the crowdsourcing system and the experiments.

Abstract

This paper proposes a novel translation-based knowledge graph embedding that preserves the logical properties of relations such as transitivity and symmetricity. The embedding space generated by existing translation-based embeddings do not represent transitive and symmetric relations precisely, because they ignore the role of entities in triples. Thus, we introduce a role-specific projection which maps an entity to distinct vectors according to its role in a triple. That is, a head entity is projected onto an embedding space by a head projection operator, and a tail entity is projected by a tail projection operator. This idea is applied to TransE, TransR, and TransD to produce lppTransE, lppTransR, and lppTransD, respectively. According to the experimental results on link prediction and triple classification, the proposed logical property preserving embeddings show the state-of-the-art performance at both tasks. These results prove that it is critical to preserve logical properties of relations while embedding knowledge graphs, and the proposed method does it effectively.

1 Introduction

Representing knowledge as a graph is one of the most effective ways to utilize human knowledge with a machine, and various large-scale knowledge graphs such as Freebase (Bollacker et al., 2008) and Yago (Suchanek et al., 2007) are available these days. However, the sparsity of the graphs makes it difficult to utilize them in real world applications. In spite of their huge volume, the relations among entities in the graphs are insufficient, which results in very limited inference of the knowledge of the graphs. Therefore, it is of importance to resolve such sparsity of knowledge graphs.

One of the most promising methods to complete knowledge graphs is to embed the graphs in a low-dimensional continuous vector space. This method learns a vector representation of a knowledge graph, and the plausibility of a certain knowledge within the graph is measured with algebraic operations in the vector space. Thus, new knowledge can be harvested from the space by finding knowledge instances with high plausibility.

The translation-based model among various knowledge-embedding models shows the state-of-the-art performance of knowledge graph completion (Bordes et al., 2013; Wang et al., 2014; Lin et al., 2015; Ji et al., 2015). TransE (Bordes et al., 2013) is one of the well-known translation-based approaches to this problem. When a set of knowledge triples (h, r, t) composed of a relation (r) and two entities (h and t) is given, it finds vector representations of h, t, and r by compelling the vector of t to be same with the sum of the vectors of h and r. While TransE embeds all relations in a single vector space, TransH (Wang et al., 2014) and TransR (Lin et al., 2015) assume that each relation has its own embedding space. On the other hand, Ji et al. (2015) found out that even a single relation or a single entity usually has multiple types. Thus, they have proposed TransD which allows multiple mapping matrices of entities and relations.

Even though these translation-based models achieve high performance in knowledge graph completion, they all ignore logical properties of rela-

Proceedings of NAACL-HLT 2016, pages 907–916,
San Diego, California, June 12-17, 2016.

tions. That is, transitive relations and symmetric relations lose their transitivity or symmetricity in the vector space generated by the translation-based models. As a result, the models can not complete only new knowledge with such relations, but also new knowledge with a relation affected by the relations. In most knowledge graphs, transitive or symmetric relations are common. For instance, FB15K, one of the benchmark datasets for knowledge graph completion, has a number of transitive and symmetric relations. About 20% of triples in FB15K have a transitive or a symmetric relation. Therefore, the ignorance of logical properties of relations becomes a serious problem in knowledge graph completion.

The main reason why existing translation-based embeddings can not reflect logical properties of relations is that they do not consider the role of entities. An entity should be a different vector in the embedding space according to its role. Therefore, the solution to preserve the logical properties of relations in the embedding space is to distinguish the role of entities while embedding entities and relations.

In this paper, we propose a role-specific projection to preserve logical properties of relations in an embedding space. This can be implemented by projecting a head entity onto an embedding space by a head projection operator and a tail entity by a tail projection operator. As a result, an identical entity is represented as two distinct vectors. This idea can be applied to various translation-based models including TransE, TransR, and TransD. Therefore, we also propose how to modify existing translation-based models to preserve logical properties. The effectiveness of the proposed idea is verified with two tasks of link prediction and triple classification using standard benchmark datasets of WordNet and Freebase. According to the experimental results, the logical property preserving embeddings achieve the state-of-the-art performance in both tasks.

2 Related Work

The sparsity of knowledge graphs is one of the most critical issues in utilizing them in real-world applications. Thus, there have been a number of studies on completing knowledge graphs as a solution to overcome the sparsity. Link prediction is one of the promising ways for knowledge graph completion. This task predicts new relations between entities on a knowledge graph by investigating existing relations of the graph (Nickel et al., 2015; Neelakantan and Chang, 2015). The methods used for link prediction can be categorized into three groups. One group consists of the methods based on graph features. The observable features used in these methods are the paths between entity pairs (Lao and Cohen, 2010; Lao et al., 2011) and subgraphs (Gardner and Mitchell, 2015). The other group is composed of the methods based on Markov random fields. The studies belonging to this group inference new relations by probabilistic soft logic (Pujara et al., 2013) and first-order logic (Jiang et al., 2012).

Knowledge graph embedding is another prominent method for link prediction (Bordes et al., 2011; Nickel et al., 2011; Guo et al., 2015; Neelakantan et al., 2015). It embeds entities of a knowledge graph into a continuous low dimensional space as vectors, and embeds relations as vectors or matrices. These vectors are optimized by a score function of each knowledge graph embedding model. The Semantic Matching Energy (SME) model proposed by Bordes et al. (2014) finds vector representations of entities and relations using a neural network. When a triple (h, r, t) is given, SME makes two relation-dependent embeddings of (h, r) and (r, t). Its score function for a triple is the similarity between the embeddings. Since relations are expressed as vectors instead of matrices, the complexity of SME is relatively low compared to other embedding methods. Jenatton et al. (2012) suggested Latent Factor Model (LFM). In order to capture both the first-order and the second-order interactions between two entities, LFM adopts a bilinear function as its score function. In addition, it represents a relation as a weighted sum of sparse latent factors to work with a large number of relations. Socher et al. (2013) proposed the Neural Tensor Network (NTN) model. NTN is a highly expressive embedding model which has a bilinear tensor layer instead of a standard linear neural network layer. As a result, it can process various interactions between entity vectors. However, it is difficult to process large-scale knowledge graphs with NTN due to its high complexity.

The current main stream of knowledge graph embedding is a translation-based embedding approach. The basic idea of this embedding is that entities and

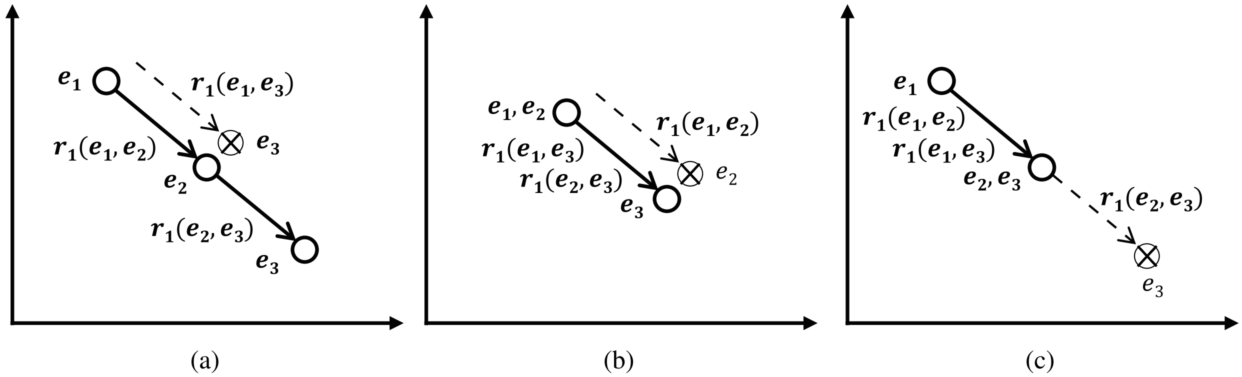

Figure 1: An example of entity vectors trained wrong by a transitive relation.

relations are represented as vectors, and relations are treated as operators to translate entities into other positions on an embedding space. Thus, they try to find vector representations of h, t, and r so that the vector of t becomes the sum of the vectors of h and r. TransE (Bordes et al., 2013) is the simplest translation-based graph embedding. It assumes that all vectors of entities and relations lie on a single vector space. As a result, it fails in dealing with the reflexivity and the multiplicities of relations except 1-to-1. The solution to this problem is to allow the entities to play different roles according to relations, but TransE is unable to do it.

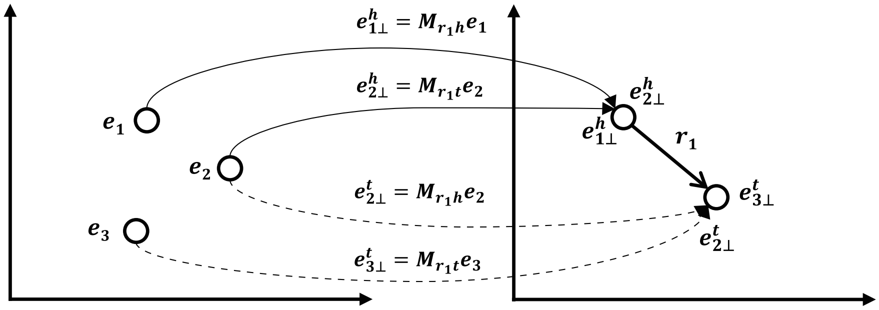
An entity plays multiple roles in TransH (Wang et al., 2014), since TransH allows entities to have multiple vector representations. In order to obtain multiple representations of an entity, TransH projects an entity vector into relation-specific hyperplanes. TransR (Lin et al., 2015) also solves the problems of TransE by introducing relation spaces. It allows an entity to have various vector representations by mapping an entity vector into relation-specific spaces rather than relation-specific hyperplanes. Although both TransH and TransR overcome the limitations of TransE, they are still not able to handle multiple types of relations which is determined by head and tail entities of each relation. For example, let us consider two triples of (*California*, *part_of*, *USA*) and (*arm*, *part_of*, *body*). Both triples have a relation *part_of* in common, but the relation should be interpreted differently in each triple. Ji et al. (2015) have proposed TransD in which a relation can have multiple relation spaces according to its entities. TransD constructs relation mapping matrices dynamically by considering entities and a relation simultaneously. For this, it introduces projection vectors for entities and relations, and then constructs the mapping matrices by multiplying these entity and relation projection vectors. As a result, every relation in TransD has multiple entity-specific spaces.

3 Loss of Logical Properties in Translation-Based Embeddings

Translation-based embeddings aim to find vector representations of knowledge graph entities in an embedding space by regarding relations as translation of entities in the space. Since they map the entities onto a vector space regardless of the role of the entities, they do not express logical properties of relations such as transitivity and symmetricity. That is, the vectors of transitive or symmetric relations do not deliver transitivity or symmetricity in the embedding spaces from translation-based embeddings.

For instance, let us consider a transitive relation. Assume that we have three triples (e_1, r_1, e_2), (e_2, r_1, e_3), and (e_1, r_1, e_3) and r_1 is a transitive relation. When the vector of r_1 is not a zero vector, there could be three types of entity vectors as shown in Figure 1. In Figure 1-(a), e_1, e_2, and e_3 are placed linearly. In this case, (e_1, r_1, e_3) can not be expressed in this figure. When e_1 and e_2 are placed at the same point like Figure 1-(b), (e_1, r_1, e_2) can not be expressed. In Figure 1-(c), (e_2, r_1, e_3) can not be expressed when e_2 and e_3 are same. In a similar way, translation-based embeddings can not express symmetric relations perfectly.

The problems caused by wrong expression of transitive and symmetric relations are two-folds.



$e^h_{1\perp} = M_{r_1h}e_1$
$e^h_{2\perp} = M_{r_1t}e_2$
$e^t_{2\perp} = M_{r_1h}e_2$
$e^t_{3\perp} = M_{r_1t}e_3$

$e^h_{4\perp}$
r_2
$e^t_{4\perp}$
$e^t_{5\perp}$

Figure 3: Simple illustration on a symmetric relation with role-specific projections.

One fold is that the relations with logical properties are common in knowledge bases. Two benchmark datasets of FB15K and WN18 in Table 2 prove it. There are 483,142 triples in FB15K, and 84,172 (= 47,841 + 36,331) triples among them have a transitive or symmetric relation. That is, the translation-based embeddings do not express triples precisely for about 17% of triples in FB15K. 22.4% of triples in another dataset WN18 also have a transitive or symmetric relation. The other is that transitive or symmetric relations do not affect the entities that are directly connected by the relations, but affect also other entities shared by non-transitive and non-symmetric relations through the entities. Therefore, it is of importance in translation-based embeddings to represent transitive and symmetric relations precisely.

4 Logical Property Preserving Embedding

4.1 Role-Specific Projection of Entity Vectors

The main reason why transitive or symmetric relations are not represented precisely by existing translation-based embeddings is that they ignore the role of entities in embedding them onto a vector space. That is, when a triple (h, r, t) is given, h and t plays different roles. However, the existing embeddings treat them equally and embed them into a space in the same way. Therefore, in order to express entities and relations more precisely, entities should be represented differently according to their role in a triple.

Figure 2 shows how entities can be represented according to their role. In this figure, solid lines represent entity mappings as head roles and dotted lines mean that entities are mapped as tails. Assume that three triples of (e_1, r_1, e_2), (e_2, r_1, e_3), and (e_1, r_1, e_3) are given with a transitive relation r_1. e_1 plays only a head role and e_3 plays only a tail role, while e_2 plays both roles. Then, the entity vectors in the entity space are mapped into the space of r_1 using two mapping matrices $\mathbf{M}_{r_1h}$ and $\mathbf{M}_{r_1t}$. That is, head entities are mapped by $\mathbf{M}_{r_1h}$, while tail entities are projected by $\mathbf{M}_{r_1t}$. Let $e^h_{1\perp}$ and $e^h_{2\perp}$ be the projected vectors of e_1 and e_2 respectively by $\mathbf{M}_{r_1h}$, and let $e^t_{2\perp}$ and $e^t_{3\perp}$ be the projected vectors of e_2 and e_3 respectively by $\mathbf{M}_{r_1t}$. $e^h_{1\perp}$ and $e^h_{2\perp}$ are placed at the same point in the space of r_1 from (e_2, r_1, e_3) and (e_1, r_1, e_3). Similarly, $e^t_{2\perp}$ and $e^t_{3\perp}$ are same from (e_1, r_1, e_2) and (e_1, r_1, e_3). Since e_2 is used as both a head and a tail, it is mapped differently as $e^h_{2\perp}$ and $e^t_{2\perp}$, respectively. Note that all three triples are well expressed in this space.

Symmetric relations also can be expressed precisely by logical property preserving knowledge graph embedding. Assume that two triples of (e_4, r_2, e_5) and (e_5, r_2, e_4) are given with a symmetric relation r_2. Figure 3 shows how the triples are well represented. The solid lines imply that entities are mapped by $\mathbf{M}_{r_2 h}$ while the dotted lines mean that entities are mapped by $\mathbf{M}_{r_2 t}$. By placing $e^h_{4\perp}$ and $e^h_{5\perp}$ at the same point and imposing $e^t_{4\perp}$ and $e^t_{5\perp}$ at the same point, r_2 is precisely expressed as a symmetric relation in the embedding space.

4.2 Realization of Logical Property Preserving Embedding

Due to the simplicity of role-specific projection of entity vectors, it can be applied to various translation-based embeddings. In this paper, we apply it to TransE, TransR, and TransD.

4.2.1 TransE

The score function of TransE is

$$f_r^E(h,t) = \|\mathbf{h} + \mathbf{r} - \mathbf{t}\|_{l_{1/2}},$$

where $\mathbf{h}$, $\mathbf{t} \in \mathbb{R}^n$, and $\mathbf{r} \in \mathbb{R}^n$ are the vectors of a head entity, a tail entity, and a relation on a single embedding space. In the logical property preserving TransE (lppTransE), $\mathbf{h}$ and $\mathbf{t}$ should be mapped differently. For this purpose, we adopt a head and a tail space mapping matrices of $\mathbf{M}_h \in \mathbb{R}^{n\times n}$ and $\mathbf{M}_t \in \mathbb{R}^{n\times n}$. As a result, the score function of lppTransE becomes

$$f_r^{lppE}(h,t) = \|\mathbf{M}_h\mathbf{h} + \mathbf{r} - \mathbf{M}_t\mathbf{t}\|_{l_{1/2}}.$$

This is similar to the score function of TransR. The difference between lppTransE and TransR is that both h and t are mapped by a single mapping matrix for r in TransR, while h is mapped by $\mathbf{M}_h$ and t is by $\mathbf{M}_t$ in lppTransE.

4.2.2 TransR

The entities in TransR are mapped into vectors in different relation space according to a relation. Thus, its score function is defined as

$$f_r^R(h,t) = \|\mathbf{M}_r\mathbf{h} + \mathbf{r} - \mathbf{M}_r\mathbf{t}\|_{l_{1/2}},$$

where $\mathbf{M}_r \in \mathbb{R}^{m\times n}$ is a mapping matrix for a relation r which is represented as $\mathbf{r} \in \mathbb{R}^m$. Thus, in the logical property preserving TransR (lppTransR), the mapping matrix of each relation is split into a head mapping matrix $\mathbf{M}_{r_h} \in \mathbb{R}^{m\times n}$ and a tail mapping matrix $\mathbf{M}_{r_t} \in \mathbb{R}^{m\times n}$. Then, the score function of lppTransR is

$$f_r^{lppR}(h,t) = \|\mathbf{M}_{r_h}\mathbf{h} + \mathbf{r} - \mathbf{M}_{r_t}\mathbf{t}\|_{l_{1/2}}.$$

With these two distinct mapping matrices, entities can have two different vector representations in the same relation space.

4.2.3 TransD

TransD maps entity vectors into different vectors in relation spaces according to entity and relation types. That is, the entity vectors are mapped by entity-relation specific mapping matrices. Thus, its score function is defined as

$$f_r^D(h,t) \quad = \quad \|\mathbf{M}_{rh}\mathbf{h} + \mathbf{r} - \mathbf{M}_{rt}\mathbf{t}\|_{l_{1/2}},$$

where $\mathbf{M}_{rh} \in \mathbb{R}^{m\times n}$ and $\mathbf{M}_{rt} \in \mathbb{R}^{m\times n}$ are entity-relation specific mapping matrices. These mapping matrices are computed by multiplying projection vectors of an entity and a relation as follows.

$$\begin{aligned}\mathbf{M}_{rh} &= \mathbf{r}_p\mathbf{h}_p^\intercal + \mathbf{I}^{m\times n},\\ \mathbf{M}_{rt} &= \mathbf{r}_p\mathbf{t}_p^\intercal + \mathbf{I}^{m\times n},\end{aligned}$$

where $\mathbf{h}_p, \mathbf{t}_p$ and $\mathbf{r}_p$, are the projection vectors for a head, a tail and a relation.

The logical property preserving TransD (lppTransD) divides $\mathbf{r}_p$ into two projection vectors $\mathbf{r}_{p_h}$ and $\mathbf{r}_{p_t}$ to reflect the role of entities. The mapping matrices then becomes

$$\begin{aligned}\mathbf{M}'_{rh} &= \mathbf{r}_{p_h}\mathbf{h}_p^\intercal + \mathbf{I}^{m\times n},\\ \mathbf{M}'_{rt} &= \mathbf{r}_{p_t}\mathbf{t}_p^\intercal + \mathbf{I}^{m\times n}.\end{aligned}$$

Then, its score function is

$$f_r^{lppD}(h,t) \quad = \quad \left\|\mathbf{M}'_{rh}\mathbf{h} + \mathbf{r} - \mathbf{M}'_{rt}\mathbf{t}\right\|_{l_{1/2}}.$$

Table 2: A simple statistics on datasets.

Dataset	#Rel	#Ent	#Train	#Valid	#Test	#Transitive	#Symmetric	Ratio
WN11	11	38,696	112,581	2,609	10,544	822	1,597	2.2%
FB13	13	75,043	316,232	5,908	23,733	262	4,152	1.4%

Table 1: Complexity of knowledge graph embedding models.

Model	No. of parameters
TransE	$\mathcal{O}\left(N_e n + N_r n\right)$
TransR	$\mathcal{O}\left(N_e n + N_r \left(m+1\right) n\right)$
TransD	$\mathcal{O}\left(2N_e n + 2N_r m\right)$
lppTransE	$\mathcal{O}\left(N_e n + N_r n + n^2\right)$
lppTransR	$\mathcal{O}\left(N_e n + N_r \left(2m+1\right) n\right)$
lppTransD	$\mathcal{O}\left(2N_e n + 3N_r m\right)$

4.3 Training Logical Property Preserving Embeddings

Since all logical property preserving embeddings are based on the score function used by previous translation-based knowledge graph embeddings, they can be trained using a margin-based ranking loss defined as

$$L = \sum_{(h,r,t)\in P} \sum_{(h',r,t')\in N} \max(0, f_r^*(h,t)+\gamma-f_r^*(h',t')),$$

where f_r^* is the score function of a corresponding logical property preserving embedding. Here, P and N are sets of correct and incorrect triples, and γ is a margin. N is constructed by replacing a head or a tail entity in an existing triple because a knowledge graph has only correct triples. All logical property preserving embeddings are optimized by stochastic gradient descent.

The complexities of the logical property preserving embeddings are shown in Table 1. N_e and N_r in this table are the number of entities and relations, and n and m are the dimensions of entity and relation embedding spaces. Their complexity mainly depends on the number of relations. Thus, the increased complexities of the logical property preserving embeddings is not significant, when compared with TransE, TransR, and TransD.

5 Experiments

The superiority of the proposed logical property preserving embeddings is shown through two kinds of tasks. The first task is *link prediction* (Bordes et al., 2013). This task predicts the missing entity when there is a missing entity in a given triple. The other is *triple classification* (Socher et al., 2013). This task aims to decide whether a given triple is correct or not.

5.1 Data Sets

Two popular knowledge graphs of WordNet (Miller, 1995) and Freebase (Bollacker et al., 2008) are used for evaluating embeddings. WordNet provides the semantic relations among words, and there exist its two widely-used subsets which are WN11 (Socher et al., 2013) and WN18 (Bordes et al., 2014). WN18 is used for link prediction, and WN11 is adopted for triple classification. Freebase represents general facts about the world. It has two subsets of FB13 (Socher et al., 2013) and FB15K (Bordes et al., 2014). FB15K is used for both triple classification and link prediction, while FB13 is employed only for triple classification.

Table 2 summarizes a simple statistics of each dataset. #Triples is the number of training triples in each benchmark dataset. #Transitive and #Symmetric are the number of triples which have transitive and symmetric relations, respectively. Ratio denotes the proportion of triples of which relation is transitive or symmetric. As shown in this table, the triples with a transitive or symmetric relation take a large proportion in WN18 and FB15K.

5.2 Link Prediction

For the evaluation of link prediction, we followed the evaluation protocols and metrics used in previous studies (Socher et al., 2013; Bordes et al., 2013; Lin et al., 2015; Ji et al., 2015). To compare the

Table 4: Experimental results on link prediction.

Dataset	WN18				FB15K			
Metric	Mean Rank		Hits@10 (%)		Mean Rank		Hits@10 (%)

Table 3: Parameter values in link prediction.

Dataset	Model	α	B	γ	n, m	D.S
WN18	lppTransE	0.001	1,440	1	50	L_1
	lppTransR	0.001	1,440	1	50	L_1
	lppTransD	0.001	1,440	2	50	L_1
FB15K	lppTransE	0.001	480	1	100	L_1
	lppTransR	0.001	4,800	1	100	L_1
	lppTransD	0.0001	4,800	2	100	L_1

methods for this task, two metrics of mean rank and Hits@10 are used. The mean rank measures the average rank of all correct entities, and Hits@10 is the proportion of correct triples ranked in top 10. Since there are two evaluation settings of "raw" and "filter" in this task (Bordes et al., 2013), we report both results. In addition, we report the results for two sampling methods of "bern" and "unif" (Wang et al., 2014) as the previous studies did.

There are five parameters in the proposed property preserving embeddings. They are a learning rate α, the number of training triples in each mini-batch B[1], a margin γ, the embedding dimension for entities and relations (n and m), and a dissimilarity measure in embedding score functions (D.S). The parameter values used in our experiments are given at Table 3. The iteration number of stochastic gradient descent is 1,000.

Table 4 shows the results on link prediction. The results of previous studies are referred from their report, since the same datasets are used. The values between parentheses are the improvement over their base models. The logical property preserving embeddings outperform all other methods for both "bern" and "unif" on WN18 except lppTransR with "bern" in the raw setting. In the raw setting, lppTransE, lppTransR, and lppTransD achieve 79.5%, 79.6%, and 80.5% of Hits@10 respectively in "bern", which are 4.1%, -0.2%, and 0.9% higher than those of TransE, TransR, and TransD. The logical property preserving embeddings show even higher performance in the filter setting. Hits@10 of lppTransD in "bern" is 94.3%, while that of TransD in "unif" is 92.5% and that in "bern" is 92.2%. Thus, lppTransD improves 2.1% over TransD in "bern". Especially, this performance of lppTransD is 1.8% higher than that of TransD in "unif", the previous state-of-the-art performance.

The logical property preserving embeddings outperform their base models also on FB15K. TransE is improved most significantly with this dataset. The improvements by lppTransE in the raw setting are 12.5% in "unif" and 14.0% in "bern", while those in the filter setting are 25.8% in "unif" and 26.0% in "bern". In addition, its Hits@10 exceeds those of TransH and TransR. That is, even if TransH and TransR were proposed to tackle the problem of TransE, the proposed lppTransE solves the problem better than TransH and TransR. lppTransD achieves just a little bit lower Hits@10 than TransD in "bern", but the improvements in the filter setting are notice-

[1] α and B are related with stochastic gradient descent.

Table 6: Parameter values in triple classification.

Dataset	Model	α	B	γ	n, m	D.S
WN11	lppTransE	0.01	120	2	20	L_1
	lppTransR	0.001	120	4	20	L_1
	lppTransD	0.0001	1,000	1	100	L_2
FB13	lppTransE	0.001	30	1	100	L_1
	lppTransR	0.0001	300	1	100	L_1
	lppTransD	0.0001	300	1	100	L_2
FB15K	lppTransE	0.001	480	1	100	L_1
	lppTransR	0.001	4,800	1	100	L_1
	lppTransD	0.0001	4,800	2	100	L_1

able. Since Hits@10 of TransD in "bern" is the best performance ever reported, that of lppTransD in "bern" becomes a new state-of-the-art performance.

Table 5 exhibits Hits@10s according to mapping property of the relations of FB15K. The notable trend of this table is that the logical property preserving embeddings show much higher Hits@10 than their base models in N-to-1 and N-to-N, while their Hits@10s are similar to those of their base models in 1-to-1 and 1-to-N. This is notable with TransD and lppTransD. lppTransD improves TransD, the previous state-of-the-art method by 7.3% (N-to-1) and 3.7% (N-to-N) in predicting head, and by 0.9% (N-to-1) and 0.3% (N-to-N). Note that it is important to verify if logical property preserving embeddings achieve good performances in N-to-N, since all transitive relations and some symmetric relations are, in general, N-to-N. According to this table, Hits@10s of most logical property preserving embeddings are improved significantly in N-to-N, which proves that the proposed method solves transitivity and symmetricity problem of previous embeddings.

5.3 Triple Classification

Three datasets of WN11, FB13, and FB15K are used in this task. WN11 and FB13 have negative triples, but FB15K has only positives. Thus, we generated negative triples for FB15K by following the strategy of (Socher et al., 2013). As a result, the classification accuracies on FB15K can not be compared directly with previous studies, and the accuracies on FB15K in this table are those obtained with our dataset. The parameter values for training TransE, TransH, TransR, and TransD are borrowed from their reports, and those for logical property preserving embeddings are shown in Table 6.

Table 7: Accuracies on triple classification. (%)

Dataset	WN11	FB13	FB15K
TransE (unif)	75.9	70.9	80.3
TransE (bern)	75.9	81.5	80.8
TransH (unif)	77.7	76.5	81.9
TransH (bern)	78.8	83.3	82
TransR (unif)	85.5	74.7	82.6
TransR (bern)	85.9	82.5	82.7
TransD (unif)	85.6	85.9	84.2
TransD (bern)	86.4	**89.1**	84.8
lppTransE (unif)	81.3 (+5.4)	72.3 (+1.4)	83.2 (+2.9)
lppTransE (bern)	81.3 (+5.4)	83.4 (+1.9)	83.6 (+2.8)
lppTransR (unif)	85.5 (+0.0)	79.5 (+4.8)	83.4 (+0.8)
lppTransR (bern)	85.5 (-0.4)	83.1 (+0.6)	84.6 (+1.9)
lppTransD (unif)	86.1 (+0.5)	86.6 (+0.7)	84.7 (+0.5)
lppTransD (bern)	86.2 (-0.2)	88.6 (-0.5)	**85.3** (+0.5)

Table 7 shows the accuracies of triple classification on the three datasets. The logical property preserving embeddings in general outperform their base models. lppTransE always shows higher accuracy than TransE, lppTransR than TransR except for WN11, and lppTransD than TransD in FB15K. One thing to note is that the improvements by the logical property preserving embeddings are always observed in FB15K, while those in WN11 and FB13 are small or slightly negative. This can be explained with the number of triples with a transitive or symmetric relation in the datasets. As shown in Table 2, the triples with such a relation take just a small portion of WN11 and FB13. The ratio of those triples is less than 2.3% in these datasets. However, as noted before, more than 17% triples are such ones in FB15K. Thus, the improvement in FB15K is remarkable. The other thing to note is that lppTransD shows the best accuracy in FB15K. These results imply that the proposed logical property preserving embeddings solve the problems of existing translation-based embeddings effectively.

6 Conclusion

This paper has proposed a new translation-based knowledge graph embedding that preserves logical properties of relations. Transitivity and symmetricity are very important characteristics of relations for representing and inferring knowledge, and the triples with such a relation take a large proportion of real-world knowledge graphs. In order to preserve the logical properties in an embedding space, an entity is forced to have multiple vector represen-

Table 5: Experimental results on FB15K according to mapping properties of relations. (%)

Tasks	Predicting Head (Hits@10)				Predicting Tail (Hits@10)

lppTransD (unif)	82.7	89.5	53.2	81.6	82.3	52.6	84.8	**81.5**
lppTransD (bern)	86.0	94.2	**54.4**	**82.2**	79.7	43.2	**95.3**	79.7

tations according to its role in a triple. This idea has been applied to TransE, TransR, and TransD, and they are called as lppTransE, lppTransR, and lppTransD. Their superiority was shown through two tasks of link prediction and triple classification. The logical property preserving embeddings showed the improved performance over their base models[2]. Especially, lppTransD showed the state-of-the-art performance in both tasks. These results imply that the proposed role-specific projection is plausible to preserve logical properties of relations.

Abstract

Recurrent neural networks, particularly long short-term memory (LSTM), have recently shown to be very effective in a wide range of sequence modeling problems, core to which is effective learning of distributed representation for subsequences as well as the sequences they form. An assumption in almost all the previous models, however, posits that the learned representation (e.g., a distributed representation for a sentence), is fully compositional from the atomic components (e.g., representations for words), while non-compositionality is a basic phenomenon in human languages. In this paper, we relieve the assumption by extending the chain-structured LSTM to directed acyclic graphs (DAGs), with the aim to endow linear-chain LSTMs with the capability of considering compositionality together with non-compositionality in the same semantic composition framework. From a more general viewpoint, the proposed models incorporate additional prior knowledge into recurrent neural networks, which is interesting to us, considering most NLP tasks have relatively small training data and appropriate prior knowledge could be beneficial to help cover missing semantics. Our experiments on sentiment composition demonstrate that the proposed models achieve the state-of-the-art performance, outperforming models that lack this ability.

1 Introduction

Recurrent neural networks, particularly long short-term memory (LSTM), have recently shown to be very effective in a wide range of sequence modeling problems, including speech recognition (Graves et al., 2013), automatic machine translation (Sutskever et al., 2014; Cho et al., 2014), and image-to-text conversion (Vinyals et al., 2014), among many others. The specific memory copying and gating configurations in LSTM's memory blocks render an effective mechanism in capturing both short and distant interplays in an input sequence.

In modeling sequences, core to many problems is to learn effective distributed representations for subsequences and the sequences they form. A strong assumption in most previous models, however, posits that the learned representation (e.g., a distributed representation for a sentence) is fully compositional from the atomic components (e.g., representations for words), while non-compositionality is a basic phenomenon in human languages and other modalities, which does not only include rather rigid cases such as idiomatic expressions (e.g., *kick the bucket*) but also *soft* cases that are harder to make a binary judgment.

A framework with the capability to consider both compositionality and non-compositionality in semantic composition are of theoretic interest. From a more pragmatical viewpoint, if one is able to holistically obtain the representations for a sequence (e.g., for the bigram *must try* in a customer-review corpus for sentiment analysis), it would be desirable that a composition model has the ability to choose the sources of knowledge it can trust more: the composition of subsequences of this sequence, the holistic representation, or a soft combination of them, in the process of semantic composition. In such situations,

Proceedings of NAACL-HLT 2016, pages 917–926,
San Diego, California, June 12-17, 2016.

whether this sequence (*must try*) is indeed compositional or non-compositional may often be blurry or may not be an explicit concern of applications.

In this paper, we extend the popular chain-structured LSTM to directed acyclic graph (DAG) structures, with the aim to endow conventional LSTM with the capability of considering compositionality and non-compositionality together. From a more general viewpoint, the proposed models are along the line of incorporating external knowledge into recurrent neural models, which is interesting to us, considering that most NLP tasks have relatively limited amount of training data, and external prior knowledge could be beneficial to help cover missing semantics. The proposed models unify the compositional power of recurrent neural networks (RNN) and additional prior knowledge. In general, neural nets are powerful approaches for composition, which can fit very complicated compositional functions underlying the annotated data (Cybenko, 1989; Hornik, 1991). Over that, externally obtained semantics could help cope with missing information in limited training data.

We demonstrated the models' effectiveness in sentiment composition, a popular semantic composition problem that optimizes a sentiment objective. We show that the proposed models achieve the state-of-the-art performance on two benchmark datasets, without any feature engineering, by unifying the compositional strength of LSTM with external semantic knowledge.

2 Related Work

Linear and Structured RNN Linear-chain RNN, particularly LSTM, has been applied to a wide range of problems as in (Graves et al., 2013; Sutskever et al., 2014; Cho et al., 2014; Vinyals et al., 2014), among many others. While the models take a linear encoding process to absorb input symbols, they are capable of implicitly capturing rather complicated structures embedded in the input sequences.

Recent research has also moved beyond linear-chain LSTM. For example, in (Tai et al., 2015; Zhu et al., 2015b; Le and Zuidema, 2015), LSTM was extended to tree structures. The results show that tree-structured LSTM achieves the-state-of-the-art performance on semantic tasks such as paraphrasing detection and sentiment analysis, due to its abilities in capturing both local and long-distance interplay over the structures.

In this work, we proposed DAG-structured LSTM for modeling sequences of text. Unlike the tree-structured LSTM, where the structures are used for considering syntax, the proposed models leverage DAG structures to incorporate external semantics including non-compositional or holistically learned semantics.

Compositionality Semantic composition exists in multiple modalities, including images and vision (Lake, 2014; Hummel, 2001; Socher et al., 2011; van der Velde and de Kamps, 2006). In human languages, the recent years have seen extensive interests on distributional approaches. The research includes the influential pioneering work that examined a number of explicit forms of compositional functions (Mitchell and Lapata, 2008).

More recent works explored neural networks, e.g., (Socher et al., 2013; Irsoy and Cardie, 2014; Kalchbrenner et al., 2014; Tai et al., 2015; Le and Zuidema, 2015; Zhu et al., 2015c) among many others, which extended the success of word-level embeddings (Collobert et al., 2011; Mikolov et al., 2013; Chen et al., 2015) and modeled sentences through semantic composition. In general, neural models can fit very complicated functions and can be a universal approximator (Cybenko, 1989; Hornik, 1991).

In obtaining the distributed representation for longer spans of text from its subsequences, previous neural models assume full compositionality from the atomic components and disregard non-compositionality and in general prior semantics. Some very recent work (Zhu et al., 2015a) has started to address this problem in recursive neural networks with the assumption of the availability of parse information. In this work, we extend the general sequence models, chain-structured LSTM, to directed acyclic graphs (DAGs) in order to consider prior semantics, including non-compositional or holistically learned semantics. We utilize DAG structures to unify different sources of semantics.

From the decomposition direction, modeling non-constitutionality could potentially help learn the representations for the atomic components (e.g., words) as well, by avoiding backpropagating unnecessary errors to the atom level. For example, the errors received by the block *kick the bucket*, may not need to be passed down to the word level and potentially confuse the embedding of the component words *kick* or *bucket*.

3 DAG-Structured LSTM

The DAG-structured LSTM aims to integrate compositional, non-compositional, and in general external semantics in semantic composition. Figure 1 depicts an example of DAG-structured LSTM (referred to as DAG-LSTM in the remainder of the paper) in modeling a sentence.

The proposed DAG-LSTM networks consist of four types of nodes, denoted in Figure 1 with different colors. The blue nodes (0, 1, 2, 6, and 7) correspond to normal chain-structured LSTM memory blocks. The yellow nodes (5 and 8) model non-compositional knowledge. The purple nodes (3 and 4), which we call *fork blocks* or *fork nodes* in this paper, are the modified versions of regular LSTM nodes, summarizing history for different types of outgoing blocks. The merging memory block is depicted in red (node 9), aiming at infusing information from multiple histories and deciding which sources will be considered more. Each category of these four types of memory blocks share its own parameters or weight matrices; e.g., the two yellow blocks share the same parameters.

3.1 Compositional and Non-compositional Memory Blocks

The conventional components of DAG-LSTM in Figure 1 are nodes 0, 1, 2, 6, and 7, which implement linear-chain LSTM memory blocks that we will not discuss in detail here (refer to (Graves, 2012) for a good introduction and discussion.)

The yellow nodes (blocks 5 and 8) model non-compositional knowledge. In general, the goal is incorporating external, holistic knowledge. Specifically for the sentiment composition task that we experiment with in this paper, we leverage two different types of such external knowledge: (1) sentiment of words and ngrams holistically learned from external, larger corpora, and (2) sentiment of words and phrases from human prior, i.e., annotation assigned by human subjects. We concatenate these two resources (in form of vectors) to be a longer vector for nodes 5 and 8. Note that the models allow both the number of hidden units and the embedding spaces of a non-compositional node to be different from those of a compositional node.

Accordingly, the DAG-LSTM employs two types of paths, compositional path (shortened as c-path) and non-compositional path (nc-path), to incorporate different knowledge sources. For example, the c-path in the figure connects nodes 3, 4, 6, 7, and 9, which model the regular sequential compositional procedure. The two nc-paths explore non-compositional knowledge. The path 4-5-9 considers the composition vector accumulated at node 4 so far with the non-compositional knowledge of the phrase *must try*. Similarly, the path 3-8-9 considers holistic representation for the negated phrase *not must try*. Note that negation by itself has shown to be a rather complicated non-linear function (Zhu et al., 2014a), if being modeled only compositionally. The model here provides the flexibility to consider both compositional and non-compositional representations. All knowledge from these three paths are then merged, to obtain the comprehensive representation so far, at node 9. Later in the experiment section, we will discuss how to obtain prior non-compositional knowledge, from both human heuristics/annotation and from automatically learned resources.

3.2 Fork Memory Blocks

The fork blocks (node 3 and 4) summarize history obtained so far for different types of outgoing blocks (node 5 and 6 from node 4) that are either compositional or non-compositional. More specifically, the cell and output vectors of a fork node will be passed to multiple paths as intuitively shown in Figure 2. While the forward propagation of a fork block is the same as that of a regular LSTM block, during backpropagation, the errors are summed over multiple outgoing blocks and passed back to the memory cell and output layer of the current node.

More specifically, for each memory block, assume that the error passed to the hidden vector is ϵ_t^h. The derivatives of the output gate δ_t^o, forget gate δ_t^f and input gate δ_t^i are computed as follows:

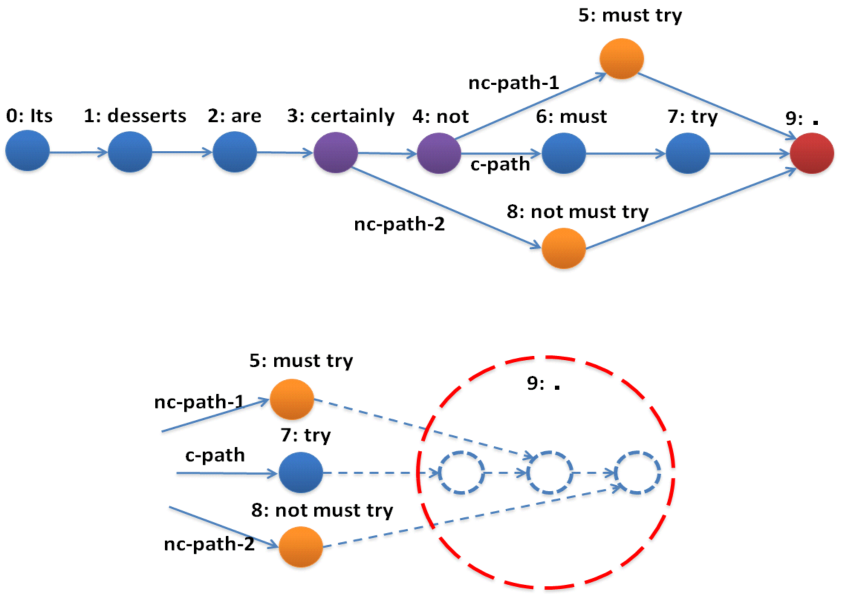

Figure 1: An example of DAG-LSTM in modeling a sentence. Nodes with different colors contain different types of LSTM memory blocks.

$$\epsilon_t^h = \frac{\partial \sum_p O_p}{\partial h_t} \tag{1}$$

$$\delta_t^o = \epsilon_t^h \otimes \tanh(c_t) \otimes \sigma'(o_t) \tag{2}$$

$$\delta_t^f = \epsilon_t^c \otimes c_{t-1} \otimes \sigma'(f_t) \tag{3}$$

$$\delta_t^i = \epsilon_t^c \otimes \tanh(x_t) \otimes \sigma'(i_t) \tag{4}$$

where $\sigma'(x)$ is the element-wise derivative of the logistic function over vector x. Since it can be computed with the activation of x, we relax the notation a bit to write it over the activated vectors in these equations. The underscript p is representative of parent over different paths (both non-compositional paths and compositional path). ϵ_t^c is the derivative over the cell vector and it is calculated as follows:

$$\begin{aligned}\epsilon_t^c =& \epsilon_t^h \otimes o_t \otimes g'(c_t) + (W_{co})^T \delta_t^o \\ &+ \sum_p [(W_{ci}^L)^T \delta_p^i + \epsilon_p^c \otimes f_p^L + (W_{cf}^L)^T \delta_p^f]\end{aligned} \tag{5}$$

where $g'(x)$ is the element-wise derivative of the *tanh* function. It can also be directly calculated from the *tanh* activation of x. The superscript T over the weight matrices means matrix transpose.

3.3 Merging Blocks

Merging blocks (node 9 in Figure 1) accumulate and summarize multiple histories. For the specific example in Figure 1, the merging block combines information from two non-compositional paths and one compositional path.

Binarization In this paper, we propose to *binarize* the nodes in the merging process. Taking Figure 1 as an example, binarization is performed as depicted in the bottom subfigure. We merge the compositional path (c-path) with one of the non-compositional path (nc-path) and then another. With this binarization trick, we can handle nodes with any number of incoming edges (degrees) with the same architecture of memory block. We made all the binarized merging nodes (the three dotted-lined nodes in the lower subfigure of Figure 1) to share the same parameters (weight matrices), as during merging we should treat compositional and non-compositional history (5, 7, 8) in the same way, by their content but not by how many words they contain. Note that since the dimension of the output vectors and memory cell vectors of different paths are the same, one has the choice of using other variants of memory blocks such as those described in (Tai et al., 2015; Le and Zuidema, 2015; Zhu et al., 2015c).

Again, note that we use merging node to consider noncompositional and prior knowledge in DAG, but the above tree-LSTM was proposed to wire with syntactic structures to consider syntactic information. In addition, in DAG, the merging nodes work together with fork nodes to correctly forward-propagate and back-propagate compositional and non-compositional knowledge jointly.

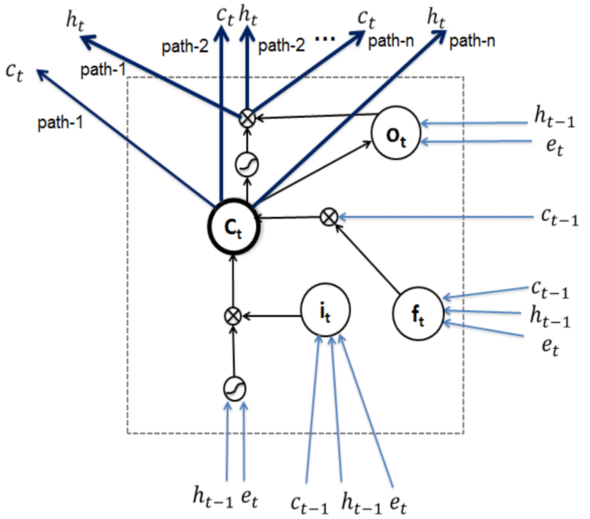

Figure 2: An example of a fork memory block. Both the hidden vectors h_t and cell vectors c_t are passed along multiple outgoing paths to the future blocks. ⊗ denotes a Hadamard product, and the ”s” shape sign is a squashing function (in this paper the *tanh* function).

4 Experiment Set-Up

In this paper, we study the proposed models on a semantic composition task that determine the sentiment of a piece of text. We use social-media messages from the official SemEval Sentiment Analysis in Twitter competition. Analyzing social-media text has attracted extensive attention (Nakov et al., 2016; Kiritchenko et al., 2014; Mohammad et al., 2014; Mohammad et al., 2015; Zhu et al., 2014b; Mohammad et al., 2013a) and have many applications. Sentimental analysis of such data presents a unique set of challenges as well; for example, the tweet posts are often short, use informal languages, and are often not linguistically well-formed. Syntactic analysis such as parsing is much less reliable in such data than in news articles, and sequential models without depending on deep linguistic analysis (e.g., parsing) are adopted by most previous work.

In obtaining the sentiment of a text span, e.g., a sentence, early work often factorized the problem to consider smaller pieces of component words or phrases with bag-of-words or bag-of-phrases models (Liu and Zhang, 2012; Pang and Lee, 2008). More recent work has started to model composition process (Choi and Cardie, 2008; Moilanen and Pulman, 2007; Socher et al., 2012; Socher et al., 2013; Irsoy and Cardie, 2014; Kalchbrenner et al., 2014; Tai et al., 2015; Zhu et al., 2015b; Le and Zuidema, 2015), more closely. In general, the composition process is critical in the formation of the sentiment of a text span, which has not been well modeled yet and more work would be desirable.

4.1 Data and Evaluation Metric

In our experiments, we use the official data from the SemEval-2013 (Wilson et al., 2013) and SemEval-2014 (Rosenthal et al., 2014) Sentiment Analysis in Twitter challenges. The task attempts to determine the sentiment category of a tweet; that is, detecting whether an entire tweet message conveys a positive, negative, or neutral sentiment.

To give a rough idea about the data, the SemEval-2013 tweets were collected through the public streaming Twitter API during a period of one year: between January 2012 and January 2013. The dataset is comprised of 5,192 positive and 2,150 negative and 6,383 neutral tweets split into the training (8,258 tweets), development (1,654 tweets), and test (3,813 tweets) sets. For more details, please refer to (Wilson et al., 2013; Rosenthal et al., 2014). In our experiments, we report our results on the official in-domain (tweets) test data but not out-of-domain (e.g., SMS) test data to better observe the supervised performances of our models but not the domain adaptation performance.

Following the official specification, we use macro-averaged F-score to evaluate the performances.

4.2 Prior Knowledge

As briefly discussed in Section 3, we use two different sources of prior, non-compositional knowledge. These two types of resources encode: (1) sentiment of ngrams automatically learned from an external, much larger corpus, and (2) sentiment of ngrams assigned by human annotators. Below, we introduce them in further details.

Automatically Learned Knowledge Following the method proposed in (Mohammad et al., 2013b), we learn sentimental ngrams from Tweets, e.g., the sentiment knowledge for the bigram *must try*. The unsupervised approach utilizes *hashtags*, which can be regarded as conveying freely available (but noisy) human annotation of sentiment. More specifically, certain words in tweets are specially marked with the hash character (#) to indicate the topic, sentiment polarity, or emotions such as joy, sadness, angry, and surprised. With enough data, such artificial annotation can be used to learn the sentiment of ngrams by their likelihood of co-occurring with such hashtagged words.

More specifically, a collection of 78 seed hashtags closely related to *positive* and *negative* such as *#good, #excellent, #bad,* and *#terrible* were used (32 positive and 36 negative). These terms were chosen from entries for *positive* and *negative* in the Roget's Thesaurus. A set of 775,000 tweets that contain at least a positive hashtag or a negative hashtag were used as the learning corpus. A tweet was considered positive if it had one of the 32 positive seed hashtags, and negative if it had one of the 36 negative seed hashtags. The association score for an ngram w was calculated from these pseudo-labeled tweets as follows:

$$score(w) = PMI(w,positive) - PMI(w,negative) \tag{6}$$

where PMI stands for pointwise mutual information, and the two terms in the formula calculate the PMI between the target ngram and the pseudo-labeled positive tweets as well as that between the ngram and the negative tweets, respectively. Accordingly, a positive *score(.)* indicates association with positive sentiment, whereas a negative score indicates association with negative sentiment.

We use in our experiments the unigrams, bigrams and trigrams learned from the dataset with the occurrences higher than 5. We assign these ngrams into one of the 5 bins according to their sentiment scores obtained with Formula 6: $(-\infty, -2]$, $(-2, -1]$, $(-1, 1)$, $[1, 2)$, and $[2, +\infty)$. Each ngram is now given a one-hot vector, indicating the polarity and strength of its sentiment. For example, a bigram with a score of -1.5 will be assigned a 5-dimensional vector $[0, 1, 0, 0, 0]$, indicating a weak negative. Note that we can also take into other forms of sentiment embeddings, such as those learned in (Tang et al., 2014).

Manually Encoded Semantics In addition, we also leveraged prior knowledge from human, i.e., manually encoded semantics, for the task here. This includes a widely used sentiment lexicon, the MPQA Subjectivity Lexicon (Wilson et al., 2005), which encodes the prior knowledge that the human annotators have about the sentiment of words. The MPQA, which draws from the General Inquirer and other sources, has sentiment labels for about 8,000 words. The contained words marked with their prior polarity (positive or negative) and a discrete strength of evaluative intensity (strong or weak). We convert them to value -1.0, -0.5, 0, 0.5, 1, corresponding to *strong negative*, *weak negative*, *neutral*, *weak positive*, *strong positive*, respectively.

4.3 Training Details

Our networks aim to minimize the cross-entropy error (Socher et al., 2013). The models learn the weight matrices used in those different memory blocks described above in addition to learning word embedding. For all Twitter messages, the error is calculated as a regularized sum:

$$E(\theta) = \sum_i \sum_j t^i_j \log {y^{sen_i}}_j + \lambda \left\|\theta\right\|^2_2 \tag{7}$$

where $y^{sen_i} \in \mathbb{R}^{c\times1}$ is predicted distribution and $t^i \in \mathbb{R}^{c\times1}$ the target distribution. c is the number of classes or categories, and $j \in c$ denotes the j-th element of the multinomial target distribution; i iterates over root nodes, θ are model parameters, and λ is a regularization parameter. We tuned our model against the development data set.

The DAG-LSTM and LSTM results reported here are all obtained by setting the size of the hidden units to 10, batch size to 10 and learning rate to 0.1, which achieved the best performance during development.

5 Results

5.1 Overall Performance

Table 1 presents the macro-averaged F-scores of different models on the official test sets of the SemEval-2013 and SemEval-2014 Sentiment Analysis in Twitter. The first row of results show the majority baseline where a majority classifier simply predicts all test cases into the most frequent class observed in training data. SVM is a support vector machine classifier applied to unigram features, as reported in (Nakov et al., 2016). In addition, we list the results of top three models described in the official reports of SemEval-2013 (Wilson et al., 2013) and SemEval-2014 (Rosenthal et al., 2014), respectively.

Method	**SemEval-13**	**SemEval-14**
Majority baseline	29.19	34.46
Unigram (SVM)	56.95	58.58
3^{rd} best model	64.86	69.95
2^{nd} best model	65.27	70.14
The best model	69.02	70.96
LSTM-DAG	70.88	71.97

Table 1: Performances of different models in official evaluation metric (macro F-scores) on the test sets of SemEval-2013 and SemEval-2014 Sentiment Analysis in Twitter in predicting the sentiment of the tweet messages.

The results show DAG-LSTM achieves a macro-averaged F-score of 70.88% on the SemEval-2013 test set and 71.97% on the SemEval-2014 test set, which outperform the models officially reported in the competition. Note that DAG-LSTM performs no feature engineering, but unifies LSTM with the external semantic knowledge to perform semantic composition within the DAG structures, where LSTM, as discussed earlier in the paper, possesses strong modeling and composition power through capturing distant interplay and complicated structures embedded in sequences, while prior knowledge used covers missing semantics in the limited training data.

Note that further improvement, including that reported in (Zhu et al., 2014b), is additionally possible, which was achieved by building better resources through discriminating affirmative and negative context. Such improvement could be orthogonally combined with our model, while in this paper, we are interested in the basic modeling problems and leave such engineering as future work. Note also that the external resources we use in this paper is the same or less than the top official system we compare to in Table 1.

5.2 Effect of DAG Paths

To provide a more detailed analysis on the effect of different paths in DAG-LSTM, Table 2 include the ablation results obtained by removing different types of paths gradually. The table show that by removing all the paths that incorporate the prior semantics, a regular LSTM (last row of the table) achieves the f-scores of a 64.0% and 66.4% on the two test sets, which is far less than the best result we have achieved; But the performance of the regular LSTM is still much better than that of unigram-based SVM reported in Table 1, suggesting the usefulness of the LSTM composition compared to bag-of-word models.

Method	**SemEval-13**	**SemEval-14**
DAG-LSTM		
Full paths	70.88	71.97
Full – {autoPaths}	69.36	69.27
Full – {triPaths}	70.16	70.77
Full – {triPaths, biPaths}	69.55	69.93
Full – {manuPaths}	69.88	70.58
LSTM without DAG		
Full – {autoPaths,manuPaths}	64.00	66.40

Table 2: Ablation performances (macro-averaged F-scores) of DAG-LSTM with different types of paths being removed.

When removing the paths corresponding to automatic lexicons, the performance dropped to 69.36% and 69.27% on the SemEval-2013 and SemEval-2014 dataset, respectively. If removing all paths corresponding to manual lexicons, the performance dropped to 69.88% and 70.58%. In both test sets, the paths corresponds to automatic lexicon have more impact on the ablation performance than manual-lexicon paths, which agree with the observation reported in previous top systems that use conventional feature-based classifiers (Mohammad et al., 2013a), suggesting the usefulness of the automatically acquired semantics. The table also lists more details of removing trigram and bigram paths.

In addition to the ablation models reported in Table 2, we also created an additional model that incorporated into the basic chain LSTM the external knowledge only for longest n-grams but not for their substrings. This experiment is supposed to investigate the effect of DAG structures that integrate knowledge for different granularities of ngrams in comparison to the LSTM that incorporates the external knowledge only for the longest n-grams. On SemEval-2014 official set, the performance (Macro-F) of this model is 69.37, compared with DAG-LSTM (71.97) and chain LSTM (66.40). On Semeval-2013, Macro-F is 68.81, compared with DAG-LSTM (70.88) and chain LSTM (64.00). After some manual analysis, we observe that in tweets where DAG-LSTM works better than this baseline model, the prior sentiment of the longest n-grams is often noisy and not very reliable; in this case, the weight matrix of DAG-LSTM helps choose more reliable resources, e.g., composition from lower-order ngrams.

6 Conclusions and Discussions

In obtaining the distributed representation for longer text spans from its subsequences, previous neural models assume fully compositionality from the atomic components and often disregard the non-compositionality and in general prior semantics. In this paper, we extend chain-structured LSTM to a directed acyclic graph (DAG) structure, with the aim to provide the popular chain LSTM with the capability of considering both compositionality and non-compositionality in a single semantic composition framework. We demonstrated the models' effectiveness in a sentiment composition task, a popular semantic composition problem that optimizes a sentiment objective. We use two official SemEval datasets to detect the sentiment expressed by social-media messages. The proposed models achieve the state-of-the-art performance without any feature engineering, through unifying the composition strength of LSTM with external holistic semantics.

We consider our work as an attempt towards unifying the strong modeling power of neural models with proper prior or external knowledge. This is an intriguing direction for us, as most NLP tasks lack training data, compared with speech recognition or image classification where neural models have achieved more significant successes.

While we specifically treat LSTM in this paper, it should be rather straightforward to adapt the proposed idea to other architectures of recurrent neural networks.

Abstract

Identification of short text similarity (STS) is a high-utility NLP task with applications in a variety of domains. We explore adaptation of STS algorithms to different target domains and applications. A two-level hierarchical Bayesian model is employed for domain adaptation (DA) of a linear STS model to text from different sources (e.g., news, tweets). This model is then further extended for multitask learning (MTL) of three related tasks: STS, short answer scoring (SAS) and answer sentence ranking (ASR). In our experiments, the adaptive model demonstrates better overall cross-domain and cross-task performance over two non-adaptive baselines.

1 Short Text Similarity: The Need for Domain Adaptation

Given two snippets of text—neither longer than a few sentences—short text similarity (**STS**) determines how semantically close they are. STS has a broad range of applications: question answering (Yao et al., 2013; Severyn and Moschitti, 2015), text summarization (Dasgupta et al., 2013; Wang et al., 2013), machine translation evaluation (Chan and Ng, 2008; Liu et al., 2011), and grading of student answers in academic tests (Mohler et al., 2011; Ramachandran et al., 2015).

STS is typically viewed as a *supervised* machine learning problem (Bär et al., 2012; Lynum et al., 2014; Hänig et al., 2015). SemEval contests (Agirre et al., 2012; Agirre et al., 2015) have spurred recent progress in STS and have provided valuable training data for these supervised approaches. However, similarity varies across domains, as does the underlying text; e.g., syntactically well-formed academic text versus informal English in forum QA.

Our goal is to effectively use domain adaptation (DA) to transfer information from these disparate STS domains. While "domain" can take a range of meanings, we consider adaptation to different (1) sources of text (e.g., news headlines, tweets), and (2) applications of STS (e.g., QA vs. answer grading). Our goal is to improve performance in a new domain with few in-domain annotations by using many out-of-domain ones (Section 2).

In Section 3, we describe our Bayesian approach that posits that per-domain parameter vectors share a common Gaussian prior that represents the global parameter vector. Importantly, this idea can be extended with little effort to a nested domain hierarchy (domains within domains), which allows us to create a single, unified STS model that *generalizes across domains as well as tasks*, capturing the nuances that an STS system must have for tasks such as short answer scoring or question answering.

We compare our DA methods against two baselines: (1) a domain-agnostic model that uses all training data and does not distinguish between in-domain and out-of-domain examples, and (2) a model that learns only from in-domain examples. Section 5 shows that across ten different STS domains, the adaptive model consistently outperforms the first baseline while performing at least as well as the second across training datasets of different sizes. Our multitask model also yields better overall results over the same baselines across three related tasks: (1) STS, (2) short answer scoring (SAS), and (3) answer sentence ranking (ASR) for question answering.

Proceedings of NAACL-HLT 2016, pages 927–936,
San Diego, California, June 12-17, 2016.

2 Tasks and Datasets

Short Text Similarity (STS) Given two short texts, STS provides a real-valued score that represents their degree of semantic similarity. Our STS datasets come from the SemEval 2012–2015 corpora, containing over 14,000 human-annotated sentence pairs (via Amazon Mechanical Turk) from domains like news, tweets, forum posts, and image descriptions.

For our experiments, we select ten datasets from ten different domains, containing 6,450 sentence pairs.[1] This selection is intended to maximize (a) the number of domains, (b) domain uniqueness: of three different news headlines datasets, for example, we select the most recent (2015), discarding older ones (2013, 2014), and (c) amount of per-domain data available: we exclude the FNWN (2013) dataset with 189 annotations, for example, because it limits per-domain training data in our experiments. Sizes of the selected datasets range from 375 to 750 pairs. Average correlation (Pearson's r) among annotators ranges from 58.6% to 88.8% on individual datasets (above 70% for most) (Agirre et al., 2012; Agirre et al., 2013; Agirre et al., 2014; Agirre et al., 2015).

Short Answer Scoring (SAS) SAS comes in different forms; we explore a form where for a short-answer question, a gold answer is provided, and the goal is to grade student answers based on how similar they are to the gold answer (Ramachandran et al., 2015). We use a dataset of undergraduate data structures questions and student responses graded by two judges (Mohler et al., 2011). These questions are spread across ten different assignments and two examinations, each on a related set of topics (e.g., programming basics, sorting algorithms). Inter-annotator agreement is 58.6% (Pearson's ρ) and 0.659 (RMSE on a 5-point scale). We discard assignments with fewer than 200 pairs, retaining 1,182 student responses to forty questions spread across five assignments and tests.[2]

Answer Sentence Ranking (ASR) Given a factoid question and a set of candidate answer sentences, ASR orders candidates so that sentences containing the answer are ranked higher. Text similarity is the foundation of most prior work: a candidate sentence's relevance is based on its similarity with the question (Wang et al., 2007; Yao et al., 2013; Severyn and Moschitti, 2015).

For our ASR experiments, we use factoid questions developed by Wang et al. (2007) from Text REtrieval Conferences (TREC) 8–13. Candidate QA pairs of a question and a candidate were labeled with whether the candidate answers the question. The questions are of different types (e.g., *what*, *where*); we retain 2,247 QA pairs under four question types, each with at least 200 answer candidates in the combined development and test sets.[3] Each question type represents a unique topical domain—*who* questions are about persons and *how many* questions are about quantities.

3 Bayesian Domain Adaptation for STS

We first discuss our base linear models for the three tasks: Bayesian L_2-regularized linear (for STS and SAS) and logistic (for ASR) regression. We extend these models for (1) adaptation across different short text similarity domains, and (2) multitask learning of short text similarity (STS), short answer scoring (SAS), and answer sentence ranking (ASR).

3.1 Base Models

In our base models (Figure 1), the feature vector $\boldsymbol{f}$ combines with the feature weight vector $\boldsymbol{w}$ (including a bias term w_0) to form predictions. Each parameter $w_i \in \boldsymbol{w}$ has its own zero-mean Gaussian prior with its standard deviation σ_{w_i} distributed uniformly in $[0, m_{\sigma_w}]$, the covariance matrix $\boldsymbol{\Sigma}_w$ is diagonal, and the zero-mean prior L_2 regularizes the model.

In the linear model (Figure 1a), S is the output (similarity score for STS; answer score for SAS) and is normally distributed around the dot product $\boldsymbol{w}^T\boldsymbol{f}$. The model error σ_S has a uniform prior over a prespecified range $[0, m_{\sigma_S}]$. In the logistic model (Figure 1b) for ASR, the probability p that the candidate sentence answers the question, is (1) the sigmoid of $\boldsymbol{w}^T\boldsymbol{f}$, and (2) the Bernoulli prior of A, whether or not the candidate answers the question.

The common vectors $\boldsymbol{w}$ and $\boldsymbol{f}$ in these models enable joint parameter learning and consequently multitask learning (Section 3.3).

Figure 1: Base models for STS, SAS and ASR. Plates represent replication across sentence pairs. Each model learns weight vector $\boldsymbol{w}$. For STS and SAS, the real-valued output S (similarity or student score) is normally distributed around the weight-feature dot product $\boldsymbol{w}^T \boldsymbol{f}$. For ASR, the sigmoid of this dot product is the Bernoulli prior for the binary output A, relevance of the question's answer candidate.

3.2 Adaptation to STS Domains

Domain adaptation for the linear model (Figure 1a) learns a separate weight vector $\boldsymbol{w}_d$ for each domain d (i.e., applied to similarity computations for test pairs in domain d) alongside a common, global domain-agnostic weight vector $\boldsymbol{w}_*$, which has a zero-mean Gaussian prior and serves as the Gaussian prior mean for each $\boldsymbol{w}_d$. Figure 2 shows the model. Both $\boldsymbol{w}_*$ and $\boldsymbol{w}_d$ have hyperpriors identical to $\boldsymbol{w}$ in Figure 1a.[4]

Each $\boldsymbol{w}_d$ depends not just on its domain-specific observations but also on information derived from the global, shared parameter $\boldsymbol{w}_*$. The balance between capturing in-domain information and inductive transfer is regulated by Σ_w; larger variance allows $\boldsymbol{w}_d$ more freedom to reflect the domain.

Figure 2: Adaptation to different STS domains. The outer plate represents replication across domains. Joint learning of a global weight vector $\boldsymbol{w}_*$ along with individual domain-specific vectors $\boldsymbol{w}_d$ enables inductive transfer among domains.

3.3 Multitask Learning

An advantage of hierarchical DA is that it extends easily to arbitrarily nested domains. Our multitask learning model (Figure 3) models topical domains nested within one of three related tasks: STS, SAS, and ASR (Section 2). This model adds a level to the hierarchy of weight vectors: each domain-level $\boldsymbol{w}_d$ is now normally distributed around a task-level weight vector (e.g., $\boldsymbol{w}_{\text{STS}}$), which in turn has global Gaussian mean $\boldsymbol{w}_*$.[5] Like the DA model, all weights in the same level share common variance hyperparameters while those across different levels are separate.

Again, this hierarchical structure (1) jointly learns global, task-level and domain-level feature weights enabling inductive transfer among tasks and domains while (2) retaining the distinction between in-domain and out-of-domain annotations. A task-specific model (Figure 1) that only learns from in-domain annotations supports only (2). On the other hand, a non-hierarchical joint model (Figure 4) supports only (1): it learns a single shared $\boldsymbol{w}$ applied to any test pair regardless of task or domain. We compare these models in Section 5.

[4] Results do not improve with individual domain-specific instances of σ_S and $\boldsymbol{\sigma}_w$, consistent with Finkel and Manning (2009) for dependency parsing and named entity recognition.

[5] We use the same variable for the domain-specific parameter $\boldsymbol{w}_d$ across tasks to simplify notation.

4 Features

Any feature-based STS model can serve as the base model for a hierarchical Bayesian adaptation framework. For our experiments, we adopt the feature set of the ridge regression model in Sultan et al. (2015), the best-performing system at SemEval-2015 (Agirre et al., 2015).

Input sentences $S^{(1)} = (w^{(1)}_1, ..., w^{(1)}_n)$ and $S^{(2)} = (w^{(2)}_1, ..., w^{(2)}_m)$ (where each w is a token) produce two similarity features. The first is the proportion of content words in $S^{(1)}$ and $S^{(2)}$ (combined) that have a semantically similar word—identified using a monolingual word aligner (Sultan et al., 2014)—in the other sentence. The overall semantic similarity of a word pair $(w^{(1)}_i, w^{(2)}_j) \in S^{(1)} \times S^{(2)}$ is a weighted sum of lexical and contextual similarities: a paraphrase database (Ganitkevitch et al., 2013, PPDB) identifies lexically similar words; contextual similarity is the average lexical similarity in (1) dependencies of $w^{(1)}_i$ in $S^{(1)}$ and $w^{(2)}_j$ in $S^{(2)}$, and (2) content words in [-3, 3] windows around $w^{(1)}_i$ in $S^{(1)}$ and $w^{(2)}_j$ in $S^{(2)}$. Lexical similarity scores of pairs in PPDB as well as weights of word and contextual similarities are optimized on an alignment dataset (Brockett, 2007). To avoid penalizing long answer snippets (that still have the desired semantic content) in SAS and ASR, word alignment proportions outside the reference (gold) answer (SAS) and the question (ASR) are ignored.

The second feature captures finer-grained similarities between related words (e.g., `cell` and `organism`). Given the 400-dimensional embedding (Baroni et al., 2014) of each content word (lemmatized) in an input sentence, we compute a sentence vector by adding its content lemma vectors. The co-

Task	Current SOA	Our Model
STS	Pearson's r = 73.6%	Pearson's r = 73.7%
SAS	Pearson's r = 51.8% RMSE = 19.6%	Pearson's r = 56.4% RMSE = 18.1%

ASR	MAP = 74.6%
	MRR = 80.8%
		MAP = 76.0%
		MRR = 82.8%

Table 1: Our base linear models beat the state of the art in STS, SAS and ASR.

sine similarity between the $S^{(1)}$ and $S^{(2)}$ vectors is then used as an STS feature. Baroni et al. develop the word embeddings using `word2vec`[6] from a corpus of about 2.8 billion tokens, using the Continuous Bag-of-Words (CBOW) model proposed by Mikolov et al. (2013).

5 Experiments

For each of the three tasks, we first assess the performance of our base model to (1) verify our sampling-based Bayesian implementations, and (2) compare to the state of the art. We train each model with a Metropolis-within-Gibbs sampler with 50,000 samples using PyMC (Patil et al., 2010; Salvatier et al., 2015), discarding the first half of the samples as burn-in. The variances m_{σ_w} and m_{σ_S} are both set to 100. Base models are evaluated on the entire test set for each task, and the same training examples as in the state-of-the-art systems are used. Table 1 shows the results.

Following SemEval, we report a weighted sum of correlations (Pearson's r) across all test sets for STS, where the weight of a test set is proportional to its number of pairs. Our model and Sultan et al. (2015) are almost identical on all twenty test sets from SemEval 2012–2015, supporting the correctness of our Bayesian implementation.

Following Mohler et al. (2011), for SAS we use RMSE and Pearson's r with gold scores over all answers. These metrics are complementary: correlation is a measure of consistency across students while error measures deviation from individual scores. Our model beats the state-of-the-art text matching model of Mohler et al. (2011) on both metrics.[7]

Finally, for ASR, we adopt two metrics widely used in information retrieval: mean average precision (MAP) and mean reciprocal rank (MRR). MAP assesses the quality of the ranking as a whole whereas MRR evaluates only the top-ranked answer sentence. Severyn and Moschitti (2015) report a convolutional neural network model of text similarity which shows top ASR results on the Wang et al. (2007) dataset. Our model outperforms this model on both metrics.

5.1 Adaptation to STS Domains

Ideally, our domain adaptation (DA) should allow the application of large amounts of out-of-domain training data along with few in-domain examples to improve in-domain performance. Given data from n domains, two other alternatives in such scenarios are: (1) to train a single *global* model using all available training examples, and (2) to train n *individual* models, one for each domain, using only in-domain examples. We present results from our DA model and these two baselines on the ten STS datasets discussed in Section 2. We fix the training set size per domain and split each domain into train and test folds randomly.

Models have access to training data from all ten domains (thus nine times more out-of-domain examples than in-domain ones). Each model (global, individual, and adaptive) is trained on relevant annotations and applied to test pairs, and Pearson's r with gold scores is computed for each model on each individual test set. Since performance can vary across different splits, we average over 20 splits of the same train/test ratio per dataset. Finally, we evaluate each model with a weighted sum of average correlations across all test sets, where the weight of a test set is proportional to its number of pairs.

Figure 5 shows how models adapt as the training set grows. The global model clearly falters with larger training sets in comparison to the other two models. On the other hand, the domain-specific model (i.e., the ten individual models) performs poorly when in-domain annotations are scarce. Importantly, the adaptive model performs well across different amounts of available training data.

To gain a deeper understanding of model performance, we examine results in individual domains. A single performance score is computed for every model-domain pair by taking the model's average

[6] `https://code.google.com/p/word2vec/`

[7] Ramachandran et al. (2015) report better results; however, they evaluate on a much smaller random subset of the test data and use in-domain annotations for model training.

global	72.08 ±0.14	72.21 ±0.21	72.21 ±0.28	72.27 ±0.31	72.32 ±0.35	72.39 ±0.53	72.39 ±0.63
individual	71.18 ±0.89	72.16 ±0.62	72.21 ±0.54	72.63 ±0.4	72.8 ±0.41	72.98 ±0.53	73.01 ±0.6
adaptive	72.14 ±0.18	72.5 ±0.25	72.43 ±0.34	72.69 ±0.35	72.86 ±0.37	72.98 ±0.55	73.03 ±0.6

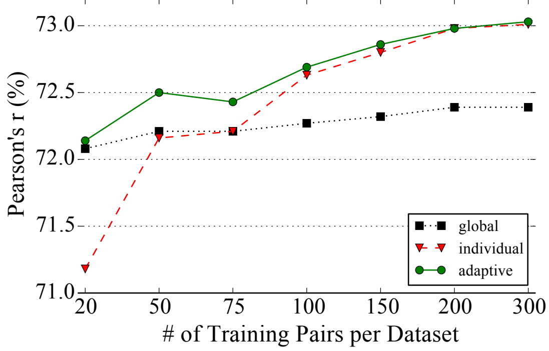

Figure 5: Results of adaptation to STS domains across different amounts of training data. Table shows mean±SD from 20 random train/test splits. While the baselines falter at extremes, the adaptive model shows consistent performance.

correlation in that domain over all seven training set sizes of Figure 5. We then normalize each score by dividing by the best score in that domain. Each cell in Table 2 shows this score for a model-domain pair. For example, Row 1 shows that—on average—the individual model performs the best (hence a correlation ratio of 1.0) on QA forum answer pairs while the global model performs the worst.

While the adaptive model is not the best in every domain, it has the best worst-case performance across domains. The global model suffers in domains that have unique parameter distributions (e.g., MSRpar-test: a paraphrase dataset). The individual model performs poorly with few training examples and in domains with noisy annotations (e.g., SMT: a machine translation evaluation dataset). The adaptive model is much less affected in such extreme cases. The summary statistics (weighted by dataset size) confirm that it not only stays the closest to the best model on average, but also deviates the least from its mean performance level.

5.1.1 Qualitative Analysis

We further examine the models to understand *why* the adaptive model performs well in different extreme scenarios, i.e., when one of the two baseline models performs worse than the other. Table 3 shows feature weights learned by each model from a split with seventy-five training pairs per domain and how well each model does.

	r	.7677	**.7865**	.7844

Table 3: Feature weights and correlations of different models in three extreme scenarios. In each case, the adaptive model learns relative weights that are more similar to those in the best baseline model.

All three domains have very different outcomes for the baseline models. We show weights for the alignment (w_1) and embedding features (w_2). In each domain, (1) the relative weights learned by the two baseline models are very different, and (2) the adaptive model learns relative weights that are closer to those of the best model. In SMT, for example, the predictor weights learned by the adaptive model have a ratio very similar to the global model's and does just as well. On Answers-students, however, it learns weights similar to those of the in-domain model, again approaching best results for the domain.

Table 4: Sentence pairs from SMT and MSRpar-test with gold similarity scores and model errors (Global, Individual and Adaptive). The adaptive model error is very close to the best model error in each case.

Table 4 shows the effect of this on two specific sentence pairs as examples. The first pair is from SMT; the adaptive model has a much lower error than the individual model on this pair, as it learns a higher relative weight for the embedding feature in this domain (Table 3) via inductive transfer from out-of-domain annotations. The second pair, from MSRpar-test, shows the opposite: in-domain annotations help the adaptive model fix the faulty output of the global model by upweighting the alignment feature and downweighting the embedding feature.

The adaptive model gains from the strengths of both in-domain (higher relevance) and out-of-domain (more training data) annotations, leading to good results even in extreme scenarios (e.g., in domains with unique parameter distributions or noisy annotations).

5.2 Multitask Learning

We now analyze performance of our multitask learning (MTL) model in each of the three tasks: STS, SAS and ASR. Multitask baselines resemble DA's: (1) a global model trained on all available training data (Figure 4), and (2) nineteen task-specific models, each trained on an individual dataset from one of the three tasks (Figure 1). The smallest of these datasets has only 204 pairs (SAS assignment #1); therefore, we use training sets with up to 175 pairs per dataset. Because the MTL model is more complex, we use a stronger regularization for this model (m_{σ_w}=10) while keeping the number of MCMC samples unchanged. As in the DA experiments, we compute average performance over twenty random train/test splits for each training set size.

Figure 6 shows STS results for all models across different training set sizes. Like DA, the adaptive model consistently performs well while the global and individual models have different failure modes. However, the individual model does better than in DA: it overtakes the global model with fewer training examples and the differences with the adaptive model are smaller. This suggests that inductive transfer and therefore adaptation is less effective for STS in the MTL setup than in DA. Later in this section, coarse-grained ASR annotations (binary as opposed to real-valued) in MTL may provide an explanation for this.

global	71.79 ±0.39	71.94 ±0.34	72.05 ±0.39	72.07 ±0.29	72.11 ±0.38	72.23 ±0.31	72.05 ±0.41
individual	70.57 ±1.45	72.06 ±0.56	72.32 ±0.55	72.67 ±0.44	72.73 ±0.51	72.9 ±0.33	72.75 ±0.41
adaptive	71.99 ±0.43	72.18 ±0.27	72.55 ±0.33	72.67 ±0.35	72.75 ±0.43	72.93 ±0.34	72.8 ±0.37

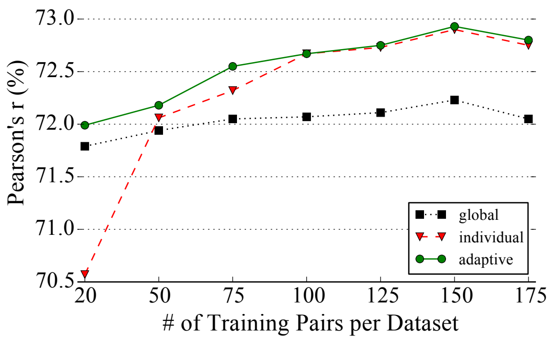

Figure 6: Multitask learning for STS: mean±SD from twenty random train/test splits. The adaptive model consistently performs well while the baselines have different failure modes.

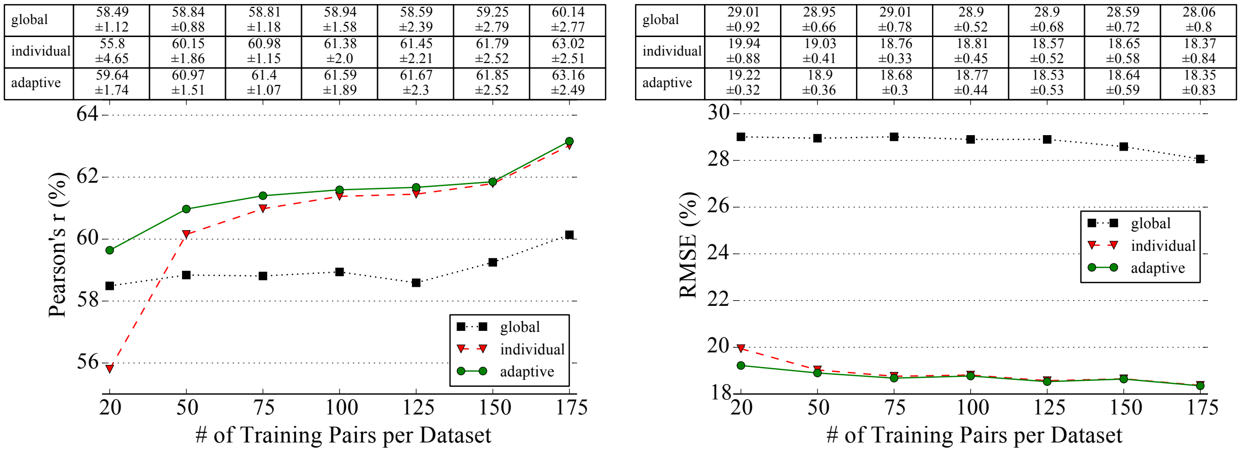
The performance drop after 150 training pairs is a likely consequence of the random train/test selection process.

For SAS, the adaptive model again has the best overall performance for both correlation and error (Figure 7). The correlation plot is qualitatively similar to the STS plot, but the global model has a much higher RMSE across all training set sizes, indicating a parameter shift across tasks. Importantly, the adaptive model remains unaffected by this shift.

The ASR results in Figure 8 show a different pattern. Contrary to all results thus far, the global model performs the best in this task. The individual model consistently has lower scores, regardless of the amount of training data. Importantly, the adaptive model stays close to the global model even with very few training examples. The ASR datasets are heavily biased towards negative examples; thus, we



global	58.49 ±1.12	58.84 ±0.88	58.81 ±1.18	58.94 ±1.58	58.59 ±2.39	59.25 ±2.79	60.14 ±2.77

use stratified sampling to ensure each ASR training set has balanced examples.

A reason for the global model's strength at ASR may lie in the finer granularity of the real-valued STS and SAS scores compared to binary ASR annotations. If a fine granularity is indeed desirable in training data, as a model that ignores in-domain and out-of-domain distinction, the global model would be affected the least by coarse-grained ASR annotations. To test this hypothesis, we train a linear model on all STS examples from SemEval 2012–2015 and apply it to the ASR test set via a logistic transformation. This model indeed demonstrates better results (MAP=.766, MRR=.839) than our base model trained on ASR annotations (Table 1). This is an unusual scenario where in-domain training examples matter less than out-of-domain ones, hurting domain-specific and adaptive models.

Going back to STS, this finding also offers an explanation of why adaptation might have been less useful in multitask learning than in domain adaptation, as only the former has ASR annotations.

6 Discussion and Related Work

For a variety of short text similarity tasks, domain adaptation improves average performance across different domains, tasks, and training set sizes. Our adaptive model is also by far the least affected by adverse factors such as noisy training data and scarcity or coarse granularity of in-domain examples. This combination of excellent average-case and very reliable worst-case performance makes it the model of choice for new STS domains and applications.

Although STS is a useful task with sparse data, few domain adaptation studies have been reported. Among those is the supervised model of Heilman and Madnani (2013a; 2013b) based on the multilevel model of Daumé III (2007). Gella et al. (2013) report using a two-level stacked regressor, where the second level combines predictions from n level 1 models, each trained on data from a separate domain. Unsupervised models use techniques such as tagging examples with their source datasets (Gella et al., 2013; Severyn et al., 2013) and computing vocabulary similarity between source and target domains (Arora et al., 2015). To the best of our knowledge, ours is the first systematic study of supervised DA and MTL techniques for STS with detailed comparisons with comparable non-adaptive baselines.

7 Conclusions and Future Work

We present hierarchical Bayesian models for supervised domain adaptation and multitask learning of short text similarity models. In our experiments, these models show improved overall performance across different domains and tasks. We intend to explore adaptation to other STS applications and with additional STS features (e.g., word and character n-gram overlap) in future. Unsupervised and semi-supervised domain adaptation techniques that do not assume the availability of in-domain annotations or that learn effective domains splits (Hu et al., 2014) provide another avenue for future research.

Abstract

Textual similarity measurement is a challenging problem, as it requires understanding the semantics of input sentences. Most previous neural network models use coarse-grained sentence modeling, which has difficulty capturing fine-grained word-level information for semantic comparisons. As an alternative, we propose to explicitly model pairwise word interactions and present a novel similarity focus mechanism to identify important correspondences for better similarity measurement. Our ideas are implemented in a novel neural network architecture that demonstrates state-of-the-art accuracy on three SemEval tasks and two answer selection tasks.

1 Introduction

Given two pieces of text, measuring their semantic textual similarity (STS) remains a fundamental problem in language research and lies at the core of many language processing tasks, including question answering (Lin, 2007), query ranking (Burges et al., 2005), and paraphrase generation (Xu, 2014).

Traditional NLP approaches, e.g., developing hand-crafted features, suffer from sparsity because of language ambiguity and the limited amount of annotated data available. Neural networks and distributed representations can alleviate such sparsity, thus neural network-based models are widely used by recent systems for the STS problem (He et al., 2015; Tai et al., 2015; Yin and Schütze, 2015).

However, most previous neural network approaches are based on *sentence modeling*, which first maps each input sentence into a fixed-length vector and then performs comparisons on these representations. Despite its conceptual simplicity, researchers have raised concerns about this approach (Mooney, 2014): Will fine-grained word-level information, which is crucial for similarity measurement, get lost in the coarse-grained sentence representations? Is it really effective to "cram" whole sentence meanings into fixed-length vectors?

In contrast, we focus on capturing fine-grained word-level information directly. Our contribution is twofold: First, instead of using sentence modeling, we propose *pairwise word interaction modeling* that encourages explicit word context interactions across sentences. This is inspired by our own intuitions of how people recognize textual similarity: given two sentences $sent_1$ and $sent_2$, a careful reader might look for corresponding semantic units, which we operationalize in our pairwise word interaction modeling technique (Sec. 5). Second, based on the pairwise word interactions, we describe a novel *similarity focus layer* which helps the model selectively identify important word interactions depending on their importance for similarity measurement. Since not all words are created equal, important words that can make more contributions deserve extra "focus" from the model (Sec. 6).

We conducted thorough evaluations on ten test sets from three SemEval STS competitions (Agirre et al., 2012; Marelli et al., 2014; Agirre et al., 2014) and two answer selection tasks (Yang et al., 2015; Wang et al., 2007). We outperform the recent multi-perspective convolutional neural networks of He et al. (2015) and demonstrate state-of-the-art accuracy on all five tasks. In addition, we conducted ablation

Proceedings of NAACL-HLT 2016, pages 937–948,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

studies and visualized our models to show the clear benefits of modeling pairwise word interactions for similarity measurement.

2 Related Work

Feature engineering was the dominant approach in most previous work; different types of sparse features were explored and found useful. For example, n-gram overlap features at the word and character levels (Madnani et al., 2012; Wan et al., 2006), syntax features (Das and Smith, 2009; Xu et al., 2014), knowledge-based features using WordNet (Fellbaum, 1998; Fern and Stevenson, 2008) and word-alignment features (Sultan et al., 2014).

The recent shift from sparse feature engineering to neural network model engineering has significantly improved accuracy on STS datasets. Most previous work use sentence modeling with a "Siamese" structure (Bromley et al., 1993). For example, Hu et al. (2014) used convolutional neural networks that combine hierarchical structures with layer-by-layer composition and pooling. Tai et al. (2015) and Zhu et al. (2015) concurrently proposed tree-structured long short-term memory networks, which recursively construct sentence representations following their syntactic trees. There are many other examples of neural network-based sentence modeling approaches for the STS problem (Yin and Schütze, 2015; Huang et al., 2013; Andrew et al., 2013; Weston et al., 2011; Socher et al., 2011; Zarrella et al., 2015).

Sentence modeling is coarse-grained by nature. Most recently, despite still using a sentence modeling approach, He et al. (2015) moved toward fine-grained representations by exploiting multiple perspectives of input sentences with different types of convolution filters and pooling, generating a "matrix" representation where rows and columns capture different aspects of the sentence; comparisons over local regions of the representation are then performed. He et al. (2015) achieves highly competitive accuracy, suggesting the usefulness of fine-grained information. However, these multiple perspectives are obtained at the cost of increased model complexity, resulting in slow model training. In this work, we take a different approach by focusing directly on pairwise word interaction modeling.

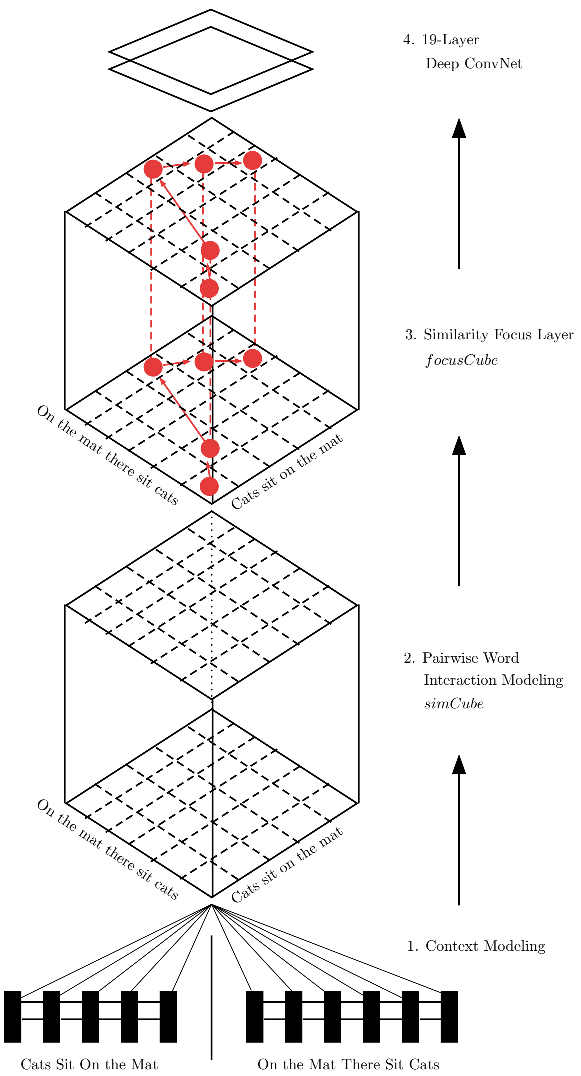

Figure 1: Our end-to-end neural network model, consisting of four major components.

3 Model Overview

Figure 1 shows our end-to-end model with four major components:

1. Bidirectional Long Short-Term Memory Networks (Bi-LSTMs) (Graves et al., 2005; Graves et al., 2006) are used for context modeling of input sentences, which serves as the basis for all following components (Sec. 4).
2. A novel pairwise word interaction modeling technique encourages direct comparisons between word contexts across sentences (Sec. 5).
3. A novel similarity focus layer helps the model identify important pairwise word interactions across sentences (Sec. 6).

4. A 19-layer deep convolutional neural network (ConvNet) converts the similarity measurement problem into a pattern recognition problem for final classification (Sec. 7).

To our best knowledge this is the first neural network model, a novel hybrid architecture combining Bi-LSTMs and a deep ConvNet, that uses a similarity focus mechanism with selective attention to important pairwise word interactions for the STS problem. Our approach only uses pretrained word embeddings, and unlike several previous neural network models (Yin and Schütze, 2015; Tai et al., 2015), we do not use sparse features, unsupervised model pretraining, syntactic parsers, or external resources like WordNet. We describe details of each component in the following sections.

4 Context Modeling

Different words occurring in similar semantic contexts of respective sentences have a higher chance to contribute to the similarity measurement. We therefore need word context modeling, which serves as a basis for all following components of this work.

LSTM (Hochreiter and Schmidhuber, 1997) is a special variant of Recurrent Neural Networks (Williams and Zipser, 1989). It can capture long-range dependencies and nonlinear dynamics between words, and has been successfully applied to many NLP tasks (Sutskever et al., 2014; Filippova et al., 2015). LSTM has a memory cell that can store information over a long history, as well as three gates that control the flow of information into and out of the memory cell. At time step t, given an input x_t, previous output h_{t-1}, input gate i_t, output gate o_t and forget gate f_t, $LSTM(x_t, h_{t-1})$ outputs the hidden state h_t based on the equations below:

$$i_t = \sigma(W^i x_t + U^i h_{t-1} + b^i) \tag{1}$$

$$f_t = \sigma(W^f x_t + U^f h_{t-1} + b^f) \tag{2}$$

$$o_t = \sigma(W^o x_t + U^o h_{t-1} + b^o) \tag{3}$$

$$u_t = tanh(W^u x_t + U^u h_{t-1} + b^u) \tag{4}$$

$$c_t = i_t \cdot u_t + f_t \cdot c_{t-1} \tag{5}$$

$$h_t = o_t \cdot tanh(c_t) \tag{6}$$

$$LSTM(x_t, h_{t-1}) = h_t \tag{7}$$

$$BiLSTMs(x_t, h_{t-1}) = \{LSTM^f, LSTM^b\} \tag{8}$$

where σ is the logistic sigmoid activation, W^*, U^* and b^* are learned weight matrices and biases. LSTMs are better than RNNs for context modeling, in that their memory cells and gating mechanisms handle the vanishing gradients problem in training.

We use bidirectional LSTMs (Bi-LSTMs) for context modeling in this work. Bi-LSTMs consist of two LSTMs that run in parallel in opposite directions: one (forward $LSTM^f$) on the input sequence and the other (backward $LSTM^b$) on the reverse of the sequence. At time step t, the Bi-LSTMs hidden state h_t^{bi} is a concatenation of the hidden state h_t^{for} of $LSTM^f$ and the hidden state h_t^{back} of $LSTM^b$, representing the neighbor contexts of input x_t in the sequence. We define the $unpack$ operation below:

$$h_t^{for}, h_t^{back} = unpack(h_t^{bi}) \tag{9}$$

Context modeling with Bi-LSTMs allows all the following components to be built over word contexts, rather than over individual words.

5 Pairwise Word Interaction Modeling

From our own intuitions, given two sentences in a STS task, a careful human reader might compare words and phrases across the sentences to establish semantic correspondences and from these infer similarity. Our pairwise word interaction model is inspired by such behavior: whenever the next word of a sentence is read, the model would compare it and its context against all words and their contexts in the other sentence. Figure 2 illustrates this model.

We first define a comparison unit for comparing two hidden states $\overrightarrow{h_1}, \overrightarrow{h_2}$ of Bi-LSTMs.

$$coU(\overrightarrow{h_1}, \overrightarrow{h_2}) = \{\cos(\overrightarrow{h_1}, \overrightarrow{h_2}), L_2Euclid(\overrightarrow{h_1}, \overrightarrow{h_2}), DotProduct(\overrightarrow{h_1}, \overrightarrow{h_2})\} \tag{10}$$

Cosine distance (cos) measures the distance of two vectors by the angle between them, while L_2 Euclidean distance ($L_2Euclid$) and dot-product distance ($DotProduct$) measure magnitude differences. We use three similarity functions for richer measurement.

Algorithm 1 provides details of the modeling process. Given the input $x_t^a \in sent_a$ at time step t where $a \in \{1, 2\}$, its Bi-LSTMs hidden state h_{at}^{bi} is the concatenation of the forward state h_{at}^{for} and the

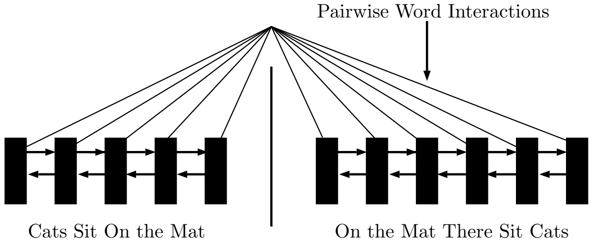

Figure 2: Pairwise word interaction modeling. Sentences are encoded by weight-shared Bi-LSTMs. We construct pairwise word interactions for context comparisons across sentences.

Algorithm 1 Pairwise Word Interaction Modeling

```
Initialize: $simCube \in R^{13 \cdot |sent_1| \cdot |sent_2|}$ to all 1
**for** each time step $t = 1...|sent_1|$ **do**
    **for** each time step $s = 1...|sent_2|$ **do**
        $h_{1t}^{for}, h_{1t}^{back} = unpack(h_{1t}^{bi})$
        $h_{2s}^{for}, h_{2s}^{back} = unpack(h_{2s}^{bi})$
        $h_{1t}^{add} = h_{1t}^{for} + h_{1t}^{back}$
        $h_{2s}^{add} = h_{2s}^{for} + h_{2s}^{back}$
        $simCube[1:3][t][s] = coU(h_{1t}^{bi}, h_{2s}^{bi})$
        $simCube[4:6][t][s] = coU(h_{1t}^{for}, h_{2s}^{for})$
        $simCube[7:9][t][s] = coU(h_{1t}^{back}, h_{2s}^{back})$
        $simCube[10:12][t][s] = coU(h_{1t}^{add}, h_{2s}^{add})$
    **end for**
**end for**
**return** $simCube$
```

backward state h_{at}^{back}. Algorithm 1 proceeds as follows: it enumerates all word pairs (s, t) across both sentences, then perform comparisons using the coU unit four times over: 1) Bi-LSTMs hidden states h_{1t}^{bi} and h_{2s}^{bi}; 2) forward hidden states h_{1t}^{for} and h_{2s}^{for}; 3) backward hidden states h_{1t}^{back} and h_{2s}^{back}; and 4) the addition of forward and backward hidden states h_{1t}^{add} and h_{2s}^{add}. The output of Algorithm 1 is a similarity cube $simCube$ with size $R^{13 \cdot |sent_1| \cdot |sent_2|}$, where $|sent_*|$ is the number of words in the sentence $sent_*$. The 13 values collected from each word pair (s, t) are: the 12 similarity distances, plus one extra dimension for the padding indicator. Note that all word interactions are modeled over word contexts in Algorithm 1, rather than individual words.

Our pairwise word interaction model shares similarities with recent popular neural attention models (Bahdanau et al., 2014; Rush et al., 2015). However, there are important differences: For example, we do not use attention weight vectors or weighted representations, which are the core of attention models. The other difference is that attention weights are typically interpreted as soft degrees with which the model attends to particular words; in contrast, our word interaction model directly utilizes multiple similarity metrics, and thus is more explicit.

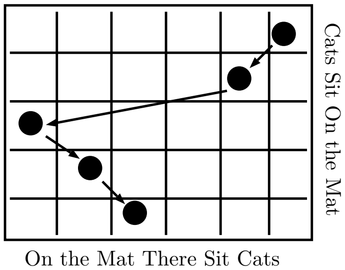

Figure 3: The similarity focus layer helps identify important pairwise word interactions (in black dots) depending on their importance for similarity measurement.

6 Similarity Focus Layer

Since not all words are created equal, important pairwise word interactions between the sentences (Sec. 5) that can better contribute to the similarity measurement deserve more model focus. We therefore develop a similarity focus layer which can identify important word interactions and increase their model weights correspondingly. This similarity focus layer is directly incorporated into our end-to-end model and is placed on top of the pairwise word interaction model, as in Figure 1.

Figure 3 shows one example where each cell of the matrix represents a pairwise word interaction. The similarity focus layer introduces re-weightings to word interactions depending on their importance for similarity measurement. The ones tagged with black dots are considered important, and are given higher weights than those without.

Algorithm 2 shows the forward pass of the similarity focus layer. Its input is the similarity cube $simCube$ (Section 5). Algorithm 2 is designed to incorporate two different aspects of similarity based on $cosine$ (angular) and $L2$ (magnitude) similarity, thus it has two symmetric components: the first one is based on $cosine$ similarity (Line 5 to Line 13); and the second one is based on $L2$ similarity (Line 15 to Line 23). We also aim for the goal that similarity values of all found important word in-

Algorithm 2 Forward Pass: Similarity Focus Layer

```
1: Input: $simCube \in R^{13 \cdot |sent_1| \cdot |sent_2|}$
2: Initialize: $mask \in R^{13 \cdot |sent_1| \cdot |sent_2|}$ to all $0.1$
3: Initialize: $s1tag \in R^{|sent_1|}$ to all zeros
4: Initialize: $s2tag \in R^{|sent_2|}$ to all zeros
5: $sortIndex_1 = sort(simCube[10])$
6: for each $id = 1...|sent_1| + |sent_2|$ do
7:     $pos_{s1}, pos_{s2} = calcPos(id, sortIndex_1)$
8:     if $s1tag[pos_{s1}] + s2tag[pos_{s2}] == 0$ then
9:         $s1tag[pos_{s1}] = 1$
10:        $s2tag[pos_{s2}] = 1$
11:        $mask[:][pos_{s1}][pos_{s2}] = 1$
12:    end if
13: end for
14: Re-Initialize: $s1tag, s2tag$ to all zeros
15: $sortIndex_2 = sort(simCube[11])$
16: for each $id = 1...|sent_1| + |sent_2|$ do
17:     $pos_{s1}, pos_{s2} = calcPos(id, sortIndex_2)$
18:     if $s1tag[pos_{s1}] + s2tag[pos_{s2}] == 0$ then
19:         $s1tag[pos_{s1}] = 1$
20:         $s2tag[pos_{s2}] = 1$
21:         $mask[:][pos_{s1}][pos_{s2}] = 1$
22:     end if
23: end for
24: $mask[13][:][:] = 1$
25: $focusCube = mask \cdot simCube$
26: return $focusCube \in R^{13 \cdot |sent_1| \cdot |sent_2|}$
```

teractions should be maximized. To achieve this, we sort the similarity values in descending order (Line 5 for $cosine$, Line 15 for $L2$). Note channels 10 and 11 of the $simCube$ contain $cosine$ and $L2$ values, respectively; the padding indicator is in Line 24.

We start with the $cosine$ part first, then $L2$. For each, we check word interaction candidates moving down the sorted list. Function $calcPos$ is used to calculate relative sentence positions pos_{s*} in the $simCube$ given one interaction pair. We follow the constraint that no word in both sentences should be tagged to be important more than once. We increase weights of important word interactions to 1 (in Line 11 based on $cosine$ and Line 21 based on $L2$), while unimportant word interactions receive weights of 0.1 (in Line 2).

We use a mask matrix, $mask$, to hold the weights of each. The final output of the similarity focus layer is a focus-weighted similarity cube $focusCube$, which is the element-wise multiplication (Line 25) of the matrix $mask$ and the input $simCube$.

The similarity focus layer is based on the following intuition: given each word in one sentence, we look for its semantically similar twin in the other sentence; if found then this word is considered important, otherwise it contributes to a semantic difference. Though technically different, this process shares conceptual similarity with finding translation equivalences in statistical machine translation (Al-onaizan et al., 1999).

The backward pass of the similarity focus layer is straightforward: we reuse the $mask$ matrix as generated in the forward pass and apply the element-wise multiplication of $mask$ and inflow gradients, then propagate the resulting gradients backward.

7 Similarity Classification with Deep Convolutional Neural Networks

The $focusCube$ contains focus-weighted fine-grained similarity information. In the final model component we use the $focusCube$ to compute the final similarity score. If we treat the $focusCube$ as an "image" with 13 channels, then semantic similarity measurement can be converted into a pattern recognition (image processing) problem, where we are looking for patterns of strong pairwise word interactions in the "image". The stronger the overall pairwise word interactions are, the higher similarity the sentence pair will have.

Recent advances from successful systems at ImageNet competitions (Simonyan and Zisserman, 2014; Szegedy et al., 2015) show that the depth of a neural network is a critical component for achieving competitive performance. We therefore use a deep homogeneous architecture which has repetitive convolution and pooling layers.

Our network architecture (Table 1) is composed of spatial max pooling layers, spatial convolutional layers (Conv) with a small filter size of 3×3 plus stride 1 and padding 1. We adopt this filter size because it is the smallest one to capture the space of left/right, up/down, and center; the padding and stride is used to preserve the spatial input resolution. We then use fully-connected layers followed by the final softmax layer for the output. After each spatial convolutional layer, a rectified linear units (ReLU) non-linearity layer (Krizhevsky et al., 2012) is used.

The input to this deep ConvNet is the $focusCube$, which does not always have the same size because

Table 1: Deep ConvNet architecture given two padding size configurations for final classification.

the lengths of input sentences vary. To address this, we use zero padding. For computational reasons we provide two configurations in Table 1, for length padding up to either 32×32 or 48×48. The only difference between the two configurations is the last pooling layer. If sentences are longer than the padding length limit we only use the number of words up to the limit. In our experiments we found the 48×48 padding limit to be acceptable since most sentences in our datasets are only $1-30$ words long.

8 Experimental Setup

Datasets. We conducted five separate experiments on ten different datasets: three recent SemEval competitions and two answer selection tasks. Note that the answer selection task, which is to rank candidate answer sentences based on their similarity to the questions, is essentially the similarity measurement problem. The five experiments are as follows:

1. Sentences Involving Compositional Knowledge (SICK) is from Task 1 of the 2014 SemEval competition (Marelli et al., 2014) and consists of 9,927 annotated sentence pairs, with 4,500 for training, 500 as a development set, and 4,927 for testing. Each pair has a relatedness score $\in [1, 5]$ which increases with similarity.

Table 2: Description of STS2014 test sets.

2. Microsoft Video Paraphrase Corpus (MSRVID) is from Task 6 of the 2012 SemEval competition (Agirre et al., 2012) and consists of 1,500 annotated pairs of video descriptions, with half for training and the other half for testing. Each sentence pair has a relatedness score $\in [0, 5]$ which increases with similarity.
3. Task 10 of the 2014 SemEval competition on Semantic Textual Similarity (STS2014) (Agirre et al., 2014) provided six different test sets from different domains. Each pair has a similarity score $\in [0, 5]$ which increases with similarity. Following the competition rules, our training data is only drawn from previous STS competitions in 2012 and 2013. We excluded training sentences with lengths longer than the 48 word padding limit, resulting in 7,382 training pairs out of a total of 7,592. Table 2 provides a brief description of the test sets.
4. The open domain question-answering WikiQA data is from Bing query logs by Yang et al. (2015). We followed the same pre-processing steps as Yang et al. (2015), where questions with no correct candidate answer sentences are excluded and answer sentences are truncated to 40 tokens. The resulting dataset consists of 873 questions with 8,672 question-answer pairs in the training set, 126 questions with 1,130 pairs in the development set, and 243 questions with 2,351 pairs in the test set.
5. The TrecQA dataset (Wang et al., 2007) from the Text Retrieval Conferences has been widely used for the answer selection task during the past decade. To enable direct comparison with previous work, we used the same training, development, and test sets as released by Yao et al. (2013).

The TrecQA data consists of 1,229 questions with 53,417 question-answer pairs in the *TRAIN-ALL* training set, 82 questions with 1,148 pairs in the development set, and 100 questions with 1,517 pairs in the test set.

Training. For experiments on SICK, MSRVID, and STS2014, the training objective is to minimize the KL-divergence loss:

$$loss(\theta) = \frac{1}{n}\sum_{k=1}^{n} KL\left(f^k \mid\mid \widehat{f_\theta^k}\right) \qquad (11)$$

where f is the ground truth, $\widehat{f_\theta}$ is the predicted distribution with model weights θ, and n is the number of training examples.

We used a hinge loss for the answer selection task on WikiQA and TrecQA data. The training objective is to minimize the following loss, summed over examples $\langle x, y_{gold}\rangle$:

$$loss(\theta, x, y_{gold}) = \sum_{y' \neq y_{gold}} \max(0, 1 + f_\theta(x, y') - f_\theta(x, y_{gold})) \qquad (12)$$

where y_{gold} is the ground truth label, input x is the pair of sentences $x = \{S_1, S_2\}$, θ is the model weight vector, and the function $f_\theta(x, y')$ is the output of our model.

In all cases, we performed optimization using RMSProp (Tieleman and Hinton, 2012) with backpropagation (Bottou, 1998), with a learning rate fixed to 10^{-4}.

Settings. For the SICK and MSRVID experiments, we used 300-dimension GloVe word embeddings (Pennington et al., 2014). For the STS2014, WikiQA, and TrecQA experiments, we used 300-dimension PARAGRAM-SL999 embeddings from Wieting et al. (2015) and the PARAGRAM-PHRASE embeddings from Wieting et al. (2016), trained on word pairs from the Paraphrase Database (PPDB) (Ganitkevitch et al., 2013). We did not update word embeddings in all experiments.

We used the SICK development set for tuning and then applied exactly the *same* hyperparameters to *all* ten test sets. For the answer selection task (WikiQA and TrecQA), we used the official trec_eval scorer to compute the metrics Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR) and selected the best development model based on MRR for final testing. Our timing experiments were conducted on an Intel Xeon E5-2680 CPU.

Due to sentence length variations, for the SICK and MSRVID data we padded the sentences to 32 words; for the STS2014, WikiQA, and TrecQA data, we padded the sentences to 48 words.

Table 3: Test results on SICK grouped as: (1) RNN variants; (2) SemEval 2014 systems; (3) Sequential LSTM variants; (4) Dependency and constituency tree LSTMs. Evaluation metrics are Pearson's r, Spearman's ρ, and mean squared error (MSE). Rows in grey are neural network models.

9 Results

SICK Results (Table 3). Our model outperforms previous neural network models, most of which are based on sentence modeling. The ConvNet work (He et al., 2015) and TreeLSTM work (Tai et al., 2015) achieve comparable accuracy; for example, their difference in Pearson's r is only 0.1%. In comparison, our model outperforms both by 1% in Pearson's r, over 1.1% in Spearman's ρ, and 2-3% in MSE. Note that we used the same word embeddings, sparse distribution targets, and loss function as in He et al. (2015) and Tai et al. (2015), thereby representing comparable experimental conditions.

MSRVID Results (Table 4). Our model outperforms the work of He et al. (2015), which already reports a Pearson's r score of over 0.9,

ficial measure) of Pearson's r scores calculated based on the number of sentence pairs in each test set. We show the 1st ranked (Sultan et al., 2014), 2nd (Kashyap et al., 2014), 3rd (Lynum et al., 2014) systems in the STS2014 competition, all of which are based on heavy feature engineering. Our model does not use any sparse features, WordNet, or parse trees, but still performs favorably compared to the STS2014 winning system (Sultan et al., 2014).

WikiQA Results (Table 6). We compared our model to competitive baselines prepared by Yang et al. (2015) and also evaluated He et al. (2015)'s multi-perspective ConvNet on the same data. The neural network models in the table, paragraph vector (PV) (Le and Mikolov, 2014), CNN (Yu et al., 2014), and PV-Cnt/CNN-Cnt with word matching features (Yang et al., 2015), are mostly based on sentence modeling. Our model outperforms them all.

Table 7: Test results on TrecQA data.

TrecQA Results (Table 7). This is the largest dataset in our experiments, with over 55,000 question-answer pairs. Only recently have neural network approaches (Yu et al., 2014) started to show promising results on this decade-old dataset. Previous approaches with probabilistic tree-edit techniques or tree kernels (Wang and Manning, 2010; Heilman and Smith, 2010; Yao et al., 2013) have been successful since tree structure information permits a fine-grained focus on important words for similarity comparison purposes. Our approach essentially follows this intuition, but in a neural network setting with the use of our similarity focus layer. Our model outperforms previous work.

10 Analysis

Ablation Studies. Table 8 shows the results of ablation studies on SICK and WikiQA data. We removed or replaced one component at a time from the full system and performed re-training and re-testing. We found large drops when removing the context modeling component, indicating that the context information provided by the Bi-LSTMs is crucial for the following components (e.g., interaction modeling). The use of our similarity focus layer is also beneficial, especially on the WikiQA data. When we replaced the entire similarity focus layer with a random dropout layer ($p = 0.3$), the dropout layer hurts accuracy; this shows the importance of directing the model to focus on important pairwise word interactions, to better capture similarity.

Table 9: Comparison of training efficiency and number of tunable model parameters on SICK data. Timing is the average epoch time in seconds for training on a single CPU thread.

ConvNet model uses multiple types of convolution and pooling for sentence modeling. This results in a wide architecture with around 10 million tunable parameters. Our approach only models pairwise word interactions and does not require such a complicated architecture. Compared to that previous work, Table 9 shows that our model is 3.4× faster in training and has 83% fewer tunable parameters.

Visualization. Table 10 visualizes the cosine value channel of the $focusCube$ for pairwise word interactions given two sentence pairs in the SICK test set. Note for easier visualization, the values are multiplied by 10. Darker red areas indicate stronger pairwise word interactions. From these visualizations, we see that our model is able to identify important word pairs (in dark red) and tag them with proper similarity values, which are significantly higher than the ones of their neighboring unimportant pairs. This shows that our model is able to recognize important fine-grained word-level information for better similarity measurement, suggesting the reason why our model performs well.

11 Conclusion

In summary, we developed a novel neural network model based on a hybrid of ConvNet and Bi-LSTMs for the semantic textual similarity measurement problem. Our pairwise word interaction model and the similarity focus layer can better capture fine-grained semantic information, compared to previous sentence modeling approaches that attempt to "cram" all sentence information into a fixed-length vector. We demonstrated the state-of-the-art accuracy of our approach on data from three SemEval competitions and two answer selection tasks.

Abstract

For many low-resource languages, spoken language resources are more likely to be annotated with translations than transcriptions. This bilingual speech data can be used for word-spotting, spoken document retrieval, and even for documentation of endangered languages. We experiment with the neural, attentional model applied to this data. On phone-to-word alignment and translation reranking tasks, we achieve large improvements relative to several baselines. On the more challenging speech-to-word alignment task, our model nearly matches GIZA++'s performance on gold transcriptions, but without recourse to transcriptions or to a lexicon.

1 Introduction

For many low-resource languages, spoken language resources are more likely to come with translations than with transcriptions. Most of the world's languages are not written, so there is no orthography for transcription. Phonetic transcription is possible but too costly to produce at scale. Even when a minority language has an official orthography, people are often only literate in the language of formal education, such as the national language. Nevertheless, it is relatively easy to provide written or spoken *translations* for audio sources. Subtitled or dubbed movies are a widespread example.

One application of models of bilingual speech data is documentation of endangered languages. Since most speakers are bilingual in a higher-resource language, they can listen to a source language recording sentence by sentence and provide a spoken translation (Bird, 2010; Bird et al., 2014). By aligning this data at the word level, we hope to automatically identify regions of data where further evidence is needed, leading to a substantial, interpretable record of the language that can be studied even if the language falls out of use (Abney and Bird, 2010; Bird and Chiang, 2012).

We experiment with extensions of the neural, attentional model of Bahdanau et al. (2015), working at the phone level or directly on the speech signal. We assume that the target language is a high-resource language such as English that can be automatically transcribed; therefore, in our experiments, the target side is text rather than the output of an automatic speech recognition (ASR) system.

In the first set of experiments, as a stepping stone to direct modeling of speech, we represent the source as a sequence of phones. For phone-to-word alignment, we obtain improvements of 9–24% absolute F1 over several baselines (Och and Ney, 2000; Neubig et al., 2011; Stahlberg et al., 2012). For phone-to-word translation, we use our model to rerank *n*-best lists from Moses (Koehn et al., 2007) and observe improvements in BLEU of 0.9–1.7.

In the second set of experiments, we operate directly on the speech signal, represented as a sequence of Perceptual Linear Prediction (PLP) vectors (Hermansky, 1990). Without using transcriptions or a lexicon, the model is able to align the source-language speech to its English translations nearly as well as GIZA++ using gold transcriptions.

Our main contributions are: (i) proposing a new task, alignment of speech with text translations, including a dataset extending the Spanish

Proceedings of NAACL-HLT 2016, pages 949–959,
San Diego, California, June 12-17, 2016.

Fisher and CALLHOME datasets; (ii) extending the neural, attentional model to outperform existing models at both alignment and translation reranking when working on source-language phones; and (iii) demonstrating the feasibility of alignment directly on source-language speech.

2 Background

To our knowledge, there has been relatively little research on models that operate directly on parallel speech. Typically, speech is transcribed into a word sequence or lattice using ASR, or at least a phone sequence or lattice using a phone recognizer. This normally requires manually transcribed data and a pronunciation lexicon, which can be costly to create. Recent work has introduced models that do not require pronunciation lexicons, but train only on speech with text transcriptions (Lee et al., 2013; Maas et al., 2015; Graves et al., 2006). Here, we bypass phonetic transcriptions completely, and rely only on translations.

Such data can be found, for example, in subtitled or dubbed movies. Some specific examples of corpora of parallel speech are the European Parliament Plenary Sessions Corpus (Van den Heuvel et al., 2006), which includes parliamentary speeches in the 21 official EU languages, as well as their interpretation into all the other languages; and the TED Talks Corpus (Cettolo et al., 2012), which provides speech in one language (usually English) together with translations into other languages.

As mentioned in the introduction, a steppingstone to model parallel speech is to assume a recognizer that can produce a phonetic transcription of the source language, then to model the transformation from transcription to translation. We compare against three previous models that can operate on sequences of phones. The first is simply to run GIZA++ (IBM Model 4) on a phonetic transcription (without word boundaries) of the source side. Stahlberg et al. (2012) present a modification of IBM Model 3, named Model 3P, designed specifically for phone-to-word alignment. Finally, pialign (Neubig et al., 2011), an unsupervised model for joint phrase alignment and extraction, has been shown to work well at the character level (Neubig et al., 2012) and extends naturally to work on phones.

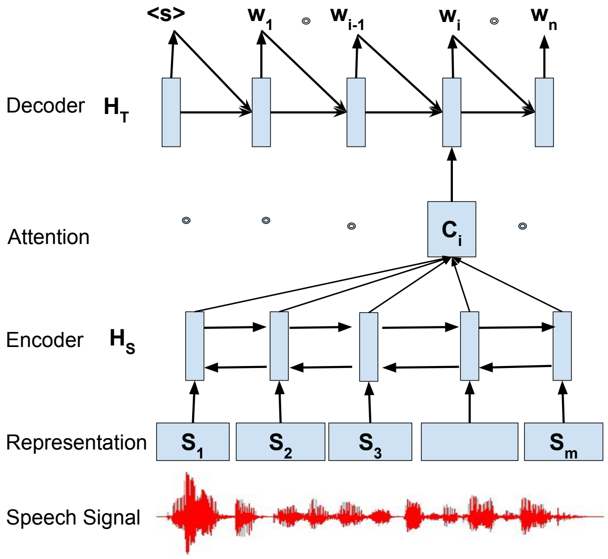

Figure 1: The attentional model as applied to our tasks. We consider two types of input: discrete phone input, or continuous audio, represented as PLP vectors at 10ms intervals

3 Model

We base our approach on the attentional translation model of Cohn et al. (2016), an extension of Bahdanau et al. (2015) which incorporates more fine grained components of the attention mechanism to mimic the structural biases in standard word based translation models. The attentional model encodes a source as a sequence of vectors, then decodes it to generate the output. At each step, it "attends" to different parts of the encoded sequence. This model has been used for translation, image caption generation, and speech recognition (Luong et al., 2015; Xu et al., 2015; Chorowski et al., 2014; Chorowski et al., 2015). Here, we briefly describe the basic attentional model, following Bahdanau et al. (2015), review the extensions for encoding structural biases (Cohn et al., 2016), and then present our novel means for adapting the approach handle parallel speech.

3.1 Base attentional model

The model is shown in Figure 1. The speech signal is represented as a sequence of vectors $S_1, S_2, \ldots, S_m$. For the first set of experiments, each S_i is a 128-dimensional vector-space embedding of a phone. For the second set of experiments, each S_i is the

39-dimensional PLP vector of a single frame of the speech signal. Our model has two main parts: an encoder and a decoder. For the encoder, we used a bidirectional recurrent neural network (RNN) with Long Short-Term Memory (LSTM) units (Hochreiter and Schmidhuber, 1997); we also tried Gated Recurrent Units (Pezeshki, 2015), with similar results. The source speech signal is encoded as sequence of vectors $H_S = (H_S^1, H_S^2, \dots, H_S^m)$ where each vector H_S^j $(1 \leq j \leq m)$ is the concatenation of the hidden states of the forward and backward LSTMs at time j.

The attention mechanism is added to the model through an alignment matrix $\alpha \in \mathbb{R}^{n \times m}$, where n is the number of target words. We add <s> and </s> to mark the start and end of the target sentence. The row $\alpha_i \in \mathbb{R}^m$ shows where the model should attend to when generating target word w_i. Note that $\sum_{j=1}^m \alpha_{ij} = 1$. The "glimpse" vector c_i of the source when generating w_i is $c_i = \sum_j \alpha_{ij} H_S^j$.

The decoder is another RNN with LSTM units. At each time step, the decoder LSTM receives c_i in addition to the previously-output word. Thus, the hidden state[1] at time i of the decoder is defined as $H_T^i = \text{LSTM}(H_T^{i-1}, c_i, w_{i-1})$, which is used to predict word w_i:

$$p(w_i \mid w_1 \cdots w_{i-1}, H_S) = \text{softmax}(g(H_T^i)), \qquad (1)$$

where g is an affine transformation. We use 128 dimensions for the hidden states and memory cells in both the source and target LSTMs.

We train this model using stochastic gradient descent (SGD) on the negative log-likelihood for 100 epochs. The gradients are rescaled if their L2 norm is greater than 5. We tried Adagrad (Duchi et al., 2011), AdaDelta (Zeiler, 2012), and SGD with momentum (Attoh-Okine, 1999), but found that simple SGD performs best. We implemented dropout (Srivastava et al., 2014) and the local attentional model (Luong et al., 2015), but did not observe any significant improvements.

3.2 Structural bias components

As we are primarily interested in learning accurate alignments (roughly, attention), we include the modelling extensions of Cohn et al. (2016) for incorporating structural biases from word-based translation models into the neural attentional model. As shown later, we observe that including these components result in a substantial improvement in measured alignment quality. We now give a brief overview of these components.

Previous attention. In the basic attentional model, the alignment is calculated based on the source encoding H_S and the previous hidden state H_T^{i-1} of the target, $\alpha_i = \text{Attend}(H_T^{i-1}, H_S)$, where Attend is a function that outputs m attention coefficients. This attention mechanism is overly simplistic, in that it is incapable of capturing patterns in the attention over different positions i. Recognising and exploiting these kinds of patterns has proven critical in traditional word based models of translation (Brown et al., 1993; Vogel et al., 1996; Dyer et al., 2013). For this reason Cohn et al. (2016) include explicit features encoding structural biases from word based models, namely absolute and relative position, Markov conditioning and fertility:

1. previous alignment, α_{i-1}
2. sum of previous alignments, $\sum_{j=1}^{i-1} \alpha_j$
3. source index vector, $(1, 2, 3, \dots, m)$; and
4. target index vector $(i, i, i, \dots, i)$.

These features are concatenated to form a feature matrix $\beta \in \mathbb{R}^{4 \times m}$, which are added to the alignment calculation, i.e., $\alpha_i = \text{Attend}(H_T^{i-1}, H_S, \beta)$.

Coverage penalty. The sum over previous alignments feature, described above provides a basic fertility mechanism, however as it operates locally it is only partially effective. To address this, Cohn et al. (2016) propose a global regularisation method for implementing fertility.

Recall that the alignment matrix $\alpha \in \mathbb{R}^{n \times m}$, each α_i is normalized, such that $\sum_j \alpha_{ij} = 1$. However, nothing in the model requires that every source element gets used. This is remedied by encouraging the columns of the alignment matrix to also sum to one, that is, $\sum_i \alpha_{ij} = 1$. To do so, we add a regularization penalty, $\lambda \sum_{j=1}^m \left\| \sum_{i=1}^n \alpha_{ij} - 1 \right\|_2^2$ to the objective function where λ controls the regularization strength. We tune λ on the development set and found that $\lambda = 0.05$ gives the best performance.

[1] The LSTM also carries a memory cell, along with the hidden state; we exclude this from the presentation for clarity of notation.

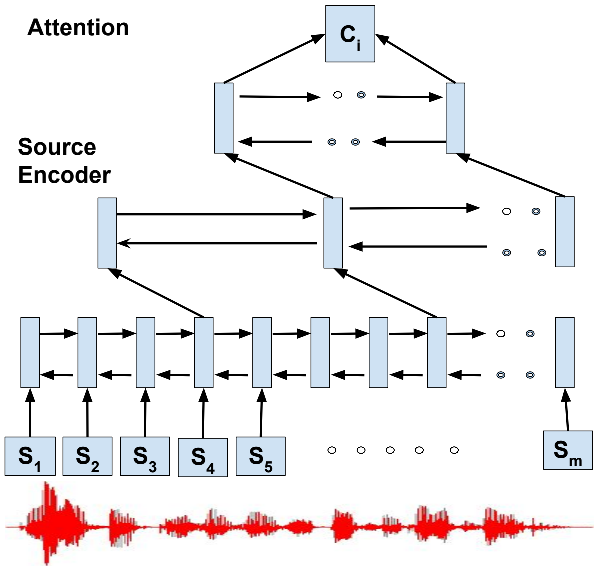

Figure 2: Stacking three layers of LSTM to the source side as in the second set of experiments

4 Extensions for Speech

We can easily apply the attentional model to parallel data, where the source side is represented as a sequence of phones. In cases where no annotated data or lexicon are available, we expect it is difficult to obtain phonetic transcriptions. Instead, we would like to work directly with the speech signal. However, dealing with the speech signal is significantly different than the phone representation, and so we need to modify the base attentional model.

4.1 Stacked and pyramidal RNNs

Both the encoder and decoder can be made more powerful by stacking several layers of LSTMs (Sutskever et al., 2014). For the first set of experiments below, we stack 4 layers of LSTMs on the target side; further layers did not improve performance on the development set.

For the second set of experiments, we work directly with the speech signal as a sequence of PLP vectors, one per frame. Since the frames begin at 10 millisecond intervals, the sequence can be very long. This makes the model slow to train; in our experiments, it seems not to converge at all. Following Chan et al. (2016), we use RNNs stacked into a pyramidal structure to reduce the size of the source speech representation. As illustrated in Figure 2, we stack 3 layers of bidirectional LSTMs. The first layer is the same as the encoder H_S described in Figure 1. The second layer uses every fourth output of the first layer as its input. The third layer selects every other output of the second layer as its input. The attention mechanism is applied only to the top layer. This reduces the size of the alignment matrix by a factor of eight, giving rise to vectors at the top layer representing 80ms intervals, which roughly correspond in duration to input phones.

4.2 Alignment smoothing

In most bitexts, source and target sentences have roughly the same length. However, for our task of aligning text and speech where the speech is represented as a sequence of phones or PLP vectors, the source can easily be several times larger than the target. Therefore we expect that a target word will commonly align to a run of several source elements. We want to encourage this behavior by smoothing the alignment matrix.

The easiest way to do this is by post-processing the alignment matrix. We train the model as usual, and then modify the learned alignment matrix α by averaging each cell over a window, $\alpha'_{ij} := \frac{1}{3}(\alpha_{i,j-1} + \alpha_{ij} + \alpha_{i,j+1})$. The modified alignment matrix, α', is only used for generating hard alignments in our alignment evaluation experiments. We can smooth further by changing the computation of α_{ij} during training. We flatten the softmax by adding a temperature factor, $T \geq 1$:

$$\alpha_{ij} = \frac{\exp(e_{ij}/T)}{\sum_k \exp(e_{ik}/T)}$$

Note that when $T = 1$ we recover the standard softmax function; we set $T = 10$ in both experiments.

5 Experimental Setup

We work on the Spanish CALLHOME Corpus (LDC96S35), which consists of telephone conversations between Spanish native speakers based in the US and their relatives abroad. While Spanish is not a low-resource language, we pretend that it is by not using any Spanish ASR or resources like transcribed speech or pronunciation lexicons (except in the construction of the "silver" standard for evaluation, described below). We also use the English translations produced by Post et al. (2013).

We treat the Spanish speech as a sequence of 39-dimensional PLP vectors (order 12 with energy and first and second order delta) encoding the power spectrum of the speech signal. We do not have gold standard alignments between the Spanish speech and English words for evaluation, so we produced "silver" standard alignments. We used a forced aligner (Gorman et al., 2011) to align the speech to its transcription, and GIZA++ with the `gdfa` symmetrization heuristic (Och and Ney, 2000) to align the Spanish transcription to the English translation. We then combined the two alignments to produce "silver" standard alignments between the Spanish speech and the English words.

Cleaning and splitting the data based on dialogue turns, resulted in a set of 17,532 Spanish utterances from which we selected 250 for development and 500 testing. For each utterance we have the corresponding English translation, and for each word in the translation we have the corresponding span of Spanish speech.

The forced aligner produces the phonetic sequences that correspond to each utterance, which we use later in our first set of experiments as an intermediate representation for the Spanish speech.

In order to evaluate an automatic alignment between the Spanish speech and English translation against the "silver" standard alignment, we compute alignment precision, recall, and F1-score as usual, but on links between Spanish PLP vectors and English words.

6 Phone-to-Word Experiments

In our first set of experiments, we represent the source Spanish speech as a sequence of phones. This sets an upper bound for our later experiments working directly on speech.

6.1 Alignment

We compare our model against three baselines: GIZA++, Model 3P, and pialign. For pialign, in order to better accommodate the different phrase lengths of the two alignment sides, we modified the model to allow different parameters for the Poisson distributions for the average phrase length, as well as different null alignment probabilities for each side.[2] We used the settings `-maxsentlen 200 -maxphraselen 20 -avgphraselenF 10 -nullprobF 0.001`, improving performance by 1.6% compared with the default setting. For Model 3P, we used the settings `-maxFertility 15 -maxWordLength 20`, unrestricted `max[Src/Trg]SenLen` and 10 `Model3Iterations`. We chose the iteration with the highest score to report as the baseline.

Model	F-score	Δ
GIZA++	29.7	−13.0
Model 3P	31.2	−11.5
Pialign (default)	42.4	−0.3
Pialign (modified)	44.0	+1.3
Base model	42.7	+0
+ alignment features	46.2	+3.5
+ coverage penalty	48.6	+5.9
+ stacking	46.3	+3.6
+ alignment smoothing	47.3	+4.6
+ alignment/softmax smoothing	48.2	+5.5
All modifications	53.6	+10.9

Table 1: On the alignment task, the base model performs much better than GIZA++ and Model 3P, and at roughly the same level as pialign; modifications to the model produce further large improvements. The Δ column shows the score difference compared with the base model.

The attentional model produces a soft alignment matrix, whose entries α_{ij} indicate $p(s_j \mid w_i)$ of aligning source phone s_j to target word w_i. For evaluation, we need to convert this to a hard alignment that we can compare against the "silver" standard. Since each word is likely to align with several phones, we choose a simple decoding algorithm: for each phone s_j, pick the word w_i that maximizes $p(w_i \mid s_j)$, where this probability is calculated from alignment matrix α using Bayes' Rule.

Table 1 shows the results of the alignment experiment. The base attentional model achieved an F-score of 42.7%, which is much better than GIZA++ and Model 3P (by 13% and 11.5% absolute, respectively) and at roughly the same level as pialign. Adding our various modifications one at a time

[2] Our modifications have been submitted to the pialign project.

		reranker	
aligner	decoder	none	AM
AM (all mods)		14.6	
GIZA++	Moses	18.2	19.9
pialign	Moses	18.9	19.8
pialign (mod)	Moses	20.2	21.1
Word-based Reference		34.1	

Table 2: BLEU score on the translation task. Using the attentional model (AM) alone (first row) significantly underperformed Moses. However, using the AM as a reranker yielded improvements across several settings. The word-based reference translation provides the upper bound for our phoneme-based systems.

yields improvements ranging from 3.5% to 5.9%. Combining all of them yields a net improvement of 10.9% over the base model, which is 9.4% better than the modified pialign, 22.4% better than Model 3P, and 23.9% better than GIZA++.

6.2 Translation

In this section, we evaluate our model on the translation task. We compare the model against the Moses phrase-based translation system (Koehn et al., 2007), applied to phoneme sequences. We also provide baseline results for Moses applied to word sequences, to serve as an upper bound. Since Moses requires word alignments as input, we used various alignment models: GIZA++, pialign, and pialign with our modifications. Table 2 shows that translation performance roughly correlates with alignment quality.

For the attentional model, we used all of the modifications described above except alignment smoothing. We also used more dimensions (256) for hidden states and memory cells in both encoder and decoder. The decoding algorithm starts with the symbol <s> and uses beam search to generate the next word. The generation process stops when we reach the symbol </s>. We use a beam size of 5, as larger beam sizes make the decoder slower without substantial performance benefits.

As shown in Table 2, the attentional model achieved a BLEU score of 14.6 on the test data, whereas the Moses baselines achieve much better BLEU scores, from 18.2 to 20.2. We think this is because the attentional model is powerful, but we don't have enough data to train it fully given that the output space is the size of the vocabulary. Moreover, this attentional model has been configured to optimize the alignment quality rather than translation quality.

We then tried using the attentional model to rerank 100-best lists output by Moses. The model gives a score for generating the next word $p(w_i|w_1 \cdots w_{i-1}, H_S)$ as in equation (1). We simply compute the score of a hypothesis by averaging the negative log probabilities of the output words,

$$\text{score}(w_1 \cdots w_n) = -\frac{1}{n}\sum_{i=1}^{n} \log(p(w_i|w_1 \cdots w_{i-1}, H_S)),$$

and then choosing the best scoring hypothesis. Table 2 shows the result using the attentional model as the reranker on top of Moses, giving improvements of 0.9 to 1.7 BLEU over their corresponding baselines. These consistent improvements suggest that the probability estimation part of the attentional model is good, but perhaps the search is not adequate. Further research is needed to improve the attentional model's translation quality. Another possibility, which we leave for future work, is to include the attentional model score as a feature in Moses.

Table 3 shows some example translations comparing different models. In all examples, it appears that using pialign produced better translations than GIZA++. Using the attentional model as a reranker for pialign further corrects some errors. Using the attentional model alone seems to perform the worst, which is evident in the third example where the attentional model simply repeats a text fragment (although all models do poorly here). Despite the often incoherent output, the attentional model still captures the main keywords used in the translation.

We test this hypothesis by applying the attentional model for a cross-lingual keyword spotting task where the input is the English keyword and the outputs are all Spanish sentences (represented as phones) containing a likely translation of the keyword. From the training data we select the top 200 terms as the keyword based on tf.idf. The relevance judgment is based on exact word matching. The attentional model achieved 35.8% precision, 43.3%

recall and 36.0% F-score on average on 200 queries. Table 4 shows the English translations of retrieved Spanish sentences. In the first example, the attentional model identifies *mañana* as the translation of *tomorrow*. In the second example, it does reasonably well by retrieving 2 correct sentences out of 3, correctly identifying *dejamos* and *salgo* as the translation of *leave*.

7 Speech-to-Word Experiments

In this section, we represent the source Spanish speech as a sequence of 39 dimensional PLP vectors. The frame length is 25ms, and overlapping frames are computed every 10ms. As mentioned in Section 4.1, we used a pyramidal RNN to reduce the speech representation size. Other than that, the model used here is identical to the first set of experiments.

Using this model directly for translation from speech does not yield useful output, as is to be expected from the small training data, noisy speech data, and an out-of-domain language model. However, we are able to produce useful results for the ASR and alignment tasks, as presented below.

	PER (%)
Our model	24.3
Our model + monotonic	22.3
Chorowski et al. (2014)	18.6
Graves et al. (2013)	17.7

Table 5: Phone-error-rate (PER) for various models evaluated on TIMIT

7.1 ASR Evaluation

To illustrate the utility of our approach to modelling speech input, first, we evaluate on the more common ASR task of phone recognition. This can be considered as a sub-problem of translation, and moreover, this allows us to benchmark our approach against the state-of-the-art in phone recognition. We experimented on the TIMIT dataset. Following convention, we removed all the SA sentences, evaluated on the 24 speaker core test set and used the 50 auxiliary speaker development set for early stopping. The model was trained to recognize 48 phonemes and was mapped to 39 phonemes for testing. We extracted 39 dimensional PLP features from the TIMIT dataset and trained the same model without any modification. Table 5 shows the performance of our model. It performs reasonably well compared with the state-of-the-art (Graves et al., 2013), considering that we didn't tune any hyper-parameters or feature representations for the task. Moreover, our model is not designed for the monotonic constraints inherent to the ASR problem, which process the input without reordering. By simply adding a masking function (equation 2 from Chorowski et al. (2014)) to encourage the monotonic constraint in the alignment function, we observe a 2% PER improvement. This is close to the performance reported by Chorowski et al. (2014) (Table 5), despite the fact that they employed user-adapted speech features.

7.2 Alignment Evaluation

We use alignment as a second evaluation, training and testing on parallel data comprising paired Spanish speech input with its English translations (as described in §5), and using the speech-based modelling techniques (see §4.) We compare to a naive baseline where we assume that each English letter (not including spaces) corresponds to an equal number of Spanish frames. The results of our attentional model and the baseline are summarized in Table 6. The attentional model is substantially lower than the scores in Table 1, because the PLP vector representation is much less informative than the gold phonetic transcription. Here, we have to identify phones and their boundaries in addition to phone-word alignment. However, the naive baseline does surprisingly well, presumably because our (unrealistic) choice of Spanish-English does not have very much reordering.

Figure 3 presents some examples of Spanish speech and English text, showing a heat map of the alignment matrix α (before smoothing). Due to the pyramidal structure of the encoder, each column roughly corresponds to 80ms. In the example on the left, the model is confident at aligning *a little* with columns 1–5, which corresponds roughly to their correct Spanish translation *algo*. We misalign the word *of* with columns 8–10, when the correct alignment should be columns 5–6, corresponding

ru	AM (all mods)	27.4
es	GIZA++	29.7

Table 6: Alignment of Spanish speech to English translations. In the first two rows, no gold or automatic transcriptions of any sort are used. In the next three rows, non-Spanish phone recognizers (cz, hu, ru) are used on the Spanish speech and the attentional model is run on the noisy transcription; this does better than no transcriptions. The last row is an unfair comparison because it uses gold Spanish (es) phonetic transcriptions; nevertheless, our model performs nearly as well.

to Spanish translation *de*. The word *knowledge* is aligned quite well with columns 7–10, corresponding to Spanish *conocimiento*. The example on the right is for a longer sentence. The model is less confident about this example, mostly because there are words that appear infrequently, such as the personal name *Irma*. However, we are still observing diagonal-like alignments that are roughly correct. In both examples, the model correctly leaves silence (`sil`) unaligned.

As a middle ground between assuming gold phonetic transcriptions (cf. Section 6) and no transcriptions at all, we use noisy transcriptions by running speech recognizers for other languages on the Spanish speech: Russian (ru), Hungarian (hu) and Czech (cz) (Vasquez et al., 2012). These distantly related languages were chosen to be a better approximation to the low-resource scenario. All three models perform better than operating directly on the speech signal (Table 6), and notably, the Russian result is nearly as good as GIZA++'s performance on gold phonetic transcriptions.

8 Conclusion

This paper reports our work to train models directly on parallel speech, i.e. source-language speech with English text translations that, in the low-resource setting, would have originated from spoken translations. To our knowledge, it is the first exploration of this type. We augmented the Spanish Fisher and CALLHOME datasets and extended the alignment F1 evaluation metric for this setting. We extended the attentional model of Bahdanau et al. to work on parallel speech and observed improvements relative to all baselines on phone-to-word alignment. On speech-to-word alignment, our model, without using any knowledge of Spanish, performs almost as well as GIZA++ using gold Spanish transcriptions.

Language pairs with word-order divergences and other divergences will of course be more challenging than Spanish-English. This work provides a proof-of-concept that we hope will spur future work towards solving this important problem in a true low-resource language.

Acknowledgments

Abstract

This paper introduces information density and machine translation quality estimation inspired features to automatically detect and classify human translated texts. We investigate two settings: discriminating between translations and comparable originally authored texts, and distinguishing two levels of translation professionalism. Our framework is based on delexicalised sentence-level dense feature vector representations combined with a supervised machine learning approach. The results show state-of-the-art performance for mixed-domain translationese detection with information density and quality estimation based features, while results on translation expertise classification are mixed.

1 Introduction

Translations, regardless of the method they were produced with, are different from their source texts and from originally authored comparable texts in the target language. This has been confirmed by many linguistic studies on translation properties commonly called *translationese* (Gellerstam, 1986). These studies show that translations tend to share a set of lexical, syntactic and/or textual features distinguishing them from non-translated texts. As most of these features can be measured quantitatively, we are able to automatically distinguish translations from originals (Baroni and Bernardini, 2006; Ozdowska and Way, 2009; Kurokawa et al., 2009). This is useful for Statistical Machine Translation (SMT), as language and translation models can be improved if the translation direction and status of the data (translation or original) is known (Lembersky, 2013).

Research on translationese has recently focused on exploring features capturing aspects of translationese such as simplification, explicitation, convergence, normalisation and shining-through (Volansky, 2012; Ilisei, 2012). Here we extend this work as follows: (i) we investigate the impact of information density and surprisal features, (ii) we explore the use of features used in machine translation quality estimation (Blatz et al., 2003; Specia et al., 2010), (iii) we explore classification between originally authored text and trainee and professional translation, as well as between professional and trainee translation. In order to avoid biasing classification by topic content, throughout our experiments we use fully delexicalised features, resulting in dense vector representations (rather than sparse vectors, where the size of the vectors can be up to and in fact exceed the size of the vocabulary). We show that information theory as well as translation quality estimation inspired features achieve state-of-the-art results in mixed-domain original vs. human translation classification.

Languages provide speakers with a large number of possibilities of how they may encode messages. These include the choice of phonemes, words, syntactic structures, as well as arranging sentences in discourse. Speakers' decisions regarding these choices are influenced by diverse factors: cognitive processing limitations can impact variation in linguistic encoding across all linguistic levels. Text production conditions, including monolingual vs. multilingual settings, can influence this variation: in

Proceedings of NAACL-HLT 2016, pages 960–970,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

translation, choices can be shaped by aspects of both the source and the target language.

Contrastive studies have shown that information density is distributed differently in English and German (Doherty, 2006; Fabricius-Hansen, 1996). These contrasts may impact translation, and in case of source language shining through[1], we would expect to observe differences between translations and comparable originals in terms of information density. Additionally, translations are often more specialised and more conventionalised than originals (excluding translation of fictional texts). In this paper we investigate whether and to what extent information density based features are useful in human translation classification.

Quality estimation (QE) (Blatz et al., 2004; Ueffing and Ney, 2005) is the attempt to learn models that predict machine translation quality without access to a reference translation at prediction time. Translation, manual or automatic, is always a process of transforming a source into a target text. This process is prone to error. In this paper we explore whether and to what extent the extensive research on QE can be brought to bear on the problem of human translation vs. originals classification, and in particular the discrimination between novice and professional translation output.

Below we explore the ability of our features to distinguish between 1) non-translated texts and translations by professionals, 2) non-translated texts and translations by translator trainees, and 3) the two translation varieties that diverge in the degree of translation experience. We report results in terms of accuracy and f-score, and provide a feature analysis in order to understand the role of the information density and QE inspired features in the task.

The paper is organised as follows: related work is presented in Section 2. The experimental setup is detailed in Section 3, followed by the results and analysis in Section 4. A discussion about our results compared to previous work is given in Section 5. Finally, conclusion and future work are provided in Section 6.

2 Related Work

We briefly review previous work on translationese, information density, machine translation quality estimation and studies on human translation expertise.

2.1 Translationese

A number of corpus-based studies on translation have shown that it is possible to automatically predict whether a text is an original or a translation (Baroni and Bernardini, 2006; Koppel and Ordan, 2011). These approaches are based on the concept of translationese – a term coined to capture the specific language of translations by Gellerstam (1986). The idea is that translations exhibit properties which distinguish them from original texts, both the source texts of the translation and comparable texts originally authored in the target language. Baker (1993; 1995) claimed these properties to be universal, i.e. (source) language-independent, emphasising general effects of the process of translation.

However, translationese includes features involving both source and target language. Most linguistic studies distinguish *explicitation* – a tendency to spell things out rather than leave them implicit and *implicitation* (the opposite effect), *simplification* – a tendency to simplify the language used in translation, *normalisation* – a tendency to exaggerate features of the target language and to conform to its typical patterns, *levelling out* or *convergence* – a relatively higher level of homogeneity of translated texts compared to non-translated ones, and *interference* or *shining through* (e.g. Teich (2003)). While simple lexicalised features including word tokens and character n-grams can produce near perfect classification results for in-domain data (Avner et al., 2014), a significant amount of work has gone into devising features that can capture presumed linguistic aspects of translationese (Volansky, 2012). Rabinovich et al. (2015) explore unsupervised discrimination of translations based on principal components analysis for dimensionality reduction followed by a clustering step. The method is robust to unbalanced and heterogeneous datasets, which may be useful to handle mixed domain, genre and source of data, a common situation when training language and translation models.

Automatic classification of original vs. translated

[1] If translations demonstrate features more typical for the source language, see e.g. Teich (2003).

texts has applications in machine translation, especially in studies showing the impact of the nature (original vs. translation) of the text in translation and language models used in SMT. Kurokawa et al. (2009) show that taking directionality into account when training an English-to-French phrase-based SMT system leads to improved translation performance. Ozdowska & Way (2009) analyse the same language pair and demonstrate that the nature of the original source language has an impact on the quality of SMT output. Lembersky et al. (2012) show that BLEU scores can be improved by language models compiled from translated texts and not from comparable originally authored ones.

2.2 Information Density

In a natural communication situation, speakers tend to exploit variations in their linguistic encoding – modulating the order, density and specificity of their expressions to avoid informational peaks and troughs that may result in inefficient communication. This is often referred to as the *uniform information density* hypothesis (Frank and Jaeger, 2008). The information conveyed by an expression can be quantified by its *surprisal*, a measure of how predictable an expression is given its context. Simplification and explicitation may impact the average information density measured on translated texts compared to comparable originally authored ones in the same language. Source language interference should result in peaks of measured surprisal values in translated texts, while the information density may remain uniform in originals.

According to Hale (2001), a surprisal model allows the estimation of the probability of a parse tree given a sentence prefix. Levy (2008) showed that a lexical-based surprisal measure can be obtained by computing the negative log probability of a word given its preceding context: $S = -\log P(w_{k+1}|w_1 \dots w_k)$. Following Demberg et al. (2013), we estimate surprisal in three ways, at the word, part-of-speech and syntax levels, based on n-gram language models and language models trained on unlexicalised part-of-speech sequences and flattened syntactic trees. Note that all resulting feature vectors do not represent lexical information but information theoretic surprisal measures.

2.3 Quality Estimation

Machine translation QE is the process of estimating how accurate an automatic translation is through characteristic features of the source and target texts, and (possibly) also the translation engine, with a supervised machine learning setting to estimate quality scores. QE can be applied at the word, sentence and document level (Gandrabur and Foster, 2003; Ueffing et al., 2003; Blatz et al., 2003; Scarton and Specia, 2014).

Many different delexicalised dense features have been explored in previous work on QE, including language and topic models, n-best lists, etc. (Quirk, 2004; Ueffing and Ney, 2004; Specia and Gimenez, 2010; Rubino et al., 2013a). It has been shown that the performance of a supervised classifier to distinguish between originals and automatic translations is correlated with the quality of the machine translated texts (Aharoni et al., 2014): low quality translation, containing grammatical and syntactic errors, as well as incorrect lexical choices, are robust indicators of automatic translations. In the case of human translation, to the best of our knowledge, there are no empirical studies on the level of professional expertise in the translation process and its correlation with the performance of a translationese classifier.

2.4 Translator Experience

Jääskeläinen (1997) describes translational behaviour of professionals and non-professionals who perform translation from English into Finnish. Carl and Buch-Kromann (2010) apply psycholinguistic methods in their analysis. They present a study of translation phases and processes for student and professional translators, relating translators' eye movements and keystrokes to the quality of the translations produced. They show that the translation behaviour of novice and professional translators differs with respect to how they use the translation phases. Englund Dimitrova (2005) develops a combined process and product analysis and compares translators with different levels of translation experience, but concentrates only on cohesive explicitness.

Most of these works are rather process-oriented than product-oriented, which means that features of translated texts are rarely taken into account. However, some of the findings are valuable for the analysis of translated texts. For instance, Göpferich & Jääskeläinen (2009) find that with increasing translation competence, translators focus on larger translation units, which can impact the choice of linguistic encoding translators use.

3 Experimental Setup

Our experiments are designed to investigate underexplored topics focusing on (i) information theoretic and (ii) machine translation QE features in translation classification. We use dense vector representations with fully delexicalised features and investigate three hypotheses:

1. originals & professional translations should be close in terms of quality and thus more difficult to separate automatically,
2. originals & student translations should be distant in terms of quality and thus easier to classify,
3. professional & student translations should both contain translationese features and thus may be very difficult to differentiate.

3.1 Supervised Classification

In order to train a classifier and predict binary labels on unseen data, we use a dense vector sentence-level representation associated with a class $(\mathbf{x}_i, y_i)$, $i = 1, \ldots, l$ (l is the number of training instances) with $\mathbf{x}_i \in R^n$ (n is the size of a dense vector) and $y \in \{-1, 1\}^l$. We train classification models with a support vector machine SVM (the C-SVC implementation in LIBSVM (Chang and Lin, 2011)) as a quadratic optimization problem:

$$\min_{\omega,b,\xi} \quad \tfrac{1}{2}\omega^T\omega + C\sum_{i=1}^{l}\xi_i \ ,$$
$$\text{subject to} \quad y_i(\omega^T\phi(x_i) + b) \geq 1 - \xi_i \ , \quad \xi_i \geq 0 \ .$$

ϕ is a kernel function and allows the projection of training data to a higher dimensional space. We use the radial basis function (RBF) kernel, as it produced the best empirical results compared to linear and polynomial kernels. We predict the class for unseen instances x as follows:

$$f(x) = \text{sgn}(\omega^T\phi(x) + b).$$

Corpus	Token (M)	Sentence (k)
Europarl Originals	4.1	155.5
Literature Originals	1.3	48.1
Literature Translations	1.4	45.8
Politics Originals	0.2	9.7
Politics Translations	0.2	8.7

Table 1: Details of the corpora used to train language and n-gram frequency models for originally authored texts and translations.

Two hyper-parameters have to be set for C-SVC with the RBF kernel: the regularisation parameter (or penalty) C and the kernel parameter γ. We use grid-search to find optimal values, performing a 5-fold cross-validation on the training data. To avoid over-fitting, we use a held-out development set to evaluate the models obtained.

3.2 Datasets

The datasets used in our experiments are separated into two subsets: corpora used to extract features and corpora used to train, tune and test our classifiers. The former are taken from the publicly available bilingual English-German parallel corpora consisting of parliamentary proceedings, literary works and political commentary, compiled by (Rabinovich et al., 2015). These corpora are used individually to train language models and compute n-gram frequency distributions. Basic corpus statistics are presented in Table 1. The latter ones are composed of German texts, taken from the VARTRA corpora (Lapshinova-Koltunski, 2013), which were either originally written in German (originals) or translated from English (translations).

Originals and translations belong to the same genres and registers and can be considered comparable. They include a mixture of literary, tourism and popular-scientific texts, instruction manuals, commercial letters and political essays and speeches. The VARTRA translations are split in two sets: one produced by professional translators, and one produced by translator trainees. Details are presented in Table 2. We extract balanced subsets of training, tuning and testing data containing three, one and two thousands sentences, respectively, of each type.

Corpus	Token (k)	Sentence (k)
Originals	121.7	6.0
Professional Translations	125.2	6.0
Student Translations	126.2	6.0

Table 2: Details of the comparable corpora used as training, development and test sets for the originals versus translation classification experiments.

3.3 Feature Sets

For classification, input text is represented as a set of feature vectors. The features capture aspects of information density and translation QE. Throughout we use unlexicalised lower-dimensional dense vectors rather than high-dimensional lexicalised sparse vectors to minimize the input of specific content on classification results. We extract a total of 778 features[2] and separate them into four subsets corresponding to broad but distinct characteristics of original and translated sentences: surface and distortion features are related to QE, surprisal and complexity features are inspired by information theory.

Surface Features - 13 surface features based on meta representations of sentences' lexical form. Features include sentence and average word length, the number of word tokens and number of punctuation marks. Three case-based features capture the number of upper-cased letters and words, and a binary feature indicates whether a sentence starts with an upper-case character. Another binary value encodes whether the sentence ends with a period. Two features are obtained from the ratio between the number of upper-cased and lower-cased letters, the number of punctuation marks and the length of the sentence. Finally two features capture the number of periods merged with words and words with mixed-case characters.

Surprisal Features - 225 features based on the surprisal measure presented in Section 2.2 are extracted using language models trained on words, delexicalised part-of-speech and flattened syntactic trees. The language models are trained on individual[3] corpora presented in Table 1. We extract n-gram ($n \in [1;5]$) log-probabilities and perplexities, with and without the tags indicating the beginning and ending of sentences, using the SRILM toolkit (Stolcke et al., 2011).

Complexity Features - 315 features based on n-gram frequencies, indicating how frequent the lexical choices, part-of-speech and flattened syntactic sequences present in the text to be classified are. As for the surprisal features, we use the same originally authored and translated texts individually to extract n-grams frequency quartiles. We extract the percentage of n-grams ($n \in [1;5]$) occurring in each quartile. Frequency percentages are averaged at the sentence level, leading to 4 features per sentence (one per quartile) given a value of n, for each corpus used to define the frequency quartiles. This approach allows us to avoid encoding raw n-gram features and keep a dense vector representation (Blatz et al., 2003).

Distortion Features - 225 features based on the possible distortion in lexical, part-of-speech and syntactic structures observed between originals and translations, as well as between different levels of translation experience. These features are extracted the same way as the suprisal features, but based on language models trained on sentence-level reversed text. The backward language model features are popular in translation quality estimation studies and show interesting results (Duchateau et al., 2002; Rubino et al., 2013b).

3.4 Preprocessing and Tools

All data used in our experiments are sentence-split, lower-cased and tokenised using the CoreNLP toolkit (Manning et al., 2014). The part-of-speech tags and syntactic trees required to extract some features are obtained with the same set of tools. For parsing, we use the probabilistic context-free grammar model trained on the Negra corpus (Brants et al., 2003) and described in (Rafferty and Manning, 2008), before flattening the trees as illustrated in Figure 1. Both part-of-speech and flattened syntac-

[2] Too many to list in the paper, a complete list is provided with the additional material submitted.

tic trees are then delexicalised in order to remove all surface forms from the representations.

4 Results and Analysis

Below we provide details on discriminating between originally authored texts and translations, followed by the prediction of translation experience comparing professional translators and students. Finally, we evaluate feature importance with individual and ensemble feature selection techniques.

4.1 Original vs Translated Texts

Two sets of experiments are conducted to discriminate between originals and professional translations (Table 3) and originals and student translations (Table 4). For each classification task, we evaluate feature groups on the test set containing $4,000$ unseen sentences balanced over two classes, reporting overall accuracy, and also precision, recall and f-score. Finally, a classification model is trained and evaluated combining all features.

Originals vs. professional translations reaches a maximum accuracy of 70.0% using the distortion feature set with surprisal a close second at 69.2%. The difference is not statistically significant (bootstrap resampling at $p < 0.05$). They outperform the other types of features, as well as the combination of all feature types. Per class evaluation shows a similar trend with the best performing feature sets. The results show that originals and professional translations exhibit differences in terms of sequences of words, part-of-speech and syntactic tags which are captured by language model based features.

		Originals			Professional		
Feature set	Acc (%)	P	R	F	P	R	F
Surface	54.7	0.54	0.64	0.58	0.56	0.46	0.50
Surprisal	69.2*	0.66	0.77	0.71	0.73	0.61	**0.66**
Complexity	65.3	0.63	0.73	0.68	0.68	0.57	0.62
Distortion	**70.0***	0.66	0.81	**0.73**	0.75	0.59	**0.66**
All	66.5	0.64	0.74	0.69	0.70	0.59	0.64

Table 3: Accuracy, precision, recall and F-measure obtained on the originals versus professional translations classification task. Best results in bold and statistically significant winner marked with * ($p < 0.05$).

		Originals			Student		
Feature set	Acc (%)	P	R	F	P	R	F
Surface	57.8	0.58	0.58	0.58	0.58	0.58	0.58
Surprisal	69.7*	0.69	0.72	0.70	0.71	0.67	**0.69**
Complexity	65.4	0.62	0.81	0.70	0.73	0.49	0.59
Distortion	70.8*	0.69	0.75	**0.72**	0.73	0.66	**0.69**
All	**71.1***	0.69	0.76	**0.72**	0.73	0.66	**0.69**

Table 4: Accuracy, precision, recall and F-measure obtained on the originals versus student translations classification task. Best results in bold and statistically significant winner marked with * ($p < 0.05$).

The classification of originals and student translations shows that the combination of the four feature types leads to the most accurate classifier, followed by the distortion and the surprisal sets (with equivalent accuracy results at $p < 0.05$). The two latter feature sets are the best performing ones overall based on the two classification tasks. Comparing the two tasks, originally authored texts are closer to professional translations and more distant to student translations, which validates two of our hypotheses listed in Section 3.

4.2 Translation Expertise

In order to investigate whether our third assumption is correct, we perform binary classification between professional and student translations (Table 5). The results, barely above the 50% baseline, show the proximity of the two types of translations according to our feature sets, which supports our third assumption. The combination of four feature types reaches the highest accuracy, followed by the distortion and complexity sets. However, the surprisal features do not seem to be helpful in differentiating between the professional and the student translations, compared to the two previous binary classification tasks.

This result indicates that the surprisal measure is a reliable source of information to determine whether a sentence is originally authored or a translation, but it is not reliable to separate two translations produced by translators with different levels of expertise. The features inspired by translation quality estimation do not reach high accuracy results: it seems that the difference between professional and student translations cannot be tied to properties of the surface level or lexical choices of the human translators as indirectly captured by our features.

		Professional			Students		
Feature set	Acc (%)	P	R	F	P	R	F
Surface	54.5	0.56	0.43	0.48	0.54	0.66	0.59
Surprisal	55.7	0.57	0.48	0.52	0.55	0.64	0.59
Complexity	56.0	0.56	0.55	0.56	0.56	0.57	0.56
Distortion	57.7	0.58	0.55	0.56	0.57	0.60	0.59
All	**58.7***	0.59	0.57	**0.58**	0.58	0.61	0.59

Table 5: Accuracy, precision, recall and F-measure obtained on the professional versus student translations classification task. Best results in bold and statistically significant winner marked with $\star$ ($p < 0.05$).

4.3 3-way Classification

Table 6 shows the confusion matrix obtained with the classifier trained on the combination of the four feature sets. This classifier reaches third position overall in terms of accuracy, behind the distortion and surprisal sets with first and second positions, respectively. This ranking of classifiers trained on different feature sets follows the trend observed in the originals versus professional translation binary classification task.

		Reference		
		Originals	Professional	Student
Prediction	Originals	1318	656	544
	Professional	276	699	491
	Student	406	645	965

Table 6: Confusion matrix obtained using a classifier trained on the four feature sets for the multi-class task, separating originals, professional and student translations.

The training method chosen for the multi-class problem is the *one against one*, where individual classifiers are first trained on each binary classification task before being combined to form the final multi-class classifier (Hsu and Lin, 2002). The results indicate that our feature sets distinguish originally authored texts from professional and student translations (first line of the matrix), while the professional translations are more difficult to separate from the two other types of text. Also, student translations have characteristics differing from originals and professional translations, which can be captured with our feature sets (last line of the matrix). However, the columns of the confusion matrix show that originals are not necessarily closer to professional translations, as indicated by the first column where a larger amount of gold originals are incorrectly classified as student translations. The same trend is observable in the last column. These results go against the hypothesis that originals and student translations are easier to separate, a phenomenon which does not appear for the binary classification task (originals vs. student translations).

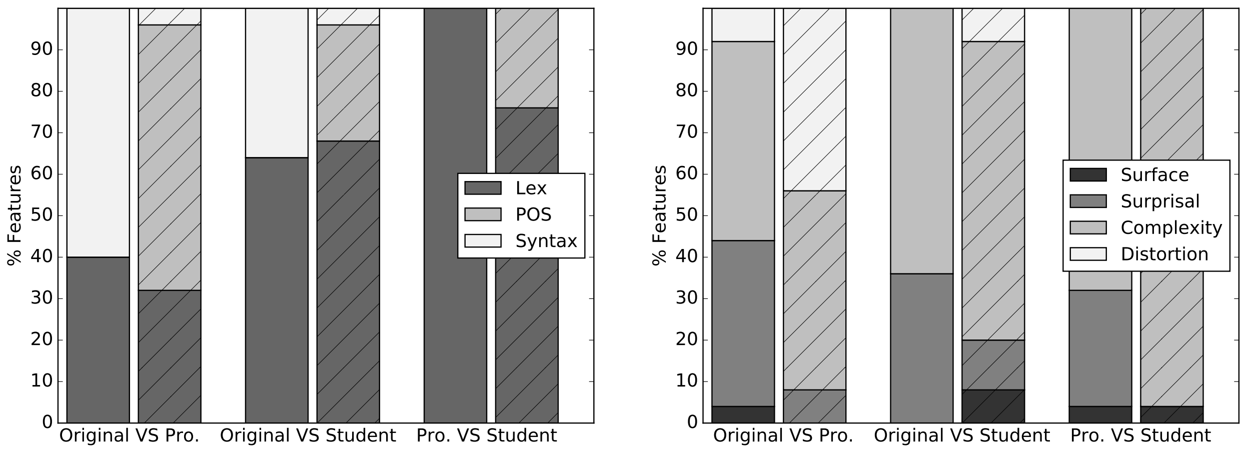
4.4 Feature Performance

Evaluating the performance of our feature sets is done by calculating the discriminative power of each feature individually which allows us to rank features according to their correlation with a class given a classification task. We follow the ”f-score” measure (1) as proposed by Chen (2006):

$$F(i) \equiv \frac{\left(\bar{x}_i^{(+)} - \bar{x}_i\right)^2 + \left(\bar{x}_i^{(-)} - \bar{x}_i\right)^2}{\frac{1}{n_+ - 1}\sum_{k=1}^{n_+}\left(\bar{x}_{k,i}^{(+)} - \bar{x}_i^{(+)}\right)^2 + \frac{1}{n_- - 1}\sum_{k=1}^{n_-}\left(\bar{x}_{k,i}^{(-)} - \bar{x}_i^{(-)}\right)^2} \qquad (1)$$

with training vectors x_k and $k = 1, \ldots, m$, binary classes n_+ and n_- for positive and negative instances, $\bar{x}_i$, $\bar{x}_i^{(+)}$, $\bar{x}_i^{(-)}$ the average of the ith feature of the whole, positive and negative instances, and $\bar{x}_{k,i}^{(+)}$ and $\bar{x}_{k,i}^{(-)}$ the ith feature of the kth positive or negative instance. The measure indicates how discriminative a feature is given a binary classification task. A drawback of the *f-score* is that it does not take into account possible feature complementarity.

We report the distribution of the top 25 features amongst the three levels of analysis: lexical, POS and syntax (Figure 2a), as well as amongst the four



(a) Lexical, POS and syntax.

(b) Surface, surprisal, complexity and distortion.

Figure 2: Distributions of the top 25 most important features according to individual discriminative power (left bars) and ensemble of randomised trees (right hatched bars).

feature types: surface, surprisal, complexity and distortion (Figure 2b). The results show that POS features are not ranked as the most discriminant ones when evaluated individually, while syntactic features are the most important ones for the originals vs. professional translation task and lexical features have the highest discriminative power for the two other tasks. When looking at the feature types, we see that complexity features, based on n-gram frequencies, are the most discriminant for the three tasks, followed by the surprisal features, while the distortion and surface features do not have a strong discriminative power. Most of the top n-gram based features rely on sequences between 1 and 3 words, indicating that higher order n-grams are not important features when considered individually. Surprisal, distortion and complexity features are based on external resources (detailed in Table 1) and the corpus of political texts translated into German is the most useful one when used to extract the complexity and surprisal features, which can be explained by the presence of political speeches and essays in the VARTRA corpus.

The results obtained on individual feature discriminative power do not reflect the ones obtained using features grouped by types. Individually, features indicating complexity based on n-gram frequencies are ranked highest. However, only a few of the distortion features appear in the discriminative ranking while this feature type reaches the highest accuracy scores on the three binary classification tasks. These results indicate that features are highly complementary within a group of a particular type, but also between different types. To capture possible relationships between features, we conduct a non-linear feature selection using the forest of randomised trees approach (Geurts et al., 2006) and present the results for the top 25 features in Figure 2 (right hatched bars).

The tree-based feature ranking method shows the complementarity of words and POS features, while the syntactic ones appear in the top 25 for the original vs. translation tasks for both levels of expertise. When looking at the feature types, the originals vs. professional task relies mainly on a mixture of distortion and complexity features, and surprisal indicators are totally absent from the top 25 for the professional vs. student task. For both tasks involving student translation, the complexity features are the most important ones, and simple surface features are useful, such as the average words occurrence per sentence or the ratio between the number of punctuation marks and the sentence length. The most useful external resource used to extract n-gram based features is again the political corpus, indicating once more the domain proximity of our datasets.

Individually, syntactic features appear to be highly discriminant when classifying between originals and translations (regardless expertise), which may indicate two translationese phenomena: simplification, translators use less complex constructions, and interference (shining through), source syntax shines through in translated texts. The ensemble ranking shows that surprisal and distortion, although not as important as complexity and distortion, are important indicators of translationese as they appear in both tasks where originals are classified against translations. These feature types are not present in the top 25 if only translated texts are classified.

5 Discussion

Previous research (Baroni and Bernardini, 2006; Volansky, 2012) has shown that high classification accuracy ($> 80\%$) can be achieved using lexicalised token n-gram sparse feature vectors. As a sanity check, we conduct a set of experiments for each of our classification tasks using token unigram frequency as features, normalised by the segment length. The vocabulary defining the feature vector dimensionality is taken from the training sets, using the data presented in Table 2 only, leading to $25,561$ features. The same classification setup as presented in Section 3 is used and we observe accuracy results reaching 78.0%, 83.3% and 65.2% for original vs. professional, originals vs. student and professional vs. student classifications respectively. For the three-way task, an accuracy score of 62.7% is reached. These results are substantially lower than the ones reported by Volansky (2012), mostly because of the text chunks size, which has a strong impact on performance as shown by Rabinovich and Wintner (2015). In our work, we classify each sentence individually as they appear naturally in the corpus, while most previous studies are based on artificial chunks of approximately $2,000$ tokens. An other explanation of the low performing unigram-based features is related to our mixed-domain setting, as it was shown that classifiers' performance drop drastically when trained on this type of features and tested on out-of-domain data (Rabinovich and Wintner, 2015).

6 Conclusion

This paper presented a first step in using information density, and especially surprisal and complexity inspired features, as well as features used in translation quality estimation, as indicators of translationese for originally authored and manually translated text classification. We focused on separating originals and translations produced by humans with different levels of expertise and showed that translationese features based on information density and quality estimation are useful indicators of whether a text was manually translated or originally produced. We conducted experiments in a mixed-domain setting, including literary, tourism and scientific texts, as well as instruction manuals, commercial letters and political essays and speeches.

Our experiments on feature type evaluation show that the best performing one is a set of quality estimation inspired distortion indicators, extracted from backward language models trained on originally authored and translated texts. When features are evaluated individually according to the ”f-score” measure (Chen and Lin, 2006), the most discriminative ones are from the complexity subset, extracted from n-gram frequency quartiles, followed by surprisal features, both extracted at the lexical and syntactic levels. The features ensemble evaluation based on randomised trees reveals feature complementarity and shows that extracting complexity and distortion indicators at the lexical and POS levels leads to the highest performing sets.

The features used in our experiments are extracted at the word-level. As future work, we plan to extend our feature sets to information theoretic aspects of character-level indicators, such as character n-grams frequencies and language models, encoding complexity and surprisal respectively. This approach would allow to capture sub-word information density indicators, such as morphological information (Avner et al., 2014).

Abstract

Computational approaches to simultaneous interpretation are stymied by how little we know about the tactics human interpreters use. We produce a parallel corpus of translated and simultaneously interpreted text and study differences between them through a computational approach. Our analysis reveals that human interpreters regularly apply several effective tactics to reduce translation latency, including sentence segmentation and passivization. In addition to these unique, clever strategies, we show that limited human memory also causes other idiosyncratic properties of human interpretation such as generalization and omission of source content.

1 Human Simultaneous Interpretation

Although simultaneous interpretation has a key role in today's international community,[1] it remains underexplored within machine translation (MT). One key challenge is to achieve a good quality/speed tradeoff: deciding when, what, and how to translate. In this study, **we take a data-driven, comparative approach and examine:** (i) What distinguishes simultaneously interpreted text (Interpretese[2]) from batch-translated text (Translationese)? (ii) What strategies do human interpreters use?

Most previous work focuses on qualitative analysis (Bendazzoli and Sandrelli, 2005; Camayd-Freixas, 2011; Shimizu et al., 2014) or pattern counting (Tohyama and Matsubara, 2006; Sridhar et al., 2013). In contrast, we use a more systematic approach based on feature selection and statistical tests. In addition, most work ignores *translated* text, making it hard to isolate strategies applied by interpreters as opposed to general strategies needed for any translation. Shimizu et al. (2014) are the first to take a comparative approach; however, they directly train MT systems on the interpretation corpus without explicitly examining interpretation tactics. While some techniques can be learned implicitly, the model may also learn undesirable behavior such as omission and simplification: byproducts of limited human working memory (Section 4).

Prior work studies simultaneous interpretation of Japanese↔English (Tohyama and Matsubara, 2006; Shimizu et al., 2014) and Spanish↔English (Sridhar et al., 2013). We focus on Japanese↔English interpretation. Since information required by the target English sentence often comes late in the source Japanese sentence (e.g., the verb, the noun being modified), we expect it to reveal a richer set of tactics.[3] Our contributions are three-fold. First, we collect new human translations for an existing simultaneous interpretation corpus, which can benefit future comparative research.[4] Second, we use classification and feature selection methods to examine linguistic characteris-

[1] Unlike consecutive interpretation (speakers stop after a complete thought and wait for the interpreter), simultaneous interpretation has the interpreter to translate *while* listening to speakers.

[2] Language produced in the process of translation is often considered a dialect of the target language: "Translationese" (Baker, 1993). Thus, "Interpretese" refers to interpreted language.

[3] The tactics are consistent with those discovered on other language pairs in prior work, with additional ones specific to head-final to head-initial languages.

[4] https://github.com/hhexiy/interpretese

San Diego, California, June 12-17, 2016.

tics comparatively. Third, we categorize human interpretation strategies, including word reordering tactics and summarization tactics. Our results help linguists understand simultaneous interpretation and help computer scientists build better automatic interpretation systems.

2 Distinguishing Translationese and Interpretese

In this section, we discuss strategies used in Interpretese, which we detect automatically in the next section. Our hypothesis is that tactics used by interpreters roughly fall in two non-exclusive categories: (i) *delay minimization*, to enable prompt translation by arranging target words in an order similar to the source; (ii) *memory footprint minimization*, to avoid overloading working memory by reducing communicated information.

Segmentation Interpreters often break source sentences into multiple smaller sentences (Camayd-Freixas, 2011; Shimizu et al., 2013), a process we call segmentation. This is different from what is commonly used in speech translation systems (Fujita et al., 2013; Oda et al., 2014), where translations of segments are directly concatenated. Instead, humans try to incorporate new information into the precedent partial translation, e.g., using "which is" to put it in a clause (Table 1, Example 3), or creating a new sentence joined by conjunctions (Table 1, Example 5).

Passivization Passivization is useful for interpreting from head-final languages (e.g., Japanese, German) to head-initial languages (e.g., English, French) (He et al., 2015). Because the verb is needed early in the target sentence but only appears at the end of the source sentence, an obvious strategy is to wait for the final verb. However, if the interpreter uses passive voice, they can start translating immediately and append the verb at the end (Table 1, Examples 4–5). During passivization, the subject is often omitted when obvious from context.

Generalization Camayd-Freixas (2011) and Al-Khanji et al. (2000) observe that interpreters focus on delivering the gist of a sentence rather than duplicating the nuanced meaning of each word. More frequent words are chosen as their retrieval time is faster (Dell and O'Seaghdha, 1992; Cuetos et al., 2006) (e.g., "honorific" versus "polite" in Table 1, Example 1). Although Volansky et al. (2013) show that generalization happens in translation too, it is likely more frequent in Interpretese given the severe time constraints.

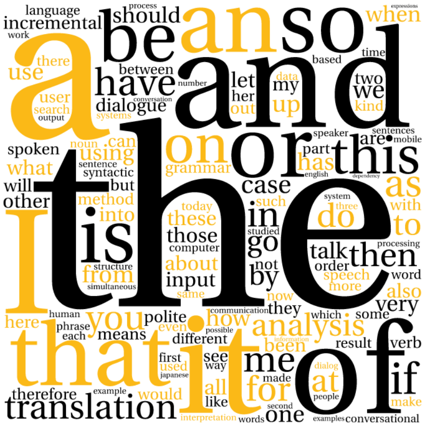

Figure 1: A word cloud visualization of Interpretese (black) and Translationese (gold).

Summarization Faced with overwhelming information, interpreters need efficient ways to encode meaning. Less important words, or even a whole sentence can drop, especially when the interpreter falls behind the speaker. In Table 1, Example 2, the literal translation "as much as possible" is reduced to "very", and the adjective "Japanese" is omitted.

Before we study these characteristics quantitatively in the next section, we visualize Interpretese and Translationese by a word cloud in Figure 1. The size of each word is proportional to the difference between its frequencies in Interpretese and Translationese (Section 3). The word color indicates whether it is more frequent in Interpretese (black) or Translationese (gold). "the" is over-represented in Interpretese, a phenomenon also occurs in Translationese vs. the original text (Eetemadi and Toutanova, 2014). More conjunction words (e.g., "and", "so", "or", "then") are used in Interpretese, likely for segmentation, whereas "that" is more frequent in Translationese—a sign of clauses. In addition, the pronoun "I" occurs more often in Translationese while "be" and "is" occur more often in Interpretese, which is consistent with our passivization hypothesis.

	Source (S), translation (T) and interpretation (I) text	Tactic
1	(S) この日本語の待遇表現の特徴ですが英語から日本語へ直訳しただけでは表現できないといった特徴があります. (T) (One of) the characteristics of *honorific* Japanese is that it can not be *adequately* expressed when using a direct translation (from English to Japanese). (I) Now let me talk about the characteristic of the Japanese *polite* expressions. ⟨‖⟩ And such such expressions can not be expressed *enough* just by translating directly.	*generalize* segment ⟨‖⟩ (omit)
2	(S) で三番目の特徴としてはですねえ出来る限り自然な日本語の話言葉とてその出力をするといったような特徴があります. (T) Its third *characteristic* is that its output is, as much as possible, in the natural language of spoken (Japanese). (I) And the third *feature* is that the translation could be produced in a very natural spoken language.	*generalize* summarize (omit)
3	(S) まとめますと我々は派生文法という従来の学校文法とは違う文法を使った日本語解析を行っています.その結果従来よりも単純な解析が可能となっております. (T) In sum , we've conducted an analysis on the Japanese language , using a grammar different from school grammar, called derivational grammar. (As a result,) we were able to produce a simpler analysis (than the conventional method). (I) So, we are doing Japanese analysis based on derivational grammar, ⟨‖⟩ which is different from school grammar, ⟨‖⟩ which enables us to analyze in simple way.	segment ⟨‖⟩ (omit)
4	(S) つまり例えばこの表現一は認識できますが二から四は認識できない. (T) They might *recognize* expression one but not *expressions* two to four. (I) The phrase number one only is *accepted* ⟨‖⟩ and *phrases* two, three, four were not *accepted*.	*generalize* passivize segment ⟨‖⟩
5	(S) 以上のお話をまとめますと自然な発話というものを扱うことができる音声対話の方法ということを考案しました. (T) In summary , we have *devised* a way for voice interaction systems to handle natural speech. (I) And this is the summary of what I have so far stated. The spontaneous speech can be dealt with by the speech dialog method ⟨‖⟩ and that method was *proposed*.	*generalize* passivize segment ⟨‖⟩

Table 1: Examples of tactics used by interpreters to cope with divergent word orders, limited working memory, and the pressure to produce low-latency translations. We show the source input (S), translated sentences (T), and interpreted sentences (I). The tactics are listed in the rightmost column and marked in the text: more general translations are highlighted in *italics*; ⟨‖⟩ marks where new clauses or sentences are created; and passivized verbs in translation are underlined. Information appearing in translation but omitted in interpretation are in (parentheses). Summarized expressions and their corresponding expression in translation are underlined by wavy lines.

3 Classification of Translationese and Interpretese

We investigate the difference between Translationese and Interpretese by creating a text classifier to distinguish between them and then examining the most useful features. We train our classifier on a bilingual Japanese-English corpus of spoken monologues and their simultaneous interpretations (Matsubara et al., 2002). To obtain a three-way parallel corpus of aligned translation, interpretation, and their shared source text, we first align the interpreted sentences to source sentences by dynamic programming following Ma (2006).[5] This step results in 1684 pairs of text chunks, with 33 tokens per chunk on average. We then collect human translations from Gengo[6] for each source text chunk (one translator per monologue). The original corpus has four interpretors per monologue. We use all available interpretation by copying the translation of a text chunk for its additional interpretation.

3.1 Discriminative Features

We use logistic regression as our classifier. Its job is to tell, given a chunk of English text, which translation produced it. We add ℓ_1 regularization to select the non-zero features that best distinguish Interpretese from Translationese. We experiment with three dif-

[5] Sentences are defined by sentence boundaries marked in the corpus, thus coherence is preserved during alignment.

[6] http://gengo.com ("standard" quality).

ferent sets of features: (1) **POS:** n-gram features of POS tags (up to trigram); [7] (2) **LEX:** word unigrams; (3) **LING:** features reflecting linguistic hypothese (Section 2), most of which are counts of indicator functions normalized by length of the chunk (Appendix A).

The top linguistic features listed in Table 3 are consistent with our hypotheses. The most prominent ones—also revealed by POS and LEX—are the segmentation features, including counts of conjunction words (CC), content words (nouns, verbs, adjectives, and adverbs) that appear more than once (repeated), demonstratives (demo) such as *this, that, these, those*, segmented sentences (sent), and proper nouns (NNP). More conjunction words and more sentences in a text chunk are signs of segmentation. Repeated words and the frequent use of demonstratives come from transforming clauses to independent sentences. Next are the passivization features, indicating more passivized verbs (passive) and fewer pronouns (pronoun) in Interpretese. The lack of pronouns may be results of either subject omission during passivization or general omission. The last group are the vocabulary features, showing fewer numbers of stem types, token types, and content words in Interpretese, evidence of word generalization. In addition, a smaller number of content words suggests that interpreters may use more function words to manipulate the sentence structure.

3.2 Classification Results

Recall that our goal is to understand Interpretese, not to classify Interpretese and Translationese; however, the ten-fold cross validation accuracy of LING, POS, LEX are 0.66, 0.85, and 0.94. LEX and POS yield high accuracy as some features are overfitting, e.g., in this dataset, most interpreters used "parsing" for "構文解析" while the translator used "syntactic analysis". Therefore, they do not reveal much about the characteristics of Interpretese except for frequent use of "and" and CC, which indicates segmentation. Similarly, Volansky et al. (2013) and Eetemadi and Toutanova (2014) also find lexical features very effective but not generalizable for detecting Translationese and exclude them from analysis. One reason for the relatively low accuracy of LING may be inconsistent use of strategies among humans (Section 4).

LING		POS		LEX	
CC	+	⟨S⟩ CC	+	And	+
repeated	+	. CC	+	parsing	+

content	–	NN CC RB	–	Furthermore	–

Table 3: Top 10 highest-weighted features in each model. The sign shows whether it is indicative of Interpretese (+) or Translationese (–).

4 Strategy Analysis

To better understand under what situations these tactics are used, we apply two-sample t-tests to compare the following quantities between Interpretese and Translationese: (1) number of inversions (non-monotonic translations) on all source tokens (inv-all), verbs (inv-verb) and nouns (inv-noun); (2) number of segmented sentences; (3) number of natural passivization (pass-st), meaning copying a passive construction in the source sentence into the target sentence, and intentional passivization (pass-t), meaning introducing passivization into the target sentence when the source sentence is in active voice; (4) number of omitted words on the source side and inserted words on the target side;[8] (5) average word frequency given by Microsoft Web n-gram—higher means more common.[9] For all pairs of samples, the null hypothesis H_0 is that the means on Interpretese and Translationese are equal; the alternative hypotheses and results are in Table 2.

As expected, segmentation and intentional passivization happen more often during interpretation. Interpretese has fewer inversions, especially for verbs; reducing word order difference is important for delay minimization. Since there are two to four different interpretations for each lecture, we further analyze how consistent humans are on these decisions. All interpreters agree on segmentation 73.7% of the time, while the agreement on passivization is

[7] We prepend ⟨S⟩ and append ⟨E⟩ to all sentences.

[8] The number of unaligned words in the source or target.

Sample	inv-all	inv-verb	inv-noun	segment	pass-t	pass-st	omit	insert	word freq
H_a	$\mu_I < \mu_T$			$\mu_I > \mu_T$	$\mu_I > \mu_T$		$\mu_I > \mu_T$		$\mu_I > \mu_T$
t-stat	-1.55	**-3.81**	**-2.13**	**4.21**	**5.67**	1.41	**16.16**	**10.66**	**7.88**
p-value	.12	<.001	.03	<.001	<.001	.16	<.001	<.001	<.001

Table 2: Two-sample t-tests for Interpretese and Translationese. The test statistics are bolded when we reject H_0 at the 0.05 significance level (two-tailed).

only 57.1%—passivization is an acquired skill; not all interpreters use it when it can speed interpretation.

The tests also confirm our hypotheses on generalization and omission. However, these tactics are not inherent to the task of simultaneous interpretation. Instead, they are a byproduct of humans' limited working memory. Computers can load much larger resources into memory and weigh quality of different translations in an instant, thus potentially rendering the speaker's message more accurately. Therefore, directly learning from corpus of human interpretation may lead to suboptimal results (Shimizu et al., 2014).

5 Conclusion

While we describe how Translationese and Interpretese are different and characterize *how* they differ, the contribution of our work is not just examining an interesting, important dialect. Our work provides opportunities to improve conventional simultaneous MT systems by exploiting and modeling human tactics. He et al. (2015) use hand-crafted rules to decrease latency; our data-driven approach could yield additional strategies for improving MT systems. Another strategy—given the scarcity and artifacts of interpretation corpus—is to select references that present delay-minimizing features of Interpretese from translation corpus (Axelrod et al., 2011). Another future direction is to investigate cognitive inference (Chernov, 2004), which is useful for semantic/syntactic prediction during interpretation (Grissom II et al., 2014; Oda et al., 2015).

A Feature Extraction

We use the Berkeley aligner (Liang et al., 2006) for word alignment, the Stanford POS tagger (Toutanova et al., 2003) to tag English sentences, and Kuromoji [10] to tokenize, lemmatize and tag Japanese sentences. Below we describe the features in detail.

Inversion: Let $\{A_i\}$ be the set of indexes of target words to which each source word w_i is aligned. We count A_i and A_j ($i < j$) as an inverted pair if $\max(A_i) > \min(A_j)$. This means that we have to wait until the jth word to translate the ith word.

Segmentation: We use the `punkt` sentence segmenter (Kiss and Strunk, 2006) from NLTK to detect sentences in a text chunk.

Passivization: We compute the number of passive verbs normalized by the total number of verbs. We detect passive voice in English by matching the following regular expression: a *be* verb (be, are, is, was, were etc.) followed by zero to four non-verb words and one verb in its past participle form. We detect passive voice in Japanese by checking that the dictionary form of a verb has the suffix “れる”.

Vocabulary To measure variety, we use V_t/N and V_s/N, where V_t and V_s are counts of distinct tokens and stems, and N is the total number of tokens. To measure complexity, we use word length, number of syllables per word, approximated by vowel sequences; and unigram and bigram frequency from Microsoft Web N-gram.

Summarization We use the sentence compression ratio, sentence length, number of omitted source words, approximated by counts of unaligned words, and number of content words.

Acknowledgments

We thank CIAIR (Nagoya University, Japan) for providing the interpretation data which formed the foundation of this research. We also thank Alvin Grissom II, Naho Orita and the reviewers for their insightful comments. This work was supported by NSF grant IIS-1320538. LSTM Neural Reordering Feature for Statistical Machine Translation

Yiming Cui, Shijin Wang and **Jianfeng Li**
iFLYTEK Research, Beijing, China
{ymcui,sjwang3,jfli3}@iflytek.com

Abstract

Artificial neural networks are powerful models, which have been widely applied into many aspects of machine translation, such as language modeling and translation modeling. Though notable improvements have been made in these areas, the reordering problem still remains a challenge in statistical machine translations. In this paper, we present a novel neural reordering model that directly models word pairs and their alignment. Further by utilizing LSTM recurrent neural networks, much longer context could be learned for reordering prediction. Experimental results on NIST OpenMT12 Arabic-English and Chinese-English 1000-best rescoring task show that our LSTM neural reordering feature is robust, and achieves significant improvements over various baseline systems.

1 Introduction

In statistical machine translation, the language model, translation model, and reordering model are the three most important components. Among these models, the reordering model plays an important role in phrase-based machine translation (Koehn et al., 2004), and it still remains a major challenge in current study.

In recent years, various phrase reordering methods have been proposed for phrase-based SMT systems, which can be classified into two broad categories:

(1) *Distance-based RM*: Penalize phrase displacements with respect to the degree of non-monotonicity (Koehn et al., 2004).

(2) *Lexicalized RM*: Conditions reordering probabilities on current phrase pairs. According to the orientation determinants, lexicalized reordering model can further be classified into word-based RM (Tillman, 2004), phrase-based RM (Koehn et al., 2007), and hierarchical phrase-based RM (Galley and Manning, 2008).

Furthermore, some researchers proposed a reordering model that conditions both current and previous phrase pairs by utilizing recursive auto-encoders (Li et al., 2014).

In this paper, we propose a novel neural reordering feature by including longer context for predicting orientations. We utilize a long short-term memory recurrent neural network (LSTM-RNN) (Graves, 1997), and directly models word pairs to predict its most probable orientation. Experimental results on NIST OpenMT12 Arabic-English and Chinese-English translation show that our neural reordering model achieves significant improvements over various baselines in 1000-best rescoring task.

2 Related Work

Recently, various neural network models have been applied into machine translation.

Feed-forward neural language model was first proposed by Bengio et al. (2003), which was a breakthrough in language modeling. Mikolov et al. (2011) proposed to use recurrent neural network in language modeling, which can include much longer context history for predicting next word. Experimental results show that RNN-based language model significantly outperform standard feed-forward language model.

Proceedings of NAACL-HLT 2016, pages 977–982,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

Devlin et al. (2014) proposed a neural network joint model (NNJM) by conditioning both source and target language context for target word predicting. Though the network architecture is a simple feed-forward neural network, the results have shown significant improvements over state-of-the-art baselines.

Sundermeyer et al. (2014) also put forward a neural translation model, by utilizing LSTM-based RNN and Bidirectional RNN. In bidirectional RNNs, the target word is conditioned on not only the history but also future source context, which forms a full source sentence for predicting target words.

Li et al. (2013) proposed to use a recursive auto-encoder (RAE) to map each phrase pairs into continuous vectors, and handle reordering problems with a classifier. Also, they suggested that by both including current and previous phrase pairs to determine the phrase orientations could achieve further improvements in accuracy (Li et al., 2014).

By far, we have noticed that this is the first time to use LSTM-RNN in reordering model. We could include much longer context information to determine phrase orientations using RNN architecture. Furthermore, by utilizing the LSTM layer, the network is able to capture much longer range dependencies than standard RNNs.

Because we need to record fixed length of history information in SMT decoding step, we only utilize our LSTM-RNN reordering model as a feature in 1000-best rescoring step. As word alignments are known after generating n-best list, it is possible to use LSTM-RNN reordering model to score each hypothesis.

3 Lexicalized Reordering Model

In traditional statistical machine translation, lexicalized reordering models (Koehn et al., 2007) have been widely used. It considers alignments of current and previous phrase pairs to determine the orientation.

Formally, when given source language sentence $f = \{f_1, ..., f_n\}$, target language sentence $e = \{e_1, ..., e_n\}$, and phrase alignment $a = \{a_1, ..., a_n\}$, the lexicalized reordering model can be illustrated in Equation 1, which only conditions on a_{i-1} and a_i, i.e. previous and current alignment.

$$p(\mathbf{o}|\mathbf{e},\mathbf{f}) = \prod_{i=1}^{n} p(o_i|e_i, f_{a_i}, a_{i-1}, a_i) \qquad (1)$$

In Equation 1, the o_i represents the set of phrase orientations. For example, in the most commonly used MSD-based orientation type, o_i takes three values: M stands for *monotone*, S for *swap*, and D for *discontinuous*. The definition of MSD-based orientation is shown in Equation 2.

$$o_i = \begin{cases} M, & a_i - a_{i-1} = 1 \\ S, & a_i - a_{i-1} = -1 \\ D, & |a_i - a_{i-1}| \neq 1 \end{cases} \qquad (2)$$

For other orientation types, such as LR and MSLR are also widely used, whose definition can be found on Moses official website [1].

Recent studies on reordering model suggest that by also conditioning previous phrase pairs can improve context sensitivity and reduce reordering ambiguity.

4 LSTM Neural Reordering Model

In order to include more context information for determining reordering, we propose to use a recurrent neural network, which has been shown to perform considerably better than standard feed-forward architectures in sequence prediction (Mikolov et al., 2011). However, RNN with conventional backpropagation training suffers from gradient vanishing issues (Bengio et al., 1994) .

Later, the long short-term memory was proposed for solving gradient vanishing problem, and it could catch longer context than standard RNNs with sigmoid activation functions. In this paper, we adopt LSTM architecture for training neural reordering model.

4.1 Training Data Processing

For reducing model complexity and easy implementation, our neural reordering model is purely lexicalized and trained on word-level.

We will take LR orientation for explanations, while other orientation types (MSD, MSLR) can be induced similarly. Given a sentence pair and

[1] `http://www.statmt.org/moses/`

its alignment information, we can induce the word-based reordering information by following steps. Note that, we always evaluate the model in the order of target sentence.

(1) If current target word is one-to-one alignment, then we can directly induce its orientations, i.e. $\langle left \rangle$ or $\langle right \rangle$.

(2) If current source/target word is one-to-many alignment, then we judge its orientation by considering its first aligned target/source word, and the other aligned target/source words are annotated as $\langle follow \rangle$ reordering type, which means these word pairs inherent the orientation of previous word pair.

(3) If current source/target word is not aligned to any target/source words, we introduce a $\langle null \rangle$ token in its opposite side, and annotate this word pair as $\langle follow \rangle$ reordering type.

Figure 1 shows an example of data processing.

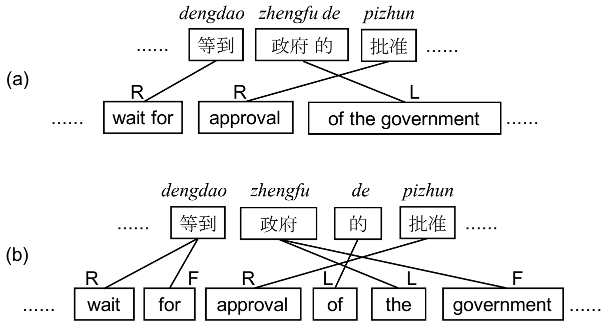

Figure 1: Illustration of data processing. (a) Original reordering (omit alignment inside each phrase); (b) processed reordering, all alignments are regularized to word level, R-right, L-left, F-follow.

4.2 LSTM Network Architecture

After processing the training data, we can directly utilize the word pairs and its orientation to train a neural reordering model.

Given a word pair and its orientation, a neural reordering model can be illustrated by Equation 3.

$$p(\mathbf{o}|\mathbf{e},\mathbf{f}) = \prod_{i=1}^{n} p(o_i|e_1^i, f_1^{a_i}, a_{i-1}, a_i) \quad (3)$$

Where $e_1^i = \{e_1, ..., e_i\}$, $f_1^{a_i} = \{f_1, ..., f_{a_i}\}$. Inclusion of history word pairs is done with recurrent neural network, which is known for its capability of learning history information.

The architecture of LSTM-RNN reordering model is depicted in Figure 2, and corresponding equations are shown in Equation 4 to 6.

$$y_i = W_1 * f_{a_i} + W_2 * e_i \quad (4)$$

$$z_i = LSTM(y_i, W_3, y_1^{i-1}) \quad (5)$$

$$p(o_i|e_1^i, f_1^{a_i}, a_{i-1}, a_i) = softmax(W_4 * z_i) \quad (6)$$

The input layer consists both source and target language word, which is in one-hot representation. Then we perform a linear transformation of input layer to a projection layer, which is also called embedding layer. We adopt extended-LSTM as our hidden layer implementation, which consists of three gating units, i.e. input, forget and output gates. We omit rather extensive LSTM equations here, which can be found in (Graves and Schmidhuber, 2005). The output layer is composed by orientation types. For example, in LR condition, the output layer contains two units: $\langle left \rangle$ and $\langle right \rangle$ orientation. Finally, we apply softmax function to obtain normalized probabilities of each orientation.

5 Experiments

5.1 Setups

We mainly tested our approach on Arabic-English and Chinese-English translation. The training corpus contains 7M words for Arabic, and 4M words for Chinese, which is selected from NIST

System	Dev	Test1	Test2
Ar-En	MT04-05-06 (3795)	MT08 (1360)	MT09 (1313)
Zh-En	MT05-08 (2439)	MT08.prog (1370)	MT12.rd (820)

Table 1: Statistics of development and test set. The number of segments are indicated in brackets.

OpenMT12 parallel dataset. We use the SAMA tokenizer[2] for Arabic word tokenization, and in-house segmenter for Chinese words. The English part of parallel data is tokenized and lowercased. All development and test sets have 4 references for each segment. The statistics of development and test sets are shown in Table 1.

The baseline systems are built with the open-source phrase-based SMT toolkit Moses (Koehn et al., 2007). Word alignment and phrase extraction are done by GIZA++ (Och and Ney, 2000) with L0-normalization (Vaswani et al., 2012), and grow-diag-final refinement rule (Koehn et al., 2004). Monolingual part of training data is used to train a 5-gram language model using SRILM (Stolcke, 2002). Parameter tuning is done by K-best MIRA (Cherry and Foster, 2012). For guarantee of result stability, we tune every system 5 times independently, and take the average BLEU score (Clark et al., 2011). The translation quality is evaluated by case-insensitive BLEU-4 metric (Papineni et al., 2002). The statistical significance test is also carried out with paired bootstrap resampling method with $p < 0.001$ intervals (Koehn, 2004). Our models are evaluated in a 1000-best rescoring step, and all features in 1000-best list as well as LSTM-RNN reordering feature are retuned via K-best MIRA algorithm.

For neural network training, we use all parallel text in the baseline training. As a trade-off between computational cost and performance, the projection layer and hidden layer are set to 100, which is enough for our task (We have not seen significant gains when increasing dimensions greater than 100). We use an initial learning rate of 0.01 with standard SGD optimization without momentum. We trained model for a total of 10 epochs with cross-entropy criterion. Input and output vocabulary are set to 100K and 50K respectively, and all out-of-vocabulary words are mapped to a $\langle unk \rangle$ token.

5.2 Results on Different Orientation Types

At first, we test our neural reordering model (NRM) on the baseline that contains word-based reordering model with LR orientation. The results are shown in Table 2 and 3.

As we can see that, among various orientation types (LR, MSD, MSLR), our model could give consistent improvements over baseline system. The overall BLEU improvements range from 0.42 to 0.79 for Arabic-English, and 0.31 to 0.72 for Chinese-English systems. All neural results are significantly better than baselines ($p < 0.001$ level).

In the meantime, we also find that "Left-Right" based orientation methods, such as LR and MSLR, consistently outperform MSD-based orientations. The may caused by non-separability problem, which means that MSD-based methods are vulnerable to the change of context, and weak in resolving reordering ambiguities. Similar conclusion can be found in Li et al. (2014) .

Ar-En System	Dev	Test1	Test2
Baseline	43.87	39.84	42.05

5.3 Results on Different Reordering Baselines

We also test our approach on various baselines, which either contains word-based, phrase-based, or hierarchical phrase-based reordering model. We only show the results of MSLR orientation, which is relatively superior than others according to the results in Section 5.2.

+NRM_MSLR	27.86	26.46	24.73
Baseline_hier	27.56	26.29	24.38
+NRM_MSLR	28.02	26.49	24.67

Table 4: Results on various baselines for Arabic-English and Chinese-English system. "wbe": word-based; "phr": phrase-based; "hier": hierarchical phrase-based reordering model. All NRM results are significantly better than baselines ($p < 0.001$ level).

In Table 4 and 5, we can see that though we add a strong hierarchical phrase-based reordering model in the baseline, our model can still bring a maximum gain of 0.59 BLEU score, which suggest that our model is applicable and robust in various circumstances. However, we have noticed that the gains in Arabic-English system is relatively greater than that in Chinese-English system. This is probably because hierarchical reordering features tend to work better for Chinese words, and thus our model will bring little remedy to its baseline.

6 Conclusions

We present a novel work that build a reordering model using LSTM-RNN, which is much sensitive to the change of context and introduce rich context information for reordering prediction. Furthermore, the proposed model is purely lexicalized and straightforward, which is easy to realize. Experimental results on 1000-best rescoring show that our neural reordering feature is robust, and could give consistent improvements over various baseline systems.

In future, we are planning to extend our word-based LSTM reordering model to phrase-based reordering model, in order to dissolve much more ambiguities and improve reordering accuracy. Furthermore, we are also going to integrate our neural reordering model into neural machine translation systems.

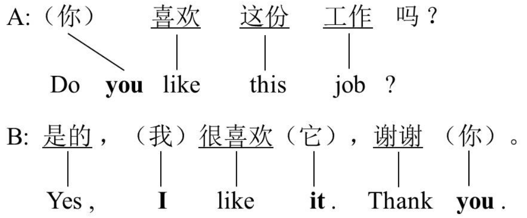
Abstract

Dropped Pronouns (DP) in which pronouns are frequently dropped in the source language but should be retained in the target language are challenge in machine translation. In response to this problem, we propose a semi-supervised approach to recall possibly missing pronouns in the translation. Firstly, we build training data for DP generation in which the DPs are automatically labelled according to the alignment information from a parallel corpus. Secondly, we build a deep learning-based DP generator for input sentences in decoding when no corresponding references exist. More specifically, the generation is two-phase: (1) DP position detection, which is modeled as a sequential labelling task with recurrent neural networks; and (2) DP prediction, which employs a multilayer perceptron with rich features. Finally, we integrate the above outputs into our translation system to recall missing pronouns by both extracting rules from the DP-labelled training data and translating the DP-generated input sentences. Experimental results show that our approach achieves a significant improvement of 1.58 BLEU points in translation performance with 66% F-score for DP generation accuracy.

1 Introduction

In pro-drop languages, certain classes of pronouns can be omitted to make the sentence compact yet comprehensible when the identity of the pronouns can be inferred from the context (Yang et al., 2015). Figure 1 shows an example, in which Chinese is a pro-drop language (Huang, 1984), while English is not (Haspelmath, 2001). On the Chinese side, the subject pronouns {你 (*you*), 我 (*I*)} and the object pronouns {它 (*it*), 你 (*you*)} are omitted in the dialogue between Speakers A and B. These omissions may not be problems for humans since people can easily recall the missing pronouns from the context. However, this poses difficulties for Statistical Machine Translation (SMT) from pro-drop languages (e.g. Chinese) to non-pro-drop languages (e.g. English), since translation of such missing pronouns cannot be normally reproduced. Generally, this phenomenon is more common in informal genres such as dialogues and conversations than others (Yang et al., 2015). We also validated this finding by analysing a large Chinese–English dialogue corpus which consists of 1M sentence pairs extracted from movie and TV episode subtitles. We found that there are 6.5M Chinese pronouns and 9.4M English pronouns, which shows that more than 2.9 million Chinese pronouns are missing.



A: （你） 喜欢 这份 工作 吗？
Do **you** like this job ?
B: 是的，（我）很喜欢（它），谢谢（你）。
Yes , **I** like **it** . Thank **you** .

Figure 1: Examples of dropped pronouns in a parallel dialogue corpus. The Chinese pronouns in brackets are dropped.

In response to this problem, we propose to find a general and replicable way to improve translation quality. The main challenge of this research is that training data for DP generation are scarce. Most

Proceedings of NAACL-HLT 2016, pages 983–993,
San Diego, California, June 12-17, 2016. ©2016 Association for Computational Linguistics

works either apply manual annotation (Yang et al., 2015) or use existing but small-scale resources such as the Penn Treebank (Chung and Gildea, 2010; Xiang et al., 2013). In contrast, we employ an unsupervised approach to automatically build a large-scale training corpus for DP generation using alignment information from parallel corpora. The idea is that parallel corpora available in SMT can be used to project the missing pronouns from the target side (i.e. non-pro-drop language) to the source side (i.e. pro-drop language). To this end, we propose a simple but effective method: a bi-directional search algorithm with Language Model (LM) scoring.

After building the training data for DP generation, we apply a supervised approach to build our DP generator. We divide the DP generation task into two phases: *DP detection* (from which position a pronoun is dropped), and *DP prediction* (which pronoun is dropped). Due to the powerful capacity of feature learning and representation learning, we model the DP detection problem as sequential labelling with Recurrent Neural Networks (RNNs) and model the prediction problem as classification with Multi-Layer Perceptron (MLP) using features at various levels: from lexical, through contextual, to syntax.

Finally, we try to improve the translation of missing pronouns by explicitly recalling DPs for both parallel data and monolingual input sentences. More specifically, we extract an additional rule table from the DP-inserted parallel corpus to produce a “pronoun-complete” translation model. In addition, we pre-process the input sentences by inserting possible DPs via the DP generation model. This makes the input sentences more consistent with the additional pronoun-complete rule table. To alleviate the propagation of DP prediction errors, we feed the translation system N-best prediction results via confusion network decoding (Rosti et al., 2007).

To validate the effect of the proposed approach, we carried out experiments on a Chinese–English translation task. Experimental results on a large-scale subtitle corpus show that our approach improves translation performance by 0.61 BLEU points (Papineni et al., 2002) using the additional translation model trained on the DP-inserted corpus. Working together with DP-generated input sentences achieves a further improvement of nearly 1.0 BLEU point. Furthermore, translation performance with N-best integration is much better than its 1-best counterpart (i.e. +0.84 BLEU points).

Generally, the contributions of this paper include the following:
